Emerging evidence suggests that the regulated subcellular localization of Sgk, a third level of cellular control of Sgk, is a physiologically important process that helps the cells integrate extracellular proliferative, stress, and differentiation signals. The control of Sgk compartmentalization provides Sgk access to its critical targets and is particularly important for integrating intracellular signaling pathways when different hormonal cues with opposite cellular functions can induce enzymatically active Sgk. Depending on the extracellular stimuli, the regulated compartmentalization of Sgk can be viewed as controlling the accessibility of this protein kinase to its substrates and nonsubstrate protein targets.

A. Stimulus and Cell Cycle Regulation of Sgk Localization to the Nucleus or the Cytoplasmic Compartment

The subcellular distribution of Sgk between the nucleus and the cytoplasm is stringently controlled in a stimulus-dependent manner in mammary epithelial cells and in ovarian cells. In serum-stimulated proliferating mammary tumor cells, a nuclear form of Sgk can be detected, whereas in glucocorticoid growth-arrested cells or in hyperosmotically stressed cells, enzymatically active Sgk is localized exclusively to the cytoplasmic compartment. During the *in vivo* transition from granulosa cells in the proliferative stage of growing follicles in the ovary to terminally differentially nongrowing luteal cells, the subcellular distribution of Sgk changes from being predominately nuclear to almost entirely cytoplasmic.

Laser scanning cytometry, which simultaneously monitors Sgk localization and DNA content in individual mammary tumor cells of an asynchronously growing population, revealed that Sgk actively shuttles between the nucleus and the cytoplasm in synchrony with the cell cycle. Sgk is predominantly nuclear in S and G2/M phase cells and resides in the cytoplasmic compartment during the G1 phase of the cell cycle. Immunofluorescence and biochemical

studies showed that treatment with glucocorticoids, which induce a G1 cell cycle arrest, or exposure to hyperosmotic stress results in a cytoplasmic form of Sgk. The precise cytoplasmic compartment in which Sgk resides has not been fully characterized, although some evidence indicates a mitochondrial location for the stressed-induced Sgk. In cells synchronously released from the G1/S boundary, Sgk exclusively localizes to the nucleus during progression through the S phase. The forced retention of exogenous Sgk in either the nucleus or the cytoplasm suppresses the growth and DNA synthesis of serum-stimulated cells. This result indicates that a key proliferative signal in mammary tumor cells is the continuous shuttling of Sgk between the nucleus and the cytoplasm. In the ovarian system, on treatment with FSH, Sgk resides in the nucleus of proliferating granulosa cells, and in terminally differentiated luteal cells, Sgk is located in the cytoplasmic compartment.

Taken together, these results suggest that the spatial and temporal regulation of Sgk is vital for executing complex growth and differentiation programs, which suggests the existence of specific regulatory mechanisms for localizing Sgk to distinct cellular compartments. Conceivably, the signal-dependent sequestration of Sgk in different subcellular locations also entails interactions with particular cellular proteins that target Sgk to specific intracellular destinations and thereby control accessibility to its protein targets.

B. Mechanism of Stimulus Regulation of Sgk Nuclear-Cytoplasmic Shuttling

A yeast two-hybrid screen demonstrated that the nuclear receptor pendulin/importin-α is a highly specific Sgk-interacting protein. *In vitro* binding assays and co-immunoprecipitations of cell extracts demonstrated that pendulin/importin-α strongly binds to Sgk. Pendulin/importin-α recognizes nuclear localization signals in its cargo proteins and then through the interactions with importin-β, the receptor–cargo protein complex is imported into the nucleus through nuclear core complexes. Mutagenesis of Sgk identified a "bipartite-like" nuclear localization signal sequence, KKAILKKKE, between amino acids 131 and 139 in Sgk. This sequence mediates the *in vitro* binding of Sgk to pendulin/importin-α and the nuclear import of Sgk. For example, mutation of the Sgk nuclear localization signal by amino acid substitutions (K to A) in the context of the full-length Sgk ablates the *in vitro* interaction of Sgk with pendulin/importin-α.

Subcellular localization studies documented that pendulin/importin-α co-localizes with Sgk to the nucleus in serum-stimulated cells and to the cytoplasmic compartment in dexamethasone-treated mammary tumor cells. One viewpoint is that the selective interactions between Sgk and pendulin/importin-α control the cell cycle-dependent nuclear localization of Sgk in serum-treated cells and play a role in distributing Sgk to the cytoplasm in glucocorticoid-treated or stressed cells. Thus, the Sgk–pendulin/importin-α interactions provide a mechanistic basis for the stimulus-regulated compartmentalization.

IX. POTENTIAL CONNECTIONS OF Sgk WITH HUMAN DISORDERS

The central role of Sgk in integrating the cross talk between nuclear receptor and plasma membrane receptor signals would predict that many physiological abnormalities would be associated with the dysfunctional regulation of expression, activity, and subcellular localization of Sgk. Indeed, recent evidence has indicated that Sgk plays a role in the pathology of certain human disorders. Alterations in Sgk expression, in combination with its cellular role in osmoregulation, suggest a role for Sgk in the nephropathy that is associated with the diabetic disease state, conceivably as part of the hyperosmotic response in the kidney to high plasma glucose levels. Similarly, Sgk has been implicated in the salt-sensitive hypertension associated with the insulin-resistance syndrome. Transforming growth factor-β stimulates Sgk expression, and this response suggests that Sgk plays a role in the fibrogenic actions of this hormonal cue and by extension is involved in fibrosing disease. Consistent with this notion, Sgk expression is elevated in fibrosing pancreatitis and in inflammatory bowel disease. The stimulus-dependent cell survival and proliferative functions of Sgk directly suggest that defects in the cellular control of Sgk signaling may be associated with a subset of human disorders with dysfunctional growth control and apoptotic mechanisms, such as cancer. The control of Sgk nuclear–cytoplasmic shuttling may be a particularly important facet of Sgk control because the nuclear form of Sgk is associated with proliferative conditions, whereas after cellular stress the cytoplasmic form of Sgk is important for cell survival and antiproliferative responses. Thus, it is tempting to consider that the nuclear Sgk substrates could provide potential targets for therapeutic intervention to

selectively dampen cell proliferation or to modulate pathological states of cells associated with the nuclear localization of Sgk. In a complementary manner, small-molecule inhibitors of Sgk kinase activity have the potential to be developed as novel therapeutic agents to control certain neoplasias by selectively regulating proliferative, survival, and/or apoptotic signaling pathways that are dependent on Sgk.

Glossary

hormone receptor signaling cascade The chain of intracellular events beginning from the activation of a hormone receptor that ends in the final response to the hormone. Also known as a signal transduction pathway.

phosphatidylinositol 3-kinase (PI3-kinase) Kinase that directly binds to tyrosine kinase receptors (or to insulin substrate-1) via a SH2 domain in its p85 subunit. PI3-kinase converts phosphatidylinositol 4,5-biphosphate to phosphatidylinositol 3,4,5-triphosphate. The PI3-kinase signal transduction pathway mediates cell survival and proliferative responses to a variety of growth factors and insulin.

phosphoinositide-dependent protein kinase-1 Protein kinase that is activated by phosphatidylinositol 3-kinase and in turn directly phosphorylates and enzymatically activates serum- and glucocorticoid-inducible protein kinase.

serum- and glucocorticoid-inducible protein kinase Protein kinase that is regulated by hormones and other extracellular signals at three distinct levels of cellular control and is a unique point of cross talk in hormone signaling cascades.

stress response The ability of cells to survive or undergo apoptosis in response to environmental stress conditions, such as changes in osmolarity, nutrient deprivation, or extreme temperatures. Generally considered to be initiated by receptor-mediated events.

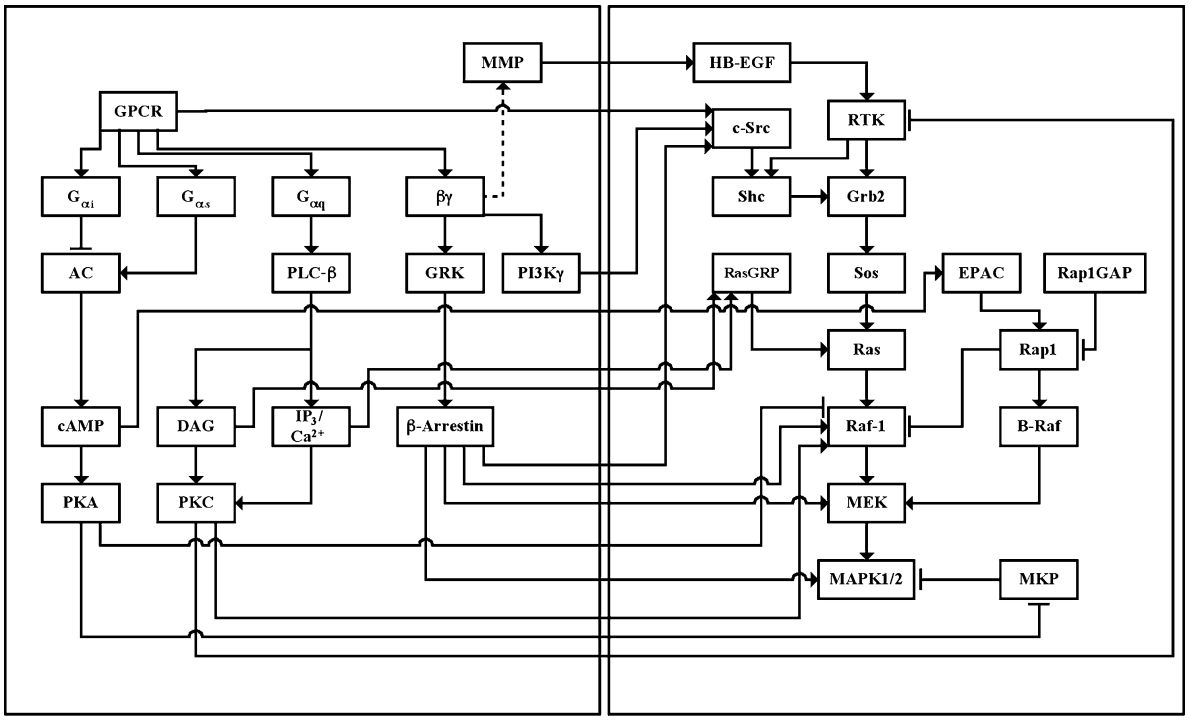

FIGURE 1 Regulation of the RTK–MAPK cascade by GPCR signaling pathways. In the right box are the components and related regulators of the RTK–MAPK cascade, and in the left box are the effectors and components of GPCR and heterotrimeric G-proteins. Within the signaling circuits, lines with arrows represent stimulation and lines with vertical bars at the end represent inhibition. Dotted lines indicate indirect regulation or regulation by unknown mechanisms. GPCR, G-protein-coupled receptor; MMP, matrix metalloproteinase; AC, adenylyl cyclase; PLC-β, phopholipase C-β; GRK, G-protein-coupled receptor kinase; PI3Kγ, phosphatidylinositol 3-kinase γ; DAG, diacylglycerol; IP_3, inositol 1,4,5-trisphosphate; PKA, protein kinase A; PKC, protein kinase C; HB-EGF, heparin-binding epidermal growth factor; RTK, receptor tyrosine kinase; Shc, Src homology and collagen; Grb2, growth factor receptor-binding protein 2; RasGRP, guanyl nucleotide-releasing protein for Ras; Sos, son of sevenless; EPAC, exchange protein directly activated by cAMP; MAPK, mitogen-activated protein kinase; MEK, MAPK kinase/ERK kinase; MKP, MAPK phosphatase.

(pleckstrin homology) domain of Sos is also essential for membrane translocation and for complete activation of Ras.

Membrane recruitment of Sos can be also accomplished by binding of Grb2/Sos to Shc (Src homology and collagen), another adapter protein that possesses a phosphotyrosine-binding (PTB) domain, a SH2 domain, and a SH3 domain. Shc forms a complex with many receptors through its PTB domain. Shc is a substrate for the RTKs and, on tyrosine phosphorylation, binds to the SH2 domain of Grb2.

Alternatively, Grb2/Sos complexes can be recruited to the cell membrane by binding to membrane-linked docking proteins, such as insulin receptor substrate 1 or fibroblast growth factor (FGF) receptor substrate 2, which become tyrosine phosphorylated in response to activation of certain RTKs.

Once in the active GTP-bound state, Ras stimulates MAP kinase kinase kinases (MAPKKKs) Rafs, which include Raf-1, A-Raf, and B-Raf. Activated Raf stimulates MAPK kinase (MAPKK), which is also called MEK (MAPK kinase/ERK kinase), by phosphorylating a key Ser residue in the activation loop. MEK then phosphorylates MAPK on Thr and Tyr residues at the activation loop, leading to its activation. Activated MAPKs phosphorylate and regulate the activity of key enzymes and nuclear proteins, which can ultimately regulate the expression of genes essential for cell proliferation.

III. G-PROTEIN-COUPLED RECEPTORS AND CELL PROLIFERATION

GPCRs are involved in diverse important biological activities, from cellular functions (cell proliferation,

cell transformation, cell differentiation, endocytosis, exocytosis, neurotransmission, chemotaxis, etc.), to physiological functions (photo- and chemoreception, secretion from endocrine and exocrine glands, blood pressure control, etc.), to morphogenesis (embryogenesis, angiogenesis, tissue regeneration, etc.).

The proliferative effect of GPCRs was recognized by the initial finding that the serotonin and muscarinic acetylcholine receptors can trigger the transformation of fibroblast cells. It also has been shown that DNA viruses encoding functional GPCRs, including human cytomegalovirus, Herpesvirus saimiri, and Kaposi's sarcoma-associated herpes virus, can contribute to malignant transformation and ultimately to human cancer due to their persistent activity. The ability of GPCRs to affect cell growth was further confirmed by the identification of the naturally occurring activated mutants of G_α in various cancers. The activated mutants $G_{\alpha s}$, $G_{\alpha i2}$, and $G_{\alpha 12}$ are referred to as the *gsp*, *gip2*, and *gep* oncogenes, respectively.

The signaling pathways mediating the proliferative effects of GPCRs and heterotrimeric G-proteins are still under intensive study. The RTK–MAPK pathway appears to play an essential role in cell proliferation. The emerging picture is that GPCRs achieve their mitogenic effect through the regulation of the RTK–MAPK pathway at different levels by multiple mechanisms.

IV. HETEROTRIMERIC G-PROTEINS AND THEIR SECOND MESSENGER-GENERATING SYSTEMS

Approximately 20 mammalian G-protein α-subunits have been identified. Based on their primary sequence similarity, they are divided into four families: G_s, G_i, G_q, and G_{12}. These G-protein α-subunits regulate the activity of several second-messenger-generating systems. The members of the G_q family control the activity of phosphatidylinositol-specific phospholipases, such as phospholipase C-β, which hydrolyzes phosphatidylinositol 4,5-bisphosphate (to generate two second messengers, inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 and DAG in turn lead to an increase in the intracellular concentrations of free calcium $[Ca^{2+}]_i$ and the activation of a number of protein kinases, including protein kinase C (PKC). The members of the G_s family activate adenylyl cyclases, whereas G_i family members can inhibit a subset of these enzymes, thereby controlling the intracellular concentrations of cyclic AMP (cAMP). cAMP can further activate protein kinase A (PKA) and the recently identified guanine nucleotide exchange factor for small GTPase Rap1, EPAC (exchange protein directly activated by cAMP). G_α subunits of the G_i family, which includes $G_{\alpha i1}$, $G_{\alpha i2}$, $G_{\alpha i3}$, $G_{\alpha o}$, transducin ($G_{\alpha t}$), and gustducin ($G_{\alpha gust}$), also activate a variety of phospholipases and phosphodiesterases and promote the opening of several ion channels. The members of the $G_{\alpha 12}$ family stimulate small GTPase Rho through Rho guanine nucleotide exchange factors (RhoGEF), which include p115-RhoGEF, PDZ-RhoGEF, and leukemia-associated RhoGEF.

Thus far, 6 G-protein β-subunits and 12 G-protein γ-subunits have been cloned. On GPCR activation, dimers are released from the heterotrimeric complex and regulate the activity of many signaling molecules, including ion channels, phosphatidylinositol 3-kinases (PI3Ks), phospholipases, adenylyl cyclases, and receptor kinases. Distinct pools of $G_{\beta\gamma}$ subunits may play different roles in signal transmission.

V. SIGNALING BY GPCRs TO MAPK PATHWAY THROUGH SECOND MESSENGERS

A. PKA

In NIH 3T3 cells, activated $G_{\alpha s}$ and 8-Br-cAMP inhibit H-Ras-stimulated DNA synthesis and MAPK activity. Phosphorylation of Raf-1 at multiple serine residues by PKA on cAMP activation reduces the affinity of Raf for Ras and thus decreases Raf kinase activity. Also, PKA-mediated phosphorylation of a negative regulatory phosphatase of MAPKs is required for agonist-induced activation of MAPKs in T cells.

B. PKC

Activation of PKC by G-protein-coupled receptors results in EGFR phosphorylation on multiple Ser and Thr residues, including Thr-654 in the juxtamembrane domain of EGFR. PKC-induced phosphorylation of EGFR results in an inhibition of its PTK activity and in strong inhibition of EGF binding to the extracellular ligand-binding domain. PKC-mediated phosphorylation of the juxtamembrane domain of EGFR thus appears to provide a negative feedback mechanism for the control of receptor activity. Moreover, PKC can phosphorylate and activate Raf-1 and thus stimulate MAPK activity. Thus, PKC can have different effects in connecting the GPCR to RTK pathways, depending on its sites of action.

C. RasGRP

In addition to the catalytic domain, RasGRP, a guanyl nucleotide-releasing protein for Ras, consists of an atypical pair of "EF hands" that bind calcium and a DAG-binding domain. RasGRP activates Ras and causes transformation in fibroblasts. ERK1 and ERK2 are activated in rat2 cells expressing RasGRP in response to increases in membrane DAG and free cytoplasmic calcium induced by GPCR agonist endothelin-1. Sustained ligand-induced signaling and membrane partitioning of RasGRP are absent when the DAG-binding domain is deleted. RasGRP is expressed in the nervous system, where it may couple changes in DAG and possibly calcium concentrations to Ras activation.

D. Rap1 and EPAC

1. Control of the MAPK Pathway by Rap1

Ras-related protein Rap1 was identified in a screen for proteins that can suppress the transformed phenotype of fibroblasts oncogenically transformed by one of the mutated Ras genes, *K-ras*. Rap1 can interact with members of the Raf subfamily, Raf-1 and B-Raf. Its effect on the MAPK pathway depends on the interaction partners.

2. Inhibition of Raf-1 by Rap1

Rap1 binds to the serine/threonine kinase Raf-1 *in vitro*, through an interaction with both the Ras-binding domain and the adjacent cysteine-rich region of Rap1 and, in addition, the two proteins co-immunoprecipitate. It has been proposed that Rap1 inhibits Ras/ERK signaling by trapping Raf-1 in an inactive complex.

3. Activation of B-Raf by Rap1

In some cell types, Rap1 is implicated in the activation of the MAPK pathway. The mechanism may be that Rap1 binds to and activates the Raf family member B-Raf. The evidence for this interaction includes the direct binding of Rap1 to, and activation of, B-Raf *in vitro* and the fact that inhibitors of Rap1, such as Rap1 GTPase-activating protein (Rap1GAP) and Rap1N17, abolish the activation of the B-Raf–MAPK pathway. The different effect of Rap1 on B-Raf (activating) and Raf-1 (inactivating) is thought to reside in the interaction of Rap1 with the cysteine-rich region of the two kinases, as swapping the two domains reverses the effect of Rap1 on the two proteins.

4. EPAC

Rap1 is activated in response to a range of stimuli through a number of second-messenger molecules, including cAMP, Ca^{2+}, and diacylglycerol. PKA is activated by cAMP. However, by using inhibitors and mutants, it was found that PKA is not involved in the cAMP-induced activation of Rap1. Indeed, although PKA phosphorylates Rap1 near its carboxy-terminus, this phosphorylation is not required for cAMP-dependent activation. The search of sequence databases for possible Rap1 GEFs that might be directly regulated by cAMP led to the discovery of EPAC. In addition to containing homologies to other GEFs for Ras-like proteins, EPAC possesses sequences related to the regulatory subunit of PKA. EPAC is activated both *in vitro* and *in vivo* by direct binding of cAMP. Also, EPAC mutant with deletion of the cAMP-binding domain activates Rap1 *in vitro*. This indicates that the cAMP-binding domain normally inhibits the exchange activity of EPAC until cAMP binds, most likely causing a conformational change that relieves the inhibition.

VI. SIGNALING BY GPCRs TO MAPK PATHWAY THROUGH OTHER HETEROTRIMERIC G-PROTEIN EFFECTORS

A. RTK

RTK can be transactivated through an extracellular pathway on GPCR stimulation. It has been shown that a chimeric RTK consisting of the EGFR ectodomain and the transmembrane and intracellular portion of the PDGF receptor (PDGFR) is transactivated by treatment of Rat1 fibroblasts with GPCR ligands but endogenous PDGFR is not. Hence, GPCR-induced transactivation of the artificial RTK does not involve an intracellular pathway and is dependent on the extracellular ligand-binding domain of the EGFR. In the presence of diphtheria toxin mutant CRM197 that specifically blocks heparin-binding EGF (HB-EGF) function or the matrix metalloprotease inhibitor batimastat (BB94), lysophosphatidic acid (LPA)-, carbachol-, or tetradecanoyl-phorbol-13-acetate (TPA)-induced transactivation of the EGFR and tyrosine phosphorylation of SHC are completely abrogated in COS-7 and HEK 293 cells. Flow cytometric analysis directly confirms cell surface ectodomain shedding of proHB-EGF on treatment with GPCR agonists or TPA. Therefore, it has been proposed that activation of heterotrimeric G-proteins by agonist-occupied GPCR induces the extracellular activity of a transmembrane

metalloproteinase, which leads to the extracellular processing of a transmembrane growth factor precursor and release of the mature factor, and consequently stimulates RTKs and MAPKs.

B. PI3Kγ

Overexpression of PI3Kγ in COS-7 cells activates MAPK in a $G_{\beta\gamma}$-dependent fashion. Wortmannin, an inhibitor of PI3Ks, or expression of a catalytically inactive mutant of PI3Kγ abolishes the stimulation of MAPK by $G_{\beta\gamma}$ or in response to stimulation of M2 muscarinic G-protein-coupled receptors.

Expression of a mutant Sos protein lacking the domain involved in Ras-specific guanine nucleotide exchange activity, a dominant negative mutant N17-Ras, or a dominant negative mutant of Raf-1 inhibits MAPK stimulation by PI3Kγ without affecting MAPK stimulation by the activated form of MEK. Therefore, signaling from G-protein-dependent receptors, $G_{\beta\gamma}$, and PI3Kγ to the MAPK pathway occurs upstream of Sos. Expression of PI3Kγ in COS-7 cells stimulates tyrosine phosphorylation of Shc and enhances the association of Shc with Grb2, whereas a mutant of Shc lacking the tyrosine phosphorylation site, Y317F, suppresses the stimulation of MAPK induced by LPA, the expression of $G_{\beta\gamma}$ and carbachol in m2-transfected cells, the expression of PI3Kγ, or the expression of the Src-related tyrosine kinase Fyn. The nonspecific tyrosine kinase inhibitor genistein or the Src-like specific inhibitor PP1 potently blocks MAPK activation by PI3Kγ. Thus, stimulation of MAPK by PI3Kγ requires a tyrosine kinase that, in turn, phosphorylates Shc and induces its association with Grb2. Therefore, receptors coupled to heterotrimeric G-proteins can stimulate the MAPK pathway through $G_{\beta\gamma}$ subunits, PI3Kγ, a tyrosine kinase, and Shc.

VII. SIGNALING BY HEPTAHELICAL RECEPTORS TO MAPK PATHWAY THROUGH HETEROTRIMERIC G-PROTEIN-INDEPENDENT PATHWAYS

A. β-Arrestin-Mediated Recruitment of Src Kinase and Activation of MAPK Pathway

Stimulation of β_2 adrenergic receptors (β_2ARs) results in the dissociation of heterotrimeric G-proteins into $G_{\alpha s}$-GTP and $G_{\beta\gamma}$ subunits. The release of $G_{\beta\gamma}$ facilitates GRK (G-protein-coupled receptor kinase)-mediated phosphorylation of the agonist-occupied receptor. β-Arrestin-1 functions as an adapter, binding to both GRK-phosphorylated receptor and c-Src. β-Arrestin-1 mutants, disrupted either in c-Src binding or in the ability to target receptors to clathrin-coated pits, block β_2AR-mediated activation of the MAP kinases Erk1 and Erk2. β-Arrestin-1 binding, which terminates receptor–G-protein coupling, can initiate a second wave of signal transduction in which the "desensitized" receptor functions as a critical structural component of a mitogenic signaling complex.

In HEK-293 cells expressing angiotensin II type 1a receptors (AT1aR), angiotensin stimulation triggers β-arrestin-2 binding to the receptor and internalization of AT1aR-β–arrestin complexes. Within these complexes, β-arrestin-2 acts as a scaffold to assemble component kinases of the MAPK cascade, Raf-1, MEK1, and ERK2.

B. c-Src

The β_3AR can directly recruit c-Src. Unlike the other GPCRs, the β_3AR is not phosphorylated by G-protein receptor kinases and thus does not bind to β-arrestin and undergo internalization. Interestingly, β_3AR contains proline-rich sequences in both the third intracellular loop and the carboxyl-tail, which appear to mediate the interaction with the SH3 domain of c-Src and activate the MAPK cascade. Disruption of these proline-rich sequences abolishes the ability of the receptor to bind c-Src and to stimulate the MAPK pathway without affecting the signaling by the heterotrimeric G-proteins.

VIII. MECHANISMS FOR CONTROLLING THE SPECIFICITY OF SIGNALING PATHWAYS

It is apparent that signaling pathways are intertwined with one another to form a large network that is subjected to stimulatory and inhibitory inputs. Such complexity is essential for mediating the pleiotropic biological processes in response to the myriad of extracellular cues. However, it also poses an enormous challenge for the cell to maintain the specificity of the signaling pathways. Several mechanisms have been proposed for the control of specificity in cell signaling.

A. Cell-Specific Profiling of Signaling Components

As more and more signaling pathways and downstream effectors have been identified, each receptor may activate many potential pathways and effectors. However, the biological outcome of signals generated at the cell surface in response to receptor stimulation is

strongly dependent on the developmental stages and cell types. For instance, in early development, FGFR1 plays an important role in the control of cell migration, a process that is crucial for mesodermal patterning and gastrulation, whereas stimulation of FGFR1 in fibroblasts leads to cell proliferation. Moreover, activation of a given membrane receptor by a specific ligand transduces a unique biological response, even though these pathways utilize a common repertoire of proteins. PDGF and EGF, for instance, stimulate unique biological responses in their target tissues, although the intracellular signaling pathways that are activated by PDGF and EGF are very similar indeed.

In addition, activation of the same signaling molecules in different cells leads to distinct responses. For example, stimulation of PI3K by insulin in muscle cells results in the enhancement of metabolic processes, whereas stimulation of PI3K by nerve growth factor (NGF) in neuronal cells leads to an anti-apoptotic signal. Similarly, when cAMP increases on GPCR activation, the MAPK pathway is stimulated in neuronal PC12 cells but inhibited in fibroblast NIH 3T3 cells.

The most plausible explanation for these observations is that there is cell type- and stage-specific expression of signaling components, such as effector proteins and transcriptional factors, in different cell types and at different developmental stages. Therefore, a similar input can lead to a different output in a different cellular context.

B. Combinatorial Control

Signal specificity can be defined in part by a combinatorial recruitment during signaling processes. For instance, even though every RTK contains a core PTK, there exist some other regulatory elements that recruit and activate a unique set of signaling proteins via their own tyrosine autophosphorylation sites and by means of the tyrosine phosphorylation sites on closely associated docking proteins. The combinatorial recruitment of a particular complement of signaling proteins from a common preexisting pool of signaling cassettes is one mechanism for control of signal specificity. This process is further regulated by differential recruitment of stimulatory and inhibitory proteins by the different receptors and downstream effector proteins, leading to fine-tuning of cellular responses.

C. Scaffold Proteins

It has been shown that scaffolding proteins that bind simultaneously to several proteins are able to insulate common components of signaling pathways from closely related signaling cascades. In yeast, Sterile 11 (Ste11) is shared by two signaling pathways and functions as the MAPKKK. The scaffolding protein Ste5 has been shown to interact with a pheromone-activated G-protein and with components of the MAP kinase cascade. Ste5 forms a complex with Ste11, Ste7, and Fus3, leading to insulation of the pheromone-induced MAP kinase cascade from the closely related osmolarity response pathway, in which MAPKK Pbs2 acts as both the scaffolding protein and the intermediate kinase that relays signal from MAPKKK Ste11 to downstream MAP kinase Hog1.

Of note, the output of signaling cascades through scaffold protein is determined by a balance of all components. Too much or too little of any component in the scaffolded complexes may decrease the output of the pathway. Therefore, a scaffolded pathway is in principle more sensitive to fluctuations in the concentrations of pathway components, even though scaffolds have the advantage of facilitating efficient signaling with specificity.

D. Cellular Compartmentalization

In recent years, it has become apparent that the cellular localization of signaling components involved in cell signaling has a profound impact on their biological activity. As mentioned above, AT1aR activation can lead to $G_{\beta\gamma}$ release, which facilitates GRK-mediated phosphorylation of the receptor. The phosphorylated residues on the receptor function as docking sites for β-arrestin translocation from the cytoplasm; the β-arrestin further acts as a scaffolding protein for the assembly of c-Src, Raf-1, MEK1, and ERK2. For RTK signaling, many of the targets of RTKs are located at the cell membrane, and membrane translocation is required for activation of many cellular processes. Binding of SH2, PTB, or SH3 domains to activated receptors or to membrane-linked docking proteins leads to membrane translocation. In addition, membrane translocation is regulated in part by PH or FYVE domains, two protein modules that bind to different phosphoinositides.

The translocation of activated ERK1/2 proteinss from the cytoplasm into the nucleus is another example of the role of protein localization in cell signaling.

E. Signal Duration and Amplitude

Signal duration and signal strength are essential determinants of signal transmission and biological responses. For instance, RTKs that induce transient

stimulation of MAPK (e.g., EGFR) stimulate PC12 cell proliferation, whereas RTKs that stimulate a sustained and robust MAPK response (e.g., NGF receptor, FGFR) promote neuronal differentiation of the same cells. Alternatively, overexpression of EGFR in PC12 cells leads to sustained MAPK response, resulting in cell differentiation, although the same receptors give a proliferative response when expressed at lower levels. These experiments show that the biological outcome (proliferation versus differentiation) is determined by the integrative amplitude of various inputs over time. Signal threshold can be determined by the specific activity of a given RTK and by the balanced action of the various inhibitory or stimulatory signals that are regulated by other pathways. For example, the signal generated by an RTK can be prolonged by increasing the intracellular cAMP level that enhances B-Raf activity by activation of Rap1. Signaling pathways are also subjected to multiple negative feedback mechanisms at the level of the receptor itself by inhibitory protein tyrosine phosphatases and by receptor endocytosis and degradation. In addition, the specific activity of key effector proteins can be negatively regulated by inhibitory signals. The balance between the various stimulatory and inhibitory responses will ultimately determine the strength and duration of the signals that are transmitted through the networks of signaling cascades following their initiation at the cell surface in response to receptor stimulation.

IX. SUMMARY

It is very common for signaling pathways activated from membrane receptors to be interconnected with one another via complicated intracellular protein networks. As an example, the proliferative response generally controlled by the RTK–MAPK pathway can be regulated by GPCR signaling pathways at multiple levels by different mechanisms. The frequently applied tool of targeted gene disruption used by geneticists for analyzing signaling pathways is complicated by the existence of redundant signaling pathways and multitasking components shared by multiple signaling cascades. Consequently, more sophisticated tools should be developed and applied for the analysis of cellular signaling pathways. To understand the control of the specificity among signaling networks, there is a need for new techniques for determination of protein localization and measurement of kinetics of cellular signaling events in the context of living cells and even in the live animal. In addition, detailed analyses of gene expression patterns by microarray analysis of genes that are expressed in response to growth factor stimulation of cells derived from normal or pathological tissues will reveal new links between signaling pathways. Finally, for the future study of cellular signaling networks, the modern biochemists, geneticists, and transductionists will benefit from the adoption of approaches that have been developed by engineers to describe complicated networks.

Glossary

G-protein-coupled receptor Seven-transmembrane protein that is usually (but not always) coupled to heterotrimeric G-proteins to achieve its biological functions.

mitogen-activated protein kinase (MAPK) cascade MAPKs constitute a family of kinases that are activated by phosphorylation in response to extracellular stimuli. MEKs, the kinases that phoshorylate MAPKs, are themselves regulated by phosphorylation. Such sequential chains of kinase phosphorylation and activation are called kinase cascades.

receptor tyrosine kinase Transmembrane receptor with a single membrane-spanning region that possesses intrinsic protein tyrosine kinase activity in its cytoplasmic domain and ligand-binding ability in its extracellular domain.

scaffold protein A protein capable of binding to multiple signaling components, thereby providing a platform to relay signals and achieve specificity of communication among components.

Somatostatin

MALCOLM J. LOW
Oregon Health and Science University

Somatostatins are cyclic neuropeptides that exert a broad array of inhibitory and modulatory activities in the endocrine, gastrointestinal, nervous, and immune systems. The archetypal somatostatin, somatotropin release-inhibiting factor, inhibits secretion of pituitary growth hormone. It interacts with five known somatostatin subtypes. The recent development of small-molecule receptor-subtype-specific ligands and new genetic models of somatostatin peptide and receptor mutations promises to provide more definitive answers to the unresolved questions of somatostatin function in extrahypothalamic brain tissue.

I. INTRODUCTION

A peptide that potently inhibited growth hormone (GH) release from cultured pituitary cells was unexpectedly identified during the early efforts to isolate a GH-releasing factor from hypothalamic extracts. The factor responsible for both this inhibition of GH secretion and the inhibition of insulin secretion by a pancreatic islet extract was eventually purified from porcine hypothalamus and its amino acid sequence determined by Brazeau and colleagues in 1973. This cyclic peptide containing 14 amino acids was named somatostatin (SS14). Subsequently, a second N-terminal extended form, SS28, was identified as a secretory product from various tissues. Both forms of mammalian somatostatin are derived posttranslationally from a common prohormone by the action of specific prohormone convertases. In addition, the isolation of SS28(1–12) in some tissues suggests that SS14 can also be secondarily processed from SS28. SS14 is the predominant form of somatostatin produced in the brain (including the hypothalamus) and most other tissues, whereas SS28 is found in highest concentrations in the gastrointestinal tract, especially the small intestine.

The biological activities of somatostatin are much wider than the inhibition of GH secretion for which it was named. Somatostatin also inhibits thyrotropin secretion from the pituitary and has nonpituitary roles, including neurotransmitter or neuromodulator activity in the central and peripheral nervous systems and regulatory functions in the gut and pancreas. As a pituitary regulator, somatostatin is a true neurohormone, i.e., a neuronal secretory product that enters the blood (hypophyseal–portal circulation) to affect cell function at remote sites. In the gut, somatostatin is present in both the myenteric plexus (where it acts as a neurotransmitter) and in epithelial cells, where it influences the function of adjacent cells by a paracrine mechanism. Somatostatin can influence its own secretion from pancreatic delta cells (an autocrine function) in addition to acting as a paracrine factor on other endocrine cell types in pancreatic islets. Gut exocrine secretion can be modulated by intralumenal action, so somatostatin can also be considered to be a lumone. Because of its wide distribution, broad spectrum of regulatory effects, and evolutionary history, this peptide can be regarded as an archetypal gut–brain peptide.

II. EVOLUTION OF THE SOMATOSTATIN GENE FAMILY

The genes that encode somatostatin in humans and a number of other species exhibit striking sequence homology, even in primitive jawless fish (Fig. 1).

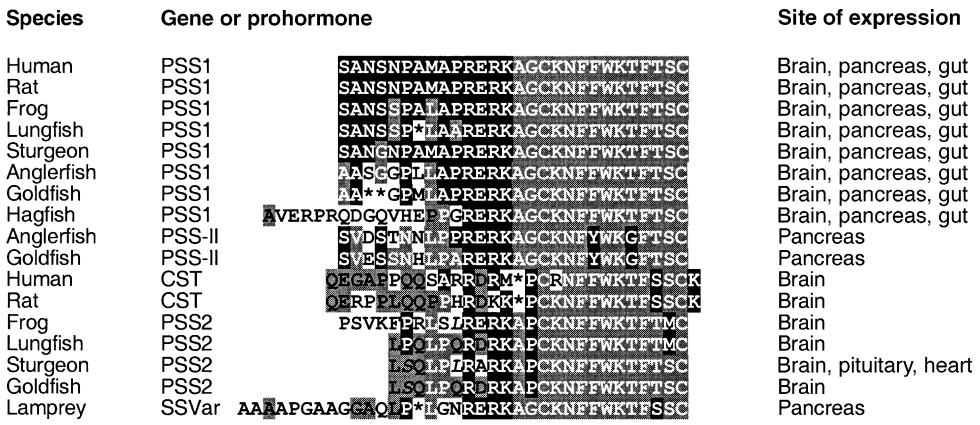

FIGURE 1 Amino acid sequence comparisons of somatostatin-like peptides in species of different vertebrate taxa. The conserved mammalian sequence of SS28 derived from prosomatostatin 1 (PSS1) is shown for humans and rats. The cyclic SS14 peptide (gray shading) at the C-terminus of SS28 has been conserved in all vertebrate PSS1 genes. Teleost fish have a second gene encoding PSS-II that is proteolytically processed to a SS28-like peptide characterized by the C-terminal sequence of [Tyr^{7}, Gly^{10}]SS14. A mammalian cortistatin (CST) gene encodes either human CST17 (DRMPCRNFFWKTFSSCK) or rat CST14 (PCKNFFWKTFSSCK), both of which have 11 amino acid homologies with SS14. Frog, lungfish, sturgeon, and goldfish have a PSS2 gene that may be the orthologue of mammalian CST. Lampreys (*Lampetra fluviatilis*) produce a variant of SS14 (SSVar) containing the [Ser^{12}] but not the [Pro^{2}] substitutions present in CST. Amino acid identity among sequences is indicated by the different combinations of font shading. An asterisk (*) has been inserted in some sequences to maximize alignment.

Furthermore, the amino acid sequence of SS14 is identical in all vertebrates. Until recently, it was accepted that all tetrapods have a single gene encoding both SS14 and SS28 whereas teleost fish have two nonallelic prosomatostatin genes (PSS1 and PSS-II), each of which encodes only one form of the mature somatostatin peptides. Comparative endocrinologists have inferred that a common ancestral gene underwent a gene duplication event after the split of teleosts from the ancestors of tetrapods.

However, both lampreys and amphibians, which pre- and postdate the teleost evolutionary divergence, respectively, have now been shown to contain at least two distinct PSS genes. A more distantly related gene identified in mammals encodes cortistatin (CST), a somatostatin-like peptide that is highly expressed in cortex and hippocampus. Rat CST14 differs from SS14 by three amino acid residues but has high affinity for all known subtypes of somatostatin receptors (see later). The human gene sequence predicts a tripeptide-extended CST17 and a further N-terminally extended CST29 (Fig. 1). A revised evolutionary concept of the somatostatin gene family is that a primordial gene underwent duplication during or before the advent of chordates and the two resulting genes subsequently underwent differing rates of mutation to produce the distinct prosomatostatin and procortistatin genes in mammals. A second gene duplication likely occurred in teleosts to generate PSS1 and PSS-II from the ancestral somatostatin gene.

III. SOMATOSTATIN GENE ORGANIZATION AND REGULATION

The mammalian gene has a relatively simple organization consisting of two coding exons separated by one intron (Fig. 2). A single promoter directs transcription of the PSS1 gene in all tissues and there are no known alternative mRNA splicing events. Apart from its expression in neurons of the periventricular and arcuate hypothalamic nuclei and involvement in GH secretion, somatostatin is highly expressed in the cortex, lateral septum, extended amygdala, reticular nucleus of the thalamus, hippocampus, and many brain stem nuclei in human and rat brain tissue. Cortistatin, present in the brain at a small fraction of the levels of somatostatin and in a more limited distribution, is primarily confined to the cortex and hippocampus.

The molecular mechanisms underlying the developmental and hormonal regulation of somatostatin gene transcription have been most extensively studied in pancreatic islets and islet-derived cell lines. Less is known concerning the regulation of somatostatin

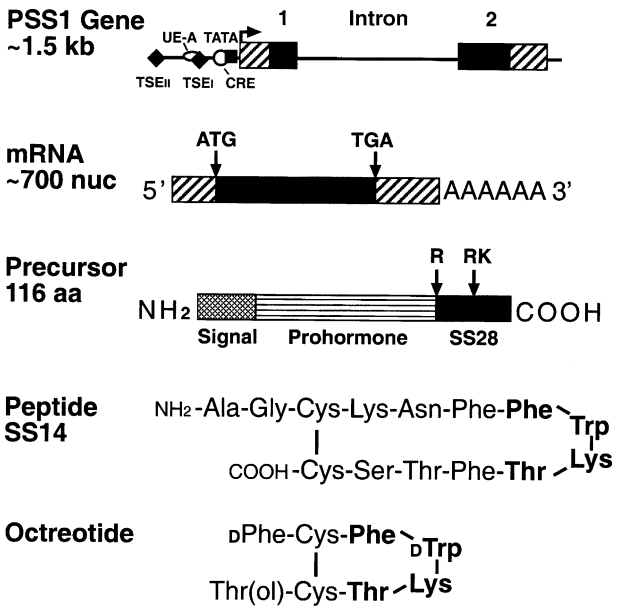

FIGURE 2 Summary of somatostatin biosynthesis in mammals. Structures of the mammalian PSS1 gene, mRNA, precursor protein, mature SS14 peptide, and the synthetic SSTR agonist octreotide are presented schematically. The promoter elements in the PSS1 gene (TSE, UE-A, CRE, and TATA) are discussed in the text. The 5′ and 3′ untranslated regions of exons 1 and 2 and within the corresponding polyadenylated mRNA are indicated by diagonal stripes. ATG, Translation initiation codon; TGA, translation stop codon; R, arginine; K, lysine.

gene expression in neurons, except that activation is strongly controlled by binding of the phosphorylated transcription factor cyclic adenosine monophosphate (cAMP) response element binding protein (CREB) to its cognate CRE contained in the promoter immediately 5′ to a consensus TATA sequence. Experiments performed in transgenic mice suggest that accurate neural-specific somatostatin gene expression requires distal genomic elements in addition to the proximal 300 nucleotides that are sufficient for islet cell expression. The proximal enhancer elements in the somatostatin gene promoter that bind complexes of homeodomain-containing transcription factors (PAX6, PBX, and PREP1) and up-regulate transcription in pancreatic islets may actually represent gene silencer elements in neurons (promoter elements TSE_{II} and UE-A). Conversely, another related cis-element in the somatostatin gene (promoter element TSE_I) apparently binds a homeodomain transcription factor PDX1 (also called STF1/IDX1/IPF1) that is common to developing brain, pancreas, and foregut and regulates gene expression in both the central nervous system (CNS) and gut.

Similar to other genes encoding polypeptide precursors, the posttranslational intracellular trafficking and processing of PSS represent additional control points in the expression of somatostatin (Fig. 2). A peptide motif assuming an amphipathic α-helical conformation near the N-terminus of PSS appears to play an essential role in targeting the prohormone through the endoplasmic reticulum and Golgi compartments that constitute part of the regulated secretory pathway. A second highly conserved amino acid motif, NPAMAP (in single-letter code: N, asparagine; P, proline; A, alanine; M, methionine) within the SS28(1–12) sequence is important for directing the endoproteolytic processing of PSS1 to either SS28 at the 5′ single basic amino acid (Arg) residue or to SS14 at the 3′ paired basic amino acid (Arg-Lys) residues by appropriate prohormone convertases.

IV. SOMATOSTATIN RECEPTORS

Five somatostatin receptor subtypes (SSTR1–SSTR5) have been identified by gene cloning techniques, and one of these (SSTR2) is expressed in two alternatively spliced forms, SSTR2a and SSTR2b. The SSTRs are members of the rhodopsin-like G-protein-coupled receptor clan, and their unique amino acid signature is provided by a seven-element fingerprint of peptide sequences located in conserved regions of the N- and C-termini, extra- and intracellular loops, and transmembrane domains. They are most closely related to the vertebrate opioid receptors and the invertebrate allatostatin receptor family. The five SSTR subtypes are encoded by separate genes located on different chromosomes, are expressed in unique or partially overlapping distributions in multiple target organs, and differ in their coupling to second-messenger signaling molecules, and therefore in their range and mechanism of intracellular actions. The subtypes also differ in their binding affinity to specific somatostatinergic ligands. Some of these differences have important implications for the use of somatostatin analogues in diagnostic imaging and in pharmacotherapy.

All SSTR subtypes are coupled to pertussis-toxin-sensitive G-proteins and bind SS14 and SS28 with high affinity in the low-nanomolar range, although SS28 has a modestly higher affinity for SSTR5. SSTR1 and SSTR2 are the two most abundant subtypes in brain and probably function as both postsynaptic

receptors and presynaptic autoreceptors in the hypothalamus and limbic forebrain, respectively. SSTR4 is most highly expressed in the hippocampus. SSTR3 is uniquely localized on nonmotile neuronal cilia, structures that have an unknown role in neuronal signaling. All the subtypes are expressed in the pituitary, but SSTR2 and SSTR5 are the most abundant receptors on somatotrophs. These two subtypes are also the most physiologically important in pancreatic islets. SSTR5 is responsible for inhibition of insulin secretion from beta cells and SSTR2 is essential for inhibition of glucagon from alpha cells (Table 1).

Binding of somatostatin to its receptors leads to activation of one or more inhibitory G-proteins (G_i/G_o), which in turn inhibit adenylyl cyclase activity and decrease the concentration of intracellular cAMP. Other G-protein-mediated actions common to all SSTRs are activation of a vanadate-sensitive phosphotyrosine phosphatase (PTP) and modulation of mitogen-activated protein kinases (MAPKs). MAPK activity has been reported to be increased by SSTR1 and SSTR4, decreased by SSTR2 and SSTR5, and modulated in both directions by SSTR3. Different subsets of SSTRs can activate inwardly rectifying K^+ channels and/or inhibit voltage-dependent Ca^{2+} channels. The net effects of SSTR coupling to these membrane conductances include hyperpolarization of the resting membrane potential, decreased frequency of action potentials, and decreased probability of vesicle release from nerve terminals. SSTR1 also activates a Na^+/H^+ exchanger and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)/kainate glutamate receptors, whereas SSTR2 inhibits non-*N*-methyl-D-aspartate (NMDA) glutamate receptors in some cells. SSTR2 and SSTR4 have been reported to couple positively to phospholipase C/inositol 1,4,5-trisphosphate and phospholipase A_2 activities, respectively.

The lowering of intracellular cAMP and Ca^{2+} are the most important mechanisms for the inhibition of hormone secretion from endocrine cells, whereas actions on PTP and MAPK are postulated to play a role in antiproliferative effects of somatostatin on tumor cells. Recent provocative data suggests that SSTRs may form oligomeric complexes, including in some cases heterodimers with non-SSTRs, greatly increasing the possible signaling complexity of somatostatin ligands.

V. REGULATION OF HORMONE SECRETION BY SOMATOSTATIN

A. Inhibition of GH Secretion and GH Negative Feedback

In the pituitary, somatostatin directly inhibits secretion of GH and thyrotropin and, under limited conditions, of prolactin and adrenocorticotropic hormone (ACTH), from their respective cell types. However, the full role of somatostatin in the regulation of GH secretion is much more complex and involves a constant interplay with hypothalamic growth hormone-releasing hormone (GHRH), circulating hormones, and additional modulatory peptides at the level of both the pituitary and the hypothalamus. The predominant hypothalamic influence on GH release is stimulatory, thus section of the pituitary stalk or lesions of the ventromedial hypothalamus cause reductions of basal and induced GH release. When the somatostatinergic component is inactivated (e.g., by antisomatostatin antibody injection in rats), basal GH levels and GH responses to the usual provocative stimuli are enhanced. Negative feedback

TABLE 1 Diverse Inhibitory Functions of Somatostatin on Nervous, Endocrine, Gastrointestinal, and Immune System Cell Secretion[a]

Organ	Cell type	Factor inhibited	SS receptor
Brain (hypothalamus)	SS neuron	Somatostatin	SSTR1
Brain (hypothalamus)	GHRH neuron	GHRH	SSTR2
Brain (hippocampus)	CA1 pyramidal	Glutamate	SSTR4
Pituitary gland	Somatotroph	Growth hormone	SSTR2, SSTR5
Pancreatic islet	β cell	Insulin	SSTR5
Pancreatic islet	α cell	Glucagon	SSTR2
Stomach	Parietal cell	HCl	SSTR2
Immune system	T lymphocyte	Interferon γ	SSTR2

[a]Abbreviations: SS, somatostatin; GHRH, growth hormone-releasing hormone; SSTR, somatostatin receptor.

control of GH release is mediated by GH and by insulin-like growth factor-I (IGF-I), which is synthesized in the liver under control of GH. Direct GH effects on the hypothalamus act by short-loop feedback, whereas those involving IGF-I and other circulating factors influenced by GH, including free fatty acids and glucose, are long-loop systems analogous to the pituitary–thyroid and pituitary–adrenal axes. Control of GH secretion thus includes two closed-loop systems (GH and IGF-I) and one open-loop regulatory system (neural) (Fig. 3).

Although most of the evidence for a direct role of GH in its own negative feedback has been derived from animals, an elegant study in normal men demonstrated that GH pretreatment blocks the subsequent GH secretory response to GHRH by a pathway that is dependent on somatostatin. The mechanism responsible for this GH feedback via the hypothalamus has been largely elucidated in rodent models. GH receptors are selectively expressed on somatostatin neurons in the hypothalamic periventricular nucleus and on neuropeptide Y (NPY) neurons in the arcuate nucleus. Expression of the

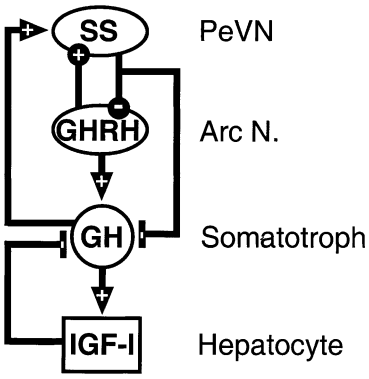

FIGURE 3 Regulatory feedback loops in the hypothalamic control of pituitary growth hormone secretion. Growth hormone-releasing hormone (GHRH) and somatostatin (SS) are the principal stimulatory and inhibitory factors mediating GH secretion. GH stimulates the synthesis and release of insulin-like growth factor-I (IGF-I) from hepatocytes, which inhibits GH secretion from the pituitary. GH also inhibits its own secretion by a short-loop feedback circuit involving the stimulation of somatostatin neurons in the periventricular nucleus (PeVN) of the hypothalamus. A common neural mechanism leading to the inhibition of GH secretion is the activation of somatostatin neurons. Stimulatory and inhibitory neuronal synapses are represented by circular terminals marked with a plus or minus sign, respectively. Stimulatory and inhibitory hormonal pathways are represented by arrows with a plus sign or bars with a minus sign, respectively. Arc N, Arcuate nucleus.

c-fos gene in both populations of GH receptor-positive neurons is acutely elevated by GH administration, indicating an activation of hypothalamic circuitry that includes these neurons. Data from many experiments strongly support a model of GH negative feedback regulation that involves the primary activation of periventricular somatostatin neurons by GH. These tuberoinfundibular neurons then inhibit GH secretion directly by release of somatostatin in the median eminence, but in addition they indirectly inhibit GH secretion by way of collateral axonal projections to the arcuate nucleus that synapse on and inhibit GHRH neurons (Fig. 3).

B. Neural Regulation of Tuberoinfundibular Somatostatin and GHRH

GHRH-containing nerve fibers that terminate adjacent to portal vessels in the external zone of the median eminence arise principally from within, above, and lateral to the infundibular nucleus in the human hypothalamus, corresponding primarily to the rodent arcuate nucleus. Perikarya of the tuberoinfundibular somatostatin neurons are located almost completely in the medial periventricular nucleus and parvocellular component of the anterior paraventricular nucleus. Neuroanatomical and functional evidence suggests a bidirectional synaptic interaction between the two peptidergic systems.

Multiple extrahypothalamic brain regions provide efferent connections to the hypothalamus and regulate GHRH and somatostatin neuronal activity. Somatosensory and affective information are integrated and filtered through the amygdaloid complex. The basolateral amygdala provides an excitatory input to the hypothalamus whereas the central extended amygdala, which includes the central and medial nuclei of the amygdala together with the bed nucleus of the stria terminalis, provides a γ-aminobutyric acid (GABA)ergic inhibitory input. Many intrinsic neurons of the hypothalamus also release GABA, often with a peptide cotransmitter. Excitatory cholinergic fibers arise to a small extent from forebrain projection nuclei, but mostly from hypothalamic cholinergic interneurons, which densely innervate the external zone of the median eminence. Similarly, the origin of dopaminergic and histaminergic neurons is local, with their cell bodies located in the hypothalamic arcuate and tuberomammillary bodies, respectively. Two important ascending pathways to the medial basal hypothalamus regulate GH secretion and they originate from serotonergic neurons in the raphe nuclei and adrenergic neurons

in the nucleus of the tractus solitarius and ventral lateral nucleus of the medulla.

Both GHRH and somatostatin neurons express pre- and postsynaptic receptors for multiple neurotransmitters and peptides. The α2-adrenoreceptor agonist clonidine reliably stimulates GH release, and for this reason a clonidine test has been a standard diagnostic tool in pediatric endocrinology. The net stimulatory effect on GH secretion appears to involve a dual mechanism of action—inhibition of somatostatin neurons and activation of GHRH neurons—and is blocked by the specific α2 antagonist yohimbine. In addition, a partial attenuation of the effects of clonidine by 5-hydroxytryptamine ($5\text{-}HT_1/5\text{-}HT_2$) antagonists suggests that some of the relevant α2 receptors are located presynaptically on serotonergic nerve terminals and increase serotonin release. Both norepinephrine and epinephrine play physiological roles in the adrenergic stimulation of GH secretion. Adrenergic α1 agonists have no effect on GH secretion in humans but β2 agonists such as the bronchodilator salbutamol inhibit GH secretion by stimulating the release of somatostatin from nerve terminals in the median eminence. These effects are blocked by propranolol, a nonspecific β antagonist. Dopamine generally has a net effect of stimulating GH secretion, but the relative importance of different dopamine receptor subtypes and their localization on specific neuronal structures in the hypothalamus is not known.

The effect of serotonin (5-hydroxytryptamine) on GH release in humans has been difficult to decipher because of the large variety of 5-HT receptor subtypes. However, clinical studies with the receptor-selective agonist sumatriptan clearly implicate the $5\text{-}HT_{1D}$ receptor subtype in the stimulation of basal GH levels. The drug also potentiates the effect of a maximal dose of GHRH, invoking in its mechanism of action the recurring theme of GH disinhibition by inhibition of hypothalamic somatostatin neurons. Histaminergic pathways acting through H1 receptors play only a minor, conditional stimulatory role in GH secretion in man.

Acetylcholine (ACh) appears to be an important physiological regulator of GH secretion. Blockade of muscarinic (m1) ACh receptors reduces or abolishes GH secretory responses to GHRH, glucagon, arginine, morphine, and exercise. In contrast, drugs that potentiate cholinergic transmission increase basal GH levels and enhance GH response to GHRH in normal individuals or in patients with obesity or Cushing's disease. *In vitro*, acetylcholine inhibits somatostatin release from hypothalamic fragments, and acetylcholine can act directly on the pituitary to inhibit GH release. There may even be a paracrine cholinergic control system within the pituitary. However, the sum of evidence suggests that the primary mechanism of action of m1 agonists is to inhibit somatostatin neuronal activity or the release of peptide from somatostatinergic terminals.

Many neuropeptides in addition to GHRH and somatostatin are involved in the modulation of somatotroph activity in the human. GH secretion is stimulated by galanin, opioid peptides, and ghrelin, the endogenous ligand for the growth hormone secretagogue receptor (GHS-R), each of which act at least in part by a GHRH-dependent mechanism. A larger number of neuropeptides are known or suspected to inhibit GH secretion in humans, at least under certain circumstances. The list includes NPY, corticotropin-releasing hormone (CRH), calcitonin, oxytocin, neurotensin, vasoactive intestinal peptide (VIP), and thyrotropin-releasing hormone (TRH). Inhibitory actions of NPY are well established in the rat. Its effect on GH secretion is secondary to stimulation of somatostatin neurons and is of particular interest because of the presumed role in GH autofeedback (discussed earlier) and the integration of GH secretion with regulation of energy intake and expenditure.

C. Somatostatin and GH Secretory Rhythms

GH secretion in young adults exhibits a true circadian rhythm over a 24-h period, characterized by greater nocturnal secretion that is independent of sleep onset. However, GH release is further facilitated when slow-wave sleep coincides with the normal circadian peak. Under basal conditions, GH levels are low most of the time, with an ultradian rhythm of about 10 (men) or 20 (women) secretory pulses per 24 h, as calculated by deconvolution analysis. Both sexes have an increased pulse frequency during the nighttime hours, but the fraction of total daily GH secretion associated with the nocturnal pulses is much greater in men. Overall, women have more continuous GH secretion and more frequent GH pulses that are of more uniform size compared to men. These sexually dimorphic patterns in the human are actually quite similar to those in the rat, although not as extreme.

The neuroendocrine basis for sex differences in the ultradian rhythm of GH secretion is not fully understood. Gonadal sex steroids play both an organizational role during development of the hypothalamus and an activational role in the adult, in which they regulate gene expression of many of the peptides and

receptors central to GH regulation. In the human, unlike the rat, the hypothalamic actions of testosterone appear to be predominantly due to its aromatization to 17β-estradiol and interaction with estrogen receptors. Hypothalamic somatostatin appears to play a more prominent role in men than in women for the regulation of pulsatile GH secretion, and this difference is postulated to be a key factor in producing the sexual dimorphism.

D. Somatostatin Effects on Gastrointestinal and Immune Systems

Somatostatin exerts inhibitory effects on virtually all endocrine and exocrine secretions of the pancreas, gut, and gallbladder (Table 2). Somatostatin also inhibits secretion by the salivary glands and, under some conditions, the secretion of parathyroid hormone and calcitonin. Somatostatin blocks hormone release in many endocrine-secreting tumors, including insulinomas, glucagonomas, VIPomas, carcinoid tumors, and some gastrinomas. Somatostatin and SSTR expression are coinduced by inflammatory and immune reactions in macrophages, T lymphocytes, splenocytes, and synovial fibroblasts in rheumatoid arthritis, consistent with paracrine or autocrine modulation of proliferative and hormonal responses in these cells.

TABLE 2 Physiologic Effects of Somatostatin in the Gastrointestinal Tract and Other Tissues

Inhibits hormone secretion from	Inhibits other gastrointestinal actions
Stomach and intestine	Gastric acid secretion
Gastrin	Gastric and jejunal fluid secretion
Secretin	Gastric emptying
Gastrointestinal polypeptide	Pancreatic bicarbonate secretion
Motilin	Pancreatic enzyme secretion
Glicentin (enteroglucagon)	(stimulates intestinal absorption of water and electrolytes)
Vasoactive intestinal peptide	Gastrointestinal blood flow
Pancreatic islets	Vasopressin-stimulated water transport
Insulin	Bile flow
Glucagon	Extragastrointestinal actions
Somatostatin	Inhibits the function of activated immune cells
Genitourinary tract	Induction of apoptosis
Renin	Inhibition of tumor growth

VI. EXTRAHYPOTHALAMIC SOMATOSTATIN AND BRAIN FUNCTION

The physiological actions of somatostatin in extrahypothalamic brain tissue remain the subject of active investigation. In the striatum, somatostatin increases the release of dopamine from nerve terminals by a glutamate-dependent mechanism involving SSTR2. In the pontine reticular formation, somatostatin blocks fear-potentiated acoustic startle responses and attenuates the increase of neuronal activity produced by the application of glutamate. Somatostatin is widely coexpressed with NPY in the limbic cortex and hippocampus GABAergic interneurons that modulate the excitability of pyramidal neurons. Temporal lobe epilepsy is associated with a marked reduction in somatostatin-expressing neurons in the hippocampus, consistent with a putative inhibitory action on seizures. Somatostatin has general arousal properties and induces rapid eye movement (REM) sleep whereas cortistatin, in contrast, has neuronal depressant actions and stimulates slow-wave sleep. A wealth of correlative data has linked reduced forebrain and cerebrospinal fluid concentrations of somatostatin with Alzheimer's disease, major depression, and other neuropsychiatric disorders, raising speculation about the role of somatostatin in modulating neural circuits underlying cognitive and affective behaviors.

VII. DIAGNOSTIC AND THERAPEUTIC USES OF SOMATOSTATIN

A. Somatostatin Analogues and Pharmacotherapy

An extensive pharmaceutical discovery program has been ongoing to synthesize somatostatin analogues with receptor subtype selectivity and improved pharmacokinetics and oral bioavailability compared to the native peptide. Initial efforts focused on the rational design of constrained cyclic peptides that incorporated D-amino acid residues and included the [Trp^8-Lys^9] dipeptide of somatostatin, which structure-function studies demonstrated is necessary for high-affinity binding of the peptide to its receptor. Many such analogues have been studied in clinical trials, including octreotide (Fig. 2), lanreotide, vapreotide, and the hexapeptide MK678. Each of these compounds is an agonist with similarly high-affinity binding to SSTR2 and SSTR5, moderate binding to SSTR3, and no (or low) binding to SSTR1 and SSTR4. More recently, a combinatorial chemistry approach

has led to a new generation of nonpeptidyl somatostatin agonists that bind selectively and with subnanomolar affinity to each of the five SSTR subtypes. In contrast to the marked success in development of potent and selective somatostatin agonists, there is a relative paucity of useful antagonists.

The actions of octreotide (SMS 201-995, or Sandostatin) illustrate the general potential of somatostatin analogues in therapy. This compound controls excess secretion of GH in acromegaly in most patients and shrinks tumor size in about one-third. Octreotide is also indicated for the treatment of thyrotropin-secreting adenomas that recur after surgery. It is used to treat other functioning, metastatic neuroendocrine tumors, including carcinoid, VIPoma, glucagonoma, and insulinoma, but is seldom of use for the treatment of gastrinoma. It is also useful in the management of many forms of intractable diarrhea (acting on salt and water excretion mechanisms in the gut) and to reduce external secretions in pancreatic fistulas (thus permitting healing). A decrease in blood flow to the gastrointestinal tract is the basis of its use in bleeding esophageal varices associated with hepatic cirrhosis and portal hypertension, but it is not effective in the treatment of bleeding from peptic ulcers.

The only major undesirable side effect of octreotide is reduction of bile production and of gallbladder contractility, leading to "sludging" of bile and an increased incidence of gallstones. Other common adverse effects, including nausea, abdominal cramps, flatulence, and diarrhea secondary to malabsorption of fat, usually subside spontaneously within 2 weeks of continued treatment. Long-term octreotide therapy is not associated with impaired glucose tolerance, despite an inhibitory effect on insulin secretion, presumably because of compensating reductions in carbohydrate absorption and GH and glucagon secretion that are also caused by the drug.

B. Somatostatin Receptor Imaging and Cytotoxic Therapies

Somatostatin analogues labeled with a radioactive tracer have been used as external imaging agents for a wide range of disorders. A ^{111}In-labeled analogue of octreotide (Octreoscan) has been approved for clinical use in the United States and several other countries. A majority of the neuroendocrine tumors and many pituitary tumors that express SSTRs are visualized by external imaging techniques after administration of this agent; a variety of nonendocrine tumors and inflammatory lesions are also visualized, all of which have in common the expression of SSTRs. Such tumors include non-small-cell cancer of the lung, meningioma, breast cancer, and astrocytomas. Because activated T cells of the immune system display SSTRs, inflammatory lesions that take up the tracer include sarcoidosis, Wegener's granulomatosis, tuberculosis, and many cases of Hodgkin's disease and non-Hodgkin's lymphoma. Although the tracer lacks specificity in differential diagnosis, its ability to identify the presence of abnormality and the extent of the lesion provides important information for management, including tumor staging. The use of a portable radiation detector in the operating room makes it possible to ensure the completeness of removal of medullary thyroid carcinoma metastases. New developments in the synthesis of positron emission tomography (PET) tracers chelated to octreotide have allowed for the sensitive detection of meningiomas less than 1 cm in diameter and located beneath osseous structures at the base of the skull.

The ability of somatostatin to inhibit the growth of normal and some neoplastic cell lines and to reduce the growth of experimentally induced tumors in animal models has stimulated interest in somatostatin analogues for the treatment of cancer. Somatostatin's tumorostatic effects may be a combination of direct actions on tumor cells due to inhibition of growth factor receptor expression, inhibition of MAPK, and stimulation of PTP. SSTR1, SSTR2, SSTR4, and SSTR5 can all promote cell cycle arrest associated with induction of the tumor suppressor retinoblastoma (Rb) and p21, whereas SSTR3 can trigger apoptosis accompanied by induction of the tumor suppressor p53 and the proapoptotic protein Bax. In addition, somatostatin has indirect effects on tumor growth by its inhibition of circulating, paracrine, and autocrine tumor growth-promoting factors and it can also modulate the activity of immune cells and influence tumor blood supply. Despite this promise, the therapeutic utility of octreotide as an antineoplastic agent remains controversial.

Two new treatment approaches in preclinical trials may yet effectively utilize somatostatin receptors in the arrest of cancer cells. The first is receptor-targeted radionuclide therapy using octreotide chelated to a variety of γ- or β-emitting radioisotopes. Theoretical calculations and empirical data suggest that radiolabeled somatostatin analogues can deliver a tumoricidal radiotherapeutic dose to some tumors after receptor-mediated endocytosis. A variation on this theme is the chelation of a cytotoxic chemotherapeutic agent to a somatostatin analogue. A second approach involves somatic-cell gene therapy

to transfect SSTR-negative pancreatic cancer cells with an SSTR gene. Therapeutic results could occur from the creation of autocrine or paracrine inhibitory growth effects or with the addition of targeted radionuclide treatments.

VIII. SUMMARY

Somatostatin is a phylogenetically ancient peptide that occupies numerous regulatory niches in diverse organ systems. Comparative genomic analyses suggest that at least two gene duplications of a primordial somatostatin gene have occurred in the past 500 million years of vertebrate evolution, yielding a family of related peptides that signal through five different subtypes of somatostatin receptors. In the simplest terms, somatostatin can be considered a paninhibitory factor for a large number of hormones, including pituitary growth hormone, cytokines, and exocrine secretions, in addition to its roles in modulating neuronal activity and regulating cell proliferation. A great deal of largely circumstantial evidence points to widespread activity of somatostatin within neural circuits underlying locomotor, cognitive, and emotional processes.

Glossary

cAMP response element Consensus nucleotide sequence 5′-TGACGTCA-3′; found in the promoter of many hormone-regulated genes, including somatostatin; a specific binding site for the transcriptional activator cAMP response element binding protein (CREB).

hypophyseotropic hormones Neurotransmitters, including neuropeptides, dopamine, and γ-aminobutyric acid; secreted from tuberoinfundibular neurons and conveyed as hormones through the long portal vessels, acting at a distance on pituitary cells and regulating their function.

mitogen-activated protein kinases Protein serine/threonine kinases that mediate intracellular signaling through three major mitogen-activated protein kinase cascades: ERK1/ERK2, JNK/SAPK, and p38.

octreotide A commonly used eight-residue peptidyl analogue of SS14 with a long biological half-life and efficacy as an agonist at SSTR2 and SSTR5.

phosphotyrosine phosphatase Enzyme that catalyzes the dephosphorylation of tyrosine residues from signaling molecules and thereby opposes the action of protein tyrosine kinases, which are key mediators of cellular responses such as proliferation and differentiation.

prohormone A precursor (either peptide or steroid) to an active hormone; produced in significant amounts as an intermediate in the pathway of production of the active hormone.

somatostatins Cyclic neuropeptides, the archetype being SS14, or somatotropin release-inhibiting factor, so named for one of its biological activities, inhibition of the secretion of pituitary growth hormone.

somatostatin receptors, types 1–5 Five subtypes of G-protein-coupled, seven-transmembrane-domain somatostatin receptors.

tuberoinfundibular neurons Located in several nuclei of the medial basal hypothalamus; project axons to the median eminence and infundibulum (pituitary stalk) and release their neurotransmitters adjacent to the fenestrated, tuberohypophyseal portal blood vessels supplying the pituitary gland.

Spermatogenesis, Hormonal Control of

SARAH MEACHEM AND ROBERT MCLACHLAN
Prince Henry's Institute of Medical Research, Australia

The process of spermatogenesis in the adult testis depends on two pituitary hormones, follicle-stimulating hormone and luteinizing hormone; luteinizing hormone, in turn, stimulates the production of androgens, notably testosterone. Specific cellular sites during spermatogenesis are specifically and conjointly regulated by hormonal activities. Production of viable, healthy sperm is a complex process that requires a high degree of cellular, hormonal, and molecular interactions; understanding the precise mechanisms of hormonal interaction is significant in developing a strategy for the design of an effective male hormonal contraceptive.

I. INTRODUCTION

Production of fertile sperm, a testicular process under the control of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), is necessary for reproductive viability. LH stimulates the production of androgens, notably testosterone, which is required for the attainment of male secondary sexual characteristics. Results from a wide array of animal and human experiments have identified specific cellular sites during spermatogenesis that are specifically and conjointly regulated by FSH and testosterone. It appears, however, that FSH is not essential for sperm production, because animals congenitally lacking FSH can be fertile, although their testis size and total sperm output are diminished. It seems that FSH plays an important role in establishing the foundations for full adult spermatogenesis by controlling the population of Sertoli cells, which determine adult spermatogenic capacity. In addition, FSH acts to optimize sperm production via involvement in multiple steps of spermatogenesis, most notably the steps involving the earliest germ cell forms, the spermatogonia. Testosterone is essential for spermatogenesis, particularly in supporting spermatid meiosis and maturation. Understanding the basic physiology of sperm production has important ramifications for understanding the common problem of male infertility and, conversely, in the design of a hormonal contraceptive. Thus far, clinical studies of androgen-based contraception have shown that there are two sites of inhibition, both dependent on gonadotropin suppression, at the level of the spermatogonia and sperm release. The following brief review of the basic endocrine control and organization of the testis prefaces a more detailed discussion of the hormonal control of spermatogenesis.

II. OVERVIEW OF THE HYPOTHALAMIC–PITUITARY–TESTICULAR AXIS

The adult testis has two main functions, to produce sperm for fertility and to produce androgens for maintaining secondary sexual traits. Sperm and androgen production are dependent on stimulation by the gonadotropins LH and FSH. The gonadotropins are produced by and secreted from the anterior pituitary in response to gonadotropin-releasing hormone (GnRH) stimulation from the hypothalamus. LH exerts its effects on testicular Leydig cells to stimulate the production and secretion of androgens, most notably testosterone. Testosterone is essential for the initiation and maintenance of

spermatogenesis and exerts its effects on the germ cells via receptors on Sertoli, Leydig, and peritubular cells. FSH acts via specific G-protein-coupled surface receptors located exclusively on Sertoli cells and is important for normal testicular growth and sperm production (see Fig. 1).

The process of sperm production, or spermatogenesis, in many mammals is a continuous process that takes place throughout the reproductive life span of the animal. However, in some mammals, spermatogenesis shows marked seasonal variation; in others, a single wave of spermatogenesis is followed by sterility. Spermatogenesis is a complicated process in which stem cells (called spermatogonia) undergo a complex sequence of proliferative and differentiation steps before they give rise to mature sperm (Fig. 1). Spermatogonia must proceed through three main phases before giving rise to mature sperm: (1) spermatogonia first undergo mitosis; (2) cells called spermatocytes then undergo reduction of a diploid chromosome number by the process of meiosis; (3) haploid, round spermatids are finally transformed into highly organized motile spermatozoa, a process termed spermiogenesis. The last event in spermiogenesis is the release of spermatozoa from the seminiferous epithelium into

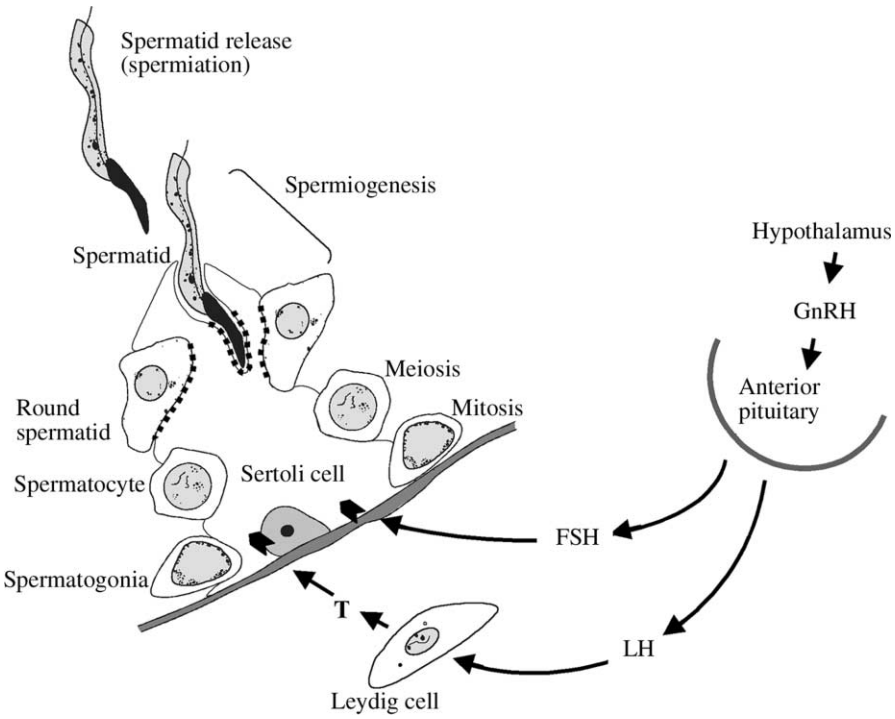

FIGURE 1 The hormonal control of spermatogenesis and structural organization of the testis. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are secreted from the anterior pituitary under the influence of gonadotropin-releasing hormone (GnRH) from the hypothalamus. FSH targets the developing germ cells via specific G-protein-coupled receptors (▲) on the Sertoli cell plasma membrane; LH stimulates the Leydig cells to produce and secrete androgens, predominantly testosterone (T), which in turn exerts its effects on the developing germ cells via nuclear receptors (▲) in the Sertoli cell. Spermatogenesis is an elaborate process by which spermatogonia must proceed through multiple mitotic divisions, then meiosis, to produce haploid, round spermatids; these steps are followed by a complex sequence of morphological transformations that give rise to spermatozoa (spermiogenesis), ending in release of the spermatozoa from the Sertoli cell, into the tubule lumen (spermiation). In humans, the total time for spermatogonia to develop into mature sperm is 65 days; this time varies depending on the species. Extensive animal studies have shown that spermatogenesis depends on both FSH and T, each having both independent and synergistic effects on spermatogenesis. Although FSH is not essential for spermatogenesis, it plays a key role establishing the size of the Sertoli cell population during testicular development and in supporting spermatogonial development in adult animals. In contrast, T is required for the complete maturation of spermatids, and both FSH and T have been shown to play an important role in promoting spermatocyte and spermatid survival and in maintaining specialized junctions (⋯) involved in the adhesion of spermatids to the Sertoli cell.

the tubule lumen, a process termed spermiation. These phases of spermatogenesis occur along similar lines in all mammals and have been well described.

III. ORGANIZATION OF THE TESTIS

The mammalian testis is encapsulated by a dense connective tissue called the tunica albuginea. The testis is composed of two major compartments, the seminiferous tubules, containing the nurturing Sertoli cells and the developing germ cells, and the interstitium, where Leydig cells and other interstitial cells reside. The testis contains many seminiferous tubules, which are convoluted loops connected at both ends to the excurrent duct system, also known as the rete testis. The mature spermatozoa pass from the tubules into the rete testis and then pass through the efferent ducts to the epididymis for final maturation before being capable of fertilizing an egg. The seminiferous tubules consist of the seminiferous epithelium and the lumen. Within the epithelium, the Sertoli cell provides structural and nutritional support for the developing germ cells; the lumen allows sperm and secretory products to be transported out of the testis. The interstitium contains the blood and lymphatic vessels responsible for the supply of nutrients into and out of the testis. Leydig cells are responsible for the generation of testosterone and other steroids.

The seminiferous epithelium has three compartments with different functions. Tight junctional complexes connecting the adjacent Sertoli cells form two permanent (basal and adlumenal) compartments and a temporary, intermediate compartment. Spermatogonia and early spermatocytes reside in the basal compartment. These cells have relatively free access to nutrients coming from the lymphatic and vascular systems. The intermediate compartment is formed during transit of spermatocytes from the basal to the adlumenal compartment, which involves the successive breakdown and formation of tight junctions. The adlumenal compartment contains all later stage germ cell types and is stringently controlled by the Sertoli cells via the tight junctional complexes, which limit the passage of macromolecules into the adlumenal environment. The junction is commonly referred to as the blood–testis barrier and becomes functional in early postnatal life. Numerous other Sertoli cell attachments to the developing germ cells assist in maintaining the structural integrity of the epithelium and provide a link for the cells to communicate. The success of spermatogenesis relies on the communication between all testicular cells.

IV. HORMONAL DEPENDENCY OF SPERMATOGENESIS

The hormonal control of spermatogenesis has been studied extensively for many years, and differing emphasis has been placed on the relative roles of endocrine, paracrine, and autocrine factors. It must be understood that the complexity of germ cell development and the intricate intercellular relationships make it difficult to define clearly the exact control of each step in sperm production. In a wide range of experimental paradigms, different species have been used, different approaches to manipulating hormone levels have been employed, and, most importantly, there have been many different methods for describing or quantifying changes in germ cell production. Broadly speaking, hormone withdrawal and replacement have been used to dissect out the factors that regulate initiation, maintenance, and restoration of the spermatogenic process. This has varied from the complete withdrawal of pituitary factors by hypophysectomy, to active immunization with GnRH, to treatment with GnRH antagonists, and to the use of congenitally GnRH-deficient mice. The relatively selective withdrawal of testosterone has been achieved by sex steroid treatment (which causes gonadotropin suppression and a resultant decrease in testicular testosterone levels to $<5\%$ of normal), treatment with antiandrogens, and immunization against LH. FSH withdrawal has been achieved by disrupting FSH action by genetically modifying mice and by passively immunizing animals against FSH. A diverse range of qualitative and quantitative end points has been used to evaluate the effects of hormone on spermatogenesis. The advent of sophisticated stereological methods for quantitative analysis of cell populations has led to major advances in defining the sites of hormone action.

The precise mechanism by which FSH and testosterone exert their effects on the developing germ cells has not been elucidated but involves a highly orchestrated molecular and genomic response. Studies on the role of FSH and testosterone indicate that both hormones have independent and synergistic effects on germ cell development.

V. FSH DEPENDENCY

FSH plays a key role in the development of the immature testis, particularly by controlling the size of the Sertoli cell population, which is set early in postnatal life. This is of particular importance for

the adult animal because Sertoli cell number dictates sperm output. After debating many conflicting data from animal models, there is agreement that some degree of complete spermatogenesis can be initiated and maintained in the absence of FSH; however, quantitatively normal spermatogenesis depends on FSH. FSH acts at multiple sites in the spermatogenic pathway by promoting spermatogonial proliferation and survival and viability of later germ cell types by presumably maintaining structures and proteins involved in attachment of the germ cell to the Sertoli cell. More specifically, rat and monkey studies have shown that FSH plays a major role in supporting spermatogonial development, with FSH having more pronounced effects on certain subpopulations. FSH has been shown to play a role in later germ cell types, supporting spermatocytes and round spermatid development presumably by supporting cell survival. The specialized Sertoli cell junctional apparatus has been shown to be a hormone-sensitive structure; the structures are found between Sertoli cells and at stages from mature round spermatids to mature sperm before spermiation. This specialized apparatus has been shown to be disorganized in long-term gonadotropin-deplete rats and can be restored by FSH treatment, suggesting that FSH is important for the maintenance of the junctional apparatus. *In vitro* experiments on Sertoli and round spermatid cultures suggest that FSH is important for adherence of the round spermatids to the Sertoli cells. Finally, FSH may be involved in the release of mature sperm from the epithelium, based on reports that more sperm are retained within the seminiferous epithelium following acute FSH withdrawal. Another way that FSH can support germ cell development is via the Leydig cells. FSH has been shown to regulate Leydig cell products that play a role in spermatogenesis and promote maturation of the Leydig cell population.

VI. TESTOSTERONE DEPENDENCY

Spermatogenesis has an absolute requirement for testosterone, particularly for the maturation of spermiogenic cells. Data from rodent models of testosterone replacement provide no evidence that testosterone supports spermatogonial development, although rodent models expressing high levels of testicular testosterone appear to have a detrimental effect on spermatogonial development. The viability of spermatocytes and spermatids is enhanced in the presence of testosterone and there are marked increases in cell degeneration in the absence of testosterone. The major lesion following selective testosterone withdrawal is during rat spermiogenesis, wherein sperm production is ablated as a consequence, at least in part, of the premature release of round spermatids from the seminiferous epithelium. Hence, round spermatid maturation is dependent on testosterone, which promotes the attachment of round spermatids to the Sertoli cells, possibly by induction of structures and proteins involved in cell adhesion. Finally, sperm release (spermiation) is also partly dependent on testosterone, because when testicular testosterone is reduced, mature sperm are retained and phagocytosed within Sertoli cells.

It has been established that testosterone is the active androgen supporting spermatogenesis in the normal testis; however, within the testis, testosterone can be metabolized by 5α-reductase enzymes to a more potent androgen, dihydrotestosterone (DHT). There is some evidence to support the notion that when testosterone levels are low (such as during LH suppression, when the level falls to $<5\%$ of normal), metabolism of testosterone to DHT may be important in maintaining some degree of spermatogenesis.

VII. FSH AND TESTOSTERONE SYNERGY

There are many reports suggesting that FSH and testosterone act synergistically and that they exert the same biological effect. For example, it is clear that germ cell apoptosis/viability can be regulated by FSH and testosterone. Acute models of gonadotropin suppression/replacement in rats have revealed that both FSH and testosterone affect spermiation but that both are required for normality. FSH and testosterone can stimulate Sertoli cell products such as androgen-binding protein and transferrin. Synergy has been shown to play a role in maintaining proteins involved in cell adhesion. Sertoli cell N-cadherin, one such protein, has been shown to be maximally produced *in vitro* in the presence of both FSH and testosterone. Furthermore, *in vitro* studies of round spermatids and Sertoli cells show that binding of round spermatids to Sertoli cells is dependent on testosterone only in the presence of FSH. In addition, *in vivo* studies show that spermiogenesis is restored in hypophysectomized testosterone-replaced rats when FSH is administered. Monkey and human studies have demonstrated the relevance of several of these hormonally sensitive steps, notably spermatogonial development and

sperm release, which are disrupted following gonadotropin suppression. Whether these are the results of independent or synergistic actions of FSH and testosterone in these species is unclear.

VIII. RELEVANCE TO MALE CONTRACEPTIVE DEVELOPMENT

Studies in animals and humans have improved our understanding of the physiological basis of male contraception based on testosterone administration to suppress gonadotropins. Two major sites of spermatogenesis in humans have been identified as hormone sensitive, i.e., spermatogonial development and spermiation. Given the data from animal models, it appears that FSH withdrawal is important for spermatogonial development and that both FSH and testosterone are critical for spermiation. Clinical studies have shown that the extent of spermatogenic suppression and time of onset vary among individuals and between racial groups. Although not proved, it is thought that these differences may be attributed to differences in the degree and onset of gonadotropin suppression, and that faster and deeper suppression of both FSH and testosterone will lead to a more profound inhibition of spermatogenesis and thus create an effective contraceptive. Some studies provide evidence indicating that administration of progestins in combination with androgens may provide this desired effect, although further investigation is necessary. Another issue relating to variations in the degree of spermatogenic suppression between racial groups may be differences in androgen metabolism by 5α reduced enzymes; whether these differences are genetic or environmental, such as diet, is unclear.

IX. CONCLUSION

Control of sperm production is mediated by FSH and LH via testosterone. A wide variety of animal models, most notably rodent models, coupled with quantitative analyses of testicular cell populations, have recognized that the sperm generation pathway contains steps sensitive to the independent action of FSH and testosterone and steps requiring synergistic actions. It is apparent that FSH is particularly important for early testicular growth, particularly in establishing the size of the Sertoli cell population and in supporting spermatogonial development in adulthood. Testosterone, however, is critical for maturation of round spermatids, because FSH is unable to complete this vital step; sperm release seems to require both hormones. Limited monkey and human studies have shown that gonadotropin suppression results in inhibition of spermatogonial development and sperm release. Further elucidation of the precise mechanisms by which these hormones affect sperm production will be significant for the design of the first effective hormonal contraceptive strategy for men.

Glossary

follicle-stimulating hormone Pituitary hormone that induces germ cell production and development of their supporting cells in the ovary and testis.

hormone Substance released by an endocrine gland; travels through the bloodstream to exert an effect on remote cells, tissues, and organs.

luteinizing hormone Pituitary hormone that acts with follicle-stimulating hormone to stimulate sex hormone release.

Sertoli cells The "nurse" cells of the seminiferous epithelium; provide nutritional and structural support for developing germ cells.

spermatids Haploid germ cells produced by the second meiotic division in spermatogenesis; differentiate into mature spermatozoa.

spermatocytes Tetraploid germ cells that undergo two meiotic divisions, yielding haploid spermatids.

spermatogenesis Process whereby spermatogonia divide and differentiate into mature spermatozoa.

spermatogonia Diploid germ cells that divide and differentiate; the most immature germ cell type.

stereological Methodology that allows structural information (for instance, estimation of cell number) to be derived from sections of a structure.

testosterone Male sex hormone (androgen) secreted by interstitial Leydig cells of the testis; responsible for triggering development of sperm and secondary sexual characteristics.

Stem Cell Factor[1]

DIANA LINNEKIN, TANYA JELACIC, AND SHIVAKRUPA
National Cancer Institute, Maryland

Stem cell factor (SCF) is a growth factor that binds the receptor tyrosine kinase Kit, leading to the activation of multiple signal transduction components, including members of the Src family. SCF is essential for the survival, growth, and maturation of stem cells involved in gametogenesis, hematopoiesis, and melanogenesis.

I. INTRODUCTION AND HISTORICAL PERSPECTIVE

Although stem cell factor (SCF) was cloned in 1990, this growth factor has a remarkably rich history. The receptor for SCF is the receptor tyrosine kinase (RTK) Kit. In mice, the c-Kit gene product maps to the *White Spotting* (*W*) locus on chromosome 5 and SCF maps to the *Steel* (*Sl*) locus on chromosome 10. Mice with mutations in the *W* locus were first identified in 1927. These animals were characterized by alterations in coat pigmentation, abnormalities in reproduction, and macrocytic anemia. In 1956, mice with the identical defects were found to have mutations in the *Sl* locus. The complementary nature of the phenotypes of these animals suggested that the *W* and *Sl* gene products were a receptor and its ligand. The isolation of the v-Kit oncogene from the Hardy–Zuckerman 4 strain of feline sarcoma virus by Peter Besmer and co-workers in 1986 set the stage to test this possibility formally. In 1987, the c-Kit proto-oncogene was cloned and the following year it was mapped to the *W* locus. Multiple groups then cloned the ligand for Kit and demonstrated that it mapped to the *Sl* locus. The cloning of SCF allowed

[1] The content of this publication does not necessarily reflect the views or policies of the Department of Health and Human Services, nor does mention of trade names, commercial products, or organizations imply endorsement by the U. S. Government.

rigorous assessment of its biological activities. Indeed, this growth factor proved to be critical for stem cells involved in gametogenesis, hematopoiesis, and melanogenesis. Although clinical use of SCF may be limited by its capacity to activate mast cells, gain-of-function mutations in Kit are associated with a variety of diseases in humans. Thus, understanding the cellular and molecular biology of the SCF receptor may be useful in designing approaches for treatment of these disorders, as well as harnessing the considerable biological potency of the ligand.

II. THE SCF LIGAND

SCF, also termed mast cell growth factor, Kit ligand, and Steel factor, is the ligand for the receptor tyrosine kinase Kit. The human SCF gene is located on chromosome 12q22–q24, is 50 kb in length, and consists of eight exons. The murine SCF gene has been mapped to chromosome 10 in a region flanked by genes encoding peptidase-2 and phenylhydroxylase. The cDNA for SCF has been cloned and sequenced from a variety of species including human, mouse, rat, pig, and chicken [Accession Nos. (mouse) U44725; (human) M59964; (rat) M59966; (pig) L07786; and (chicken) D13516]. The first exon of the human SCF gene codes for the signal peptide required for membrane anchoring of SCF. Exons 2 through 6 code for the transmembrane region. Exon 7 codes for the extracellular region and exon 8 encodes the cytoplasmic tail. SCF protein is found as both a soluble form (sSCF or SCF^{165}) and a membrane-bound form (mSCF or SCF^{220}). These forms are generated by alternate splicing of a primary transcript at exon 6. One splice product gives rise to a protein of 275 amino acids containing a cleavable amino-terminal signal peptide. The cleavage of the signal peptide gives rise to SCF^{248}, also designated KL-1 or SCF-1. It contains an extracellular domain, a 22-amino-acid transmembrane domain, and a 36-amino-acid cytoplasmic domain. SCF^{248} undergoes proteolytic cleavage at Ala-165 to generate the soluble form of SCF, SCF^{165}. The other splice variant of SCF lacks the proteolytic cleavage site and gives rise to a membrane-bound form of SCF, SCF^{220}, also termed KL-2 or SCF-2.

Soluble SCF exists as a heavily glycosylated 50 to 60 kDa noncovalent homodimer that can dissociate and reassociate in solution. The recently described crystal structure revealed a large dimerization region and a charged receptor-binding region that includes hydrophobic crevices. The concentration of soluble SCF in human serum is approximately 3 ng/ml. Consequently, it exists primarily as a monomer. In contrast, the close proximity of mSCF in the plasma membrane results in the dimerization of this molecule. Dimerization of membrane-bound SCF facilitates signaling through the Kit receptor. Both forms of SCF are biologically active, with distinct as well as overlapping functions. Membrane-bound SCF induces more persistent tyrosine kinase activation than soluble SCF. This is likely due to the slower internalization of Kit after binding this form of the growth factor.

SCF is expressed by stromal cells, fibroblasts, and endothelial cells and is also present at low levels in the circulation. SCF is also expressed along the migratory pathway of stem cells in embryos and this plays an important role in development. Sertoli cells, ovarian follicular cells, brain, and olfactory bulb also express SCF. The ratio of membrane SCF to soluble SCF varies considerably in different tissues. Fibroblasts, brain, thymus, spleen, and bone marrow express higher levels of SCF^{248}, whereas placenta, cerebellum, and testis have higher levels of SCF^{220}. The exact mechanism of regulation of the levels of different SCF proteins is unknown.

III. THE SCF RECEPTOR

The receptor for SCF is Kit, a receptor tyrosine kinase sharing homology with receptors for platelet-derived growth factor (PDGF) and colony-stimulating factor-1 (CSF-1). Kit has also been designated as stem cell factor receptor and CD117. The gene for human c-Kit has been mapped to 4q11–q34, spans approximately 70 kb of DNA, and has 21 exons [GenBank Accession Nos. (human) X06182 and (mouse) Y00864]. Human Kit encodes a 145 kDa glycosylated protein (GenBank Accession No. 1817733) containing an extracellular domain of approximately 500 amino acids, a 30-amino-acid juxtamembrane domain, a cytoplasmic kinase domain divided into two parts by a 77-amino-acid kinase insert region, and a 50-amino-acid carboxy-terminal tail region. The extracellular domain contains five immunoglobulin-like repeat regions, the first three of which constitute the ligand-binding domain. The fourth immunoglobulin-like domain is involved in receptor dimerization and the function of the fifth domain has not been defined. Some of these features are illustrated in Fig. 1. An alternative splice form of Kit, termed KitA, has a four-codon insertion (GNNK) in the extracellular domain just proximal to the membrane-spanning region. Both forms are co-expressed in most tissues. Another variant of Kit that consists of only the second

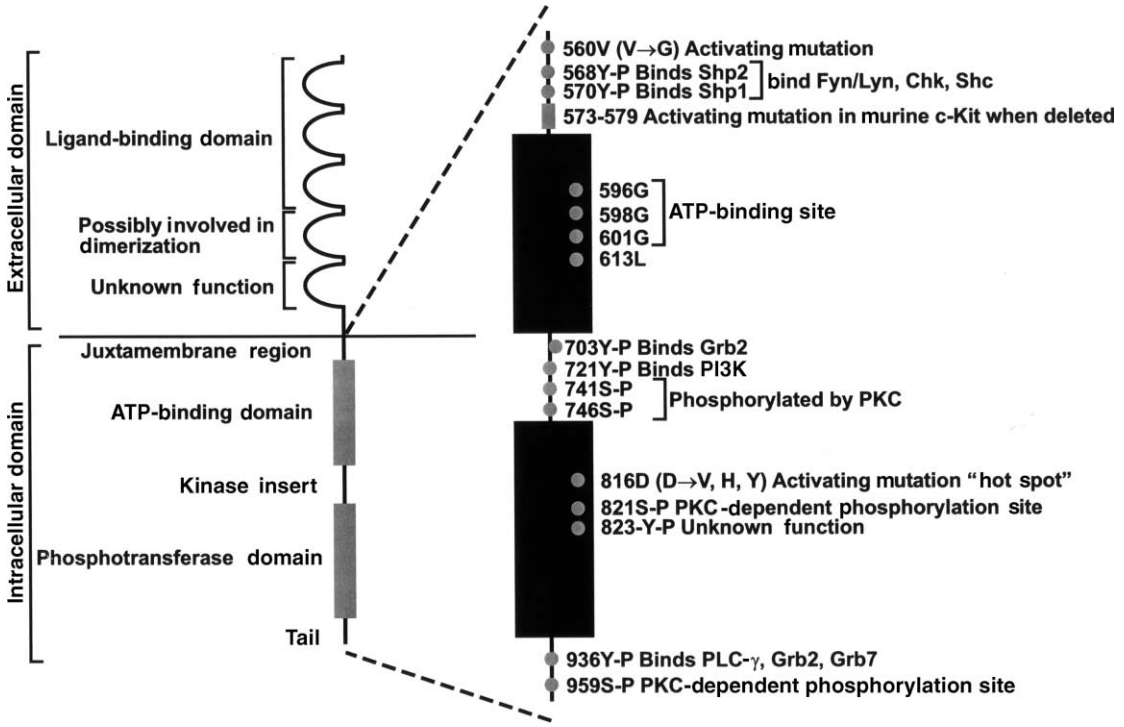

FIGURE 1 Structure–function relationships of the Kit receptor tyrosine kinase. The extracellular domain of Kit is divided into five immunoglobulin-like regions. The intracellular domain is composed of the juxtamembrane region, the catalytic domain, a kinase insert, and a carboxy-tail. Amino acids that contribute to the activation of Kit or that interact with specific signaling molecules are designated by small circles.

catalytic domain and the carboxy-terminal tail is expressed in spermatids. Full-length Kit is proteolytically cleaved in a process dependent on the fifth immunoglobulin-like domain, to give rise to a soluble form of Kit. The function of soluble Kit is not fully defined; however, it binds to SCF and may act as a receptor antagonist *in vivo*.

Kit is expressed in a variety of different cells. In hematopoietic tissue, it is expressed in stem cells, progenitor cells (pluripotent as well as progenitors committed to the myeloid, lymphoid, erythroid, and megakaryocytic lineages), bone marrow mononuclear cells with lymphoid markers, and mast cells. In most hematopoietic lineages, Kit expression decreases during maturation. However, mast cells, activated platelets, and some subsets of NK cells are exceptions. Nonhematopoietic cells expressing Kit include melanocytes, spermatozoa, vascular endothelium, interstitial cells of Cajal (ICCs), breast glandular epithelial cells, sweat glands, astrocytes, oocytes, theca cells, and renal tubules. Kit is also expressed in the human endometrium and placenta during pregnancy.

Surface expression of Kit is regulated by multiple mechanisms. Interaction with SCF induces internalization of the receptor through clathrin-coated pits. Kit is also ubiquitinated and can be degraded in either the lysosome or the proteasome pathway. In addition, certain cytokines regulate surface expression of Kit. Transforming growth factor-β can induce the downregulation of Kit through reductions in mRNA stability. This is also seen with interleukin-3 (IL-3) stimulation in mast cells. The processing of membrane-bound receptor to generate the soluble form also determines the surface expression levels of Kit in umbilical endothelial cells, mast cells, and human plasma.

IV. BIOLOGY

Kit and SCF are expressed in many tissues. The correct function of these proteins is necessary for maintenance of gastrointestinal motility, hematopoiesis, melanogenesis, gametogenesis, and some aspects of central nervous system (CNS) function. The following section

will summarize the biological role of SCF and Kit in each of these organ systems.

A. Central Nervous System

The widespread expression of Kit and SCF in the CNS of adult animals was a surprising finding since the *W* and *Sl* mutant mice do not exhibit gross CNS abnormalities. However, a subtle abnormality has recently been demonstrated in *Ws*/*Ws* adult rats, which express a Kit mutant with impaired kinase activity. These rats have reduced long-term potentiation (LTP) in the mossy fiber–CA3 pathway of the hippocampus. Impaired spatial learning and memory in the Morris water maze test were also observed in these animals. *Sl*/*Sl*^{d} mice, which express the soluble but not the transmembrane form of SCF, are also known to have impaired hippocampal learning, but have normal LTP.

B. Gastrointestinal Tract

The ICCs are unusual cells in that they have characteristics of smooth muscle cells, fibroblasts, and neuronal cells. These are the only cells in the gastrointestinal tract (GI) tract that express Kit. The discovery of this exclusive expression of Kit revolutionized the study of these cells. Immunostaining for Kit *in situ* allowed visualization of the complex network that ICCs form throughout the GI tract. Although expression of Kit is universal among the ICCs, expression of other proteins varies, and there are different subpopulations of ICCs within the different regions of the GI tract.

ICCs have characteristics similar to cells of both neural crest and mesenchymal origins. However, studies in the late 1990s revealed that ICCs and the surrounding smooth muscle cells are both derived from mesenchymal precursors that express Kit. Precursors that contact SCF maintain Kit expression and develop into ICCs. Precursors that do not interact with SCF lose Kit expression and develop into smooth muscle cells. Mature smooth muscle cells express SCF, which is necessary for the maintenance of the ICC phenotype of their neighbors.

The ICCs are the pacemaker cells of the GI tract, generating and propagating the slow waves that control the frequency of contraction. Thus, the ICC network is essential to GI motility. These cells also integrate motor signals from the enteric nervous system. Kit signaling is essential to pacemaker function. Chronic exposure to antibodies specific for Kit or to inhibitors of signaling molecules downstream of Kit [i.e., the phosphatidylinositol 3-kinase (PI3K) inhibitors Wortmannin and LY-294002] lead to the loss of slow waves and eventually reductions in the number of ICCs. Interestingly, some subpopulations of ICCs are more resistant to these treatments than others. Similarly, subpopulations of ICCs are altered to differing extents in mice with different *W* or *Sl* mutations.

C. Hematopoietic Cells

Expression of Kit and SCF is necessary for hematopoiesis in the fetal liver and in adult bone marrow. Kit is expressed primarily on hematopoietic stem cells, pluripotential progenitor cells, and early myeloid, lymphoid, erythroid, and megakaryocytic progenitors, whereas SCF is expressed by supporting stromal cells. SCF supports the survival of the stem cells and pluripotential progenitors, but induces only limited increases in proliferation as a single factor. However, SCF, in combination with certain other growth factors, strongly induces the proliferation of progenitors leading to a variety of lineages. SCF and erythropoietin stimulate the growth of erythroid progenitors. SCF and IL-3 induce the proliferation of progenitors that can differentiate into granulocytes, macrophages, and mast cells. SCF and thrombopoietin stimulate the growth of megakaryocytic progenitors. Expression of Kit decreases as differentiation progresses and is eventually lost altogether on most mature hematopoietic cells. Mast cells, activated platelets, and a subset of natural killer cells are the only fully differentiated hematopoietic cells that express Kit. SCF has a potent effect on mast cells and can induce them to migrate, proliferate, and degranulate.

D. Melanocytes

Expression of Kit and SCF is necessary for normal pigmentation of skin and hair. The precursors of melanocytes, the pigment-producing cells, arise in the neural crest in the embryo and migrate to the epidermis. The migratory path of the Kit-expressing melanocyte precursors is defined by SCF-expressing mesenchymal cells. Injection of pregnant mice with antibody that blocks binding of SCF during this phase of melanocyte migration leads to offspring that are almost completely lacking in pigmentation. However, injections that do not coincide with melanocyte migration do not alter pigmentation.

After birth, Kit is expressed in melanocytes in the hair follicles and skin, and SCF is expressed in

keratinocytes. Hair follicles cycle between states of rest (telogen), active growth (anagen), and regression (catagen). Kit signaling is necessary for the replacement of melanocytes when the follicles progress from telogen to anagen. Injection of antibody specific for Kit into hair follicles at this stage leads to the growth of unpigmented hairs. However, if the injection is not repeated, the follicles produce fully pigmented hairs during their next anagenic phase. In addition to maintaining normal pigmentation in the skin, Kit signaling plays a role in hyperpigmentation in response to ultraviolet B (UVB) light. Both Kit expression and SCF expression increase in response to UVB light. Although the expression of other enzymes involved in melanin production is not dependent on Kit signaling, the expression of tyrosinase, the critical rate-limiting enzyme, is dependent on an increase in cyclic AMP levels mediated by Kit signaling. Thus, injection of anti-Kit antibodies into the skin prevents the hyperpigmentation response to UVB light.

E. Germ Cells

Expression of Kit and SCF is essential for the formation of primitive gonads in the embryo and for normal fertility in adult animals. Primordial germ cells (PGCs) in both sexes originate outside the genital ridge. PGCs express Kit, whereas cells in and on the way to the genital ridge express SCF. The PGCs follow a "trail" of SCF-expressing cells from their point of origin to the genital ridge. Along the way and at their destination, they proliferate. After the expansion of PGCs in the genital ridge, the primitive gonads differentiate into ovaries or testes, and Kit expression decreases and remains at low levels until the onset of puberty. Although Kit and SCF are crucial for the establishment of primitive gonads in both sexes, their role in adult reproductive function varies with sex. Certain *W* and *Sl* mutations cause infertility in one sex but not in the other.

In adult males, Kit is expressed by spermatogonia and primary spermatocytes, and SCF is expressed by Sertoli cells. Mature spermatozoa express a unique form of Kit that is severely truncated. This form of the protein may be involved in releasing the oocyte from arrest at fertilization. Injection of this protein into oocytes induces parthenogenesis. The necessity of both Kit and SCF is demonstrated by the infertility of male W^v and Sl^d mutant mice, which have reduced Kit function and a lack of transmembrane SCF, respectively.

In adult females, Kit is expressed in oocytes and theca cells, and SCF is expressed by the surrounding granulosa cells. Interaction between Kit and SCF is necessary for follicular development and maturation, but not ovulation and luteinization. There is also evidence that Kit signaling is involved in driving oocytes into meiotic arrest.

V. MECHANISMS OF ACTION

A. Receptor Dimerization and Autophosphorylation

As described above, Kit is a RTK. As a monomer, Kit is essentially inactive. Similar to other RTKs, the conformation of the juxtamembrane region imposes structural constraints that reduce spontaneous activation. This may be due to the formation of an α-helical structure by the unoccupied Kit monomer. Consequently, mutations in this region can activate Kit in the absence of ligand. Binding of SCF induces the rapid dimerization of Kit. This is likely promoted by interaction with noncovalently bound ligand dimers. *In vitro*, the first, second, and third Ig-like regions are sufficient to induce the dimerization of soluble forms of Kit. Biochemical data suggest that portions of the fourth immunoglobulin domain contribute to the dimerization of full-length Kit protein in cells. Ligand binding to wild-type Kit induces rapid increases in receptor autophosphorylation. Although the intracellular domain of Kit contains 22 tyrosine residues, autophosphorylation of only tyrosines 568, 570, 703, 721, 823, and 936 of human Kit has been confirmed.

B. Autophosphorylation of Kit and Initiation of Downstream Signaling Pathways

Multiple signal transduction components are activated after autophosphorylation of Kit. This occurs, in part, through recruitment of SH2-containing proteins to the Kit receptor complex via phosphorylated tyrosine residues. Two important residues in the recruitment of adapter proteins and signaling components to the human Kit receptor complex are tyrosines 568 and 570 in the juxtamembrane region. These are docking sites for Src family members, Shc and Chk (Csk-homologous kinase). In addition, the protein tyrosine phosphatases Shp1 and Shp2 have been reported to interact with tyrosines 569 and 567 on murine Kit, respectively. These correspond to tyrosines 570 and 568 on human Kit. Although most reports indicate that mutation of either of these

residues has minimal effects on SCF-mediated growth, the mutation of both residues dramatically impairs growth. Thus, the juxtamembrane region is critical in providing docking sites for a variety of proteins involved in SCF signal transduction as well as maintaining inactive Kit monomers.

Of the signaling components shown to interact with the Kit juxtamembrane region, Src family members have been studied most extensively. Those activated by SCF include Lyn, Fyn, and likely Src and Yes, as well as others. Tyrosine 568 of human Kit is the predominant binding site for Src family members. Interestingly, mutation of this residue results in only subtle alterations in responses to SCF. In contrast, Lyn-deficient mast cells and hematopoietic progenitors have more dramatic abnormalities in SCF-mediated responses. Furthermore, data obtained with Src family inhibitors and dominant inhibitory mutants support an important role for this kinase family in Kit stimulus-response coupling mechanisms. This likely occurs through signaling components activated independent of tyrosine 568. Src family members contribute to the activation of the Jnk family of serine/threonine kinases. Jnks 1 and 2 contribute to the SCF-induced proliferation of mast cells.

Activation of the Ras–Raf–mitogen-activated protein (MAP) kinase cascade may also be initiated through the Kit juxtamembrane region in a Src-dependent manner. In transfected porcine aortic endothelial cells, mutation of tyrosine 570 reduces SCF-induced activation of ERKs and mutation of tyrosine 568 nearly eliminates it. Concomitant with this are decreases in the phosphorylation of Shc that are dependent on Src family members. In contrast, SCF has been reported to activate ERKs in mast cells expressing Y567F murine Kit. Thus, initiation of the ERK signaling pathway likely occurs through multiple sites on Kit. For example, *in vitro* studies have shown that growth factor receptor-binding protein 2 (Grb2) can bind tyrosine 703 or 936 in the kinase insert or carboxy-tail, respectively. Furthermore, ERKs may be activated through different mechanisms in distinct cell lineages

Tyrosine 721 in the kinase insert domain is another important autophosphorylation site on human Kit. Mutation of tyrosine 719, the corresponding residue in murine Kit, does not significantly impair Kit activity, but does eliminate recruitment of PI3K to the Kit receptor complex. Infection of mast cells with this mutant results in a reduction of SCF-induced adhesion of mast cells to fibronectin, as well as minor alterations in survival and growth. Similar defects have been observed in mast cells derived from mice engineered to express this mutant. In addition, significant defects in spermatogenesis occur in transgenic mice expressing Y719F Kit, but no alterations in pigmentation or steady state hematopoiesis were observed. Therefore, direct interaction of Kit and PI3K is essential for maturation of sperm and contributes to some aspects of SCF-mediated responses in mast cells, but is not required for Kit-dependent pigmentation or hematopoiesis. Interestingly, bone marrow mast cells derived from mice deficient for p85α PI3K had dramatic decreases in SCF-induced proliferation *in vitro*. Thus, PI3K also contributes to SCF-mediated responses through mechanisms independent of tyrosine 719.

Two signaling components activated downstream of PI3K are Akt and Jnks. Activation of Akt is dependent on the interaction of PI3K and Kit. Similar to numerous other growth factors, Akt contributes to the capacity of SCF to promote viability. In contrast, activation of Jnk1 and Jnk2 is involved in SCF-induced proliferation.

In the second catalytic domain, phosphorylation of tyrosine 821 of murine Kit (corresponding to tyrosine 823 of human Kit) makes critical contributions to the SCF-induced survival and proliferation of mast cells. Signaling components that interact with this site remain to be identified. Interestingly, tyrosine 821 is not required for SCF-induced activation of PI3K, Ras, or ERKs or for induction of c-myc, c-myb, c-fos, or junB.

Tyrosine 936 is an autophosphorylation site in the carboxy-tail of Kit. *In vitro* studies have shown that it binds to phospholipase Cγ (PLC-γ) and Grb7. The role of the interaction of these proteins with Kit in SCF-mediated responses is not known. Phosphorylation of PLC-γ requires tyrosine 728 in the kinase insert region of murine Kit. This is not critical for proliferation induced by soluble SCF but is required for responses to membrane-bound SCF.

C. Serine Phosphorylation of Kit

In addition to the important role of autophosphorylated tyrosine residues in Kit signaling, this receptor is also heavily phosphorylated on serine residues. A series of elegant studies by Lars Rönnstrand and coworkers demonstrated that protein kinase C (PKC) isoforms are responsible for serine phosphorylation of Kit at multiple sites. Serines 741 and 746 on human Kit are directly phosphorylated by PKC, and serines 821 and 959 are PKC-dependent sites. Serine phosphorylation reduces interaction of Kit

with multiple SH2-containing proteins and is associated with decreased mitogenic responses to SCF as well as increased migration. Increased association with PI3K and increases in Akt activity have been observed in cells expressing Kit with serines 741 and 746 mutated.

D. Kit Signaling and the Janus Kinase/Signal Transducers and Activators of Transcription Pathway

The Janus kinase/signal transducers and activators of transcription (JAK/STAT) pathway is critical for responses mediated by ligands interacting with cytokine receptor superfamily members. Less is known about the activation of this pathway by RTKs such as Kit. We have shown that SCF rapidly and transiently activates JAK2. In addition, reduction in expression of JAK2 using antisense oligonucleotides partially impairs SCF-induced growth. The region of Kit coupling to activation of JAK2 remains to be identified. SCF also activates Stat family members, including Stat1 and Stat5. Stat1 interacts with tyrosine residues in the second catalytic domain of Kit, whereas full activation of Stat5 requires the carboxy-tail of Kit. Stat3 is also phosphorylated on serine residues after stimulation with SCF. Importantly, activation of the JAK/STAT pathway is extremely rapid, transient, and lineage-specific. One means of negatively regulating this pathway could be through Socs1 (suppressor of cytokine signaling). This protein interacts with Kit and constitutive expression reduces SCF-induced growth. Shp1 is also a negative regulator of Kit signaling that may down-regulate JAK2 activity. A summary of the structure–function relationships of the intracellular region of Kit is summarized in Fig. 1. Furthermore, some of the signaling pathways activated by Kit are shown in Fig. 2.

E. Signaling through Different Receptor and Ligand Isoforms

Two isoforms of human Kit result from alternate splicing of mRNA. This results in the insertion of a 4-amino-acid sequence just proximal to the membrane-spanning region in the extracellular domain. Although the biological significance of this insert remains unclear, recent studies suggest differences in internalization, signaling, and possibly transforming activity of these isoforms. Differences in the signaling of soluble and membrane-bound SCF have also been reported. The kinetics of ligand-induced phosphorylation of Kit are more protracted after stimulation with membrane-bound SCF than with soluble SCF. Thus, this isoform may be more biologically potent. Furthermore, PI3K and PLC-γ may make different contributions to biological responses mediated by soluble SCF versus membrane-bound SCF.

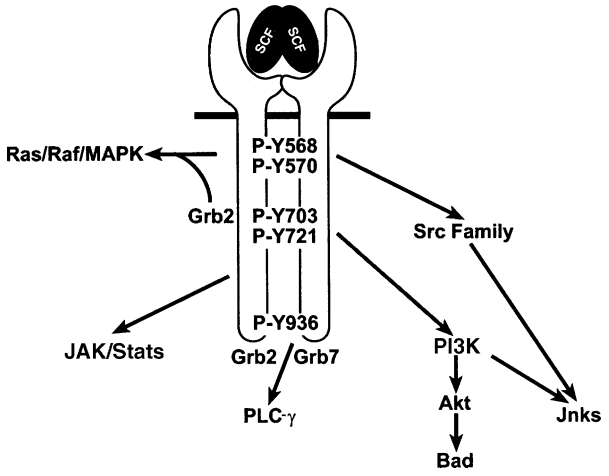

FIGURE 2 Signaling pathways activated by Kit. SCF binds Kit, induces dimerization, and increases autophosphorylation activity of this receptor tyrosine kinase. The indicated autophosphorylation sites recruit signaling components coupled to the biochemical pathways indicated.

F. Transcription Factors: Activation and/or Induction

As described above, Stat family members phosphorylated after stimulation with SCF include Stat1, Stat3, and Stat5. SCF-induced increases in the DNA-binding activity of both Stat1 and Stat5 have also been reported. Both of these proteins interact with Kit, but it remains to be determined whether Kit directly activates Stat family members or whether nonreceptor kinases such as JAK2 or a Src family member are upstream activators. *In vitro* studies have shown that Kit can phosphorylate Stat1 directly. The role of these events in SCF-mediated responses is yet to be established.

The micropthalmia transcription (Mi) factor is a member of the basic/helix-loop-helix/leucine zipper family. It is highly tissue-specific and expressed in both melanocytes and mast cells. Mice or humans lacking this protein have defects in pigmentation and a reduction in mast cell numbers. Signaling through Kit results in serine phosphorylation of Mi via activation of ERKs. This increases the transcriptional activity of Mi by increasing association with the

transcriptional co-activator p300/CREB-binding protein (where CREB is Ca^{2+}/cAMP-response element-binding protein).

One family of transcription factors regulated downstream of Akt is the forkhead family. Recent studies indicate that SCF induces the phosphorylation of FOXO1a, 3a, and 4. This did not require the activation of ERKs, p38, or PKC but did require PI3K.

SCF also induces the expression of a variety of immediate-early response genes that are transcription factors. These include c-myc, c-fos, junB, c-myb, and egr-1.

VI. PATHOPHYSIOLOGY

A. Preliminary Comments

As discussed above, Kit makes important contributions to the development and function of hematopoietic, germ cell, and pigmented tissues. It is also important in terms of the function of different aspects of the CNS and the GI tract. The critical nature of Kit in normal physiology is highlighted by the aberrations resulting from the absence of functional Kit or its ligand SCF. In addition, a number of diseases are associated with overexpression or gain-of-function mutations.

B. Gain-of-Function Mutations

The Kit proto-oncogene was identified after the discovery of the v-*Kit* oncogene in the Hardy–Zuckerman strain of feline sarcoma virus. The v-Kit protein contains the catalytic domain and kinase insert region of Kit, but is missing the extracellular domain, as well as portions of the carboxyl-tail and juxtamembrane region. The capacity of Kit to be usurped by a retrovirus as a transforming protein suggested that alterations in the expression or activity of this kinase could be involved in other disease processes. Indeed, in the past decade, gain-of-function mutations in Kit have been identified and associated with a variety of human diseases including gastrointestinal stromal cell tumors (GISTs), mastocytosis, leukemia, lymphoma, germ cell tumors, and small cell carcinoma of the lung.

Two regions of Kit where gain-of-function mutations occur with high frequency are the juxtamembrane region and the second catalytic domain. As described earlier, the secondary structure of the juxtamembrane region maintains the unoccupied receptor in a conformation that inhibits catalytic activity. Mutations in this region alter this configuration and often result in increases in Kit kinase activity in the absence of ligand. The second catalytic domain is the ATP-binding pocket and is another hotspot for activating mutations of Kit. Mutations in the analogous region of Flt3, Met, Ron, and Ret also activate these RTKs.

Gain-of-function mutations in the second catalytic domain of Kit were originally described in mastocytoma cell lines of human, mouse, and rat origin in the early 1990s. More recently, mutations in this region have been found in patients with a variety of different diseases, many of which involve hematopoietic cells. In 1995, mutations in codon 816 of Kit were first described in patients with mastocytosis. Mutations in this region have also been found in some patients with core binding factor leukemias, sinonasal lymphomas, and germ cell tumors. Interestingly, patients with more than one of these conditions have been reported. Mastocytosis can be associated with myeloproliferative disease. Patients with both mastocytosis and germ cell tumors have also been reported.

In 1998, mutations in the juxtamembrane region of Kit were found in patients with GISTs. Interestingly, these mutations occur at higher frequencies in patients with malignant GIST than in those with benign tumors. Malignant GIST is extremely resistant to chemo- and radiotherapy. In 2001, astonishing improvement in a patient with malignant GIST was reported after treatment with STI571, an inhibitor of bcr-abl, Kit, and the PDGF receptor. Subsequent to these findings, the results of several clinical trials indicate that this drug is tremendously beneficial in the treatment of patients with malignant GISTs. *In vitro*, STI571 inhibits the kinase activity of Kit juxtamembrane mutants at lower concentrations than wild-type Kit. Furthermore, cells expressing this form of mutant Kit undergo apoptosis after exposure to this drug. Thus, targeted inhibition of mutant Kit shows great promise in the treatment of GIST.

C. Alterations in Expression of Kit

In acute myeloid leukemia (AML), large percentages of patients express Kit on leukemic blast cells. This has led to speculation that Kit may be a molecular target for the treatment of AML. Treatment of one AML patient refractory to standard chemotherapy regimens with the Kit inhibitors SU5416 and SU6668 induced remission. However, it remains to be determined whether this approach will be helpful in

the management of this disease in the majority of patients.

Inappropriate expression of Kit, SCF, or both has been reported in patients with breast cancer, small cell carcinoma of the lung (SCCL), melanoma, and some tumors of the CNS. Among these diseases, the role of Kit and SCF expression in SCCL and melanoma have been studied most extensively. Therefore, the remainder of this section will focus on studies relating to these two diseases.

Although Kit plays an important role in the development of melanocytes, expression in mature melanocytes may lead to apoptosis. Interestingly, decreases in Kit expression have been observed in tissues from melanoma patients. A strong correlation between reductions in the transcription factor activator protein-2 (AP-2) and Kit expression have been reported. Since the Kit reporter contains multiple AP-2 sites, the loss of AP-2 may lead to a reduction in the expression of Kit and facilitate the escape of melanoma cells from SCF-induced apoptosis. Ectopic expression of Kit in a melanoma cell line dramatically reduced metastatic potential *in vivo*.

In contrast to melanoma, co-expression of Kit and SCF contributes to autocrine growth of SCCL. Seventy percent of SCCL cell lines or primary tumor specimens co-express Kit and its ligand. The role of this putative autocrine loop in the growth of these cells has been illustrated by several approaches. Ectopic expression of a dominant-inhibitory Kit mutant, as well as treatment with drugs that inhibit Kit activity such as AG1296, STI571, SU5416 and SU6597, dramatically inhibits the growth of SCCL cells.

D. Loss-of-Function Mutations

The phenotypes of the various *W* and *Sl* mutant mice demonstrate the critical role of SCF and Kit in germ cell development, pigmentation, and hematopoiesis, as well as in the functioning of the intestinal tract and portions of the CNS. Reviews extensively describing these animals are listed under Further Reading. This section will briefly summarize the effect of mutations in the Kit or SCF genes in each of these organ systems in mice and indicate whether corresponding defects have been noted in humans.

Mutations in Kit have been associated with defects in pigmentation in mice, rats, pigs, and humans. This may also contribute to roan coloring in horses. In humans, loss-of-function mutations in one allele of Kit are associated with autosomal

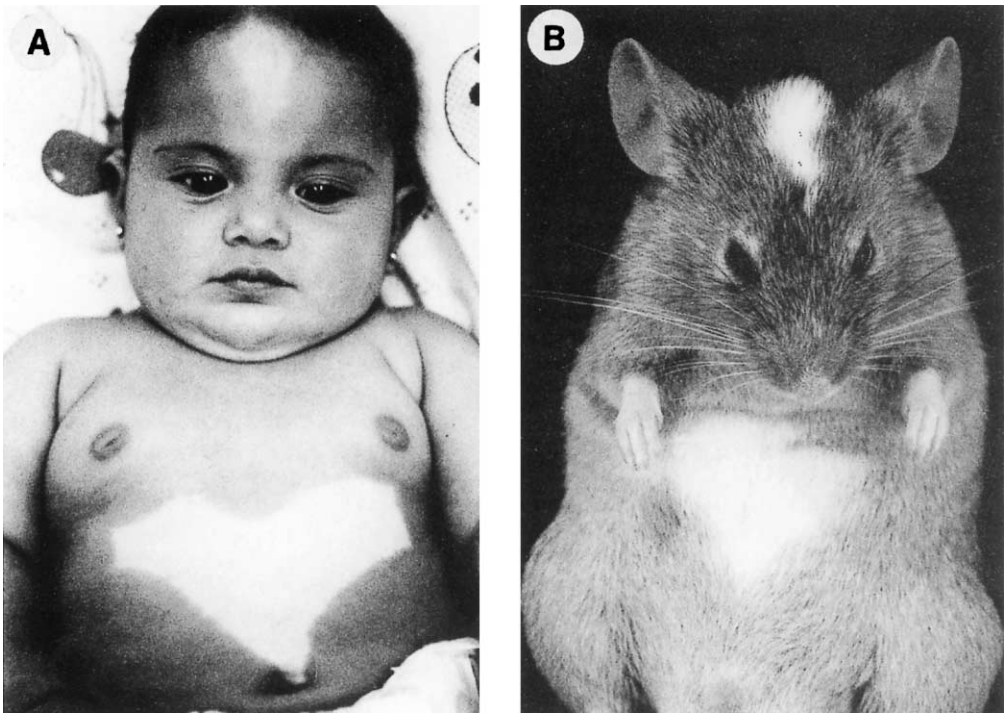

FIGURE 3 Loss-of-function mutations in one allele of Kit cause alterations in pigmentation in humans and mice. Reprinted from Fleischman *et al.* (1991) *Proc. Natl. Acad. Sci. USA* **88**, p. 10885, with permission.

dominant piebaldism. Mutations in the first catalytic domain of human Kit have been observed in many of these patients. Similar to *W* and *Sl* mice, which are heterozygotes for dominant inhibitory mutations, white spots are observed on the ventral trunk, forehead, and extremities. Shown in Fig. 3 are a child and a mouse that are both heterozygotes for the identical loss-of-function mutation in Kit.

Kit contributes to the development of the interstitial cells of Cajal and these cells are important in the pacemaker activity of the gastrointestinal tract. The importance of Kit in normal intestinal function is highlighted by the abnormality in intestinal pacemaker activity in *W* mice. In humans with autosomal dominant piebaldism, there is an increased frequency of megacolon and other gastrointestinal difficulties. Loss of ICCs is associated with motility disorders in human (e.g., Hirschsprung's disease) and other animals (e.g., grass sickness in horses).

W and *Sl* mice also have dramatic alterations in hematopoietic tissue. The more severe variants are mast cell deficient and have macrocytic anemia. The anemia results from decreases in numbers of erythroid progenitors, particularly those corresponding to CFUe (colony forming unit erythroid). No dramatic defects in hematopoiesis have been noted in humans with mutations in Kit. However, the patients examined have had mutations in only one allele of the Kit gene. Similarly, heterozygotic *W* mice have very mild alterations in hematopoietic tissue. Thus, it is unknown whether Kit plays the same nonredundant role in hematopoiesis in humans as it does in mice.

The gene products for both Kit and SCF are expressed at high levels in the murine hippocampus. As discussed previously, mice and rats with mutations in SCF or Kit have deficits in hippocampal-dependent learning. In addition, there are reductions in numbers of sensory nerves in some *W* and *Sl* mice, as well as reports of auditory deficiencies in rats with mutations in Kit. In humans, retardation and sensorineural deafness have been reported in patients with autosomal dominant piebaldism.

The development of both sperm and oocytes requires functional Kit and SCF. Mice with severe defects in either gene product are sterile. Exciting recent studies demonstrate that the interaction of Kit with PI3K is required for spermatogenesis in mice. More subtle alterations in oogenesis may also depend on the association of PI3K and Kit. In humans, reductions in Kit may be linked to defects in sperm development. Kit is also a candidate gene for contributions to ovarian failure.

VII. SUMMARY

SCF binds the receptor tyrosine kinase Kit. Interaction of this ligand and receptor induces rapid autophosphorylation of Kit, dimerization, and activation of multiple signaling components, including Src family members, the JAK/STAT pathway, the Ras–Raf–MAP kinase cascade, PI3K, and PLCγ. SCF promotes the survival, growth, and maturation of stem cells from multiple lineages. In addition, when combined with other growth factors, SCF is potently synergistic. Loss of expression of either Kit or SCF is lethal in mice. Mice with mutations resulting in reductions in expression or function of Kit or SCF have defects in pigmentation and hematopoiesis, are mast cell deficient, and have reproductive difficulties. Mutations resulting in the activation of Kit in the absence of ligand are associated with human diseases, including GISTs, mastocytosis, sinonasal lymphomas, germ cell tumors, and some myeloid leukemias. Inappropriate co-expression of Kit and SCF has been implicated in SCCL, and down-regulation of Kit on melanocytes may contribute to metastatic melanoma.

Glossary

hematopoiesis Development of multiple lineages of blood cells from a pluripotential stem cell. These include red blood cells, platelets, lymphocytes (T and B), natural killer cells, monocytes, and granulocytes (neutrophils, eosinophils, and mast cells). This process is regulated by soluble and membrane-bound growth factors, cell contact, and interaction with the extracellular matrix.

receptor tyrosine kinase Membrane-spanning protein that binds ligand via the extracellular domain and contains a protein tyrosine kinase in the intracellular domain. Interaction with ligand promotes dimerization and subsequent increases in the catalytic activity of the kinase.

signal transduction The process of transferring information from the extracellular milieu to the cellular interior and ultimately into the nucleus. This biochemical process is integral to the control of cellular survival, growth, development, and function.

Steroid Hormone Receptor Family: Mechanisms of Action

MILAN K. BAGCHI

University of Illinois, Urbana-Champaign

The steroid hormones, which include the sex steroids (estrogen, progesterone, and androgens) and adrenal steroids (glucocorticoids and mineralocorticoids), have long been known to control the growth, development, and homeostasis of various mammalian tissues.

I. INTRODUCTION

The biological action of a steroid hormone is mediated by its cognate intracellular receptor, which regulates the expression of a specific set of genes in the nucleus. The steroid receptors belong to a large, evolutionarily related family of transcription factors, known as the nuclear receptor (NR) superfamily. This family, which has 48 members, also includes the receptors for thyroid hormones, retinoic acids, and vitamin D as well as receptors for a variety of other metabolic ligands. Many orphan receptors, for which the ligands remain undiscovered, also belong to this family. The signal transduction pathway of the NRs has been studied extensively as a model system to investigate the fundamental mechanisms of eukaryotic gene regulation. These studies have provided a blueprint for the mechanism of action of these important cellular regulatory molecules. The goal of this article is to provide a brief overview of the current mechanistic concepts and emerging models of the NR pathway.

II. FUNCTIONAL DOMAINS OF NUCLEAR RECEPTORS

Biochemical, molecular genetic, and structure–function analyses during the mid to late 1980s revealed that the NRs possess a modular structure containing discrete functional domains consistent with their role as ligand-inducible transcription factors (Fig. 1). Generally, the receptor structure is composed of three principal modules: (1) an evolutionarily conserved DNA-binding domain (DBD), which anchors the NR to its target DNA, (2) a somewhat less conserved carboxy-terminal ligand-binding domain (LBD), and (3) a poorly conserved amino-terminal activation function region, AF-1. A flexible hinge region (D) joins the DBD and LBD. Mutational analysis of the LBD led to the identification of a highly conserved second activation function region, AF-2, which is

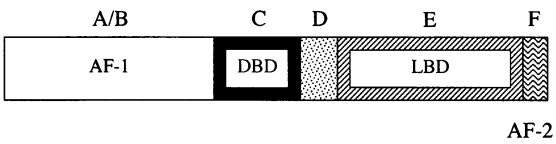

FIGURE 1 Functional domains (A/B, C, D, E, and F) of a prototype nuclear hormone receptor. The DBD (C) and LBD (EF) represent DNA- and ligand-binding domains, respectively. AF-1 (A/B) and AF-2 (F) indicate constitutive and ligand-inducible transcriptional activation function regions, respectively.

essential for ligand-dependent activation by NRs. In certain receptors, such as thyroid hormone and retinoic acid receptors, the LBD functions as a repression domain in the absence of ligand. In addition, the LBD contains signals for receptor homo- and/or heterodimerization and nuclear localization. The LBD is, therefore, a uniquely important domain involved in many aspects of receptor function.

III. HORMONE-INDUCED ACTIVATION

Hormones play a pivotal role in activating NRs. A steroid receptor is functionally inactive in cells in the absence of its cognate hormone. Several lines of evidence suggest that the unliganded receptor exists in an oligomeric complex in association with several heat-shock proteins, which are thought to function as chaperone proteins. In this inactive state, the receptor does not interact with DNA. Hormone binding leads to the disaggregation of the receptor from heat-shock proteins and converts it to a form that is able to bind DNA. For certain steroid receptors, such as the glucocorticoid and mineralocorticoid receptors, ligand binding occurs in the cytoplasm of target cells, inducing nuclear translocation of the ligand–receptor complex. Although the hormone-occupied receptors are always localized in the nucleus, many of the NRs are found in the nuclear compartment even in the absence of their cognate ligands. Certain NRs, such as thyroid hormone receptor (TR) and retinoic acid receptor (RAR), bind to DNA in the unliganded state and function as transcriptional repressors of target genes.

Hormone binding triggers a striking conformational change in the LBD of the receptor. Crystal structures of various NR LBDs complexed with agonist or antagonist ligand have thrown considerable light on the molecular nature of this structural change. In the absence of ligand, the LBD structure, which is composed of 12 contiguous α-helices, has a fairly open conformation. The hormone fits into a hydrophobic pocket formed by different layers of helices and directly contacts several amino acid residues of the receptor. On hormone binding, the LBD assumes a rather compact conformation. Comparison of the crystal structures of unliganded and liganded NRs suggested that hormone binding induces a dramatic repositioning of helix 12. Whereas in the unliganded NR, helix 12 extends away from the LBD, in the liganded receptor, this helix folds back tightly against the body of the LBD and makes contacts with the ligand itself. This ligand-induced rearrangement creates a surface consisting of residues contributed by helices 3, 4, and 12 that is utilized by the hormone-bound receptor for interaction with transcriptional co-regulators, such as co-activators (see below), which play critical roles in the hormonal signal transduction pathways.

IV. TARGET DNA RECOGNITION

A critical step in the hormone-response pathway of NRs is the recognition of the target gene by the receptor. This may occur through direct interaction of the DBD with specific enhancer sequences referred to as hormone-response elements (HREs) or through protein–protein interactions with other classes of DNA-bound transcription factors, such as activating protein 1 (AP-1) or Sp1, at the target promoter. For the classical steroid receptors, estrogen receptor (ER), glucocorticoid receptor (GR), progesterone receptor (PR), androgen receptor (AR), and mineralocortocoid receptor (MR), the response elements contain a 15 bp core sequence, composed of two half-sites of 6 bp (AGAACA for GR, PR, AR, and MR; AGGTCA for ER) arranged in a dyad axis of symmetry (palindromic). The half-sites are separated by 3 bp of random composition. These receptors bind to their response elements as head-to-head homodimers. DNA recognition by these NRs involves contacts of amino acids present in two interdependent zinc-finger structures in the DBD with specific base pairs within the major groove of the core HRE motif and the phosphate backbone.

Nonsteroid receptors, such as the TR, RAR, and vitamin D receptor (VDR), bind to response elements that contain direct repeats of a core recognition motif, AGGTCA. These receptors bind mostly as heterodimers with the retinoid X receptor (RXR). A RXR–TR heterodimer can bind to response elements consisting of direct repeats or inverted palindromes of the core AGGTCA motif. The number of base pairs separating the direct repeats of the core recognition motif determines DNA-binding specificities of different heterodimeric pairs. For example, direct repeats separated by 3, 4, and 5 bp represent response elements for VDR, TR, and RAR, respectively.

V. TRANSCRIPTIONAL ACTIVATION

In a target cell, a DNA- and hormone-bound NR is thought to regulate gene expression by influencing local chromatin structure and enhancing the transcription initiation process at the target promoter. Studies exploiting steroid receptor-regulated *in vitro*

gene expression systems indicated that the promoter-bound receptor stimulates transcriptional initiation by facilitating the formation of a stable preinitiation complex containing RNA polymerase II and other basal transcription factors. The precise mechanism by which the receptor achieves this effect remains to be determined. The receptor may promote transcription initiation by facilitating recognition of the promoter by a certain initiation factor(s) or simply by stabilizing the promoter DNA–protein complex once it is formed or perhaps by influencing both reactions. Recent work from a number of laboratories indicates that a class of mediator proteins, termed co-activators, is recruited by the receptor to modify chromatin structure. The co-activators may also function as signaling intermediates between the hormone-occupied receptors and the RNA polymerase II transcription machinery.

A surprisingly large number of nuclear receptor-interacting proteins that may serve as co-activators have been isolated using yeast two-hybrid screening, far Western cloning, and biochemical methods based on NR affinity chromatography. A hallmark of these putative co-activators is that they interact with the nuclear receptors in a ligand-dependent manner and enhance their transcriptional activity. The steroid receptor co-activator-1 (SRC-1), which stimulates transactivation by several nuclear hormone receptors, was the first co-activator reported for the NR superfamily. Additional receptor-interacting proteins, TIF2/GRIP1 and pCIP/ACTR/RAC3/AIB1, which show striking structural similarity to SRC-1, were soon isolated by other laboratories. The remarkable similarity in amino acid sequence among these proteins, all of which exhibit an approximate molecular size of 160 kDa, indicates the existence of a p160 family of nuclear receptor co-activators.

In addition to the p160 family of proteins, several other potential co-activators have been described. Prominent among these is the transcriptional co-activator CREB-binding protein (CBP, where CREB denotes Ca^{2+}/cyclic AMP response element-binding protein) and its homologue p300. It is believed that CBP/p300 is recruited as a secondary co-activator of NRs through its direct interaction with primary p160 co-activators. There is strong biochemical evidence that CBP/p300 co-exists with one or more p160 proteins in a large receptor-co-activation complex. These co-activators work together in a synergistic fashion to enhance ligand-dependent transactivation mediated by nuclear receptors. Microinjection of an anti-SRC-1 or anti-CBP antibody into cultured cells partially blocked ligand-dependent gene activation by PR, ER, and other nuclear receptors. Most importantly, gene knockout studies show that loss of SRC-1 function partially impaired the physiological actions of several NRs.

A CBP-associated factor (p/CAF), the mammalian homologue of yeast GCN5, is reported to interact with CBP and the p160 proteins, as well as directly with NR LBDs. p/CAF is also reported to function as a co-activator of several NRs. Interestingly, all three co-activators, p160s, CBP, and p/CAF, possess intrinsic histone acetyltransferase (HAT) activities, suggesting that they might function as chromatin remodelers. Furthermore, CBP has been shown to interact directly with the components of the RNA polymerase II machinery. Collectively, these results indicate that the p160 family of proteins, CBP/p300, and possibly additional co-factors like p/CAF act in unison with the activated nuclear receptors to remodel chromatin structure and then directly recruit the basal transcription apparatus to effect steroid-dependent gene activation.

Another class of co-activator that plays a critical role in NR-mediated transactivation is the thyroid receptor-associated protein/vitamin D receptor-interacting protein (TRAP/DRIP) complex, comprising 13–15 polypeptides. This complex interacts with the LBD of many NRs in a hormone-dependent manner. A single subunit, TRAP220/DRIP205, anchors the entire complex to the LBD and enhances NR-mediated transactivation in an *in vitro* chromatin-free transcription system. Additional protein–protein interactions between the TRAP/DRIP150 subunit and the AF-1 of GR have been documented. Unlike the p160/CBP complex, the TRAP/DRIP complex is devoid of HAT activity. Several subunits of the TRAP/DRIP complex are also present in a mammalian complex corresponding to the yeast mediator complex that associates with the RNA polymerase II holoenzyme. These findings raise the possibility that the TRAP/DRIP complex, once recruited by a NR, may stimulate transcription by directly contacting and influencing the activity of the RNA polymerase II machinery at the core promoter.

The fact that the p160/CBP complex possesses HAT activity but the TRAP/DRIP complex does not has led to the proposal that these co-activator complexes interact with the receptor in a two-step sequential manner to effect transcriptional activation. According to this hypothesis, the NR initially recruits the SRC/CBP complex, which remodels and opens up the chromatin. This is followed by the recruitment of the TRAP/DRIP complex, which interacts with and stimulates the activity of the RNA polymerase II

initiation apparatus. Although this is an attractive model, it is not clear how a strict temporal order of recruitment can be maintained or an efficient exchange of co-activators can be achieved. Furthermore, one also needs to consider the possibility that these co-activators function in parallel pathways of receptor-dependent activation, which might be operative in a promoter-specific manner.

Ligand binding to a NR acts as a switch for co-activator recruitment. For steroid receptors such as the GR, ER, and PR, ligand-induced release of receptor-associated heat-shock proteins likely precedes co-activator binding. For certain other receptors such as TR and RAR, ligand-dependent displacement of co-repressors might be a necessary prerequisite for co-activator action. In both cases, the ligand-induced conformational change in the receptor LBD generates a surface to which the co-activator protein docks. Recent studies in several laboratories indicated that multiple conserved leucine-rich sequences, termed NR boxes, exist in the p160 family of co-activators. These NR boxes contain the signature LXXLL motif, where L is leucine and X is any amino acid. An amphipathic helical peptide containing a LXXLL motif mediates the interaction of the co-activator with the LBDs of various nuclear receptors. The leucine residues 1 and 5 form intimate contacts with well-conserved amino acids within the core hydrophobic pocket of the LBD. The residues immediately surrounding the LXXLL motif determine receptor specificity. Crystal structure data support the view that two LXXLL motifs of a single SRC-1 molecule may interact with the individual AF2 domains of both subunits of a NR homo- or heterodimer. Recent studies also indicate that the AF-1 domains of several steroid receptors have the ability to interact with and recruit p160 co-activators, although the molecular basis of this interaction is unclear. One can envision that the co-activator molecule, once docked via interaction with AF-1 or AF-2, may then function as a physical bridge between the transactivation domain of the receptor and the RNA polymerase II transcription machinery during gene activation. Further studies are clearly necessary to test this plausible mechanism.

VI. TRANSCRIPTIONAL REPRESSION

Transcriptional repression by ligand-bound NRs is well documented. Typically, overexpression of a given nuclear receptor ("interfering receptor") in a transient transfection system often results in the repression of ligand-induced transcriptional activation of target genes by another member of the superfamily ("activating receptor"). Such mutually antagonistic interactions have been described between various pairwise combinations of the steroid receptors ER, GR, PR, and TR and also between NRs and AP-1. No DNA binding by the interfering receptor is required for this effect. Conceptually, transcriptional interference or "squelching" occurs due to the interaction of the activation domains of nuclear receptors with a common but limiting target protein, such as a co-activator, in their signaling pathways. Consistent with this hypothesis, overexpression of SRC-1 appears to alleviate the antagonistic competition between liganded ER and PR in a cell. Similar overexpression of CBP/p300 was also noted to partially overcome the antagonistic interplay between GR and AP1, indicating that this co-activator could be a limiting component common to both signal transduction pathways.

Another mode of transcriptional repression, termed silencing, is displayed by certain nuclear receptors, such as TR and RAR. These receptors actively repress the transcription of cellular genes bearing the cognate hormone-response elements. In the absence of hormone, TR or RAR binds to its response element in a ligand-independent manner and functions as a silencer of basal level transcription from the target promoter. Ligand binding to the receptor releases transcriptional silencing and leads to the activation of target gene expression. The mechanism of this ligand-induced switch from repression to activation of gene expression is a topic of intense investigation in many laboratories.

Recent studies indicated that transcriptional silencing by TR or RAR is dictated, in part, by the association of the receptor with cellular co-repressors. A number of candidate co-repressors have been described among which two distinct but structurally related co-repressors, NR co-repressor (NCoR) and silencing mediator of retinoid and thyroid receptors (SMRT), have been studied most extensively. NCoR/SMRT harbors multiple independent repression domains, which contribute to its overall repression function. The co-repressor uses its carboxy-terminal receptor interaction domain to interact with unliganded TR or RAR but fails to interact with the ligand-occupied receptors. Within the receptor interaction domain of the co-repressor, two CoRNR boxes containing I/LXXI/VI signature motifs mediate interactions with the unliganded LBD. These amphipathic helical sequences are reminiscent of the LXXLL

motifs found in the co-activator. It is likely that one NCoR/SMRT molecule is bound per DNA-bound heterodimer, with each CoRNR box contacting a single NR LBD.

The critical determinants of receptor–co-repressor interaction appear to be the presence of the I/LXXI/VI motifs in the co-repressor and the structure of the NR LBD. Although the co-repressor uses the same hydrophobic pocket in the NR LBD that is used by the co-activator, there are important differences. The AF-2 helix is clearly inhibitory to co-repressor binding. In the unliganded receptor, this helix is displaced outside the ligand-binding pocket, allowing the co-repressor to bind. Ligand binding triggers a dramatic change in the position of helix 12, resulting in the displacement of the co-repressor and formation of the co-activator-binding surface. Ligand-induced exchange of co-repressors with co-activators can conceivably take place without the receptor coming off the DNA.

Recent biochemical studies indicate that NCoR/SMRT exists in a large multiprotein complex containing histone deacetylase 3 (HDAC3) and additional polypeptides such as WD40 repeat protein TBL1 and G-protein suppressor 2. Although HDAC3 is the most prevalent histone deacetylase that was found biochemically to be associated with the co-repressor complex, there are reports that NCoR/SMRT associates with Sin 3, HDAC1, and HDAC2. Once anchored to the DNA-bound NR, the co-repressor complex apparently utilizes the histone deacetylase to maintain a repressive chromatin state. In addition, one can envisage that one or more repression domains of the recruited co-repressor may directly contact critical components of the basal transcription machinery and negatively impact the assembly of a functional initiation complex.

NCoR and SMRT are also involved in the transcriptional repression pathway of nuclear receptors other than TR and RAR. Most interestingly, estrogen or progesterone receptor complexed with certain antagonist ligands recruits these co-repressors to the target promoter to block transcription. In tamoxifen- or raloxifen-bound estrogen receptor, due to the presence of an additional side chain in the antagonist, helix 12 is positioned improperly. Helix 12, instead of packing normally as in the hormone-bound LBD, overlaps with the surface that docks the co-activator. This ligand-specified variation prevents co-activator interaction and facilitates co-repressor binding. The recruited co-repressor then negatively modulates the transcriptional activity of the target promoter.

VII. REGULATION OF CHROMATIN STRUCTURE

In the cell, the transcription units are packaged into nucleosomes and remain in a repressed state. An essential first step in the NR-dependent gene activation pathway is, therefore, chromatin remodeling. Several multisubunit ATP-dependent chromatin-remodeling complexes, such as yeast SWI/SNF or *Drosophila* ISWI, which use the energy of ATP to alter nucleosome structure, have been characterized. Brg1, a subunit of human SWI/SNF, interacts with the GR and is required for efficient receptor-dependent activation of a MMTV (mouse mammary tumor virus) promoter stably integrated into chromosomal DNA. Brg1 is also recruited to an ER-regulated promoter in response to the hormone and critically regulates the transcriptional activity of the receptor. Furthermore, the addition of purified Brg1 to an *in vitro* transcription system reconstituted from chromatinized templates facilitated RAR-dependent transactivation. Taken together, these results point to an important role of ATP-dependent chromatin remodelers in NR-mediated gene activation.

NR-associated factors can also remodel chromatin by modulating acetylation of histones in nucleosomes. Whereas certain co-activators are found to possess intrinsic histone acetyltransferase activity, the co-repressors are associated with histone deacetylases. It is known that hyperacetylation of the lysine-rich tails of histones H3 and H4 on a chromatin DNA can destabilize nucleosomes and facilitate the binding of transcription factors to the promoter regulatory elements, leading to gene activation. Hypoacetylation of acetylated H3 and H4 by deacetylases, on the other hand, creates a repressive chromatin conformation, leading to gene repression. It is therefore postulated that targeted recruitment of acetyltransferase or deacetylase to a particular gene may modulate its transcriptional activity. The recruitment of a co-repressor by a promoter-bound receptor is thought to induce local hypoacetylation of histones to create a repressive chromatin conformation, leading to gene repression. The recruitment of a co-activator, in contrast, would lead to local hyperacetylation of histones, which may destabilize nucleosomes on a chromatin DNA. This, in turn, is likely to allow the binding of a RNA polymerase II transcription initiation complex at the core promoter, leading to gene activation. Consistent with this hypothesis, many of the candidate nuclear receptor co-activators, such as CBP, p/CAF, and SRC-1/p160, are known to possess intrinsic histone

acetyltransferase activity. Additionally, recent reports suggested that CBP/p300 or SRC-1 enhanced steroid receptor-dependent transactivation from a chromatinized hormone-responsive template. It has been shown that this effect involves the acetylation of histones and is critically dependent on HAT activity of CBP/p300.

Unliganded TR functions as a repressor of a target promoter by recruiting a co-repressor complex containing histone deacetylase to the promoter. In the presence of thyroid hormone, the co-repressor complex containing the deacetylase is released from the promoter-bound receptor, thereby relieving the transcriptional repression. The receptor then recruits a co-activator complex, which consists of one or more histone acetyltransferases, to promote gene activation. The co-activators and co-repressors appear to act by regulating histone acetylation at the target promoter in an opposing fashion (Fig. 2).

In addition to acetylation, other covalent modifications, such as phosphorylation, methylation, and ubiquitination of histones and nonhistone proteins, have been known to modulate NR function at the target promoter. There is ample evidence that phosphorylation via various kinase cascades influences the transactivation activity of several members of the steroid receptor superfamily such as the GR, PR, and ER. There is now evidence that specific phosphorylation events may modulate co-activator recruitment and function. For example, mitogen-activated protein kinase (MAPK)-induced phosphorylation of specific serine residues in the AF-1 of ER-β facilitates SRC-1 recruitment by the tamoxifen-complexed receptor. In contrast, MAPK-induced phosphorylation in the amino-terminus of peroxisome proliferator-activated receptor-γ leads to inhibition of receptor function.

Most striking among the hormone- and NR-induced chemical modifications at the target promoter is the methylation of nucleosome and transcriptional co-factors by a family of arginine-specific methyltransferases. The p160 co-activators, anchored to promoter-bound NRs, recruit the co-activator-associated methyltransferase 1 (CARM1). Interestingly, the carboxy-terminal region of p160 proteins contains distinct binding sites for both CARM1 and CBP/p300. Consistent with this scenario, CARM1 and p300 synergistically stimulate transactivation by ER and this synergism is dependent on the presence of a p160 co-activator. Whereas CARM1 methylates specific arginine residues in histone H3, CBP/p300 possesses intrinsic HAT activity. It is therefore conceivable that CARM1 and p300 cooperate to induce multiple concurrent histone modifications to induce efficient chromatin remodeling, which allows subsequent recruitment of the transcription machinery. It is also interesting to note that CARM1 and CBP/p300 can undergo direct protein–protein interaction with each other. A functional consequence of this interaction is methylation of CBP/p300 by CARM1. Although the methylated CBP/p300 retains HAT activity and can still act as a co-activator for NR-mediated

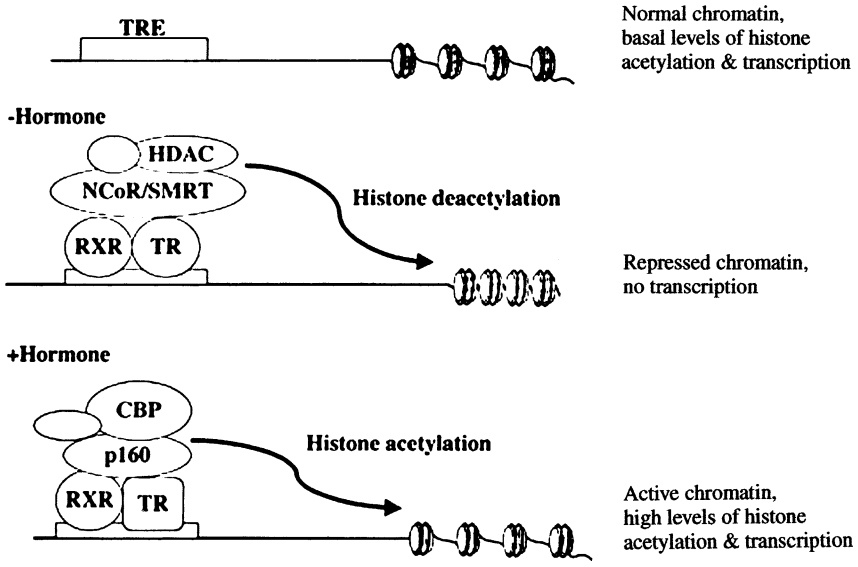

FIGURE 2 A model of nucleosomal remodeling of a TR-responsive promoter by co-repressor and co-activator complexes containing HDAC and HAT activities, respectively. TRE indicates thyroid hormone-response element.

transcription, it fails to interact with CREB, resulting in a block in CREB activation. These results unveil a new regulatory mechanism involving co-factor methylation and stress the point that a combinatorial network of various NRs, their ligands, and co-regulatory proteins underlie the complexity of hormonal signaling.

VIII. SUMMARY

The research on the NR pathway, which was initiated with the discovery of the concept of steroid receptors by Elwood Jensen and colleagues more than 40 years ago, has made tremendous progress through the years and led to the development of the best-understood model of eukaryotic gene regulation to date. The recent discovery of the co-activators and co-repressors has added additional layers of complexity to this regulatory pathway. Many details of the biochemistry, structure, function, and biology of these new molecules remain to be explored. A better mechanistic understanding of how the interplay of these co-regulatory molecules regulates the expression of specific NR-regulated genes during development and homeostasis in living cells will likely emerge from future studies.

Glossary

AF-1 and AF-2 Amino-terminal and carboxyl-terminal activation function regions of a nuclear receptor.

chromatin DNA packaged into nucleosomes or histone octamers.

co-activator A cellular co-regulatory protein that facilitates gene activation by a transcription factor.

co-repressor A cellular co-regulatory protein that facilitates gene repression by a transcription factor.

histone acetyltransferase An enzymatic activity that transfers an acetyl group from acetyl coenzyme A to histones.

histone deacetylase An enzymatic activity that removes an acetyl group from histones.

hormone antagonist A drug that counteracts the action of a hormone by binding to a nuclear receptor.

hormone-response element Short DNA sequences bound by nuclear receptors.

***in vitro* transcription** Study of RNA synthesis from a DNA template in cell extracts.

methyltransferases Enzymes that promote methylation of substrates.

nuclear receptors A family of ligand-inducible transcription factors.

Steroid Nomenclature

ANTHONY W. NORMAN AND HELEN L. HENRY
University of California, Riverside

Steroids are relatively complex organic molecules with approximately 18–27 carbon atoms. To accurately describe the nature and position of the functional groups attached to steroids (and other organic molecules), chemists have devised a formal system of nomenclature. This article provides an introduction to steroid nomenclature and provides the systematic names of some common steroids as well as the structures of several steroid hormones.

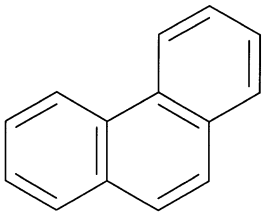
I. BASIC RING STRUCTURE

Steroids are derived from a phenanthrene ring structure (**1**) to which a pentano ring has been attached; this yields in the completely hydrogenated form cyclopentanoperhydrophenanthrene or the sterane ring structure (**2**).

Steroid structures are not normally written with all the carbon and hydrogen atoms as illustrated in 2 of Fig. 1; instead, the shorthand notation as presented for sterane (**3**, Fig. 1) is usually employed. In this representation, the hydrogen atoms are not indicated and unless specified otherwise it is assumed that the cyclohexane (A, B, C) or cyclopentane (D) rings are fully reduced; that is, each carbon has its full complement of carbon and/or hydrogen bonds. Also indicated in sterane (**3**) is the standard numbering system for all the carbon atoms in the four rings as well as the letter designation of each ring of a steroid.

II. CLASSES OF STEROIDS

In vertebrate systems, there are six families of steroid hormones that can be classified both on a



Phenanthrene

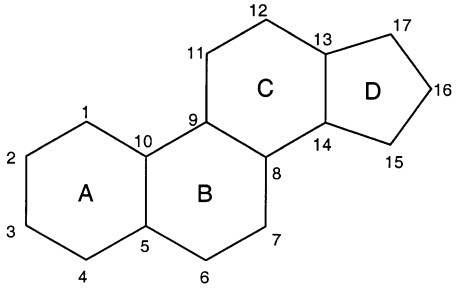
Cyclopentanoperhydrophenanthrene (sterane)
(2)



Sterane
(3)

FIGURE 1 Parent ring structures of steroids. Phenanthrene (**1**) is the building block to generate the two 4-ring structures **2** and **3**. The structures for cyclopentanoperhydrophenanthrene (**2** and **3**) represent the same molecule; in **2**, all the hydrogen atoms are indicated, whereas in **3** the tetrahedral bonding of all carbons is assumed (no double bonds are present) and for the sake of convenience the hydrogen atoms are not shown. In (**3**), the standard numbering system for the carbons of the A, B, C, and D rings of the steroid nucleus is indicated.

structural basis and on a biological (hormonal) basis. They are the estrogens (female sex steroids), the androgens (the male sex steroids), the progestins, the mineralocorticoids, the glucocorticoids, and vitamin D along with its daughter metabolites. The bile acids, structurally related to cholesterol, constitute a seventh class of steroids. All of these steroids are biologically derived from cholesterol (Fig. 2).

III. STRUCTURAL MODIFICATION

The basic steroid ring structures illustrated in sterane (**3**) can undergo an array of modifications by introduction of hydroxyl or carbonyl substituents and by introduction of unsaturation (double or triple bonds). In addition, heteroatoms such as nitrogen or sulfur can replace the ring carbons, and halogens and or amino groups may replace steroid hydroxyl moieties. Ring size can be expanded or contracted by addition or removal of carbon atoms. The consequences of these structural modifications are

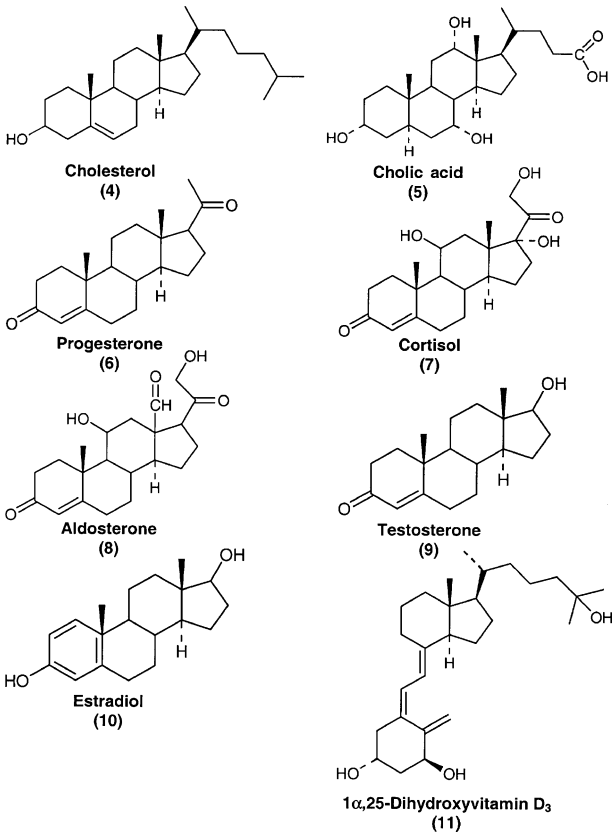


FIGURE 2 Structure of cholesterol (**4**) and cholic acid (a bile acid) (**5**) and representative structures of a steroid hormone from each steroid family (structures **6**–**10**). The hormone form of vitamin D_3 is $1\alpha,25(OH)_2$ vitamin D_3 (**11**).

TABLE 1 Steroid Nomenclature Conventions

Modification	Prefix	Suffix
Hydroxyl group (–HO)	Hydroxy	-ol
Hydroxyl above plane of ring	β-OH	—
Hydroxyl below plane of ring	α-OH	—
Keto or carbonyl group (C=O)	Oxo-	-one
Aldehyde (–CHO)	—	-al
Carboxylic acid (COOH)	Carboxy	-oic acid
Double bond (–C=C–)	—	-ene
Triple bond (–C≡C–)	—	-yne
Saturated ring system	—	-an
One less carbon atom	-Nor	—
One additional carbon atom	-Homo	—
One additional oxygen atom	-Oxo	—
One less oxygen atom	-Deoxy	—
Two additional hydrogen atoms	-Dihydro	—
Two less hydrogen atoms	-Dehydro	—
Two groups on same sides of plane	*Cis*	—
Two groups on opposite sides of plane	*Trans*	—
Other ring forms (rings A and B *trans*, as in allopregnane)	Allo	—
Opening of a ring (as in vitamin D)	Seco-	—
Conversion at a numbered carbon from conventional orientation (as in epicholesterol or 3α-cholesterol)	-Epi	—

designated by application of the standard organic nomenclature conventions of steroids. The pertinent aspects of this system are summarized in Table 1. Prefixes and suffixes are used to indicate the type of structural modification. Any number of prefixes may be employed (each with its own appropriate carbon number and specified in order of decreasing preference of acid, lactone, ester, aldehyde, ketone, alcohol, amine, and ether); however, only one suffix is permitted.

The formal names of steroids are devised in accordance with the official nomenclature rules for steroids laid down by the International Union of Pure and Applied Chemistry. Table 2 lists the trivial and systematic names of a number of common steroids.

IV. ASYMMETRIC CARBONS

An important structural feature of any steroid is the presence of asymmetric carbon atoms and designation in the formal nomenclature of the structural isomer that is present. For example, reduction of pregnane-3-one (**12**) to the corresponding 3-alcohol (**13**) will produce two epimeric steroids (**14**) and (**15**)

(see Fig. 3). The resulting hydroxyl may be above the plane of the A ring and is so designated on the structure (**14**) by a solid line; it is referred to as a -3β-ol. The epimer or -3α-ol (**15**) has the hydroxyl below the plane of the A ring and is so designated by a dotted line for the –C···OH bond. If the α or β orientation of a substituent group is not known, it is designated with a wavy –C–OH line.

Another locus where asymmetric carbon atoms play an important role in steroid structure determination is the junction between each of the A, B, C, and D rings. Figure 4 illustrates these relationships for cholestanol and coprostanol. In the 5α form, the 19-methyl and the α-hydrogen on carbon 5 are on opposite sides of the plane of the A:B ring; this is referred to as a *trans* fusion. When the l9-methyl and β-hydrogen on carbon 5 are on the same side of the A:B ring fusion, this is denoted *cis* fusion. In this case, the steroid structure can no longer be drawn in one plane (as in **24**). Thus, in all 5β steroid structures that have *cis* fusion between rings A and B, the A ring is bent into a second plane that is approximately at right angles to the B:C:D rings (see **24** of Fig. 4). Thus, each of the ring junction carbons is potentially asymmetric and the naturally occurring steroid will have only one of the two possible orientations at each ring junction. Although there are two families of naturally occurring steroids with either *cis* or *trans* fusion of the A:B rings, it is known that the ring fusions of B:C and C:D in virtually all naturally occurring steroids are *trans*.

The chemical determination and designation of the absolute configuration of asymmetric carbon atoms on the side chain according to formal rules of nomenclature are complex. The "sequence rules" of Cahn *et al.* must be applied. These rules describe operational procedures to generate an unambiguous nomenclature specification of the absolute configu-

TABLE 2 Trivial and Systematic Names of some Common Steroids

Trivial name	Systematic name
Aldosterone	18,11-Hemiacetal of 11β,21 -dihydroxy-3,20-dioxopregn -4-ene-18-al
Androstenedione	Androst-4-ene-3, 17-dione
Androsterone	3α-Hydroxy-5a-androstan-17-one
Cholecalciferol (vitamin D_3)	9,10-Secocholesta-5,7,10(19) -trien-3β-ol
Cholesterol	Cholest-5-ene-3β-ol
Cholic acid	3α,7α,12α,-Trihydrozy-5b-cholan -24-oic acid
Corticosterone	11β,21-Dihydroxypregn-4-ene-3, 20-dione
Cortisol	11β,17,21-Trihydroxypregn-4-ene -3,20-dione
Cortisone	17,21-Dihydroxypregn-4-ene-3, 20-dione
Dehydroepiandrosterone	3β-Hydroxy-5-androstene-17-one
Deoxycorticosterone	21-Hydroxypregn-4-ene-3,20-dione
Ergocalciferol (vitamin D_2)	9,10-5-eco-5,7,10(19), 22-ergostatetraen-3β-ol
Ergosterol	5,7,22-Ergostatrien-3-β-ol
Estriol	Estra-1,3,5(10)-triene-3,16α, 17β-triol
Estrone	3-Hydroxyestra-1,3,5(10) -triene-17-one
Etiocholanolone	3α,-Hydroxy-5b-androstane-17-one
Lanosterol	8,24-Lanostadiene-3β-ol
Lithocholic acid	3α,-Hydroxy-5β-cholan-24-oic acid
Progesterone	Pregn-4-ene-3,20-dione
Testosterone	17β-Hydroxyandrost-4-ene-3-one

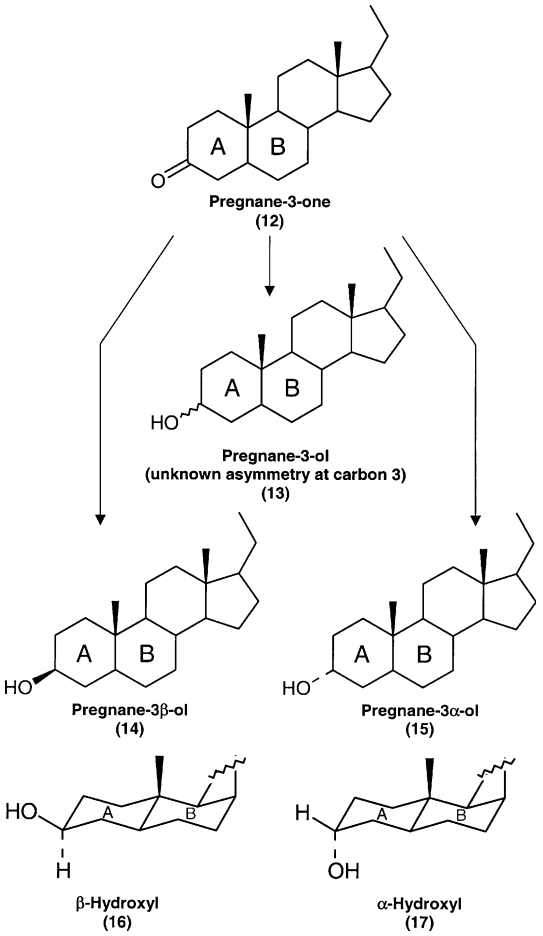

FIGURE 3 Structural consequences resulting from reduction of pregnane-3-one (**12**). The orientations of the α- and β-hydroxyls of compounds pregnane-3β-ol and pregnane-3α-ol as equatorial (**16**) or axial (**17**) substituents, respectively, on the chair version of the A rings are shown in the bottom row.

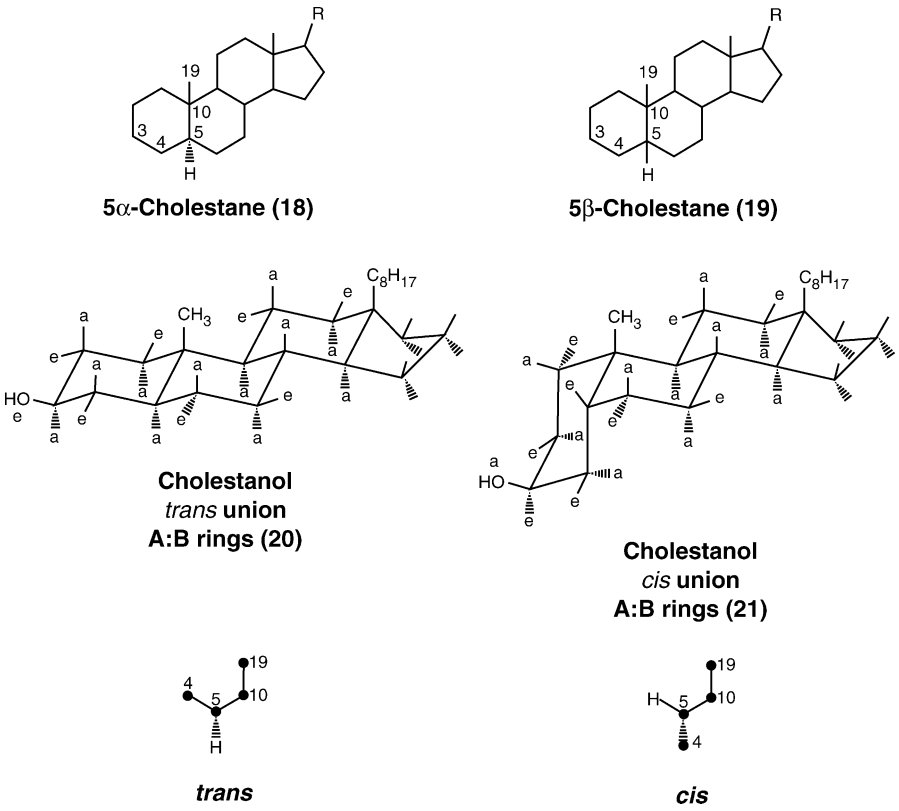

FIGURE 4 Structural relationships resulting from *cis* or *trans* A:B ring fusion in two typical steroids. In 5α-cholestane and cholestanol, the A:B ring fusion is *trans*, whereas in 5β-cholestane and coprostanol, the A:B ring fusion is *cis*. The orientation of substituents around carbon 5 for the *cis* and *trans* circumstances is illustrated in the bottom row. a, axial orientation; e, equatorial orientation; ●–●, carbon–carbon bonds.

ration of all chemical compounds whether they be steroids, sugars, amino acids, thiopolymers, or other compounds.

Glossary

asymmetric carbon A carbon atom in a complex molecule that is chemically bonded to four different substituents.

chirality The right- or left-handedness of an asymmetric carbon of organic molecules.

steroid A member of the lipid class of compounds composed of the four-ring cyclopentanoperhydrophenanthrene nucleus, it is the basic structural component of steroid hormone families such as estrogens, progestogens, androgens, mineralocorticoids, glucocorticoids, and vitamin D and its metabolites.

Steroidogenic Acute Regulatory (StAR) Protein, Cholesterol, and Control of Steroidogenesis

JEROME F. STRAUSS, III

University of Pennsylvania Medical Center

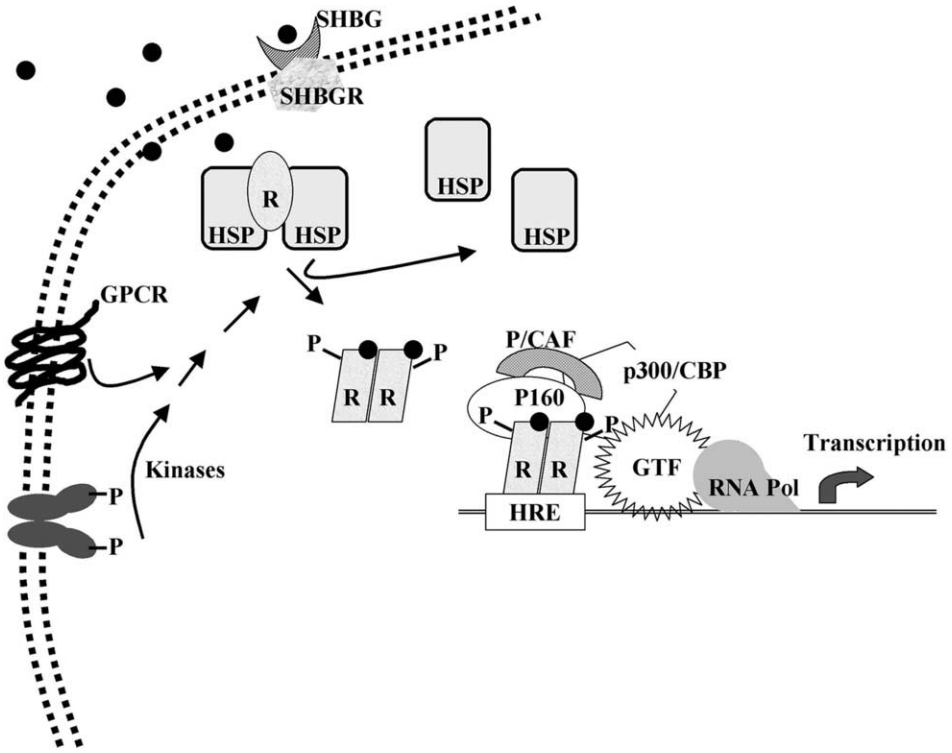

FIGURE 1 In the absence of hormone, steroid receptors (R) associate with heat-shock proteins (HSP). Binding of steroid (●) results in dissociation from heat-shock proteins, dimerization, and binding to specific hormone response elements (HRE) in the promoters of target genes. The receptor recruits co-activators, including the p160 (also called steroid receptor co-activator) family of proteins, P/CAF, and p300/CBP. These proteins perform a variety of functions, including acetylation of histones, and interact with general transcription factors (GTF) to stimulate transcription of target genes. Activation of a variety of membrane receptors, including G-protein-coupled receptors (GPCR) and growth factor receptors, stimulates a cascade of phosphorylations; this results in enhanced phosphorylation (P) of steroid receptors and their associated proteins, altering the resulting transcriptional activity. Among the signaling pathways that can be induced is steroid-mediated activation of steroid hormone-binding globulin (SHBG) and its receptor, steroid hormone-binding globulin receptor (SHBGR), which elevates cAMP levels, activating protein kinase A. In some cases, altered cell signaling is sufficient to activate a steroid receptor in the absence of any hormone, a pathway termed ligand-independent activation.

containing sequences (hormone response elements) specifically recognized by the receptor; these sequences are in the promoters of target genes. In addition, the receptors recruit complexes of proteins, termed co-activators, which serve a variety of functions to enhance the transcriptional activity of the receptor. Among the best characterized activities of the co-activators is the ability to acetylate histones at target genes, opening up chromatin and allowing access for RNA polymerase and other factors needed for transcription. The receptors and their co-activators are phosphoproteins. Signals emanating from membrane receptors, including growth factor receptors and G-protein-coupled receptors, regulate the phosphorylation and activity of the steroid receptors. Sometimes these changes in cell signaling are sufficient to activate a steroid receptor in the absence of hormone, a process termed ligand-independent activation.

The general structures of the steroid receptors are very conserved; the structure of the estrogen receptor-α is depicted in Fig. 2. Steroid receptors contain highly conserved DNA-binding domains, which consist of two Zn^{2+} finger motifs (region C) and less well-conserved hormone-binding domains (region E) linked to the DNA-binding domain by the hinge region (D). The hormone-binding domains also contain a region important for transcriptional activity, activation function-2, (AF-2), which binds co-activators, facilitating transcription. The hinge region contains a nuclear localization signal. Some receptors contain an additional carboxyl-terminal

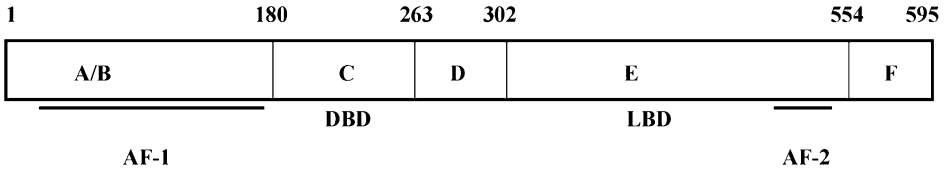

FIGURE 2 The general structural organization of a steroid receptor, depicting the structure of the human estrogen receptor-α. All receptors contain regions A–E. The numbering indicates the amino acid positions bordering the functional domains in estrogen receptor-α. Regions C and E of steroid receptors contain the DNA-binding domain (DBD) and the ligand-binding domain (LBD), respectively. Within the A/B domain and the E domain, each steroid receptor contains a region important for transcriptional activity (AF-1 and AF-2). Region D, termed the hinge region, contains a nuclear localization signal. Although estrogen receptor-α contains an F domain, which is not required for hormone binding, some receptors lack this region.

segment (F), which is not required for hormone binding. The amino-terminal regions of the receptors (A/B) are the least conserved and are the most variable in length, ranging from less than 200 amino acids in the estrogen receptor to more than 500 in the progesterone receptor. This region contains an additional activation function (AF-1). The relative importance of AF-1 and AF-2 in inducing transcription is dependent on receptor, promoter, cell type, and activation signal.

III. REGULATION OF STEROID RECEPTOR FUNCTION BY CELLULAR SIGNALING PATHWAYS

Two major approaches have been utilized to assess the role of cellular signaling in the activity of steroid receptors. The first method is to modulate the activity of cellular signaling pathways and to determine the effect on receptor activity. The advantage of this scheme is that one can rapidly identify cellular signaling pathways that contribute to the regulation of steroid receptors. However, it is frequently difficult to identify the means by which the alterations in cell signaling modulate the receptor activity. The target of the kinases may be the receptor, associated proteins, or both. The second technique is to mutate phosphorylation sites in the steroid receptors and to determine the roles of the individual phosphorylation sites. This approach is limited by the necessity of first identifying the phosphorylation sites in the steroid receptors, a difficult undertaking that has not been completed for the majority of the steroid receptors.

A. Activation of Steroid Receptors by Cellular Signaling Pathways

Investigators have known for a long time that some steroid-regulated genes are also regulated by signal transduction pathways. Initially, it was assumed that the cell signaling pathways were acting independently of steroid receptors through proteins such as cAMP response element binding protein (CREB), the activation of which is dependent on phosphorylation. However, it is now evident that alterations in kinase activity can activate some steroid receptors in the absence of hormone. This was first shown by introducing into cells lacking the progesterone receptor a plasmid encoding the chicken progesterone receptor and a reporter plasmid containing progesterone response elements linked to the coding region of chloramphenicol acetyltransferase (CAT). CAT activity, induced in response to progesterone or 8-Br cyclic adenosine monophosphate (cAMP) (an activator of protein kinase A), was then measured. Surprisingly, both treatments induced CAT activity and both were dependent on the progesterone receptor. Subsequent studies revealed that activators of diverse signal transduction pathways cause ligand-independent activation of chicken progesterone receptor. These include epidermal growth factor (EGF), which acts through a membrane-bound receptor that induces its tyrosine kinase activity, and dopamine, which acts through a serpentine membrane receptor that causes activation of G-protein-coupled pathways. Responses of steroid receptors to signal transduction pathways are receptor, activator, and cell type specific. The estrogen receptor appears to be the most responsive of the receptors. Although there are unique genes for most of the steroid receptors, the discovery of a second gene encoding an estrogen receptor has altered the nomenclature in the field. The estrogen receptor that was cloned originally and is the best studied is now termed ER-α; the more recently discovered receptor is termed ER-β. Discussions of the estrogen receptor in literature prior to 1996 refer to ER-α. Many stimuli, including dopamine, 8-Br cAMP, EGF, and other growth factors, activate ER-α, and there is evidence

that ER-β can also be activated by cell signaling pathways in the absence of hormone. Most studies of ligand-independent activation have been done in cells transfected with expression plasmids for receptors and with artificial reporters, raising the question of whether such activation can occur *in vivo*. Two types of studies support the belief that these are pathways that contribute to biological activity *in vivo*. First, EGF can induce responses (such as DNA synthesis) that are also induced by estrogen in the uteri of ovariectomized mice; the EGF action is blocked by the estrogen receptor antagonist, ICI 164384, indicating that EGF is acting through the estrogen receptor. Moreover, EGF fails to induce DNA synthesis in the uteri of mice that lack ER-α. Second, dopamine can induce a sexual receptivity response in rats (lordosis) that is normally progesterone dependent. Administration of a progesterone receptor antagonist, mifepristone, inhibits this response, confirming that dopamine is acting through the progesterone receptor.

Other steroid receptors are less responsive to changes in cell signaling. Although the human androgen receptor can be activated under specific circumstances by treatments that elevate cAMP levels or by growth factors, in many cases the changes in cell signaling are insufficient to activate the receptor, although they do increase the response to hormone. Although avian and rodent progesterone receptors can be activated in the absence of ligand, comparable conditions fail to activate the human progesterone receptor. However, treatment with growth factors or activation of protein kinase A does enhance hormone-dependent activity. Moreover, treatment with 8-Br cAMP causes the antagonist mifepristone to act as an agonist. The glucocorticoid receptor responds similarly. It is resistant to ligand-independent activation, but altered cell signaling enhances activity either in combination with agonists or with the antagonist mifepristone.

B. Role of Phosphorylation in Steroid Receptor Action

All of the steroid receptors, as well as some, if not all, of the co-activators, are phosphoproteins. Although the identification of the phosphorylation sites is incomplete, most have been identified. The number of sites in each receptor ranges from as few as four in chicken progesterone receptor to more than a dozen in the human progesterone receptor. The sites are predominantly serines, although phosphothreonine has been identified in the glucocorticoid receptor and in the human progesterone receptor. Tyrosine phosphorylation in these proteins occurs rarely. Under some conditions, phosphorylation of Tyr-537 in the hormone-binding domain of the estrogen receptor is detected. A majority of the phosphoserines and phosphothreonines are followed by prolines, implicating proline-directed kinases, such as the cyclin-dependent kinases and the mitogen-activated kinases, in the regulation of their phosphorylation. Almost all the phosphorylation occurs in the amino termini of the receptors. The major exception is a Ser-Pro motif in the hinge region of the steroid receptors. In contrast to the other sites, this site appears to be conserved among all receptors, and phosphorylation has been demonstrated in chicken and human progesterone receptors, mouse estrogen receptor, and human androgen receptor. Typically, the receptors exhibit some phosphorylation in the absence of hormone, but the degree of phosphorylation is enhanced upon hormone treatment. The phosphorylation of some sites such as Ser-118 in the estrogen receptor and several of the sites in the progesterone receptor is almost exclusively dependent on hormone or an activating signal such as EGF.

The roles of the phosphorylation sites are diverse and have not been fully elucidated. Reported functions range from increasing response to low levels of hormone, to altering affinity for DNA, regulating transcriptional activity, and playing a role in the stability of the receptors. One of the best characterized sites is Ser-118 in human ER-α. This site is phosphorylated either in response to hormone or to treatment with EGF. Mutation of this site to an alanine modestly reduces the transcriptional activity of the receptor in response to hormone. However, a negative charge (provided either by a phosphate or an artificially substituted glutamic acid) at this position is absolutely required for EGF-induced activation of ER-α in some cell lines. Substitution of a glutamic acid for the serine is insufficient to produce a constitutively active receptor. Thus, EGF must induce phosphorylation either of other sites in ER-α or, more likely, on associated proteins to induce ligand-independent activation.

The receptors are substrates for a variety of kinases. Although most of the sites are proline-directed kinase sites, the human progesterone receptor contains a casein kinase II site, and Ser-167 in the human estrogen receptor is a potential target of multiple kinases, including casein kinase II, Rsk, and Akt. Estrogen, progesterone, and glucocorticoid receptors are all substrates for the cyclin-dependent kinase 2 (Cdk2); activation of Cdk2 enhances the transcriptional activity of estrogen and glucocorticoid

receptors. On treatment with EGF, Ser-118 in the estrogen receptor is phosphorylated by mitogen-activated protein kinase (MAPK; also called extracellular signal-regulated kinase, or ERK), contributing to ligand-independent activation. However, hormone-induced phosphorylation of Ser-118 is not dependent on MAPK; instead, cyclin H Cdk7 plays a role in hormone-dependent phosphorylation.

There are receptor-specific effects on steroid receptors of the MAPK family of proline-directed kinases, which includes the ERK, Jun N-terminal kinase (JNK) or stress-activated protein kinase, and p38/HOG signaling cascades. Activation of JNK stimulates the activity of ER-α whereas it inhibits the activity of the glucocorticoid receptor through phosphorylation of Ser-246 in the glucocorticoid receptor. Activation of ERK stimulates the activity of estrogen and progesterone receptors, but inhibits glucocorticoid receptor activity. Thus, the activities of the steroid receptors are regulated by many kinases and the consequences are receptor specific.

In addition to altering the activities of the steroid receptors through phosphorylation of the receptors, signal transduction pathways alter phosphorylation and activity of co-activators. This aspect of receptor function is less well studied, but there is good evidence that the steroid receptor co-activator (SRC) family of nuclear receptor co-activators is phosphorylated by ERK and that these phosphorylations modulate the ability of the SRC proteins to serve as co-activators.

IV. STEROID RECEPTOR INTERACTIONS WITH REGULATED TRANSCRIPTION FACTORS

Although steroid receptor activities, which result from binding directly to specific DNA sequences, are the best characterized of steroid receptor actions, there is ample evidence that steroid receptors also regulate transcription of target genes through interactions with other transcription factors, independently of a direct interaction of the receptor with the DNA. These activities may be stimulatory or inhibitory, depending on the target gene, receptor, and interacting transcription factor. Conversely, these transcription factors influence the activities of the steroid receptors. In some cases, the cross talk involves DNA-independent protein/protein interactions, and in others, the response is dependent on the sequence including and surrounding the element to which the transcription factor binds in its target gene. Steroid receptors influence several of the transcription factors for which expression, subcellular localization, and activity are highly dependent on cellular signaling pathways.

A. NF-κB

Steroid receptors modulate the function of nuclear factor κB (NF-κB), a ubiquitously expressed transcription factor. Five members of the family have been identified, with the most well-characterized active complex being a heterodimer of the p50 and p65 (RelA) subunits. Prior to activation, p50 and p65 are located in the cytoplasm and are bound to an inhibitory κB subunit, IκB. Activating signals such as growth factors or inflammatory cytokines such as tumor necrosis factor α (TNFα) induce phosphorylation of IκB, leading to its degradation by the proteasome pathway. This frees the p50/p65 complex, permitting nuclear translocation, binding to DNA, and activation of target genes. Steroid receptors interact with NF-κB through the p65 subunit and can reciprocally modulate transcriptional activity. Both ER-α and androgen receptor-dependent mutual repression of NF-κB activity have been reported. Repression may occur either through direct physical interaction or through competition for a limited pool of co-activators. The best studied example of mutual repression between a steroid receptor and NF-κB is the functional interaction between glucocorticoid receptor and NF-κB. Studies of glucocorticoid receptor repression of NF-κB-induced activation of intercellular adhesion molecule or interleukin (ICAM-1 or IL-8) genes, for example, reveal that the glucocorticoid receptor interacts with RelA at the promoter, but does not block binding of RelA to DNA or formation of the preinitiation complex. However, the presence of the glucocorticoid receptor blocks phosphorylation of Ser-2 in the carboxyl-terminal domain (CTD) of RNA polymerase, a step required for transcription of target genes.

B. AP-1

The proteins that bind to AP-1 response elements are diverse, consisting of complexes containing either a heterodimer of Fos and Jun transcription factors or homodimers of Jun proteins alone. These proteins are regulated both at the level of transcription and by posttranslational modification. Originally characterized as proteins that are activated by protein kinase C, these proteins are regulated by numerous cell signaling pathways. Among these is the JNK pathway. Functional interactions between AP-1 proteins and steroid receptors are numerous and the response is

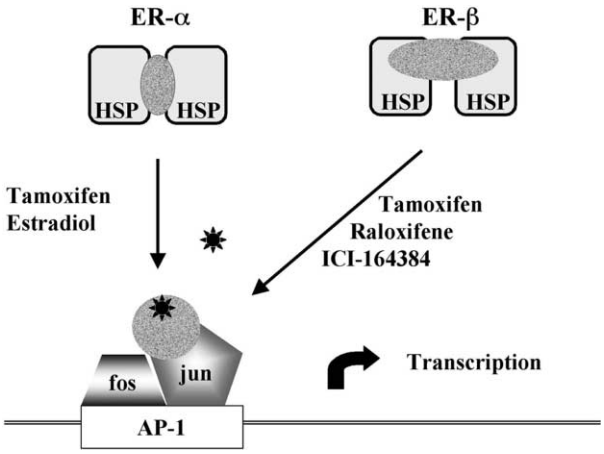

FIGURE 3 Estrogen receptor-mediated activation of transcription through an activator protein (AP-1) site. Estrogen receptors can promote transcription of a target gene through binding to the Jun partner of a Fos/Jun heterodimer bound to an AP-1 site. Although both estrogen receptor-α (ER-α) and ER-β are capable of activating transcription through AP-1 sites, the hormone specificity of the activation differs. HSP, Heat-shock protein complex.

receptor and promoter specific. Both ER-α and ER-β interact with AP-1 complexes. ER-α stimulates AP-1 activity on treatment with either an agonist such as estradiol or an antagonist such as tamoxifen (Fig. 3). Surprisingly, ER-β stimulates AP-1 activity only on binding antagonists. ER interacts with the Jun partner of the heterodimer. The finding that antagonists of conventional hormone response element-dependent transcription can stimulate estrogen receptor-dependent transcription through AP-1 elements complicates the simple model of antagonists as compounds that block the actions of steroid receptors. The ability of a specific compound to antagonize receptor activity is clearly not universal, but is dependent on the function measured.

In contrast to the estrogen receptor, the glucocorticoid receptor frequently inhibits the activity of AP-1 on activation by agonists, although this is, again, dependent on the promoter. The glucocorticoid receptor inhibits the activity of the AP-1 element in the proliferin gene when a Fos/Jun heterodimer binds to the site, but stimulates the activity of Jun homodimers. Similar to the ER, the glucocorticoid receptor binds to Jun; mutations in the glucocorticoid receptor that abrogate binding to conventional hormone response elements do not eliminate regulation of AP-1 proteins either *in vitro* or in a transgenic mouse expressing only the mutant receptor. The striking difference in phenotype between glucocorticoid receptor null mice (embryonic lethal) and mice expressing only a glucocorticoid receptor that lacks the ability to bind to a hormone response element provides strong evidence that many glucocorticoid receptor actions do not require binding to a conventional response element. For example, the glucocorticoid effects on the immune system are retained in mice with the mutant receptor.

Although studies of the androgen receptor have not been as extensive, there is evidence that AP-1 complexes acting through the Jun partner can inhibit the activity of the androgen receptor and that the androgen receptor inhibits the activity of the AP-1 complex.

C. Interactions with Other Transcription Factors

The functional interaction of steroid receptors with other transcription factors is an active area of research. Among the other transcription factors that interact with steroid receptors are a member of the signal transducer and activator of transcription (STAT) family of transcription factors, STAT5. STAT proteins are cytoplasmic prior to activation. Activation of membrane-bound receptors, including cytokine receptors, causes activation of the Janus family tyrosine kinases (Jak kinases), which, in turn, phosphorylate cytoplasmic STAT proteins, promoting dimerization of the STAT proteins, translocation to the nucleus, and transcriptional activation. Both STAT proteins and glucocorticoid receptors are cytoplasmic in the absence of activating signals. Activation of either can promote nuclear localization of the other. These interactions can stimulate or inhibit the activities of the transcription factors. Activation of the glucocorticoid receptor stimulates STAT-dependent transcription of the β-casein gene, but STAT can also inhibit glucocorticoid receptor activity. Another example of a steroid receptor influencing transcription of target genes through other transcription factors is the activation of the cathepsin D gene by estradiol through interaction of estrogen receptor with the transcription factor Sp-1.

V. STEROID-INDUCED ACTIVATION OF CELLULAR SIGNALING PATHWAYS

Steroids, acting through classical steroid receptors as well as through other means, induce the activation of a variety of signal transduction pathways. Although there has been evidence for a role of steroids in the activation of cellular signaling pathways for

many years, elucidation of the precise mechanisms by which steroids transmit signals to activate kinases is a relatively new and active field of research. The actions of steroids are transmitted by diverse means, including through classical steroid receptors associated with membranes or acting in the cytoplasm, through steroid hormone-binding globulin, and through G-protein-coupled receptors. In addition, there is evidence for membrane receptors, which are structurally unrelated to classical steroid receptors, but these have not yet been cloned and little is known about these proteins.

A variety of studies have provided evidence that either the classical steroid receptor proteins or closely related proteins function as activators of cell signaling pathways. Membrane-bound glucocorticoid and estrogen receptors contain regions on the extracellular surface that cross-react with antibodies to the well-characterized estrogen and glucocorticoid receptors. Binding of estradiol by the membrane estrogen receptor in GH3 pituitary cells induces release of prolactin and subsequent activation of its signaling cascade. Interestingly, one of the ER-α antibodies blocks estradiol-induced prolactin response whereas another induces prolactin release in the absence of estradiol. Finally, reduction in ER-α expression in these cells using antisense oligonucleotides inhibits membrane estrogen receptor expression.

Steroid hormones acting through estrogen, androgen, or progesterone receptors can activate ERK through interaction with and activation of Src kinase, a tyrosine kinase. Although the result, i.e. activation of Src kinase, is similar, estrogen receptors and progesterone receptors interact with different regions of Src. Downstream actions of estradiol, such as activation of endothelial nitric oxide synthase (NOS), are blocked by inhibitors of ERK activation, suggesting a role for ERK in many estradiol-dependent nongenomic actions. In many instances steroids induce rapid alterations in calcium flux and/or induce the activities of a variety of kinases. Some of these actions appear to be independent of classical steroid receptors, although the mechanisms that induce the changes in signaling molecules have not been identified. In one case, a G-protein-coupled receptor (GPCR) is activated.

One steroid pathway that has been partially elucidated is the sex hormone-binding globulin (SHBG) pathway. SHBG serves as a carrier for steroids in the blood. In addition, it has the capacity to bind to a specific membrane receptor. When receptor-bound SHBG binds to an appropriate steroid, such as estradiol or dihydrotestosterone (DHT), the levels of cAMP are increased (Fig. 4). The receptor for SHBG has not been cloned, but there is indirect evidence that it is a G-protein-coupled-receptor because compounds or proteins that inhibit G-protein signaling block SHBG-mediated induction of cAMP.

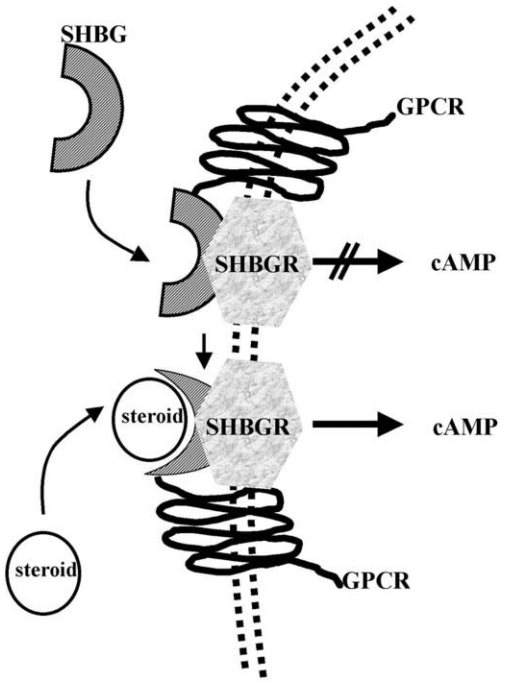

FIGURE 4 Steroids increase cAMP levels through activation of steroid hormone-binding globulin receptor (SHBGR). In the absence of an activating steroid, the steroid hormone-binding globulin (SHBG) can bind to SHBGR, but does not induce production of cAMP. Binding of steroid activates the receptor, which may be a G-protein-coupled receptor (GPCR), or associates with a GPCR to stimulate synthesis of cAMP.

VI. SUMMARY

Steroid hormone action and cellular signaling pathways intersect at many levels of the signaling pathways, providing many opportunities for mutual regulation and feedback between steroid receptors, kinases, and downstream transcription factors regulated by signal transduction pathways. For example, when an estrogen receptor-containing cell is exposed to estradiol, the result is a plethora of signaling events, including classical gene regulation through estrogen response elements, regulation of a subset of genes regulated by other transcription factors, such as AP-1 and Sp-1, and direct induction of a variety of cell signaling pathways leading to kinase activation.

Glossary

agonist Compound that binds to a cellular receptor, stimulating its biological activity.

antagonist Compound that binds to a cellular receptor and blocks agonist-dependent induction of biological activity.

co-activator Molecule that binds to a transcription factor and stimulates the transcription of the target gene to which the factor is bound.

G-protein-coupled receptors Seven-transmembrane-spanning regions (also termed serpentine regions) that interact with heterotrimeric GTP-binding proteins, resulting in alterations in downstream signaling.

proteasome Large protein complex responsible for degrading proteins that have typically been modified by ubiquitination.

Stress

PAUL J. ROSCH

New York Medical College, Valhalla, and American Institute of Stress

Stress, a term used interchangeably to refer to stimuli and to the psychophysiologic responses and pathologic consequences when such stimuli are severe or prolonged, is a highly personalized phenomenon. It is thus difficult to define, much less measure. Our current concepts of stress derive from early studies of physiologic responses to stressors, but technological advances have provided new insights into the mechanisms that may be involved in mediating the role of stress in different disorders.

Steroidogenic acute regulatory protein (StAR) plays an essential role in controlling the rate-determining step of steroid hormone synthesis. StAR is a 30 kDa protein and its mRNA is found at high levels in tissues that are involved in steroidogenesis: human adrenal cortex, ovary, and testis. It is also found at lower levels in other tissues (e.g., kidney). This article discusses the role of StAR, its structure and activity, the regulation of the *StAR* gene, and possible models for the mechanism of action of the protein.

I. INTRODUCTION

Cholesterol is the substrate for steroid hormone synthesis, and in humans, circulating lipoproteins are the major source of cholesterol used for steroidogenesis. Low-density lipoproteins (LDLs) are a primary reservoir of steroidogenic cholesterol, although other lipoproteins including very-low-density lipoproteins and high-density lipoproteins (HDLs) also contribute to the steroidogenic pool. The LDL receptor family and HDL (SR-BI) receptors are highly expressed on cells that produce large amounts of steroids, and tropic hormones up-regulate the expression of these receptors, ensuring that an adequate supply of substrate is available for steroid biosynthesis. *De novo* synthesis provides cholesterol for steroidogenesis when lipoprotein-derived substrate is insufficient. Excess cholesterol accumulated by steroidogenic cells is esterified and stored in cytoplasmic lipid droplets ready for mobilization by cholesterol ester hydrolase, which is activated by protein kinase A in response to tropic hormone stimulation. Thus, in contrast to protein hormone-secreting glands, which store preformed hormone, steroidogenic glands store hormone precursors.

The initial step in steroid hormone synthesis is the cleavage of the cholesterol side chain to form pregnenolone. This reaction is catalyzed by an enzyme system located on the matrix side of the inner mitochondrial membranes consisting of cytochrome P450 side chain cleavage ($P450_{scc}$); adrenodoxin, an iron sulfur protein electron shuttle; and adrenodoxin reductase, a flavoprotein that transfers electrons from NADPH to adrenodoxin. Cholesterol must be translocated from the relatively cholesterol-rich outer mitochondrial membrane to the inner mitochondrial membrane to come into contact with $P450_{scc}$, requiring it to traverse the aqueous space separating the two membranes. The acute regulation of steroidogenesis is due largely to the increased delivery of the hydrophobic cholesterol to the inner mitochondrial membrane. This acute mode of regulation of steroidogenesis is superimposed on the longer-term control that includes changes in the transcription of genes involved in steroid biosynthesis, cellular cholesterol uptake, and intracellular sterol trafficking.

In vivo and *in vitro* studies from more than 30 years ago demonstrated that cycloheximide and other inhibitors of translation block tropic hormone-stimulated pregnenolone production and cause cholesterol to accumulate in the outer mitochondrial membranes. These observations led to the concept that the acute increase in steroidogenesis requires a short-lived, cycloheximide-sensitive protein that is activated or synthesized in response to tropic hormone stimulation. Orme-Johnson and colleagues and Stocco and colleagues reported the induction of an ~30 kDa phosphoprotein in cells stimulated by tropic hormones or cyclic AMP (cAMP) analogues. The 30 kDa protein was localized to mitochondria and shown to be derived from a larger precursor molecule. The 30 kDa protein was subsequently isolated from MA-10 Leydig tumor cells and partial amino acid sequences were obtained, allowing the cloning of the cDNA for the murine protein and later the human protein. The protein was named steroidogenic acute regulatory protein (StAR) and it was proposed to be the cycloheximide-sensitive factor controlling the rate-determining step in steroidogenesis.

II. THE CRITICAL ROLE OF StAR

The following evidence supports the notion that StAR has a critical role in steroid hormone synthesis: (1) Expression of StAR in MA-10 Leydig tumor cells correlates with the enhanced steroidogenesis. (2) In monkey kidney COS-1 cells, which are not steroidogenic, co-transfection of StAR and the cholesterol side-chain cleavage system results in enhanced steroidogenesis. In the absence of StAR, COS-1 cells expressing the cholesterol side-chain cleavage system produce substantial amounts of pregnenolone only when a polar hydroxysterol precursor that readily enters into mitochondria is provided as an exogenous substrate. However, COS-1 cells expressing both StAR and the cholesterol side-chain cleavage enzyme are capable of producing large amounts of

pregnenolone from endogenous cholesterol. StAR also increases cholesterol flux through other mitochondrial P450 enzymes that oxidize cholesterol including P450c27, the enzyme that synthesizes 27-hydroxycholesterol, a bile acid precursor and potent regulator of cellular sterol homeostasis. (3) Mutations that inactivate StAR cause congenital lipoid adrenal hyperplasia, a rare autosomal recessive disorder in which the synthesis of all adrenal and gonadal steroid hormones is severely impaired at the cholesterol side-chain cleavage step, resulting in massive accumulation of cholesterol in the adrenal cortex and testicular Leydig cells. (4) Targeted deletion of the murine StAR gene results in a phenotype in nullizygous mice that mimics human congenital lipoid adrenal hyperplasia.

III. MOLECULAR GENETICS OF CONGENITAL LIPOID ADRENAL HYPERPLASIA

The clinical phenotype of congenital lipoid adrenal hyperplasia includes the onset of profound adrenocortical insufficiency shortly after birth, hyperpigmentation reflecting increased production of proopiomelancortin, elevated plasma renin activity as a consequence of reduced aldosterone synthesis, and male pseudo-hermaphroditism resulting from deficient fetal testicular testosterone synthesis. The affected offspring are the products of uneventful pregnancies, delivered at term. Early in the disease, the steroidogenic cells of the enlarged adrenal cortices in affected individuals are engorged with lipid droplets containing cholesterol esters, giving rise to the condition's name. Administration of adrenocorticotropic hormone or human chorionic gonadotropin to subjects with congenital lipoid adrenal hyperplasia does not elicit the normal acute increase in serum levels of adrenal or gonadal steroid hormones.

Congenital lipoid adrenal hyperplasia is a rare disease, except in Japan and Korea, where it accounts for 5% or more of all cases of congenital adrenal hyperplasia. Mutations in the *StAR* gene have been identified in more than 60 unrelated patients with congenital lipoid adrenal hyperplasia. Analysis of DNA from the parents of several patients confirmed that this disease is inherited in an autosomal recessive pattern. Mutations found in the *StAR* gene, which is composed of seven exons and is located on chromosome 8p11.2, include frameshifts caused by deletions/insertions, splicing errors, and nonsense and missense mutations, all of which lead to the absence of StAR protein or the production of functionally inactive protein. Several nonsense mutations were shown to result in C-terminal truncations of StAR. One of these mutations, Q258X, which results in the deletion of the final 28 amino acids of the StAR protein, accounts for 80% of the known mutant alleles in the affected Japanese population. All of the known point mutations that produce amino acid substitutions occur in exons 5–7 of the gene, the exons that encode the C-terminus. The metabolic defect in congenital lipoid adrenal hyperplasia is progressive, with adrenal and gonadal steroidogenesis becoming increasingly impaired with time after birth. A model has been proposed to explain the disease process that postulates the existence of some StAR-independent steroidogenesis prior to the severe cellular damage resulting from cholesterol accumulation and cholesterol oxidation, which ultimately results in a nonfunctional steroidogenic cell (Fig. 1). Comparison of the clinical course of 46,XX females with congenital lipoid adrenal hyperplasia to that of 46,XY subjects reinforced the proposed pathophysiological mechanism. 46,XX females underwent spontaneous puberty and secondary sexual development, whereas 46,XY patients were unable to undergo spontaneous puberty and had insufficient testicular androgen production *in utero* to masculinize the external genitalia. The sparing of some ovarian function in the face of mutations that inactivate StAR reflects the presence of modest StAR-independent steroidogenesis in follicles that is sufficient to sponsor estradiol synthesis. Because the ovary is essentially steroidogenically quiescent during fetal life and because follicles produce steroids only when they are recruited to mature, most follicles are spared from the ravages of cholesterol engorgement, leaving a source of viable, albeit impaired, steroid-producing cells at the time of puberty.

IV. STRUCTURE AND ACTIVITY OF StAR

Human StAR is synthesized as a 285-amino-acid protein in the cytoplasm. The N-terminus of StAR is characteristic of proteins imported into mitochondria: the first 26 amino acid residues are predicted to form an amphipathic helix. Pulse–chase studies reveal that newly synthesized StAR pre-protein (37 kDa) is rapidly imported into mitochondria and processed to the mature 30 kDa form. The pre-protein has a very short half-life (minutes) but the mature form is longer-lived (hours). Drugs that collapse the mitochondrial proton gradient inhibit StAR import, and agents that block mitochondrial matrix metalloendoproteinases prevent the cleavage of the StAR N-terminal mitochondrial targeting sequence from imported protein.

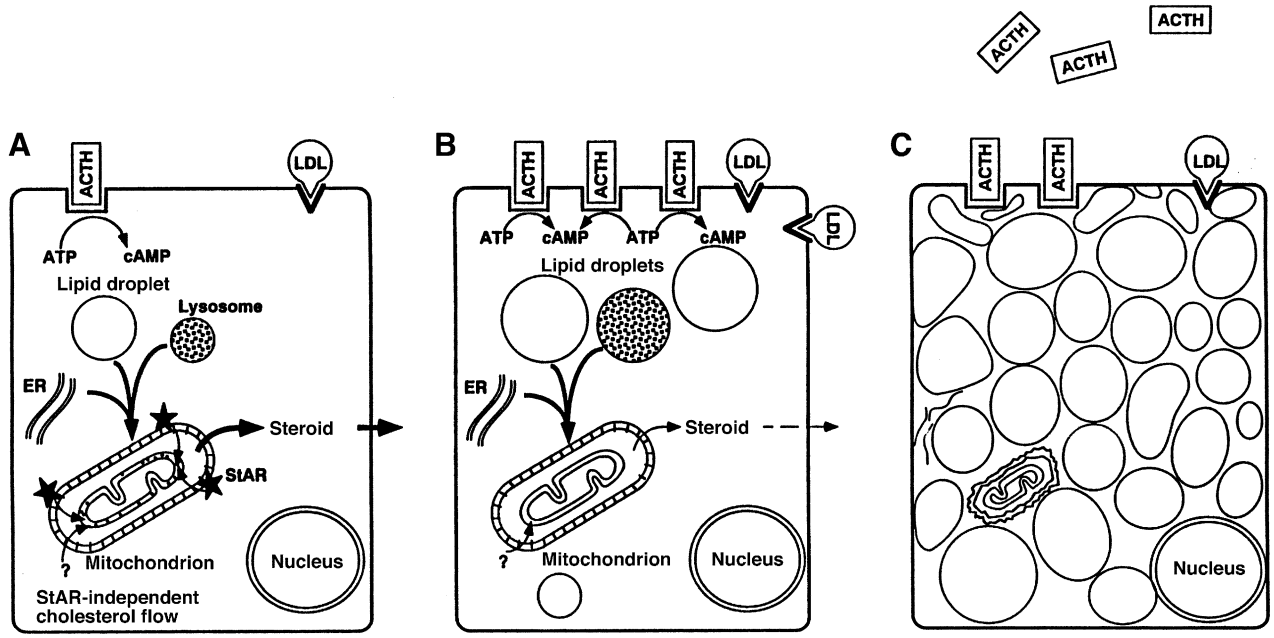

FIGURE 1 Model of the pathophysiology of congenital lipoid adrenal hyperplasia. (A) Normal adrenal cell. (B) Adrenal cell deficient in StAR at an early stage of the disease. The efficient flow of cholesterol to the inner mitochondrial membranes is impaired, leaving only a modest StAR-independent steroidogenesis. Consequently, corticotropin secretion is increased, resulting in adrenal cortical hyperplasia and increased uptake of LDL cholesterol, with accumulation of internalized cholesterol in lipid droplets due to inefficient movement of the substrate to P450scc. (C) Late stage of the disease, with massive accumulation of cholesterol in cytoplasmic lipid droplets, leading to organelle compression and auto-oxidation of cholesterol with subsequent peroxidative damage to proteins and organelles and a severe impairment of steroidogenesis.

To identify the domains of StAR critical for steroidogenesis, Arakane *et al.* generated StAR mutants and examined their activity in COS-1 cells transfected with the cholesterol side-chain cleavage enzyme. Deletion of the C-terminal 28 amino acids ablated StAR's steroidogenic activity, whereas removal of the last 10 amino acids reduced steroidogenic activity by 50%. These experiments indicated that residues in the C-terminus are critical for StAR's activity. The location of critical domains in the C-terminus of StAR is consistent with the analysis of gene mutations causing congenital lipoid adrenal hyperplasia in which mutations that inactivate StAR result from amino acid replacements located in exons encoding the C-terminal half of the protein.

It has been suggested that StAR takes on a molten globule configuration at pH 3.5–4.0, a pH that may be generated in the immediate vicinity of mitochondria. The molten globule configuration may facilitate the unfolding of StAR in preparation for action on the mitochondria and the subsequent movement through the import pore into the mitochondrial matrix. As discussed below, the crystal structure of a protein with a C-terminal domain similar to that of StAR has been determined. The crystal structure reveals that the StAR C-terminus contains a hydrophobic tunnel that can bind cholesterol.

V. THE ROLE OF PHOSPHORYLATION

The mature StAR protein contains two consensus sequences for cAMP-dependent protein kinase phosphorylation at serine 57 and serine 195. Tropic hormones act via cAMP-mediated signaling cascades to rapidly increase the production of steroids. The cAMP second-messenger system activates protein kinase A, which phosphorylates proteins on either threonine or serine residues in a specific sequence context. Phosphorylation of StAR is a plausible mechanism by which preexisting or newly synthesized StAR can be rapidly activated.

Serine 195 of human StAR must be phosphorylated for maximal steroidogenic activity. cAMP promotes the incorporation of phosphorus into this residue within minutes of stimulation. The other consensus protein kinase phosphorylation site at serine 57 does not appear to be essential for StAR's steroidogenic activity. In contrast, mutation of serine 195 to an aspartic acid residue, which mimics the

charge effect of phosphorylation, modestly increased the steroidogenic activity of the protein. These observations suggest that post- or co-translational modification of StAR can increase the activity of existing or newly made StAR protein, providing a mechanism by which tropic hormones acting through the intermediacy of cAMP can rapidly increase steroidogenesis.

VI. THE TISSUE-SPECIFIC EXPRESSION OF StAR

Tissues that express StAR at high levels carry out tropic hormone-regulated mitochondrial sterol hydroxylations through the intermediacy of cAMP. StAR mRNA is abundant in human adrenal cortex, ovary, and testis. It is also found in lower abundance in kidney and monocytes, findings consistent with the fact that 1α-hydroxylation of vitamin D takes place in the kidney as well as monocyte/macrophages, a reaction catalyzed by a mitochondrial P450 enzyme. The brain also expresses StAR in some species, which may reflect a role in neurosteroid production. StAR mRNA was not detected in the human placenta, an observation that is consistent with the fact that pregnancies hosting a fetus affected with congenital lipoid adrenal hyperplasia go to term. Although estrogen production is impaired in these pregnancies as a result of diminished fetal adrenal androgen production, placental progesterone synthesis is not significantly affected, indicating that the trophoblast cholesterol side-chain cleavage reaction is independent of StAR.

StAR protein is detectable in thecal cells of human ovarian follicles in the adult ovary, but only in granulosa cells of luteinized follicles. Theca and granulosa cells of the fetal ovaries do not stain for StAR. StAR is prominent in fetal and adult testicular Leydig cells and present at low levels in Sertoli cells of adult testis. In the kidney, StAR is localized to the distal convoluted tubules. These observations are consistent with the clinical phenotype of congenital lipoid adrenal hyperplasia in which fetal adrenal and testicular steroidogenesis is markedly affected, whereas ovarian steroidogenic activity is spared to some extent because the ovaries are relatively quiescent until puberty.

VII. THE *StAR* GENE AND ITS REGULATION

The abundance of StAR protein in steroidogenic cells is determined primarily by the rate of *StAR* gene transcription. In differentiated cells, *StAR* transcription is rapidly (within 15 to 30 min) activated by the cAMP signal transduction cascade. In differentiating cells (e.g., luteinizing granulosa cells), the induction of *StAR* transcription takes a longer time (hours) and requires on-going protein synthesis. *StAR* gene transcription is controlled, in part, by steroidogenic factor-1 (SF-1), also known as Ad4BP, an orphan nuclear receptor. The human *StAR* promoter contains three cooperative *cis* elements that bind SF-1 and are required for cAMP stimulation of *StAR*transcription. In addition to SF-1, CCAAT enhancer-binding protein-β, Sp1, GATA-4, and SREBP-1a (a member of the transcription factor family that governs the expression of many genes involved in lipid metabolism) contribute to the transcriptional control of StAR expression in a positive fashion, whereas DAX-1, another orphan nuclear receptor, inhibits *StAR* transcription, probably through interactions with SF-1.

VIII. HOW DOES StAR WORK?

StAR was originally thought to stimulate cholesterol movement from the outer to the inner mitochondrial membrane as it was imported into the mitochondria. The importation process was proposed to create contact sites between the two membranes, allowing cholesterol to flow down a chemical gradient. However, a StAR mutant lacking the N-terminal 62 amino acids (N-62 mutant) that contain the mitochondrial targeting sequence was as effective as wild-type StAR in stimulating steroidogenesis. The overexpressed N-62 StAR protein was distributed throughout the cytoplasm of the transfected cells, whereas wild-type StAR was almost exclusively located inside mitochondria. Recombinant human N-62 StAR stimulated pregnenolone production by isolated ovarian mitochondria in a dose- and time-dependent fashion, with significant increases in steroid production observed within minutes with nanomolar concentrations. A mutant recombinant protein in which the A218V mutation, which is found in subjects with congenital lipoid adrenal hyperplasia, was completely inactive. The recombinant N-62 StAR also stimulated the transfer of cholesterol but not phosphatidylcholine from cholesterol-rich phosphatidylcholine vesicles to sterol-poor acceptors. The transfer of sterols in these assays could not be ascribed to fusion of the donor vesicles and acceptor membranes. These experiments are most consistent with the idea that StAR enhances the desorption of cholesterol from sterol-rich donor membranes (Fig. 2).The desorption process may involve the

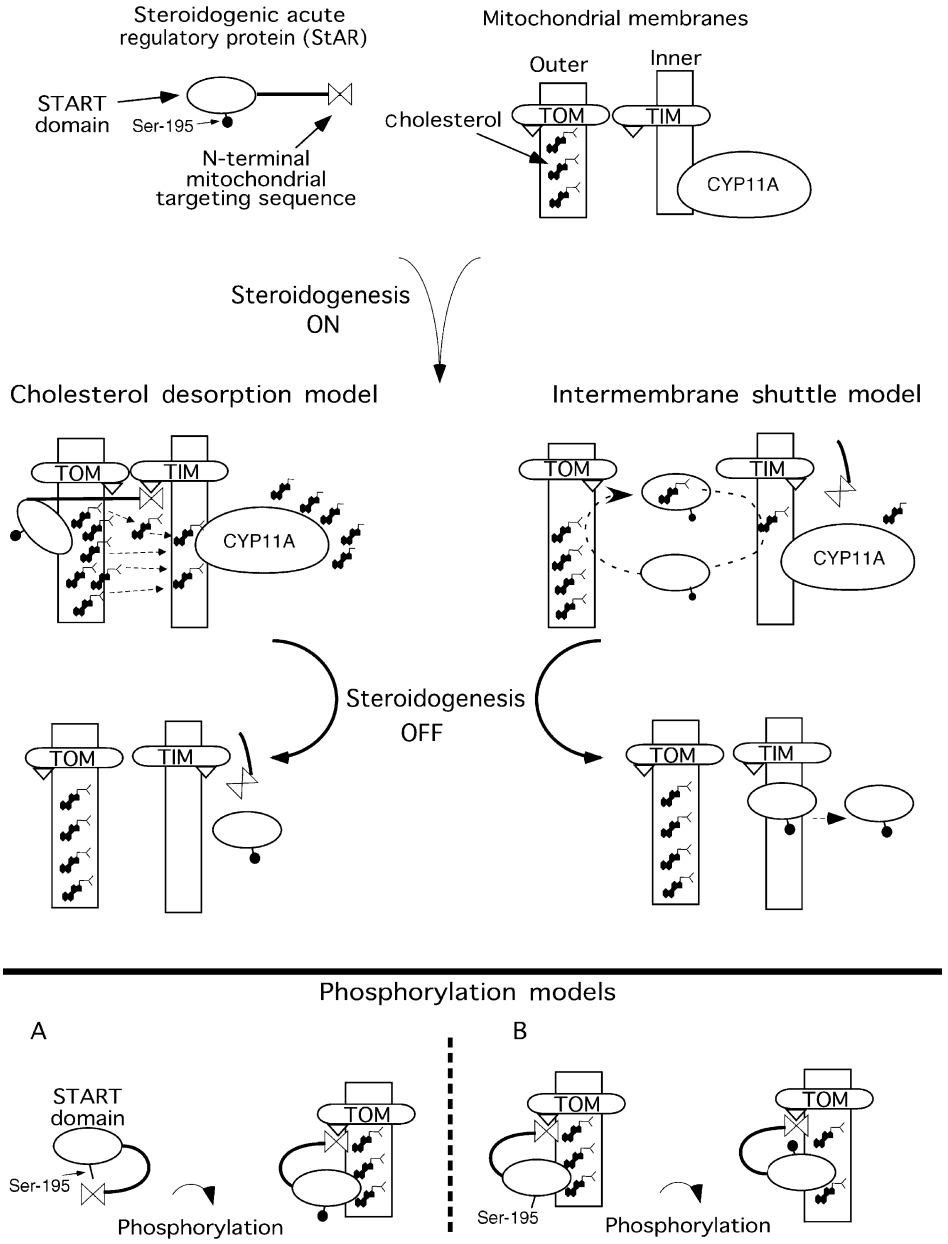

FIGURE 2 Models of StAR action. The StAR N-terminal mitochondrial targeting sequence binds to one or more of the known transmembrane outer mitochondrial transporters (TOM) and transmembrane inner mitochondrial transporters (TIM), linking it to the importation machinery. Cholesterol desorption model: The C-terminus of the protein (START domain) stimulates cholesterol desorption. The importation of the START domain removes the protein from its site of action, terminating sterol movement to the inner membrane. During or following importation, the StAR pre-protein is processed to yield the mature StAR form. Intermembrane shuttle model: The StAR protein is imported into the intermembrane space [the StAR-related lipid transfer (START) domain predicted model], and the targeting sequence is proteolytically cleaved, leaving the START domain in the intermembrane space, where it rapidly oscillates from the outer to the inner mitochondrial membranes, delivering cholesterol one molecule at a time. StAR is removed from the intermitochondrial space by an undetermined mechanism, thereby terminating sterol movement. Phosphorylation models: (A) Cyclic AMP-mediated phosphorylation of serine 195 located in the START domain of StAR reduces an inhibitory action of the N-terminal targeting sequence on StAR function, allowing more efficient interaction with the mitochondria. Alternatively (B), cyclic AMP-mediated phosphorylation of serine 195 might reduce an inhibitory action of the N-terminal targeting sequence on the START domain, allowing greater activity of this sterol transporter domain.

binding of cholesterol by the StAR C-terminus, which forms a hydrophobic tunnel, as predicted from the crystal structure of a StAR-like protein (MLN64), that can accommodate cholesterol molecules. Although the ability of StAR to bind cholesterol might suggest that it functions as shuttle, the relatively small amount of StAR in cells and its short functional life cannot account for the needed flux of cholesterol to P450scc if StAR can move only one or two moles of sterol per mole of StAR. Consequently, a "catalytic" role for the protein is required.

The observations reviewed above suggest a mechanism of StAR action that entails the efficient targeting of newly synthesized StAR pre-protein to the mitochondria by the protein's N-terminus. On reaching the mitochondria, the StAR C-terminus interacts with the relatively sterol-rich outer membrane, causing cholesterol to desorb from the outer membrane and transit to the relatively sterol-poor inner membrane, perhaps through preexisting contact sites. The import of StAR into the mitochondria and its subsequent processing remove the protein from its locus of action, effectively terminating sterol movement from the outer to the inner mitochondrial membranes. Thus, the mature protein represents a record of the past action of StAR.

It has been attractive to postulate that a "receptor" for StAR on the mitochondrial outer membrane is involved in the cholesterol translocation process. The hypothetical receptor, which could be a protein or a lipid, is evidently not specific for mitochondria of steroidogenic cells, since StAR works in the context of COS-1 cells, which are not normally steroid hormone-producing cells. The fact that immunohistochemical and electron microscope studies suggest that N-62 StAR mutants are not selectively accumulated by mitochondria argues against an abundance of high-affinity receptors for the StAR C-terminus on the mitochondria. Hence, either very few high-affinity sites or transient interactions are sufficient to promote cholesterol movement.

IX. StAR PARALOGUES

When StAR was first identified, it was thought to be a unique molecule. It is now evident that a family of proteins sharing a domain that is similar to the C-terminus of StAR exist, the so-called StAR-related lipid transfer (START) domain proteins. The absence of StAR from the human placenta, an organ that produces a significant amount of pregnenolone, documented the existence of StAR-independent steroidogenesis but raised the possibility that another protein might subserve StAR's function in the placenta. MLN64, a gene discovered to be amplified in breast and ovarian cancer cells, shares significant structural homology with StAR. MLN64 was shown to increase pregnenolone production in COS-1 cells expressing the cholesterol side-chain cleavage enzyme system. MLN64 is anchored to late endosomes through N-terminal membrane-spanning domains; freeing the C-terminus of MLN64, which is homologous to StAR, from the membrane-spanning domains increases steroidogenic activity. Cleavage of the MLN64 protein releasing its C-terminus apparently occurs in various tissues, including the human placenta. Thus, the MLN64 C-terminus may replace StAR's function in the placenta. The roles of other START domain proteins in intracellular sterol trafficking and in steroidogenesis remain to be explored.

Steroid Receptor Crosstalk with Cellular Signaling Pathways

NANCY L. WEIGEL AND IRINA U. AGOULNIK
Baylor College of Medicine

Steroid hormone receptors are hormone-activated transcription factors. Regulated by a wide variety of cell signaling pathways, steroid hormone receptors alter phosphorylation of target proteins. Conversely, steroids and their receptors act at many levels to regulate diverse cell signaling pathways and their target transcription factors. Thus, the actions of steroids and other cellular regulators are intricately intertwined.

I. INTRODUCTION

As hormone-activated transcription factors, the steroid hormone receptors and the cell signaling-regulated transcription factors such as activator protein 1 (AP-1) can regulate components of each other's pathways at the transcriptional level. The focus here, however, is on the cross-regulation of the activities of the signaling pathway components. Three major mechanisms are of importance: (1) regulation of steroid receptor phosphorylation and function by cellular signaling pathways, (2) interactions between steroid receptors and transcription factors that have activities regulated by cellular signaling pathways, and (3) activation of cellular signaling pathways by steroids.

II. STEROID RECEPTOR STRUCTURE AND FUNCTION

The steroid hormone receptors belong to a large family of ligand-activated transcription factors; the family includes steroid receptors such as the estrogen and androgen receptors, receptors for thyroid hormone and retinoic acid, and a large number of receptors for other small, hydrophobic molecules. In the absence of hormone, steroid receptors associate with heat-shock protein complexes, which hold the receptor in a conformation capable of binding hormone and protect the receptor from degradation (Fig. 1). The location of the receptor in the absence of hormone is specific to the receptor and sometimes to the cell type. Glucocorticoid and androgen receptors are predominantly cytoplasmic in the absence of hormone, whereas the estrogen and progesterone receptors are predominantly nuclear. The steroid hormones are hydrophobic cholesterol derivatives and can freely pass through the cell membrane. Binding of hormone causes conformational changes in the hormone-binding domain that favor dissociation from the heat-shock protein complexes. The receptors form dimers and associate with DNA

I. ORIGINS OF THE STRESS CONCEPT

A. Claude Bernard's Milieu Intérieur and Walter Cannon's "Homeostasis"

Although the word "stress" has been used for over five centuries as a synonym for distress, its current meaning dates back only six decades, when the term was essentially coined by the brilliant Canadian investigator Hans Selye. Selye's concept of stress had its roots in the research of Claude Bernard, who first demonstrated the mechanisms responsible for maintaining blood sugar levels and body temperature within a physiologic range whenever normalcy was threatened. In his 1865 "Introduction to the Study of Experimental Medicine", Bernard wrote that "all the vital mechanisms, however buried they may be, have only one object: that of preserving constant the conditions of life in the milieu intérieur (internal environment). …It is a fixity of the *milieu intérieur* which is the condition of free and independent life." Bernard also identified the existence of ductless (endocrine) glands, as opposed to those with ducts (exocrine), and originated the term "internal secretion."

A half-century later, Walter Cannon referred to this "fixity of the milieu intérieur" as the "steady state" and coined the term "homeostasis" to describe the numerous balancing mechanisms necessary to maintain the steady state. In studying the motor activities responsible for progressively propelling food through the gut, he noted that when his experimental animals were hungry, peristaltic waves increased in frequency and amplitude; however, if they became frightened, no such increases were seen and there was a diminution or even transient cessation of peristalsis. His further investigations revealed that this and other responses during fright were due to an outpouring of adrenaline and stimulation of the sympathetic nervous system. By 1915, Cannon had concluded that the greatest stimulation occurred under conditions of extreme hunger, thirst, fear, or rage, and during sexual activity. All of these situations automatically and immediately precipitated a cascade of coordinated nervous system and metabolic responses throughout the body. Cannon theorized that these integrated activities had been exquisitely honed over the lengthy course of evolution to facilitate "fight or flight" life-saving measures. He summarized the mechanisms responsible for maintaining heart rate, blood pressure, temperature, and blood concentrations of sugar, protein, fat, calcium, and oxygen during normal and emergency conditions in "The Wisdom of the Body," first published in 1932.

B. Hans Selye and "They Just Looked Sick"

As a medical student, Selye had noted that patients who subsequently developed very different diseases often exhibited identical signs and symptoms during the first few days of their illness. They all had low-grade fevers, feelings of malaise, fatigue, generalized aches, and "they just looked sick." He was 18 and excited about the possibility of using his weekends to study the mechanisms that might be responsible for these common nonspecific signs and symptoms, but was advised that this would be fruitless and that he should devote any spare time to his studies. Selye graduated first in his class; he later earned a doctorate in organic chemistry and received a Rockefeller scholarship in 1931, which he used to study under the renowned biochemist, J. B. Collip, at McGill Medical School. At the time, only two ovarian hormones had been identified, but Collip thought there was a third and Selye was sent to the Montreal slaughterhouses to retrieve as many cow ovaries as possible. Collip processed these into an extract for Selye to inject into female rats; the rats were subsequently examined for any changes in tissues that might be attributed to a new ovarian hormone. Not only were no such effects detected, but most of the rats became very sick and several died.

Although Selye found no gross or microscopic changes in the ovaries or breasts of the injected rats, he observed that all of the animals showed ulcerations in the stomach, enlargement of the adrenals, and shrinkage of the thymus and lymphoid tissues. The most plausible cause seemed to be some contaminant in Collip's chemical concoction. There was a bottle of formaldehyde used to fix tissues for microscopic study in front of him; on a whim, he injected liberal amounts of this toxic substance into several rats and was amazed to find that it produced results identical to those observed with Collip's new extract. Injecting other toxic chemicals produced these same changes; he subsequently demonstrated (in experiments that would be impossible to perform today) that noxious physical and/or emotional stimuli could produce these same pathologic changes. Selye viewed these common pathologic findings, as well as the very early similar symptoms in sick patients he had observed as a medical student, as a nonspecific response to what he chose to call "biologic stress."

In 1936, Selye submitted his findings to the editor of *Nature*, in the form of a 74-line letter; the editor agreed to publish the letter if Selye omitted the word "stress," because at the time, in colloquial speech, the word had the connotation of "nervous strain." Also,

Selye was unaware that stress had been used for centuries by engineers and physicists to describe something quite different from what Selye was proposing. Hooke's Law (1658) stated that the magnitude of stress (an external force) would produce a proportional amount of strain (deformation) in a metal, depending on its degree of malleability. Therefore, "strain" would have been preferable, and Selye later complained on several occasions that, had he been aware of this, he would have gone down in history as the father of the "strain" concept. Considerable confusion was created when his research had to be translated into other languages. In 1946, when invited to explain his theories at the prestigious Collège de France, where 100 years previously, the great Claude Bernard had presented his concept of *the milieu intérieur*, the academicians responsible for maintaining the purity of the French language were unable to find a suitable word or phrase to convey Selye's concept of biologic stress. After several days of debate, they decided that a new word would have to be created and *le stress* was born, quickly followed by *el stress*, *il stress*, *lo stress*, *der stress* in other European languages, with similar neologisms in Russian, Japanese, Chinese, and Arabic. Stress is one of the few words still preserved extant in languages that do not use the Latin alphabet.

Other difficulties arose as "stress" was increasingly incorporated into vernacular speech and eventually became a popular buzzword; it was used interchangeably to refer to both physical and emotional challenges, the body's response to these stimuli, as well as to the pathological consequences of such interactions. Even Selye had difficulties when he tried to extrapolate his laboratory research to humans. In helping him to prepare his *First Annual Report on Stress* 1951, I included a critical letter that had appeared in the *British Medical Journal*. Using verbatim citations from Selye's own writings, one physician had concluded that "stress, in addition to being itself, was also the cause of itself, and the result of itself." Because it was apparent that most people viewed stress as some unpleasant threat, Selye had to create a new word, "stressor," to differentiate stimulus from response. Another problem was that all of his experiments had been conducted in laboratory animals and had focused only on the damaging effects of stress. It was apparent that stress was not always necessarily harmful for humans. Increased stress results in increased productivity—up to a certain level that differs for each of us. It is only when this level is exceeded that damage is apt to occur. Nor is stress always a synonym for something bad. Winning a race or election may be just as stressful as losing, or more so. A passionate kiss and contemplating what might follow could be described as stressful but hardly comparable to the feeling experienced during a root canal procedure. Were the physiological changes associated with "good" stress different? Could good stress negate the effects of bad stress? Selye subsequently created "eustress" to refer to good stress that might promote health.

II. THE GENERAL ADAPTATION SYNDROME AND DISEASES OF ADAPTATION

Selye viewed the initial stereotyped response to stress described in his 1936 *Nature* report as a "call to arms" of the body's defense mechanisms and referred to it as an "alarm reaction." If a state of stress persisted, a "stage of resistance" ensued, during which there was increased adaptation to the noxious stimulus. When prolonged further, resistance/adaptation became inadequate or disappeared in a third and final stage of exhaustion. He termed this three-phased response the General Adaptation Syndrome, the initial component being the alarm reaction, when adaptation had not yet been acquired, a subsequent stage of resistance, during which adaptation to the offending stimulus was maximal, and a final stage of exhaustion, when all resistance was lost.

Autopsy findings during various phases of the General Adaptation Syndrome revealed pathologic changes in the cardiovascular system, kidneys, gastrointestinal tract, soft tissues, and other structures reminiscent and often indistinguishable from those seen in patients with rheumatoid arthritis, disseminated lupus, gastrointestinal ulcers, and cardiovascular and kidney disorders. Selye reasoned that if stress could produce this type of pathology in his laboratory animals, perhaps it could contribute to these and other diseases in humans; he referred to these as "diseases of adaptation." These pathologic changes were influenced by various factors, including the nature and severity of the stressor, the duration of exposure, and prior sensitization through dietary alterations or the administration of certain steroids. He subsequently discovered how to produce consistently different disorders such as myocardial necrosis or nephrosclerosis by placing the animals on a high-sodium diet and administering desoxycorticosterone acetate (DOCA). Conversely, a high-potassium diet and strategies that conserved potassium minimized myocardial damage.

III. STRESS-RELATED DISORDERS AND MECHANISMS OF ACTION

Selye identified over two dozen different steroids in the adrenal venous effluent, but it was difficult to distinguish between those with physiologic hormonal activities and others that represented metabolites or precursors having little clinical significance. After numerous experiments, he concluded that there were three main types of adrenal cortical hormones, which he classified as glucocorticoids, mineralocorticoids, and testoids. Glucocorticoids, or "sugar hormones," produced in the zona fasciculata had a pronounced influence on carbohydrate metabolism because they promoted gluconeogenesis by breaking down protein to provide glucose. Other catabolic or antianabolic effects included lympholysis, eosinopenia, and inhibition of inflammation. Whereas these anti-inflammatory effects delayed wound healing and increased susceptibility to infection, glucocorticoids such as cortisone were later found to provide clinical benefits, especially in patients with rheumatoid arthritis. Mineralocorticoids, or "salt hormones," such as DOCA, manufactured in the zona glomerulosa, had their major effects on electrolytes by promoting the reabsorption of sodium and the excretion of potassium. The testoids, or sex steroids, also known as "protein" hormones, originated in the zona reticularis and appeared to have similar but much weaker effects than testosterone on secondary sex characteristics and protein anabolism. Selye's categorizations were somewhat deceptive because the close structural similarity of all adrenal cortical steroids resulted in overlapping effects. Glucocorticoids had some sodium retention properties and mineralocorticoids could mimic certain glucocorticoid carbohydrate responses. When 9a-halogenated and 2-methylated analogues of cortisone were subsequently synthesized, it was found that they had very potent glucocorticoid and mineralocorticoid actions. Conversely, compounds with a double bond in the 1 and 2 positions separated these effects.

In 1937, Selye tried to determine what stimulated the adrenal cortex during stress. Until the late nineteenth century, the human pituitary was thought to be a vestigial organ and no pituitary hormone had yet been isolated. After many complicated surgical interventions, he discovered that only removal of the anterior pituitary prevented the adrenal cortical response to stress. Experiments designed to elucidate the role of the pituitary showed that administering crude lyophilized anterior pituitary extract (LAP), the only hypophyseal product that was available at the time, definitely caused enlargement of the adrenal cortex. Of equal interest was the observation that LAP tended to simulate the damaging effects of DOCA with respect to the production of nephrosclerosis and myocardial damage during stress. When subsequent advances led to the isolation and purification of pituitary hormones, it became obvious that adrenocorticotropic hormone (ACTH) was not responsible for these LAP effects. On the other hand, somatotropic hormone (STH) or growth hormone could, under certain conditions, produce changes similar to those observed with DOCA and LAP. Further investigations revealed that STH could antagonize or reverse the catabolic effects of ACTH and tended to prevent the weight loss and susceptibility to infection seen following the administration of ACTH and glucocorticoids. For example, the rat's normal resistance to tuberculosis could be temporarily lost by pretreatment with ACTH but was restored when STH was administered concomitantly. ACTH clearly stimulated the production of glucocorticoids and STH augmented mineralocorticoid activities either by increasing their production or by exaggerating their effects. This suggested that there were checks and balances between ACTH and STH in the pituitary and between glucocorticoids and mineralocorticoids in the adrenal. ACTH and glucocorticoids had strong anti-inflammatory effects whereas STH and mineralocorticoids stimulated inflammatory and proliferative connective tissue responses. How these activities were influenced by emotional stress in humans or could contribute to "diseases of adaptation" was not clear.

When DOCA was used to treat patients with adrenal insufficiency due to adrenalectomy or Addison's disease, there were reports of focal areas of necrosis in the heart and skeletal muscle, evidence of periarteritis nodosa, nephrosclerosis, worsening of joint distress, and even the development of incapacitating arthritis, as had been seen in experimental animals. The tendency to develop hypertension even with very small doses of DOCA was also a frequent problem encountered during the treatment of adrenal insufficiency. DOCA is not manufactured in any appreciable amount in humans. When aldosterone, the naturally occurring human mineralocorticoid, became available, attempts to demonstrate its ability to counter the anti-inflammatory effects of cortisone or produce the pathology seen with DOCA in laboratory studies were disappointing. It seemed unlikely that aldosterone caused significant pathology in humans but subsequent evidence supports Selye's theory. Researchers have now confirmed that aldos-

terone can contribute to cardiovascular and renal pathology as well as to fibrosis and collagen formation by promoting sodium influx and hypertrophy in vascular smooth muscle cells, generation of oxygen free radicals, and stimulation of growth factors and by potentiating the pressor effects of angiotensin II.

Extrapolating the results of animal studies to humans can be hazardous. This is especially true when dealing with stress-related research. Contemporary stress is most often due to a variety of emotional challenges that can occur several times a day, rather than to the physical threats primitive man was subjected to on a sporadic basis. Although "flight or fight" responses to severe stress can occur, we are much more apt to experience other signs and symptoms that are subtler and cover a wide range of emotional and physical responses, as illustrated in Table 1.

Although there is a great deal of anecdotal evidence that stress can contribute to emotional and physical disorders, attempting to prove this by delineating the mechanisms of actions that may be involved is difficult. There are numerous confounding influences and no animal models that reflect the wide range of emotions that humans experience. The consensus of opinion is that when secreted in response to acute stress, hormones such as adrenaline and cortisol stimulate protective body defense mechanisms and help the body adapt, but when repeatedly invoked or produced in excess for sustained periods, the resultant physiologic responses become damaging. The most relevant research has focused on the cardiovascular system, showing that stress due to lack of control on the job, for example, results in hypertension and coronary heart disease. Other factors, such as social instability, can also cause changes in clotting factors that contribute to heart attacks and strokes. One report has revealed that the 40% spike in mortality rates seen in Russian men following the fall of communism was largely due to cardiovascular disease.

Chronic stress has been shown to reduce immune system resistance to the common cold and has been implicated in other viral-linked disorders, ranging from herpes and autoimmune disease syndrome (AIDS) to certain malignancies. Repeated and/or long-term stress can also affect how we age, especially with respect to neuronal brain damage. Memory loss for recent events, one of the hallmarks of aging, is due to progressive atrophy of the hippocampus, which is responsible for memory retrieval and learning. As the old adage goes, "You can't teach an old dog new tricks." Stress hormones such as cortisol cause the same type of hippocampal shrinkage seen in the elderly. Studies show that patients suffering from depression or posttraumatic stress disorder often

TABLE 1 Common Signs and Symptoms of Stress

1. Frequent headaches, jaw clenching, or pain
2. Gritting and grinding teeth
3. Stuttering or stammering
4. Tremors; trembling of lips or hands
5. Neck ache, back pain, or muscle spasms
6. Light headedness, faintness, or dizziness
7. Ringing, buzzing or "popping" sounds
8. Frequent blushing or sweating
9. Cold or sweaty hands or feet
10. Dry mouth or problems swallowing
11. Frequent colds, infections, or herpes sores
12. Rashes, itching, hives, or "goose bumps"
13. Unexplained or frequent "allergy" attacks
14. Heartburn, stomach pain, or nausea
15. Excess belching or flatulence
16. Constipation, diarrhea, or loss of bowel control
17. Difficulty breathing or frequent sighing
18. Sudden attacks of life-threatening panic
19. Chest pain, palpitations, or rapid pulse
20. Frequent urination
21. Diminished sexual desire or performance
22. Excess anxiety, worry, guilt, or nervousness
23. Increased anger, frustration, or hostility
24. Depression or frequent or wild mood swings
25. Increased or decreased appetite
26. Insomnia, nightmares, or disturbing dreams
27. Difficulty concentrating; racing thoughts
28. Trouble learning new information
29. Forgetfulness, disorganization, or confusion
30. Difficulty in making decisions
31. Feeling overloaded or overwhelmed
32. Frequent crying spells or suicidal thoughts
33. Feelings of loneliness or worthlessness
34. Little interest in appearance or punctuality
35. Nervous habits; fidgething or feet tapping
36. Increased frustration, irritability, or edginess
37. Overreaction to petty annoyances
38. Increased number of minor accidents
39. Obsessive or compulsive behavior
40. Reduced work efficiency or productivity
41. Lies or excuses to cover up poor work
42. Rapid or mumbled speech
43. Excessive defensiveness or suspiciousness
44. Problems in communication or sharing
45. Social withdrawal and isolation
46. Constant tiredness, weakness, or fatigue
47. Frequent use of over-the-counter drugs
48. Weight gain or loss without dietary changes
49. Increased smoking, alcohol, or drug use
50. Excessive gambling or impulse buying

complain of memory loss for recent events and difficulties in learning and concentration that correlate with increased cortisol levels. An increase in blood sugar, insulin, and cholesterol levels and a decrease in bone density and muscle mass have also been linked to chronic stress. These and other adverse effects can be aggravated by poor lifestyle habits, such as alcohol, drug, and tobacco abuse, faulty diet, and lack of exercise, all of which are also often stress related.

To test the hypothesis that allostatic load reflected the effects of stress on the body and contributed to disease, a group of healthy elderly people were studied; their blood pressure, blood glucose, and cholesterol levels were correlated with cortisol measurements. Follow-up 3 years later confirmed that those with the highest allostatic loads were the ones most apt to develop newly diagnosed cardiovascular disease and were significantly more likely to show declines in mental as well as physical functioning.

Advances in our understanding of how the body responds to stress or to any attempt to change the status quo have always depended on the information available about biochemical and physiologic functions. Although Claude Bernard first described the existence of endocrine glands, he had scant knowledge of their activities. Walter Cannon knew little about the functions of the adrenal cortex, nor was Hans Selye aware of the host of neurotransmitters (such as endorphins, dopamine, and serotonin) that play an important part in the response to stress. The endorphins, which have powerful effects on mood and pain perception, are secreted simultaneously with ACTH in amounts that are proportional to the magnitude of the stressful stimulus. Measurements following the removal of the pituitary or adrenal, or following the administration of dexamethasone, confirm that the production and release of endorphins are regulated by the same adrenal steroid feedback mechanisms that control the secretion of ACTH, the premier stress hormone.

There are far more questions than answers about how the body responds to stress or how emotions can contribute to disease. As René Dubos noted, "what happens in the mind of man is always reflected in the diseases of his body." Selye's proposal that stress-related hormones caused different diseases was criticized as being simplistic because the available data supported other interpretations, such as a "permissive" or "conditioning" role. It was pointed out that interactions between stress and the adrenal could include the following effects:

- Nonspecific effects due to overproduction of corticoids.
- Nonspecific effects due to decreased elimination of corticoids.
- Nonspecific effects due to conditioning of the target by corticoids, causing increased sensitivity.
- Nonspecific effects due to the stressor, but requiring the presence of corticoids to maintain tissue reactivity.
- Specific effects due to the stressor, and not influenced by adrenal factors.
- Specific effects due to the stressor, and requiring adrenal activity.
- Any combination of the above.

The stress saga is far from over. Many of Selye's theories may be incorrect or incomplete based on subsequent observations. However, as he often reminded me, "Theories don't have to be correct, only facts do. Some theories are valuable for their heuristic merit, in that they encourage others to discover new facts that lead to better theories." Selye's concepts of stress and its effects on health are a good example of this and are likely to be his greatest legacy.

Glossary

alarm reaction First stage of the General Adaptation Syndrome in which gastric ulcerations, adrenal hypertrophy, and shrinkage of the thymus and lymphatic tissues are consistently seen within 48 h following exposure to noxious stimuli.

desoxycorticosterone acetate Adrenal cortical steroid with predominant effects on electrolytes such as sodium and potassium.

diseases of adaptation Maladies observed during the course of the General Adaptation Syndrome in experimental animals; Selye believed the maladies were the counterpart of diseases in humans with similar pathologic changes.

eustress Selye's term for "good" stress that promotes health.

General Adaptation Syndrome Selye's term for the manifestations of stress in the whole body following prolonged stress exposure; the syndrome develops over time in three phases: the alarm reaction, the stage of resistance, and the stage of exhaustion.

homeostasis Walter Cannon's term for the body's tendency to maintain physiological stability in response to influences that threaten to disturb the steady state.

milieu intérieur Claude Bernard's term for the internal environment of the body, or the "soil" in which all biologic reactions occur.

stage of exhaustion Third and final stage of the General Adaptation Syndrome, during which the ability to adapt to stress is exhausted and death often ensues.

stage of resistance Second stage of the General Adaptation Syndrome, during which the body's resistance to stress is maximized.

stressor Selye's term for any stimulus that produces a state of stress.

Stress and Reproduction

JUDY L. CAMERON

Oregon National Primate Research Center, Oregon Health and Science University

Many forms of stress, including energetic stresses (e.g., undernutrition, exercise, temperature stress, and lactation), stresses associated with injury and illness (e.g., pain and infection), and psychosocial stresses (e.g., fear, anxiety, and discomfort), can lead to a suppression of reproductive hormone secretion and, if sustained, a suppression of fertility. Exposure to stress in the adolescent period can delay the onset of puberty. Stress-induced reproductive dysfunction can occur in both females and males.

I. INTRODUCTION

All forms of stress act primarily at the level of the central nervous system (CNS) to lead to a suppression of the activity of the hypothalamic neurons that provide the central neural drive to the reproductive axis [i.e., gonadotropin-releasing hormone (GnRH) neurons]. Not all stresses cause a suppression of reproductive axis activity in all animals. Multiple factors, including dominance rank, magnitude of the stress, perception of the stress, aggressiveness of the animal, and level of activity of the reproductive axis prior to stress exposure, play important roles in modulating the response of the reproductive axis to both acute and chronic stresses. The neural mechanisms by which stress signals modulate the function of GnRH neurons are in the early stages of being mapped. Although some neural systems, such as the hypothalamic–pituitary–adrenal axis, are activated by many stresses, they do not play a causal role in all forms of stress-induced reproductive dysfunction.

II. REPRODUCTIVE CONSEQUENCES OF STRESS

Stress exposure can be acute, chronic, or intermittent and vary from mild to severe. The reproductive consequences of stress exposure depend on both the severity of the stress and the duration of the stress. Individual differences in stress sensitivity also play an important role in determining the outcome of stress exposure. In females, mild or acute forms of stress can lead to a suppression of circulating gonadotropin secretion, which in turn can lead to a lengthening of the menstrual cycle (primarily due to a lengthening of the follicular phase due to slow follicular development), a suppression of ovulation, or impaired luteal function (characterized by low progesterone secretion and in more severe cases a shortening of the luteal phase). Exposure to more severe or chronic forms of stress can result in impaired ovarian cyclicity with the occurrence of irregular menstrual cycles (oligomenorrhea) or the complete loss of menstrual cyclicity (amenorrhea). As ovarian steroid production is decreased, there is also a decline in secondary sexual

characteristics, including breast size and amount of subcutaneous fat. In males, stress-induced reproductive impairment is characterized by a decrease in testosterone secretion and thus a loss of libido and a decrease in spermatogenesis and hormonal support for secondary sexual characteristics. Chronic stress occurring during the process of pubertal development can impair the progression of puberty, leading in some cases to a very marked delay in the pubertal development of reproductive capacity and the accompanying development of secondary sexual characteristics.

The primary site of stress-induced disruption of the reproductive axis appears to be at the level of the GnRH neurons, which provide the central neural drive to the reproductive axis (Fig. 1). Using animal models of various stresses, it has been shown for at least some stresses that GnRH secretion is impaired. However, more typically, it is inferred that GnRH secretion is impaired by measuring a suppression in pituitary gonadotropin secretion. This conclusion is further supported by the finding that in all conditions of stress-induced reproductive dysfunction studied to date, administration of exogenous GnRH can stimulate the function of the reproductive axis, indicating that stress is not acting to directly suppress pituitary or gonadal activity. In some forms of acute stress, a fall in gonadotropin secretion can be noted within minutes to hours. With more subtle stresses, impairment of gonadotropin secretion is generally noted when the stress is present on a chronic basis.

III. MULTIPLE FORMS OF STRESS

A. Energetic Stresses

1. Undernutrition

Much of what is known about mechanisms by which nutritional status modulates the activity of the reproductive axis comes from the clinical study of patients with the psychiatric disorder anorexia nervosa. This syndrome involves an obsessive fear of being fat and leads to a profound decrease in food intake and extreme weight loss that can become life-threatening. Nearly all women who develop anorexia nervosa show a loss of ovarian cyclicity and amenorrhea. Gonadotropin secretion during the weight loss phase of anorexia nervosa is very low and often nonpulsatile in nature or pulsatile only during the nighttime period, as it is in the early pubertal period. Anorexia can often start in the teenage years, and if it starts prior to menarche, it can delay menarche for many years, holding the girl in a prepubertal state long beyond the normal time of puberty. This delay in activation of adult-like gonadotropin secretion and ovarian function is accompanied by minimal secretion of the ovarian steroid hormones, and thus development of secondary sexual characteristics is delayed. Such a prolongation of childhood and maintenance of a girlish body habitus can be advantageous in certain sports, such as ballet, and the prevalence of anorexia in girls participating rigorously in such sports is much higher than in the normal population. Although over 90% of anorexic patients are female, the incidence of this disease is increasing in males, and they too show a profound suppression of reproductive hormone secretion and a loss of fertility and sexual function when low body weight is sustained.

A number of studies with experimental animals show that brief periods of severe undernutrition (such as fasting) can also lead to a suppression of reproductive hormone secretion. In addition, decreased reproductive hormone secretion has been documented in humans after several days of fasting. However, in general, fertility would not be expected to be compromised by brief periods of undernutrition because sperm production and development of oocytes take place over a prolonged period (weeks to months). There is evidence in rodents that acute undernutrition in the late follicular phase can block ovulation, but this has not been demonstrated in larger species.

The relationship between chronic mild-to-moderate undernutrition and activity of the reproductive axis is more controversial. There is generally little animal research addressing this question, probably because maintaining animals on diets for a prolonged period of time would be a rather inefficient method of determining the mechanisms by which energy availability modulates reproductive function, in terms of both time and money. Livestock that are maintained with suboptimal nutritional support have compromised fertility, but again, most of the experimental work examining the mechanisms by which nutrition impairs fertility in these species has utilized rather severe forms of undernutrition. In human populations in which mild to moderate undernutrition is relatively common, minimal impact on adult fertility has been reported. However, there are stronger correlations between moderate nutritional compromise and later timing of puberty onset, as well as poorer pregnancy outcome. Overall, it would appear that although prolonged periods of mild to moderate undernutrition do have some impact on function of the reproductive axis and fertility, the impact is relatively weak compared to either acute or chronic forms of severe undernutrition.

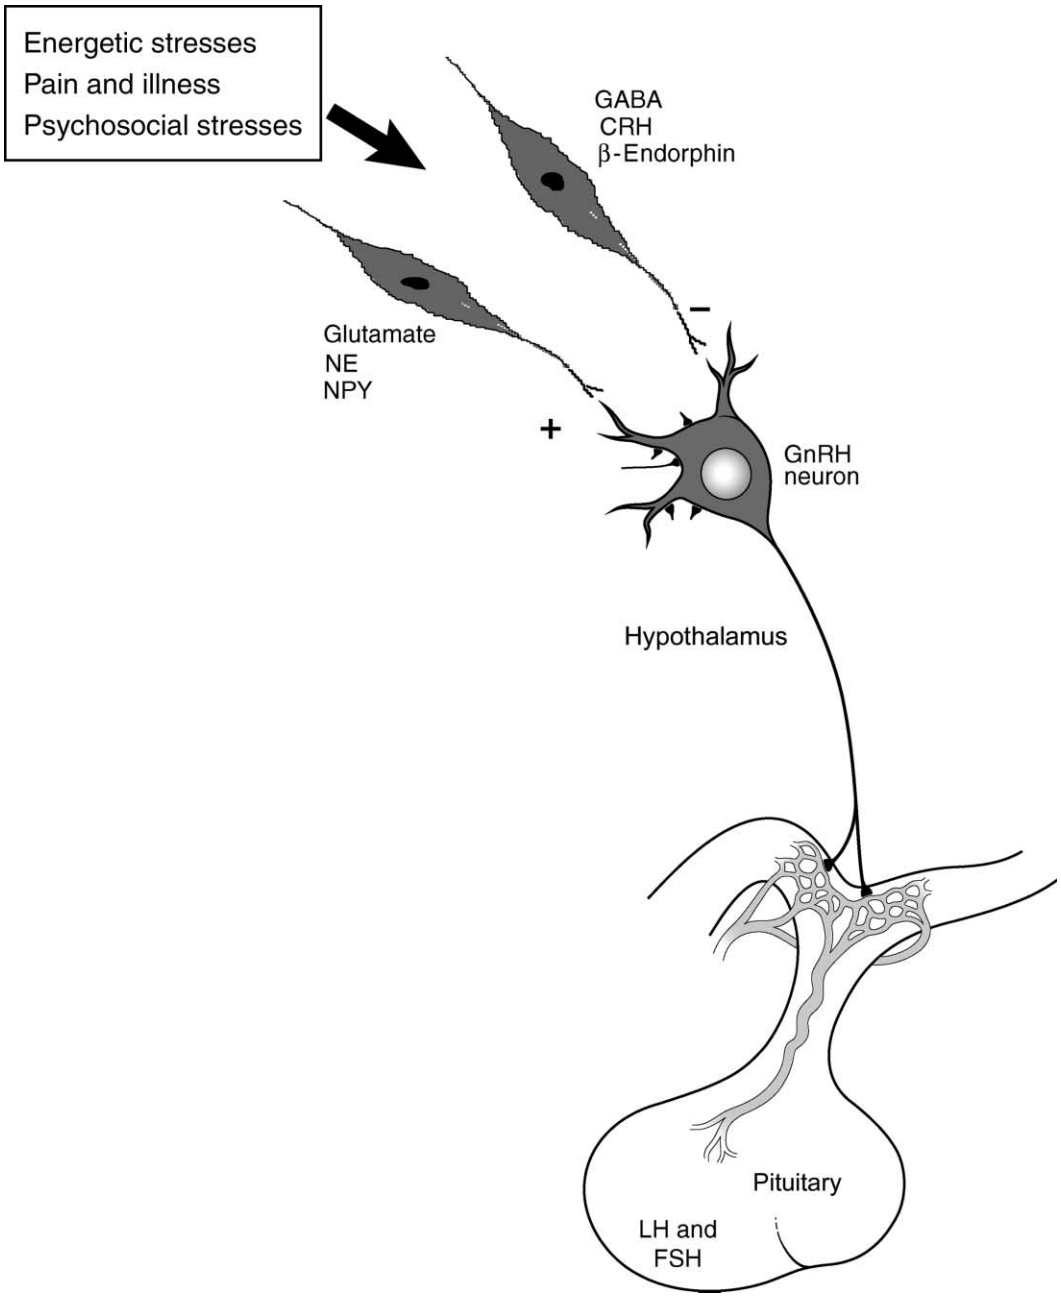

FIGURE 1 Schematic diagram showing that stresses act to suppress the activity of the reproductive axis by affecting neural systems that modulate the activity of hypothalamic GnRH-containing neurons.

2. Exercise

Women participating in vigorous exercise training programs have an increased incidence of menstrual disorders. These range from irregular cyclicity to a complete loss of menstrual cycles for prolonged periods of time. The more marked forms of exercise-induced reproductive dysfunction are associated with low circulating levels of luteinizing hormone (LH), follicle-stimulating hormone, and estrogen. If exercise regimens are very heavy in the adolescent years, individuals can experience a delay in puberty, which can be quite extensive in length. Exercise-induced reproductive dysfunction can be very rapidly reversed by a brief hiatus in the exercise regimen, as often occurs in athletes when they experience an injury or take a vacation. Exercise-induced reproduc-

tive dysfunction can also be rapidly reversed by increasing food intake, indicating that the mechanism by which exercise impairs reproductive function involves decreases in energy availability. Moreover, reproductive dysfunction in athletic women is often associated with the presence or history of eating disorders or an abnormal preoccupation with weight and diet. Exercise-induced reproductive dysfunction is more prevalent in females participating in sports where emphasis is put on a lean body image, such as ballet, compared to sports where increased body mass in encouraged. Exercise-induced reproductive dysfunction is less commonly reported in men, perhaps in part because of the lower emphasis on leanness and in part because changes in reproductive hormones in men are less readily detected compared to loss of menstrual cycles in women.

3. Lactation

Energetic stress occurring during lactation is also an important regulator of fertility and has the potential to profoundly suppress the activity of the reproductive axis. Suppression of the hypothalamic–pituitary–gonadal axis stems both from the energetic drain associated with milk production and from other neuroendocrine signals that occur with lactation, including increased prolactin and oxytocin release. As with other energetic stresses, the degree of reproductive suppression is directly related to the energy stress; thus, in animals there is good evidence that nursing a greater number of offspring has more of a suppressive effect on reproductive function than nursing one or two offspring. In humans, provision of breast milk as the sole source of nutrition for an infant, with no bottle supplementation, generally leads to a longer period of postpartum amenorrhea. Other important variables that play a role in determining the effects of lactation on reproduction include the frequency of nursing and the amount of food available to the mother.

4. Pain, Illness, and Immunological Stresses

Chronic illness and exposure to pain, such as in patients with fibromyalgia, can be associated with an increased incidence of reproductive dysfunction. Inflammation and other conditions associated with activation of the immune system can also lead to a suppression of reproductive function, particularly when CNS levels of cytokines are elevated. Much of the experimental work examining the interactions between immune activation and the activity of the reproductive axis has utilized acute administration of endotoxin. This inflammatory-like stress is accompanied by a suppression of LH secretion, a delay in folliculogenesis, and decreases in luteal function. However, the response of the reproductive axis is influenced by the endocrine environment at the time of the inflammatory challenge. For example, an elevation in CNS interleukin-1α levels can rapidly suppress LH secretion in nonhuman primates when estrogen levels are low, but leads to an elevation of LH secretion in the presence of significant estrogen concentrations.

5. Psychosocial Stress

The effects of behaviorally induced stresses, that is, psychological and social stresses involving elicitation of anxiety, fear, and discomfort, on reproductive function have been studied extensively in animal models. Both restraint stress and the expectation of mild footshock (as a conditioned stimulus) can lead to rapid suppression of reproductive hormone secretion in rodent models. In human populations, it has been more difficult to selectively study the impact of psychosocial stress on reproductive function because these stresses rarely occur in isolation from other stresses or in a timely fashion so that they can be easily studied. One of the best characterized forms of psychosocial stress-induced reproductive dysfunction comes from studies of women who present to infertility clinics with functional hypothalamic amenorrhea (FHA). By definition FHA is a state of subfertility that is not associated with substantial undernutrition or exercise, does not involve lactation, and is not associated with any organic or structural causes of decreased fertility. Studies of women with FHA show that they experience more psychological stress than other women, although they do not experience more stressful life events, but rather react more profoundly to the stressful events they do experience. They also show increased activation of physiological systems that respond to stress, including increased activation of the hypothalamic–pituitary–adrenal axis. Treatment of these patients with cognitive behavior therapy or with drugs that reduce the activity of some central neural systems that are activated by stress can restore fertility, although not in all cases. For example, both opiate antagonists and metaclopromide, a dopamine agonist, have been shown to stimulate reproductive hormone secretion and restore menstrual cyclicity in some, but not all women with FHA.

Although the majority of studies examining the effects of psychosocial stress on reproduction have documented stress-induced suppression of reproductive function, there are a handful of human studies

that have reported that girls who have grown up under conditions of family stress, such as in homes where the father is absent, in homes where there has been family conflict, or in homes where the parents have divorced, enter puberty at a significantly earlier age. However, mechanisms by which such stress exposure would advance the onset of puberty have not been established. Moreover, there is the possibility that early stress exposure does not cause advancement of puberty, but rather, that the likelihood of early puberty and exposure to early life family stresses may simply be correlated because they are both influenced by a common factor(s). For example, one of the factors governing the age of menarche in a girl is the age of her mother at menarche. Thus, it is possible that mothers who experienced early menarche are more likely to have family conflict or divorce when their children are young and to have daughters who exhibit early menarche.

A more detailed understanding of how psychosocial stress can impact on reproduction comes from animal studies, with investigations in nonhuman primates having particular relevance to understanding this human condition. Nonhuman primates live in complex social groups and have higher cortical brain areas similar to those of humans; moreover, the anatomical and functional organization of their reproductive axis is very similar to that of humans. A number of studies have shown that acute stresses (i.e., restraint, receipt of aggressive attacks, and placement in an unfamiliar social situation) can rapidly suppress reproductive hormone secretion in a variety of nonhuman primates. However, not all acute stresses have this effect, particularly those that are associated with less direct threat to the individual. Thus, the perception of severity of stress appears to be an important factor in determining whether a stress will lead to a suppression of reproductive hormone secretion. Chronic exposure to social stresses (such as troop reorganization or being placed in a new social environment) can lead to a marked and sustained suppression of reproductive hormone secretion. However, not all individuals respond to chronic stresses with suppressed reproductive function. Studies have shown a high degree of correlation between aggressiveness and testosterone titers, with the more aggressive males showing higher circulating levels of testosterone. Dominance rank, particularly in times of social instability, is also often correlated with circulating testosterone levels in males. It has also been hypothesized that social status (i.e., dominance rank) plays an important role in determining lifetime reproductive success in primates, with subordinate animals experiencing a greater degree of social stress and having a lesser degree of reproductive success. However, the support for this hypothesis is not uniform and this remains a controversial notion. It would appear that multiple factors, including dominance rank, magnitude of stress, perception of the stress, aggressiveness of the animal, and level of activity of the reproductive axis prior to stress exposure, can play important roles in modulating the response of the reproductive axis to both acute and chronic stresses (Fig. 2).

IV. MECHANISMS OF STRESS ACTION

There are two general ways in which stress exposure is thought to be able to suppress GnRH neuronal activity, by increasing the activity of neural systems that are inhibitory to GnRH neurons or decreasing the activity of neural systems that are stimulatory to GnRH neurons (Fig. 1). To date, most attention has been focused on the activation of inhibitory systems; however, the complete neural mechanisms by which stress modulates the reproductive axis for any of the stresses discussed in this article are far from being understood. The mechanisms by which various forms

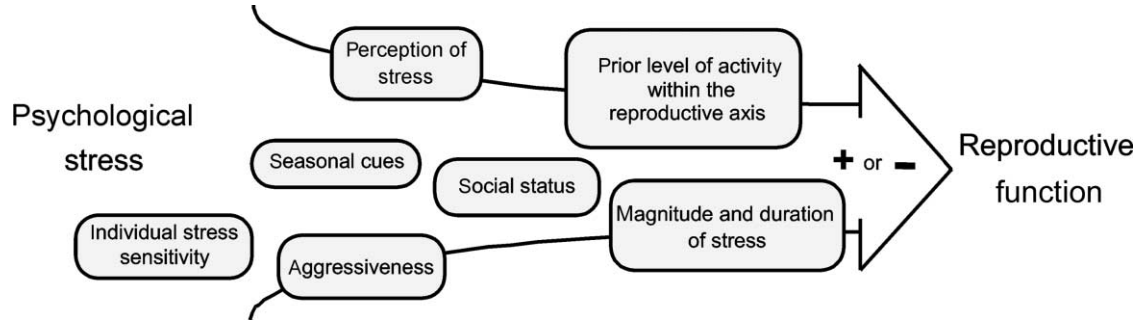

FIGURE 2 Schematic diagram showing modulatory factors that play an important role in determining whether stress exposure will lead to reproductive dysfunction within an individual.

of stress impair reproductive axis activity appear to have some common elements, but there also appear to be mechanisms that are specific to each type of stress. For example, many forms of stress can activate the hypothalamic–pituitary–adrenal axis, and experimental studies have shown that CRH can suppress the activity of GnRH neurons and that several forms of stress-induced impairment of reproductive function can be reversed by administering an antibody to CRH (i.e., footshock stress and inflammatory stresses). However, transgenic mice without expression of the CRH gene still show stress-induced suppression of reproductive hormone secretion in response to restraint stress and undernutrition. Thus, the activation of a particular neural system in response to stress does not necessarily indicate a causal role for that neurotransmitter in the etiology of stress-induced reproductive dysfunction. For many forms of stress, neural systems that are activated and inhibited are beginning to be mapped, but the role of these systems in mediating the suppression of GnRH neuronal activity, and how information regarding various modulatory factors (e.g., dominance status, perception of stress, and aggressiveness) interacts with these systems, awaits future research.

Glossary

amenorrhea A loss of ovarian cyclicity.
corticotropin-releasing hormone The hypothalamic neuropeptide that stimulates pituitary production and secretion of adrenocorticotropin, a hormone that regulates adrenal function.
functional hypothalamic amenorrhea A clinical state of subfertility in women resulting from stress exposure.
gonadotropin-releasing hormone The hypothalamic neuropeptide that stimulates pituitary production and secretion of gonadotropins.
gonadotropins Luteinizing hormone and follicle-stimulating hormone; hormones produced by the anterior pituitary gland that regulate ovarian and testicular function.
menarche The time of first menstrual bleeding.
stress An internal or external stimulus that causes a physiological challenge or evokes a state of anxiety.

Systemins

Clarence A. Ryan and Gregory Pearce
Washington State University

Systemin is an 18-amino-acid polypeptide hormone that is released in *Solanaceae* species from sites where there is tissue damage. Systemin activates genes throughout plant tissues for defense against predators and pathogens. The wound hormone is cleaved from a 200-amino-acid precursor called prosystemin that is synthesized in vascular bundle cells.

I. INTRODUCTION

Polypeptide hormones are common regulators of numerous physiological processes in eukaryotes. In 1922, the first polypeptide hormone discovered, insulin, was initially identified in the pancreatic secretions of dogs. Following the discovery of insulin, hundreds of polypeptide hormones that regulate a wide variety of physiological processes were isolated and characterized.

Polypeptide hormones in animals are nearly always produced as precursors that are proteolytically processed to their active forms. Many of the polypeptide hormones are derived from precursors that contain one copy of the hormone, but in many cases, the precursor contains more than one copy, and in other cases more than one type of hormone is produced from a single precursor.

Before 1991, polypeptides were not recognized as signaling molecules in plants; small organic molecules were thought to regulate the numerous physiological processes that govern growth and development. Evidence that supported a role for polypeptides as signaling molecules was not obvious. In 1991, an 18-amino-acid polypeptide called systemin was isolated and was found to regulate the expression of defensive genes in tomato leaves in response to insect attacks or severe mechanical wounding. Since then, five families and subfamilies of polypeptide signals that fulfill the definition of hormones have been identified in plants as regulators of various processes of defense and development.

II. TOMATO SYSTEMIN

Systemin, like animal polypeptide hormones, is derived proteolytically from the C-terminal region of a 200-amino-acid precursor protein called prosystemin (Fig. 1). The systemin precursor does not exhibit a signal sequence at its N-terminus, is not glycosylated or posttranslationally modified, is found in the cytoplasm, and is not known to be associated with any organelles. Alanine substitutions at each amino acid residue in systemin have variable effects on activity, with only a substitution of Thr to Ala at

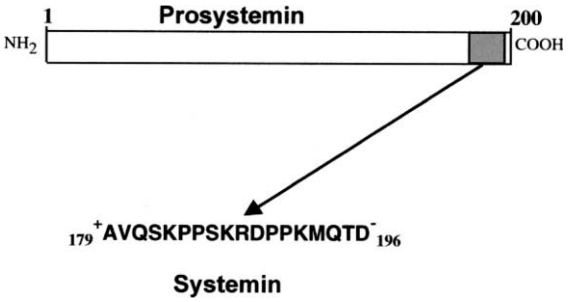

FIGURE 1 The location of the systemin sequence within its precursor, prosystemin.

position 17 totally eliminating activity. This analogue is a powerful antagonist of native systemin. Removal of the C-terminal Asp totally abolishes activity, and it too is a potent antagonist of native systemin. The N-terminal 14 amino acids are likely involved in receptor binding, whereas the C-terminal sequence [MQTD (using the one-letter amino acid code): M, methionine; Q, glutamine; T, threonine; and D, aspartic acid] appears to have a direct role in signaling.

The tertiary structure of systemin in solution has been analyzed by nuclear magnetic resonance (NMR) and circular dichroism spectroscopy; systemin exists as a mixture of random coils with β-sheet and β-turn motifs. The most interesting features of the systemin sequence are the prolines, at positions 6, 7, 12, and 13, which suggests that a poly(l-proline) II 3_1 helix secondary structure is present in the central region of the polypeptide. The polyproline II 3_1 helix may provide a signature kink in the systemin structure that is likely important to its recognition by the systemin receptor.

Prosystemin, generated in *Escherichia coli* or in a baculovirus/insect cell system, has been found to be as active as systemin. It has not been determined whether the intact prosystemin protein is active without being processed, or whether it is processed after being supplied to the plants. A prosystemin lacking the systemin sequence is totally inactive when supplied to excised tomato plants, indicating that the systemin sequence must be present for signaling to occur.

III. TOMATO SYSTEMIN HOMOLOGUES

Homologues of tomato prosystemin genes are found in other Solanaceae species, including potato, black nightshade, and bell pepper. The homologues are highly conserved among the species, with identities ranging from 73–88% and each encoding a systemin sequence that contains at most two to three amino acid replacements compared to tomato systemin

Tomato	AVQSKPPSKRDPPKMQTD
Potato-1	AVHSTPPSKRDPPKMQTD
Potato-2	AAHSTPPSKRDPPKMQTD
Nightshade	AVRSTPPPKRDPPKMQTD
Pepper	AVHSTPPSKRPPPKMQTD

FIGURE 2 Amino acid sequences of systemins from potato, nightshade, and pepper, compared to the sequence of tomato systemin. Conserved amino acids are in bold type.

(Fig. 2). No substitutions have been found among the seven residues at the C-terminus, and all prolines are conserved. Each systemin actively induces defense genes in tomato plants, with the exception that the nightshade systemin is about 10-fold less effective than the others.

IV. TOBACCO SYSTEMIN

A homologue of the tomato prosystemin gene has not been found in tobacco, a more distant relative of the tomato than nightshade, pepper, and potato. Additionally, tomato systemin does not induce defense gene expression in leaves of tobacco plants. A search for tobacco systemin in leaves of tobacco plants has resulted in the isolation of two tobacco 18-amino-acid hydroxyproline-rich, glycosylated polypeptides that are structurally dissimilar from tomato systemin, but that possess a strong defense gene induction in tobacco plants. All of the plant-derived polypeptides that activate defense genes are included under the general name of systemins. The two tobacco systemins, called Tob Sys I and Tob Sys II, are produced from a single gene that encodes a 150-amino-acid polyprotein precursor from which both systemins are processed, one systemin from the N-terminal region and one from the C-terminal region (Fig. 3).

Tobacco prosystemin bears no homology to tomato systemin, but the central regions of both of the tobacco systemins contain hydroxyproline-rich regions, which are similar to the proline-rich regions found in tomato systemin. These regions would likewise cause a kinking of the secondary structure and, like tomato systemin, are likely to be important in recognition of the polypeptides by their respective receptors.

V. MODE OF ACTION

A synthetic ^{14}C-labeled tomato systemin derivative has been shown to be mobile when applied to wounds, and its movement in the phloem correlates with the movement of the systemic signal that is produced in response to wounding. Prosystemin synthesis is localized in the vascular bundles of the plants, and systemin signaling may be amplified in parenchyma cells as it moves through the phloem. This scenario is temporally compatible with the known rate of movement of the wound signal from a severe wound site to cells throughout the plants.

The functional role of systemin has been demonstrated by transforming tomato plants with an antisense prosystemin gene, driven by the constitutive 35S promoter. The transgenic antisense plants exhibit a severely reduced systemic induction of defense genes in response to wounding and are rapidly consumed by *Manduca sexta* larvae. However, supplying the plants with systemin through their cut stems results in a normal response. Additionally, tomato plants that are transformed with prosystemin cDNA in the sense orientation, driven by the 35S promoter, act as if they are in a permanently wounded state, synthesizing defense proteins constitutively. This phenotype is apparently caused by expression of the gene in cells in which it is not normally expressed, resulting in the release of systemin at a low but constitutive level, causing the plants to behave as if they are under attack by chewing insects. Grafting wild-type tomato scions to rootstocks overexpressing prosystemin also causes the wild-type scions to accumulate defense proteins as if they are wounded. This appears to be the result of the constitutive release of systemin in the rootstock. Wild-type plants grafted onto wild-type rootstocks do not exhibit this response. These experiments support the role of systemin as a mobile signal.

Systemin interacts with a 160-kDa membrane-bound receptor with a K_D of about 10^{-13} M and initiates a signal transduction cascade that activates over 20 defensive genes that help protect the plant from insect and pathogen attacks.

Two sets of genes are activated in response to wounding and systemin—signal pathway genes and defensive genes directly involved in deterring predators. Signal pathway genes are activated within 1–4 h after wounding and include the prosystemin gene and genes that code for some members of the octadecanoid pathway. The octadecanoid pathway is part of the signaling pathway that leads to synthesis of jasmonic acid, a second messenger for up-regulating the pathway as well as for signaling downstream activation of the defense response. The defensive genes are activated at about 4–8 h after wounding and they code for several proteinase inhibitor proteins that have specificities against all four classes of proteolytic

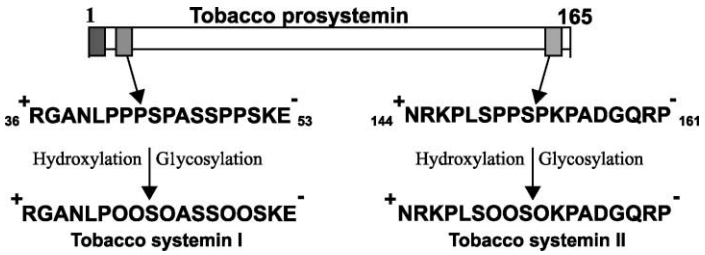

FIGURE 3 The origin of Tob Sys I and Tob Sys II from a common precursor. The precursor consists of 165 amino acids that contain a 16-amino-acid signal sequence (in black) that is lost during processing through the secretory pathway. Within the secretory pathway, the prolines are modified to hydroxyprolines and carbohydrate units are attached. The specific hydroxyprolines that are glycosylated have not been identified.

enzymes, and also for polyphenol oxidase. The proteinase inhibitor proteins can inhibit proteolytic digestive enzymes of attacking organisms, whereas the polyphenolase cross-links proteins in the digestive tracts of the predators, reducing the nutritional value of the proteins. The overall effect of the defense response is to facilitate systemic signaling and to reduce the ability of the predators to obtain nutrition from plant proteins, resulting in protein starvation.

VI. SUMMARY

Homologues of tomato systemin with a high percentage of amino acid similarities are found in potato, black nightshade, and pepper. Systemins have also been found in tobacco but are structurally different than tomato systemin and are cleaved from a polyprotein precursor. However, all systemins contain a central motif containing prolines or hydroxyprolines; this motif is likely involved in providing a structure that is recognized by cellular receptors. Although systemins have been isolated only from Solanaceae species, systemic signaling for defense is known to occur in over 100 plant families in which systemins may also play a hormonal role in signaling.

Glossary

octadecanoid pathway Signaling pathway in many plants; regulates a variety of cell-specific responses and is initiated by release of linolenic acid from membranes, in response to specific signals. Free linolenic acid is converted to jasmonic acid, a second messenger that activates genes, via several enzymes that cumulatively comprise this pathway.

polypeptide hormones Found ubiquitously in animals as two major classes: those synthesized in the endoplasmic reticulum, processed through the secretory pathway, stored in vesicles, and released in response to an appropriate signal, and those synthesized in the secretory pathway, anchored to membranes with the hormone domain in the extracellular space, and released by proteolysis in response to an appropriate signal. Polypeptide hormones have been identified only recently in plants, and their mode of synthesis, storage, and release is poorly understood.

prohormone Precursor of an active hormone.

prohormone processing enzyme Enzyme that processes polypeptide prohormones to their active form.

prosystemin Precursor of a systemin.

systemins Polypeptide plant hormones that are released following attack (wounding) by insects and pathogens; regulate activation of defense-related genes.

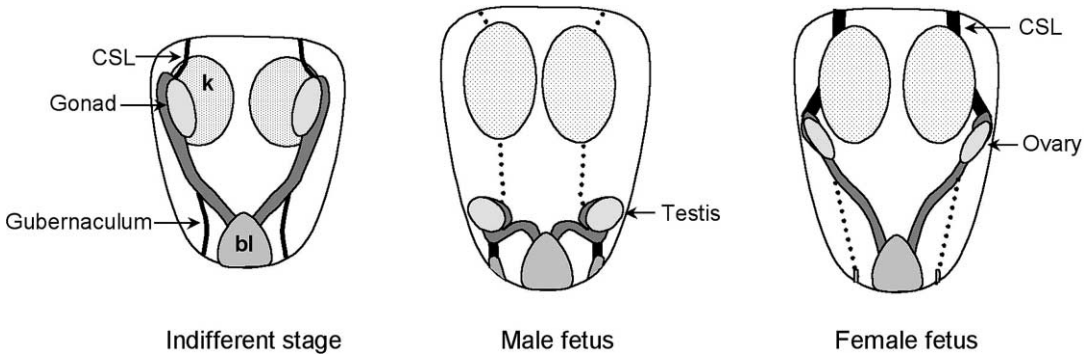

FIGURE 1 Sexually dimorphic development of the cranial suspensory ligament (CSL) and the gubernaculum. At the undifferentiated stage, before gonadal sex determination and differentiation have started, each gonad is located next to a kidney (k). The gonad and its associated duct system are attached to the abdominal body wall by two ligaments: the cranial suspensory ligament (CSL) and the gubernaculum. In the male fetus, the first phase of testis descent results the testis being positioned lateral to the bladder (bl), connected to the inguinal region via a developing gubernaculum; development of the CSL is lacking. In the female fetus, the ovary is found in a position lateral to the kidney, attached to a well-developed CSL; there is no further development of the gubernaculum. Based on Emmen, J. M., McLuskey, A., Adham, I. M., Engel, W., Grootegoed, J. A., and Brinkman, A. O. (2000). Hormonal control of gubernaculum development during testis descent: Gubernaculum outgrowth in vitro requires both insulin-like factor 3 and androgen. *Endocrinology* **141**, 4720–4727. Copyright owner, The Endocrine Society.

are related to, and include, transforming growth factor-β. The term hormone in the name AMH refers to its signaling role, rather than giving information about its position in the context of the endocrine and growth factor classification system. The action of AMH is mediated by a multimeric complex containing two related serine/threonine kinase receptors, a type I receptor and a type II receptor. The type II receptor for AMH (AMHR-II) has been identified, whereas ALK2 and ALK6 (BMPR-1B) are considered as candidate AMH type I receptors.

AMH is the first hormonal factor known to be produced by the testis, in the precursor Sertoli cells following embryonic testis determination. Later in life, these cells will develop into mature Sertoli cells, providing support to the germ cells during spermatogenesis. In addition to being the first testicular secreted hormonal factor, another hallmark of AMH production involves its testis specificity. The *AMH* gene is silent in embryonic ovaries and is also not transcribed in any other tissue.

B. AMH Action

Much is known about the role of AMH in embryonic/fetal sex differentiation. Evidence from studies on both humans and laboratory animals shows that AMH induces the regression of the Müllerian ducts in the male embryo. In the female, the Müllerian ducts develop into oviducts and uterus (and also the upper part of the vagina). Male *AMH* and *AMHRII* knockout mice, which are deficient for either AMH or AMHRII, retain Müllerian ducts that will develop. Also, female transgenic mice expressing AMH during fetal life lack oviducts and a uterus. There exists a rare syndrome in humans, called persistent Müllerian duct syndrome (PMDS), in which 46,XY individuals have Müllerian duct derivatives. PMDS in humans has been associated with mutations in either the *AMH* gene or the *AMHRII* gene. Patients with PMDS often have undescended testes. Additional research demonstrated that boys born with undescended testes often show a relatively low AMH level. Taken together, the available evidence indicates that incomplete regression of the Müllerian duct system in boys can lead to impairment of testis descent. However, this impairment is caused mainly by mechanical interference, due to the presence of female genital duct structures. Typically, the undescended testes are not seen in the mouse models. Male *AMH* knockout mice retain Müllerian ducts but their testes descend normally. In contrast to human females, which have a simple uterus, the uterus in rodents is bicornuate and highly movable, allowing the testes to reach the scrotum in a PMDS situation. Furthermore, female transgenic mice overexpressing AMH do not demonstrate ovarian descent or any difference in the position of the ovaries. The current view is that AMH is not a hormonal factor that is directly involved in the control of testis descent.

III. ANDROGENS

A. Androgens and the Androgen Receptor

Following the onset of AMH production by Sertoli cells, the next step in testis differentiation involves the formation of an interstitial population of Leydig cells situated in between the testicular tubules. Whereas the tubules are the spermatogenic compartment of the testis, the interstitial Leydig cells are responsible for steroid hormone production, or steroidogenesis, during fetal and postnatal life. The main steroid hormone to be produced is testosterone, formed by a series of enzymatic conversions from cholesterol. An important metabolite of testosterone is 5α-dihydrotestosterone. Each androgen has a quite specific role during male sexual differentiation; testosterone is directly involved in differentiation and development of the Wolffian duct-derived structures, including the epididymides, whereas 5α-dihydrotestosterone is the main active ligand in the differentiation and development of the prostate and male external genitalia.

The actions of testosterone and 5α-dihydrotestosterone are mediated by the androgen receptor, which is a member of the family of nuclear receptors. The available evidence indicates that there is only one gene encoding one type of androgen receptor. The *androgen receptor* (*AR*) gene is located on the X chromosome, in the human at Xq11–q12, and consists of eight coding exons, encoding a protein with a molecular mass of approximately 110 kDa. A polyglutamine stretch, encoded by a polymorphic $(CAG)_nCAA$ repeat, is present in the NH_2-terminal domain. Variation in length (9–33 glutamine residues) is observed in the human population, and the length of the repeat has been suggested to be negatively associated with a very mild modulation of androgen receptor activity. Whether subtle differences in $(CAG)_nCAA$ repeat lengths are important for modulation *in vivo* of androgen receptor activity is still a matter of debate, but could possibly play a role in later life, in relation to aging.

B. Androgen Insensitivity Syndrome

It is generally accepted that mutational defects in the androgen receptor can lead to impairment of the normal development of both internal and external male structures in 46,XY individuals. Detailed information about the DNA sequence of the human *AR* gene and the molecular structure of the AR protein has facilitated the study of mutational defects associated with androgen insensitivity. The end-organ resistance to androgens has been designated as androgen insensitivity syndrome (AIS). The main phenotypic characteristics of 46,XY individuals with the complete form of AIS are as follows: female external genitalia, a short and blind-ending vagina, the absence of Wolffian duct-derived structures (including epididymides) and the prostate, development of gynecomastia, the absence of pubic and axillary hair, and cryptorchidism. This cryptorchidism is not only related to the absence of male external genitalia, including a scrotum, but also is caused by marked disturbance of the early steps in the process of testis descent.

Mutations of the *AR* gene in AIS individuals are mostly single base mutations resulting in amino acid substitutions or premature stop codons, although complete or large deletions of the *AR* gene, and also intronic mutations in splice donor or acceptor sites, have been found.

Androgen insensitivity has also been noted in other mammalian species including the rat and the mouse. In the mouse, this condition also appeared to be X-linked and the locus was designated *Tfm* (testicular feminization). *Tfm* mice completely lack Wolffian duct-derived structures and show female external genitalia and cryptorchidism.

C. Androgens and Testis Descent

In male androgen-resistant *Tfm* mutant mice, development of the cranial suspensory ligament (CSL) is observed. This is of much interest, because outgrowth of this ligament is lacking in normal male mice, as opposed to its further development in normal female mice. The CSL is considered to be one of the main structures involved in determination of the gonadal position.

Several studies have supported the concept that development of the CSL is sex-dimorphic, which is probably relevant for the male-specific transabdominal phase of testis descent. When pregnant rats are treated with androgens to expose the fetuses to an increased level of androgens, this prevents the outgrowth of the CSL in the female fetuses, whereas males prenatally exposed to synthetic anti-androgens display CSL development. Furthermore, the AR is clearly expressed in primordial cells of the CSL, shortly before the onset of the first phase of testis descent, when this structure is highly sensitive to androgens. Interestingly, the sensitivity to androgens occurs within a small developmental time window and is lost after embryonic day 17 in the mouse, despite AR expression. The molecular mechanisms underlying the suppressive action of androgens on CSL develop-

ment are largely unknown and remain to be elucidated. Thus far, no evidence that cell proliferation and cell death parameters of the CSL are different in female and male mouse fetuses has been obtained. The interactions between cells and their extracellular matrix, and the controlling actions of androgens and local signaling factors in the development of the CSL primordium, need to be studied in more detail.

A second important structure, which certainly plays a major role in testis descent and also is under androgenic control, is the mesenchymal layer of the gubernaculum. Initially, in both female and male fetuses, the gubernaculum expresses AR protein. Subsequently, when the sex differentiation mechanisms have started to come into play, AR expression decreases dramatically in the female gubernaculum, compared to maintenance of AR expression in the male gubernaculum. Most likely, this is an androgen-dependent process. *In vivo* and organ culture experiments have demonstrated that rat gubernaculum tissue shows cell proliferation under the influence of androgens. Given the fact that expression of the AR, which is a prerequisite for androgen action, is detected in the mesenchymal core of rodent gubernaculum, it is suggested that androgens act directly on the mesenchymal cells. These mesenchymal cells, in turn, may elicit a growth response of the myogenic cells through paracrine mechanisms. In several androgen-responsive tissues, including the prostate, androgens act via the AR expressed in the mesenchymal compartment.

It is concluded that androgens have a clear and unmistakable role in testis descent during the first phase, as demonstrated in mice and rats. This role involves the inhibition of CSL development and the stimulation of growth of the gubernaculum, probably through an indirect action, mediated by mesenchymal cells on the muscular component of the gubernaculum.

IV. INSULIN-LIKE GROWTH FACTOR 3

A. Insl3

For many years, it has been quite clear that testicular factors, in particular androgens, are involved in the control of testis descent. Yet, it also was clear that a piece of the puzzle was missing, and as discussed herein, this missing piece does not seem to be AMH. Several investigators have put much effort in trying to identify the factor, which was believed to be produced by the testis in addition to AMH and androgens. Descendin, a candidate protein, was not characterized in molecular detail. A very strong candidate for the unknown testicular factor was recently identified, by analysis of the phenotype of *Insl3* knockout mice. The *Insl3* gene is expressed in embryonic testis, by the early Leydig cell population. Like the expression of the *AMH* gene, this expression is specifically found in testis and not in ovaries or other embryonic tissues. The phenotype of the *Insl3* knockout mice showed a complete lack of testis descent.

Insl3 is a member of the insulin-like hormone family, which includes insulin, relaxin, and insulin-like growth factors I and II. Insl3, also called relaxin-like factor, is a single gene product, and is synthesized as a prepropeptide consisting of a signal peptide, a B-chain, a connecting C-peptide, and an A-chain. It is expected that bioactive Insl3 is formed after enzymatic removal of the C-peptide, as for insulin and relaxin. Insl3 probably mediates its action through binding to a specific receptor. However, no such receptor has been identified thus far.

With regard to transcriptional control of the *Insl3* gene, it is of interest to note that the transcriptional regulator steroidogenic factor 1 (SF1) might be involved. This factor plays a prominent role in the development of the gonads and steroidogenic tissues. Based on the identification of functional SF1 sites in the *Insl3* promoter, it can be suggested that SF1 may act as a co-mediator of *Insl3* gene expression during male sex differentiation. The production of Insl3 by the fetal Leydig cells is independent of gonadotropin stimulation. However, gonadotropins become essential for the maintenance of *Insl3* expression in the postnatal and adult testis, as supported by the observation that *hpg* mice, carrying a deletion in the *GnRH* gene, lack Insl3 expression in adulthood.

B. Insl3 Deficiency

Mice with a targeted deletion of the *Insl3* gene have been generated. Since no gross abnormalities are found in female Insl3-deficient mice, which are fertile and have normal-sized litters, it was initially assumed that Insl3 plays a redundant role in ovarian function. Recently, however, careful examination of female mutant mice showed that their estrous cycle was twice as long as that of wild-type littermates. In addition, the *Insl3* knockout ovary shows an acceleration of follicular atresia and luteolysis, indicating that Insl3 plays a role in normal ovarian function during reproductive life. Male mice deficient for Insl3 have a very clear phenotype: all have undescended testes in adulthood. This phenotype was unexpected

but confirmed the previous proposed involvement of an additional testicular factor in testis descent. Analysis of male *Insl3* knockout mice revealed that gubernaculum development is severely affected. The action of both androgen and AMH appears not to be affected in these mutant mice, since they are completely virilized and no Müllerian duct remnants could be identified. The testis-specific expression of Insl3 during embryonic life is consistent with a role in gubernaculum development. It was demonstrated that impairment of spermatogenesis seen in Insl3-deficient mice is caused by the intra-abdominal position of the testis, rather than by a direct role of Insl3 in control of spermatogenesis. The molecular and cellular mechanism of Insl3 action on the gubernaculum remains to be studied.

C. Human INSL3 Gene

The human gene encoding INSL3 has been characterized and mapped to region p13.2–p12 of chromosome 19. Human serum contains a detectable level of INSL3, and the circulating INSL3 level in boys increases around puberty, resulting in a significantly higher level in postpubertal males than in females and prepubertal children. Similarly, the concentration of testosterone in plasma increases at puberty in normal boys. Since both testosterone and INSL3 are produced by testicular Leydig cells, such a correlation between testosterone and INSL3 levels might reflect coordinated control of their production.

Based on observations in mice, genetic analysis of cryptorchidism has recently been performed, by screening for *INSL3* gene mutations in cryptorchid boys. Several studies have been published, resulting in information about 350 individuals with (a history of) (one- or two-sided) cryptorchidism. Three mutations and several polymorphisms were found. Two heterozygous mutations are located in the connecting C-peptide and one mutation is found in the B-chain. No functional studies have been performed yet, so it remains to be determined whether these mutations are the underlying cause of the observed phenotypes.

It can be concluded that mutations in the *INSL3* gene appear not to be a frequent cause of cryptorchidism in human. One possible explanation might be that such a mutation will be effectively eliminated from the genetic pool, due to its adverse effect on fertility. There might also be a difference in the role of INSL3 among species. In human, mutations in the *INSL3* gene may lead to a phenotype possibly related to gonadal function but not resulting in a disturbance of testis descent.

It is to be expected that INSL3 acts through binding to a cell plasma membrane receptor. Recently, high-affinity INSL3-binding sites have been reported, although the binding molecules have not yet been identified. It would be of great interest to study the possible occurrence of INSL3 receptor mutations in the human population, in relation to the incidence of cryptorchidism.

V. ESTROGENS

Genes playing a role in the synthesis and biological action of estrogens have been identified, and mouse gene knockout models have been generated for the two genes encoding the two different estrogen receptors (ER-α and ER-β) and for the gene encoding aromatase, the enzyme that converts testosterone into estradiol. These mouse models indicate that there is no prominent direct role for estrogens in the development of the male reproductive tract, including the process of testis descent. In ER-α-deficient mice, quite excessive development of the cremaster muscle was observed, but there was no direct effect on the process of testis descent.

In contrast, exposure to an exogenous estrogenic agent before birth has been found to exert a clear adverse effect on male reproductive tract development. Urogenital tract abnormalities (including epididymal cysts, microphallus, testicular hypoplasia, and cryptorchidism) were found in male offspring of mothers taking the synthetic estrogenic compound DES (diethylstilbestrol) during pregnancy. The incidence of hypospadias, cryptorchidism, and testicular cancer in the general population has been reported to have increased over the past several decades. There is a general concern that chemicals with estrogenic activity that are present in the environment might act as endocrine disruptors and thereby contribute to the increasing incidence of male reproductive tract abnormalities, similar to that seen in DES-exposed males.

A possible mechanistic explanation for disruption of testis descent after fetal exposure to an exogenous estrogenic compound has become apparent during analysis of Insl3-deficient mice. The reproductive phenotype of Insl3-deficient mice is strikingly similar to a phenotype that can be induced by prenatal exposure of male mice to DES: an intra-abdominal position of the testes and a lack of gubernaculum development. It was hypothesized that this effect of DES might involve down-regulation of *Insl3* gene expression. Indeed, the expression of *Insl3* mRNA is markedly reduced in DES-exposed testes, compared to testes of control mice. Thus, the undescended testes

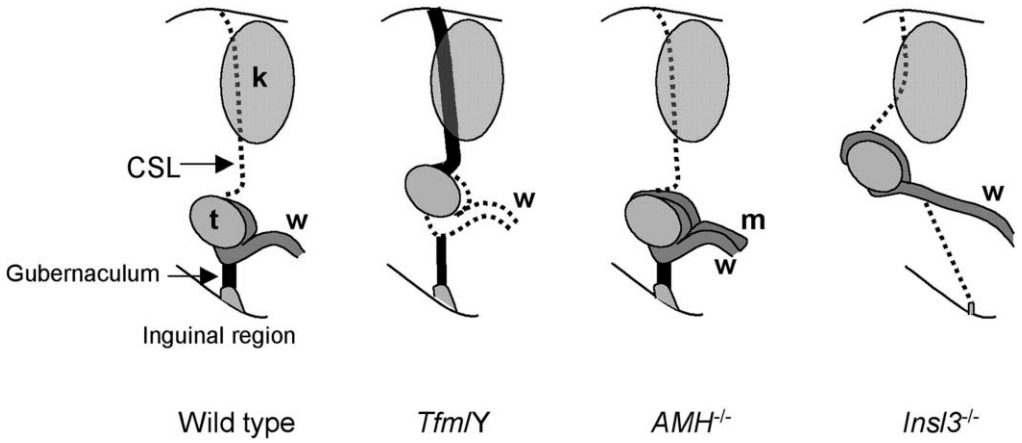

FIGURE 2 The first phase of testis descent in different genetic mouse models. In the normal (wild type) male fetus, the gubernaculum develops, whereas CSL development is lacking. When a functional androgen receptor is absent (*Tfm*/Y mouse), both the CSL and the gubernaculum develop, although shortening of the gubernaculum is less pronounced. The Wolffian duct system is not stabilized. In AMH-deficient male mice ($AMH^{-/-}$), both the Müllerian and Wolffian duct systems are maintained. CSL development is lacking, whereas the gubernaculum shows normal development. Finally, in Insl3-deficient male mice ($Insl3^{-/-}$), CSL development does not occur, and gubernaculum development is severely impaired. CSL, cranial suspensory ligament; k, kidney; m, Müllerian duct system; w, Wolffian duct system; t, testis.

observed in DES-exposed male mouse fetuses might be related to decreased Insl3 expression.

VI. CONCLUDING REMARKS

A clear picture has emerged with regard to the control of testis descent in the mouse, with androgens and Insl3 acting as principal factors (Fig. 2). However, the control of testis descent in the human male seems to involve additional factors, perhaps still unknown. It is of great importance to study this in more detail. The incidence of disturbed testis descent in the human male is very high—some type of problem is observed in at least 1% of all newborn males—and may be increasing due to environmental factors. Disturbed testis descent, resulting in unilateral or bilateral cryptorchidism, often can be completely repaired by surgical intervention. The surgical intervention might minimize the loss of fertility, as the scrotal location of the testis is needed to obtain normal spermatogenesis. Also, there is a correlation between testis maldescent and testicular cancer, which warrants the prevention and treatment of cryptorchidism, although it is not clear whether this correlation reflects a cause and effect relationship or whether a shared etiological factor is involved. By learning more about the mechanisms involved in testis descent and the factors that control this process, an understanding of other aspects of male reproductive health will be acquired.

Glossary

cranial suspensory ligament A ligament that connects the undifferentiated gonad to the upper wall of the abdominal cavity, in the early fetus. This ligament does not develop further in the male fetus, which is a prerequisite for testis descent. In adult females of most mammalian species, the cranial suspensory ligament (CSL) is a muscular cordlike structure that keeps the ovary and uterus in place, especially during pregnancy. The development and function of the human CSL are not completely understood.

cryptorchidism A disorder in which one testis or both testes do not descend into the scrotum, as detected at birth. This condition can originate from impairment at an early step or at later steps in testis descent. When cryptorchidism is not reversed spontaneously, surgical placement of the undescended testis into the scrotum is required to obtain normal spermatogenesis and fertility with the onset of adulthood.

gubernaculum A paired ligamentous cord present in both sexes that attaches to the gonad at the superior end and attaches to the bottom of the abdomen at the expanded inferior end (gubernacular bulb). Development and relative shortening of the gubernaculum, which occur only in the male, are essential for the first abdominal phase of testis descent. Later changes in the configuration of the gubernaculum are involved in passage of the testes through the inguinal canal into the scrotum.

insulin-like factor 3 A protein hormone that may be involved in the control of testis descent. During fetal development, insulin-like factor 3 (Insl3) is produced by the testis, in the interstitial Leydig cells, but not by the

ovary. Inactivation of the gene encoding Insl3 in the mouse (*Insl3* knockout) results in complete blockade of testis descent.

Thyroglobulin

GERALDO MEDEIROS-NETO

Hospital das Clinicas, University of São Paulo Medical School

Thyroglobulin (Tg) is a glycoprotein that is synthesized and secreted by thyroid cells; it is essential for the synthesis of thyroid hormone. In addition, large reserves of iodine and thyroid hormone are stored in the Tg molecule and are available for secretion when needed. Mutations in the Tg gene cause a structurally defective protein with a severely impaired ability to function. Defects in the synthesis of Tg have been described in both animals and humans, resulting in congenital goiter and reduced thyroid function.

I. INTRODUCTION

Thyroid hormone synthesis is intimately tied with thyroglobulin (Tg). Indeed, after the active transport of iodide into the thyroid cell, every subsequent step of triiodothyronine (T_3) and thyroxine (T_4) formation occurs within the Tg molecule. Thus, synthesis of T_3 and T_4 follows a metabolic pathway that depends on the integrity of the Tg structure. This large glycoprotein, a dimer of 660,000 Da, is synthesized and secreted by the thyroid cells into the lumen of the thyroid follicle (Fig. 1). Thyroglobulin serves two main purposes in the function of the thyroid gland. The first is related to the process of hormone production. Thus, Tg provides for the efficient coupling of the hormone precursors mono- and diiodotyrosine to form T_3 and T_4. The second function is that of a repository within the gland of a large supply of iodine and of hormone for secretion at a steady rate or upon demand. These two properties of Tg seem to permit the organism to operate in an

TSLPR. However, the primary sequence of the TSLPR differed from that of other members of the cytokine receptor family in several important ways. First, the second of four conserved cysteine residues in the extracellular domain was missing. Second, the hallmark WSXWS sequence found in all other members of the family was missing, with the sequences PSEWT or WTAVT present instead. The significance of these changes remains unclear. In the cytoplasmic domain, the TSLPR had a sequence that corresponded to the "Box 1" motif found in members of the cytokine receptor family, but it lacked the linked "Box 2" motif. These sequences have been shown to be important in initiating signal transduction cascades following receptor engagement through binding of members of the Janus family of protein tyrosine kinases. The final structural feature of note in the TSLPR cytoplasmic domain is a single tyrosine residue, 4 amino acids from the carboxy-terminus.

As discussed above, only cells of the hematopoietic lineage were found to bind TSLP. However, using RNA analyses, Pandey *et al.* found TSLPR mRNA in a wide variety of tissues, with the highest levels in liver, lung, and testis. Message was also found in thymus, spleen, brain, and heart. Fujio *et al.* found a similar expression profile. One possible explanation for the widespread expression of TSLPR mRNA comes from Hiroyama *et al.*, who found that myeloid cells displayed the highest levels of TSLPR expression. The expression of TSLPR mRNA in nonhematopoietic tissue may reflect the presence of resident cells of the myeloid lineage in those tissues. Support for this hypothesis comes from expression studies of the human TSLPR. Like the mouse gene, the human TSLPR gene was found to be expressed predominantly in myeloid cells, with the highest levels seen in myeloid-derived dendritic cells. The fact that these cells are known to be present throughout the body may help to explain the broad expression profile of the TSLPR gene.

As described above, two affinity classes of TSLP-binding sites were found, suggesting the possibility of multiple subunits in a functional TSLP receptor complex. In support of this model, when the TSLP-binding properties of the TSLPR were examined by Scatchard analysis, only the low-affinity binding site was seen. Clues as to the identity of this second receptor subunit were suggested by the similarities between the biological responses generated by TSLP and those generated by IL-7 (see below) and by the observation that anti-IL-7 receptor α (IL-7Rα) chain antibodies inhibited responses to TSLP. Hence, experiments were performed to test whether the IL-7Rα chain contributed to TSLP-binding affinity. Binding studies using cells transiently transfected with cDNAs encoding TSLPR, IL-7Rα, or both showed that only those cells expressing both chains displayed high-affinity TSLP binding and only cell lines expressing both receptors responded to TSLP. The absolute requirement for IL-7Rα in delivering TSLP signals was further supported by the observation that chimeric receptors containing the TSLPR cytoplasmic domain and an extracellular domain capable of homodimerization failed to generate intracellular signals when expressed in cell lines. However, responses could be stimulated when chimeric molecules including the cytoplasmic domains of the TSLPR and IL-7Rα were induced to heterodimerize. Taken as a whole, these data demonstrate that the low-affinity binding of TSLP to the TSLPR does not generate responses and that a functional TSLP receptor complex consists of the TSLPR and IL-7Rα (Fig. 1).

III. SIGNAL TRANSDUCTION THROUGH THE TSLP RECEPTOR

The inclusion of IL-7Rα in both the TSLP and IL-7 receptor complexes suggested that TSLP and IL-7 may generate similar biochemical signals. Generally speaking, cytokine binding by members of the cytokine receptor family activates a similar signaling pathway, the Janus kinase/signal transducers and activators of transcription (JAK/STAT) pathway. Following receptor engagement, one or more members of the Janus family of protein tyrosine kinases are phosphorylated, associate with the receptor at the Box 1 and Box 2 motifs, and become activated. In turn, these activated kinases phosphorylate a member of STAT family of transcription factors, leading to their dimerization, localization to the nucleus, and induced transcription of specific target genes. For example, engagement of the IL-7 receptor activates JAK1 and JAK3, leading to the tyrosine phosphorylation and subsequent activation of STAT5 (Fig. 1).

TSLP signaling studies have taken advantage of the ability of the fetal liver-derived pre-B-cell line NAG8/7 to respond to either TSLP or IL-7, allowing a comparison of the signaling properties of each receptor complex. As expected, treatment of NAG8/7 cells with IL-7 led to the tyrosine phosphorylation of JAK1, JAK3, and STAT5. Likewise, TSLP treatment of these cells led to the tyrosine phosphorylation of STAT5, but not of JAK1 or JAK3 (Fig. 1). In fact, TSLP was unable to activate any of the known JAK family members. This is in contrast to data from Fujio

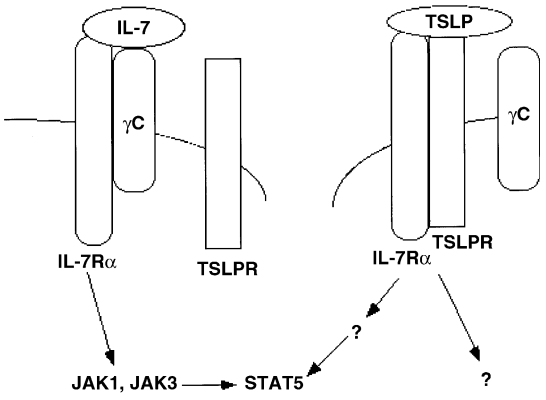

FIGURE 1 The TSLP–receptor complex utilizes the IL-7Rα chain and the TSLPR chain, but not γc. Whereas the IL-7–receptor complex utilizes the IL-7Rα chain and γc, the TSLP–receptor complex uses the IL-7Rα chain and the TSLPR complex. This leads to a number of downstream signaling differences, the most notable of which is JAK-independent activation of the STAT5 transcription factor in response to TSLP. IL-7 also activates STAT5, but does so through the more conventional pathway of activating JAKs (specifically, JAK1 and JAK3).

et al., who found that substituting the membrane-proximal region of the erythropoietin receptor with that of the TSLPR did lead to tyrosine phosphorylation of JAK2. Similarly, Hiroyama and colleagues found JAK2 constitutively associated with a chimeric receptor consisting of the extracellular domain of CD8 and the TSLPR cytoplasmic domain. One possible explanation for the different results may be that the chimeric receptors, by virtue of being homodimers, may adopt a confirmation that allows JAK2 to associate. In addition, it now appears that there is a fundamental difference in the signaling properties of the mouse and human TSLP receptors. The human receptor can recruit and activate JAK2, whereas the mouse receptor cannot. This difference may in part account for some of the unique biological properties of human and mouse TSLP (see below).

Support for the lack of JAK activation by engagement of at least the mouse TSLP receptor comes from receptor reconstitution experiments. Isaksen *et al.* used transient transfection of the hepatoma cell line HepG2 to demonstrate that TSLP signaling required STAT5 uniquely and that activation of STAT5 was independent of JAK. Treatment of cells that were co-transfected with cDNAs encoding the TSLPR, IL-7Rα, and a STAT-responsive reporter plasmid did not lead to reporter activation. However, addition of a STAT5 cDNA did lead to activation. As these cells express STAT1 and STAT3, these data showed that STAT5, but not STAT1 or STAT3, could be activated by TSLP. In addition, dominant-negative forms of JAK1 and JAK2 did not affect reporter activity driven by TSLP treatment, although responses to IL-7 were inhibited by dominant-negative JAK1. Other experiments have demonstrated that JAK3 also has no effect on TSLP-mediated responses. Collectively, these data support the notion of JAK-independent STAT5 activation. Notably however, a cDNA encoding dominant-negative Tec partially inhibited TSLP-mediated STAT5 activation, suggesting a role for Tec family kinases in TSLP signal transduction.

IV. FUNCTION OF TSLP *IN VITRO*

Three cell types have been shown to respond to TSLP *in vitro*. First, thymocytes and peripheral T cells exposed to suboptimal antigen receptor stimulation can be co-stimulated by the addition of TSLP. The magnitude of the augmentation of proliferation mediated by TSLP supplementation is similar to the co-stimulatory effect of IL-7 on the same populations. However, IL-7 alone will induce a low level of proliferation in these cells as well, whereas TSLP by itself does not promote DNA replication at all. Consistent with what is known about the TSLP receptor complex, antibody blocking experiments have shown that TSLP co-stimulation is dependent on the IL-7Rα chain and the TSLPR but is independent of γc.

Second, TSLP has been shown to influence the development of B lymphocytes in *in vitro* culture systems. B-cell development from both bone marrow and fetal liver cultures is enhanced in the presence of TSLP. However, although IL-7 will also promote B lymphopoiesis in the same culture systems, there are several differences in the effects of IL-7 and TSLP. First, the vast majority of cells that develop in IL-7-supplemented bone marrow or fetal liver cultures fail to express surface immunoglobulin M (IgM). This is due to the fact that although many of these cells have rearranged heavy chain alleles, they have not yet rearranged their light chain loci. On the other hand, most of the cells that develop in cultures supplemented with TSLP express surface IgM, indicating that these cells have successfully rearranged one or more light chain loci. However, it should also be noted that TSLP imparts a less dramatic proliferative effect than IL-7, although the absolute number of IgM^+ cells produced in TSLP-treated cultures is still generally greater than what is obtained from IL-7-treated cultures.

Similar results have been obtained evaluating the contribution of TSLP to human B-cell development using an *in vitro* culture system. Specifically, human TSLP (huTSLP) promoted the development of $CD19^+$/$VpreB^+$ pre-B cells from $CD34^+$ cord blood progenitors. However, TSLP induced only a modest increase in total cell numbers with a concomitant increase in the percentage of $CD19^+$/Vpre-B^+ cells. In contrast, IL-7 induced a prominent expansion in cell numbers, but a proportional decrease in the $CD19^+$/Vpre-B^+ cells. Moreover, addition of TSLP to $CD19^+$ cells derived from established cultures resulted in a marked increase in the number of $CD19^+$/IgM^+ cells in the absence of stroma. These events were associated with an increase in kappa light chain transcripts, suggesting that TSLP may promote light chain rearrangement, perhaps by altering locus accessibility or the expression of germ-line transcripts. These effects were not observed in cultures treated with other B-cell lineage cytokines, including IL-7. The similar influence of TSLP on B-cell development in both the mouse and human systems strongly suggests that a unique function of TSLP may be to promote the development of IgM^+ B cells.

Finally, it has recently been established that human TSLP will stimulate the maturation and survival of $CD11c^+$ dendritic cells (DCs) and induce the production of a number of chemokines that promote the recruitment of T lymphocytes. This information collectively suggests the possibility that the enhanced proliferation of T cells and thymocytes induced by TSLP after suboptimal antigen receptor stimulation could be the consequence of the maturation and up-regulation of co-stimulatory molecules on antigen-presenting cells in these cultures. However, despite these clear effects of huTSLP on human DCs, mouse TSLP does not have similar effects on mouse DCs. This species-specific difference is somewhat surprising given that, as discussed above, the mouse receptor complex is expressed at high levels on cells from the myeloid lineage.

V. BIOLOGY OF TSLP *IN VIVO*

An interesting aspect of the biology of TSLP centers around the observations that mice that are genetically deficient in the gene encoding IL-7Rα have more severe defects in the development of B and T lymphocytes than those lacking the IL-7 gene. When this observation was initially made, it was suggested that perhaps the ability of another IL-7Rα-chain-utilizing cytokine accounted for the differences. Hence, it is possible that the action of TSLP ameliorates some of the effects of IL-7 deficiency but that this is also eliminated in IL-7Rα-deficient mice. The specific differences in the developmental defects support this possibility. For example, B-cell precursors in IL-7Rα-chain knockout mice generally progress poorly beyond the pro-B-cell Hardy fraction A/B stage, which leads to dramatic reductions in mature B cells. B-cell development in IL-7-deficient mice generally proceeds to the pre-B-cell or Hardy fraction C stage, but the cells subsequently fail to expand, leading to reduced numbers of mature B cells. This is consistent with the *in vitro* activity of these two cytokines since IL-7 treatment of bone marrow or fetal liver precursors *in vitro* supports considerable expansion. TSLP, on the other hand, is less able to support expansion, but does promote maturation to later stages and some pre-B-cell expansion. Hence, it seems likely that either TSLP is responsible for the transition from the pro-B- to pre-B-cell stage normally or it can adequately serve the function of IL-7 in its absence at this stage. In any case, in the mouse, it is clear that TSLP cannot completely replace the need for IL-7 in expanding the numbers of pre-B cells *in vivo* or *in vitro*.

A possible role for TSLP in T-cell development has been suggested by the fact that the thymus was one of the areas of highest expression and by the observation that TSLP co-stimulates thymocytes and mature T cells. Moreover, observed differences in thymocyte maturation in IL-7Rα-chain- and IL-7-deficient mice also suggest this possibility. However, results regarding this hypothesis have been inconsistent. Specifically, IL-7-deficient mice have smaller thymi (approximately 10% of the normal cell numbers) and reduced numbers of T lymphocytes, although subset distributions appear grossly normal. Mice lacking IL-7Rα had an interesting dichotomy in their thymic phenotype, with some mice grossly resembling the IL-7-deficient mice and others showing more dramatic perturbations. This second group had thymocyte numbers approximately 1% of normal and they failed to develop $CD4^+$/$CD8^+$ double-positive thymocytes. Again, a potential role for TSLP in mediating these different phenotypes was suggested, although it is less clear why TSLP might partially rescue thymocyte development in some mice and not others. One possibility might be a difference in TSLP expression in these two subsets of mice in the thymus, with more severely affected individuals expressing less TSLP than the IL-7 knockout "look-a-likes." However, this is only speculation and has not been investigated.

A knockout of the *Tslp* gene has not yet been reported, but the gene encoding the receptor has

recently been disrupted. However, no discernible phenotype involving the development of either B or T lymphocytes has been noted in mice that lack the receptor. It is possible that this reflects an ability of IL-7 to completely substitute for TSLP or that the subtlety of the defect has thus far escaped detection.

Perhaps the most intriguing clues as to the function of TSLP come from the study of mice that overexpress TSLP as a transgene. Notably, mice that express the TSLP protein in immature thymocytes develop an autoimmune disease that is characterized by the development of skin lesions, splenomegaly, lymphadenopathy, and mixed leukocytic infiltrates in multiple tissues including the skin, lungs, and liver. This autoimmune disease exhibited an earlier onset with greater severity in female mice, which intriguingly is also observed in many human autoimmune diseases as well. In addition, there was considerable evidence for an accumulation of polyclonal immunoglobulins precipitating from serum samples at low temperature. Accumulation of such "cryoglobulins" is characteristic of a type III cryoglobulinonemia, which is observed in certain types of infections (e.g., hepatitis C) and in various human autoimmune diseases. Apart from the skin lesions, the nature of this autoimmune disease is considerably different than what is observed when other cytokines including IL-7 are overexpressed in transgenic mice. In addition, the phenotype of mice overexpressing TSLP under the control of the Lck proximal promoter was very similar to that of mice expressing the cytokine under control of the keratin-14 promoter. The similarity in phenotype of transgenic mice expressing the same cytokine under a different type of transcriptional regulation suggests that these soluble proteins are systemically distributed and produce similar effects regardless of their point of origin. The same was true of IL-7 transgenic mice in which different promoters drove expression of the cytokine. Hence, it seems likely that the abnormalities observed in mice overexpressing these cytokines reflect perturbations of cell populations that they normally affect and that the development and character of this autoimmune disease in TSLP-transgenic mice reveals something important about its function in the regulation of the mouse immune system.

As discussed above, there is some evidence that both IL-7 and TSLP serve different functions in mice and humans. Most notably, as discussed above, deficiencies in the mouse IL-7 or IL-7 receptor gene result in severe defects in both B- and T-cell development. However, humans deficient in the IL-7 receptor have defects in T-cell development, but normal B-cell compartments. This indicates that neither IL-7 nor TSLP signaling is an obligate requirement for B-cell development in humans. Moreover, expression of the human TSLP receptor is highest in cells of the myeloid lineage and human TSLP triggers the release of T-cell-attracting chemokines in both monocytes and dendritic cells. In addition, TSLP treatment triggers the maturation of $CD11c^+$ dendritic cells, which enhances their ability to co-stimulate T cells. This suggests a possible mechanism whereby TSLP overexpression could mediate the lymphocytic infiltrates and autoimmune disease discussed above in transgenic mice. However, it has been reported that mouse TSLP does not have the same effects on mouse monocytes and dendritic cells despite the fact that monocytes at least express both the IL-7 and the TSLP receptors.

These effects on myeloid cells have now been shown to have profound consequences on the development of allergic inflammatory responses in humans. Soumelis and co-workers have recently demonstrated that TSLP triggers the maturation of $CD11c^+$ DCs. These mature DCs promote $CD4^+$ T-cell expansion, recruit T_H2-phenotype T cells, and promote the development of T_H2 cells from naive T cells. This turns out to be physiologically important because it was also shown that epithelial cells isolated from sites of acute atopic dermatitis expressed high levels of TSLP, whereas expression was undetectable in normal skin. Collectively, these data suggest a model whereby affected skin produces TSLP and promotes the recruitment, maturation, and survival of DCs to the site and the subsequent recruitment and development of allergy-promoting T_H2 T cells.

VI. CONCLUSIONS

The initial characterization of TSLP and its biological effects suggested that it may be simply a "lesser" version of IL-7—it does everything IL-7 does, but simply not as well. The study of TSLP is still in its infancy and the availability of reagents and systems to facilitate understanding of this unique cytokine suggest that the next few years will produce a vast expansion in information regarding TSLP. At this point, it is known that TSLP can influence the development of B lymphocytes in both mice and humans. In addition, findings in TSLP transgenic mice strongly suggest that this cytokine influences immune system homeostasis at some level and can contribute to the development of autoimmune disease. Such a role is also suggested by the recent demonstration that TSLP plays a major role in allergic inflammatory responses in humans. Collec-

tively, available information suggests that TSLP is much more than just a "poor man's IL-7."

Glossary

common cytokine receptor γ-chain (γc) A transmembrane protein that was first identified for its contribution to interleukin-2 (IL-2) binding and signaling. It has subsequently been shown to be involved in binding and signaling from a number of other cytokines, which are collectively known as the γc-utilizing cytokines. These include IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21.

interleukin-7 A cytokine that promotes the growth of pre-B cells and co-stimulates thymocytes and mature T cells.

interleukin-7 receptor α-chain A transmembrane protein that was first identified for its capacity to bind interleukin-7 (IL-7). Subsequent research revealed that it binds IL-7 in conjunction with another transmembrane protein termed the common cytokine receptor γ-chain.

Janus family kinases (Jaks) A family of protein tyrosine kinases that are activated by cytokines binding to their receptors. Their best-characterized substrates are members of the signal transducers and activators of transcription family.

signal transducers and activators of transcription (Stats) A family of transcription factors that are induced to dimerize and translocate to the nucleus after being tyrosine phosphorylated in response to cytokine stimulation. This phosphorylation is most commonly carried out by members of the Janus kinase family.

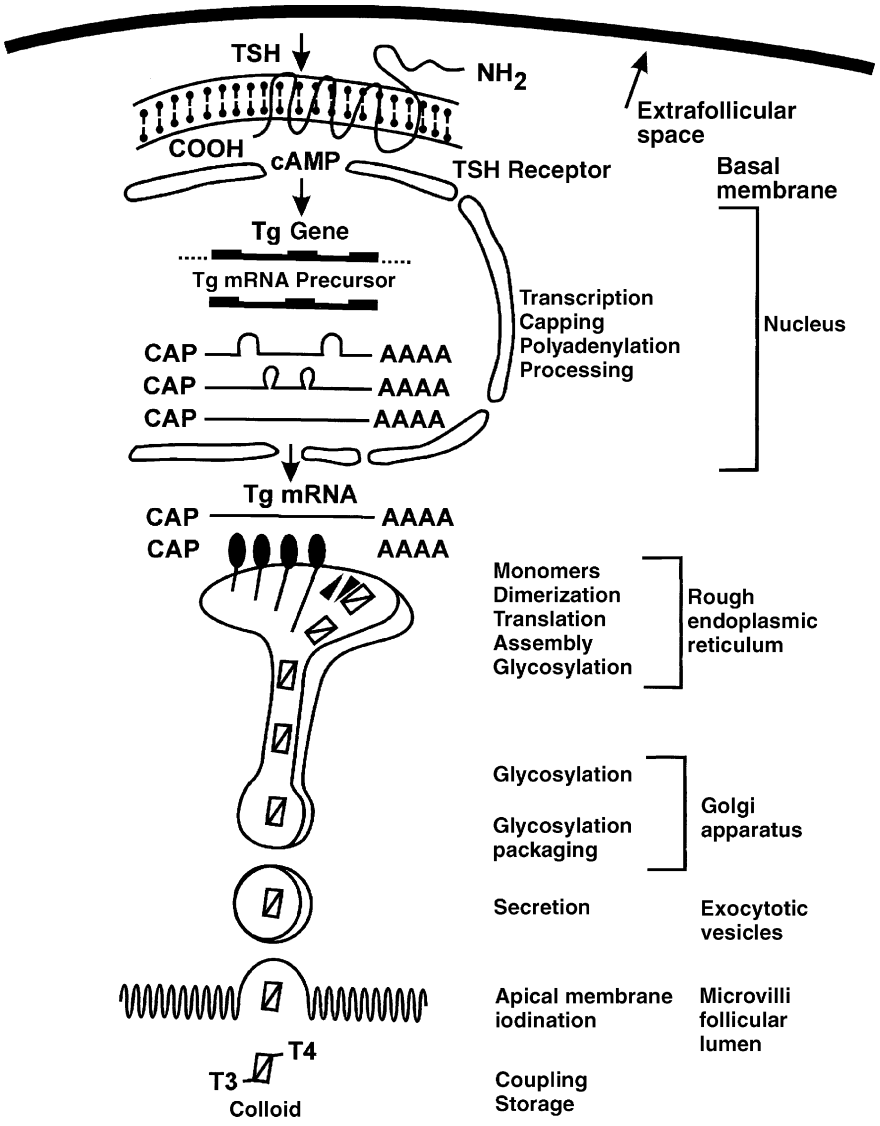

FIGURE 1 Tg gene expression, product synthesis, and Tg gene transcription are dependent on TSH stimulation through the interaction of TSH within the TSH receptor, via the cAMP pathway. The Tg gene (300 kb long) is transcribed into a Tg mRNA of 8448 bp and translated into a 2748-amino-acid (12S) Tg subunit. The mature protein is formed by joining two 12S subunits. After carbohydrate incorporation, the Tg is secreted into the follicular lumen via the Golgi apparatus. Modified from Medeiros-Neto, G., Targovnik, H. M., and Vassart, G. (1993). Defective thyroglobulin synthesis and secretion causing goiter and hypothyroidism. *Endocr. Rev.* **14**(2), 165–183, with permission from The Endocrine Society.

environment that is usually deficient in iodine and to accommodate wide variations in iodine supply. The efficiency of hormone synthesis of Tg depends on structural factors intrinsic to the protein matrix that favors the coupling reaction. It may be assumed that genetic mutations that would result in a structurally defective protein would severely impair the functional ability of Tg to serve as a matrix for the generation of T_3 and T_4.

II. THE STRUCTURE OF THYROGLOBULIN AND SYNTHESIS OF THYROID HORMONE

Thyroglobulin is synthesized on the endoplasmic reticulum as single polypeptide chains of approximately 300,000 Da. The nascent protein is transported to the Golgi, where the carbohydrate chains are completed. It then migrates to the apical membrane of the thyroid cell. Meanwhile, the iodide that has been

trapped by the thyroid also accumulates at the apical cell border. Here, a complex series of reactions occurs, in which the iodide is oxidized through the action of a thyroidal peroxidase and hydrogen peroxide and is attached to tyrosyl residues within the Tg peptide chain. At this point, the Tg molecule contains iodinated tyrosines, monoiodotyrosine (MIT), and diiodotyrosine (DIT), but no thyroid hormone.

Through a further action of the peroxidase, two DIT residues, both in peptide linkage within Tg, couple to form T_4. This occurs by the formation of a diphenyl ether from the two DITs, leaving dehydroalanine at the site formerly occupied by the DIT donating the outer ring of T_4. The other thyroid hormone (T_3) is formed by coupling one molecule of MIT with one molecule of DIT. Normally, approximately one-third of the iodine of Tg will be in the thyroid hormones T_4 and T_3, and the remainder will be in the inactive precursors DIT and MIT. By the time hormone synthesis is completed, two chains of 330,000 Da will associate to form the mature 660,000 Da Tg molecule. The two associating chains are probably identical. Thyroglobulin is stored extracellularly in the lumen of the thyroid follicle, where it is virtually the sole occupant (Fig. 1).

When the stored hormone is needed, Tg is retrieved by pinocytosis and ingested by the cell, where it fuses with lysosomes and is digested, and the hormone is released into the circulation. DIT and MIT are deiodinated and the iodine is returned to the intracellular iodide pool, where it is recycled. This is an important mechanism for iodine conservation.

The main metabolic steps of the biosynthesis of Tg appear in Fig. 1. Despite its huge size, Tg is not rich in tyrosine. Of more than 5000 amino acids in the 660,000 Da protein, only 4 to 8 are actually incorporated into hormone molecules. The synthesis of such an enormous molecule for this relatively small yield has perplexed many observers. The apparent wastefulness of this process may be explained in part by the storage function of Tg, through which large amounts of iodine are retained for long periods of time. This provides the thyroid with a constant reserve of iodine for hormone synthesis, even during periods when iodine is not immediately available from the environment.

Structural changes in the Tg molecule or its precursors, inability to couple iodotyrosines, defective glycosylation, or abnormal transport through the membrane system of the cell could impair or substantially alter the synthesis of T_4 and T_3 and result in congenital goiter and various degrees of thyroid hypofunction.

III. THE TG GENE: STRUCTURE, EXPRESSION, AND REGULATION

The Tg gene, mapped to human chromosome 8q24.2–q24.3, covers at least 300 kb of genomic DNA and contains 8.5 kb of coding sequence divided over 48 exons separated by introns varying in size up to 64 kb. In 1987, the primary structure of human Tg was deduced from the sequence of its 8448-base messenger RNA and corresponding coding DNA (cDNA) sequence of 8304 bp. More recently, it was shown that the open reading frame of human Tg consists of 8307 bp, due to an extra nucleotide triplet (CAG) after position 2952. The frame encodes 2768 amino acid residues, including the signal peptide. The revised nucleotide positions resulted in the change of 12 amino acid residues and reduced the original number of tyrosine residues in the Tg monomer from 67 to 66.

The complete coding sequence of the 8307 nucleotides of the human Tg has been published with the encoded amino acid sequence (19-amino-acid signal peptide plus 2749 amino acids). To indicate the complexity of the Tg protein, other characteristics have been included such as the acceptor and donor tyrosine residues, the sites where thyroid hormones are synthesized, the N-glycosylation sites for the addition of carbohydrate molecules, the cysteine-rich repeated domains, the acetylcholinesterase homologous domain, and the most prominent antigenic epitopes. This work also described previously identified mutations and deletions found in human thyroid pathology and homologous positions in animals with hereditary thyroid disorders linked to a Tg defect (such as goats, Afrikander cattle, and *cog/cog* mice).

Four hormonogenic acceptor sites lie at positions 5, 1291, 2554, and 2747 in human Tg. Iodothyronine donor sites are at positions 130 and 1448. The acceptor sites map to the nonrepeated amino- and carboxy-terminal segments. The central portion of the molecule does not contain hormonogenic sites, yet it probably plays an important structural role in allowing the precise positioning of the hormonogenic tyrosines.

Two mechanisms for coupling are possible, one involving the free interaction of the donor and acceptor and the other assuming rigid juxtaposition

of donor and acceptor. For this latter mechanism, a specific three-dimensional Tg structure is necessary.

The expression of the Tg gene is controlled at the level of transcription by TSH, the intracellular effects of which are mediated via cAMP. It is mimicked by forskolin, a universal activator of adenyl cyclase. No significant increase of Tg gene transcription was observed with chronic hyperstimulation of the rat thyroid gland with endogenous TSH. This indicates that the gene is close to being maximally expressed (at least in relative terms) under normal physiological conditions. In contrast, a dramatic decrease in Tg gene transcription was observed when endogenous TSH levels were suppressed. Injection of exogenous TSH in experimental animals restores transcriptional activity of the gene.

IV. ANIMAL MODELS OF DEFECTIVE Tg SYNTHESIS

Defects in Tg synthesis have been described in detail in sheep, cattle, bongo antelope, goats, and mice. Some of the animal studies are very informative. They serve as models for defective Tg synthesis in humans and provide important information about the molecular mechanisms of Tg defects.

A. Hereditary Goiter of the Afrikander Cattle

Congenital goiter with Tg deficiency has been described in a South African breed of cattle. Affected homozygotes were euthyroid despite huge goiters. The tissue contained iodoproteins, immunologically related to Tg but of abnormally low molecular weight. Iodoproteins with sedimentation coefficients of 4S, 9S, 12S, and 18S were isolated and purified into homogenous forms by gel chromatography and sucrose gradient ultracentrifugation.

In the Afrikander cattle thyroid, iodoalbumin constituted only 2.6% of the total soluble protein in the supernatant of the thyroid homogenate. In other examples of defective Tg biosynthesis, iodinated albumin frequently replaces Tg. The goiter of the homozygous animal contained a 7.3 kb Tg mRNA species in addition to the normal-sized 8.4 kb Tg mRNA. The mutation responsible for the disease is a cytosine to thymine transition, creating a stop codon at position 697 in exon 9. As a consequence, the goiter Tg mRNA encodes the shorter peptide of 75 kDa. The normal reading frame is conserved in the defective message, which is translatable into a potentially functional protein of approximately 2400 residues instead of the normal 2769 amino acids. The euthyroid state of the affected animals is compatible with the fact that the major T_4 hormonogenic region of Tg near the amino-terminus is present on both the short and the long Tg-related peptides found in the goiter.

B. Hereditary Goiter of the Dutch Goats

A strain of hypothyroid goats with congenital goiter due to a defect in Tg synthesis has been extensively studied. The disease is inherited as an autosomal recessive. Only minute amounts of Tg were detected by radioimmunoassay (RIA). Ultracentrifugation, immunodiffuson, and immunoelectrophoresis demonstrated an absence of a normal 19S Tg in the goiter tissue.

Sequencing studies on goat complementary DNA were reported. A cytosine to guanine point mutation that caused a change from TAC (Tyr) to TAG (termination signal) at amino acid position 296 was found in exon 8. Chain termination in exon 8 will result in a Tg polypeptide chain with an estimated molecular weight of 39,000 that is similar in size to the *in vitro* translation product. The Tg fragment found in the goat's goiter containing the N-terminal hormonogenic site was able to produce T_4 *in vivo*. Administration of 1 mg iodide per day to a goitrous goat resulted in iodinated Tg with an iodotyrosine:iodothyronine ratio of 2.0:2.4. This is probably why the goitrous goats could be kept euthyroid by the administration of extra iodide.

C. Hereditary Goiter of the *cog/cog* Mice

A mouse mutation that in the homozygous state (*cog/cog*) causes primary hypothyroidism with goiter has been found. Young adult mutant mice are hypothyroid, as evidenced by significantly lower total serum concentrations of T_4 and T_3 and elevated serum levels of TSH. Studies of goitrous tissue showed marked deficiency in immunoreactive Tg. Further studies demonstrated linkage of goiter to the Tg gene on chromosome 15. A single amino acid change at position 2265 (leucine to proline) causes abnormal storage of the mutant thyroglobulin in the endoplasmic reticulum.

Ultracentrifugation procedures followed by RIA were used to determine the protein sedimentation properties. A small peak in the 3S to 8S area (13.7% of the total apparent immunologic activity) contained iodinated albumin. There were also broad, overlapping peaks at 12S, 19S, and 27S (86.3%). The sedimentation properties indicate that the formation of 19S Tg was not normal. There was an increase in

unassociated 12S subunits and aggregated species larger than 19S.

V. HUMAN CONGENITAL GOITER WITH DEFECTIVE Tg SYNTHESIS

A. Clinical Features

Characteristically, the majority of patients have congenital goiter, with hypothyroidism or goiter appearing shortly after birth. Goiters are usually large and have a soft, elastic consistency. Many of these patients present as adults with nodular hyperplasia (Fig. 2). Symptoms of compression of the surrounding neck structures are quite common. Hypothyroidism may be partially compensated for by preferential T_3 secretion and normal serum T_3 levels. Therefore, many of these patients may attain near-normal stature and some are able to perform simple tasks and even to learn how to read and write. There is no impairment in hearing and the structure of the cochlea is normal in the few cases that have been examined by computerized tomography.

B. Genetics

A positive family history of goiter has been obtained in more than 50% of these patients. Both sexes are affected, but males are more frequently affected (38 females, 54 males). The parents were considered heterozygous and unaffected; frequently more than one sib was affected in a generation and the pattern of inheritance is autosomal recessive.

C. Laboratory Investigation and Diagnosis

In the early reports of defective Tg synthesis, it was found that the serum protein-bound iodine concentration (PBI) was higher than thyroxine iodine measured by RIA. This suggested the presence in serum of abnormal iodoproteins. These may be non-19S Tg subunits, iodoalbumin, iodohistidines, or iodogammaglobulin. The presence of abnormal iodoproteins is also frequently found in endemic goiter, sporadic goiter, and goitrous Hashimoto

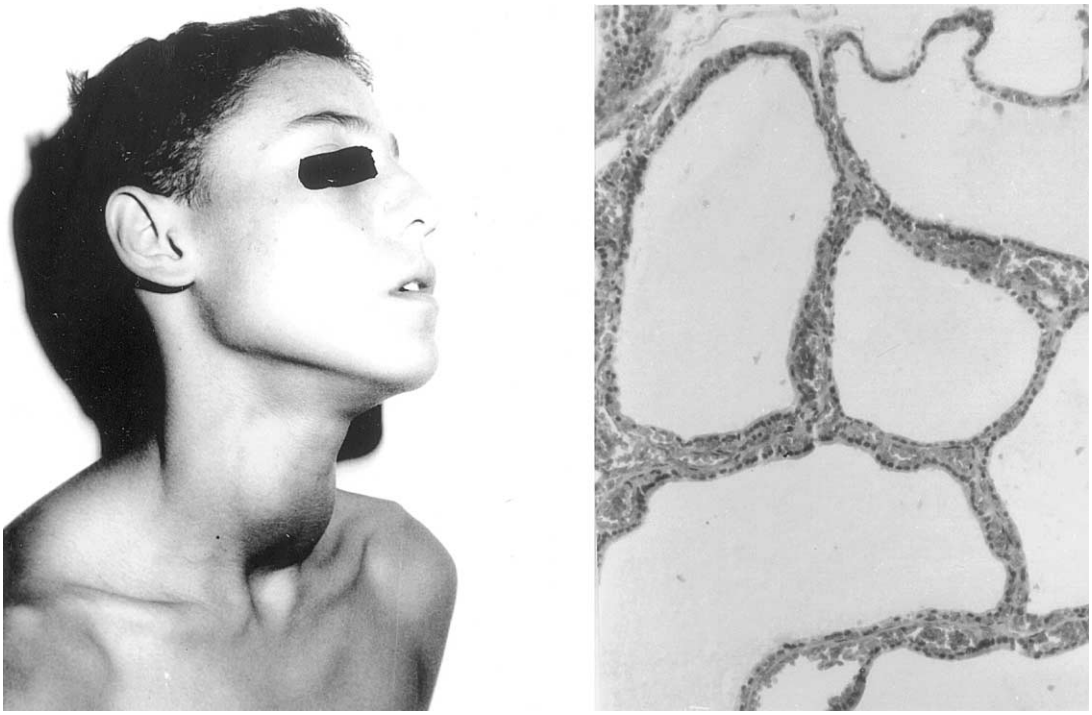

FIGURE 2 A 16-year-old male with congenital goiter with few signs of hypothyroidism treated with L-T4 since early childhood (left). Serum Tg was very low (1.8 ng/ml) and did not rise after 0.45 mg of human recombinant TSH (2.1 ng/ml) despite a large goiter (78 g). The pathological specimen was typical of a thyroglobulin defect with absent colloid (right). Immunochemistry was able to demonstrate immunoreactive Tg inside the follicular cells.

thyroiditis and should be considered as only indicative of a possible Tg defect.

With the increasing use of serum Tg determination by RIA, the presence of an abnormally low or borderline low serum Tg level in a goitrous individual became a good indicator of a Tg defect. The TSH stimulation test is used to differentiate the group of Tg defects from other possible types of dishormonogenesis. Subjects with Tg defects have relatively low or undetectable serum Tg values that do not increase 48 h after a single injection of bovine or, more recently, human recombinant TSH. By contrast, a fivefold increase in serum Tg values was obtained in goitrous patients with organification defects (low or absent thyroid peroxidase active). Therefore, goitrous patients with a suspected hereditary Tg defect may be differentiated from other congenital goitrous patients through the TSH stimulation test.

The radioiodide uptake is invariably elevated, indicating an activation of the iodine-concentrating mechanism, probably due to chronic TSH stimulation. As the thyroperoxidase system is also activated, there is an increased incorporation of iodine into protein. Since thyroglobulin is not available, albumin and other proteins are iodinated and secreted. Incorporation of iodine into proteins other than Tg generates iodotyrosines and iodohistidines. In situations in which the patient lives in an area where the supply of iodine is low, the loss of iodide may aggravate the functional deficiency of the dishormonogenetic gland. On the other hand, an adequate supply of iodide can lead to compensation for the relative lack of thyroidal Tg, as demonstrated in experimental animals.

The perchlorate discharge test is usually negative (less than 15% of the trapped iodide is released after an oral dose of 2.0 g of potassium perchlorate).

Thyroid images obtained by isotope scanning or by ultrasonography are not different from those seen in multinodular or hyperplastic goiters. Thus, although these procedures are routinely employed to estimate the thyroid volume and thyroid anatomy, they add little to the differential diagnosis.

D. Microscopic Examination

A number of reports include the histological examination of the thyroid, by both light microscopy and electron microscopy. The absence or pronounced scarcity of colloid and large follicular spaces lined by predominantly cuboidal cells with frequent atypical nuclei are indicative of a lack of Tg synthesis and chronic TSH stimulation (Fig. 2). In patients with impaired Tg export, electron microscopy has shown fragmented endoplasmic reticulum cisternae, with irregular contours that appeared overdistended. The Golgi complexes were numerous and had a large surface area. There were no colloid droplets inside the follicular cell and no immunofluorescence in the lumina after exposure to both anti-human Tg and anti-human serum albumin. Similarly, immunostaining with anti-human Tg using the immunoperoxidase method in two patients with a quantitative defect have shown Tg-related protein only inside the cytoplasm.

E. Biochemical Studies on Tissues with Defective Tg Synthesis

In patients with a defective synthesis of Tg, the normal Tg peak is usually absent in the filtration elution pattern and an abnormally large albumin peak preceding the hemoglobin peak is observed.

This pattern of absence of Tg can be confirmed by Tg radioimmunoassay. Normally, Tg is measurable in the thyroid-soluble protein fraction, ranging from 50 to 90 mg/g of tissue. In all patients with the quantitative Tg defect, the Tg content was less than 0.5 mg/g of tissue. Other methods for evaluating the presence of Tg in the thyroid extract are immunoelectrophoresis (using rabbit anti-human Tg) and sodium dodecyl sulfate-agarose gel electrophoresis. In both methods, the absence of Tg bands confirms the quantitative Tg defect.

F. Identified Defects in Human

Five different mutations in the Tg gene have been reported. All patients are homozygous for the mutations and fit the clinical description of a Tg synthesis defect, although the locations of the mutations and the corresponding defects at the protein level are strikingly dissimilar. The Tg disorders can be divided into three groups:

1. Structurally defective Tg that may not be functional or will yield thyroid hormones only at a very high intake of iodine.
2. The defective Tg molecule is not exported to the colloid (endoplasmic reticulum storage disease) as indicated in Fig. 3.
3. Defective glycosylation of Tg (low sialyc acid incorporation).

Approximately 113 patients from several families have been described in detail and molecular mechanisms have been determined in many of these patients. Two important deletions, of 68 amino acids from the

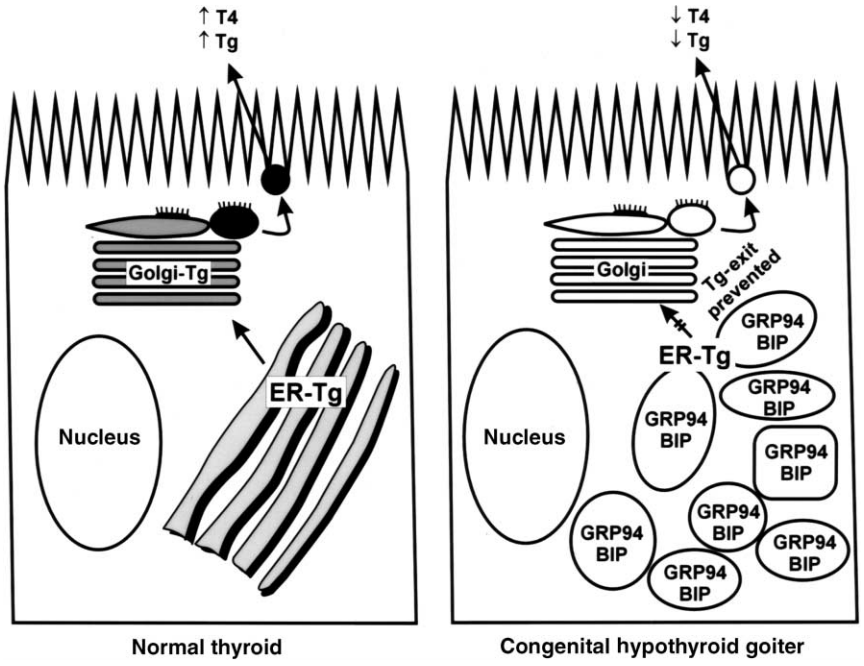

FIGURE 3 Schematic representation of the consequences of defective Tg that leads to an endoplasmic reticulum storage disease causing congenital hypothyroid goiter. In affected patients, the arrival of Tg in the Golgi complex and the subsequent secretion of Tg to form T4 are drastically inhibited. Instead, Tg accumulates in the ER, with accumulation of ER chaperones (GRP94, BIP) that assist the mutant Tg in migrating to the Golgi apparatus. The diminished synthesis of T4 triggers pituitary secretion of TSH, further stimulating the thyroid gland and contributing to goiter growth. Modified from Arvan *et al.* (1997). Intracellular protein transport to the thyrocyte plasma membrane: Potential implications for thyroid physiology. *Thyroid* 7(1), 89–105, with permission from Mary Ann Liebert Publishers.

N-terminal part of the Tg proteins and 46 amino acids of the middle of the protein, have been attributed to the in-frame deletion of exons 4 and 30, respectively.

A truncated Tg protein has been reported in a patient in whom exon 22 contains a premature stop codon that results in a very small Tg protein. The thyroid tissue also contains an alternative splice variant from which exon 22 was deleted.

In many patients, similar to the findings in *cog/cog* mice, the mutant Tg may not leave the endoplasmic reticulum, due to the quality control system of the cell. Therefore, very little Tg protein is actually stored in the colloid (Fig. 3).

VI. SERUM THYROGLOBULIN MEASUREMENTS IN THE MANAGEMENT OF THYROID CANCER

Thyroglobulin is a glycoprotein that is produced only by normal or neoplastic thyroid follicular cells. Most differentiated thyroid carcinomas secrete Tg. Patients with lung and bone metastases have the highest serum Tg concentrations, whereas those with metastases in lymph nodes may have only modest elevations of serum Tg. Medullary and anaplastic carcinomas do not secrete Tg, whereas Hürthle cell carcinoma, a variant of follicular carcinoma, secretes Tg but does not concentrate radioiodine.

Serum Tg should not be detectable in patients who have undergone total thyroidectomy followed by radioiodine ablation and its detection in such patients signifies the presence of persistent or recurrent disease.

Good thyroglobulin assays can detect concentrations as low as 1 ng/ml. The results, however, can be artifactually altered by the presence of serum anti-thyroglobulin antibodies, which are found in approximately 15% of patients with thyroid carcinoma. Tests for these antibodies should always be performed when serum thyroglobulin is measured, but the extent to which the presence of the antibodies alters the results of serum Tg assays depends on whether a radioimmunoassay (less affected) or an immunoradiometric assay (more affected) is performed.

The production of thyroglobulin in both normal and neoplastic thyroid tissue is in part dependent on TSH. Interpretation of the serum Tg concentrations should take into account the serum TSH value, as well as the presence or absence of thyroid remnants.

If the serum Tg level is detectable during L-T4 suppressive treatment, it will increase after the treatment is withdrawn, indicating that thyroid remnant or neoplastic tissue is actively producing and releasing thyroglobulin under the stimulation of endogenous TSH.

The serum thyroglobulin concentration is an excellent prognostic indicator. Patients with undetectable serum Tg concentrations after total thyroidectomy and radioiodine ablation and under L-T4 suppressive therapy are free of the disease (Fig. 4). Conversely, 80% of patients with serum thyroglobulin concentrations that are higher than 10 ng/ml during L-T4 treatment and higher than 40 ng/ml after withdrawal of L-T4 treatment have detectable foci of radioiodine uptake in the neck or bone/lung metastases (Fig. 4).

Patient 1, as shown in Fig. 4, developed a serum Tg that was close to 1 ng/ml by the end of the first postoperative year and subsequently had no recurrences during 15 years of follow-up. In contrast, patient 2 never had a serum Tg below 1 ng/ml despite a total thyroidectomy and radioiodine ablation. After approximately 5 years, this patient developed a clinically evident recurrence despite negative radioiodine scans and died of the disease 10 years later.

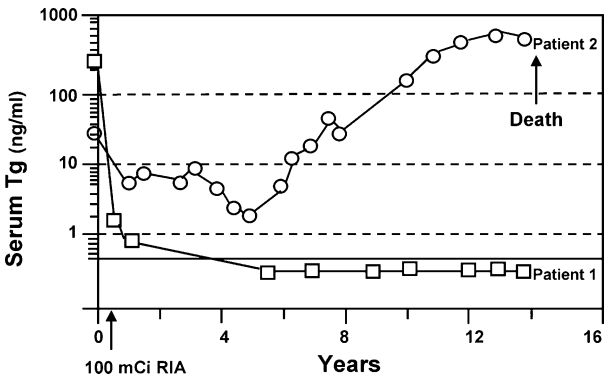

FIGURE 4 Serum Tg concentrations during L-T4 suppressive therapy in two patients. Patient 1 consistently had serum Tg levels below 1 ng/ml, whereas Patient 2 had elevated serum Tg values despite negative RAI scans. This patient developed clinically evident distant metastases. Modified from Spencer, C. A. (1998). Detection of residual and recurrent thyroid cancer by serum thyroglobulin measurement. American Thyroid Association 70th Annual Meeting, with permission.

In conclusion, it should be remembered that measurement of Tg in serum is technically challenging and it is difficult to compare serum Tg obtained by different methods. The clinical interpretation of serum Tg results should be made relative to two main factors that influence serum Tg concentrations: the mass of differentiated thyroid tissue present and the level of serum TSH and TSH receptor stimulation. Therefore, changes in the serum Tg levels during TSH suppression by L-T4 are a good indicative sign of the TSH sensitivity of the tumor and may indicate the potential efficiency of TSH suppression therapy.

Finally, the ability to stimulate serum Tg with recombinant human TSH during thyroxine suppression and to measure Tg mRNA from peripheral blood holds promise for improvement in the management of thyroid cancer patients over the next decade.

VII. SUMMARY

The integrity of the Tg protein structure is essential for adequate synthesis of thyroid hormone. Also, a large supply of iodine and of thyroid hormone is stored in the Tg molecule and is available for secretion on demand.

Mutations in the Tg gene or hyposialylated Tg due to defective sialyltransferase activity cause a structurally defective protein and severely impair the functional ability of Tg. Abnormalities in the synthesis of Tg have been described in both animals and human. Hereditary congenital goiter with or without hypothyroidism is the phenotypic major clinical finding in these species. Affected animals include sheep, cattle, bongo antelope, goats, and mice. The inheritance mode is autosomal recessive. In most animal studies, structurally abnormal Tg is present. The molecular basis for the defective Tg synthesis is attributable to a nonsense mutation in exon 9 (Afrikander cattle) and in exon 8 (Dutch goats).

In human, defective Tg synthesis has been reported in 113 patients and frequently more than one sibling is affected in a given generation. Characteristically, these patients exhibit hereditary congenital goiter with relatively low Tg levels that do not increase after stimulation with bovine TSH. High PBI concentrations with low serum T_4 values indicate the presence in serum of iodinated proteins (mainly iodoalbumin). Also, iodinated peptides are frequently excreted into the urine. Tissue studies confirm that there is no normal Tg peak on gel filtration and virtually no immunoassayable Tg in the tissue extracts.

The described mutations in the Tg gene include deletions of entire exons (exon 4 and exon 30) and point mutations with a premature stop codon generating a very truncated Tg protein. The mutant Tg protein may be functional (generating T_3 and T_4) in the constant presence of excess iodine. Many of the mutant Tg proteins are retained in the endoplasmic reticulum system of the cell and do not reach the follicular lumen (colloid).

Serum Tg measurements have greatly facilitated the clinical management of patients with differentiated thyroid cancer. The interpretation of any given Tg value requires the careful synthesis of all pertinent clinical and laboratory data available to the clinician. For instance, Tg autoantibodies remain a significant obstacle to the clinical use of Tg assays, although their presence may be indicative of persistent or residual metastatic disease. Finally, the ability to stimulate serum Tg with recombinant human TSH during L-T4 suppression and to measure Tg mRNA from peripheral blood holds promise for the management of thyroid cancer patients.

Glossary

allele Variant form of a gene at a specific locus.
autosomes A term for any chromosome other than the X or Y sex chromosome.
base pair Two nucleotides located on complementary strands of DNA and paired by hydrogen bonds.
cDNA (complementary DNA) DNA strand created *in vitro* by reverse transcription of a messenger RNA molecule.
chaperone A protein that assists in the correct folding (and assembly) of another protein.
codon Sequence of three nucleotides that encodes a particular amino acid or signals the initiation or termination of protein synthesis.
deletion Mutation that results in the removal of a sequence of DNA from a chromosome.
endocytosis Process by which extracellular material is transported into a cell, forming membrane-bound vesicles within the cytoplasm.
endonuclease Enzyme that cleaves a nucleotide chain.
endoplasmic reticulum Cellular organelle consisting of sheets of membranes; it functions in the synthesis of lipids and membrane proteins.
exon Portion of a gene that encodes a protein sequence or a specific part of a protein.
frameshift mutation Change in the DNA sequence that occurs by insertion or deletion of some number of nucleotides that is not a multiple of 3, thus altering the reading frame for protein translation.
gene Specific sequence of DNA at a particular chromosomal location; it codes for a specific protein.
heterozygote Organism with two different alleles at a particular locus.
homozygote Organism with the same alleles at a particular locus.
intron Noncoding segment of a gene that is transcribed into RNA but is spliced out before translation occurs.
linkage The association between two genes that are located near each other on the same chromosome and that as a result tend to be inherited together.
missense mutation Change in the DNA sequence that alters a codon so that it codes for a different amino acid.
mutation Change in the DNA sequence of a gene.
nonsense mutation Change in the DNA sequence that results in a codon that specifies an amino acid being replaced by a stop codon (codon that terminates protein synthesis).
oncogene Gene that can cause or contribute to cancerous growth or other unregulated cell proliferation.
PCR (polymerase chain reaction) Laboratory technique for exponentially amplifying the number of copies of a short segment of DNA.
point mutation Change in one nucleotide in a DNA molecule.
recessive allele Allele that is not expressed in the phenotype of a heterozygote, due to the presence of the dominant allele.
somatic mutation Change in the DNA sequence of any cell in an organism other than a germ cell; it cannot be inherited by the organism's offspring.

Thyroid and Reproduction

CHRISTOPHER LONGCOPE
University of Massachusetts Medical School

Thyroid hormones appear to have some effects on male and female reproductive capacities. Thyroid hormone receptors found on cells of reproductive tissues in both sexes are involved in activation of steroid hormones. Disorders of the thyroid gland are common in patient populations, and thus it is important to understand the impact thyroid dysfunction my have on sexual development and function.

I. THYROID HORMONE ACTION ON THE GONADS

Although much of the work on the effects of thyroid hormone at the tissue level has been carried out in animals, the results appear to be applicable to humans. The following discussions present the known effects of thyroid hormones on the reproductive axis in men and women.

A. Testis

Because the testis is stimulated by both luteinizing hormone (LH) and follicle-stimulating hormone (FSH), thyroid hormone effects on the pituitary, the source of LH and FSH, can result in changes in testicular function. In rats, both thyroid hormone administration and thyroidectomy result in decreases in concentrations of circulating LH and FSH. In the testis, thyroid hormone has been reported to increase LH receptors on Leydig cells initially, but with continued exposure there is a decrease in receptor number. Thyroid hormone appears to be active in the developing testis but to play a lesser role on the adult testis. Receptors for thyroid hormones, primarily TRα1 and TRα2, have been identified in prepubertal testes; primarily in the Sertoli and germ cells. Acting mainly through TRα1, thyroid hormone increases differentiation of the Sertoli cells and inhibits their proliferation. Similarly, thyroid hormone increases differentiation of Leydig cells from mesenchymal precursor cells. In adult testis, thyroid hormone has an acute effect, increasing steroid synthesis and enhancing steroidogenic acute regulatory protein (StAR) function. However, continued exposure to thyroid hormone results in decreases in both end points. Thyroid hormone also decreases aromatization in Sertoli cells. With maturation through puberty, both TRα1 and TRα2 decline in number; however, the decline appears to be much greater for TRα1 than TRα2, thus the ratio of TRα2/TRα1 increases. Because TRα2 may inhibit the action of TRα1, the fact that it is at a higher level than TRα1 may explain why thyroid hormone has less effect on the adult testis, compared to the prepubertal testis. However, male mice lacking both TRα1 and TRβ2 are fertile. Although some individuals with thyroid dysfunction may have problems related to reproduction, the presence of thyroid hormone does not appear to be absolutely necessary for male reproductive function.

B. Ovary

Thyroid hormone acts to decrease circulating levels of LH and to synergize with FSH to increase differentiation of granulosa cells. It is not clear that ovarian development is critically dependent on normal thyroid hormone levels. Thyroid hormone receptors TRα1 and TRβ1 are present in human and animal granulosa

and stromal cells. Female mice lacking either TRα1 or TRβ are fertile, but those lacking both TRα1 and TRβ1 have markedly reduced fertility. Thus, it would appear that thyroid hormones are more important for reproduction processes in females, as opposed to males. A lack of thyroid hormone has been associated with the development of polycystic ovaries in rodents. Granulosa cell aromatase activity is inhibited by excess thyroid hormone, although progesterone synthesis is increased. Thyroid hormone not only has a direct effect on ovarian steroidogenesis but also augments action of gonadotropins in steroid synthesis. Thyroid hormones are important for normal ovulation and normal steroidogenesis.

Studies have indicated that triiodothyronine (T3) decreases estradiol secretion in both medium and large follicles but increases progesterone synthesis in medium follicles and decreases progesterone synthesis in large follicles. T3 also stimulates 3β-hydroxysteroid dehydrogenase activity in the pig corpus luteum. The development of hypothyroidism in prepubertal rats results in increased proliferation of granulosa cells but inhibition of differentiation. No copora lutea are noted in the ovaries of hypothyroid rats. Receptors for thyroid hormone have been noted in the endometrium and excess thyroid hormone in mice may cause a thickened endometrium. Thyroxine (T4) has been noted to decrease estradiol uptake by the rat uterus, but thyrotoxicosis in rats results in a decreased response to estrogen in the uterus.

II. CLINICAL ASPECTS OF THYROID DYSFUNCTION

A. Hypothyroidism

1. Males

Hypothyroidism during pregnancy may lead to the condition known as cretinism. Hypothyroidism does not appear to interfere with gonadal development in the male fetus, however, and cretins usually have a normal reproductive tract. As a reflection of the role of thyroid hormone in stimulating the differentiation of Sertoli cells, hypothyroidism in early life results in an increased number of Sertoli cells and an accordingly enlarged testis. Leydig cells may also be increased in number. Thus, hypothyroidism occurring in prepubertal boys may be associated with enlarged testis and precocious pseudopuberty. True puberty will occur in these individuals, however, and they will be capable of normal reproduction. Prepubertal hypothyroidism is more commonly associated with delayed sexual maturation.

Hypothyroidism in adults may be associated with defects in spermatogenesis and fertility, but this is not a universal phenomenon and many hypothyroid men will be fertile. In part, this is a manifestation of the degree of hypothyroidism. Hypothyroidism may alter the pituitary responsiveness to gonadotropin-releasing hormone (GnRH), resulting in lower levels of LH and a decrease in levels of circulating testosterone. In addition, hypothyroidism can be associated with hyperprolactinemia, which can be associated with hypogonadism.

2. Females

Perhaps because thyroid dysfunction is more common in women than in men, there have been more studies of hypothyroidism in females. Female cretins generally have normally developed reproductive tracts at birth. Hypothyroidism in prepubertal girls may cause precocious pseudopuberty with galactorrhea, caused by an increase in prolactin, and vaginal bleeding as a result of increased ovarian estrogen secretion, which stimulates the endometrium. The exact mechanisms are uncertain, but these conditions may be due to excess pituitary secretion of thyroid-stimulating hormone (TSH) and gonadotropins. A more common result of hypothyroidism in girls is delayed menarche and sexual maturation.

In postpubertal women, hypothyroidism is often associated with menstrual dysfunction, menometrorrhagia (irregular menstrual cycle) being the commonest. However, the incidence of menstrual irregularities appears to be less common now than previously. Earlier studies reported that 60–80% of hypothyroid women had menstrual abnormalities as compared to only 23% in more recent studies. The commonest symptom is menometrorrhagia in most studies. Anovulation is frequently present and endometrial biopsies often are out of phase. Paradoxically, hypothyroid women taking oral contraceptives may report an absence of withdrawal bleeding. LH and FSH levels are often low and, although this may be a direct result of low thyroid hormone levels, prolactin levels are often elevated and may result in hypogonadism.

B. Hyperthyroidism

1. Males

Excess thyroid hormone in prepubertal males may result in early maturation; a marked excess of thyroid hormone may cause a decrease in testis volume and an impairment of sexual development associated with low levels of LH.

In adults, increased levels of thyroid hormone result in an increase in circulating levels of sex hormone-binding globulin (SHBG) and an increase in circulating levels of testosterone and estradiol. Free testosterone levels generally remain within the normal range but bioavailability may be decreased. The increase in estrogen levels can be sufficient to cause gynecomastia. An increase in LH levels may occur; but this is not a universal finding. In males with thyrotoxicosis, fertility may be decreased because of low sperm counts and alterations in sperm motility. Receptors for T3 have been found in rat epididymis and these may play a role in the sperm abnormalities.

2. Females

In prepubertal women, thyrotoxicosis can result in delayed sexual maturity, but women with polycystic fibrous dysplasia (McCurre–Albright syndrome) may have associated precocious puberty and thyrotoxicosis. In adult women, menstrual abnormalities are frequently noted, with oligo- or amenorrhea being common. Gonadotropin levels are increased but the ovulatory peak of LH may be absent.

III. PREGNANCY

It has been proposed that hypothyroid women rarely became pregnant, but, despite the frequency of anovulation, pregnancy in untreated hypothyroid women is not uncommon. The course of pregnancy and its eventual outcome are influenced by thyroid function, and, in turn, pregnancy has an effect on thyroid function in euthyroid women.

Pregnancy in an untreated hypothyroid woman is associated with an increased risk of spontaneous abortion, gestational hypertension, low-birth-weight infants, and congenital fetal malformations. Subclinical hypothyroidism, i.e., elevated TSH levels with borderline low T4 and T3 levels, has been reported to be associated with an increased risk for these abnormalities. The frequency of these disorders is difficult to determine because of the scattered nature of the reports, many of which involve a questionable diagnosis of hypothyroidism or the institution of appropriate treatment at the time of diagnosis.

In a normal pregnancy, the high levels of human chorionic gonadotropin (hCG) stimulate the thyroid gland and there is a small increase in thyroxine and free T4 and T3. Elevations of thyroid hormone levels in turn suppress TSH levels. As hCG levels fall, the stimulus to the thyroid decreases and TSH levels start to rise.

Thyroid hormone has been shown to increase the concentration of SHBG, but the marked increase in thyroxine-binding globulin (TBG) and SHBG that occurs in pregnancy is secondary to the increase in estrogen levels. As TBG levels rise, the levels of T4 and T3 also increase and in most normal pregnancies will be above the upper limits for normal nonpregnant women. The free T4 and free T3 levels remain within the normal limits. However, in pregnant women being treated with replacement doses of thyroid hormone, the dose will need to be increased because of the increase in TBG.

Thyrotoxicosis in pregnant women is also associated with abnormalities, and there is an increased risk of low-birth-weight infants, congenital fetal malformations, pre-eclampsia, and premature delivery. Pregnant women with thyrotoxicosis are usually treated with an antithyroid drug, although in extreme cases surgery may be indicated. Antithyroid drugs cross the placenta and can act on the fetal thyroid, resulting in a fetal goiter. Thus, the dose of the antithyroid drug should be kept at the lowest dose needed to ameliorate the thyrotoxicosis, and in many instances can be discontinued in the third trimester.

In the postpartum period, thyroiditis may develop in association with hypothyroidism or hyperthyroidism. Either condition may be transient or prolonged.

Glossary

galactorrhea Production and secretion of milk from breast tissue.

granulosa cells Line the follicle in the ovary; take up and aromatize androgens to estrogens, primarily estradiol.

gynecomastia Enlargement of the breast; usually used in reference to the male breast.

Leydig cells Present in the interstitial space of the testes; stimulated by luteinizing hormone to synthesize steroids, primarily the androgen testosterone.

Sertoli cells Line the seminiferous tubules of the testes; necessary for spermatogenesis; respond to follicle-stimulating hormone.

sex hormone-binding globulin Protein made in the liver that binds certain steroids with high affinity, making them less available for uptake by tissues compared to albumin-bound or free (bioavailable) steroids. The binding affinity of SHBG is highest for dihydrotestosterone and testosterone but less for estradiol.

Thyroid Hormone Action on the Heart and Cardiovascular System

BERND R. GLOSS
University of California, San Diego

Both hyperthyroidism and hypothyroidism are associated with changes in cardiac function. A number of genes expressed in the heart are known to be regulated by thyroid hormone. This article examines the changes in cardiac performance that are associated with changes in thyroid hormone levels and discusses thyroid hormone regulation of target gene expression in the heart.

I. INTRODUCTION

In the late 1700s, a physician named Caleb Hillier Parry described an interesting correlation that he had observed during his medical career. He noted that an enlargement of the thyroid gland coincided with an enlargement of the heart.

Since these early descriptions of the correlation between thyroid disorders and cardiac function, many detailed studies have crystallized the concept that there must be genes in the heart that are regulated by thyroid hormone and that up- or down-regulation of such genes brings about the physiological effects in the heart that are observed in a particular thyroid condition. What are the changes in cardiac physiology that are associated with elevated or lowered thyroid hormone levels?

Hyperthyroidism is associated with an elevated heart rate (tachycardia) and to a significant degree also with cardiac arrhythmias. In addition, the speed and force of cardiac contraction are both elevated and there are hemodynamic changes largely caused by a decreased arterial tone and increased venous tone. Because most of the biological actions of thyroxine are mediated by its conversion to triiodothyronine (T3), in the hyperthyroid state T3 increases heart rate (chronotropic effects), increases the force and speed

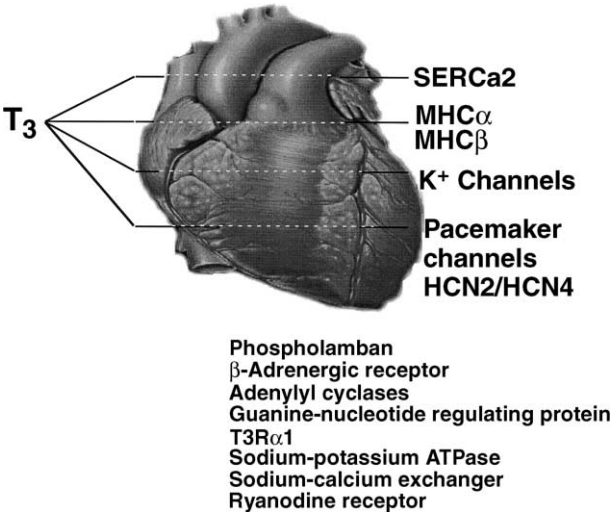

FIGURE 1 Thyroid hormone in the form of T3 regulates the cardiac genes listed in this figure. The regulatory regions of the genes on the right have been studied extensively and in some the T3-response elements have been identified and characterized.

of systolic contraction (inotropic effect), and accelerates diastolic relaxation (lusitropic effect).

Hypothyroidism, in the long run, causes a lowering in heart rate (bradycardia) and often leads to an elevated blood pressure. It is the hemodynamic changes combined with the altered metabolic functions, for example, hypercholesterolemia, that eventually manifest in a failing heart, often in conjunction with coronary artery disease.

The T3-induced changes in hyper- and hypothyroidism in cardiac target genes are best studied in rodents and will be discussed in detail in Section II. Figure 1 illustrates schematically which target genes are described in this article and lists other genes known to be influenced by thyroid hormone but that are less well studied thus far.

II. T3 TARGET GENES IN THE HEART

A. The SERCa2 Gene

Thyroid hormone regulates the expression of sarcoplasmic–endoplasmic calcium ATPase type 2a (SERCa2) in myocytes. When rodents are injected with thyroxine at a dose of 1 mg per kilogram of body weight to make them hyperthyroid, both the mRNA for the SERCa2 gene and the protein levels are elevated. Figure 2 shows a Northern blot with total ventricular RNA of mice with different thyroid status. Conversely, when rodents are made hypothyroid by treatment with 5-propyl-2-thiouracil and a low-iodine diet, the mRNA for SERCa2a as well as the protein levels are reduced by 20–30% (see Fig. 2). Interestingly, it has been noted that in heart failure patients and in rodents with failing hearts, the SERCa2 gene is down-regulated. Aortic constriction (banding) in mice and rats that leads to cardiac hypertrophy also reduces the transcription of the SERCa2 gene. Very recent findings indicated that in both the failing heart and the hypertrophied heart, the levels of thyroid hormone receptors, especially the T3Rα1 receptor, are reduced, which in turn could be the reason for the diminished transcription of the SERCa2 gene.

B. The Myosin Heavy Chain Genes

The gene for myosin heavy chain α (MHCα) encodes a large protein that is part of the thick filament in myocytes, facilitating contraction and relaxation. Transcription of the α isoform is regulated by thyroid hormone, as shown in Fig. 2, especially in mice, where hyperthyroidism leads to an elevation of

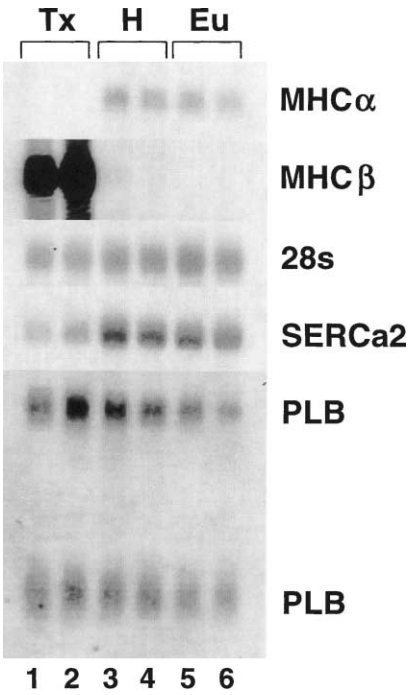

FIGURE 2 Northern blot with mouse heart total RNA. The mRNA levels in ventricles of hypothyroid (Tx, lanes 1 and 2), hyperthyroid (H, lanes 3 and 4), and euthyroid (Eu, lanes 5 and 6) animals were determined by probing the blot with radiolabeled oligonucleotides for myosin heavy chain α (MHCα), myosin heavy chain β (MHCβ), and 28S rRNA or with cDNA probes random-labeled for sarcoplasmic–endoplasmic reticulum calcium ATPase (SERCa2) and phospholamban (PLB).

transcripts and protein in cardiac myocytes. Particularly in the mouse heart, the up-regulation of MHCα expression is linked to the development of the neonatal myocyte into an adult myocyte and the onset of MHCα isoform expression coincides with an increase in circulating T3 and tetraiodothyronine levels during this developmental process.

The gene for the MHCβ isoform encodes a high-molecular-weight protein similar to MHCα and also localizes to the thick myosin filament. Transcription of the MHCβ gene is also regulated by thyroid hormone, and in mouse myocytes this T3 regulation is reversed compared with MHCα, which is nicely demonstrated in Fig. 2. In the adult mouse heart, there is very little MHCβ transcription when the animals are euthyroid; however, in hypothyroidism, the transcription of MHCβ is strongly induced, which points to a T3-dependent negative regulation of the promoter of this gene. This ligand-dependent repression of the MHCβ gene can be reestablished when the euthyroid status is restored.

It should be noted here that the expression of the myosins in general is very species specific although in mammals all members of the MHC gene family are regulated by T3. Surprisingly, however, whether T3 induces or represses the expression of a given MHC gene depends not only on the gene itself, but also on the muscle in which it is expressed. Indeed, the same gene can be induced by T3 in one muscle and repressed in another.

C. The K^+ Channel Genes

Some genes for the cardiac delayed inward rectifier potassium channels have been cloned in recent years. These channels are pores in the plasma membrane that are not always homogenous structures but are composed of two or more different proteins encoded by different genes. This makes it difficult to study the regulation of one particular gene and make a conclusion regarding the effect on a particular current that flows across the membrane using the channel pore that contains the gene product studied.

Nevertheless, a strong correlation was found between the prolonged relaxation times in hypothyroid papillary muscles of the mouse heart and reduced expression of genes that code for delayed inward rectifier channels, namely, Kv1.4, Kv4.2, and Kv4.3. Patch-clamping cardiac myocytes from hypothyroid hearts have indeed shown a reduced net current flow across the plasma membrane, which could explain the prolonged repolarization time and relaxation period observed in hypothyroid mouse papillary muscles. Conversely, in hyperthyroid animals, the Kv4.3 gene was moderately up-regulated and the Kv1.4 gene was strongly up-regulated. This could lead to a faster repolarization of the myocyte to accommodate the more rapid action-potential cycles needed for the faster heartbeat that is observed in hyperthyroidism.

The Kv1.5 gene was also investigated for its regulation by thyroid hormone. In hypothyroid rat hearts, this gene was markedly down-regulated in contrast to the hyperthyroid status when the gene was expressed at a higher level. Interestingly, these thyroid hormone-induced changes in gene expression were not found in the mouse heart, which points toward a possible species-specific action of the thyroid hormone signaling pathway on this gene, similar to the species-specific regulation of the myosin genes by thyroid hormone.

The Long QT syndrome is a dominant autosomal disease, in some cases linked to congenital deafness. It can be linked to mutations in various ion channel genes, among them the KvLQT1 gene. In hypothyroid animals, the QT interval of the electrocardiogram (ECG) is significantly prolonged and the question of whether the KvLQT1 gene was down-regulated in hypothyroidism was examined. This was not the case, however, it was found that an associated protein encoded by the minK gene was actually up-regulated in hypothyroidism and down-regulated in hyperthyroidism. The increased expression of minK could potentially interfere with the gating properties of the pore formed by KvLQT1 and thereby contribute to the prolongation of the QT interval in the ECG.

D. Pacemaker Channels

Rapid rhythmic changes in membrane potentials are most prevalent in the cells of the brain and the heart. Rhythmic pacing of neuronal networks has been implicated with the encoding and controlling of information flow in the CNS. The involvement of a membrane current that was called I_h in the brain and I_f in the heart has been fairly well characterized. Recently, the HCN gene family whose gene products constitute the I_h or I_f channel was discovered. This article focuses on the two family members that are expressed in the heart, namely, HCN2 and HCN4. Both genes are highly homologous and their encoded proteins form the entire or at least the majority of the pore-forming units that presumably carry the I_f current. The I_f current acts at the very end of the action potential in cardiac myocytes just before the membrane rapidly depolarizes and the cell contracts. It is believed that the activation of the

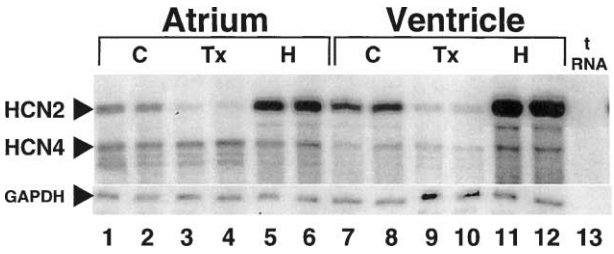

FIGURE 3 RNase protection, showing the mRNA levels for the pacemaker channels HCN2 and HCN4 in atria (lanes 1–6) and ventricles (lanes 7–12) of euthyroid (C), hypothyroid (Tx), and hyperthyroid (H) mice. In lane 13, a tRNA control was hybridized to all probes used and no specific protected signal was detected. A probe for the glyceraldehyde3-phosphate dehydrogenase (GAPDH) was used to confirm equal RNA input into each hybridization.

channel serves as a trigger for a new depolarization/repolarization cycle. These cycles are slower at a reduced heart rate and faster at an elevated heart rate. Because thyroid hormone modulates heart rate, the T3 responsiveness of the HCN2 and HCN4 genes has been investigated. Indeed, it could be demonstrated that mRNA levels for both genes are elevated in hyperthyroidism and diminished in hypothyroidism in mouse, rat, and rabbit hearts. Data from RNase protection experiments in mouse hearts are shown in Fig. 3. Because heart rate is controlled from the sinus node in the right atrium, the expression of HCN2 and HCN4 in atria and ventricles was studied and it was found that HCN2 is regulated by T3 in atria and ventricles; however, HCN4 responds to T3 only in ventricles and not in atria. The reason for this differential regulation of the pacemaker channels is currently unknown.

III. T3 EFFECTS ON MYOCYTE PHYSIOLOGY

When myocytes are isolated from adult or neonatal rat hearts and put in tissue culture, a spontaneous contraction can be observed. Addition of T3 to the culture medium increases this spontaneous beating, indicating an effect of T3 on the contractile physiology of these cells. Prolonged treatment of myocytes with T3 also increases the protein content of these cells, similar to what is seen in cardiac hypertrophy. Although not all of these T3 effects can be explained on the molecular level, the transcriptional stimulation of the SERCa2 gene by T3 and the concomitant decrease of phospholamban mRNA, as shown in Fig. 2, facilitate a more efficient shift of calcium from the cytoplasm into the sarcoplasm. The relocation of calcium to the cytoplasm to bring about a contraction via the myosin/actin apparatus works through the ryanodine channel in the sarcoplasm; interestingly, the gene for this channel is also up-regulated by T3. In this way, T3 increases the calcium transients between the sarcoplasm and the cytoplasm, which provides for more rapid contraction/relaxation cycles. To coordinate the increased calcium cycling in the myocyte with an increased contractile capability, depolarizing and repolarizing must be accelerated as well. The depolarizing trigger could potentially be shifted toward a more positive voltage by modulating the I_f current that works just before the depolarization phase of the myocyte action potential. This is schematically indicated in Fig. 4, showing a ventricular myocyte action potential diagram. An increase of mRNA for HCN2 and HCN4 by T3 could potentially bring about the voltage shift in the I_f current. In the repolarization phase of the action potential, several delayed inward rectifier potassium channels control the flow of K^+ ions into the cytoplasm. Most of the genes that encode these potassium channels have been identified and it could be shown that Kv1.4, Kv1.5, Kv4.2, Kv4.3, and the minK gene are regulated by T3. This provides a basis for accelerated and decelerated depolarization and repolarization, indirectly evident in ECGs of hyper- and hypothyroid animals.

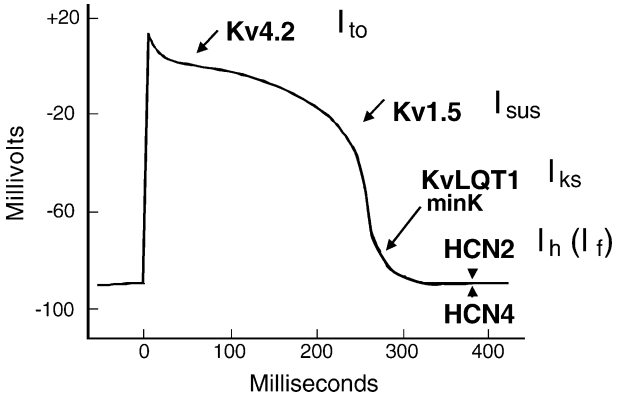

FIGURE 4 Ventricular action potential curve. During a single contraction of a ventricular myocyte, its membrane potential changes within 300 to 400 ms from a resting negative potential of 80–90 mV to a positive potential of approximately 20 mV. This is largely due to a rapid influx of sodium and calcium ions. The slow repolarization phase is characterized mainly by potassium efflux through channels that carry the I_{to}, I_{sus}, and I_{ks} currents. Pacemaker channels carry the I_h or I_f current with both sodium and potassium ions, triggering the rapid depolarization phase. I_{to}, transient outward potassium current; I_{sus}, sustained outward potassium current; I_{ks}, slow delayed rectifier potassium current.

Finally, the mechanical contraction apparatus within the cytoskeleton of the myocyte can be modified by T3. Especially in rodents, the myosin heavy chains (MHCα and MHCβ) that make up the thick filament of the contractile apparatus are thyroid hormone responsive. Transcription of MHCα is activated by T3, whereas transcription of MHCβ is repressed. In the mouse, this leads to an almost complete myosin isoform switch in hypo- and hyperthyroidism. Myosin V3 contains only MHCβ and myosin V1 is composed of two molecules of MHCα. In hypothyroidism, the V3 form, which hydrolyzes ATP slowly and therefore causes a slower contraction, dominates. In contrast, euthyroid and hyperthyroid mouse hearts contain the fast ATP-hydrolyzing V1 myosin that facilitates a rapid contraction.

Taken together, these findings indicate that thyroid hormone regulation of gene expression links the calcium pumps, ion channels, and myosins with one another for a coordinated faster performance or slower performance in the hyperthyroid heart and hypothyroid heart, respectively.

IV. TARGET GENE PROMOTERS

The most extensively studied promoters are those of the myosin heavy chain genes and the promoter of the rat SERCa2 gene. The MHCα promoter contains a complex arrangement of transcription factor-binding sites; these include the classical TATA-box and CAAT-box, a muscle enhancer factor 2 (MEF2)-binding site, a brain factor 2 (BF2) site, and a PNR (pannier gene encoded GATA transcription factor) element that binds two Ets factors as well as a thyroid hormone response element (TRE) with the consensus sequence 5′-AGGTGAcaggAGGACA-3′. Further upstream of the transcription start site at approximately −1.9 kb, a DNase I hypersensitive site that contained a conserved GATA-binding factor motif was found.

The rat and mouse MHCβ promoter is very strongly repressed by T3; a transferable negative regulatory element has not yet been found but several hexamer half-sites close to the transcription start site have been identified. It has also been hypothesized that the promoter could be T3 inhibited by a mechanism proposed for negative regulation by the glucocorticoid and retinoic acid receptors. In these models, the ligand-bound receptor molecules interact with positive-acting transcription factors (presumably off DNA), preventing them from transactivating their target gene. Among the factors proposed to bind to the MHCβ promoter within 300 bp upstream of the transcription start site are TFIID (TATA box binding factor IID)-binding TATA-box, MyoD (muscle gene-transactivating helix-loop-helix factor), NFe (tissue specific nuclear factor), SP1 (Simian-virus 40 protein 1), M-CAT (muscle specific TEF), and AP5/GT-II (TEF-I binding element), as well as other binding sites that are shared between many muscle specific genes. Which of these factors could be inhibited by the ligand-bound T3 receptor is currently not known.

The rat SERCa2 promoter has been examined also. T3 responsiveness lies within 560 bp upstream of the transcription start site, and three TREs have been identified. All three TREs are needed for full activation or repression by non—ligand-bound T3R, but each TRE has a different half-site configuration. TRE1 is a direct repeat spaced by 4 nucleotides (DR + 4), TRE2 is an inverted palindrome spaced by 4 nucleotides (IP + 4), and TRE3 is configured as an IP + 6. Interestingly, a novel thyromimetic (GC-1) stimulates TRE1 but represses TRE2 and TRE3 when each TRE is isolated by pairwise mutation of the other two in the natural promoter context. The TREs of the rat SERCa2 promoter can potentially interact with the other transcription factors that bind to the promoter. One such interaction has been demonstrated with the MEF2a factor potentiating the T3 stimulation in a T3Rα isoform-specific manner. Other factors that could bind to the region within 560 bp upstream of the transcription start site are the TFIID-binding TATA-box, C/EBP (CCAAT/enhancer binding protein), SP1, and an E-box-binding helix-loop-helix protein.

Very recently, the promoters of the T3-regulated delayed inward rectifier potassium channel Kv4.2 and the pacemaker channels HCN2 and HCN4 were cloned. The Kv4.2 region linked to a CAT reporter gene responded significantly to T3 stimulation in neonatal rat myocyte transfections. The promoter regions of HCN2 and HCN4 have not been characterized fully and the HCN2 region failed to respond to T3 when linked to a reporter gene, which raises the possibility that other mechanisms besides transcriptional regulation may operate on this gene to elevate and diminish mRNA levels in hyper- and hypothyroidism, respectively.

V. T3 RECEPTOR EXPRESSION IN THE HEART

The above-described changes in nuclear gene regulation are likely to be mediated by the nuclear hormone receptors that bind T3. The ligand-binding isoforms that are found in the heart are the T3Rα1 and T3Rβ1 isoforms. Expression of T3Rα1 dominates in

the heart with the mRNA levels of T3Rβ1 approximately 30% of those for T3Rα1. This is shown in an RNase protection experiment with total RNA from mouse hearts in Fig. 5. In the liver, for example, this ratio in inverted with the T3Rα1 mRNA levels approximately 10% of the T3Rβ1 mRNA levels. Which factors promote enhanced expression of the T3Rα gene in the heart and a lower ratio of expression of the T3Rβ gene is currently unknown.

Much has been learned from the knockout of the α or β isoforms of the thyroid hormone receptors in the mouse. Lack of T3Rα expression in the heart led to bradycardia and a "hypothyroid-like" gene expression profile. In contrast, lack of T3Rβ expression in the heart had virtually no phenotype when the animals were brought to a euthyroid status, except for the notion that T3Rα expression was reduced by nearly 40% in T3Rβ knockout animals (see Fig. 5). Interestingly, homozygous mutation of the ligand-binding domain of T3Rβ in the mouse to generate a dominant negative receptor significantly disturbed T3Rα action. This shows that T3Rβ is obviously expressed in the same cardiac cells as T3Rα. The question arises as to why T3Rβ cannot compensate for the lack of T3Rα expression. Do certain promoters of cardiac genes respond preferentially to T3Rα, and if so, what are the discriminating elements in such promoters? Further studies are necessary to understand the contribution of each receptor isoform in the heart, for example, analyzing the cardiac phenotype and gene expression in receptor double-knockout mice. Rescue experiments of knockout mice with specific T3R isoforms in a cardiac gene therapy experiment will also reveal what each isoform can contribute to cardiac function. Finally, the temporal and spatial disruption of either T3R isoform in the heart will enable a refined analysis of the cardiac phenotype in inherently euthyroid animals.

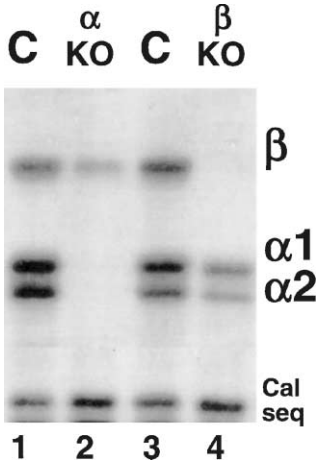

FIGURE 5 RNase protection, showing the mRNA levels for thyroid hormone receptors β (β1 and β2), α1 (α1), and α2 (α2) in mouse ventricles. Controls (C, lanes 1 and 3) were hybridized with RNA from isogenic wild-type animals of the respective mouse strain that was lacking either thyroid hormone receptor α (lane 2) or thyroid hormone receptor β (lane 4), designated αKO and βKO, respectively. To control for equal RNA input in each lane, a probe for calsequestrin (Calseq) was used.

VI. SUMMARY

Thyroid status in humans and in animals influences cardiac output. This article has attempted to describe the known molecular targets in the heart that T3 reaches to alter cardiac performance. The genes that are regulated by T3 contribute to the lusitropic effect, for example, the potassium channels Kv1.4, Kv1.5, Kv4.2, Kv4.3, and minK. Genes that contribute to the inotropic effect are, on the one hand, calcium pumps and channels like SERCa2a, phospholamban, ryanodine channel and the sodium–calcium exchanger and, on the other hand, the myosin heavy chains. The chronotropic effect of T3 probably has several components including the pacemaker channels that are up-regulated in hyperthyroid tachycardia and down-regulated in hypothyroid bradycardia. But there are also reports that the β-adrenergic receptor, adenylyl cyclase, and the T3Rα gene itself are regulated by T3, which may contribute to the chronotropic effect. Some of the target gene promoters have been characterized very well and contain distinct thyroid hormone-response elements, as well as muscle-specific elements. Other promoters still lack TREs and there may be other mechanisms by which T3 regulates the expression of those genes. Two isoforms of the thyroid hormone-binding nuclear receptors are expressed in the heart, T3Rα1 and T3Rβ1. Both seem to be present in the same myocytes but subserve distinct functions that are currently under intense investigation.

Glossary

K^+ channels Multisubunit structures located in the plasma membrane that gate the flux of potassium into the cell. These include the so-called delayed inward rectifier channels that open to repolarize the cell after a contraction. Some of the genes for individual subunits are regulated by thyroid hormone.

myosins Proteins that are part of the contractile fibers found in myocytes. The genes for myosin heavy chain α

(MHCα) and myosin heavy chain β (MHCβ) are regulated by thyroid hormone in some species. In rodents, MHCα is predominant in the adult heart and MHCβ can be strongly induced by hypothyroidism.

pacemaker channels The genes for these channels were only recently cloned and this article focuses on those that are expressed in the heart and regulated by thyroid hormone, namely, the HCN2 and HCN4 genes. A characteristic of the I_f conductance constituted by the gene products of HCN2 and HCN4 is that both sodium and potassium ions are conducted through the pore. Furthermore, gating is regulated by cyclic AMP and hyperpolarization of the cell membrane.

phospholamban A small 6 kDa protein that associates with SERCa2a and regulates the calcium pump activity dependent on the phospholamban phosphorylation status.

SERCa2a Sarcoplasmic-endoplasmic calcium ATPase type 2a is found primarily in the myocytes of the heart. The approximately 100 kDa protein is embedded in the sarcoplasmic membrane and transports calcium from the cytoplasm into the sarcoplasm while hydrolyzing ATP to ADP. The expression of the gene coding for SERCa2a is regulated by thyroid hormone.

Thyroid Hormone Action on the Skeleton and Growth

GRAHAM R. WILLIAMS

Imperial College London, Hammersmith Campus, London

The skeleton is a specialized and complex organ that remodels its structure in response to systemic, local, and physical signals. It is highly vascularized, contains the hematopoietic bone marrow, and provides structural support and a reserve of calcium and phosphate ions for the maintenance of mineral homeostasis. Bone is formed either by direct transformation and ossification of condensed mesenchyme (intramembranous ossification) or by replacement of a cartilage scaffold with calcified bone (endochondral ossification). Development and growth of the skull and closure of its sutures result from intramembranous ossification. Linear growth, fracture repair, and bone remodeling, together with development of the remaining skeleton, result from endochondral ossification. A considerable number of clinical, epidemiological, and basic scientific studies indicate that thyroid hormones play a key role in skeletal development. They are essential for normal linear growth and are important regulators of bone turnover and the maintenance of bone mass.

I. CLINICAL AND EPIDEMIOLOGICAL OBSERVATIONS

Hypothyroidism in childhood causes growth arrest together with delayed bone age, epiphyseal dysgenesis, and immature body proportion. Furthermore, up to 50% of patients with the phenotypically variable syndrome of resistance to thyroid hormone (RTH), caused by mutant thyroid hormone receptor (TR) β proteins, suffer from growth retardation and developmental abnormalities of bone that may reflect tissue hypothyroidism. Thyroxine (T4) replacement therapy in hypothyroid children induces rapid catch-up growth that may be incomplete because bone age advances faster than height, leading to early epiphyseal growth plate fusion and speculation that skeletal responses to thyroid hormones are exaggerated in hypothyroidism. Accordingly, childhood thyrotoxicosis causes accelerated growth and advanced bone age, which may lead to premature growth plate closure and short stature. Advanced intramembranous ossification may also result in craniosynostosis in thyrotoxic children due to premature closure of the skull sutures. Indeed, stimulation of mineral apposition and osteogenesis, resulting in premature narrowing of the skull sutures, has been documented in a hyperthyroid rat model.

Thyrotoxicosis in adults results in increased bone turnover and net bone loss and causes osteopenia and fracture in patients with established disease. Thus, a series of studies has shown that thyrotoxicosis is associated with reduced bone density and an increased risk of osteoporotic hip fracture. Postmenopausal women are particularly at risk when confounding factors including age and sex are accounted for. Such findings have led to the contentious issue regarding whether treatment of hypothyroid or thyroid cancer patients with supraphysiological doses of T4 is also associated with osteoporosis and increased fracture risk. The current consensus suggests that overzealous treatment with T4, leading to suppression of circulating thyrotropin (TSH) concentrations, is probably associated with increased fracture risk, particularly in postmenopausal women and in those with a previous history of thyrotoxicosis.

II. THYROID HORMONE RECEPTORS

The complex actions of thyroid hormone (3,5,3′-L-triiodothyronine, T3) are mediated by TR proteins, which function as hormone-inducible transcription factors that regulate the expression of target genes and are members of the superfamily of hormone and orphan nuclear receptors. The TRα and TRβ genes are conserved in vertebrates. TRα encodes the widely expressed α1 and α2 C-terminal variants: TRα1 is a functional receptor that binds T3 and DNA, whereas TRα2 fails to bind T3 and is a weak antagonist *in vitro*, although its physiological role is unknown. A novel promoter in intron 7 of TRα generates the truncated Δα1 and Δα2 variants that act as repressors *in vitro* and have been implicated in intestinal development. TRβ encodes the functional β1, β2 isoforms and a new β3 N-terminal variant was recently identified in rat. TRβ2 expression is restricted to pituitary and hypothalamus, where it primarily regulates the activity of the hypothalamo–pituitary–thyroid feedback loop, but β1 and β3 are expressed widely. A truncated rat TRΔβ3 isoform is also expressed widely and acts as a potent antagonist in vitro, but its physiological significance is not yet known.

TRs are located at sites of intramembranous and endochondral bone formation in a variety of species; TRα1, TRα2, and TRβ1 mRNAs and proteins are expressed in osteoblasts and osteocytes and in reserve and proliferative zone epiphyseal growth plate chondrocytes. Functional TRs have also been identified in primary cultured osteoblasts and growth plate chondrocytes and in immortalized osteoblastic and chondrogenic cells from several species. Recent reports suggest that skeletal osteoblastic responses to T3 may vary according to anatomical site, although the mechanisms responsible for these findings are unknown. Thyroid hormones also stimulate osteoclastic bone resorption, but this effect is likely to be mediated by T3-responsive osteoblasts, as osteoclasts do not express functional TRs.

III. THE EPIPHYSEAL GROWTH PLATE

The epiphyses and metaphyses of long bones originate from independent ossification centers and are separated by a growth plate, which becomes ossified after puberty when epiphyseal fusion occurs (Fig. 1). In the normal growth plate, reserve zone progenitor cells lie immediately below the epiphysis and mature chondrocytes are located above the primary spongiosum, which communicates with the bone marrow. Immature reserve zone cells undergo clonal expansion to form organized columns in the proliferative zone, where they secrete a cartilage matrix containing type II collagen and proteoglycans. The largest proliferative cells differentiate to form hypertrophic chondrocytes, which secrete type X collagen, enlarge by five times their volume, and eventually undergo apoptosis to leave a cartilage scaffold. New blood

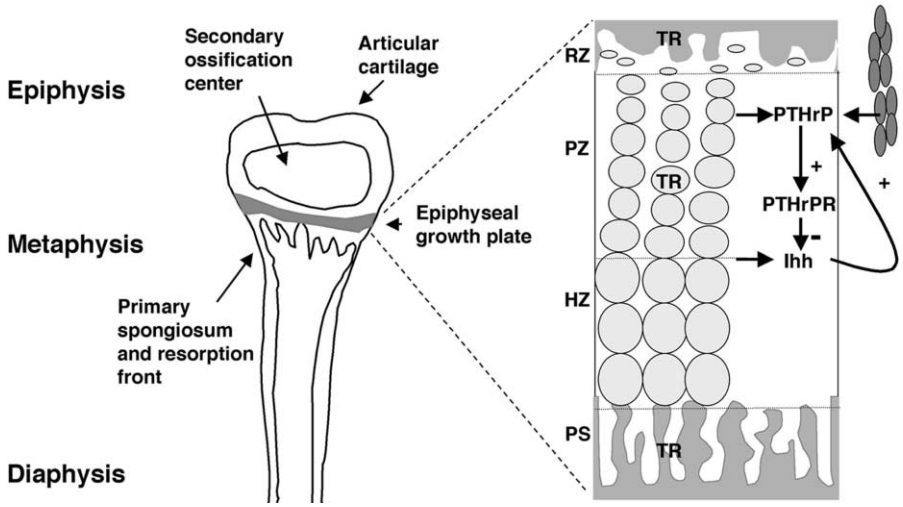

FIGURE 1 Long bone showing the location of the epiphyseal growth plate and an enlarged view to show the organization of chondrocytes, the localized expression of thyroid hormone receptors, and the feedback loop that controls the pace of chondrocyte proliferation. RZ, reserve zone; PZ, proliferative zone; HZ, hypertrophic zone; PS, primary spongiosum; TR, thyroid receptor; Ihh, Indian hedgehog; PTHrP, parathyroid hormone-related peptide; PTHrPR, PTHrP receptor.

vessels enter from the primary spongiosum and osteoblasts invade the growth plate to lay down trabecular bone on this cartilage template and complete the endochondral ossification process. Recent experiments have established that the pace of chondrocyte differentiation and bone formation is regulated by a negative feedback loop involving the paracrine factors Indian hedgehog (Ihh) and parathyroid hormone-related peptide (PTHrP). Ihh is secreted by pre-hypertrophic chondrocytes and stimulates PTHrP production from the peri-articular region of the epiphysis during bone development. PTHrP acts on PTHrP-receptor-expressing pre-hypertrophic chondrocytes to maintain cell proliferation, reduce Ihh production, and complete a feedback loop in which PTHrP exerts a negative signal that inhibits hypertrophic chondrocyte differentiation and delays bone formation (Fig. 1).

IV. THYROID HORMONE EFFECTS ON CHONDROCYTES AND GROWTH

Hypothyroidism results in gross abnormalities of growth plate structure with disorganized proliferating chondrocyte columns, abnormal cartilage matrix, reduced hypertrophic chondrocyte differentiation, and impaired vascular invasion of the growth plate at the primary spongiosum (Fig. 2). Alterations in PTHrP and PTHrP receptor mRNA expression in growth plate chondrocytes were identified in hypothyroid and thyrotoxic animals, suggesting that the setpoint of the critical Ihh/PTHrP feedback loop is sensitive to thyroid status. Whereas the majority of these effects probably result from direct actions of T3 in TR-expressing chondrocytes, other studies also indicate that the hypothyroid growth plate is relatively insensitive to the actions of growth hormone (GH) because of reduced local expression of insulin-like growth factor-I (IGF-I). Similar findings of delayed hypertrophic chondrocyte differentiation and impaired neovascularization of newly formed cartilage in fracture callus in hypothyroid rats reinforce the view that endochondral ossification during skeletal growth and repair requires thyroid hormones.

Until recently, the locations of T3 target cells within the growth plate were unknown. It has been shown that TRα1, TRα2, and TRβ1 proteins are expressed in reserve and proliferating zone chondrocytes but not in hypertrophic cells, suggesting that progenitor cells and proliferating chondrocytes are primary T3-target cells but that differentiated chondrocytes may lose the ability to express TRs and become unresponsive. A large body of data, in a variety of *in vitro* model systems using chondrocytes derived from several species, indicates that T3 regulates chondrocyte proliferation and the organization of proliferating chondrocyte columns, is required for terminal hypertrophic differentiation,

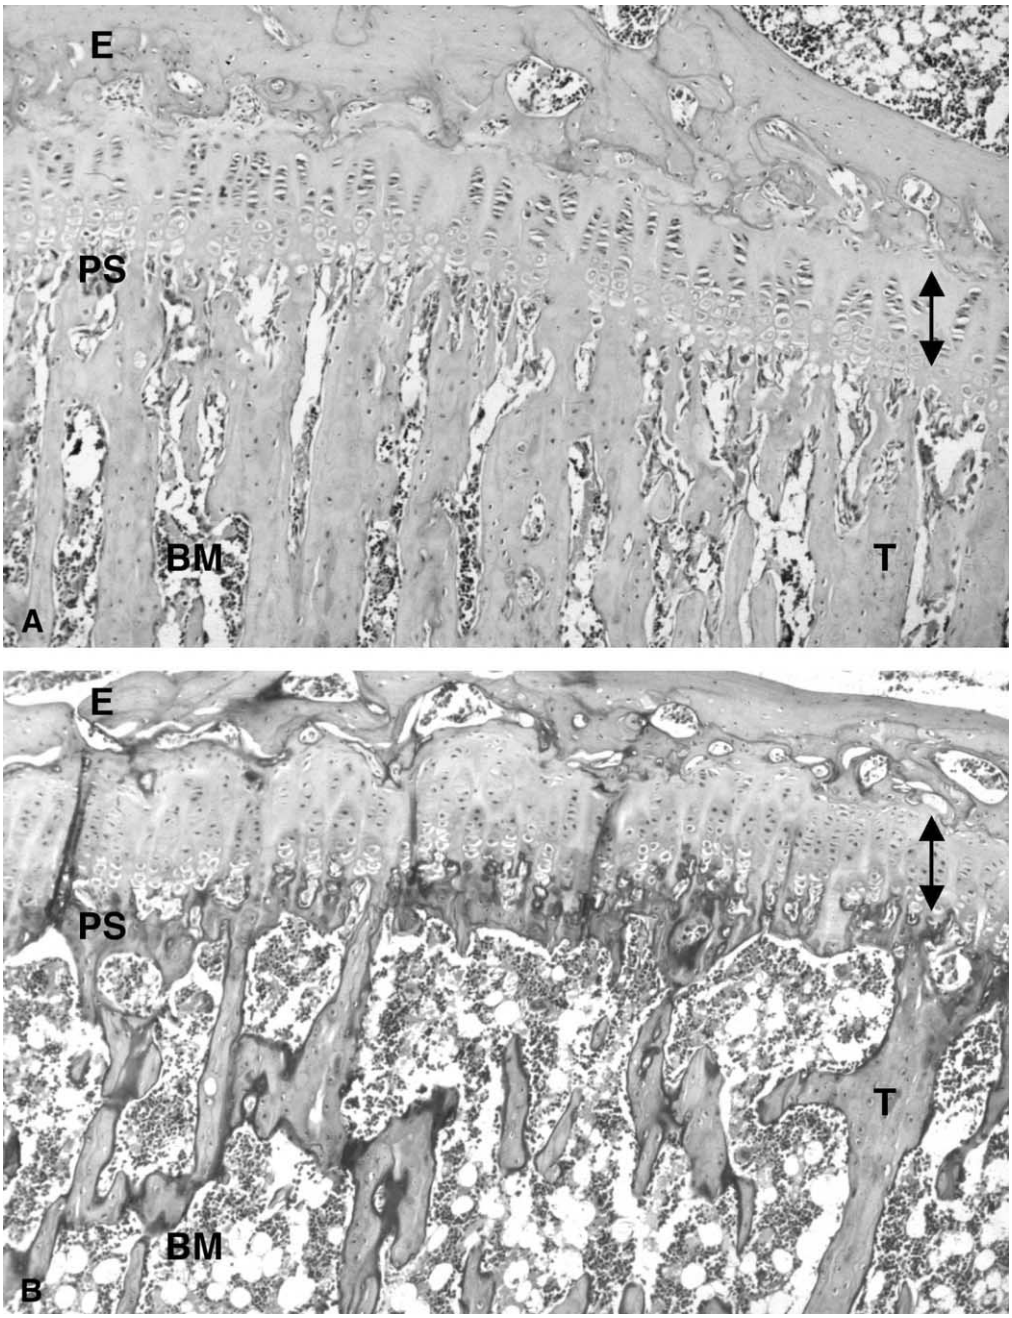

FIGURE 2 Sections of proximal tibial growth plate from 12-week-old euthyroid (A) and hypothyroid (B) rats stained with hematoxylin and eosin. The euthyroid growth plate contains organized columns of chondrocytes with neovascularization at the primary spongiosum. Longitudinal trabecular bone lies in continuity with proliferating and hypertrophic chondrocyte columns. The hypothyroid growth plate is disorganized and neovascularization is absent. Trabecular bone formation is diminished and disorganized relative to normal. E, epiphysis; PS, primary spongiosum; BM, bone marrow; T, trabecular bone; arrow delineates the growth plate.

and induces calcification of cartilage matrix. In other studies, rat tibial growth plate chondrocytes grown in primary suspension culture express TRs and maintain their differentiation potential. In this system, T3 directly inhibits clonal expansion and cell proliferation, while simultaneously promoting hypertrophic chondrocyte differentiation. Recent studies indicate that T3 might achieve this by induction of cyclin-

dependent kinase inhibitors that may arrest cell cycle progression in proliferating chondrocytes and enable terminal hypertrophic differentiation to progress.

V. GROWTH ABNORMALITIES IN TR NULL MICE

The skeletal phenotypes of TR knockout mice reinforce the view that T3 acts directly in growth plate cartilage but reveal the complexity of thyroid hormone action in bone (Table 1). Deletion of the TRβ gene does not result in growth retardation or evidence of developmental abnormalities in bone and cartilage, indicating that TRβ is not essential for skeletal development. Nevertheless, the creation of distinct mouse models with different RTH mutations in TRβ has highlighted the phenotypic variability of the human RTH syndrome as only one mouse model, harboring the severe $TR\beta^{PV}$ mutation, suffers from impaired growth.

Several TRα knockouts have been produced, in which differing products of the TRα locus were deleted, with varying effects on the skeleton and on thyroid and GH/IGF-I status. $TR\alpha1^{-/-}$ mice lack expression of TRα1 and Δα1, but TRα2, Δα2, and β are retained and skeletal development is normal. Combination of the $TR\alpha1^{-/-}$ and $\beta^{-/-}$ mutations to produce a $TR\alpha1^{-/-}$ $\beta^{-/-}$ double knockout results in growth retardation and delayed bone maturation. $TR\alpha1^{-/-}$ $\beta^{-/-}$ mice are growth hormone and IGF-I deficient; GH replacement reverses some of the growth retardation but does not influence the defective ossification, indicating that T3 exerts important direct effects on growth plate chondrocytes but mediates some of its effects on growth via GH and IGF-I.

In contrast, in $TR\alpha^{-/-}$ mice there is growth arrest after weaning and disorganization of growth plate chondrocytes with delayed cartilage mineralization and bone formation. The $TR\alpha^{-/-}$ mutation results in deletion of TRα1 and α2 but preservation of Δα1, Δα2, and TRβ. These animals become progressively hypothyroid in the postnatal period due to impaired thyroid hormone production and the skeletal phenotype can be rescued by T4 replacement, suggesting that TRβ can compensate for TRα in the growth plate in appropriate circumstances. Nevertheless, the delayed bone maturation seen in $TR\alpha^{-/-}$ mice is not further modified in mice harboring a $TR\alpha^{-/-}\beta^{-/-}$ double gene deletion, suggesting that TRβ, in contrast to TRα, is dispensable in bone.

These studies have been interpreted to suggest that the non-T3-binding variants TRα2, Δα1, and Δα2 may play important roles in bone development. Thus, mice devoid of all TRα isoforms were generated. These $TR\alpha^{0/0}$ mice display growth delay and retarded endochondral ossification with evidence of impaired hypertrophic chondrocyte differentiation and disorganized growth plate architecture. $TR\alpha^{0/0}$ mice express TRβ and maintain normal TSH concentrations with slightly reduced T4 levels, indicating mildly increased thyroid hormone sensitivity and further suggesting that TRα is functionally predominant in bone. $TR\alpha^{0/0}\beta^{-/-}$ double-mutant

TABLE 1 Genotypes and Growth Characteristics of Thyroid Hormone Receptor (TR) Null Mice

TR Knockout	Deleted TR mRNAs	Expressed TR mRNAs	Thyroid status	GH Status	Growth Retardation
$\alpha1^{-/-}$	α1, Δα1	α2, Δα2, all β isoforms	Mildly hypothyroid	Normal	−
$\alpha^{-/-}$	α1, α2	Δα1, Δα2, all β isoforms	Grossly hypothyroid	Normal	++
$\alpha^{0/0}$	All α isoforms	All β isoforms	Euthyroid[a]	Normal	+
$\beta^{-/-}$	All β isoforms	All α isoforms	RTH	Mildly deficient	−
$\beta2^{-/-}$	β2	All α isoforms, β1, β3, Δβ3	RTH	Mildly deficient	−
$\alpha1^{-/-}\beta^{-/-}$	α1, Δα1, all β isoforms	α2, Δα2	Severe RTH	GH/IGF-I[b] deficient	++
$\alpha^{-/-}\beta^{-/-}$	α1, α2, all β isoforms	Δα1, Δα2	Severe RTH	Not determined	++
$\alpha^{0/0}\beta^{-/-}$	All α isoforms, all β isoforms	None	Severe RTH	GH deficient	++

Note. GH, growth hormone; RTH, resistance to thyroid hormone; IGF-I, insulin-like growth factor-I, GH status was determined by comparison of pituitary GH mRNA expression in wild-type and mutant animals.

[a] Dynamic testing demonstrated mild increased pituitary sensitivity to thyroid hormones.

[b] GH and IFG-I serum concentrations and GH mRNA.

mice are viable and more severely growth retarded than their $TR\alpha^{0/0}$ counterparts but less so than $Pax8^{-/-}$ mice in which congenital hypothyroidism results from thyroid follicular cell agenesis. Taken together, these findings indicate that differing consequences result from thyroid hormone deficiency, in which unoccupied receptors are present, compared to TR deficiency, and suggest a physiological role for unliganded TR or non-T3-binding TR variants in bone development. They also indicate that the TRα gene is essential for skeletal development and the timing of bone mineralization.

VI. THYROID HORMONE EFFECTS ON OSTEOBLASTS, OSTEOCLASTS, AND BONE TURNOVER

Thyroid hormones activate bone-forming osteoblasts and bone-resorbing osteoclasts, but in hyperthyroidism the normally tightly coupled activities of these two cell types are dissociated, resulting in bone loss. The bone remodeling cycle begins with activation of osteoclast lineage cells, which begin to resorb bone. Osteoblasts invade the area once a certain resorption depth is reached and lay down new matrix, which is mineralized to form new bone in areas of previous resorption. The activation–resorption–formation cycle normally lasts up to 200 days and occurs at discrete sites called bone-remodeling units. Bone remodeling occurs at differing rates in trabecular and cortical bone and in differing anatomical locations. The rate at which each site undergoes remodeling is known as the activation frequency and this is a major determinant of total bone turnover. Bone resorption, matrix deposition, and mineralization times are shortened in hyperthyroidism and the activation frequency is increased. These disproportionate changes uncouple osteoblasts and osteoclasts and lead to a net bone loss of approximately 10% per remodeling cycle in hyperthyroidism.

It is clear that osteoblasts express functional TRs, which have been identified at the mRNA and protein levels, by nuclear T3-binding activity and in transient transfection studies using T3-inducible reporter genes. Although osteoblasts in primary culture and several osteoblastic cell lines respond directly to T3 *in vitro*, the specific consequences of T3 stimulation vary considerably between studies. Such differences may occur between species and depend on the degree of cellular confluence, the stage of osteoblast differentiation, the cell type, passage number, and origin, and the dose and duration of T3 treatment. Furthermore, the response of osteoblastic cells to T3 has been reported to vary according to the anatomical site from which the cultured cells originate. Thus, T3 has been shown to stimulate, inhibit, or have no effect on osteoblastic cell proliferation. A general consensus, however, indicates that osteoblast activity is stimulated by T3. T3 increases production of osteocalcin and collagen type I matrix proteins, collagenase 3, gelatinase B, tissue inhibitor of metalloproteinase-1, alkaline phosphatase, IGF-I, IGF-binding proteins 2 and 4, fibroblast growth factor receptor 1, interleukin-6, and interleukin-8 in various osteoblastic cell culture systems. Furthermore, T3 may potentiate some of the osteoblast responses to PTH by modulating the expression of PTH/PTHrP receptor. Despite the many potential T3 target genes identified in osteoblasts, little information is available regarding mechanisms by which their expression is modulated and T3 regulation in many cases may be indirect and involve other signaling pathways. In contrast to effects on the activity of mature osteoblasts, osteoblast progenitor cell differentiation is inhibited by thyroid hormones, although the effects in vitro are complex and dose-related and involve interactions with other factors including IGF-I, steroid hormones, vitamin D, cytokines, and other growth factors.

Bone resorption is stimulated by T3 in bone organ cultures by mechanisms that are unclear but certainly complex and likely to involve other systemic hormones and locally acting cytokines. There is controversy regarding whether osteoclasts express TRs, although most studies indicate they do not and co-culture experiments have revealed that osteoclastic bone resorption is stimulated by T3 only in the presence of osteoblastic cells. These findings suggest that the resorptive effects of T3 in bone are mediated via direct stimulation of TR-expressing osteoblasts, which may induce the recruitment and differentiation of osteoclast progenitor cells or increase the activity of mature osteoclasts.

Glossary

cortical bone Dense surface layer of mature compact bone.

endochondral ossification Bone formation by replacement of a preformed cartilage scaffold that occurs during skeletal development and fracture repair.

epiphyseal growth plate Specialized strip of cartilage located at the ends of long bones, in which programmed proliferation and maturation of chondrocytes result in the production of cartilage to form a template for new bone formation during linear growth.

intramembranous ossification Bone formation by direct transformation and ossification of condensed mesenchyme that occurs during development of flat bones, including the skull, mandible, scapula, and ileum.

osteoporosis A progressive systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue with a consequent increase in bone fragility and susceptibility to fracture.

primary spongiosum Region of trabecular bone forming the interface between the growth plate and bone marrow and the site for neovascularization and osteoblast invasion during endochondral ossification.

trabecular bone Interior network of organized calcified spongy bone, the space between which contains bone marrow and communicates with the marrow cavity.

Thyroid Hormone Receptor Isoforms

PAUL M. YEN

National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Maryland

Multiple isoforms of thyroid hormone receptors are expressed in a variety of tissues. Serving as transcription factors, these receptors play isoform-specific roles in regulation of hormonal activity and target gene expression. Genetic studies of the isoforms as well as their tissue expression, hormone regulation, and isoform-specific functions with respect to phenotype and transcription of target genes provide insights into mechanisms of disorders related to thyroid hormones.

I. TR ISOFORMS AND RELATED GENE PRODUCTS

Thyroid hormone receptors (TRs) are ligand-dependent transcription factors that belong to the nuclear hormone receptor superfamily. TRs and other nuclear hormone receptor family members share a similar domain organization in that they contain a central DNA-binding domain with two zinc fingers, a carboxy-terminal ligand-binding domain, and multiple transactivation domains (Fig. 1). They also bind to thyroid hormone response elements (TREs) composed of two or more hexamer sequences arranged as direct repeats or inverted repeats (separated by four and six nucleotides, respectively), typically located in the promoter region of target genes.

There are two major TR isoforms, TRα and TRβ, encoded on separate genes located on human chromosomes 17 and 3, respectively. The multiple TR isoforms have been found in tissues of amphibia, chicks, mice, rats, and humans. In mammalian species, TRα and TRβ vary from 400 to slightly over 500 amino acids in size and contain highly homologous DNA-binding and ligand-binding domains (Fig. 2). Both TR isoforms bind triiodothyronine (T3) with high affinity and mediate thyroid hormone-regulated gene expression. In positively regulated target genes, liganded TR recruits co-activators such as the steroid-related co-activator (SRC) family members and other cofactors that lead to increased histone acetylation of chromatin in the promoter of target genes (Fig. 3). This may then be followed by recruitment of another complex that contains components of the RNA polymerase II complex, which, in turn, leads to recruitment and stabilization of RNA polymerase II and enhanced transcription. In contrast, unliganded TRs bind to TREs and recruit corepressors, including the silencing mediator of retinoic acid and thyroid hormone (SMRT) receptors and the nuclear receptor corepressor (N-CoR), with histones deacetylases, which cause decreased acetylation of local chromatin and repression of transcription.

In addition to the TRs encoded by the two TR genes, TR isoforms can be produced by alternative splicing. Alternative splicing of the initial RNA transcript of the TRα gene generates two mature mRNAs, each encoding two proteins, TRα-1 and c-erbAα-2. In the rat, these proteins are identical from amino acid residue 1 to residue 370, but their respective sequences diverge markedly afterward. As a consequence of the replacement of the carboxy terminus with a 122-amino-acid sequence, c-erbAα-2 does not bind T3. Additionally, c-erbAα-2 binds TREs weakly but cannot transactivate thyroid hormone-responsive genes. It also may block TH action on certain target genes by binding to TREs and preventing TRs from regulating transcription.

The TRα gene also encodes another gene product, rev-erbA, on the opposite strand. The rev-erbA mRNA contains a 269-nucleotide stretch that is complementary to the c-erbAα-2 mRNA due to its transcription from the DNA strand opposite of that used to generate TRα-1 and c-erbAα-2. The protein product also belongs to the nuclear hormone receptor superfamily, is expressed in adipocytes and muscle cells, and can bind to TREs and retinoic acid response elements (RAREs) and repress gene transcription. However, rev-erbA should be considered an orphan receptor because its cognate ligand and function are not known. The rev-erbA receptor may be involved in regulating the splicing that generates c-erbAα-2 because increased levels of rev-erbA mRNA correlate with increased TRα-1 mRNA relative to c-erbAα-2. The rev-erbA receptor also may be involved in adipocyte differentiation.

The TRβ gene also generates two isoforms, TRβ-1 and TRβ-2. This gene contains two promoter regions that regulate the transcription of an mRNA encoding TRβ-1 or TRβ-2. One or both of the coding mRNAs are generated by selective promoter choice. The amino acid sequences of the DNA-binding, hinge region, and ligand-binding domains of these two TRβ isoforms are identical; however, the amino-terminal regions share no sequence homology. Both are bona

fide receptors in that they bind TREs and TH with high affinity and specificity and mediate TH-dependent transcription. Expression of the two TRβ isoforms may be regulated by pituitary-specific transcription factors such as Pit-1.

II. TISSUE EXPRESSION OF TR ISOFORMS

TRα-1 and TRβ-1 mRNAs and proteins are ubiquitously expressed in rat and human tissues. However, TRα-1 mRNA has highest expression in rat skeletal muscle and brown fat whereas TRβ-1 mRNA has highest expression in brain, liver, and kidney. TRβ-2 mRNA and protein have a restricted tissue expression in the anterior pituitary, hypothalamus, and developing brain and inner ear. In chicks and mice, TRβ-2 mRNA also is expressed in the developing retina. Last, a number of short forms of TRα and TRβ generated by alternative splicing of mRNA or by use of intrinsic promoters have been found in embryonic stem cells and in fetal bone cells, and may have biological significance. In particular, some of these short forms have dominant negative activity on TH-mediated transcription and may also affect intestine and bone development.

III. HORMONAL REGULATION OF TR ISOFORMS

TR mRNA regulation varies among the different isoforms. In the intact rat anterior pituitary, T3 decreases TRβ-2 mRNA, modestly decreases TRα-1 mRNA, and slightly increases rat TRβ-1 mRNA. Despite these countervailing effects, the total T3 binding decreases by 30% in the T3-treated rat pituitary. In other tissues, T3 slightly decreases TRα-1 and c-erbAα-2 mRNA, with the exception of the brain, where c-erbAα-2 levels are not changed. TRβ-1 mRNA is minimally affected in nonpituitary tissues. The hypothalamic tripeptide, thyrotropin-releasing hormone (TRH), also regulates TR mRNA expression because it decreases TRβ-2 mRNA, slightly decreases TRα-1 mRNA, and minimally affects TRβ-1 mRNA in cultured rat pituitary cells. Retinoic acid blunts the negative regulation by T3 in these cells. Additionally, in patients with nonthyroidal illness who have decreased circulating serum free T3 and tetraiodothyronine (T4) levels, TRα and TRβ mRNAs are increased in peripheral mononuclear cells and liver biopsy specimens. Thus, increased TR expression may potentially compensate for decreased circulating thyroid hormone levels in these patients.

IV. ISOFORM-SPECIFIC REGULATION OF TARGET GENES

The amino acids of each of the TR isoforms are highly homologous across mammalian species. This conservation suggests that there may be important specialized functions for each TR isoform. Recent studies have suggested that TRβ-1 may exhibit isoform-specific regulation of the TRH and myelin basic protein genes, and TRβ-2 may play important roles in the regulation of the growth hormone and thyroid-stimulating hormone β (TSHβ) gene expression in the pituitary. The differential expression of TR isoforms in various tissues (e.g., TRβ-1 is the

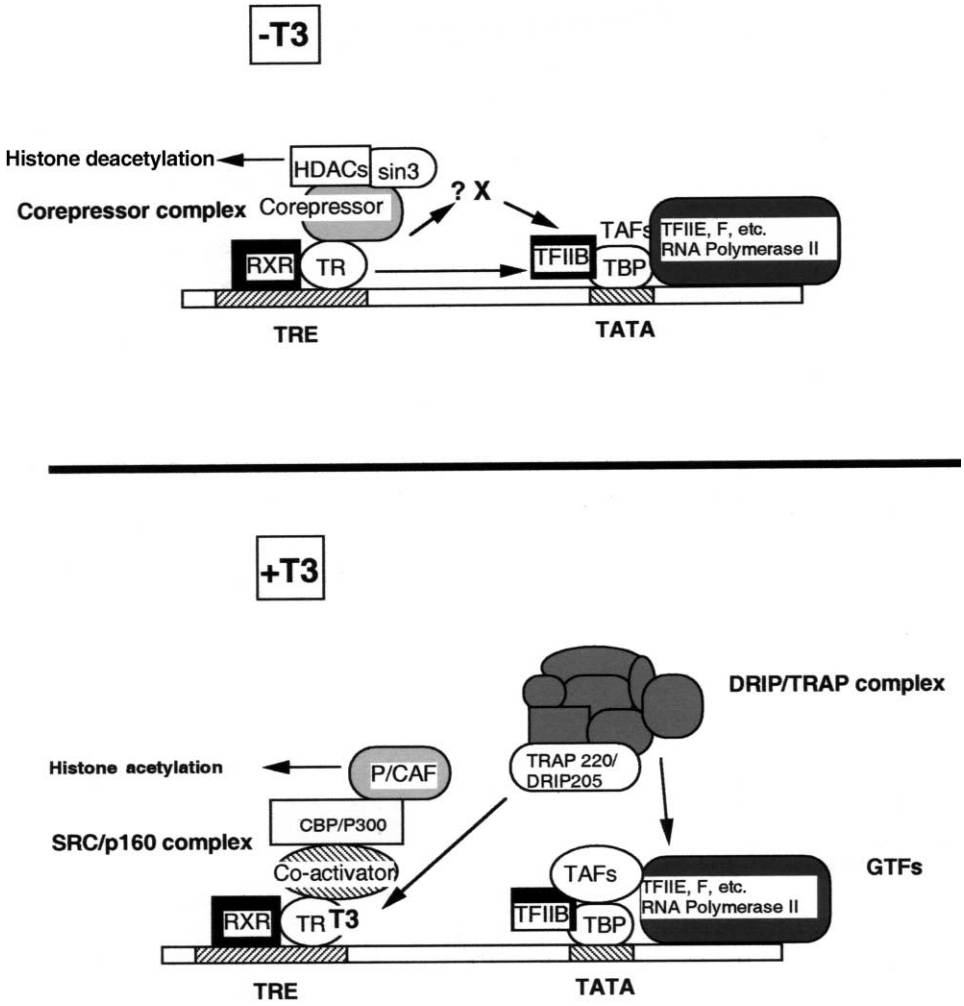

FIGURE 3 Molecular model for basal repression in the absence of triiodothyronine (T3) and transcriptional activation in the presence of T3. Possible additional cofactors (X) remain to be identified. predominant isoform expressed in liver whereas TRα-1 is the major isoform expressed in heart) has fostered attempts to develop TRβ-specific thyroid hormone analogues that may have cholesterol-lowering effects but minimal cardiac toxicity.

V. TR KNOCKOUT MODELS OF TR ISOFORMS

The selective ablation of TR isoforms in mice by homologous recombination has provided insight on the roles of TR isoforms in the development and function of various tissues. Two different groups have generated TRα knockout mice that have different phenotypes. The structure of the TRα gene is complex because it encodes TRα-1, c-erbAα-2 (which cannot bind T3), and rev-erbA (generated from the opposite strand encoding TRα); thus, the locus of homologous recombination will determine which isoforms will be knocked out. Transgenic mice in which both TRα-1 and c-erbAα-2 have been deleted (TRα $-/-$) have a more severe phenotype, involving hypothyroidism, intestinal malformation, growth retardation, and early death shortly after weaning. The early death can be partially rescued by T3 injection of pups. Transgenic mice that lack only TRα-1 (TRα-1 $-/-$) have a milder phenotype compared to TRα $-/-$ mice because they have decreased body temperature and heart rate and a prolonged electrocardiogram

ventricular depolarization/repolarization (QT) interval. These findings suggest that TRα-1 plays an important role in regulating cardiac function. The differences in the two knockout phenotypes could be due to specific functions of c-erbAα-2; however, specific knockout of c-erbAα-2 does not affect the survival of pups. Short TRα isoforms can be generated from an internal promoter within the seventh intron, which then have dominant negative activity on wild-type TR function. It thus is likely that these short TR isoforms may be responsible for the more severe phenotype of the TRα − /− knockout mice. In this regard, a TRα knockout mouse that lacks both TRα-1 and c-erbA α-2, and does not express the short TRα isoforms ($TR\alpha_{o/o}$), has a milder phenotype compared to $TR\alpha_{-/-}$.

TRβ knockout mice ($TR\beta_{-/-}$) display modest phenotypic changes, including elevated TSH and T4, thyroid hyperplasia, and hearing and retinal defects. These abnormalities in the hypothalamic–pituitary–thyroid (HPT) axis are similar to those seen in patients with the syndrome of resistance to thyroid hormone. Additionally, these findings suggest a critical role for TRβ in the development of the auditory and visual systems. Interestingly, ligand-independent elevation of TSH is normal in hypothyroid TRβ − /− mice, but the suppression of TSH by TH is impaired. Recently, TRβ-2 has been selectively knocked out. The mice had elevated levels of TH and TSH, implicating TRβ-2 as the major TR isoform regulating TSH production. Interestingly, the mice did not have any hearing defects, suggesting that TRβ-2 may not be required for auditory development or that its function can be compensated by TRβ-1.

Because the TRα-1 and TRβ knockout mice have relatively mild phenotypes, it is likely that the TR isoforms may have redundant transcriptional activity and can compensate for each other in most target genes. To examine the effects of abolishing all TR isoforms, TRα-1 − /− TRβ − /− double knockouts have been generated and, surprisingly, these mice are still viable. These mice have markedly elevated T4, T3, and TSH levels and large goiters. The mice also have growth retardation and decreased fertility, as well as impaired bone development and reduced bone mineral content. Furthermore, the mice have reduced heart rate and impaired control of body temperature, similar to the TRα-1 − /− mice. It is noteworthy that the effects on peripheral tissues generally are milder in the double-knockout mice compare to those seen in congenital hypothyroidism. It is possible that non-genomic effects of TH may be involved in double-knockout mice but not in mice with congenital hypothyroidism. It also is possible that lack of TRs is less deleterious than the presence of TRs during hypothyroidism. Because unliganded TRs bind to TREs and recruit corepressors to repress basal transcription of some positively regulated target genes, it is possible that critical target genes may be shut down in the hypothyroid mice whereas basal transcription is maintained in the double-knockout mice.

VI. CONCLUSION

Tissue-restricted expression and knockout mice studies suggest that the multiple TR isoforms may have specialized roles, although cotransfection studies suggest that most of the known target genes can be coregulated. Future studies with microarrays, proteomics, and isoform-specific ligands, perhaps in conjunction with knockout mice, should help identify isoform-specific roles in the transcription of specific genes.

Glossary

basal repression Target gene transcription repression by unliganded thyroid hormone receptor and its recruitment of corepressors.

dominant negative activity Blockade of thyroid hormone receptor transcriptional activity by a transcription factor or mutant receptor, typically by competitive binding to the thyroid hormone response element.

nuclear hormone receptor superfamily Nuclear receptor family that includes the steroid, vitamin D, retinoic acid, and thyroid hormone receptors.

thyroid hormone response elements Discrete enhancer sequences in the promoters of target genes to which thyroid hormones bind and regulate transcription.

thyroid hormones Triiodothyronine (T3) and thyroxine (T4); secreted by the thyroid gland and converted by peripheral deiodination.

transactivation Ligand-dependent transcription of target genes mediated by a thyroid hormone receptor and its recruitment of co-activators.

Thyroid Hormone Receptor, TSH and TSH Receptor Mutations

ROY E. WEISS AND PETER M. SADOW
University of Chicago

The thyroid hormone receptor interacts with the thyroid hormone triiodothyronine, which is secreted from the thyroid following interaction of thyroid-stimulating hormone and its receptor. Mutations in any of the genes regulating the production and function of these molecules lead to pathological conditions. In addition to the importance of these mutations as a cause of human disease, such errors of nature allow for an understanding of the structure and function of these molecules in normal physiology.

I. INTRODUCTION

At each juncture in the hypothalamic–pituitary–thyroid axis, there is an interaction between hormone and receptor that produces a specific biologic effect. Thyrotropin-releasing hormone (TRH), secreted from the hypothalamus, interacts with TRH receptors on the thyrotroph cell surface. This results in production and release of thyroid-stimulating hormone (TSH) from the pituitary. TSH, in turn, interacts with thyroid follicular cell surface receptors, resulting in synthesis and release of thyroid hormones (THs) from the thyroid gland. Finally, TH binds to nuclear TH receptors in target tissues for TH action. All of this is controlled by a series of negative feedback loops at the level of the hypothalamus and pituitary involving primarily TH. The focus of this article is on what has been learned from mutations in these hormones and their receptors in humans, how the mutations relate to human disease, and the structure and function of these molecules in normal physiology.

Abnormalities in either the hormone or the receptor can result in altered states of hormone sensitivity, such as resistance (loss of function) or hypersensitivity (gain of function). In the human thyroid axis, there are examples of both types of mutations. Resistance is defined as a condition of reduced or absent target tissue responsiveness to the hormone. Resistance manifests as higher than normal levels of the hormone without the expected biological effect. Resistance may be due to any of the following reasons: (1) a mutation in the hormone, resulting in altered biologic activity; (2) production of a substance, such as an antibody, that interferes with hormonal action; (3) an abnormal receptor due to a loss-of-function mutation, resulting in failure to bind the hormone or failure to activate the appropriate postreceptor response cascade; (4) an abnormality in any of the multiple cofactors involved in the process of hormone action; or (5) any postreceptor defect, such as abnormal G-protein, that could also result in

hormone resistance. "Pseudoresistance" refers to lab assay results indicating excessive amounts of hormone when, in fact, the results are false, due to an interfering substance.

Hormone hypersensitivity is a condition of exaggerated effects of a hormone in the presence of normal to low levels of the hormone. Theoretically, this may be due to an increase in biological activity, as in a "superhormone," or to an abnormal constitutively activated receptor. Additionally, hypersensitivity can be due to a substance other than the hormone which stimulates the receptor.

II. TH RECEPTOR MUTATIONS AND RESISTANCE TO TH

A. Summary of TH Action

Thyroid hormone penetrates all body tissues and is believed to enter cells by a process of concentration-dependent passive diffusion after its dissociation from the serum hormone-binding proteins. Triiodothyronine (T3), the biologically active form of the hormone in blood, or generated from tetraiodothyronine (T4, thyroxine) within the cell, reaches its site of action, the cell nucleus. There it binds with DNA-bound specific molecules known as TH receptors (TRs). Hormone-bound TRs then interact with various cofactors that modify the receptor–ligand complex and allow it to regulate gene transcription.

B. General Introduction to Nuclear Receptors

Thyroid hormone receptors belong to the nuclear hormone receptor superfamily, which includes receptors for the sex hormones, testosterone and estrogen, as well as for vitamin D, retinoic acid, and the peroxisome proliferation receptor. These receptors are characterized by a carboxy-terminal ligand-binding domain (LBD) and a more proximal DNA-binding domain (DBD). These receptors act as nuclear transcription factors by binding to specific sequences of DNA located in target genes. In the case of TH, these sequences are TH response elements (TREs). Some regions of the receptor are involved in interacting with a variety of cofactors that modify the receptor–hormone complex on the TRE, thus modulating transcriptional activity.

C. The TR and Mode of Action

Mutations have been described that result in a failure to initiate TH-responsive transcription. Either the LBD is altered, preventing the recognition of the hormone, or the DBD or the hinge region is altered, inactivating the hormone–receptor complex. Mutations in TRs may result in the syndrome of resistance to TH. In a subject heterozygous for an abnormal TR allele, a dominant negative interaction occurs whereby the abnormal allele interferes with function of the normal allele, resulting in the phenotype of resistance.

D. Clinical Aspects of Resistance to TH

Resistance to TH (RTH) is an inherited syndrome (usually autosomal dominant) of reduced target tissue responsiveness to TH. More than 700 cases in 250 families have been described that fit this definition. It is suggested that the incidence is 1:50,000. With the exception of a single family, inheritance is autosomal dominant. In practice, patients with autosomal dominant RTH are identified by a persistent elevation of serum free 3,5,3′,5′-tetraiodothyronine and free 3,5,3′-triiodothyronine levels without TSH suppression. In these RTH patients, this combination of abnormal laboratory test results occurs in the absence of intercurrent illness, drugs, or alterations of TH transport proteins in serum. More importantly, administration of supraphysiological doses of TH fails to produce the expected suppressive effect on the secretion of pituitary TSH and the anticipated metabolic responses in peripheral tissues.

The common features of RTH are (1) elevated serum levels of free T4 and free T3, (2) normal or slightly increased concentrations of serum TSH that responds to TRH stimulation, (3) absence of typical symptoms and metabolic consequences of TH excess, and (4) goiter.

E. Molecular Basis of RTH: TRβ Mutations

Mutations in the gene encoding thyroid hormone receptor β (TRβ) have been described in the majority of families with RTH. All mutations affect the LBD or adjacent hinge region of the TRβ molecule and are distributed in three clusters (Fig. 1). In the *TRβ* gene, 43 mutations in 86 families have been found in cluster 1 (corresponding to amino acids 429–460), 49 mutations in 113 families have been found in cluster 2 (amino acids 309–383), and 16 mutations in 31 families have been found in cluster 3 (amino acids 234–282). A complete *TRβ* gene deletion has been reported in one family. Mutations have been identified in 64 codons of the *TRβ* gene, with 30 of these codons altered by more than one mutation. Of the 109 identified *TRβ* gene mutations, 71 are unique in

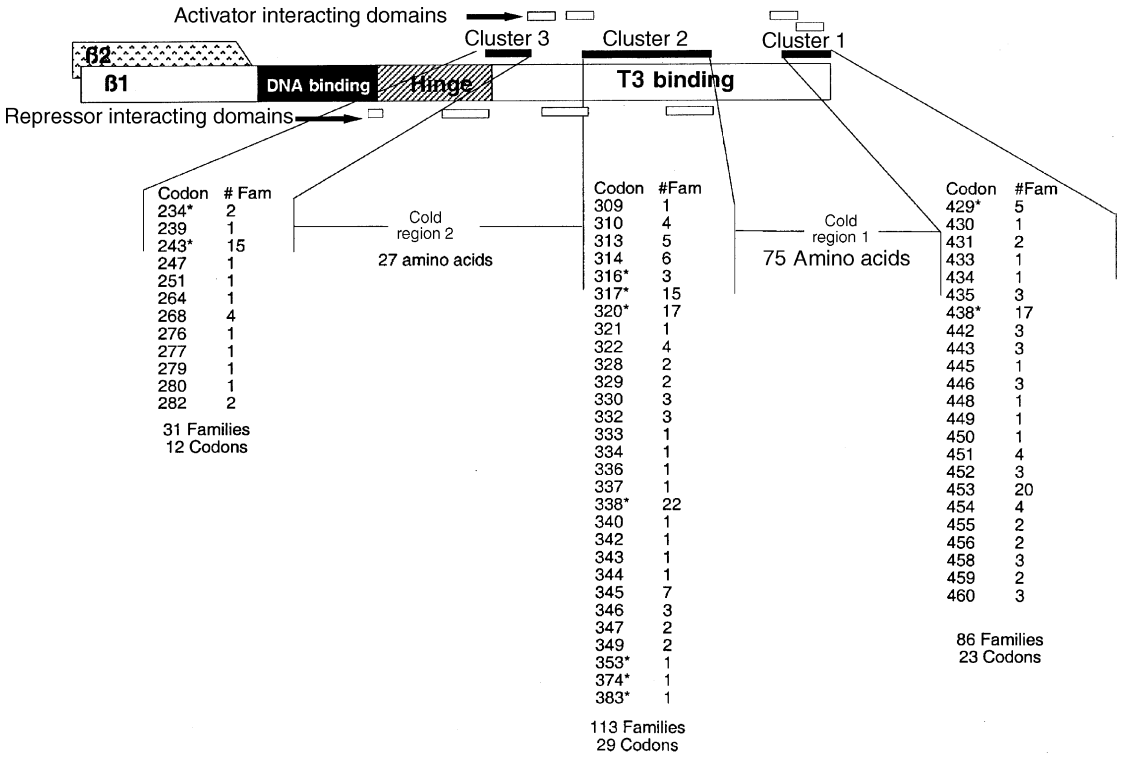

FIGURE 1 Functional domains of the thyroid hormone receptor β-subunit and reported mutations in the *TRβ* gene. The mutated codon is listed along with the number of families known to have mutations in that particular codon. There may be more than one mutation in a particular codon. In several codons, identical mutations have been found in multiple families. The mutations are present in three clusters, separated by two regions in which natural mutations have not been reported. *TRβ1* and *TRβ2* have different ATG start sites and differ only in the amino terminus. Asterisks indicate a CpG dinucleotide.

that they occur in only one family, and 38 occur in multiple unrelated families. Using the single-letter amino acid code to describe the protein mutations, the five most frequent mutations in the *TRβ* gene correspond to R338W (19 families); A317T (14 families); R438H (11 families); R243Q (10 families), and P453T (9 families). Of the mutations described, 95 (87.2%) are due to a single-base-pair substitution resulting in a single-amino-acid substitution (92) or a premature stop codon (3). The remaining mutations are due to dinucleotide substitution (1), complete deletion (1), single-base-pair deletion (1), three-base-pair deletion (5), single-base-pair insertion (4), three-base-pair insertion (1), and seven-base-pair duplication (1). Of 109 mutations, 17 occur in CpG dinucleotides and these account for 43% of the families with *TRβ* gene mutations. In 37 of 236 families with RTH, the *TRβ* mutation has occurred *de novo* and the mutant allele can be traced to the normal progenitor of one of the two parents. In contrast to syndromes of vitamin D and androgen resistance, mutations in the DNA-binding region are not found in RTH.

No mutations have been reported in the *TRα* gene. Mice with deletion of TRα1 and TRα2 isotypes have hypersensitivity to TH. Therefore, the phenotype of a mutant TRα is unlikely to manifest as RTH and may explain the lack of observed mutations in this protein.

Normal TRβ is found in 10% of RTH patients. Patients with non-TRβ RTH and patients with TRβ mutations have identical phenotypes. Whereas the majority of patients with glucocorticoid resistance syndromes usually have mutations in the glucocorticoid receptor (GR), similar to RTH, some patients have been described with non-GR glucocorticoid resistance. Based on the observation of RTH in mice deficient in steroid receptor co-activator-1 (SRC-1), it is logical to postulate that abnormalities of co-activators or corepressors, known to be involved in hormone action, may also cause hormonal resistance.

III. TSH MUTATIONS

Thyroid-stimulating hormone is a 30-kDa glycoprotein secreted by the thyrotroph; it is encoded on human chromosome 1. Similar to other glycoprotein hormones secreted by the anterior pituitary, TSH is composed of a common α-subunit noncovalently bound to a specific β-subunit. The CAGYC (C, cysteine; A, alanine; G, glycine; Y, tyrosine) region of the protein forms the "seat belt" part of the TSH β-subunit, which allows for interaction with the α-subunit. It is the unique β-subunit that confers the hormonal specificity. In some instances, as in a molar pregnancy, a condition in which there are very high levels of chorionic gonadotropin (CG), stimulation of the TSH receptor by CG α-subunit can cause hyperthyroidism. All reported mutations in the *TSHβ* gene result in significant hypothyroidism. The patients present with typical findings of central hypothyroidism, namely, low levels of T3 and T4 with inappropriately very low or absent concentrations of serum TSH. The low serum TSH concentrations can be understood based on the observation that TSHβ is degraded intracellularly. TSHβ degradation occurs when TSHβ is not bound to the α-subunit, and the mutation prevents this binding. Therefore, any abnormality of the protein in the CAGYC region would result in undetectable TSH. Whereas most cases of central hypothyroidism are associated with disruptions in other components in the pathways of the pituitary hormone axis, such as adrenocorticotropic hormone (ACTH)/cortisol or luteinizing hormone (LH)/follicle-stimulating hormone (FSH)/sex hormone, TSHβ mutations present as isolated central hypothyroidism. Attempts to stimulate pituitary secretion by thyrotropin-releasing hormone results in prolactin release but fails to result in TSH stimulation in patients with TSHβ mutations.

The first reported cases of TSHβ mutations were found in three (possibly related) Japanese families homozygous for a G to A substitution encoded in codon 29 of the *TSHβ* gene; the substitution results in a conversion of glycine to an arginine (G29R). The second abnormal TSHβ was found in two Greek families in which a G to T substitution encoded in codon 12 results in a premature stop codon and leads to the deletion of amino acid residues 12–118. A third variant described in four families is a 1-bp deletion in codon 105 that produces a frameshift. This causes Cys-105 to be converted to valine and the addition of eight nonsense amino acids. The fourth variant was described in a consanguineous Turkish family whose members were homozygous for a C to T transition at nucleotide 654 of the region encoding the TSH β-subunit, resulting in Gln-49 becoming a stop codon and premature termination of the protein. This removes the region necessary for α-subunit heterodimerization and no TSH is secreted by the thyrotrophs (Fig. 2).

IV. TSH RECEPTOR MUTATIONS

The TSH receptor (TSHR) belongs to the superfamily of G-protein-coupled receptors, which are characterized by serpentine-like looping through the membrane, with seven-transmembrane segments. The molecule can be divided into three domains: extracellular, intramembranous, and intracellular. The extracellular domain consists of the 398-residue amino-terminal segment and three extracellular loops; the membranous domain consists of seven α-helices; and the intracellular domain consists of the carboxy-terminal amino acids of the molecule, with three intracellular loops. The specificity of the receptor for the ligand is encoded in the amino-terminal segment, which is responsible for ligand recognition. The carboxy-terminal segment contains the sites that interact with the cascade of G-proteins, leading to the generation of cyclic adenosine monophosphate (cAMP). The cAMP pathway, when stimulated, results in thyroid cell growth and TH secretion. The intramembranous domain is also coupled to the activation of the phospholipase C cascade. The latter requires TSH concentrations 5–10 times higher than are required for the cAMP pathway. The phospholipase C stimulation of diacylglycerol and inositol

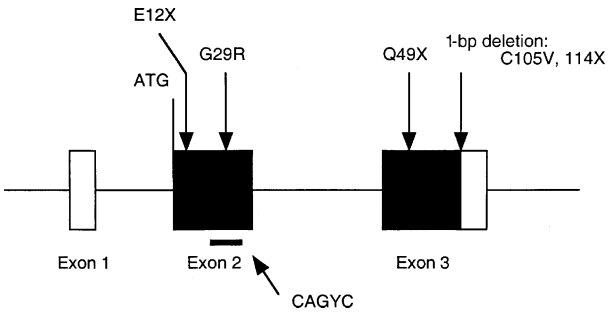

FIGURE 2 Thyroid-stimulating hormone gene mutations; organization of the *TSHβ* gene and reported mutations. The region encoding CAGYC (see text for discussion) is important for noncovalent interaction between the TSH β- and α-subunits.

phospholipase is mainly involved in the control of iodination and TH synthesis.

Abnormalities in the TSHR can result in either activation of the G-proteins in the absence of TSH, known as "gain-of-function" mutations, or reduced or absent activation of the G-proteins, known as "loss-of-function" mutations. Gain-of-function mutations in the TSHR usually result in hyperthyroidism and goiter through constitutive activity of the TSHR. This is due to a mutation activating the TSHR. Excessive amounts of TH released by the thyroid gland cause the symptoms associated with an overactive thyroid, including rapid heart beat (tachycardia), weight loss, jitteriness, fatigue, and goiter. Loss-of-function mutations in the TSHR usually cause hypothyroidism, manifesting as weight gain, tiredness, and dry skin. The hypothyroidism is caused by the resistance of the TSHR, resulting in failure of the thyroid gland to respond to TSH, despite high circulating levels of TSH. Gain-of-function and loss-of-function mutations have also been described for other glycoprotein hormone receptors, including LH, FSH, and parathyroid hormone.

To date, 39 gain-of-function mutations have been reported in the TSHR (Fig. 3). Only one of these mutations occurs in the 398-residue amino terminus; the rest occur in the third cytoplasmic loop or in the adjacent sixth transmembrane segment of the receptor. This observed clustering of mutations underlines the importance of this portion of the molecule. Of the mutations, 23 are found only as somatic mutations, 9 are found only as germ-line mutations, and 8 have been described as somatic in some families and germ-line in other families. The most common setting to observe these gain-of-function mutations is in patients with "toxic adenomas." These are nodules of the thyroid gland that autonomously secrete TH. In some series of studies, up to 80% of toxic adenomas have TSHR mutations, but other populations have a lower incidence, perhaps related to levels of environmental iodine. One TSHR mutation (L677V) was also associated with thyroid carcinoma.

A mutation of the TSHR has been determined to be the cause of familial gestational hyperthyroidism in one family whose members experienced hyperthyroidism only when pregnant. Investigation of this

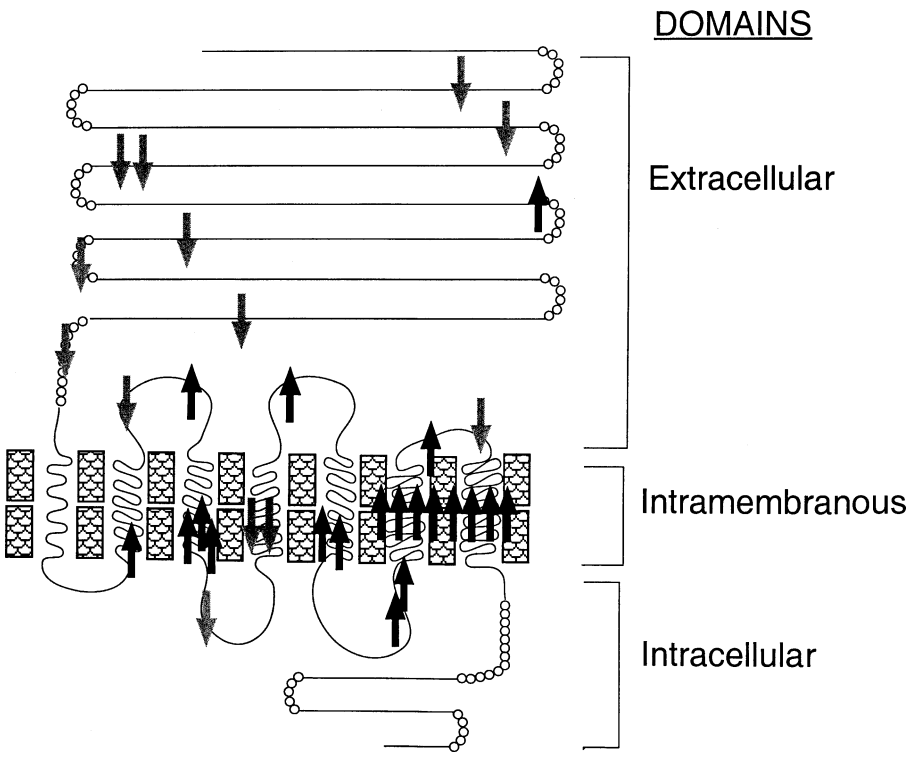

FIGURE 3 Organization of the thyroid-stimulating hormone receptor and reported mutations. Black arrows pointing up indicate gain-of-function mutations; gray arrows pointing down indicate loss-of-function mutations. Note that a majority of the gain-of-function mutations are in the intramembranous domains, whereas the loss-of-function mutations are in the extracellular domains.

family revealed a heterozygous mutation (K183R) located in the extracellular domain of the TSHR, causing chorionic gonadotropin to bind with higher affinity than TSH. However, the receptor also maintained normal responsiveness to TSH. Therefore, when the CG levels increased dramatically during pregnancy, the TSHR was activated, causing hyperthyroidism that resolved spontaneously when the CG levels decreased following delivery. This shows that some mutations can produce a promiscuous TSHR that responds to other hormones.

Cases involving 16 loss-of-function mutations in the TSHR have been described. In contrast to the gain-of-function mutations, a majority of the loss of function mutations are located in the amino-terminal extracellular domain, with the remainder in the extracellular loops of the and fourth intramembranous region. These mutations can result in either partial or complete resistance to TSH (RTSH). In all instances, TSH is elevated but does not cause goiter. In partial RTSH, there is a compensatory increase in TSH, stimulating the thyroid to produce just the needed amount of TH. In complete RTSH, the thyroid gland is completely insensitive to TSH and the patients are severely hypothyroid. Administration of TH to these patients appropriately suppresses their elevated TSH and they become euthyroid. This supports the notion that the defect in RTSH is in responding to TSH and that TH acts normally. Loss of function implies that both alleles are abnormal. Of the 14 families described, 8 were euthyroid and 6 were hypothyroid; RTSH occurred in 6 families homozygous for the TSHR mutations and 8 families were compound heterozygous.

Glossary

co-activators Molecules that modulate gene transcription, usually through bound receptor; generally have histone acetyl transferase activity, which allows for unraveling of DNA and initiation of transcription.

corepressors Proteins that modulate gene transcription in the presence of receptor; generally stabilize the receptor complex on the response element of the target gene, recruiting histone deacetylase. When ligand is present, corepressor binding is unfavorable and the corepressor dissociates from the receptor–ligand–DNA complex, allowing for the recruitment of a co-activator.

gain-of-function mutations Gene alterations that render a receptor constitutively active, in the absence of hormone. In the thyroid-stimulating hormone receptor, such mutations usually result in hyperthyroidism.

germ-line mutations Gene alterations that are present in germ cells (ova or sperm) and are thus transmitted to the progeny.

goiter Enlargement of the thyroid gland; occurs in hypothyroid states, when thyroid cells are under TSH stimulation to produce more hormone, or in hyperthyroid states, when stimulating substances, usually antibodies, bind to the TSH receptor and stimulate thyroid function.

hyperthyroidism Condition of thyroid hormone excess; commonly associated with weight loss, tachycardia, excessive sweating, heat intolerance, moist skin, and fatigue; usually due to excessive thyroid gland production of thyroid hormone.

hypothyroidism Condition of thyroid hormone deficit; commonly associated with weight gain, slow mentation, decreased energy, cold intolerance, edema, and dry skin; usually due to failure of the thyroid gland to synthesize and release thyroid hormone.

loss-of-function mutations Gene alterations that reduce or abolish receptor activity; result in impaired ligand–receptor interaction. Such mutations in thyroid-stimulating hormone receptor produce resistance to TSH, which, when severe, causes hypothyroidism. Such mutations in thyroid hormone receptor produce resistance to thyroid hormone.

resistance to thyroid hormone Inherited syndrome of reduced target tissue responsiveness to thyroid hormone. Diagnostic criteria are elevated serum levels of free thyroid hormone, nonsuppressed TSH, and absence of classic signs and symptoms of thyrotoxicosis.

resistance to thyrotropin Inherited syndrome of reduced responsiveness of the thyroid gland to TSH. All patients have elevated serum levels of TSH with serum thyroid hormone concentrations that are normal (in compensated forms) or low (in noncompensated forms).

somatic mutation Gene alteration that occurs in any cell that is not destined to become a germ cell.

thyroid hormone receptor Nuclear receptor for triiodothyronine (T3, the active form of thyroid hormone). The two thyroid hormone receptor genes, α and β, are located on human chromosomes 17 (q21–q22) and 3 (p22–p24.1), respectively. Various splicing arrangements of these genes result in several isoforms of both α and β.

Thyroid Hormone Transport Proteins: Thyroxine-Binding Globulin, Transthyretin, and Albumin

SAMUEL REFETOFF

The University of Chicago

Thyroid hormones are transported in blood bound to serum proteins. They are in equilibrium with a minute fraction of free hormones immediately available to tissues. Acquired abnormalities and inherited defects of transport proteins can have a profound effect on the serum concentration of the hormones but little or no consequences on their metabolic effects. Recognition of such defects prevents unnecessary and often harmful therapeutic interventions.

I. INTRODUCTION

Thyroxine (T_4)-binding globulin (TBG) is the principal thyroid hormone transport protein; the other two are transthyretin (TTR) and human serum albumin (HSA). TBG transports 75% of serum T_4 and TTR and HAS carry 20 and 5%, respectively. TBG also transports 75% of serum triiodothyronine (T_3). The benefit of thyroid hormone associating with proteins is unknown since the absence or inherited loss of binding function of the proteins does not result in a demonstrable disadvantage. However, it has been speculated that thyroid hormone-binding proteins may (1) safeguard the body from the effects of abrupt fluctuations in hormone secretion; (2) protect against iodine wastage by imparting macromolecular properties to the small thyroid hormone molecules and thus reducing their loss in urine; (3) facilitate the uniform cellular distribution of T_4; and (4) target the hormone to sites of inflammation through its release through TBG cleavage by neutrophil-derived elastase.

Important changes in TBG, either quantitative or qualitative, result in profound alterations in the total thyroid hormone level in serum without disturbing the free hormone concentration. Thyroid function tests in these circumstances may be misinterpreted as indicative of hyper- or hypothyroidism and could result in unnecessary treatment. Many physiologic, pathologic, and genetic conditions, as well as certain drugs, can alter the concentration of TBG (see below). In addition, drugs can compete with the binding of iodothyronine ligands.

II. STRUCTURAL, PHYSICAL, AND BIOLOGICAL PROPERTIES

A. TBG

TBG is a 54 kDa acidic glycoprotein synthesized by the liver (see Table 1). It is composed of a single polypeptide chain of 395 amino acids and four heterosaccharide units with five to nine terminal sialic acids. The carbohydrate chains are not necess-

TABLE 1 Properties of the Principal Thyroid Hormone-Binding Proteins in Serum

	TBG	TTR	HSA
Molecular weight (kDa)	54[a]	55	66.5
Structure	Monomer	Tetramer	Monomer
Carbohydrate content (%)	20

[c] Longer half-life under the influence of estrogen.

ary for hormone binding but are required for the correct posttranslational folding and secretion of the molecule. However, secreted TBG that has been properly folded can be deglycosylated without loss of its hormone-binding and immunologic properties.

Serum TBG is stable at room temperature but undergoes rapid denaturation and loses its binding activity at temperatures above 55 °C and pH below 4. The half-life of TBG *in vivo* is approximately 5 days but that of asialo TBG is only 15 min.

TBG has a single iodothyronine-binding site with higher affinity for T_4 than T_3 (Table 1). In the euthyroid state, approximately one-third of TBG molecules carry thyroid hormone, mainly T_4. When fully saturated, TBG carries ~20 mg of T_4 per deciliter of serum. Normal serum concentration in adults ranges from 1.1 to 2.1 mg/dl. TBG is detected in the 12-week-old fetus, and in newborns and in children up to the age of 2–3 years, its concentration is 1.5-fold that in adults. Denatured TBG does not bind iodothyronines but can be detected with antibodies that recognize the primary structure of the molecule.

B. TTR

TTR is a 55 kDa, highly acidic tetramer devoid of carbohydrate. It forms a complex with retinol-binding protein (RBP) and thus plays a role in the transport of vitamin A.

TTR is present in blood as a stable tetramer of identical subunits, each containing 127 amino acids. Together they form a symmetrical structure with a double-barreled hydrophobic channel forming the two iodothyronine-binding sites. Yet, TTR usually binds only one T_4 molecule because the binding affinity of the second site is greatly reduced through a negative cooperative effect. The presence of RBP does not interfere with T_4 binding and vice versa.

Despite the 20-fold higher concentration of TTR in serum relative to that of TBG, it plays a lesser role in iodothyronine transport. The first T_4 molecule binds to TTR with a K_a that is approximately 100-fold higher than that for HSA and approximately 100-fold less than that for TBG. Relative to T_4, T_3 has lower affinity and tetraiodoacetic acid has higher affinity for TTR. Among the drugs that compete with T_4 binding to TTR are ethacrynic acid, salicylates, 2,4-dinitrophenol, and penicillin.

The average concentration of TTR in serum is 25 mg/dl and corresponds to a maximal binding capacity of 300 μg T_4. Changes in TTR concentration have relatively little effect on the concentration of serum iodothyronines. Only 0.5% of the circulating TTR is occupied by T_4. TTR has a relatively rapid turnover ($t_{1/2} = 2$ days). Hence, acute diminution in the rate of synthesis is accompanied by a rapid decrease of its concentration in serum.

C. HSA

HSA is a 66.5 kDa protein synthesized by the liver. It comprises 585 amino acids, has a high cysteine content, and has a high proportion of charged amino acids but contains no carbohydrate. The three

domains of the molecule can be depicted in a model as three tennis balls packaged in a cylindrical case.

HSA associates with a wide variety of substances including hormones and drugs possessing a hydrophobic region, and thus the association of thyroid hormone with HSA can be viewed as being nonspecific. Fatty acids and chloride ions decrease the binding of iodothyronine to HSA.

The biological $t_{1/2}$ of HSA is longer than that of TBG and TTR. HSA constitutes more than half of the total protein content in serum and it is thus the principal contributor to the maintenance of colloid osmotic pressure. Despite the high iodothyronine-binding capacity, the low affinity is responsible for the minor contribution of HSA to thyroid hormone transport. Thus, even the most marked fluctuations in HSA concentration, including analbuminemia, have no significant effect on thyroid hormone levels.

III. GENE STRUCTURE AND TRANSCRIPTIONAL REGULATION

A. TBG

TBG is encoded by a single-copy gene located on the long arm of the human X chromosome (Xq22.2) (see Fig. 1). The gene consists of five exons and has two polyadenylation sites giving rise to mRNAs of different sizes. The gene organization and amino acid sequences are similar to those of other members of the serine protease inhibitor family, which includes cortisol-binding globulin, α_1-anti-trypsin, and α_1-anti-chymotrypsin. An upstream sequence of 218 bp contains liver-specific enhancer elements and is required for the transcription of the TBG gene. The promoter has no estrogen receptor-binding sites and estradiol does not appear to have a direct effect on TBG gene transcription.

B. TTR

TTR is encoded by a single-copy gene located on chromosome 18 (18q11.2–q12.1). The gene consists of four exons spanning 6.8 kb. Knowledge about the transcriptional regulation of the human TTR gene comes from studies of the mouse gene structural and sequence homology, which extends to the promoter region. In both species, a TATAA-box and binding sites for hepatocyte nuclear factor-1 (HNF-1), HNF-3, and HNF-4 are located within 150 bp of the transcription start site.

Although TTR in serum originates from the liver, TTR mRNA is also found in kidney cells, the choroid plexus, and pancreatic islet cells. TTR constitutes up

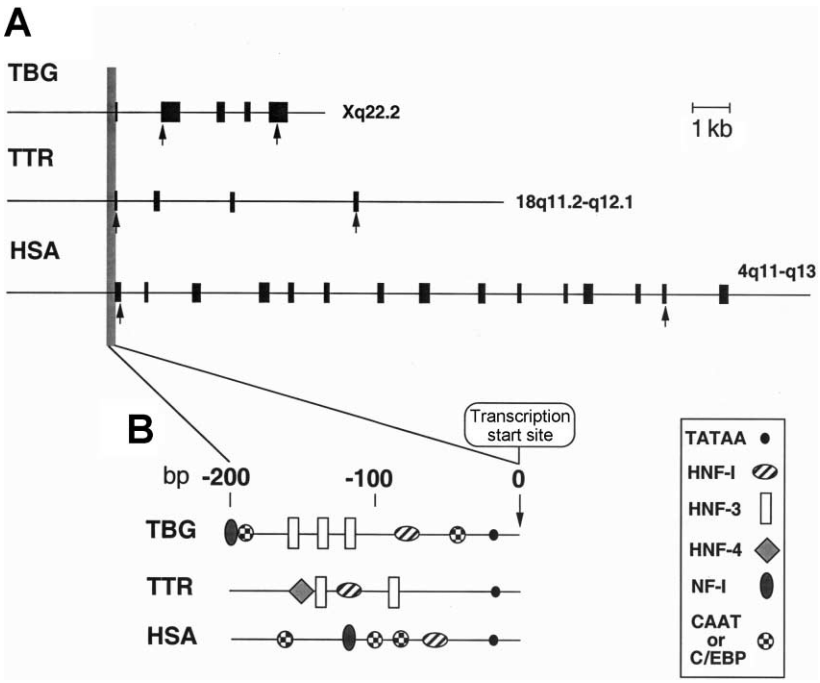

FIGURE 1 Genomic organization and chromosomal localization of thyroid hormone serum-binding proteins. (A) Filled boxes represent exons. Locations of initiation codons and termination codons are indicated by arrows. (B) Structure of promoter regions with the location of *cis*-acting transcriptional regulatory elements.

to 25% of the total protein present in ventricular cerebrospinal fluid.

C. HSA

HSA is encoded by a single-copy gene located on human chromosome 4 (4q11–q13). The gene contains 15 exons. The promoter region contains binding sites for hepatocyte-enriched nuclear proteins, such as HNF-1, CCAAT/enhancer-binding protein, and D-site binding protein, a member of the C/EBP family.

IV. ACQUIRED DEFECTS

A. TBG

Altered synthesis, degradation, or both are responsible for the majority of acquired TBG abnormalities. Severe terminal illness is undoubtedly the most common cause of an acquired decrease in TBG concentration. Interleukin-6 is a likely candidate for mediation of this effect. Altered rates of degradation are responsible for the decrease and increase of serum TBG concentration in thyrotoxicosis and hypothyroidism, respectively.

Partially desialylated TBG may be present in relatively higher proportion than intact TBG in the serum of some patients with severe liver disease and in a variety of nonthyroidal illnesses. Patients with carbohydrate-deficient glycoprotein syndrome show a characteristic cathodal shift in the relative proportion of TBG isoforms compatible with diminished sialic acid content.

Estrogen excess from an endogenous (hydatidiform mole, estrogen-producing tumors, etc.) or exogenous source is the most common cause of increased serum TBG concentrations. The levels of several other serum proteins such as corticosteroid-binding globulin and sex hormone-binding globulin are also increased. This effect of estrogen is mediated through an increase in the complexity of the oligosaccharide residues in TBG, prolonging its biological half-life.

B. TTR

The reduction of serum TTR concentration surpasses that of TBG in major illness and protein-calorie malnutrition. This is caused by either a decrease in the rate of synthesis or an increase in the rate of degradation. Increased serum TTR concentration can occur in some patients with islet cell carcinoma.

V. INHERITED DEFECTS

A. TBG

With a single exception, the inheritance of TBG abnormalities, including TBG deficiency and TBG excess, follows an X-linked pattern. Clinically, patients present with euthyroid hyper- or hypothyroxinemia. TBG deficiency can present as partial deficiency (TBG-PD) or complete deficiency (TBG-CD), depending on the serum TBG level in hemizygotes. In addition, TBG variants can be characterized by their properties that include (1) immunologic identity; (2) isoelectric focusing (IEF) pattern; (3) rate of inactivation at various temperatures or pH; and (4) affinity for ligands. More precise characterization of TBG defects requires sequencing of the TBG gene.

1. Complete Deficiency

TBG-CD is defined as an undetectable TBG concentration in hemizygotes (XY males or XO females) who express only the mutant allele. Obligatory carriers (mother or daughters of affected hemizygotes) have on the average a TBG concentration that is half that of normal individuals. On occasion, selective X-chromosome inactivation can cause a female heterozygote to manifest the hemizygous phenotype of TBG-CD. The prevalence of TBG-CD is approximately 1:15,000 newborn males.

Fifteen distinct mutations have been identified in subjects with TBG-CD (Fig. 2). Thirteen have truncated molecules due to an early stop codon. In 2 of these (TBG-K and TBG-Ja), nucleotide substitutions in introns caused abnormal splicing. In 2 other mutations, TBG-CD was caused by a missense mutations. The substitution of the normal Leu-227 with a Pro, in TBG-CD5, prevented secretion of the variant molecule due to aberrant posttranslational processing.

No mutations were found in the coding sequences or in the promoter regions of the TBG gene in two families with X-linked TBG-CD. The cause of TBG deficiency in these families remains unknown.

2. Partial Deficiency

With a prevalence of 1:4000 newborns, partial deficiency is the most common inherited TBG defect. Yet, the precise genetic error has been identified in only a few families. The serum level of TBG in hemizygotes is detectable but reduced and levels in heterozygous females often overlap the normal range. This invalidates the assignment of genotype based solely on serum TBG concentration.

Seven variants manifesting as TBG-PD have been identified. Two of these, TBG-S and TBG-A, are

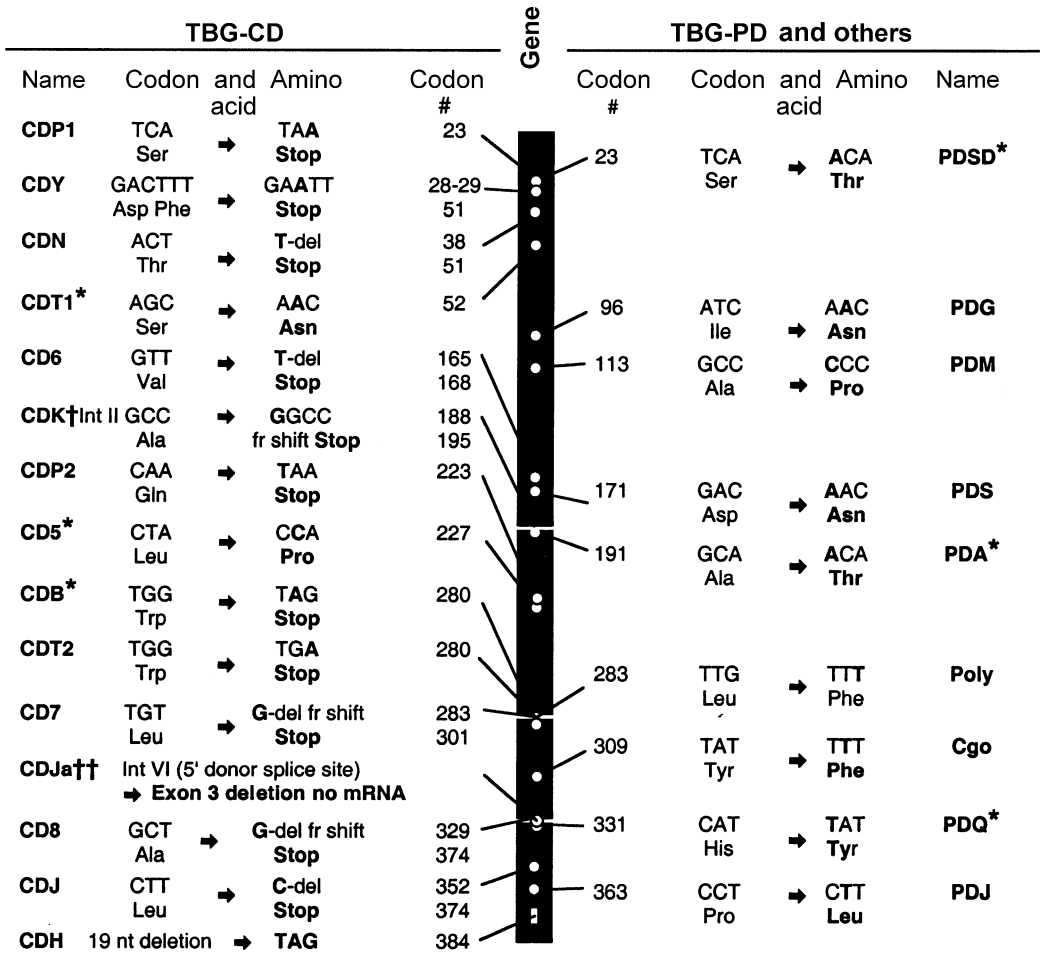

FIGURE 2 Mutations in the TBG gene and their locations. The TBG variants, in order of location, are as follows: SD, San Diego; CDP1, complete deficiency Portuguese 1; CDY, complete deficiency Yonago; CDN, complete deficiency Negev, formerly Bedouin (SDBe); CDT1, complete deficiency Taiwan 1; G, Gary; M, Montreal, CD6, complete deficiency 6; S, slow; CDK, complete deficiency Kankakee; A, Aborigine; CDP2, complete deficiency Portuguese 2; CD5, complete deficiency 5; CDB, complete deficiency Buffalo; CDT2, complete deficiency Taiwan 2; CD7, complete deficiency 7; Poly, polymorphic; Cgo, Chicago; CDJa, complete deficiency; CD8, complete deficiency 8, Quebec; CDJ, complete deficiency Japan; PDJ, partial deficiency Japan; CDH, Hatwichport. Asterisks indicate the coexistence of TBG-Poly. Dagger indicates a mutation in the acceptor splice site of intron II.

present in high frequency in some populations. TBG-S has a frequency of 5–16% in Black Africans. It has a characteristic cathodal shift on IEF due to loss of negative charge, caused by substitution of the normal Asp-171 with Asn. TBG-A was found in 40% of Australian Aborigines. It has a normal IEF pattern but is more heat-labile than the common type TBG (TBG-C). It was also found to have reduced affinity for T_4 (54%) and T_3 (30%), reducing the total T_4 and T_3 concentrations in serum out of proportion to that of TBG.

TBG-SD has a normal IEF pattern but is more - heat-labile and the affinities to T_4 and T_3 are reduced by ~50%. The mean TBG concentration in hemizygotes can be low or overlap the normal range. TBG variants that have normal serum concentrations but reduced affinity for T_4 produce erroneous values for the estimated free thyroxine index (FT_4I).

Three of the seven TBG-PD variants are characterized by decreased stability at 37 °C and hence increased levels of denatured TBG in serum that correlated inversely with the native TBG concentration. These are TBG-Q, TBG-M, and TBG-G. TBG-Q and TBG-M were found in French Canadians. Expression of TBG-G in COS-1 cells showed impaired

secretion of the variant molecule, leading to excessive intracellular degradation. This is caused by improper folding of the molecule due to the presence of an additional carbohydrate chain at a new N-linked glycosylation site.

TBG-PDJ (Japan) has only a mild reduction in heat stability, suggesting that impaired secretion is responsible for the low TBG level.

Recently, a Japanese family with partial TBG deficiency, transmitted in an autosomal dominant pattern, was described. The sequences of the proband's TBG gene and promoter region were normal. An abnormality in a transcription factor that is important for TBG gene expression is a distinct possibility.

3. TBG Variants Present in Normal Concentrations

Four TBG variants with minimal or no alterations in serum concentrations have been identified. TBG-Poly with a silent polymorphism was found in 16% of French Canadians and 20% of Japanese. TBG-Cgo is heat- and acid-resistant. The substitution of the normal Tyr-309 with a Phe ties the internal α-helixes to the molecule, stabilizing its tertiary structure.

4. TBG Excess

Inherited TBG excess is a relatively rare cause of increased TBG. The prevalence of inherited TBG excess is estimated to be 1:25,000. TBG levels in hemizygous affected subjects range from 2.5 to 5 times the normal mean value. TBGs of several unrelated families were shown to have normal properties and no abnormalities were found in the coding sequence or promoter regions of the gene. Gene dosing studies revealed that gene duplication and triplication were the causes of TBG excess in two families. The latter was proven by fluorescence *in situ* hybridization. More recently, a double TBG gene dose was found in two individuals with TBG excess, whose mothers were normal, suggesting *de novo* gene duplication occurring in gametes during meiosis.

B. TTR

Some of the TTR variants are responsible for the dominantly inherited familial amyloidotic polyneuropathy. TTR variants with reduced affinity for T_4 have little effect on the concentration of serum T_4. Only variant TTRs with a substantially increased affinity for iodothyronines produce significant elevations in serum T_4 and reverse T_3 concentrations. They account for 2% of subjects with euthyroid hyperthyroxinemia. The inheritance pattern is autosomal dominant.

A single family with elevated total T_4 concentration due to the replacement of the normal Ala-109 with a Thr has been described. The mutation increases its affinity for T_4, rT_3, tetraiodothyroacetic acid, and to a lesser extent T_3 and triiodothyroacetic acid. Crystallographic analysis of this variant TTR revealed an alteration in the size of the T_4-binding pocket. Another TTR gene mutation involving the same codon with a Val-109 has an increased affinity for T_4 that is of similar magnitude.

A more common defect found in subjects with TTR-associated hyperthyroxinemia is a point mutation in the TTR gene replacing the normal Thr-119 with Met. Despite an increase in the fraction of T_4 and rT_3 associated with this variant TTR, only a few subjects have serum T_4 levels above the upper limit of normal. Several TTR variants that do not alter the properties of the molecule and that are thus of no clinical significance have been found.

C. HSA

1. Familial Dysalbuminemic Hyperthyroxinemia

Another form of dominantly inherited euthyroid hyperthyroxinemia, later to be linked to the albumin gene, is known as familial dysalbuminemic hyperthyroxinemia (FDH). It is the most common cause of an inherited T_4 increase in the Caucasian population, producing on the average a twofold increase in the serum total T_4 concentration. The prevalence varies from 0.01 to 1.8%, depending on ethnic origin, with the highest prevalence occurring among Hispanics. This form of FDH has not been reported in subjects of African or Asian origin. Falsely elevated free T_4 values, when estimated by standard clinical laboratory techniques, have often resulted in inappropriate treatments.

FDH is suspected when serum total T_4 concentration is increased without a proportional elevation in total T_3 level and nonsuppressed serum TSH. Half of affected subjects have also rT_3 values above the normal range (Table 2). Since the same combination of test results is found in subjects with the Thr-109 TTR variant, the diagnosis of FDH should be confirmed by the demonstration of an increased proportion of the total serum T_4 migrating with HSA. This form of FDH is caused by a missense mutation in codon 218 of the HSA gene replacing the normal Arg with a His. Its association with a $SacI^+$ polymorphism suggests a founder effect and is compatible with ethnic predilection of FDH.

TABLE 2 Serum Iodothyronines in FDH

Variant	Serum concentration (fold of the normal mean)			Binding affinity (K_a) of the variant albumins as fold of the normal mean	
	T_4 (μg/dl)	T_3 (ng/dl)	rT_3 (ng/dl)	T_4	T_3
R218H	16.0 (2)	147 (1.2)	29 (1.4)	10–15	4
R218P	146 (18.2)	253 (2.3)	135 (6.1)	11–13[a]	1.1[a]

[a]Determined at saturation. Affinities are higher at the concentration of T_4 and T_3 found in serum.

Two other mutations of the HSA gene that increased the affinity of the molecule for iodothyronines have been recently identified. One is also located in codon 218 but the mutant amino acid is Pro. This variant HSA has a 90-fold increase in the affinity to T_4, resulting in serum total T_4 concentrations that are 22-fold the mean normal and the highest observed in any physiological or pathological circumstances. Corresponding increases of rT_4 and T_3 are on the average 5- and 2-fold the normal mean (Table 2). The other mutation, a replacement of the normal Leu-66 with a Pro, produces a 40-fold increase in the affinity for T_3 but only a 0.5-fold increase in the affinity for T_4. As a consequence, patients have hypertriiodothyroninemia but not hyperthyroxinemia. It should be noted that serum T_3 concentrations are falsely low, or even undetectable, when measured using an analogue of T_3 as a tracer rather than a radioisotope.

2. *Bisalbuminemia and Analbuminemia*

Variant HSAs, with altered electrophoretic mobility, produce "bisalbuminemia" in heterozygotes. T_4 binding has been studied in subjects from unrelated families with a slow HSA variant. In one study, only the slow-moving HSA bound T_4, while in another study, both did. The differential binding of T_4 to one of the components of bisalbumin may be due to enhanced binding to the variant component with a charged amino acid sequence.

Analbuminemia is extremely rare. T_4 transport has been studied in only two subjects with this homozygous condition. The virtual absence of HSA had no clear effect on the concentration of serum iodothyronines as judged by determination of protein-bound iodine, despite an increased binding capacity of TBG and TTR. TBG and TTR become normalized when serum HSA was restored to normal by multiple transfusions.

Thyroid-Stimulating Hormone (TSH)

H. MIRCESCU, J. C. GOFFART, AND J. E. DUMONT
Université Libre de Bruxelles

The subject of this article is the action of thyroid-stimulating hormone (TSH) on the thyroid gland. The main function of the thyroid gland is the synthesis and secretion of thyroid hormones. These hormones are necessary for body and brain development in the fetus and in the child. Throughout the lifetime of an individual, they set the level of metabolism of the body and its various organs. Thyroid gland function and growth are essentially controlled by two major physiological systems: TSH from the hypophysis and iodide from the diet. The first system functions as a thermostat maintaining the serum levels of thyroid hormones at a constant level by negative feedback regulation. Thyroid hormones negatively control the synthesis and secretion of TSH by specialized cells of the anterior pituitary lobe: the thyrotrophs. TSH stimulates the function and growth of the thyroid. Serum iodide, the main precursor of thyroid hormones, negatively controls the thyroid, ensuring that the gland becomes more efficient when the supply of its substrate in the diet declines. TSH stimulates by various mechanisms all steps of iodine metabolism and thyroid hormone synthesis and secretion by the gland. On a chronic basis, it exerts trophic control of the gland, maintaining or increasing its size, i.e., the number of cells it contains in relation to the long-term level of serum thyroid hormones.

I. PHYSIOLOGICAL EFFECTS OF THYROID-STIMULATING HORMONE

Thyroid-stimulating hormone (TSH) exerts two types of effects on the thyroid gland (see Fig. 1). When

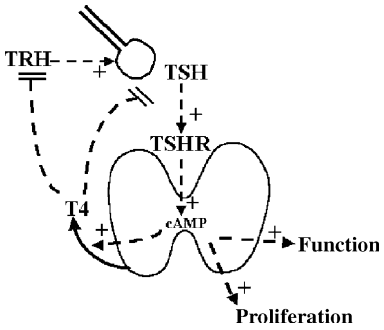

FIGURE 1 Pituitary control of the thyroid through TSH. TSHR, TSH receptor; TRH, TSH-releasing hormone; cAMP, 3′-5′ cyclic AMP.

administered acutely, it stimulates within minutes or hours thyroid hormone synthesis and secretion; in addition, its tonic level controls the growth and proliferation of the thyrocytes (see Fig. 2). The synthesis of thyroid hormones takes place at the apex of the thyrocyte, which faces a closed lumen: the follicular lumen. Synthesis requires (1) at the base of the cell, the trapping of iodide from the extracellular fluid by the Na^+/I^- symporter (NIS); (2) at the apex of the cell, the export of iodide from the cell to the lumen through specialized channels; (3) the synthesis of a very large protein, thyroglobulin (MW 680,000), which will serve as a matrix for the synthesis of thyroid hormones; (4) the export by exocytosis of thyroglobulin in the lumen; (5) the generation of H_2O_2 by a specialized enzyme, THOX (thyroid H_2O_2-generating system); (6) the oxidation of iodide and its covalent linkage to the tyrosines of thyroglobulin by thyroperoxidase using H_2O_2 as oxidizing cofactor; (7) the coupling in iodothyronines [thyroxine (T4), triiodothyronine (T3)] of iodotyrosyls of thyroglobulin by thyroperoxidase. Iodide channels, THOX, and thyroperoxidase are all located in the apical membrane of the cell.

Secretion also takes place at the apex of the cell. It involves the endocytosis of lumenal thyroglobulin, its hydrolysis in secondary lysosomes, and the secretion by an unknown mechanism of the iodothyronines released from thyroglobulin. Endocytosis may involve the bulk endocytosis of thyroglobulin by macropinocytosis or micropinocytosis with selective binding of thyroglobulin by protein acceptors, such as megalin and asialoglycoprotein, and its subsequent uptake (Fig. 3).

TSH stimulates within minutes several steps of synthesis and secretion: iodide efflux in the follicular lumen, H_2O_2 generation and thyroglobulin iodination, iodotyrosine coupling, and the uptake of thyroglobulin by macropinocytosis and therefore secretion. Iodide transport at the base of the cell is regulated by the level of the transporter NIS: its synthesis in significant amounts in response to TSH requires an effect at the level of gene transcription and therefore requires several hours.

Other effects on transcription supplement the acute effects of TSH: thus, TSH enhances the synthesis of thyroperoxidase and, in some species, of THOX and thyroglobulin. The latter effects represent the functional counterpart of the differentiating effects of TSH in thyroid cell cultures. In such cultures, stimulation of the cells by growth factors such as EGF (epidermal growth factor), hepatocyte growth factor, or phorbol esters induces proliferation and the loss of thyroid-specific gene expression, i.e., of differentiation. TSH re-induces such expression; it has a differentiating action. Such effects, involving changes in the pattern of transcription, require several hours.

In vivo or *in vitro*, if administered for at least 24 h and at a high enough level, TSH also induces thyroid cell proliferation and consequently thyroid growth. Due to the negative feedback regulation of thyroid hormones on TSH secretion, any treatment decreasing thyroid hormone secretion by inhibiting its synthesis, such as anti-thyroid drugs or iodine deficiency, will thus lead to thyroid enlargement, i.e., goiter.

Although it promotes the growth and differentiation of thyrocytes, TSH is not necessary for these developments in the fetus. Decapitated fetuses or fetuses lacking TSH develop a normal thyroid, although the growth of this thyroid will be slowed in the second part of pregnancy. By far, the most important effect of TSH in the fetus is the induction of NIS and therefore of iodide transport.

II. BIOCHEMISTRY OF TSH ACTION: THE THYROTROPIN RECEPTOR

Thyrotropin (7000 MW) is a heterodimer of an α-subunit, common to follicle-stimulating hormone,

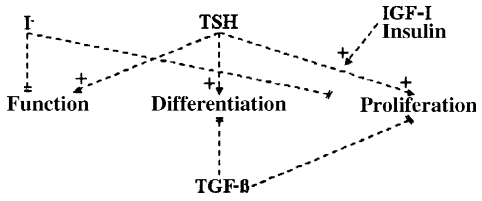

FIGURE 2 Effects of extracellular signals on human thyroid follicular cells.

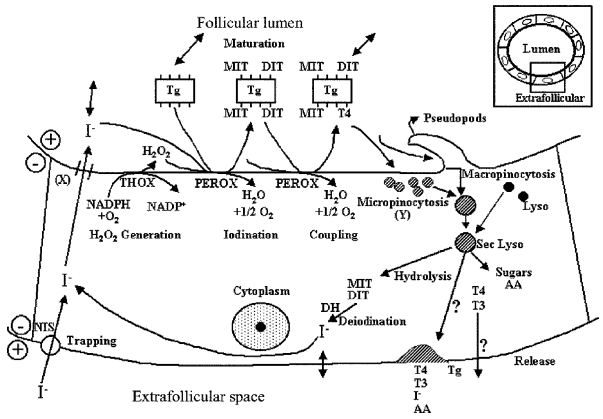

FIGURE 3 Cellular physiology of the thyroid follicular cell. AA, amino acids; DH, iodotyrosine dehalogenase; DIT, diiodotyrosine; MIT, monoiodotyrosine; NIS, Na^+/I^- symporter; PEROX, thyroid peroxidase; Tg, thyroglobulin; T4, thyroxine; THOX, thyroid H_2O_2-generating system; X, iodide apical channel; Y, acceptor involved in thyroglobulin uptake.

luteinizing hormone, and TSH, and a β-subunit specific to TSH. This glycoprotein is synthesized and secreted by the pituitary thyrotrophs. It is specifically recognized by a seven-transmembrane receptor expressed only in thyrocytes and, in some species, in some preadipocytes and adipocytes. The TSH receptor links the thyroid with its controlling system; i.e., it is its connection with the physiology of the cell. The TSH receptor is a classical seven-transmembrane receptor. It is a linear sequence of 764 amino acids from the exterior N-terminal to the interior C-terminal. Its external part contains 419 amino acids. Its doughnut-shaped structure recognizes and accommodates TSH. The membrane part of the receptor contains seven transmembrane α-helical segments, three extracellular loops, and three intracellular loops. The intracellular loops, especially the third loop, but also the second loop and the intercellular C-terminal, presumably interact with their GTP-binding protein effectors. The binding of TSH to the extracellular N-terminal induced a conformational change of the intramembrane part—a shift in the position of the α-helices—thus opening the intracellular loops for the effector GTP-binding proteins. The extracellular part of the receptor acts as an inhibitory domain, switching when bound to TSH from a negative to a positive regulator on GTP-binding proteins G_s, G_q, and G_i (Fig. 4).

The TSH receptor activates at least three effectors: the GTP-binding proteins G_s, G_q, and G_i. G_s itself activates adenylate cyclases, which generate cyclic AMP from ATP. G_q activates phospholipase C β, which generates from phosphatidylinositol 3,5-phosphate the intracellular signals inositol 1,5-phosphate and diacylglycerol. G_i inhibits adenylate cyclases and through its βγ-subunits may affect other signal transduction proteins. Although the TSH receptor is able to activate both G_s and G_q, in some species such as dog it effectively activates only G_s. In human thyroid cells, it stimulates G_s and G_q and therefore stimulates two regulatory cascades: the cyclic AMP and the phospholipase C pathways.

III. BIOCHEMISTRY OF TSH ACTION: TSH RECEPTOR-ACTIVATED CASCADES

Like other hormones, the TSH receptor exerts its effects through two biochemical cascades: the cyclic AMP pathway and the phospholipase C inositol–1,4,5-phosphate and diacylglycerol pathway.

The human thyroid cell generates cyclic AMP through adenylate cyclases III, VI, and IX. cAMP then binds to and activates at least two effector proteins: the two isoforms of protein kinase A (cyclic AMP-dependent protein kinase), which modulate the activity of target proteins through phosphorylation, and EPAC protein, a guanyl nucleotide exchanger protein that activates the small G-proteins Rap1 and Rap2, which modulate other proteins themselves. Until recently, only protein kinase A was considered, although only a few substrates have been identified in thyroid. One of these, CREB (Ca^{2+}/cAMP-response element-binding protein), is a transcription factor that is activated by phosphorylation, which might account for some transcriptional effects of cAMP. The role of the Rap activator is still unknown. Although most effects of TSH and its mediator of cAMP are currently ascribed to the action of PKA, it is surprising that, in fact, as the availability of more or less specific PKA inhibitors has followed the study of cAMP effects, such a role of PKA has only rarely been investigated.

In the human thyroid, TSH activates phospholipase C β and thus releases two intracellular signal molecules: diacylglycerol and inositol 1,4,5-trisphosphate (IP_3). This effect requires higher concentrations of TSH than the stimulation of adenylate cyclase. The role of diacylglycerol is to stimulate protein kinase C (PKC). This role can be inferred from the effects of phorbol esters, which behave as nonhydrolyzable analogues of diacylglycerol. Thus, the activation of PKC leads to the stimulation of H_2O_2 generation, protein iodination, and thyroid hormone synthesis. IP_3, on the other hand, presumably, as in other cells activates the release of Ca^{2+} stored in the endoplasmic

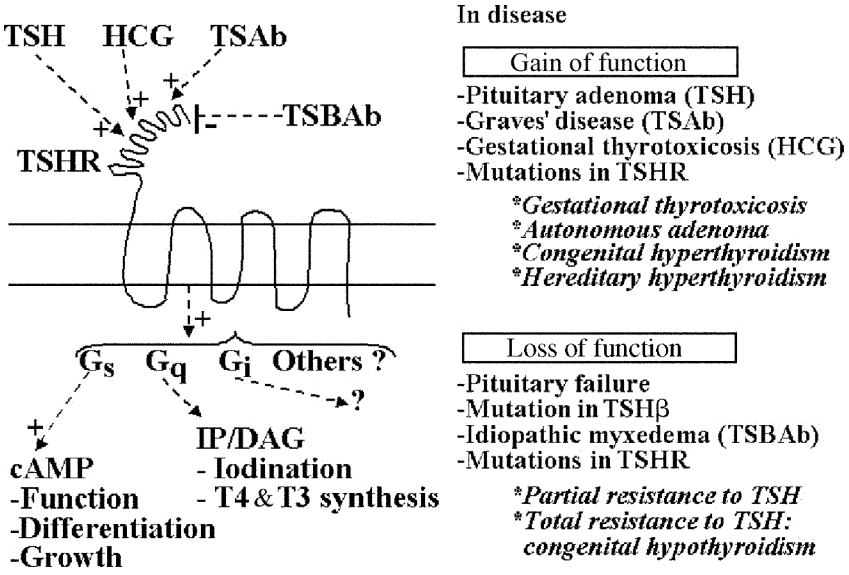

FIGURE 4 The TSH receptor. HCG, human chorionic gonadotropin; TSAb, thyroid-stimulating antibodies; TSBAb, thyroid stimulation-blocking antibodies; G_s, G_q, G_i, GTP-binding proteins mediating the activation (G_s) or inhibition (G_i) of adenylate cyclase and the activation of phospholipase (G_q).

reticulum, leading to an increased influx of extracellular calcium in the cell. Such effects of IP_3 would account for the known effects of TSH on thyrocyte calcium metabolism. Free intracellular calcium in its turn, presumably mainly through calmodulin, activates a variety of enzymes in cascade. The main physiological effect of this cascade is the activation of H_2O_2 generation and consequently of protein iodination and iodothyronine synthesis. Thus, through both arms of the phospholipase C cascade, TSH stimulates these processes; cyclic AMP, in contrast, inhibits them. These effects take place within minutes.

TSH stimulates to various extents the expression of the genes corresponding to specific thyroid proteins. These effects are mediated mostly by cyclic AMP and presumably by protein kinase A phosphorylation of various transcription factors of the CREB, cAMP response element modulator (CREM), and activator protein-1 families. Thyroid-specific transcription factors (Pax8, paired box gene 8; TTF1 and TTF2, thyroid transcription factors 1 and 2) are necessary for these syntheses but their function is not regulated directly by TSH or cyclic AMP. The induction of thyroglobulin and NIS mRNA expression requires an intermediary protein synthesis, but the induction of thyroperoxidase does not. Although the expression of NIS and TPO is greatly enhanced by TSH, that of thyroglobulin is not, but it is decreased in the absence of normal TSH levels. Of course, in time, *in vivo*, the synthesis of most proteins is increased, reflecting the growth of the cell. General protein synthesis is increased in thyroid cells by insulin and insulin-like growth factor-I (IGF-I) acting mostly through the IGF-I receptor. The synthesis of most thyroid-specific proteins is decreased by growth factors such as EGF, reflecting the dedifferentiating action of these factors.

IV. THYROTROPIN CONTROL OF THYROID GROWTH

Thyrotropin exerts a positive control on thyroid growth *in vivo*. In its absence, either because of a pituitary disease or because of a treatment with thyroid hormone, the gland becomes hypoplastic, with a decrease in the number and the size of the thyrocytes. Conversely, excess thyrotropin causes the hypertrophy of the thyroid, i.e., goiter. Inactivating or activating mutations of the TSH receptor similarly lead to thyroid atrophy or goiter. Antibodies blocking or activating the receptor have similar effects. The mechanism of the growth effect of thyrotropin has been studied *in vitro*. It corresponds to a DNA-synthesizing and mitogenic activity. It is mediated by cyclic AMP and can be mimicked by agents increasing intracellular cyclic AMP levels such as forskolin. It requires the activation of protein kinase A but this activation is not sufficient to trigger it. The role of EPAC and Rap in this action is under study. The effect of thyrotropin requires the action of IGF-I on its

receptor. The respective roles of TSH and IGF-I can be summarized as follows: IGF-I provides the necessary cyclins for the cyclin–cyclin-dependent kinase complexes, which relieve the inhibition by retinoblastoma (RB) proteins of DNA synthesis; TSH, through cyclic AMP, activates these complexes.

Although thyrotropin growth-promoting action is the main controlling factor of thyroid size after birth, it is not required for thyroid differentiation and development in early fetal life. The thyroid differentiates, migrates to its normal location, and develops, albeit to a lesser extent, in the absence of the hypophysis or when the TSH receptor is inactivated.

V. THYROTROPIN ACTION IN DISEASE

Different diseases cause abnormalities in thyrotropin action. Lack of thyrotropin action through decreased thyrotropin synthesis or secretion occurs in various pituitary diseases through congenital hypopituitarism, a defect in TSH synthesis, or pituitary destruction by an adenoma. Inactivating defects of the TSH receptor have similar effects. In all of these cases, the thyroid becomes inactive, thus causing a decrease in thyroid hormone secretion and hypothyroidism and causing atrophy of the thyroid.

Conversely, hyperstimulation of the TSH by excessive pituitary secretion, by stimulating antibodies, or by congenital activating mutations of the TSH receptor causes hyperthyroidism and goiter.

Somatic activating mutations of the TSH receptor generate a hyperactive adenoma that, because of its excessive thyroid hormone secretion, will depress TSH blood levels and induce the quiescence of the unaffected thyroid cells.

Antibodies to the TSH receptor, depending on whether their action is stimulatory or inhibitory, will cause similar diseases: Graves' disease and hyperthyroidism with the thyroid-stimulating antibodies and hypothyroidism with the thyroid stimulation-blocking antibodies.

Thyrotropin Receptor Signaling

LEONARD D. KOHN* AND MINHO SHONG†

*Edison Biotechnology Institute and Ohio University • †Chungnam National University, Korea

The functional role of the thyroid is to synthesize and secrete the thyroid hormones necessary for the normal metabolic homeostasis of every cell

in the human body. This process is under the primary control of the pituitary glycoprotein hormone, thyrotropin (TSH), but requires the coordination of multiple genes and the activities of multiple gene products. This article explains the interaction of TSH with its receptor to govern thyroid gland growth and function.

I. INTRODUCTION

In addition to stimulating the synthesis and secretion of thyroid hormones, thyroid-stimulating hormone (TSH) regulates thyroid cell function and growth. TSH acts via a single molecular entity on the surface of the cell, the TSH receptor (TSHR). TSH interacting with this receptor accomplishes its complex array of duties by using a multiplicity of signals that are coordinated with the signals of other receptors, in particular, the insulin/insulin-like growth factor-I (IGF-I) signal system.

The thyroid is composed of a multiplicity of follicles, wherein thyrocytes surround a central lumen. Each follicle is surrounded by a vascular network that imports and exports raw materials or product from the thyrocyte and follicle. The primary function of the thyroid is to synthesize thyroglobulin (TG), the thyroid hormone precursor; the TSHR signal transduction system is devoted to its synthesis, storage, iodination, and degradation.

Humans ingest iodide, the key component of thyroid hormones, in episodic bursts. TSH/TSHR, by its control of the sodium iodide symporter (NIS), regulates the ability of ingested iodide to be scavenged from the bloodstream and concentrated within the thyrocytes surrounding the follicular lumen. TSH/ TSHR is involved in iodide transport and secretion into the follicular lumen; Pendrin is one porter now known to be important for this process. TG, to which the iodide is coupled and on which iodotyrosine residues are converted to thyroid hormones, is synthesized, glycosylated, phosphorylated, and vectorially transported to the follicular lumen. Thyroid peroxidase (TPO), which is necessary to iodinate the TG and couple iodotyrosine residues to form thyroid hormones, is synthesized, inserted into the apical membrane facing the follicular lumen, and coupled to a system to generate the hydrogen peroxide necessary for the TPO-dependent iodination process. The iodinated TG is stored and then transported to the lysosome where it is degraded to form thyroid hormones. The thyroid hormones are finally secreted into the bloodstream both to maintain a steady-state level necessary to achieve normal homeostasis and to respond in stress situations. These processes are not synchronized, since the thyroid follicles are functionally heterogeneous. The TSHR and its signaling process control and coordinate all of these steps by regulating gene expression, by posttranslational activation of genes, and by inducing morphologic changes in the cell important for TG degradation and thyroid hormone release.

The TSHR also controls the growth of the thyrocytes. In this case, it is now clear that TSH/TSHR signaling is a preconditioning prelude for insulin, IGF-I, and possibly other growth factors to cause cell cycle progression. Moreover, TSH/TSHR signaling exerts a negative control on major histocompatibility (MHC) and intracellular adhesion molecule 1 gene expression to preserve self-tolerance. This is necessary to avoid an autoimmune response when TSHR-induced positive regulatory signals increase the multiplicity of genes and gene products needed for growth and function.

The concept that all of this is accomplished by a single signal transduction system, the adenylate cyclase system, and a single signaling molecule, cyclic AMP (cAMP), has been eliminated. Although some clinicians may still consider this signal the sole cause of Graves' hyperthyroidism and goiter. Graves' disease is caused by autoantibodies to the TSHR that cause its signal generation system to function excessively.

II. THE TSH RECEPTOR—STARTING POINT OF SIGNAL GENERATION

The TSH receptor is a member of the G-protein-coupled family of receptors with seven transmembrane domains. The receptor has two parts (Fig. 1), a long hydrophilic region that binds TSH followed by a region with seven hydrophobic, membrane-spanning domains, similar in sequence to other G-protein-coupled receptors and its sister receptors, the lutropin/chorionic gonadotropin receptor (LH/CGR) and follicle-stimulating hormone receptor (FSHR). Unlike many receptors in this family that couple to a single G-proteins, i.e., the α- or β-adrenergic receptors, TSHR, LH/CGR, and FSHR couple to more than one G-protein, thereby activating both the phosphatidylinositol 4,5-biphosphate (PIP_2) and cAMP cascades (Fig. 1).

The TSHR hydrophilic extracellular domain is longer than that of the LH/CGR or FSHR by approximately 60 residues (Fig. 1). These are located in a long ≥50-residue insert in the region of residues 300–400 of the TSHR and a short insert involving

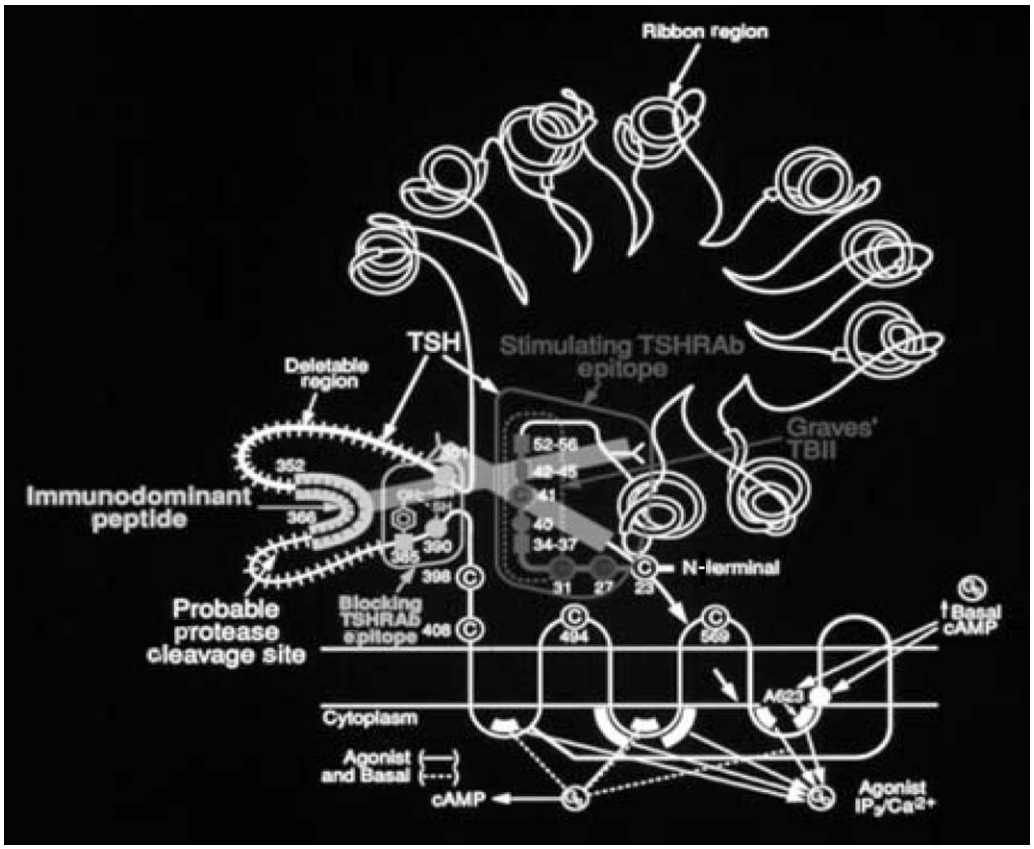

FIGURE 1 Putative model of TSHR. Determinants for blocking TSHR Abs and stimulating TSHR Abs are approximated to make up the TSH site. The former are implicated in high-affinity TSH binding and in the expression of disease by patients with idiopathic myxedema and hypothyroidism. The latter are implicated in patients with Graves' disease and hyperthyroidism. The loop between residues 303 and 382 is separated from the remainder of the external domain, since residues within it can be deleted with no loss in receptor function. This loop includes residues 352–366, which constitute the immunogenic peptide used to produce a specific antibody to the receptor. The hatched lines denote the regions of the receptor in close approximation based on antibody-peptide inhibition studies and by studies of TSHR relationships with the LH/CGR. The first, second, and third intracytoplasmic loops, particularly Ala-623 and the N- and C-terminal 5 residues of the third loop, are identified as the critical link for hormone and TSHR Ab coupling to G_q and the PIP_2 cascade. All loops interact with G_s to regulate constitutive or basal cAMP levels. The middle of the second cytoplasmic loop is coupled to agonist-increased cAMP signaling via G_s.

residues 38–47 (Fig. 1). The former region can be deleted with little loss of TSHR signaling; modification of the latter causes a loss in signal generation. TSH binds to multiple parts of this extracellular domain; however, the high-affinity binding site has important residues between residues 280 and 400. Binding to the extracellular domain perturbs the transmembrane domain where the signal is generated and induces a conformational change that converts the receptor to its agonist state.

TSHR residues 8–165 can be replaced by the equivalent N-terminal portion of the LH/CGR with no significant loss of TSHR signal generation; in contrast, stimulating TSHR autoantibodies from patients with Graves' disease largely lose their ability to increase cAMP levels or activate the PIP_2/Ca^{2+}/arachidonate signal system. The residues in this region that are important for coupling to the cAMP and PIP_2/Ca^{2+}/arachidonate signals appear to be different; critical sites linked to cAMP signaling lie predominantly between residues 90 and 165, whereas several residues important for the PIP_2/Ca^{2+}/arachidonate signal lie in the region between residues 30 and 90. The probability is that the two regions on the N-terminus, residues 30–60 and 90–165, act together in a conformational epitope, approximating helices and creating the agonist face of the TSH-binding site (Fig. 1).

Like adrenergic receptors (ARs), mutation of each of the extracellular loops of the transmembrane domain results in a loss of TSH-stimulated and TSHR autoantibody activities as a result of a conformational change rather than abnormal receptor synthesis, processing, or incorporation into the bilayer. The short cytoplasmic peptides of the transmembrane domain of the TSHR differ in length, are relatively nonhomologous among receptor types, contain one or more potential phosphorylation sites, and couple to G_q, which signals the PIP_2 cascade, as well G_s, which initiates the cAMP cascade.

Residues in the first, second, and third cytoplasmic loops are important for TSH and Graves' immunoglobulin G (IgG) induction of the PIP_2 signal, but also control constitutive cAMP levels (Fig. 1). Thus, all the first, second, and third cytoplasmic loop mutations affecting agonist-induced signaling also have decreased basal or constitutive cAMP levels and in some cases are hot spots that result in constitutively high basal cAMP signaling, i.e., in a receptor conformation that will bind and activate a G-protein in the absence of ligand. The latter mutations have been associated with functioning adenomas in patients; similar mutations in the LH/CGR are associated with precocious puberty. The middle region of the second cytoplasmic loop, particularly residues 525–527, is involved in agonist-induced G_s coupling, whereas the entire loop is important for agonist-induced G_q coupling.

The amino acid sequence in the second cytoplasmic loop, as an example, is identical in rat, human, and dog TSHR, suggesting that interactions and signals are likely to be applicable to all species of TSHR. The number of residues in the second cytoplasmic loop of TSH and LH/CGR is the same; further, the sequences of LH/CGR or FSHR are 60% identical and most differences are conservative substitutions. This suggests that the second cytoplasmic loop will share common signal transduction/G-protein interactions among the family of receptors. In the second cytoplasmic loop, the number of residues in the TSH, gonadotropin, and adrenergic receptors is the same, but the conformations of TSHR and ARs are very different with respect to helix, extended coil, or β-turn. This may contribute to the ability of the TSHR to couple to both G_s and G_q, whereas AR or muscarinic receptors couple to only one type of G-protein.

Since it is unlikely that G_q and G_s couple simultaneously and since TSHR transfections result in an increased basal cAMP level, it is possible that TSHR transmembrane domains are in a partial agonist conformation in the absence of ligand. Alternatively, there are several TSHR forms, precoupled to G_s, to G_q, or to neither one, and an equilibrium exists among them. Mutations might influence this equilibrium by allowing interactions not usually evident in the absence of ligand; they might also alter the affinity of each for G_s or G_q. This might explain curvilinear TSH-binding isotherms, i.e., high- and low-affinity binding sites, with low and high capacities, respectively. This also might explain why different concentrations of TSH are necessary to induce the cAMP and PIP_2 signals *in vitro*; i.e., the cAMP signal is linked to a high-affinity G_s-coupled TSHR form, whereas the PIP_2 signal is linked to a low-affinity G_q-coupled form.

The P_1 purinergic receptor regulates TSH and Graves' IgG induction of the cAMP and PIP_2 signals; P_1 purinergic agonists (phenylisopropyladenosine, PIA) inhibit TSHR-induced cAMP production but enhance inositol phosphate formation, despite the fact that they have little direct effect on either signal. The effect of PIA is mediated by a pertussis toxin-sensitive G-protein (G_i). The ability of TSH to modulate the cAMP signal system has also been related to pertussis toxin-sensitive ADP ribosylation of a G_i family member.

III. THE SIGNALS THEMSELVES

A. Adenylate Cyclase–cAMP Signal

A close correlation exists between TSH binding and stimulation of the adenylate cyclase/cAMP signal. It induces TG, TPO, and NIS gene expression and is important in their posttranslational activation. This dual role is exemplified by NIS, where there is a clear-cut dichotomy between gene induction (RNA levels), protein, and iodide uptake (function). Little is still known about the mechanism by which TSH activates Pax-8, the critical transcription factor that regulates NIS gene expression, or about the mechanism by which TSH activates the NIS protein. Pax-8 is the homeoprotein encoded by the PAX-8 gene, a member of the HOX network of transcription factors. Recent work suggests that cAMP modulation of redox potential is important for the activation of Pax-8 and that cAMP-modulated protein phosphorylation is important for protein activation.

The increase in cAMP activates protein kinase A. More than one form of protein kinase A exists. These differ in their regulatory subunits and in thyrocytes from different species, perhaps contributing to signal differences. Despite overwhelming evidence that kinase A mediates cAMP activity and despite the identification of a multiplicity of

phosphorylated proteins resulting from the TSH/TSHR/cAMP signal, a cohesive view remains an enigma.

TSH-increased cAMP has been linked to thyroid cell growth, and cAMP is a necessary but insufficient signal. Thus, in the absence of insulin/IGF-I, TSH increases cAMP perfectly well but does not induce growth. TSH was found to be a preconditioner for insulin/IGF-I regulation of cell cycle progression; the insulin/IGF-I effect is, at the least, related to the action of Akt or PKB, a downstream kinase of the insulin signaling system.

TSH/TSHR and cAMP, together with insulin/ IGF-I, increase 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, thereby increasing the formation of gerranylgerranyl phosphate. This eliminates p27Kip1 by accelerating its degradation; cyclin-dependent kinase 2 is activated, causing the cyclin cascade to proceed, and S6 kinase 1 (S6K1) is activated. Rho proteins necessary for S-phase development are also gerranylated and translocated to membranes during $G_{1/S}$ progression. The effect of gerranylgerranyl pyrophosphate is abolished with botulinum C3 exoenzyme, which specifically ADP ribosylates Rho proteins. The connection of TSHR/cAMP signaling to phosphatidylinositol 3-kinase (PI3K), phosphoinositide-dependent kinase 1 (PDK1), and insulin/IGF-I-coordinated actions to increase S6 kinase activity is increasingly clear (Fig. 2).

TSH/TSHR/cAMP signaling causes morphologic changes in cells. The signals induce pseudopod and microvilli formation on the apical membrane adjacent to the follicular lumen and initiate the fluid pinocytosis process whereby colloid containing TG is engulfed and taken into the cell to lysosomes for degradation. They initiate the secretion process as lysosomes that had moved to the apical membrane to fuse with the pinocytotic vesicles return toward the basal membrane while digesting the TG and converting it to amino acids. Contractile and cytoskeleton proteins are altered during this process. Increased membrane fluidity needed for these processes may derive from TSHR/cAMP signaling inducing HMG CoA reductase to produce cholesterol, not simply gerranylgerranyl phosphate.

B. PIP_2/Ca^{2+}/Arachidonate Signaling

TSH stimulates the hydrolysis of PIP_2 by phospholipase C. The best characterized functional effect of this signal is on iodide efflux from the apical membrane and H_2O_2 generation important for TPO activity, iodination of TG, and iodotyrosine coupling. The importance of this pathway in thyrocyte growth is recognized clinically. Thus, two populations of TSHR antibody (Ab)-stimulating autoantibodies exist, one increasing cAMP levels and the second increasing PIP_2/Ca^{2+}/arachidonate signaling. The two together maximally increase growth and are associated with the largest goiters.

Only approximately 50% of TSH-increased cytosolic Ca^{2+} levels is phospholipase C-dependent; the remaining 50% is linked to phospholipase A2 activation. Phospholipase A2 produces arachidonic acid; cyclooxygenase-, lipoxegenase-, and expoxygenase-derived metabolites of arachidonic acid are important end products regulating cell activity, i.e., prostaglandins and leukotrienes.

Currently, the importance of this pathway focuses on TSH-regulated hydrolysis of phosphatidylinositol 3,4-bisphosphate and phosphatidylinositol 3,4,5-trisphosphate and phosphatidylinositol 3,4-biophosphate and phosphatidylinositol 3,4,5-triphosphate. The complexity of the effects of TSH action and its connection to insulin/IGF-I regulated Akt (PKB) is illustrated in a report by Rameh and Cantley (1999).

C. PI3K Signaling

Recently, pituitary glycoprotein hormone receptors, including the TSHR, have been shown to activate PI3K-dependent signaling pathways to regulate the growth of target endocrine glands. Signaling in thyrocytes is TSHR-specific, is mediated by the cAMP signal, and involves the p85 subunit of PI3K that is bound to the TSHR as well as G_s (Fig. 2). PDK1 is a major regulator for transmitting PI3K-dependent signaling pathways to downstream kinases, such as Akt/PKB and S6K1, in response to TSH and insulin/IGF-I in thyroid cells (Fig. 2). TSH preferentially activates S6K1 signaling pathways compared to Akt/PKB in thyroid cells (Fig. 2). However, insulin independently activates two PDK1 downstream signaling pathways, Akt/PKB and S6K1, thus exhibiting synergistic actions with TSH on S6K1 activation (Fig. 2). The inhibition of S6K1 by rapamycin results in inhibition of $G_{1/S}$ cell cycle progression by TSH/insulin *in vitro*. S6K1 is also involved in the regulation of thyroid follicle activity, for example, uptake of colloid, which is regulated by endogenous TSH *in vivo*.

D. Other Signals

TSH/TSHR-increased ADP ribosylation is not mediated by cAMP and has been related to modulation of G_s. Thus, the cholera toxin subunit has an intrinsic ADP-ribosyltransferase activity that

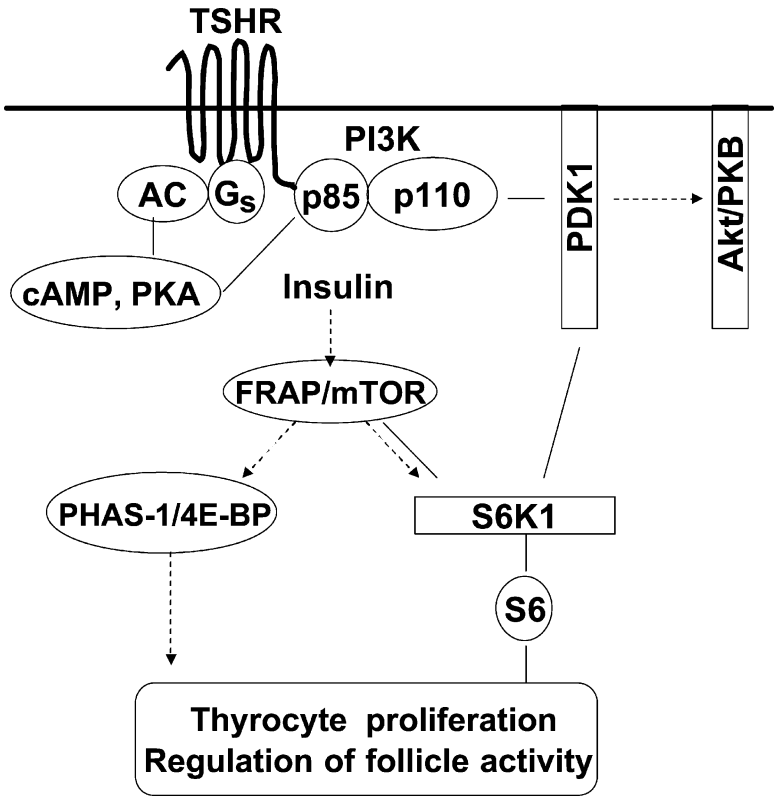

FIGURE 2 TSHR and PI3K signaling: involvement of PDK1 and link to insulin/Akt. TSHR is associated with the p85 regulatory subunit of PI3K and its PI3K activity is induced by TSH and cAMP. TSH is able to translocate PDK1 into the plasma membrane and PDK1 preferentially phosphorylates S6K1, but not Akt/PKB. However, insulin phosphorylates Akt/ PKB and PHAS-1/4E-BP1 in a PI3K- and FRAP/mTOR-dependent manner. Rapamycin inhibits the cooperative actions of PHAS-1/4E-BP1 and S6K1 and results in the inhibition of TSH-mediated follicle proliferation and activity. The solid lines represent the pathways preferentially activated by TSH and the dashed lines represent pathways activated by insulin but not by TSH in thyroid cells. PHAS-1, the small, heat- and acid-stable protein 4E-BPI; FRAP, flouride-resistant acid phosphates; mTOR, mammalian target of rapamycin.

ADP-ribosylates G_s, altering ATP/ATP hydrolysis and binding, and shifting G_s to a "permanently activated" state. TSH activates a membrane ADP-ribosyltransferase imputed to act similarly and activates a deribosylating enzyme. Little is known about the significance of this potential signal. TSH/TSHR can regulate the membrane electrical potential and pH gradient via a non-cAMP mechanism. It does not seem to involve ion flux mechanisms exhibited by prototypical seven-transmembrane domain receptors such as rhodopsin.

E. Signaling Crosstalk

Phorbol esters mimic or potentiate TSHR effects. There is clear feedback regulation between the cAMP and PIP_2 signal systems in FRTL-5 cells and transgenic animals. Catecholamines and β_1-adrenergic agents modulate TSHR signal transduction via cAMP. However, perhaps the least recognized yet most important receptor signal system able to regulate TSHR signaling is the transforming growth factor-β (TGF-β) signal.

TGF-β up-regulates upstream stimulatory factors (USF). As will be noted below, USF transcription factor sites are directly competitive with Pax-8 sites and reverse TSHR/ cAMP signal transduction by competing for Pax-8 binding, most notably on the NIS promoter. However, USF sites exist on TG, TPO, and the TSHR. TGF-β-induced Smad signaling can regulate TTF-1 action. Smad/TTF-1 complexes up-regulate Pendrin gene expression.

Basic fibroblast growth factor (bFGF) decreases TSHR mRNA levels, cAMP signal generation, and cAMP signal action. Despite this, bFGF increases thyrocyte thymidine incorporation and cell growth.

This appears to be explained by the ability of bFGF to activate the PIP_2 signal system, the Ca^{2+} signal, and a novel tyrosine kinase activity that is able to activate the insulin/c-*ras* pathway. It mimics the crosstalk between the TSHR-induced PIP_2 and cAMP signal systems.

IV. TSHR SIGNALING AND TRANSCRIPTIONAL CONTROL OF GENE EXPRESSION

A. TG, TPO, and NIS

A fundamental advance in TSHR signaling is dependent on the work of DiLauro and colleagues, who described the importance of tissue-specific thyroid transcription factors in the function of thyrocytes: thyroid transcription factor-1, (TTF-1), TTF-2, and Pax-8 (Fig. 3). TG synthesis is controlled by TTF-1, TTF-2, and Pax-8. Thus, there are three TTF-1 sites within the minimal promoter, A to C, from 5′ to 3′; the C site also binds Pax-8. TSH/TSHR/cAMP decreases TTF-1 gene expression and binding to the three TTF-1 sites but increases Pax-8 expression, phosphorylation, redox potential, and binding. This allows TG synthesis to persist or increase, despite decreases in TSHR, which is controlled by TTF-1 alone. TTF-2 is a forkhead protein controlled by insulin/IGF-I. This allows TG synthesis in the absence and in the presence of TSH, so TG can accumulate in the follicular lumen to act as an iodide trap.

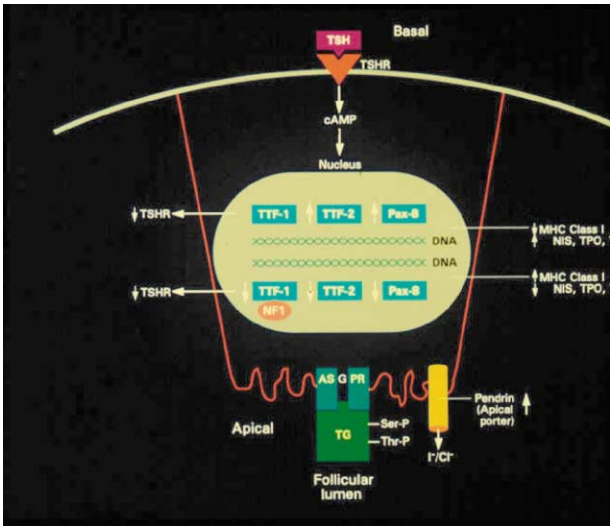

FIGURE 3 TG counteracts TSH-increased Pax-8 and TTF-2 and is additive in suppressing TTF-1. Both TSH and TG therefore decrease TSHR. TSH increases NIS, TPO, and TG, whereas TG suppresses them. TSH decreases MHC class I, whereas TG increases class I as well as the Pendrin gene product. TG activity is mediated by binding to the ASGPR; TG activity is regulated by serine and threonine phosphorylation.

TPO gene expression is similarly controlled by TSHR/cAMP signaling, TTF-1, TTF-2, and Pax-8. NIS gene expression is predominantly up-regulated by Pax-8, but not TTF-1 or TTF-2. The Pax-8 site contains within it a consensus USF-binding site termed an E-box. USFs are up-regulated and phosphorylated by TGF-β; these compete for Pax-8 binding and down-regulate NIS gene expression, counteracting TSHR/cAMP signals. USF sites also exist in the TPO B site for TTF-1, the TG TTF-1/Pax-8 site, and the downstream but not upstream TSHR TTF-1 site. USF thus plays a role in controlling the TSH/TSHR/cAMP-signaled synthesis of genes important for triiodothyronine (T3) or tetraiodothyronine (T4) formation.

B. TSHR

Signaling by TSHR/TSH/cAMP autoregulates TSHR gene expression. Thus, these signals decrease TSHR gene expression rather than up-regulate it, like TG, TPO, or NIS, because the TSHR has only a TTF-1 site and TSH/TSHR/cAMP decreases TTF-1 gene expression. Thus, gene expression of TSHR is decreased, whereas gene expression of NIS, TPO, and TG is increased because Pax-8 can replace the TTF-1. This may be an important feedback control for TSHR signaling. It is hypothesized that TSH/TSHR/ cAMP decreased TSHR gene expression is important for cell cycle progression; functional genes are expressed followed by growth signals.

C. MHC Genes

MHC class I genes are negatively regulated by the TSHR-mediated cAMP signal. Insulin and IGF-I also are negative regulators of MHC class I gene expression in the thyroid. In the thyroid, hormonal suppression of class I genes appears to be a means of preserving self-tolerance in the face of hormone action to increase the expression of tissue-specific genes such as TG, TPO, and the TSHR. TG, TPO, and the TSHR are the autoantigens associated with autoimmune disease. Inappropriate class I expression in the thyroid, i.e., if induced by interferon, viruses, or some as yet unknown agent, is hypothesized to contribute to the generation of autoimmune disease by the loss of negative regulation.

This hypothesis has been supported by studies showing that TSHR, MHC class I, and MHC class II have common *cis* elements that are regulated by the

same transcription factors. Moreover, MHC class I knockouts result in a loss in the ability to induce several autoimmune diseases. Finally, the thesis has been supported by the development of a mouse model of Graves' disease, the Shimojo model, wherein Graves' disease is induced by immunizing mice that have normal immune systems with fibroblasts overexpressing MHC class II and TSHR.

The model suggests that Graves' disease is initiated by an insult to the thyrocyte in an individual with a normal immune system. The insult, infectious or otherwise, causes double-stranded DNA or RNA to enter the cytoplasm of the cell. This causes abnormal expression of MHC class I as a dominant feature, but also aberrant expression of MHC class II, as well as changes in genes or gene products needed for the thyrocyte to become an antigen-presenting cell. A critical factor in these changes is the loss of normal TSHR/cAMP-induced negative regulation of MHC class I, MHC class II, and TSHR gene expression, which is necessary to maintain self-tolerance during TSHR-signaled increases in genes involved in growth and function. Self-tolerance of the TSHR is maintained in normals because there is a population of $CD8^+$ cells that normally suppresses a population of $CD4^+$ cells that can interact with the TSHR. This is a host self-defense mechanism that probably leads to autoimmune disease in persons with a specific viral infection or perhaps a genetic predisposition. The model is suggested to be important in explaining the development of other autoimmune diseases including systemic lupus and diabetes.

As noted above, TSHR/cAMP-induced inhibition of constitutive MHC class I gene expression requires the expression of several transcription factors. In addition, TSHR/cAMP inhibits upstream interferon-γ (IFN-γ) signaling pathways, in particular Janus kinase 1 (JAK1). TSH/TSHR-mediated inhibition of JAK1 is caused by TSH-induced suppressor of cytokine signaling-1 (SOCS-1) and SOCS-3. TSH/TSHR-induced SOCSs are negative regulators of IFN-γ-mediated signal transducer and activator of transcription 1 activation in thyroid cells. This TSH/TSHR-induced inhibitory cross talk of IFN-γ may also participate in thyrocyte survival in an autoimmune environment.

V. FEEDBACK CONTROL OF TSHR SIGNALING

As noted above, the synthesis of TG is the primary function of the thyrocyte, since this is the scaffold upon which thyroid hormones are formed. TG is now recognized not to be simply an inert scaffold for T3/T4 formation; it is an important transcriptional regulator of thyroid function and T3/T4 formation (Fig. 3). TG stored in the follicular lumen is a feedback suppressor, counterregulating the actions of TSH, insulin, and IGF-I to up-regulate TG, TPO, NIS, and TSHR gene expression by specific down-regulation of the thyroid-specific transcription factors, TTF-1, TTF-2, and Pax-8. It simultaneously up-regulates the synthesis of the Pendrin gene product, thus maximizing TG iodination in the follicular lumen even in the suppressed state. TG suppression involves binding to the asialoglycoprotein receptor (ASGPR) on the apical membrane of the thyrocyte, which faces the follicular lumen. TG suppresses TTF-1 by decreasing nuclear factor 1 binding to two sites within 200 bp of the transcriptional start site. The feedback regulation process is an important determinant of follicular heterogeneity and up-regulates the MHC class I gene. This has been related to autoimmune phenomena associated with goiters where poorly iodinated TG accumulates.

In vivo evidence supporting these data includes findings that TG binding to the apical surface of thyrocytes facing the follicular lumen suppresses iodide uptake by NIS. TG also suppresses vascular endothelial growth factor (VEGF) gene expression, decreasing vascular permeability and further decreasing iodide uptake.

In a follicle rich in follicular TG, TG would suppress NIS and VEGF/VPF (vascular permeability factor) gene expression, as well as TG and TPO expression and synthesis. In this follicle, TSH would act predominantly to cause resorption and degradation of follicular TG and the secretion of thyroid hormones into the bloodstream. Because TSH-induced resorption/degradation of TG exceeds the rate of TSH-increased synthesis and replacement of TG in the colloid, the TG concentration in the lumen of this follicle will decrease. The decrease in follicular TG releases transcriptional suppression and reinitiates TSH-increased NIS, VEGF/VPF, TG, and TPO gene expression. Pendrin gene expression is maximally induced by a low concentration of TG. The increased vascular permeability, NIS, and Pendrin gene expression will increase iodide uptake; increased TG and TPO will contribute to the synthesis and storage of T3 and T4 most efficiently. When the accumulation of follicular TG reaches a certain level, TG suppression of gene expression would again dominate TSH-stimulated gene expression and the whole process would be repeated.

Glossary

Akt (PKB) Insulin-regulated downstream serine/threonine kinase important in thyroid-stimulating hormone receptor-regulated signaling of growth and function.

Graves' disease Disorder caused by overexpression of thyroid-stimulating hormone receptor (TSHR) signaling, which is induced by TSHR autoantibodies.

major histocompatibility genes Expression in thyroid is regulated by thyroid-stimulating hormone receptor signaling and is important for preserving self-tolerance, i.e., preventing autoimmunity.

Pendrin (PDS gene product) An apical membrane iodide porter controlling iodide export from the thyrocyte into the follicular lumen.

thyroglobulin The primary protein synthesized by thyrocytes; it is both the precursor of thyroid hormone formation and a feedback regulator controlling thyroid-stimulating hormone receptor signaling.

thyroid follicle Structural component of the thyroid, composed of thyrocytes that surround a central lumen and whose function and growth are controlled by thyroid-stimulating hormone receptor signaling.

thyroid peroxidase The enzyme catalyzing the iodination of thyroglobulin and catalyzing the coupling of iodotyrosine residues to form thyroid hormones, whose activity is controlled by thyroid-stimulating hormone receptor signaling.

thyroid transcription factor-1 Thyroid-restricted transcription factor controlling thyroid-specific gene expression, whose levels and activity are controlled by thyroid-stimulating hormone receptor signaling.

thyroid transcription factor-2 Thyroid-restricted transcription factor controlling thyroid-specific gene expression, whose levels and activity are controlled by insulin signaling but which influences thyroid-stimulating hormone receptor signaling.

Thyrotropin-Releasing Hormone Receptor Signaling

MARVIN C. GERSHENGORN

National Institute of Diabetes and Digestive and Kidney Diseases of the National Institutes of Health, Maryland

Thyrotropin-releasing hormone signaling occurs primarily, if not exclusively, by binding of the hormone to one of two hormone-specific

receptor subtypes, TRH-R1 and TRH-R2, members of the large superfamily of G-protein-coupled receptors. The primary pathway of signal transduction is mediated by activation of G_q or G_{11} proteins; this, in turn, activates a series of further enzymatic reactions, leading to an increase in $[Ca^{2+}]_i$. The increase in $[Ca^{2+}]_i$ activates Ca^{2+}/calmodulin protein kinase and is further augmented by activation of cell surface membrane channels that allow influx of extracellular Ca^{2+}. One end result of all of these activities is stimulation of hormone secretion and gene transcription in the anterior pituitary.

I. INTRODUCTION

Thyrotropin-releasing hormone (TRH; thyroliberin) is a tripeptide (*pyro*-glutamyl-histidyl-proline-amide; *pyro*-Glu-His-Pro-NH_2) that functions as a hormone, a paracrine regulatory factor, and a neurotransmitter/neuromodulator. TRH initiates some, if not all, of these effects by interacting with receptors on cell surfaces. A complementary DNA (cDNA) for a TRH receptor (TRH-R) was initially cloned from mouse pituitary tissue. Using nucleotide sequence information derived from the mouse pituitary receptor, cDNA clones of rat, human, bovine, and chicken TRH-Rs were isolated. There is very high sequence homology in the protein-coding regions of these TRH-Rs. A second subtype of TRH-R was subsequently cloned from rat and then mouse tissue. The two subtypes of TRH-Rs are now referred to as TRH-R1 and TRH-R2. The primary amino acid sequences and the putative two-dimensional topologies of the two mouse TRH-Rs are illustrated in Fig. 1. The two-dimensional topology is based on hydropathy analyses of the receptor proteins and, because TRH-Rs couple primarily to G-proteins (see Section III), on the consensus two-dimensional structure of all G-protein-coupled receptors (GPCRs). The two TRH-Rs are most similar in the transmembrane regions and differ significantly within the extracellular amino terminus and within the intracellular carboxyl terminus (see Section II).

The roles of TRH-Rs in normal physiology are only partly understood. Within the central nervous system, the two TRH-R subtypes exhibit distinct patterns of expression, signaling properties, and regulation, but similar ligand-binding characteristics, thus it is likely that they serve different physiological roles. TRH-R1 is the predominant receptor in the anterior pituitary gland and has a major regulatory role in stimulating thyrotropin (thyroid-stimulating hormone; TSH) synthesis and secretion and, thereby, plays a central role in thyroid hormone homeostasis. A role for TRH-R1 in regulation of prolactin secretion from the anterior pituitary is less clear. In the central nervous system, in which there is widespread but discrete expression of the two TRH-R subtypes, a number of pharmacological experiments have been performed in which effects of inhibiting or stimulating the TRH/TRH-R systems have been observed. Nevertheless, the physiologic roles of TRH-R1 and TRH-R2 in the central nervous system have not been clearly elucidated.

The emphasis here is on the molecular aspects of cellular signaling by TRH-Rs. The following issues are addressed: TRH-R structure, how TRH binds to TRH-Rs, which coupling proteins initiate TRH-R signaling, which transduction pathways mediate signaling, and what cellular mechanisms regulate TRH-R signaling.

II. THREE-DIMENSIONAL STRUCTURE OF TRH-Rs

To understand the relationship between the three-dimensional structure of a receptor protein at an atomic level of detail and function is a major goal of receptor research. TRH-Rs, like all GPCRs, contain an extracellular amino terminus, three extracellular loops (ECLs), seven transmembrane-spanning helices (TMHs), three intracellular loops (ICLs), and an intracellular carboxyl terminus. A major advance in understanding the structure–function relationships of all GPCRs was made with the resolution of the structure of the inactive state of bovine rhodopsin by X-ray crystallography. Three-dimensional models of mouse TRH-R1 have been constructed based on data from molecular genetic experimental analyses, computer simulations, and the structure of rhodopsin. The model of TRH-R1 in the unliganded (unbound) state attempts to depict the overall structure of the receptor, including the intramolecular atomic interactions that constrain TRH-R in an inactive conformation. The model of TRH-bound TRH-R1 tries to illustrate the interactions between TRH and TRH-R1 that allow for high-affinity binding and, by comparison with the unliganded model, the changes in conformation that the receptor underwent on assuming the active state. These models are used, therefore, to generate hypotheses regarding TRH binding and the mechanism of TRH-R activation.

TRH-R1 is a cylindrical protein that traverses the cell surface membrane seven times, with the amino terminus and three loops outside of the cell membrane, facing the extracellular environment

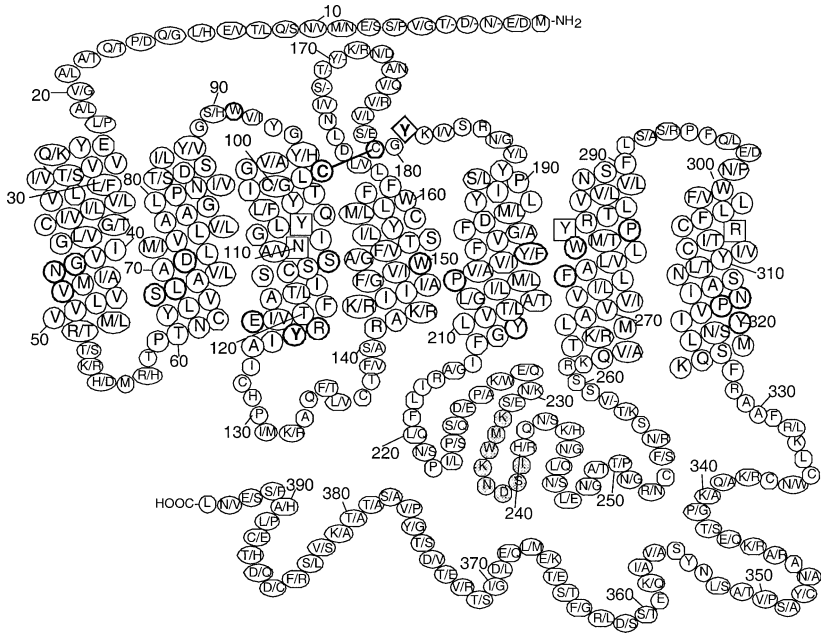

FIGURE 1 Putative two-dimensional topologies of murine TRH-R1 and TRH-R2 sequences. The amino acids are numbered beginning with the first putative residue at the amino terminus. The amino terminus and three extracellular loops are at the top and the three intracellular loops and the carboxyl terminus are at the bottom. The sequences for both receptors (TRH-R1/TRH-R2) are represented by giving within each circle the specific single-letter amino acid symbols for each position; when the amino acid at any position is the same in both receptors, the symbol is given once, and when TRH-R2 does not have a corresponding residue, a hyphen is used (X/-). Residues that are important for binding TRH (see text) are presented within squares.

[i.e., ECL-1-ECL-3: connecting TMHs 2 and 3 (ECL-1), 4 and 5 (ECL-2), and 6 and 7 (ECL-3)], and three loops within the cell [i.e., ICL-1-ICL-3: connecting TMHs 1 and 2 (ICL-1), 3 and 4 (ICL-2), and 5 and 6 (ICL-3)] (Fig. 2). The "core" of the cylinder, which does not form a channel, has projecting into it hydrophilic and hydrophobic residues that form interhelical interactions, which hold the protein in its native conformation. The side chains of specific residues that are found in the core interact directly with TRH. In contrast, positioned on the surface of the cylinder there are principally hydrophobic residues that allow interaction with the lipid environment of the cell surface membrane.

Like binding pockets for small ligands in other GPCRs, the pocket for TRH is within the upper third of the TMH core of the receptor. A computer simulation of TRH-R predicts that there is water in the core of the unliganded receptor. It is noteworthy that evidence has been presented that TRH binds initially to residues in the ECLs of TRH-Rs and then moves through a "channel" formed by the ECLs to gain access to the binding pocket within the TMHs. (The waters that are present in the "channel" are shown in Fig. 2 as the lighter gray spheres.) A number of critical interactions between TRH and residues within the TMH core of the receptor are responsible for high-affinity binding (Fig. 3). These include the hydrogen bond (H-bond) between the C–O of the *pyro*-Glu moiety of TRH and the OH group of Tyr-106 in TMH-3 of TRH-R1; the H-bond between the NH of *pyro*-Glu and the C–O of Asn-110, which is one helical turn below Tyr-106 in TMH-3; the imidazole of the His residue of TRH, in close proximity to Tyr-282 in TMH-6, forming a stacking or hydrophobic interaction; the C–O group of the Pro-NH_2, which forms the H-bond with Arg-306 in TMH-7; and the guanidino group of Arg-306, which also forms an H-bond with the backbone C–O of *pyro*-Glu. All of these interactions are important for TRH binding because mutation of any of these residues within the receptor or change by chemical synthesis of any moiety of TRH leads to decreases in binding affinity. It is noteworthy in this regard that of literally hundreds of analogues of TRH that have been synthesized, only one, *pyro*-Glu-[*methyl*]His-Pro-NH_2, exhibits a higher affinity for TRH-Rs than does native TRH.

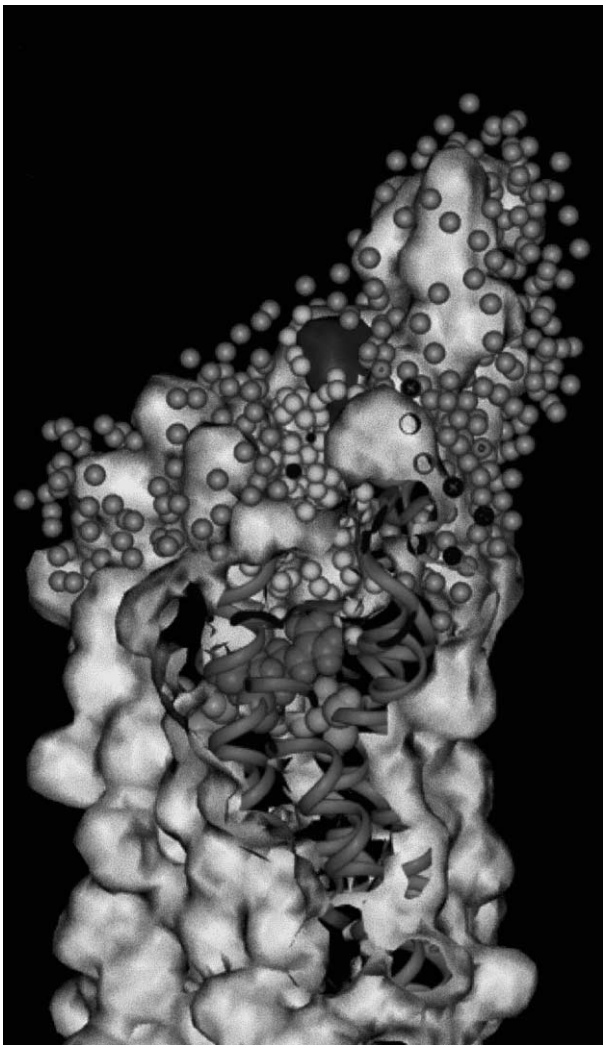

FIGURE 2 Computer-simulated three-dimensional model of mouse TRH-R1. The model was constructed by computational techniques that include the extracellular loops obtained in primary hydration cell simulations (constructed by Avia Rosenhouse-Dantzker and Roman Osman, Mount Sinai School of Medicine). The model is surrounded by a surface to illustrate the path from the initial anchoring site at Tyr-181 into the transmembrane binding pocket defined by Arg-306, Tyr-282, and Tyr-106. The waters used in the primary hydration shell simulations are displayed as dark spheres. The waters that define the path from Tyr-181 into the transmembrane binding pocket are the lighter spheres.

Although TRH-R1 and TRH-R2 differ at approximately 30% of amino acid residues within the most conserved domains of the TMHs, all of the residues just described that appear to interact directly with TRH are present at the same positions within both receptor subtypes. It is, therefore, not surprising that a series of TRH analogues that differ from one another at all three amino acids of the tripeptide have been shown to bind to both receptors with similar hierarchies of affinities.

The conformational changes within the receptor that constitute activation of TRH-Rs are not known. Because the TRH binding pocket appears to be present in the extracellular third of the TMH bundle, it is assumed that the conformational changes in the TMHs that occur on agonist binding secondarily affect the G-protein-coupling domains on the cytoplasmic surface of the receptor protein. It is probable that the unoccupied receptor is restrained in an inactive state in the absence of TRH and that TRH binding releases these restraints. Interactions between residues in different TMHs have been suggested to fulfill this function because mutation of TMH residues that are predicted to dissociate these interactions leads to receptors that are active in the absence of agonist. For example, in the model of the unliganded state of TRH-R1, there is a hydrophobic stacking interaction between Phe-199 in TMH-5 and Trp-279 in TMH-6 that holds TMH-5 and TMH-6 close to one another. In the model of TRH-bound TRH-R1, this interaction is disrupted and helices 5 and 6 are further apart. Experiments in which either Phe-199 or Trp-279 is mutated to Ala lead to receptors that are constitutively active, and models for this demonstrate positioning of TMH-5 and TMH-6 further apart than in the unoccupied receptor model due to lack of interaction of the residues in positions 199 and 279. Thus, work providing initial insights into the changes that constitute TRH-R activation caused by binding of TRH is underway.

III. TRH-Rs AND G-PROTEINS

The proposed structure of TRH-R1 is similar to that of all GPCRs and it is therefore likely that TRH-Rs couple to a heterotrimeric, signal-transducing G-protein(s) composed of α-, β-, and γ-subunits. Specific G-proteins that interact with TRH-R have been identified. TRH-Rs couple primarily to G_q and G_{11}, which are pertussis-toxin-insensitive G-proteins (see later) that activate phosphoinositide-specific phospholipase C (PPI-PLC). One of the most important observations supporting this conclusion was the demonstration that antibodies directed toward the common carboxyl terminus of these two G-protein α-subunits inhibit TRH stimulation of this enzyme activity. Several lines of evidence have been presented that support the idea that TRH-Rs couple to other G-proteins in addition to G_q and G_{11}. Bacterial toxins

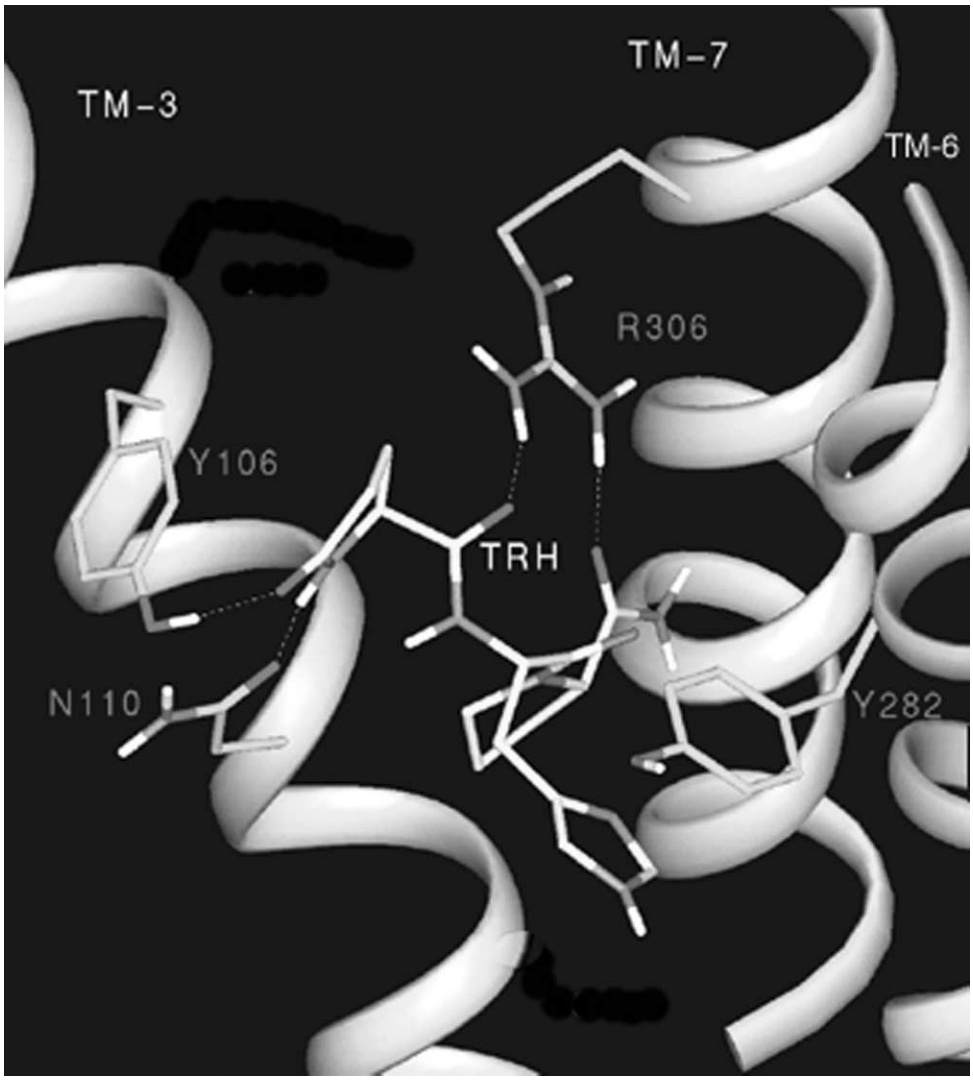

FIGURE 3 Computer-simulated three-dimensional model of the binding pocket of a mouse thyrotropin-releasing hormone receptor subtype (TRH-R1). A close-up view of TRH (light gray bond representations) in the binding pocket, showing the proposed interactions with Tyr-106 and Asn-110 in transmembrane-spanning helix 3 (TM-3), Tyr-282 in TM-6, and Arg-306 in TM-7 (dark gray). The ribbons represent the backbones of the α-helices, which are the part of the receptor that spans the cell surface membrane.

that covalently modify certain G-proteins (pertussis toxin modifies proteins of the G_i class and cholera toxin modifies proteins of the G_s class), have provided evidence in studies of model systems that G_{i2} and G_{i3} can mediate TRH stimulation of voltage-sensitive calcium channels and that TRH-Rs can couple to G_o, which is a pertussis-toxin-sensitive G-protein that is found at high levels in the brain. The most controversial aspect of TRH-R/G-protein coupling involves G_s or a G_s-like protein; G_s is known to activate adenylyl cyclase and calcium channels and to inhibit sodium channels in different cell types. Evidence has been presented that both supports and refutes coupling of TRH-Rs to G_s or G_s-like proteins. Thus, it appears that under specific conditions in model systems, TRH-Rs couple to G_q, G_{11}, G_{i2}, and G_{i3}, and, perhaps, to a G_s-like protein that does not activate adenylyl cyclase. Because the principal pathway for TRH-R signaling appears to be through the cascade initiated by phosphoinositide hydrolysis, it appears that coupling of TRH-R to G_q and G_{11} is of primary importance.

The regions of TRH-Rs that are involved in coupling to G-proteins include ICL-3 and the

carboxyl-terminal tail. In both ICL-3 and the carboxyl tail, it is the regions just underneath the cell surface membrane that are important for coupling. For example, a large part of the middle portion of ICL-3 and a large part of the distal aspect of the carboxyl tail of TRH-R1 can be deleted without any effect on $G_{q/11}$ activation. Thus, TRH-Rs behave like most GPCRs and couple selectively to a limited number of G-proteins that are members of several G-protein families.

IV. TRH-R AND SIGNAL TRANSDUCTION PATHWAYS

TRH-Rs predominantly utilize a ubiquitous second-messenger system that is initiated by the hydrolysis of phosphoinositides, which are phospholipids that contain the sugar *myo*-inositol as the polar head group, for signal transduction. When TRH binds to TRH-Rs, G_q/G_{11} proteins are activated; in turn, a PPI-PLC that is activated primarily hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_2) to generate two molecules that serve as second messengers, i.e., inositol 1,4,5-trisphosphate ($InsP_3$) and 1,2-diacylglycerol (1,2-DAG). $InsP_3$, which is water soluble, is released into the cytoplasm and diffuses away from the membrane whereas 1,2-DAG remains membrane bound. $InsP_3$ leads to release of intracellular stores of Ca^{2+} into the cytoplasm and elevates the cytoplasmic free Ca^{2+} concentration ($[Ca^{2+}]_i$), and 1,2-DAG activates protein kinase C (PKC). These two second messengers then induce signal transduction via two parallel pathways.

A central aspect of Ca^{2+} signaling stimulated by TRH is that increases in $[Ca^{2+}]_i$ are translated into changes in cellular function through a number of specific, Ca^{2+}-binding regulatory proteins or protein subunits. On binding Ca^{2+}, these proteins undergo conformational changes that regulate their activity. For example, calmodulin is a ubiquitous Ca^{2+}-binding protein that, on binding Ca^{2+}, binds to and activates several enzymes, including Ca^{2+}/ calmodulin-dependent multifunctional protein kinases, which phosphorylate a broad array of proteins and may mediate regulation of gene transcription, protein synthesis, and secretion.

TRH-R stimulation of PIP_2 hydrolysis leads to formation of $InsP_3$, which causes an elevation of $[Ca^{2+}]_i$ within seconds. $InsP_3$ rapidly diffuses in the cytoplasm away from the cell surface membrane to bind to receptors on the endoplasmic reticulum. $InsP_3$ receptors are Ca^{2+} channels that "open" on binding $InsP_3$, allowing the flow of previously sequestered Ca^{2+} from the lumen of the endoplasmic reticulum into the cytoplasm and thereby elevating $[Ca^{2+}]_i$. This component of elevation of $[Ca^{2+}]_i$ is rapid and transient. Within seconds of TRH activation of TRH-Rs in excitable cells, such as those in the anterior pituitary and nervous system, Ca^{2+} channels within the cell surface membrane are activated by a mechanism that is incompletely understood. When "opened," these channels allow rapid influx of Ca^{2+} down the electrochemical gradient from the extracellular space to the cytoplasmic compartment, thus also elevating $[Ca^{2+}]_I$. The increase in $[Ca^{2+}]_i$ secondary to stimulated Ca^{2+} influx is more prolonged. TRH-stimulated increases in $[Ca^{2+}]_i$ can occur as a rapid but transient increase followed by a plateau phase, as increases in the frequency of oscillations ("spikes"), or as a combination of a transient increase followed by a plateau with superimposed oscillations (Fig. 4). Ca^{2+} influx across the cell surface membrane is also increased when Ca^{2+} stores in the endoplasmic reticulum are depleted during TRH stimulation. This has been termed "capacitative Ca^{2+} entry" and may be more important in "nonexcitable" cells than in excitable cells. Thus, several different processes that lead to elevations in $[Ca^{2+}]_I$ or replenishment of intracellular Ca^{2+} stores, or both, are initiated rapidly after TRH-R activation.

The other limb of the PPI pathway activated after TRH stimulation of PIP_2 hydrolysis is mediated by 1,2-DAG. 1,2-DAG, in combination with phosphatidylserine (PS) and, depending on the isoenzyme subtype, with or without a requirement for an elevation of $[Ca^{2+}]_i$, activates phospholipid-dependent PKC. PKC enzymes are a family of serine and threonine kinase isoenzymes that phosphorylate many proteins involved in regulating downstream cellular responses. In unstimulated cells, the level of 1,2-DAG in membranes is very low, but 1,2-DAG accumulates in response to TRH, causing within seconds a transient translocation of some isoforms of PKC to the plasma membrane. An important proximate effect of activation of PKC is one of negative feedback to inhibit PPI signaling, which may be mediated by phosphorylation of TRH-Rs (see Section VI). The more distal effects of activation of PKC by TRH signaling include stimulation of hormone secretion and gene transcription in the anterior pituitary.

Other protein kinases are also activated after TRH-R activation. The elevation of $[Ca^{2+}]_i$ caused by TRH stimulation leads to activation of multifunctional Ca^{2+}/calmodulin-dependent protein kinase II. Evidence has been provided that this kinase has a role

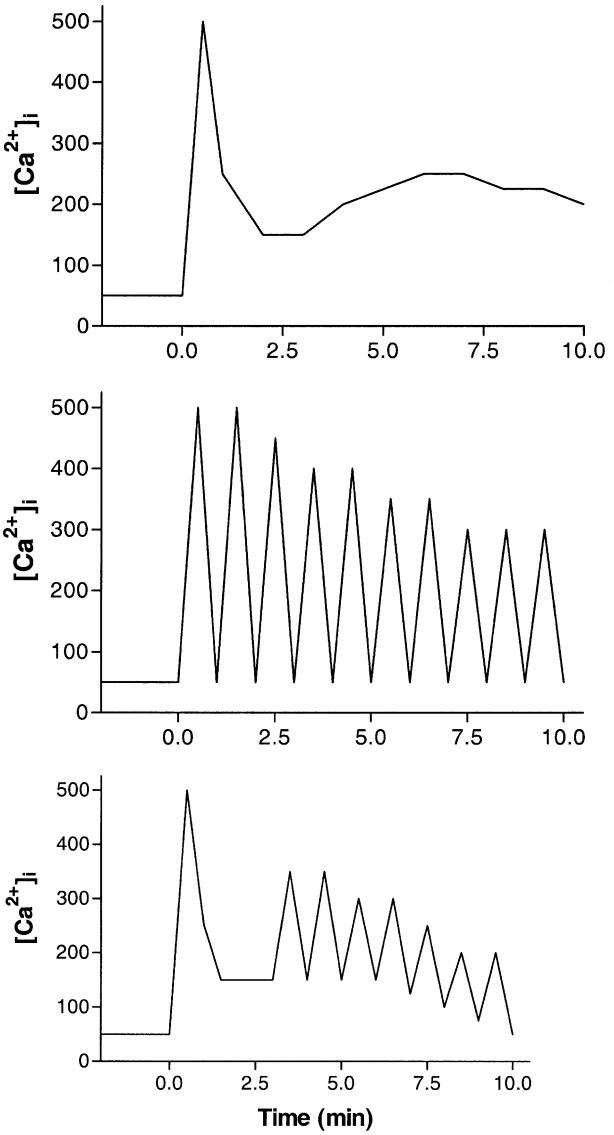

FIGURE 4 Three ways that TRH-stimulated elevations of $[Ca^{2+}]_i$ occur in pituitary cells. TRH was added to cells in tissue culture at time zero. See text for discussion.

in regulation of gene transcription in pituitary cells. TRH activates mitogen-activated protein kinases (MAPKs), a family of differentially regulated serine/threonine kinases, which also appears to lead to regulation of gene transcription. Activation of MAPK is in part secondary to PKC activation and is enhanced via the $\beta\gamma$ subunit dimer of heterotrimeric G-proteins. The set of genes regulated by these protein kinases after TRH stimulation has only begun to be delineated. Although a number of signal transduction pathways initiated by TRH-R activation have been identified, cellular responses other than stimulation of hormone synthesis and secretion by the anterior pituitary are poorly understood.

V. CONSTITUTIVE SIGNALING BY TRH-Rs

Constitutive (basal; i.e., agonist-independent) signaling is a well-documented characteristic of some native receptors and of receptors that are mutated and cause human disease. Both TRH-R subtypes, at least when they are expressed at high levels in cells in tissue culture, exhibit constitutive signaling. However, the level of basal signaling exhibited by TRH-R2 is much greater than that of TRH-R1. Indeed, in some assays in certain cell types, basal signaling by TRH-R1 cannot be measured. As with most native GPCRs, whether basal signaling occurs *in situ* under normal conditions and whether it has an important physiological role is not known for TRH-Rs. It is noteworthy that some drugs (for example, benzodiazepines) are able to bind to TRH-Rs and inhibit their basal signaling activities. Ligands that inhibit basal signaling are termed inverse agonists (or negative antagonists). Inverse agonists may be used in future studies to determine whether basal signaling by TRH-Rs is physiologically relevant.

VI. TRH DESENSITIZATION

Persistent stimulation by a constant level of TRH, as with many agonists that act at GPCRs, leads to a diminished response over time. This phenomenon of TRH-induced desensitization is an important regulatory mechanism that may be mediated at several steps in the signal transduction pathway. Perhaps the most important mechanisms of desensitization involve effects on the receptor. These include receptor phosphorylation, which decreases G-protein coupling, and receptor down-regulation, which is a decrease in the number of receptors on the cell surface. These two types of desensitization can often be dissociated because uncoupling of receptors from G-proteins occurs rapidly, within seconds to minutes, whereas receptor down-regulation is usually slower, requiring several hours.

TRH stimulation of $InsP_3$ formation rapidly causes desensitization. (TRH-induced elevation of $[Ca^{2+}]_i$ is also rapidly desensitized, but this may be due in part to depletion of Ca^{2+} stores.) Although not proved, rapid TRH desensitization likely involves receptor phosphorylation, which may be caused by the action of PKC or by a member of the family of GPCR-specific kinases. The Ser or Thr residues that are likely to be phosphorylated are within ICL-2 and ICL-3 and in the

carboxyl tail of TRH-R. These proposals are based on observations that pharmacologic activation of PKC (for example, by phorbol myristate acetate) and overexpression of GPCR kinases inhibit TRH stimulation of $InsP_3$ generation. TRH-induced TRH-R down-regulation can be observed after approximately 1 h of initiation of signaling. Down-regulation of TRH-Rs leads to diminished TRH responsiveness because the magnitude of the TRH response is usually directly related to the number of TRH-Rs expressed on the cell surfaces. TRH-R down-regulation may be caused by a number of extracellular regulatory factors, including TRH, thyroid hormones, and vasoactive intestinal polypeptide acting in pituitary cells. The number of TRH-Rs can be decreased by decreasing their rate of synthesis or by increasing their rate of degradation, or both. Changes in the rate of TRH-R protein degradation have not been studied.

Modulation of the rate of TRH-R synthesis secondary to decreases in the level of TRH-R mRNA has been shown by monitoring gene transcription and mRNA degradation. These studies were of TRH-R1 but may apply to TRH-R2 as well. Decreases in the levels of TRH-R mRNA can occur by decreasing the rate of TRH-R gene transcription or by increasing TRH-R mRNA degradation, or both. TRH causes a decrease in the level of endogenous TRH-R mRNA by increasing the rate of TRH-R mRNA degradation. This effect of TRH appears to involve activation of PKC and elevation of $[Ca^{2+}]_i$. Thus, it appears that TRH increases TRH-R mRNA degradation through its well-characterized signal transduction pathway, which is initiated by hydrolysis of PIP_2. TRH also decreases TRH-R mRNA levels by inhibiting TRH-R gene transcription; however, the signaling pathway that mediates this effect has not been demonstrated. In conclusion, down-regulation of the TRH-R number by a mechanisms that involves modulation of TRH-R protein turnover, although likely, has not been studied directly, whereas regulation of TRH-R synthesis is well documented and involves several distinct mechanisms that are initiated by different regulatory factors.

VII. TRH-R INTERNALIZATION

Internalization (or endocytosis) of TRH-Rs occurs rapidly after TRH binds. This process serves to bring TRH and receptors into the cell, where either or both can be recycled to the cell surface or sorted to lysosomes for degradation. Although it has not been specifically shown with TRH-Rs, GPCR recycling allows for receptor resensitization because protein phosphatases associated with recycling vesicles can dephosphorylate receptors that have been acutely desensitized by phosphorylation. Unoccupied TRH-Rs are almost exclusively present on the cell surface. TRH/TRH-R complexes are internalized via clathrin-coated vesicles by a mechanism that involves arrestin and perhaps dynamin. The majority of TRH and TRH-Rs recycle to the cell surface membrane under most conditions studied. On binding TRH, TRH-R2 internalizes at a much faster rate than does TRH-R1. The reason for this difference is not clear. It is thought that proteins that reside in the cell surface membrane and undergo internalization contain a "signal" that directs them to plasma membrane clathrin-coated pits, from which coated vesicles pinch off during the initial steps in internalization. Evidence has shown that two distinct domains within the carboxyl terminus of TRH-R1 are necessary for TRH-stimulated TRH-R internalization. Although it has been suggested that coupling to G-proteins is necessary for internalization, it is not clear whether there is coupling to proteins of the internalization machinery in the absence of coupling to G-proteins.

VIII. SUMMARY

The primary pathway of TRH signal transduction is mediated by activation of G_q or G_{11} proteins; activation of PPI-PLC follows, leading to formation of $InsP_3$ and 1,2-DAG. $InsP_3$ elevates $[Ca^{2+}]_i$ by releasing Ca^{2+} from the endoplasmic reticulum and 1,2-DAG activates PKC. The increase in $[Ca^{2+}]_i$ is further augmented by activation of cell surface membrane channels, allowing influx of extracellular Ca^{2+}. The elevation of $[Ca^{2+}]_i$ activates Ca^{2+}/ calmodulin protein kinase. Although increases in $[Ca^{2+}]_i$ and activation of these protein kinases are known to result in stimulation of anterior pituitary hormone secretion and gene transcription, the effects in the central nervous system are still poorly understood.

Glossary

agonist Ligand that activates a receptor.

Ca^{2+}/calmodulin-dependent protein kinase Family of serine/threonine protein kinases; activated by Ca^{2+} and calmodulin.

constitutive signaling Receptor signaling that occurs in the absence of agonist binding; also termed basal or agonist-independent signaling.

1,2-diacylglycerol Lipid product of phospholipase C-mediated hydrolysis of phospholipids; a neutral lipid with fatty acyl chains at positions 1 and 2; activates protein kinase C.

G-proteins Family of signal-transducing (or coupling) proteins made up of three subunits (α, β, and γ); activated by members of the largest family of receptors and, in turn, activate ion channels and a number of effector molecules, including enzymes such as adenylyl cyclase and phospholipase C.

G-protein-coupled receptors Seven-transmembrane-spanning (heptahelical, or serpentine) cell surface receptors that bind extracellular regulatory molecules such as hormones, neurotransmitters, and growth factors, and bind and activate G proteins.

inositol 1,4,5-trisphosphate Sugar product of phospholipase C-mediated hydrolysis of phosphatidylinositol 4,5-bisphosphate; a hexahydroxy, cyclic sugar with phosphate groups at the 1, 4, and 5 positions; activates channels in the endoplasmic reticulum to release previously sequestered Ca^{2+}.

ligand Any molecule, such as a hormone, neurotransmitter, growth factor, or drug, that binds to a receptor.

phospholipase C Lipid-hydrolyzing enzyme that cleaves phospholipids at the 3 position to form two products—the head group, such as $InsP_3$, and 1,2-diacylglycerol.

protein kinase C Serine/threonine protein kinase that is activated by 1,2-diacylglycerol, phospholipids, and/or Ca^{2+} downstream of activation of certain receptors.

Thyrotropin-Releasing Hormone (TRH)

RONALD M. LECHAN* AND ANTHONY HOLLENBERG†

**Tufts–New England Medical Center and Tufts University School of Medicine • †Harvard Medical School*

Thyrotropin-releasing hormone (TRH) arises from posttranslational processing of a large precursor protein but it is only one of several other potentially biologically active peptides derived from the same precursor. The biosynthesis of TRH is dependent on feedback regulation of thyroid hormone, mediated by its interaction with the β2 thyroid hormone receptor and negative thyroid hormone-responsive elements in the TRH gene. Whereas TRH originating in neurons of the hypothalamic paraventricular nucleus contributes to the hypothalamic tuberoinfundibular system and regulates anterior pituitary secretion, the TRH gene is expressed in many other regions of the brain and

in peripheral tissues where TRH and other proTRH-derived peptides are expressed in a region- and tissue-specific manner to exert a variety of biologic actions.

I. INTRODUCTION

The maintenance of thyroid function is dependent on a complex interplay between the hypothalamus, anterior pituitary, and thyroid gland, as well as other factors that influence the function of these organ systems. This function is critical in achieving a constant level of free thyroid hormone in the bloodstream to support peripheral tissues by affecting protein synthesis and/or altering the metabolic activity of cells, as well as for brain development during fetal growth and early infancy. The hypothalamic peptide primarily responsible for this action by stimulating the biosynthesis and release of thyrotropin (TSH) from the anterior pituitary gland is thyrotropin-releasing hormone (TRH). TSH then stimulates the release of the thyroid hormones thyroxine (T4) and tri-iodothyronine (T3) from the thyroid gland into the circulation; T4 and T3 in turn feed back on the hypothalamic TRH neurons and anterior pituitary thyrotropes, completing what is recognized as a classic example of a negative feedback loop system (Fig. 1). Elucidation of the normal anatomy and connectivity of the TRH neurons responsible for the secretion of TSH and characterization of the TRH gene has vastly improved the understanding of the normal physiology of hypophysiotropic TRH and the mechanisms by which the thyroid axis is modified under adverse conditions such as fasting, infection, and cold exposure.

TRH should not be considered to have an exclusive action on the secretion of TSH as its name suggests, however, as it also subserves a wide range of other biologic functions both within the central nervous system and in some peripheral tissues. The recognition that posttranslational products of the TRH prohormone include not only TRH but also other cryptic peptides that may have biologic activity further expands the diversity of the actions of the products of proTRH and raises the possibility that in some tissues, the primary product of posttranslational processing may not be TRH.

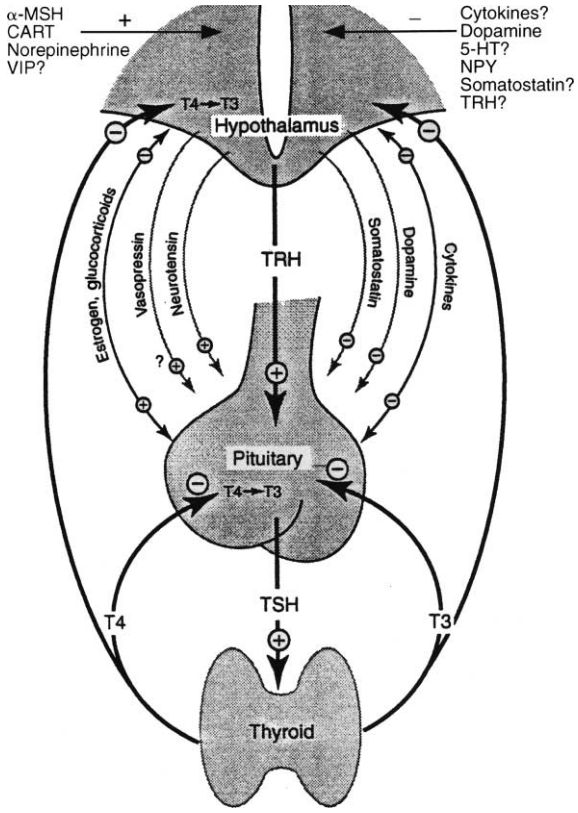

FIGURE 1 Neuroregulatory control systems involved in the secretion of thyroid hormone. Boldface lines denote the negative feedback loop of thyroid hormone on TRH secretion from the hypothalamus and TSH secretion from the anterior pituitary. Both the hypothalamic TRH neurons and the anterior pituitary thyrotropes are impinged upon by numerous other potential regulatory influences that are activated under specific physiological or pathological conditions.

II. BIOSYNTHESIS AND PROCESSING OF TRH

TRH (pyroGlu-His-ProNH_2, MW 362) arises by a mRNA-directed ribosomal mechanism and posttranslational processing of a larger precursor prohormone. The complete sequence of the TRH precursor, deduced from its cDNA, has been elucidated for frog, rat, mouse, and human and is schematically illustrated in Fig. 2. Common to each prohormone are multiple copies of a progenitor sequence for TRH, Gln-His-Pro-Gly, flanked on either side by paired basic amino acids, Lys-Arg or Arg-Arg, that are processing signals for carboxypeptidase B-like enzymes. The C-terminal glycine functions as a substrate for α-amidating enzymes that convert TRH-Gly to TRH and the N-terminal glutaminyl is modified by glutaminyl cyclase to result in the fully mature and biologically active TRH.

Rat preproTRH contains 255 amino acids and five copies of the TRH progenitor sequence and is approximately 88% homologous to the mouse preproTRH, which contains 256 amino acids and also gives rise to five copies of TRH by proteolytic

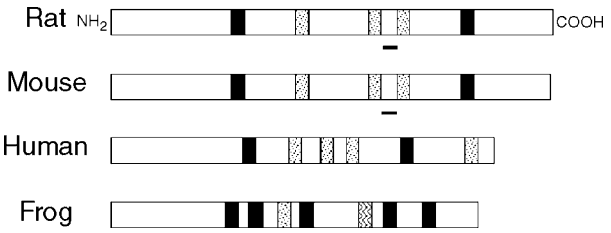

FIGURE 2 Schematic representation of rat, mouse, frog, and human preproTRH. Each sequence contains multiple copies of a TRH progenitor sequence (Gln-His-Pro) preceded by Lys-Arg and followed by Lys-Arg or Arg-Arg. Unique to the frog is one TRH progenitor sequence that is preceded by Arg-Arg and followed by Lys-Arg. The cryptic peptides preproTRH$_{160-169}$ and preproTRH$_{178-199}$ are located between the third and the fourth progenitor TRH sequences and between the fourth and the fifth progenitor TRH sequences, respectively.

processing. The human preproTRH contains 242 amino acids and six copies of the progenitor sequence for TRH. Frog brain has at least three different TRH preprohormones ranging between 224 and 227 amino acids and contains seven copies of the TRH progenitor sequence. Common to all species are the repeating progenitor sequences of TRH in the prohormone, presumably important in magnifying the response to signals that trigger TRH secretion.

In addition to the sequences that give rise to TRH, the TRH precursor contains several cryptic peptides between the TRH progenitor sequences and the N- and C-terminal flanking peptides that may be biologically active. At least one peptide, preproTRH$_{160-169}$, a decapeptide containing the amino acid sequence Ser-Phe-Pro-Trp-Met-Glu-Ser-Asp-Val-Thr that follows the third TRH sequence in the rat prohormone, is also present in mouse preproTRH and has been isolated from bovine hypothalamus. This peptide is released from the medial hypothalamus into the system of veins that conveys releasing hormones to the anterior pituitary, the portal capillary system, and specific binding sites for the decapeptide have been identified in the anterior pituitary as well as in other regions in the brain. PreproTRH$_{160-169}$ has little effect on anterior pituitary secretion by itself, but in the presence of TRH, it potentiates the secretion of TSH by increasing TSHβ mRNA in thyrotropes. The action of preproTRH$_{160-169}$ is probably not directly on thyrotropes, however, as receptors have been identified only in folliculostellate cells, a specialized glial cell of anterior pituitary origin that is not known to secrete TSH. Presumably, therefore, the effect of preproTRH$_{160-169}$ to potentiate the action of TRH on TSH secretion is indirect via paracrine interactions between the processes of folliculostellate cells and anterior pituitary thyrotropes.

In addition to TSH secretion, preproTRH$_{160-169}$ enhances both the synthesis and the secretion of prolactin and possibly growth hormone release. PreproTRH$_{160-169}$ also potentiates the effect of TRH to induce gastric acid secretion when the two peptides are simultaneously microinjected into the dorsal motor nucleus of the vagus.

PreproTRH$_{178-199}$, which separates the fourth and fifth progenitor TRH sequences, is also released from the rat median eminence but as yet, no receptors for this peptide have been identified. Claims for biologic activity of preproTRH$_{178-199}$ were based on its ability to act as a corticotropin-inhibiting factor, blocking both ACTH release and proopiomelanocortin (POMC) mRNA transcription, but these claims are still controversial. PreproTRH$_{178-199}$ may also have a number of other potential actions including inhibition of growth hormone secretion and neuroendocrine responses to stress, antidepressant activity, and neuroprotection against cerebral ischemia. PreproTRH$_{178-184}$ and preproTRH$_{186-199}$, posttranslational products of preproTRH$_{178-199}$, may have prolactin-releasing activity.

Despite the potential for the above rodent proTRH-derived peptides to have biologic activity, most of these sequences are not present in the human or frog preproTRH, raising questions as to their importance across animal species. Hydropathy profiles of the rat, human, and frog preproTRH sequences, however, do show a peak hydrophobicity over the region corresponding to the C-terminal flanking peptide. In particular, this region has remarkable resemblance over a 47- to 50-amino-acid span in the rat, mouse, and human prohormone. In the human, this sequence contains within it the sixth progenitor TRH that may have arisen from evolutionary changes between the fifth TRH coding sequence and the stop codon. No data that establish a definite biologic action of the C-terminal flanking peptide have been reported, however. Several preproTRH sequences have been identified in extracts of human hypothalamus including preproTRH$_{141-149}$, preproTRH$_{158-183}$, and preproTRH$_{192-224}$. PreproTRH$_{141-149}$ (referred to as human thyrotropin-releasing hormone-associated peptide 3 or hTAP-3) is also present in human serum and corresponds in position to the intervening sequence preproTRH$_{160-169}$ in the rat prohormone.

Processing of proTRH to its final products is region specific and dependent on the type of proces-

sing enzymes in the cell. In the hypothalamus, preproTRH is fully processed to yield all five copies of TRH and each of the spacer peptides. In contrast, in the olfactory lobes, C-terminal extended forms of TRH, preproTRH$_{154-169}$, and preproTRH$_{172-199}$ are the predominant end products, suggesting incomplete processing at Arg-Arg residues. Furthermore, in the midbrain periaqueductal gray, the N-terminal cryptic peptide preproTRH$_{83-106}$ is selectively increased during opiate withdrawal while TRH and the C-terminal peptide are reduced.

Two enzymes that are critical for the processing of proTRH are the proconvertase enzymes, PC1 and PC2. These enzymes cleave at the C-terminal end of single or paired basic amino acid residues and the remaining basic amino acids are removed by carboxypeptidases. PC1 appears to be capable of processing the entire proTRH precursor to mature TRH, whereas PC2 processes only specific regions of the prohormone. Along these lines, it is of interest that both PC1 and PC2 are present in the majority of TRH neurons in the paraventricular nucleus (PVN), whereas primarily PC2 is expressed in the olfactory lobes and periaqueductal gray. Accordingly, differences in the expression of PC1 and PC2 in different regions of the brain may be responsible for the differential processing of proTRH observed in these regions.

A schema for the processing of proTRH is shown in Fig. 3. In this model, the 26 kDa prohormone is cleaved at one of two sites to generate either 15 and 10 kDa fragments (preproTRH$_{25-151}$ and preproTRH$_{160-255}$) or 9.5 and 16.5 kDa fragments (preproTRH$_{25-112}$ and preproTRH$_{115-255}$), respectively. This initial cleavage occurs in the Golgi apparatus. Subsequently, the 15 kDa N-terminal fragment is processed in vesicles to a 6 kDa intermediate (preproTRH$_{25-74}$) and a 3.8 kDa peptide (preproTRH$_{77-106}$), and the 10 kDa fragment produces a 5.6 kDa intermediate (preproTRH$_{160-199}$) and a 5.4 kDa intermediate corresponding to the C-terminal peptide, preproTRH$_{208-255}$. The 5.6 kDa fragment is then further processed to preproTRH$_{160-169}$ and preproTRH$_{178-199}$. PreproTRH$_{178-199}$ can then be further processed to the smaller peptides, preproTRH$_{178-184}$ and preproTRH$_{186-199}$, mediated by the action of PC2. Alternatively, processing of the 9.5 kDa N-terminal fragment is proposed to yield preproTRH$_{25-50}$, preproTRH$_{53-74}$, and preproTRH$_{83-106}$, and the 16.5 kDa C-terminal fragment is proposed to yield preproTRH$_{160-199}$ and preproTRH$_{208-255}$. Following cleavage at all paired basic residues, the mature TRH (pGlu-His-Pro-NH$_2$) is generated by amidating the C-terminal end of the tripeptide using the glycine residue in the immediate precursor to TRH, TRH-Gly, as a substrate for the α-amidating enzyme, PAM, and cyclization of the N-terminal glutaminyl to pGlu by glutaminyl cyclase.

III. TRH GENE AND PROMOTER REGULATION

The murine, rat, and human TRH genomic structures are identical, with each structure containing three exons and two introns (Fig. 4); exon 1 encodes the 5′-untranslated region, whereas exon 2 and 3 contain the sequence that encodes the preproTRH message. The DNA sequences of the exons are well conserved across species, but the sequences of the introns are poorly conserved. The promoter region of the TRH gene is located immediately 5′ to exon 1 and presumably is the major locus where regulation of the gene takes place. *In vivo* studies in transgenic mice using TRH promoter fragments linked to a luciferase reporter gene suggest that sequences within the proximal promoter as well as the first exon are critical for TRH expression in the hypothalamus. It remains unclear, however, which regions of the TRH gene allow for its expression in other tissues, such as the pituitary, pancreas, or heart.

The TRH promoter region is heralded by the presence of a conserved TATAA-box, allowing for transcriptional initiation by RNA polymerase II. Just proximal to the TATAA-box is an important regulatory element, termed Site 4 (TGACCTCA), that is conserved in the mouse, rat, and human promoters (Fig. 4). This sequence is important for basal expression of the TRH promoter in many different mammalian cell lines when assessed using transfection studies. In addition, Site 4 serves as a multifunctional binding site for the transcription factor cyclic AMP-response element-binding protein (CREB) and thyroid hormone receptors (TRs), including TR homodimers and heterodimers of TR and the retinoic acid X receptor (RXR). It appears that Site 4 cooperates with a second weak TR-binding site 11 bp 3′ to Site 4 that binds both TR homodimers and TR/RXR heterodimers. Taken together, Site 4 appears to be a critical sequence within the TRH promoter that is preserved across species and controls both basal and regulated expression of the TRH gene.

The importance of Site 4 in the regulation of TRH expression was first demonstrated in functional studies in mammalian cell lines that showed that it was required for down-regulation of TRH promoter constructs by T3 in the presence of the TR. T3

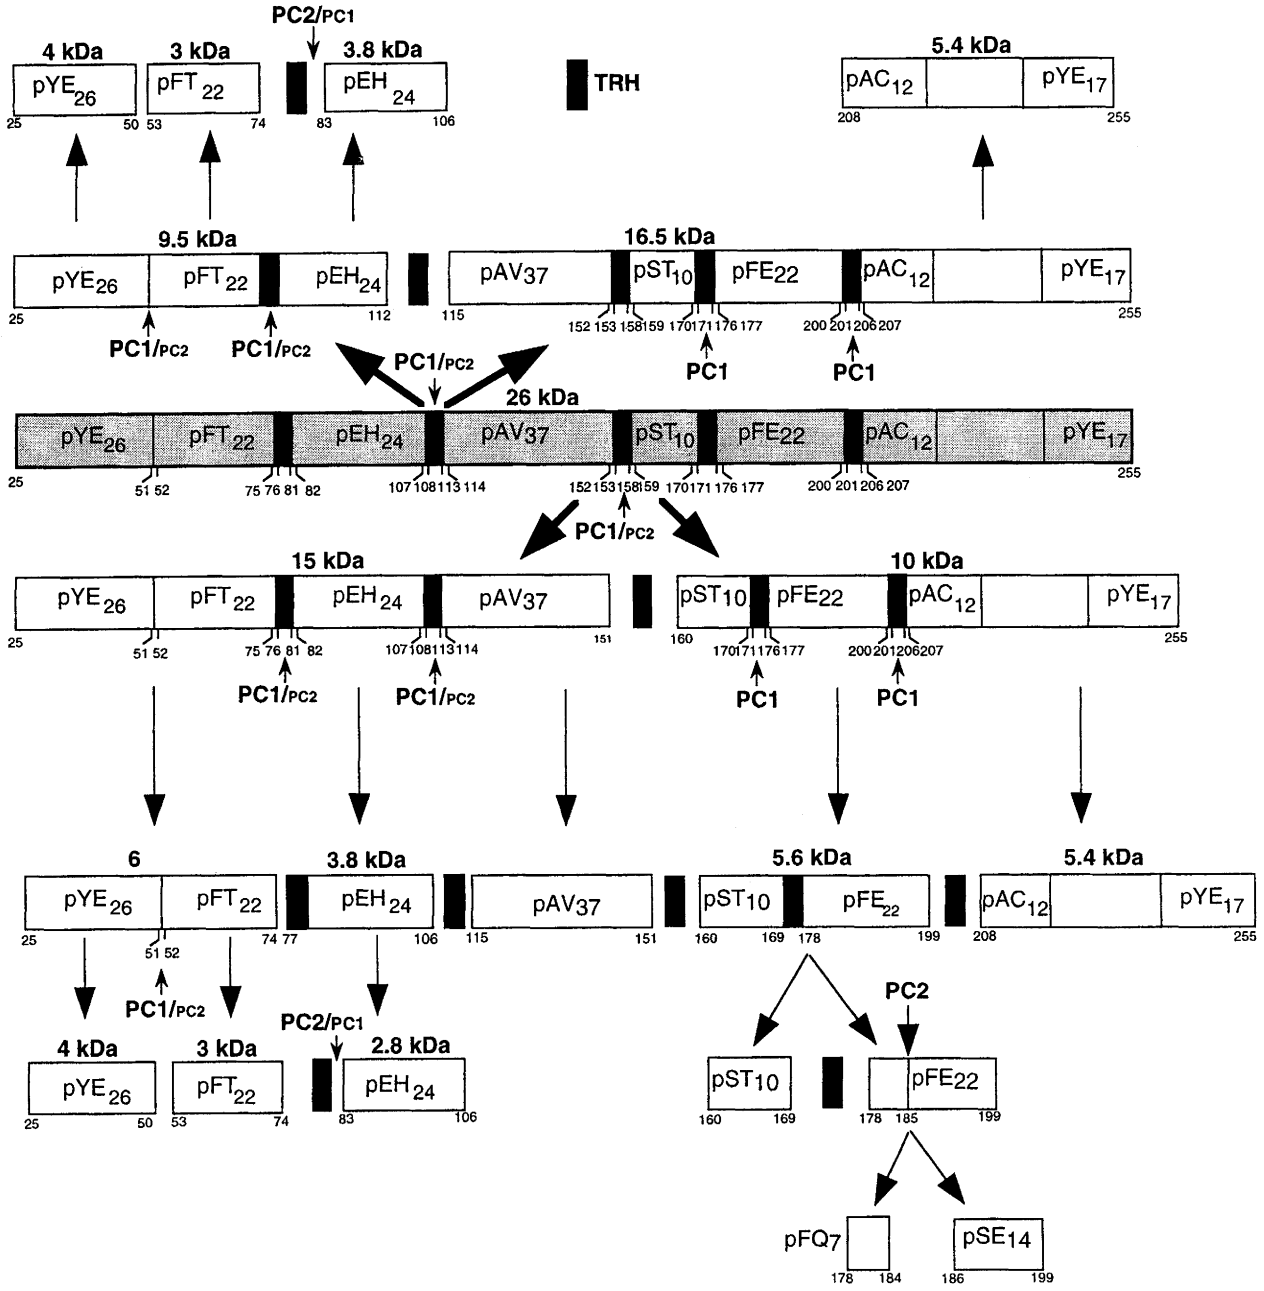

FIGURE 3 Proposed schema for processing of preproTRH. Reprinted from Nillni and Sevarino (1999), with permission from The Endocrine Society.

mediates its effects on gene expression via the three TR isoforms ($TR\alpha_1$, $TR\beta_1$, and $TR\beta_2$). $TR\alpha_1$ is expressed in many tissues but plays only a small role in negative regulation by T3. Its actions are critical for the effects of T3 in the heart, bone, and small intestine. The TRβ isoforms are products of a single gene and differ only in their amino-terminal regions. $TR\beta_1$ mediates the effect of T3 in the inner ear, liver, and kidney, and recent genetic studies have confirmed that $TR\beta_2$ is critical for negative regulation of the TRH, TSHα subunit, and TSHβ subunit genes by T3. The molecular mechanism governing negative regulation of the TRH promoter by T3 has not been firmly established. Site 4 and its surrounding region can bind $TR\beta_2$, which appears to be necessary for negative regulation. However, it is not clear which co-factors

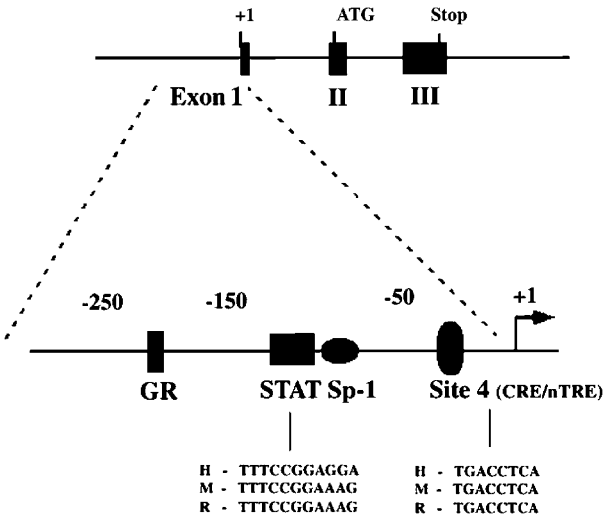

FIGURE 4 Genomic and promoter structure of TRH. The murine, rat, and human TRH genes are composed of three exons and two introns. The coding sequence for the precursor protein is present on exons 2 and 3. As depicted, the TRH promoter region precedes the transcription start site in exon 1. The proximal 250 bp sequences of the human, mouse, and rat promoters are similar and share the indicated transcription factor-binding sites. The sequences of the STAT element and Site 4 across species are indicated.

are involved. On genes positively regulated by T3, the TR isoforms are bound constitutively to thyroid hormone-response elements (TREs). In the absence of T3, they recruit the nuclear co-repressors (nuclear receptor co-repressor and silencing mediator for retinoid and thyroid hormone receptor) that repress transcription of target genes. The presence of T3 causes the release of co-repressors and the recruitment of co-activators such as SRC-1, which lead to transcriptional activation. The role of co-repressors and co-activators in the negative regulation of the TRH gene remains less clear, given that the recruitment of co-activators by $TR\beta_2$ in the presence of T3 would be expected to activate rather than repress TRH expression. However, they also appear to be important because mutations in TRs that prevent binding of either co-repressors or co-activators without altering DNA binding are unable to mediate negative regulation. In addition to Site 4, a second region within the TRH gene present within the first 55 bp of exon 1 may be important in mediating the effects of T3. This region interacts with TRβ monomers and its removal in functional studies causes a loss of negative regulation by T3.

Site 4 can also be bound by CREB. CREB binding and TR binding appear to be mutually exclusive and there is no evidence that they interact on Site 4. Thus, it is possible that they in fact compete for Site 4. CREB is bound constitutively to target promoters, usually as a homodimer or as a heterodimer with other members of the ATF-1 family. When phosphorylated by protein kinase A after activation of the cAMP signaling cascade by activators such as forskolin, PCREB recruits the co-activator CREB-binding protein (CBP), which allows for transcriptional activation of the TRH gene. CBP functions as a histone acetyl transferase, allowing modification of surrounding histones to enhance transcription. Mutation or deletion of Site 4 prevents the activation of TRH promoter constructs by forskolin. The phosphorylation of CREB, therefore, is likely a key mechanism for positive regulation of TRH gene expression, and by competing with PCREB for Site 4, $TR\beta_2$ could prevent activation of the TRH promoter. Binding of PCREB to Site 4 also has an important role in mediating the effects of melanocortin signaling on the TRH gene (see below).

Activation of the TRH gene also occurs via a canonical signal transducer and activator of transcription (STAT)-binding site in the murine and rat promoter 5′ to Site 4. A similar site in the human promoter located between −150 and −125 has also been identified, suggesting the importance of this sequence across animal species (Fig. 4). A number of STAT isoforms (STAT1, STAT3, and STAT5) have been identified and appear to be ubiquitously expressed. In the inactivated state, STAT proteins are present in the cytoplasm. Activation occurs after a cell surface receptor (usually a member of the cytokine receptor family) is bound by its ligand. This leads to a cascade that results in recruitment and activation of Janus tyrosine kinase (JAK), which in turn leads to recruitment and phosphorylation of the STAT isoforms. Tyrosine phosphorylation allows phospho-STAT to dimerize and enter the nucleus to bind to its target regulatory elements such as that found in the TRH promoter. STAT activates transcription by recruiting co-activators such as CBP. The leptin receptor also activates transcription via the JAK/STAT signaling pathway and is able to significantly enhance TRH promoter activity in transfection experiments in mammalian cells. This direct action of leptin on the TRH promoter is the best example to date of a downstream transcriptional target of the leptin signaling pathway. The presence of such a STAT site also suggests that the TRH promoter is poised to respond to other cytokine signaling pathways that could engage TRH neurons in the paraventricular nucleus (PVN) or elsewhere.

The TRH promoter also contains binding sites for the glucocorticoid receptor (GR) and Sp-1. The glucocorticoid receptor is also a member of the nuclear receptor family, and Sp-1 is a widely expressed transcription factor that binds to GC-rich motifs in target promoters. Their role in its regulation are less well understood. The GR-response element is located just upstream of the STAT element and appears to be functional in the pituitary, where glucocorticoids enhance TRH gene expression (Fig. 4). However, glucocorticoids appear to be inhibitory to TRH gene expression in the PVN. There are multiple potential Sp-1 sites within the promoter. One is located adjacent to the STAT site and is required for full induction by leptin.

IV. ANATOMY OF THE HYPOTHALAMIC TRH TUBEROINFUNDIBULAR SYSTEM

The origin of TRH-containing neurons that regulate anterior pituitary TSH secretion is the hypothalamic PVN, a triangular, midline nuclear group symmetrically located on either side of the dorsal portion of the third ventricle (Fig. 5A). The PVN is composed of two major parts: magnocellular neurons located in more lateral portions of the nucleus and parvocellular neurons located in more medial portions of the nucleus. The magnocellular component gives rise to the hypothalamic neurohypophyseal tract that carries vasopressin and oxytocin to the posterior pituitary. The parvocellular component has a number of subcompartments including anterior, medial, periventricular, ventral, dorsal, and lateral parvocellular subdivisions. TRH-synthesizing neurons are found primarily in the anterior, medial, and periventricular parvocellular subdivisions (Fig. 5B) and to a lesser extent in the dorsal and lateral subnuclei. However, only TRH neurons in medial and periventricular parvocellular subdivisions project to the median eminence (often referred to as hypophysiotropic neurons because they are involved in regulation of the anterior pituitary) and thereby are functionally distinct from the TRH neurons in the anterior parvocellular subdivision. Further support for the anatomical diversity of medial and periventricular parvocellular subdivision TRH neurons is the presence of the peptide cocaine- and amphetamine-regulated transcript (CART) in hypophysiotropic TRH neurons but not in other TRH neuronal populations.

Axons from hypophysiotropic TRH neurons in the PVN project to the median eminence, one of five so-called "circumventricular organs" in the mammalian brain that lie outside of the blood–brain barrier. Here, they terminate in the external zone of the median eminence where they have access to the fenestrated capillaries of the portal system (Fig. 5C). Some fibers also descend in the pituitary stalk to terminate in the posterior pituitary and may provide an alternative pathway by which TRH can regulate anterior pituitary secretion through the vascular channels (short portal veins) that connect the posterior pituitary to the anterior pituitary.

By residing in the PVN, TRH-producing neurons are situated in a region highly enriched by afferent inputs from other regions in the brain. These inputs are important to establish the setpoint for feedback regulation of hypophysiotropic TRH by thyroid hormone under basal conditions and during times when it is necessary to increase or decrease circulating levels of thyroid hormone (described below). Synaptic contacts between axon terminals and both the perikarya and the dendrites of TRH-producing neurons have been observed by ultrastructural analysis, including both the symmetric type, suggesting inhibitory control, and the asymmetric type, suggesting excitatory control. Symmetric synapses containing small and large electron-lucent vesicles tend to predominate on TRH perikarya, whereas both symmetric and asymmetric contacts containing small, round and oval, clear vesicles predominate on TRH dendrites. Central modulation of hypophysiotropic TRH neurons through afferent projections may also occur in the external zone of the median eminence, which could influence tuberoinfundibular TRH release by axo-axonal associations, but true axo-axonic synapses have only rarely been recognized in the mammalian median eminence.

Although several regions of the brain project to the PVN, at least two regions provide the major input to hypophysiotropic TRH neurons, brainstem catecholamine neurons and the hypothalamic arcuate nucleus (Fig. 6A). Axon terminals containing catecholamines give one of the most conspicuous innervations to TRH neurons in the PVN arising primarily from C1/A1 groups in the medulla, contributing approximately 20% of all synapses on these cells. These axons establish mostly asymmetric synapses with both perikarya and dendrites of TRH neurons, suggesting an excitatory function. Noradrenergic axon terminals have also been identified in close apposition to TRH axons in the external layer of the rat median eminence, indicating that catecholamine inputs may influence TRH hypophysiotropic neurons not only through direct effects on their perikarya and dendrites but also on their axon terminals. The trajectory of catecholamine-contain-

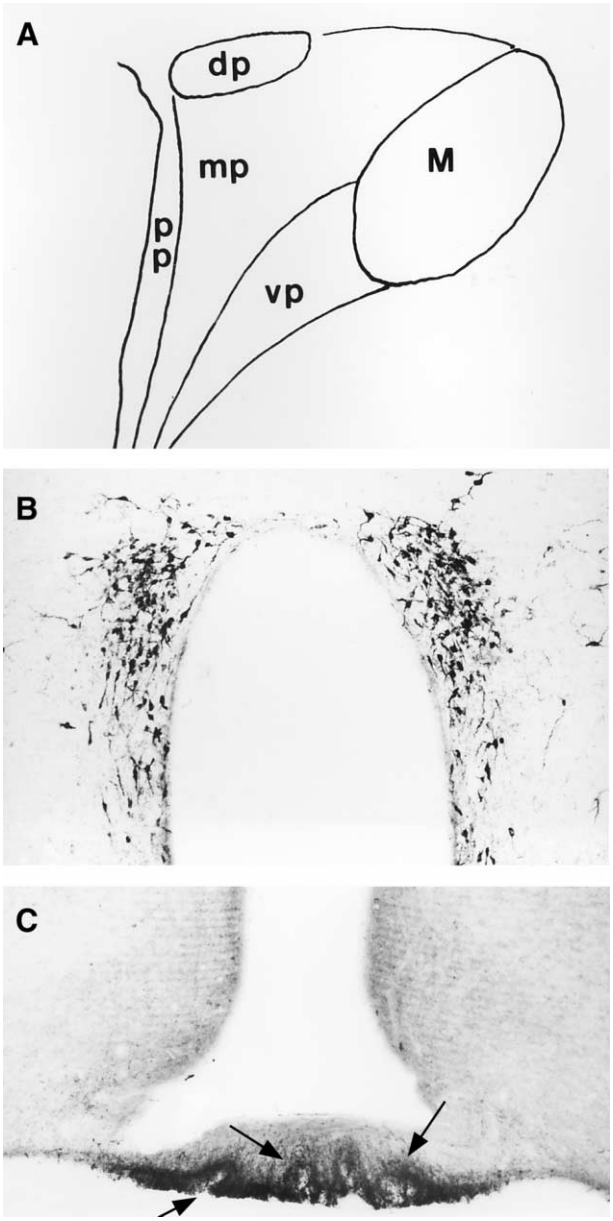

FIGURE 5 (A) Location of the major subdivisions in the PVN showing its major subdivisions. pp, periventricular parvocellular subdivision; mp, medial parvocellular subdivision; dp, dorsal parvocellular subdivision; vp, ventral parvocellular subdivision; M, magnocellular division. (B) TRH neurons originate in the medial and periventricular parvocellular subdivisions of the PVN and (C) terminate in the external zone of the median eminence in contact with capillaries of the portal vascular system (arrows).

ing axons from the brainstem is to course rostrally in the dorsal and ventral noradrenergic bundles to ultimately enter the median forebrain bundle in the hypothalamus before terminating in the PVN (Fig. 6B). Transection of the noradrenergic bundle at the level of the midbrain results in marked depletion of the catecholamine input to the PVN, in keeping with their origin from the brainstem.

At least four different peptides of arcuate nucleus origin, α-melanocortin-stimulating hormone (α-MSH), CART, neuropeptide Y (NPY), and agouti-related peptide (AGRP), are contained in axon terminals in synaptic contact with TRH hypophysiotropic neurons (Fig. 6A,C). Neurons of the arcuato-PVN pathway project their axons primarily ipsilateral to the PVN and, like the catecholamine axon trajectory from the brainstem, course through the medial forebrain bundle prior to entering the PVN. In the rat, α-MSH and CART arise from the same neurons located in lateral portions of the arcuate nucleus, whereas NPY and AGRP are both contained in a distinct population located in more medial portions of the nucleus. A similar organization is also present in the human brain, suggesting the evolutionary importance of this neuroregulatory control system. Indeed, in the rat and mouse, pharmacologic ablation of the arcuate nucleus not only results in profound reduction in the number of axons contacting TRH neurons in the PVN that contain these neuropeptides, but also reduces circulating levels of TSH and thyroid hormone.

Similar to the catecholamine innervation, asymmetric specializations between axons containing α-MSH/CART and TRH neurons in the PVN are observed, suggesting an excitatory function, whereas axon terminals containing NPY and AGRP establish primarily symmetric synaptic specializations, suggesting an inhibitory function. The latter associations are sometimes so dense as to completely envelop the perikarya and first-order dendrites of TRH neurons. In addition to the arcuate nucleus, however, which constitutes more than 80% of the NPY innervation to TRH neurons in the PVN and 100% of the AGRP innervation, brainstem catecholaminergic neurons may also contribute to the NPY innervation of hypophysiotropic TRH neurons in a minor way, particularly to their distal dendrites. Nevertheless, a major NPY projection pathway from the brainstem to the PVN does exist, but is primarily targeted to CRH neurons in the PVN. This target-specific innervation of the PVN by axons containing NPY originating from at least two discrete sources in the brain may be a mechanism by which a single peptide can exert independent actions on discrete populations of neurons under different physiologic conditions.

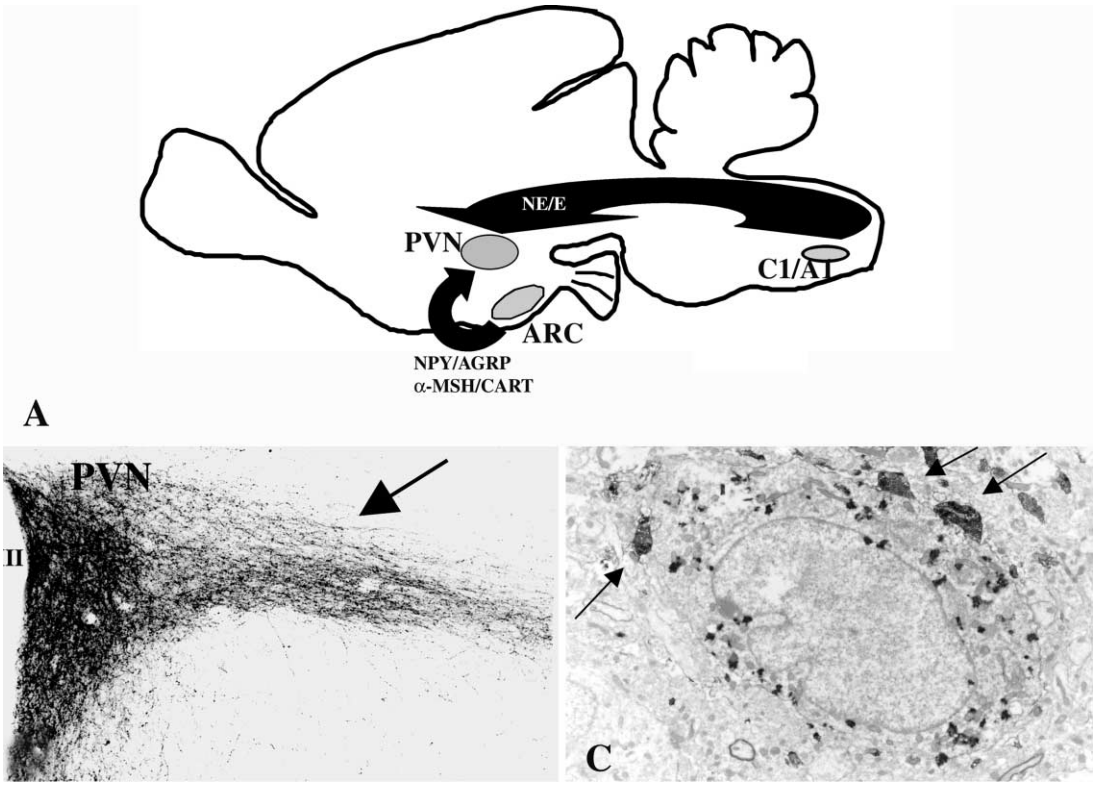

FIGURE 6 (A) Sagittal drawing of the rat brain showing two major sources of innervation of TRH neurons in the hypothalamic PVN: the hypothalamic arcuate nucleus (ARC) that carries the neuropeptides NPY, AGRP, α-MSH, and CART to the PVN and brainstem C1/A1 cell groups that carry the catecholamines norepinephrine (NE) and epinephrine (E) to the PVN. (B) Neurons arising in the arcuate nucleus and brainstem innervate the PVN by traversing the medial forebrain bundle (arrow). (C) Electron micrograph showing that these axons (arrows) establish synaptic contacts with the cell body and dendrites of TRH neurons.

V. FEEDBACK REGULATION OF HYPOPHYSIOTROPIC TRH BY THYROID HORMONE

The anatomical specificity of the TRH neuronal population in the medial and periventricular parvocellular subdivisions of the PVN is associated with a functional specificity of these cells with respect to feedback regulation by thyroid hormone. When circulating levels of thyroid hormone fall below normal values, perikaryal size and the content of proTRH and proTRH mRNA increases in these neurons, but not other TRH neurons in the forebrain (Figs. 7A and 7B). This increase is accompanied by a decline in the content of TRH in the median eminence due to an increase in the secretion of TRH into the portal blood for conveyance to the anterior pituitary. Conversely, increased circulating levels of T4 cause marked suppression of proTRH mRNA in the PVN and a reduction in the secretion of TRH into the portal plexus, establishing an inverse relationship between thyroid hormone and the biosynthesis and secretion of hypophysiotropic TRH.

The increase or decrease in the amount of hypophysiotropic TRH secreted into the portal system for conveyance to the anterior pituitary as dictated by variations in circulating levels of thyroid hormones is important in establishing the setpoint for feedback regulation by thyroid hormone on anterior pituitary TSH secretion. When portal blood TRH concentrations are low, TSH can be suppressed by less T4 circulating in the bloodstream (reduced setpoint), whereas high portal blood TRH concentrations raise the setpoint for feedback regulation by thyroid hormone. Thus, thyroidectomized animals with lesions of the hypothalamus that include the PVN can suppress TSH with smaller doses of T4 than animals with an intact hypothalamus, whereas chronic intrathecal infusion of TRH can elevate TSH and circulating free and total thyroid hormones.

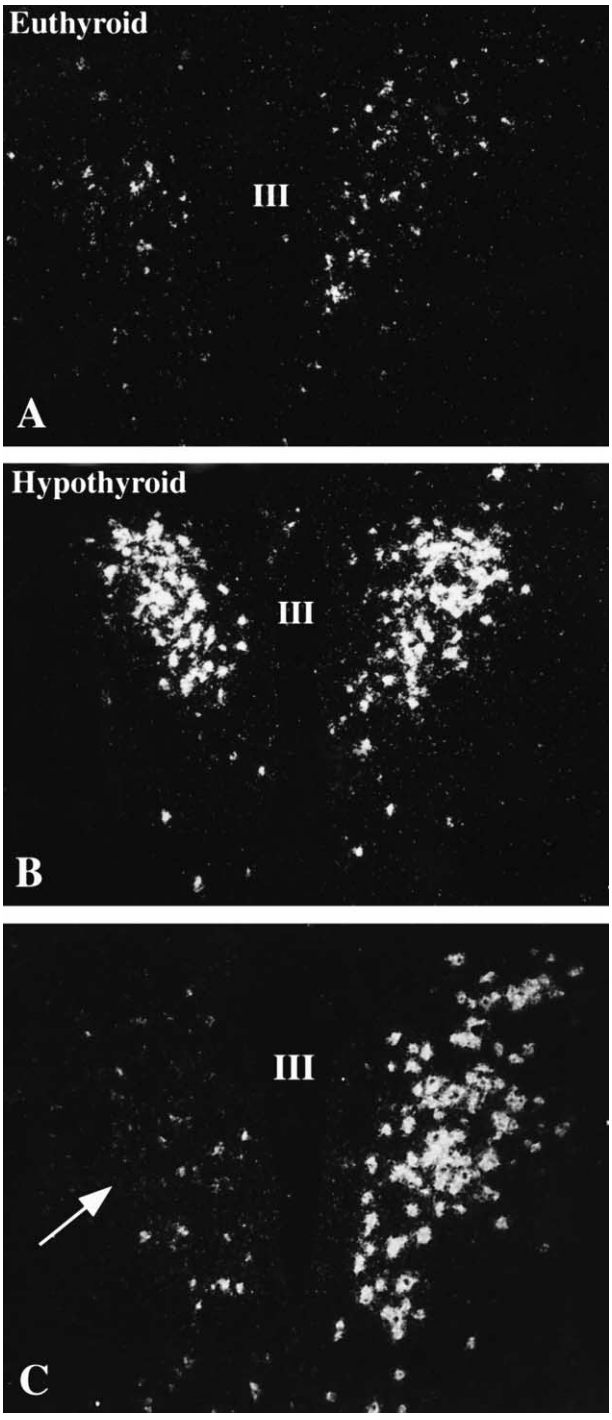

FIGURE 7 *In situ* hybridization autoradiographs of proTRH mRNA in the PVN of (A) euthyroid and (B) hypothyroid animals. Note the marked increase in hybridization signal in (B). (C) Effect of stereotaxic placement of thyroid hormone adjacent to one side of the PVN in a hypothyroid animal. Marked asymmetry of hybridization signal is apparent with diminished signal on the side of the implant (arrow).

The selectivity of TRH neurons in the medial and periventricular parvocellular subdivisions of the PVN to negative feedback regulation by thyroid hormone is an intrinsic property of these cells, mediated by the presence of thyroid hormone receptors in these neurons and the high vascular flow to the PVN. Stereotaxic implantation of microcrystals of T3 adjacent to one side of the PVN in hypothyroid animals, therefore, leads to marked inhibition of proTRH mRNA on that side, but not on the opposite side (Fig. 7C). Although TRH neurons in the PVN contain all of the known thyroid hormone receptors in their nucleus, TRα1 and TRβ2 are the most highly expressed in these cells. However, TRβ2 is the most important thyroid hormone receptor isoform responsible for thyroid hormone-mediated negative feedback regulation of TRH gene expression in hypophysiotropic neurons. Thus, mice with targeted deletion of TRβ2 alone show no significant increase in proTRH mRNA concentration in response to PTU-induced hypothyroidism or a decrease in proTRH mRNA concentration in response to the exogenous administration of T3.

The source of nuclear T3 responsible for feedback regulation of TRH neurons in the PVN differs from the source of T3 in other regions of the central nervous system (CNS) such as the cerebral cortex and anterior pituitary, where the majority of T3 arises from the intracellular monodeiodination of T4 to T3 by type II iodothyronine 5′-monodeiodinase (D2). This is because the PVN contains little, if any, D2 activity or D2 mRNA, indicating that cells in this region are not capable of intracellular conversion of T4 to biologically active T3. Thus, hypophysiotropic TRH neurons in the PVN must receive T3 from an exogenous source, directly from the bloodstream, from the cerebrospinal fluid, from adjacent glia, or by transneuronal transport. The possibility that feedback regulation by thyroid hormone on TRH neurons in the PVN is mediated exclusively by circulating levels of T3 alone is unlikely since the systemic infusion of graded doses of T3 to hypothyroid animals that restore plasma levels of T3 to normal do not suppress proTRH mRNA levels in the PVN to euthyroid levels. Only after constant infusion with higher concentrations of T3 that raise plasma T3 into the supranormal range is there an apparent reduction in hybridization signal for proTRH mRNA to euthyroid levels. Thus, the calculated plasma level of T3 required to suppress proTRH mRNA to normal in the absence of T4 is approximately 1.6 times euthyroid levels, suggesting that like other regions of the brain, feedback regulation of thyroid hormone on

TRH neurons in the PVN is partially dependent on circulating T4.

One potential source of T4 to T3 conversion is the base of the third ventricle where contained among the ependymal cells are specialized glial cells or tanycytes, which contain one of the highest concentrations of D2 mRNA in any region of the brain. Tanycytes extend apical blebs into the CSF and cytoplasmic extensions into the neuropil that envelop the portal capillaries in the median eminence and blood vessels in the hypothalamic arcuate nucleus. Thus, tanycytes may provide a cytoplasmic conduit between the bloodstream and the CSF, allowing bidirectional movement of substances between the vascular and CSF compartments. "D2 tanycytes," therefore, may have an important role in the conversion of T4 to T3 either by the uptake of T4 from the CSF or from vascular compartments in the median eminence/arcuate nucleus and then the delivery of T3 to the CSF. By volume transmission, T3 would have access to extracellular spaces in the brain, such as the hypothalamic PVN, where it could mediate actions directly on hypophysiotropic TRH neurons. Alternatively, tanycytes may release T3 directly into the arcuate nucleus through tanycyte–neuronal interactions, where it could influence the activity of arcuate nucleus neurons that have known projections to TRH neurons in the PVN.

VI. REGULATION OF HYPOPHYSIOTROPIC TRH BY COLD EXPOSURE AND SUCKLING

Thyroid hormone levels and TSH are acutely elevated by cold exposure in several animal species due to the increased secretion of TRH in the median eminence. This response is accompanied by a rapid increase in proTRH mRNA in the PVN, peaking within 30 to 60 min of the stimulus, suggesting that the response is mediated at least in part at the level of TRH gene transcription. A particularly intriguing finding regarding the acute cold-induced stimulation of the thyroid axis is that proTRH mRNA is increased at a time when circulating levels of thyroid hormone are high. This is in contrast to the mechanism of inverse feedback regulation by thyroid hormone as discussed above where proTRH mRNA would be expected to be inhibited. Thus, cold exposure may override the normal mechanism for feedback regulation by altering the setpoint for inhibition of TRH gene expression by T3.

The mechanism whereby the setpoint for feedback inhibition by thyroid hormone changes with cold exposure and suckling is still uncertain but there is strong evidence to suggest a role of catecholamines. Norepinephrine stimulates the release of TRH from hypothalamic preparations in culture, and depletion of catecholamines with inhibitors of catecholamine biosynthesis, such as α-methyl-para-tyrosine, or selective catecholamine neurotoxins, such as 6-hydroxydopamine, abolishes the response of the hypothalamic–pituitary–thyroid axis to cold exposure. In addition, the TSH response to acute cold exposure does not occur within the first 10 days after birth in the rat when the hypothalamic norepinephrine innervation is still immature. As noted previously, the PVN receives dense, afferent input from catecholamine-containing neurons in the brainstem that form asymmetric-type synaptic interactions on the cell body and dendrites of TRH neurons, suggesting an excitatory role. Norepinephrine may also stimulate TRH secretion by interacting with α-1 receptors directly in the median eminence.

Suckling increases proTRH mRNA in the PVN within 30 to 60 min of the response but for the primary purpose of increasing prolactin secretion from the anterior pituitary. TSH and thyroid hormone levels do not increase, perhaps due to the simultaneous release of oxytocin, which can attenuate TRH-induced TSH secretion. Although serotonergic afferents from the midbrain raphe may mediate this response, the mechanism for the increase in TRH gene expression remains elusive.

VII. REGULATION OF HYPOPHYSIOTROPIC TRH BY FASTING AND INFECTION (NONTHYROIDAL ILLNESS SYNDROME)

Infection and fasting also alter the normal mechanisms of feedback regulation by circulating levels of thyroid hormone on hypophysiotropic TRH. In these circumstances, however, there is a fall in thyroid hormone levels but a seemingly paradoxical reduction of proTRH mRNA in the PVN, reduced secretion of TRH into the portal blood, and low or inappropriately normal plasma TSH levels rather than the anticipated increase in all of these parameters as seen in primary hypothyroidism. Thus, these conditions override the normal feedback mechanism described above and induce a state of central hypothyroidism, commonly referred to as "nonthyroidal illness" or the "sick euthyroid syndrome" in human. By reducing thyroid thermogenesis and preserving nitrogen stores, this mechanism is an

important adaptive response to reduce energy expenditure until the adverse stimulus has been removed.

The state of central hypothyroidism induced by fasting is orchestrated by a circulating cytokine of white adipose tissue origin, leptin, which declines with fasting and is restored to normal levels by refeeding. Thus, if leptin is administered exogenously to fasting animals, the reduction in circulating levels of thyroid hormone, TSH, and hypophysiotropic proTRH mRNA in the PVN is prevented (Fig. 8). The primary action of leptin on the hypothalamic–pituitary–thyroid (HPT) axis is mediated primarily by the hypothalamic arcuate nucleus via the arcuato-PVN pathway. If the arcuate nucleus is destroyed, not only is the response of the thyroid axis to fasting abolished, its response to the exogenous administration of leptin is lost as well. The arcuate nucleus, therefore, serves as a critical locus to mediate the effects of leptin on the HPT axis and in so doing presumably establishes the setpoint for feedback sensitivity of proTRH-producing neurons in the PVN to thyroid hormone, lowering the setpoint when leptin levels are suppressed during fasting.

At least two anatomically distinct populations of neurons in the arcuate nucleus with opposing functions, the α-MSH-producing neurons that co-express CART and the NPY-producing neurons that co-express AGRP, are responsible for the actions of leptin on hypophysiotropic TRH. When leptin levels are suppressed during fasting, expression of the genes encoding POMC, the precursor protein of α-MSH, and CART are reduced simultaneously with a marked increase in the genes encoding NPY and AGRP. As suggested by the appearance of the synaptic specializations between axons containing α-MSH and CART and TRH neurons, both peptides, when administered intracerebroventricularly to fasting animals, activate proTRH gene expression and each can increase the suppressed levels of proTRH mRNA in hypophysiotropic neurons induced by fasting. Suppression of α-MSH and CART by fasting, therefore, is an important component of the effect of fasting on the thyroid axis, and their increase with refeeding may partly explain the recovery of the thyroid axis to normal. Since the TRH gene contains a multifunctional cAMP-response element that is activated by the phosphorylated form of CREB (PCREB) and inhibited by thyroid hormone bound to its receptor, and all melanocortin receptors couple to stimulatory G-proteins, an increase in cAMP generation may have the effect of decreasing the sensitivity of the TRH gene to feedback inhibition by thyroid hormone by increasing PCREB. Nevertheless, in contrast to the systemic administration of leptin, which restores the thyroid axis to normal in fasting animals, α-MSH is capable of only partly restoring circulating thyroid hormone levels and TSH, and CART has no effect on these hormones, suggesting that other central regulatory mechanisms also participate in this response.

It is likely that NPY has an important role in resetting the hypothalamic–pituitary–thyroid axis during fasting since fasting up-regulates NPY gene expression simultaneously with a decrease in POMC/-CART gene expression and NPY receptors couple to inhibitory G-proteins that reduce cAMP. An inhibitory effect of NPY is suggested by the morphologic specializations between NPY-containing axon term-

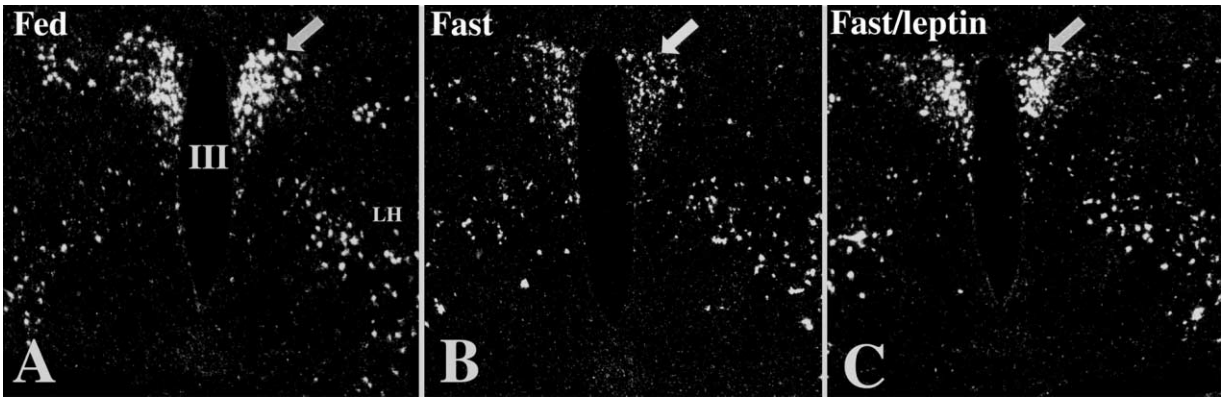

FIGURE 8 *In situ* hybridization autoradiographs of proTRH mRNA in the PVN (arrow) of (A) normal fed and (B) fasting animals. Note the marked reduction in hybridization signal by fasting. (C) ProTRH mRNA levels are restored to normal in fasting animals administered leptin.

inals and TRH neurons in the PVN. Indeed, the exogenous administration of NPY to normal, fed rats reduces circulating thyroid hormone and TSH levels and induces a greater than 50% reduction in proTRH mRNA in PVN neurons. The inhibitory action of NPY is mediated primarily by NPY Y1 and NPY Y5 receptors, with little or no effect of NPY Y2 receptors. NPY may also antagonize the activating effect of α-MSH on hypophysiotropic TRH neurons at a postreceptor level by preventing the phosphorylation of CREB.

Since the NPY-deficient transgenic mouse retains typical homeostatic responses to fasting, including a fall in thyroid hormone levels, it is likely that inhibitory factors other than NPY also contribute to the regulatory responses of fasting on the HPT axis. A likely candidate is AGRP, which is co-expressed in the same arcuate nucleus neurons and axon terminals that innervate TRH neurons in the PVN and which is also a potent inhibitor of proTRH mRNA when administered exogenously to fed animals. As AGRP is an endogenous antagonist at melanocortin receptors, its primary role may be to prevent the stimulatory effects of α-MSH on the TRH gene. Not all TRH neurons in the PVN receive contacts by α-MSH-containing axon terminals, however, indicating that AGRP may also function as an inverse agonist to constitutively active melanocortin receptors that may be uniformly expressed in hypophysiotropic TRH neurons or at a separate, as yet unknown receptor.

Although a decrease in POMC and CART gene expression contributes to fasting-induced suppression of the HPT axis, this mechanism does not appear to participate in other causes of nonthyroidal illness syndromes such as infection. In fact, following the administration of endotoxin, both POMC mRNA and CART mRNA increase in the arcuate nucleus despite suppression of proTRH mRNA in the PVN, and circulating levels of leptin are increased. Presumably, therefore, a set of regulatory controls over the hypothalamic–pituitary–thyroid axis that is different than that observed during fasting must be utilized under these conditions, superceding the stimulatory action of these substances on hypophysiotropic TRH.

The inhibitory effect of infection on hypophysiotropic TRH neurons is likely multifactorial and may involve direct and indirect effects of cytokines other than leptin such as interleukin-1, interleukin-6, tumor necrosis factor, and interferon. Supporting a direct action of cytokines on hypophysiotropic TRH neurons is the presence of a STAT-binding site in the promoter of the TRH gene. The potential contribution of cytokine-inducible inhibitors of signaling such as the SOCS (suppressor of cytokine signaling) proteins that prevent activation of the JAK/STAT pathway should also be considered. Glucocorticoids, which rise dramatically following endotoxin administration, may also contribute to the abnormal feedback responses to thyroid hormone. Both the normal circadian variation and the pulsatile secretion of TSH can be abolished by glucocorticoids, and glucocorticoids can reduce proTRH mRNA in the PVN, although the mechanism is unclear.

VIII. EXTRAHYPOTHALAMIC FUNCTIONS OF TRH

Not all populations of TRH neurons subserve a hypophysiotropic function. As noted above, even within the PVN itself, TRH neurons in the anterior and dorsal parvocellular subdivisions do not project to the median eminence and instead are probably involved in the regulation of autonomic function and behavior. There are many TRH-rich regions in the brain including such diverse groups as the lateral hypothalamus, preoptic region, olfactory lobes, periaqueductal gray, dorsal motor nucleus of the vagus, and spinal cord, to name only a few. Rather than influence anterior pituitary TSH secretion, these neurons have a number of independent functions (depending upon their location), as described in Table 1. The spinal cord, for example, contains one of the highest concentrations of TRH in the CNS, exceeding even that in the hypothalamus. Here, TRH is located in axon terminals in the intermediolateral column and ventral horn (Fig. 9), originating from a large population of neurons in the brainstem medullary raphe. The dense concentration of TRH

TABLE 1 Nonhypophysiotropic Effects of TRH/TRH-Derived Peptides

Analgesia	Increased gastric acid secretion
Anticonvulsant activity	Increased gastrointestinal motility
Arousal	Increased glucagon secretion
Cerebral vasodilation	Increased locomotor activity
Diaphoresis	Increased respiration
Facilitation of memory	Inhibition of food intake
Facilitation of motoneuron excitability	Neurotropic effects on spinal cord motoneurons
Hypertension	Peripheral vasoconstriction
Improved memory	Reduced pancreatic exocrine secretion
Increased blood pressure	Tachycardia
Increased body temperature	Tremor

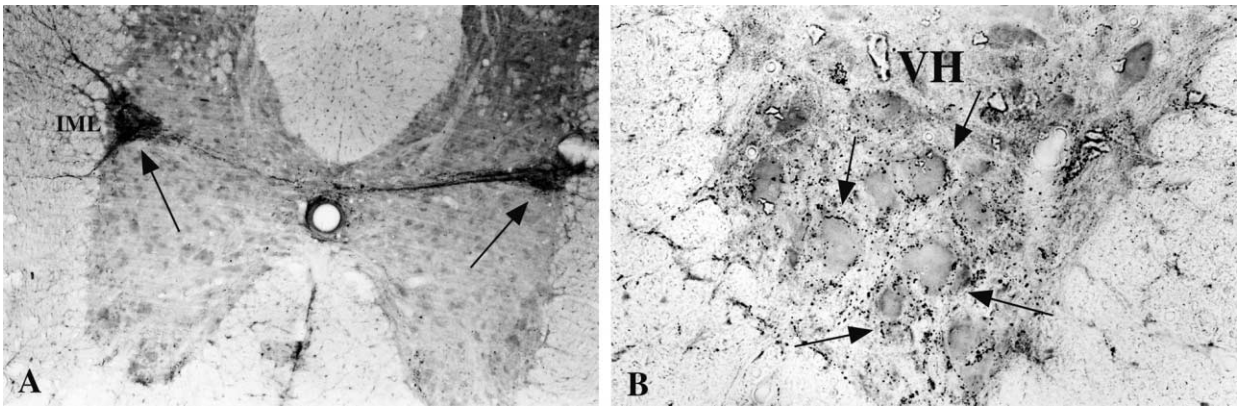

FIGURE 9 TRH terminal fields in the spinal cord (A) intermediolateral column (IML) [arrows in (A)], and (B) ventral horn (VH). Arrows in (B) show dense terminal fields in association with α-motoneurons.

in the intermediolateral column mediates some of the autonomic effects of TRH including cardiovascular function. Ventral horn TRH may act as a facilitatory (excitatory) modulator of lower motoneuron function but could also have a tropic role, stimulating the outgrowth of motoneurons and promoting recovery following traumatic or ischemic spinal injuries. The effect of TRH on gut motility and gastric acid secretion is mediated by neurons in the dorsal motor nucleus of the vagus. TRH in the hippocampus exerts an anticonvulsant action, whereas TRH in the lateral hypothalamus and septum is involved in arousal and locomotor activity. Of particular interest are regions in the brain such as the midbrain periaqueductal gray, reticular nucleus of thalamus, and olfactory bulbs, where products of the TRH prohormone other than TRH itself may be the primary end products of proTRH processing. In the periaqueductal gray, for example, opiate withdrawal results in preferential accumulation of pre-proTRH$_{83-106}$ and may be involved in nociception or recovery from the physical manifestations of opiate withdrawal.

TRH (and/or TRH mRNA) has also been identified in anterior pituitary somatotropes, where it may contribute to basal secretion of TSH by a paracrine mechanism, and in many peripheral tissues including the retina, thyroid (parafollicular cells), heart, adrenal medulla, epididymis, testis (Leydig cells), placenta (syncytiotrophoblast cells), ovary, spleen, gastrointestinal tract, and pancreas (beta cells). The demonstration that mice with targeted deletion of the TRH gene develop diabetes has implicated TRH or products of proTRH in islet cell development and/or glucose homeostasis.

Glossary

cyclic AMP-response element-binding protein A nuclear transcription factor mediating intracellular signaling systems that activate cyclic AMP.

deiodinase One of three different enzymes (D1, D2, and D3) responsible for removal of iodine from tyrosine residues to activate or inactivate thyroid hormone.

hypophysiotropic That pertaining to regulation of anterior pituitary secretion.

paraventricular nucleus A collection of small (parvocellular) and large (magnocellular) neurons in the hypothalamus that contain the neurons of origin of the thyrotropin-releasing hormone tuberoinfundibular system.

proconvertase enzymes Proteolytic enzymes of the subtilisin/kexin-like family that participate in the conversion of peptide precursors to their final biologically active forms by cleaving at the C-terminal basic amino acids.

promoter The region of a gene that directs regulation of transcription of its specific mRNA.

retinoid acid X receptor A member of the nuclear receptor family capable of forming heterodimers with thyroid hormone receptors.

signal transducers and activators of transcription A family of transcription factors mediating the effects of cytokines.

tuberoinfundibular system The collection of neurons in the brain and their axon trajectory that terminate in the neural–hemal contact zone of the hypothalamic median eminence.

Transcortin and Blood-Binding Proteins of Glucocorticoids and Mineralocorticoids

AGNÈS EMPTOZ-BONNETON, CATHERINE GRENOT, AND MICHEL PUGEAT

INSERM ERM 03 22

Transcortin or corticosteroid-binding globulin (CBG) is the specific plasma transport protein that binds glucocorticoid hormones and regulates their biological disposal to target cells. Analysis of its primary structure, gene organization, and chromosomal location shows a close relationship with α1-anti-trypsin as well as other serine protease inhibitors. During acute inflammatory stress, the fall in circulating CBG levels enhances the bioavailability of cortisol and further amplifies the acute stimulation of adrenal function. In addition to its role as a steroid transport protein, there are indications of a possible role played by CBG in the release of glucocorticoids at inflammation sites and in

steroid hormone targeting through the binding of CBG–steroid complexes to cell membranes.

I. INTRODUCTION

In blood, hydrophobic steroid hormones circulate while bound to proteins. Albumin binding is the nonspecific, high-capacity transport system that is generally nonsaturated in normal physiological circumstances, whereas corticosteroid-binding globulin (CBG), also referred to as transcortin, represents a specific high-affinity but low-capacity transport system for cortisol, the main glucocorticoid hormone secreted by adrenal glands in humans. No specific binding protein for aldosterone, which is the main mineralocorticoid hormone secreted by the adrenals, has been identified thus far.

Most vertebrate species examined have circulating CBG with varying serum concentrations and steroid-binding specificities. In each species, the binding specificity of CBG is correlated with the biological activity of glucocorticoids. In humans, CBG-binding affinity is much higher for glucocorticoids (cortisol, corticosterone, and deoxycortisol) and progesterone than for mineralocorticoids (aldosterone and deoxycorticosterone) (Table 1). The binding capacity of CBG is close to the highest physiological cortisol concentration, and more than 90% of circulating cortisol is bound to CBG. Thus, according to the free hormone hypothesis, CBG, by limiting cortisol access to target cells, regulates cortisol biodisposal.

II. STRUCTURE, BIOCHEMISTRY, AND BIOSYNTHESIS OF CBG

Human CBG is a monomeric glycoprotein of 50–55 kDa, as estimated by polyacrylamide gel electrophoresis under denaturing conditions, with one steroid-binding site per molecule. The mature protein is a 383-amino-acid polypeptide, derived from a 405-residue precursor polypeptide.

TABLE 1 Affinity (K_a) of Adrenal Steroids for CBG at 37°C

	K_a (liter·mol^{-1})
Cortisol	76×10^6
Corticosterone	76×10^6
Deoxycortisol	76×10^6
Cortisone	7.8×10^6
Aldosterone	1.9×10^6
Deoxycorticosterone	45×10^6

CBG comprises five N-linked oligosaccharide chains per molecule, of which three are biantennary and two triantennary. A pregnancy-specific variant containing only triantennary oligosaccharide chains has been described, but does not affect steroid-binding activity. These carbohydrate chains potentially influence the biological half-life of the protein and may play a role in the interaction of CBG with the membrane receptors that are reported to be present at the surface of some target cells.

CBG is a member of the serine protease inhibitor (SERPIN) superfamily and shares a high degree of sequence homology with α1-anti-trypsin (α1AT), α1-anti-chymotrypsin (AACT), and another plasma transport protein, thyroxin-binding globulin (TBG). The role of α1AT (structurally and genetically the closest to CBG) is to protect tissue from hydrolysis by elastase, released by activated neutrophils during inflammation. CBG is specifically cleaved *in vitro* by neutrophil elastase at a single site in the neighborhood of the steroid-binding site. This cleavage induces a conformational change in the molecule, resulting in a 10-fold decrease in cortisol-binding affinity and the subsequent release of cortisol from its steroid-binding site.

Circulating CBG is synthesized by the liver. However, small amounts of CBG are also present in tissues such as pituitary corticotrophs, lung, kidney, uterus, and testis. It is not yet clear whether the presence of CBG at these sites is due to local synthesis or to sequestration from blood circulation. The physiological significance of this extrahepatic production of CBG, which probably has no influence on the plasma CBG concentration but could alter the local bioavailability of steroids that bind to CBG, has also not yet been established.

III. CBG GENE

Human CBG is encoded by a single gene located on the long arm of chromosome 14, at position 32.1 (14q32.1). This region, the SERPIN gene cluster, includes five other SERPIN genes: α1AT, AACT, kallistatin, protein C inhibitor, and ATR, an anti-trypsin-related sequence.

The human CBG gene (*Cbg*) comprises five exons distributed over approximately 19 kb, with the complete coding sequence for CBG spanning exons 2 to 5 (Fig. 1). *Cis*-acting sequence elements identified in rat *Cbg* promoter (*pCbg*) and highly conserved in the human *pCbg* indicate that hepatocyte nuclear factor-1β and hepatocyte nuclear factor-3α (HNF-1β and HNF-3α), CCAAT-binding protein, D-site-bind-

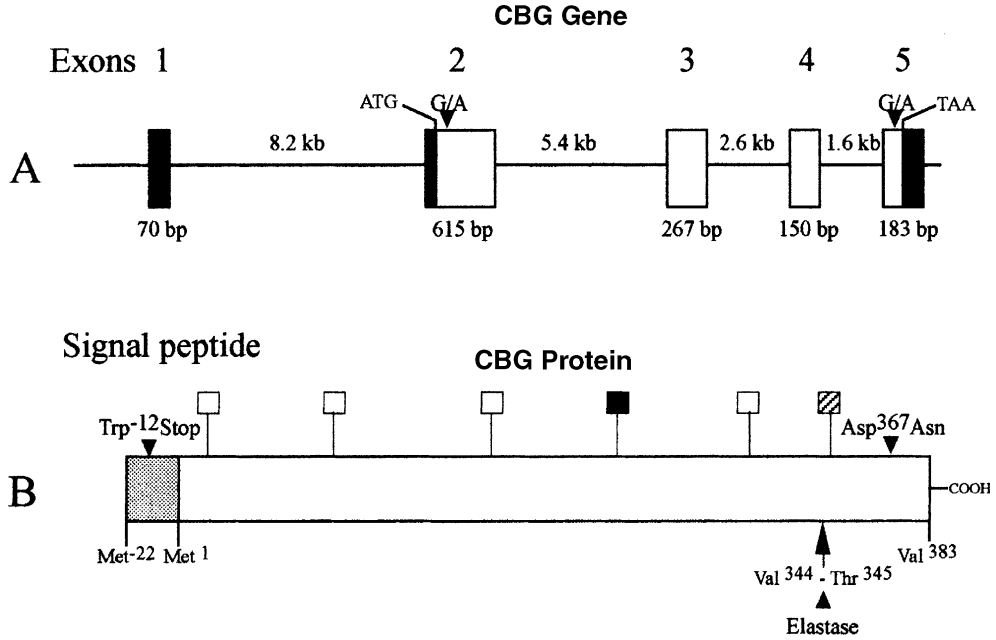

FIGURE 1 Schematic representation of the human CBG gene and CBG protein. (A) The human CBG gene comprises five exons (boxes), numbered 1–5; the black areas correspond to 5′- and 3′-untranslated regions; the size of the exons [in base pairs (bp)] is indicated at the bottom; the size of the introns [in kilobases (kb)] is indicated at the top. The start codon (ATG) and stop codon (TAA) are indicated at the top. The two known mutations inducing CBG deficiency are indicated by arrows (CBG null, c.121G → A in exon 2; and CBG Lyon, c.1254G → A in exon 5). (B) Human CBG and its signal peptide (shaded area). The consensus sites for N-linked carbohydrate chains are indicated by squares; the evolutionarily highly conserved site, essential for the production of CBG with steroid-binding activity, is shown as a black square, and the site that appears to be partially utilized is shown as a diagonally striped square. The position of the elastase cleavage site is indicated by an arrow. The amino acid substitutions corresponding to the mutations in the CBG gene are indicated by arrowheads (CBG null, $Trp^{-12}Stop$; and CBG Lyon, $Asp^{367}Asn$).

ing protein, and interleukin-6 (IL-6) can contribute to the regulation of *Cbg*. It has also been demonstrated recently that HNF-1α and HNF-4 control both the chromatin structure and the gene activity of the entire α1AT/CBG gene locus within the SERPIN gene cluster at 14q32.1.

IV. PHYSIOLOGICAL VARIATIONS

In mammals, CBG biosynthesis varies considerably during development, independently of maternal hepatic CBG biosynthesis. Fetal hepatic CBG mRNA and plasma CBG levels increase during mid to late gestation and decrease shortly before birth (rabbit, rat, and mouse) or immediately postnatally (sheep). Thereafter, the production of CBG by the liver increases during the first weeks of postnatal life. This decrease in hepatic CBG biosynthesis around the time of birth may control the amount of glucocorticoids available to tissues, especially to the lungs, the glucocorticoid-dependent maturation of which is critical to neonate survival at birth.

In humans, CBG levels are low in cord blood, rise rapidly during the first week of life, and then rise steadily during infancy (Fig. 2). Maximum plasma CBG levels are observed at 4 to 6 years of life. A decrease of 30% is observed before puberty (between 6 and 12 years), and then the level of plasma CBG decreases gradually from 12 to 18 years and remains remarkably stable throughout adult life, except in women during pregnancy. CBG levels rise from the 9th week to the 24th week of pregnancy, reach values two or three times as high as basal levels, and return to nonpregnant levels 1 week after delivery. By analogy to animal models, in which CBG variations during pregnancy reflect changes in CBG mRNA levels, this increment has been said to be associated with the inducing effect of estrogens on CBG biosynthesis rather than to a decreased clearance rate.

Gender differences in CBG levels have been reported: CBG values have a bimodal distribution in

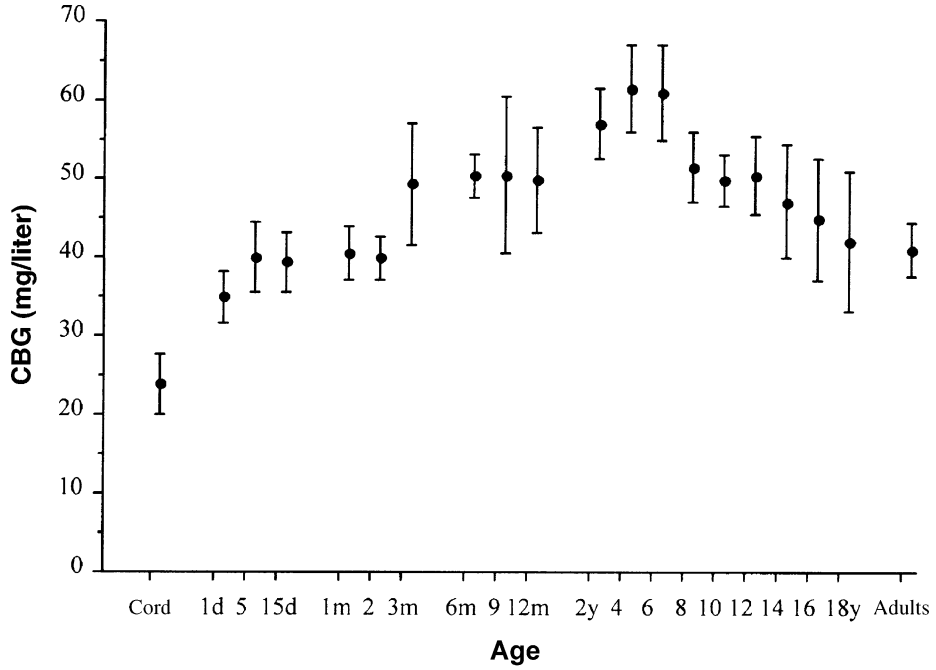

FIGURE 2 Plasma CBG levels (± SEM) according to age from birth to adulthood (cord, cord blood; d, days; m, months; y, years).

men but not in women. No diurnal fluctuation in plasma CBG levels is observed in humans, in contrast to diurnal variations in plasma glucocorticoid levels, and the level of CBG remains unchanged with aging.

V. PATHOLOGY AND FAMILIAL CBG DEFICIENCY

A. Acute Inflammation

Acute inflammation (documented in sepsis, burn injury, and cardiac surgery) induces a rapid and prolonged decrease in plasma CBG concentration. This two-step decrease can be explained by (1) an increased CBG clearance rate after proteolytic cleavage by neutrophil elastase and (2) IL-6 repression of hepatic CBG biosynthesis, as suggested by *in vitro* and *in vivo* experiments (Fig. 3). During inflammation, CBG depletion enhances the bioavailability of cortisol and further amplifies the acute stimulation of adrenal function escaping the normal cortisol negative feedback regulation.

B. Glucocorticoid Excess

Glucocorticoid excess (Cushing's syndrome or glucocorticoid treatment) is associated with low CBG levels, most likely by reduced CBG gene transcription rate, as demonstrated in adult rats. In contrast, the increased cortisol levels observed during depressive syndrome or anorexia nervosa are not associated with any significant decrease in CBG levels.

C. Insulin-Dependent Diabetes Mellitus

In insulin-dependent diabetes mellitus, CBG levels tend to be elevated and return to normal after insulin treatment. Obese subjects with glucose intolerance have higher CBG levels than do lean or normally glucose-tolerant obese subjects, and CBG levels are negatively correlated with the insulin response to intravenous glucose. These results are in line with evidence that insulin is a potent inhibitor of hepatic CBG production, as demonstrated on a human hepatoma (HepG2) cell line (Fig. 3).

D. Thyroid Disease

In thyroid diseases, CBG levels have a tendency to be negatively correlated with free thyroid-hormone levels; patients with thyroxin excess have low CBG plasma concentrations and, conversely, hypothyroid patients have high CBG levels. Treatment of hyper- or hypothyroidism normalizes CBG concentrations. The relationship between CBG and thyroid function is unclear.

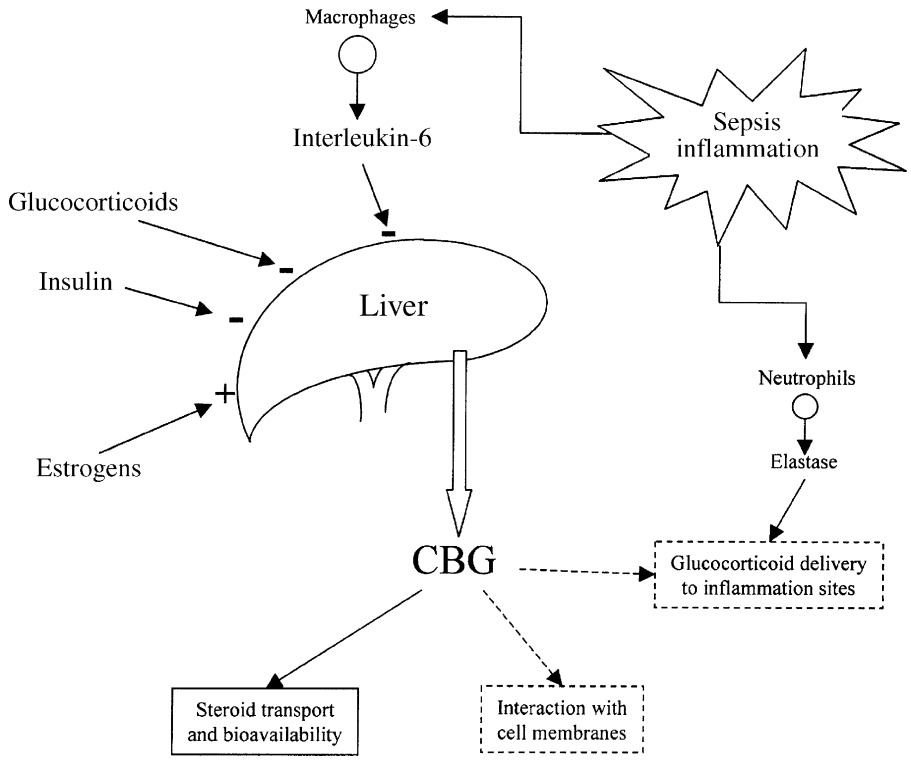

FIGURE 3 Schematic representation of CBG biosynthesis regulation and of the roles played by CBG (dashed lines indicate hypothetical roles).

E. Diseases Involving Protein Metabolism

In diseases involving protein metabolism alterations, such as liver cirrhosis and nephrotic syndrome, the CBG plasma concentration is decreased proportionally to the decrease in albumin concentration.

F. Familial CBG Deficiency

Familial CBG deficiency is a rare occurrence. Recently, two independent mutations (one in exon 2 and one in exon 5) have been described in patients with unexplained fatigue, obesity, low blood pressure, and abnormally low basal and adrenocorticotropic hormone (ACTH)-stimulated cortisol concentrations despite normal free urinary cortisol and ACTH levels. The low cortisol concentrations in CBG-deficient patients illustrate the crucial effect of CBG on the metabolic clearance rate of cortisol, whereas the normal functioning of the hypothalamo–pituitary–adrenal axis indicates that negative cortisol feedback on ACTH secretion is exerted by the free cortisol fraction, which is in the normal range in these patients. Interestingly, obesity is a common clinical feature in CBG-deficient subjects and may be explained by enhanced cortisol activity on adipose tissue, since it has recently been shown that these patients have low CBG mRNA expression in preadipocytes.

VI. ROLE OF CBG

A. Steroid Transport and Bioavailability

The main circulating cortisol fraction is bound to CBG (90 to 95%), suggesting that CBG may provide a buffer reservoir of cortisol in the vascular compartment that can become rapidly available to the free and active hormone pool by simple dissociation from CBG-binding sites. During pregnancy, increased CBG levels may optimize this cortisol reservoir function of CBG.

CBG protects cortisol from peripheral metabolism and thus reduces the rate of synthesis required by the adrenal to maintain a given level of unbound or biologically active hormone.

B. Glucocorticoid Delivery to Inflammation Sites

As a member of the SERPIN family, CBG is specifically cleaved by elastase released at the surface of activated neutrophils. It is unlikely that elastase

cleavage of CBG occurs in the general circulation because of the large surplus of α1AT (the main inhibitor of elastase). Nevertheless, at inflammation sites, CBG cleavage can occur at the surface of activated neutrophils that produce superoxide anions inactivating α1AT. Thus, large amounts of glucocorticoid could be released directly to inflammatory cells.

C. CBG Interaction with Cell Membranes

Although the intracellular presence of CBG can be attributed to *de novo* synthesis in some cases, it can only be explained by sequestration from blood circulation in many other instances, and this may involve a process of cellular internalization. In support of this notion, a specific interaction has been demonstrated between CBG and binding sites on the plasma membrane of various cell types, and the binding is influenced by the conformation of CBG and by the structure of its carbohydrate chains. Furthermore, a CBG–receptor complex has been characterized on placental plasma membranes. It has also been shown that CBG binding to trophoblast cells increases intracellular cyclic AMP levels. Taken together, these findings suggest that CBG could be involved in the guided transport of steroid hormones to target cells and transmembrane transfer of hormones and/or hormonal signals.

Glossary

free hormone hypothesis Plasma-specific binding proteins sequester circulating hormones and therefore only the non-protein-bound fraction (= free) of hormones is available for movement out of capillaries and for cell biodisposal, where it may either initiate a biological response or be metabolized and cleared from the circulation.

interleukin-6 (IL-6) One of the major cytokines secreted by macrophages. IL-6 induces the synthesis of hepatic acute-phase proteins and activates the hypothalamic–pituitary–adrenal axis during inflammation.

serine protease inhibitors (SERPIN) Superfamily of proteins that undergo a relaxed/stressed transition state on binding with serine protease to form an inactive complex. The subgroup including corticosteroid-binding globulin, α1-anti-trypsin, and α1-anti-chymotrypsin derives from a common ancestral gene by gene duplication.

Thymic Stromal Lymphopoietin (TSLP)

STEVEN D. LEVIN*‡, DAVID J. RAWLINGS*, STEVEN F. ZIEGLER†, AND ANDREW G. FARR*

*University of Washington • †Virginia Mason Research Center, Seattle, Washington • ‡ZymoGenetics, Inc., Seattle

Thymic stromal lymphopoietin was first identified as an activity in supernatants from the thymic stromal cell line, Z210R.1. This cell line was derived from medullary thymic epithelium from an adult Balb/C mouse. Specifically, conditioned media from Z210R.1 cells supported the outgrowth of B lymphocytes from fetal liver precursors, and this activity was determined to be distinct from IL-7 and other known cytokines.

I. CLONING AND CHARACTERIZATION OF TSLP

Using a cDNA library from Z210R.1 cells and a transient expression strategy, Sims *et al.* isolated a cDNA clone whose product supported the growth of the fetal liver-derived pre-B-cell line NAG8/7 in a bioassay. The cDNA encoded a protein of 140 amino acids, including the 19-amino-acid leader sequence. The mature polypeptide contained seven cysteine residues and three potential N-linked glycosylation sites. Further examination showed that the protein was predicted to fold into the canonical four-helix bundle structure common to members of the cytokine family. Expression studies have shown that thymic stromal lymphopoietin (TSLP) mRNA is most highly expressed in thymus and lung, with lower levels found in a wide variety of tissues. The *Tslp* gene was localized to mouse chromosome 18.

Recently, a cDNA clone encoding human TSLP was isolated using database search methods. The predicted amino acid sequence of the cDNA showed 43% identity with the mouse TSLP sequence and was also predicted to form a four-helix bundle structure. For both mouse and human TSLP, the most closely related member of the cytokine family was interleukin-7 (IL-7), consistent with the similarities in the biological properties of these cytokines (see below).

II. CHARACTERIZATION OF THE TSLP RECEPTOR COMPLEX

Using radiolabeled TSLP, Park and colleagues identified two classes of TSLP-binding sites, high affinity (ranging from $7 \times 10^9\ M^{-1}$ to $1.0 \times 10^{10}\ M^{-1}$) and low affinity ($< 4 \times 10^8\ M^{-1}$). All of the cell lines that were capable of binding TSLP were of hematopoietic origin, including those derived from the B-cell, T-cell, and monocyte lineages. No binding of the mouse protein was found on any human cell line tested, suggesting that TSLP binding was species-specific. Interestingly, all cell lines found to bind TSLP were also capable of binding IL-7. A direct expression cloning strategy was used to isolate cDNA clones that encode a protein capable of binding TSLP. Using either database searching or a signal-sequence trap, three other groups also isolated cDNA clones shown to encode the mouse TSLP receptor (TSLPR). In all three cases, the cDNA clones were predicted to encode a 359-amino-acid polypeptide with a resemblance to members of the cytokine receptor family. Homology studies showed that the common cytokine receptor γ-chain (γc) was most closely related to the

deletion of the TTP gene or deletion of the UA-rich element causes TNF-dependent systemic inflammatory disease.

Probably all of the TLRs, when activated, stimulate TNF production in some measure. Other stimuli, including physical stimuli such as ultraviolet light, can also activate TNF production, albeit in far lower quantities. Other cytokines may also activate TNF synthesis under some conditions. However, TNF occupies a position near the apex of the cytokine cascade that occurs following macrophage activation, and it has a greater propensity to induce the synthesis of other cytokines than to be induced. The proximal cause of TNF production in diseases such as rheumatoid arthritis and Crohn's disease is not known.

III. STRUCTURE

TNF, a homotrimer, is synthesized as a transmembrane protein but is efficiently released from membrane anchorage by the action of a matrix metalloproteinase, TNFα-converting enzyme (TACE), concurrent with synthesis, or, in some instances, at the cell surface. A trimeric quaternary structure is essential for biological activity, insofar as the protein must stimulate a conformational response in a dimeric receptor, which engages two of three identical active sites on the ligand surface. Bivalent inhibitors of TNF activity are highly effective because they occupy two of the three binding sites, leaving only one site available for receptor binding.

Paralogous proteins in the TNF superfamily are also trimeric, although some are heteromers [e.g., lymphotoxinβ (LTβ)], and most remain stably attached to the cell membrane. In this regard, the sole exception is lymphotoxinα (LTα), which is entirely secreted. The three-dimensional structure of TNFα and LTα have been solved crystallographically. Likewise, the liganded and unliganded p55 TNF receptor ectodomain structure has been solved. These studies contribute to a model of receptor activation events.

IV. RECEPTORS AND SIGNAL TRANSDUCTION

The TNF protein binds to two receptors, both of which have elongated extracellular domains with four cysteine-rich repeat motifs. Different numbers of these repeats are observed in paralogous members of the TNF receptor family, and, indeed, define the family. The type I (p55) TNF receptor is distinguished from the type II (p75) TNF receptor by the presence of a "death domain" motif in the cytoplasmic domain of the former. The death domain permits heterotypic interaction with signaling molecules such as Fas-associated death domain (FADD), TNF receptor-associated death domain (TRADD), and receptor-interacting protein (RIP), which have similar domains of their own.

Death domains ultimately elicit cell death by means of caspase recruitment and activation. FADD, in particular, is known to activate caspase-8, with ensuing activation of more distal cell apoptotic machinery. Among the critical targets for caspase cleavage is polyadenosine diphosphate (polyADP)-ribose polymerase (PARP), which is believed to kill cells when activated by consuming cellular nicotinamide adenine dinucleotide (NAD). Other targets, yet unknown, may also participate in cell killing.

The TNF signal transduction pathway is complex and, in part, is mimicked by the *imd* (immunodeficient) pathway in *Drosophila melanogaster*, which is responsible for sensing gram-negative bacterial infection. The *Drosophila* genome does not encode orthologues of TNF or either TNF receptor, but the *imd* gene encodes a facsimile of RIP, one of the transducers of TNF signals in mammals, and mutations of *imd* render flies susceptible to infection. RIP and *Drosophila* FADD signal a *Drosophila* death effector domain-like domain (DREDD), a homologue of caspase-8, *Drosophila* TAK-1, and kenny, a homologue of IκB kinase γ (IKKγ), to activate Relish, a homologue of NF-κB. *Galere*, a gene encoding a homologue of Tab2, also affects signaling through the pathway, and at the apex, a sensing protein similar to mammalian peptidoglycan recognition proteins (PGRPs) is required to transduce bacterial signals across the membrane.

In mammals, TRADD and RIP engage the strongly proapoptotic p55 TNF receptor and signal to activate proteins of the caspase cascade, as well as NF-κB. FADD, which serves the Fas receptor, is activated by interaction with TRADD. The p75 TNF receptor can, under some circumstances, mediate cell death as well, although the mechanism by which it does so is unclear. It is best known to engage members of the (TNF receptor-associated factor (TRAF) family, which leads to the activation of NF-κB. In mice, p75 stimulates lymphoid proliferation, although it also contributes to the net toxic effect of TNF.

Some of the proinflammatory effects of TNF are undoubtedly mediated by both receptors. Gene knockout work, however, has established that the preponderance of the toxicity of TNF is mediated through the p55 receptor, as is the tumoricidal effect. Receptor-selective TNF mutants have been fashioned and used to dissociate cytotoxic from growth-stimulatory effects of the two receptor subtypes.

V. BIOLOGICAL EFFECTS

Shock and inflammation are caused by TNF, which to a large extent mediates the effects of microbial toxins such as LPS. At the same time, TNF offers protection against a wide array of pathogens, including viruses (some of which have fashioned systems for TNF inhibition), gram-positive bacteria, mycobacteria, and protozoa. It is quite clear that this immunoprotective, innate immune function is the central raison d'être of TNF.

Some chronic inflammatory and autoimmune disorders are clearly orchestrated by TNF, insofar as TNF blockade has ameliorative effects, and biologically significant amounts of TNF can be found within involved tissues or in biological fluids that surround them. Both the toxic and beneficial effects of TNF are mediated by its proinflammatory actions, which include neutrophil activation, a procoagulant effect on the vascular endothelium, stimulation of proteolytic enzyme synthesis, and enhancement of microbicidal activity (including enhancement of oxidative radical production) within various cells. Hence, both the benefits and liabilities of inflammation are embodied within this single molecule and the signals that it initiates.

A developmental role for the TNF type I receptor is seen in its requirement for normal development of germinal centers and follicular dendritic cell clusters in the spleen and other peripheral lymphoid organs. LTα signaling as a part of the LTα/LTβ heteromer via the LTβ receptor has an even more pronounced role in this regard, acting to organize lymphoid tissue throughout the body. The tumorolytic effect that gave TNF its name is now seen as the combined result of the procoagulant activity that TNF exerts with disproportionate efficacy in tumor vasculature, and the apoptotic effect that it exerts on sensitive tumor cells. It is apparently something of a curiosity in a biological sense, insofar as mice lacking TNF do not seem to be more susceptible to the *in vivo* development of tumors.

VI. THERAPEUTIC MEASURES THAT INVOLVE TNF

Once regarded primarily as an antineoplastic drug—biotechnology's premiere reply to cancer—TNF proved to be far too toxic in humans to permit routine use for induction of remissions in patients with metastatic neoplasia. Isolated limb perfusion with TNF has been used with some success to treat localized tumors, such as melanomas that have not yet produced visible metastases. The greatest therapeutic success has been witnessed in the arena of TNF inhibition. Although TNF blockade has not shown significant efficacy as a means of treating septic shock, it has been highly effective in the management of selected chronic inflammatory diseases, including rheumatoid arthritis, Crohn's disease, and ankylosing spondylitis. Psoriatic arthritis has also been approached with TNF blockade, with promising results. Inhibition of TNF activity is generally not considered to be effective therapy for multiple sclerosis, ulcerative colitis, osteoarthritis, heart failure, or systemic lupus erythematosus. Indeed, TNF blockade appears to induce signs and symptoms of SLE in a small proportion of patients. This observation, taken together with the fact that several autoimmune diseases involve defects in cell death pathways, suggests that TNF-mediated apoptosis is normally required for the removal of cells that cause certain types of autoimmunity.

Although macromolecules with high specificity have been used as the most effective means of blocking TNF activity, other approaches aimed at preventing TNF signaling or preventing TNF synthesis have also been entertained. A number of small molecular antagonists of LPS signaling have been described, and some of them may also block TNF production under other circumstances. Among these, thalidomide, pentoxifylline, p38 MAPK inhibitors, and glucocorticosteroids have been studied extensively. Each class of agents displays numerous side effects, however, and in some cases, poor efficacy. Specific inhibitors of TNF or TNF receptor processing have not yet been used for clinical effect.

VII. GENETIC VARIABILITY AT THE TNF LOCUS

Although no major coding variants of the TNF gene have been reported, mutations affecting promoter sequences have been identified and exist at fairly high (polymorphic) frequency in the normal population. Numerous attempts have been made to link these polymorphisms to human disease phenotypes and, in particular, to infectious disease susceptibility or outcome. The results have been conflicting; to date, no solid proof of any relationship between a given TNF isoform and any specific phenotype has ever been made. In all events, it is possible to explain associations by linkage disequilibrium; in the most rigorous analyses, no difference in gene expression has been shown to result from mutational differences within the promoter region.

VIII. PRESENT CHALLENGES IN TNF RESEARCH

The TNF field has reached a high degree of maturity. Nonetheless, there remains much uncertainty about fine details of the TNF signaling pathways, and there are inviting possibilities that bear on the selective exploitation of these pathways. Small molecular TNF mimetic drugs might yet see a role in cancer chemotherapy, provided that their effects are channeled so as to split the proapoptotic effect of the cytokine from the proinflammatory effects. In addition, approximately 30 paralogous genes encode all of the members of the TNF receptor and ligand families in mammals. To some extent, cooperativity and receptor "sharing" occur, so that a higher degree of complexity is observed in specific target cell populations. Considerable work must still be devoted to deciphering the pathways that are involved.

Glossary

apoptosis Programmed cell death.

Crohn's disease Form of inflammatory bowel disease in which TNF is inappropriately produced and contributes to disease.

death domain Signature motif of the type I TNF receptor, responsible for inducing programmed cell death. Also found in other members of the TNF receptor superfamily.

endotoxic shock Severe, acute disorder caused by gram-negative infection; excess TNF is produced in response to bacterial lipopolysaccharide as a result of signaling via Toll-like receptor 4. Marked by fever, hypotension, and inadequate tissue perfusion.

lipopolysaccharide Principal glycolipid (also called endotoxin) of the outer membrane of gram-negative bacteria. The most potent known inducer of TNF synthesis.

lymphotoxin The closest paralogue of TNFα, but produced by different cells; also referred to as LTα and as TNFβ; also important for normal immune development and function.

rheumatoid arthritis Autoimmune inflammatory disorder, affecting joints and other tissues, in which TNF is inappropriately produced and contributes to disease.

Toll-like receptors Primary sensors of the innate immune system; named after the *Toll* gene found in *Drosophila*, provide essential signals for TNF production under conditions of infection.

tumor necrosis factor Proinflammatory cytokine mediator essential for normal immune development and function; the factor first discovered to be produced primarily by macrophages, also referred to as TNFα and as TNF.

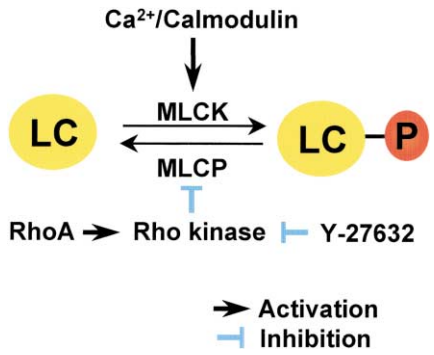

FIGURE 2 The ratio of activities of myosin light chain kinase (MLCK) and myosin light chain phosphatase (MLCP) affects contraction and relaxation in smooth muscle. Increased intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) activates calmodulin/MLCK, resulting in increased light chain (LC) phosphorylation and contraction. Inhibition of MLCP by Rho kinase linked to receptor activation sensitizes myosin light chain phosphorylation to $[Ca^{2+}]_i$.

The intracellular Ca^{2+} concentration remains the mainstay for control of myometrial contraction. In the uterus, in the absence of extracellular Ca^{2+} the force of contraction is $< 5\%$ of that obtained in the presence of extracellular Ca^{2+}. Thus, in myometrium, it appears that influx of Ca^{2+} through voltage-dependent Ca^{2+} channels in the sarcolemma is the main source of activating Ca^{2+} for initiation of contraction. However, the intimate relationship between the release of Ca^{2+} from the sarcoplasmic reticulum and the influx of Ca^{2+} through Ca^{2+}-induced Ca^{2+}-release mechanisms confounds the precise localization of activating Ca^{2+} sources. In addition, the release of Ca^{2+} from inositol trisphosphate (IP_3)-dependent Ca^{2+} stores provides additional layers of Ca^{2+} regulation. Particular pathways of excitation–contraction coupling differentially affect Ca^{2+} homeostasis. Elevation of $[Ca^{2+}]_i$ sets in motion the activation of the contractile elements by Ca^{2+}/calmodulin-dependent phosphorylation of myosin. Alterations in the Ca^{2+} sensitivity of force may arise from effects on regulatory light chain phosphorylation or other contractile proteins.

In myometrial tissues, electrical depolarization results in rapid and synchronous depolarization of smooth muscle cells, influx of extracellular Ca^{2+}, and force development. Increases in $[Ca^{2+}]_i$ precede light chain phosphorylation and force development with immediate increases in $[Ca^{2+}]_i$ after electrical stimulation. After a period of latency (200 ms), significant increases in regulatory light chain phosphorylation and force occur, and these values decrease as a function of time despite maintenance of force. In uterine smooth muscle, maintenance of force in the presence of declining levels of light chain phosphorylation is not sustained for long periods of time. Nevertheless, the recruitment of nonphosphorylated cross-bridges into force-bearing structures may be an important mechanism for force generation in uterine smooth muscle during pregnancy.

B. Activation of Contraction in Uterine Smooth Muscle During Pregnancy

In myometrium from nonpregnant women, spontaneous contractions (~ 10 per hour) are associated with cyclic increases in $[Ca^{2+}]_i$ and phosphorylation/dephosphorylation of myosin. Myosin light chain phosphorylation increases from 0.10 to 0.49 mol phosphate per mole of light chain within 10% of the time required to develop the maximal force of spontaneous contraction. During the declining phase of the contraction, force and light chain phosphorylation dissociate. Experiments from a number of laboratories indicate that, although myosin light chain phosphorylation plays an important role in the initiation of uterine contraction, other cellular mechanisms are involved in the regulation of contraction and relaxation, particularly during pregnancy. In most mammalian species, maximal force generation capacity is increased in myometrial tissues during pregnancy. In myometrium from pregnant women, similar levels of force per cross-sectional area develop in nonpregnant and pregnant women. However, the rate and extent of light chain phosphorylation during contraction are significantly diminished in tissues from pregnant women. The extent of myosin light chain phosphorylation in contracting myometrial tissues from pregnant women is very low. Modifications in $[Ca^{2+}]_i$ may be responsible for these observations because they are not due to changes in the amounts of contractile proteins or the activities of myosin light chain kinase or phosphatase. Other signal transduction pathways may be involved.

C. Mechanisms of Uterine Smooth Muscle Relaxation

Decreases in $[Ca^{2+}]_i$, brought about by Ca^{2+} extrusion or uptake into the SR, result in inactivation of MLCK, regulatory light chain dephosphorylation by myosin phosphatase, and muscle relaxation. Decreases in $[Ca^{2+}]_i$ are mediated predominantly by decreases in membrane potential and extrusion of cytoplasmic Ca^{2+} by plasma membrane Ca^{2+} pumps or uptake of

Ca^{2+} into the sarcoplasmic reticulum by SR Ca^{2+} ATPases.

Recently, the search for mediators of uterine relaxation that maintain uterine quiescence during pregnancy has been intense. For many years, cyclic AMP (cAMP) was identified as a mediator of uterine smooth muscle relaxation, and the mechanism of relaxation has been shown to occur primarily through a lowering of $[Ca^{2+}]_i$. In addition, activation of soluble guanylate cyclase by nitric oxide leading to increased tissue levels of cyclic GMP (cGMP) has been identified as a major mechanism of cGMP-induced vasorelaxation through activation of cGMP-dependent protein kinase. Activation of cGMP-dependent protein kinase also results in decreased free intracellular Ca^{2+} and increased myosin phosphatase activity in vascular smooth muscle. Although evidence supporting a role for this signaling pathway in maintenance of uterine quiescence during pregnancy has been published, experimental evidence from other studies conducted both *in vivo* and *in vitro* indicates that mechanisms other than cGMP-induced activation of cGMP-dependent protein kinase regulate myometrial relaxation during pregnancy.

D. Role of Other Thin Filament-Associated Proteins

Two thin filament-associated proteins, h-caldesmon and calponin, are believed to modify contractility by inhibiting actin-activated myosin ATPase activity and, in the case of caldesmon, by tethering actin to myosin and inhibiting the velocity of actin/tropomyosin filaments in the presence of nonphosphorylated myosin. Caldesmon is a basic protein associated with actin filaments. In uterine smooth muscle cells, caldesmon is the most abundant calmodulin-binding protein. Calponin is a smooth muscle-specific, thin-filament protein with biochemical properties very similar to those of caldesmon. However, the subcellular distribution of these two proteins differs in smooth muscle cells. The total amounts of caldesmon are increased four- to fivefold in pregnant myometrium. Although the total amount of calponin does not increase in pregnant myometrium, calponin is redistributed in pregnant myometrium with increased amounts in the cytoplasmic fraction and decreased amounts in the myofilaments, suggesting a lower affinity for cytoskeletal and myofilament proteins during pregnancy. At this time, it is not clear whether these changes in thin filament proteins are involved in the regulation of uterine contractility during pregnancy.

E. Anatomic and Cellular Considerations of Uterine Contractility

Myometrium belongs to the broad classification of smooth muscles termed phasic smooth muscle. Phasic smooth muscle is characterized by transient increases in force generation in response to K^+, initiation of force by action potentials inherent in the muscle cell, and differential expression patterns of contractile proteins. In general, phasic contractile activity of the myometrium (either spontaneous contractions or in response to K^+) is a response to the underlying electrical activity of the muscle cells. As such, contraction and relaxation of myometrium result from the cyclic depolarization and repolarization of muscle cell membranes, and the driving force for contractility is extracellular Ca^{2+}. The action potentials (voltage- and time-dependent changes in membrane ionic permeabilities) are characterized by depolarization and repolarization phases. The depolarization phase is due to an inward current carried predominantly by Ca^{2+} ions and Na^+ ions. The outward current (repolarization) is carried by K^+ ions consisting of fast voltage-dependent and slow Ca^{2+}-activated components. Thus, the frequency and intensity of myometrial contractions are proportionate to the consistency and duration of action potentials in each muscle cell and the total number of cells that are active. The number of cells activated in response to the action potential is thereby determined by the propagation of the electrical impulses in myometrial cells, i.e., low-resistance pathways for current spread. Intercellular channels specified as gap junctions link cells by allowing the passage of inorganic ions and small molecules from one cell to another. Uterine contractions are thereby controlled by intracellular signal transduction mechanisms and by intercellular communications involving the synthesis, organization, size, and gating of gap junctions.

II. REGULATION OF CA^{2+} SENSITIVITY OF THE CONTRACTILE ELEMENTS

A. Ca^{2+}Sensitivity of Myosin Light Chain Phosphorylation

1. Regulation of Myosin Light Chain Phosphorylation by Phosphorylation of Myosin Light Chain Kinase

The sensitivity of MLCK to activation by Ca^{2+}/calmodulin is diminished upon phosphorylation at a

regulatory site A. As predicted, phosphorylation of MLCK has been shown to desensitize light chain phosphorylation to $[Ca^{2+}]_i$. Initial investigations on the phosphorylation-dependent desensitization of MLCK focused on the possibility that phosphorylation of MLCK by cAMP may be a potential mechanism whereby increases in cAMP and activation of protein kinase A lead to the relaxation of smooth muscle. In human myometrium and other smooth muscles, however, cAMP does not cause relaxation via phosphorylation of MLCK. Nevertheless, MLCK is phosphorylated at site A by calmodulin kinase II, resulting in desensitization of the contractile elements to elevated levels of intracellular Ca^{2+}. During the initiation of contraction and rapid phase of light chain phosphorylation (between 0.5 and 2 s in electrically stimulated tissues), there are no changes in MLCK activation properties. Thereafter, MLCK is phosphorylated and the Ca^{2+} sensitivity of light chain phosphorylation is diminished.

2. Regulation of Myosin Light Chain Phosphorylation by Myosin Phosphatase Activity

The Ca^{2+} sensitivity of myosin regulatory light chain phosphorylation is affected by myosin phosphatase activity. Protein serine/threonine phosphatases are regulated by protein–protein interactions with formation of oligomeric complexes that direct phosphatase catalytic subunits toward specific substrates by association with regulatory proteins. In addition, phosphatase subunits and their inhibitor proteins are regulated by phosphorylation. Smooth muscle myosin light chain phosphatase is a holoenzyme consisting of three subunits: a 38 kDa catalytic subunit (PP1C), a myosin-targeting subunit (MYPT, 110–133 kDa), and a small 20 kDa subunit. The small subunit has no established function and is not required for either catalytic activity or activation of the catalytic subunit.

Two well-described myosin phosphatase inhibitory pathways may result in increased levels of myosin phosphorylation and force in response to contractile agonists. Although most of the work in this area has been conducted in other muscles, recent studies suggest that these pathways may be involved in the regulation of myometrial contractions as well. The first is through the small GTPase RhoA, in which GTP-bound RhoA translocates to the membrane and activates Rho kinase. Activation of Rho kinase results in inhibition of myosin phosphatase activity either through direct phosphorylation of the myosin-binding subunit or through other indirect mechanisms. Dissociation of $PP1_C$ from the M complex occurs by phosphorylation of MYPT. Dissociation of the catalytic subunit from the myosin-targeting subunit results in the inhibition of phosphatase activity. The second signaling pathway, present in only some smooth muscles, involves phosphorylation of a phosphatase inhibitor, CPI-17 (PKC-potentiated phosphatase inhibitor protein-17 kDa), CPI-17 phosphorylation inhibits the catalytic subunit of myosin phosphatase. Currently, there is no information regarding the role of CPI-17 in uterine smooth muscle.

In myometrium, the expression of RhoA protein does not change during pregnancy. Expression of Rho kinase, however, increases in the uterus during pregnancy. The potential role of the RhoA/Rho kinase pathway in oxytocin-induced uterine contraction has been reported. A Rho-kinase inhibitor, Y-27632, inhibits oxytocin-induced rat uterine contraction on day 21 of pregnancy in a concentration-dependent manner. In rat myometrium, Y-27632 has no effect on oxytocin-induced increases in intracellular Ca^{2+}; yet, it is reported that oxytocin-induced increases in light chain phosphorylation are attenuated. Oxytocin increases the phosphorylation of MYPT, and the Rho-kinase inhibitor Y-27632 reduces phosphorylation of the phosphatase subunit by oxytocin. These results indicate that agonist-induced contractions involving G-protein-coupled receptors in the uterus may involve Ca^{2+} sensitization through Rho-kinase-associated inhibition of myosin phosphatase. In addition to the well-described up-regulation of oxytocin receptors during pregnancy, up-regulation of Rho kinase in the myometrium during pregnancy may augment responsiveness to oxytocin.

B. Myosin Light Chain Phosphorylation/Force Relationship

Conditions in which small increases in light chain phosphorylation result in large increases in force have been most frequently reported when smooth muscles are stimulated with activators of protein kinase C (PKC). In human myometrium, it appears that PKC augments agonist-induced contractions. In some smooth muscles, activators of PKC act to cause a slow, forceful contraction, but light chain phosphorylation is not increased. In rat myometrium, phorbol esters inhibit contraction by inhibiting increases in $[Ca^{2+}]_i$. It should be noted that PKC activators may also stimulate contractions with concomitant increases in $[Ca^{2+}]_i$ and phosphorylation

of myosin light chain in some smooth muscles from some species.

Several laboratories working with a variety of smooth muscle types have reported that force may be desensitized (rather than sensitized) to increases in light chain phosphorylation. For example, both arterial and uterine muscles are relaxed upon addition of high external Mg^{2+} without reduction in myosin light chain phosphorylation, and high concentrations of sodium nitroprusside have been shown to relax arterial smooth muscle without decreases in light chain phosphorylation. It has been proposed that complex interactions of the contractile proteins with thin filament regulatory proteins may alter the myosin light chain phosphorylation/force relationship, particularly in myometrium during pregnancy.

III. MODULATION OF UTERINE CONTRACTILITY BY STEROID HORMONES AND PREGNANCY

A. Estrogen and Progesterone

It has been suggested that the contractile phenotype of uterine smooth muscle is increased by estradiol treatment and decreased by progesterone. The concept that estrogen promotes a "contractile" state and progesterone gives rise to "quiescence" suggests that the tissue functions as one or the other of these physiological states depending on the hormonal milieu. In general, procontractile mechanisms are expressed and function under estrogen domination, and prorelaxant mechanisms act under the influence of progesterone. Many examples in the literature suggest that this paradigm may be operative in myometrial cells. Estrogen results in increased expression of oxytocin receptors, connexin-43, and smooth muscle myosin. Estrogen also acts to increase smooth muscle-specific expression of cGMP-dependent protein kinase, and this protein is involved in smooth muscle relaxation. Progesterone opposes the effect of estrogen on many, but not all, estrogen-regulated myometrial proteins. Thus, in most species at term, progesterone withdrawal, together with increasing levels of estrogen, leads to increased expression of oxytocin receptors, cervical collagenase, and formation of gap junctions, thereby providing effective contractions of labor and cervical ripening.

In ovariectomized animals, estrogen increases the expression of oxytocin receptor mRNA, even if combined with progesterone. Importantly, however, progesterone inhibits estrogen-induced increases in oxytocin-binding sites. It has been shown that progesterone inhibits oxytocin receptor binding and oxytocin-induced increases in the generation of intracellular second messengers though nongenomic mechanisms. The precise mechanisms of steroid-induced modulation of G-protein-linked receptor signaling remain to be determined.

B. Pregnancy

This article has alluded to the effects of pregnancy on the contractile machinery of uterine smooth muscle. Although beyond the scope of this article, it should be noted that the uterus, like other smooth muscles, is regulated by the expression of a number of G-protein-coupled receptors. The best characterized of uterine G-protein-coupled receptors is the high-affinity oxytocin receptor.

Unlike the closely related vasopressin receptors, oxytocin receptor expression is highly regulated in a tissue-specific manner. Specifically, prior to parturition, uterine oxytocin receptors are increased up to 100-fold. Although, in the human, increases in oxytocin receptor are less dramatic than in many other species (approximately 2-fold), virtually every mammalian species exhibits changes in the expression of uterine oxytocin receptors before or during parturition. Moreover, expression of the receptor decreases dramatically within 24 h of parturition. Temporal expression patterns in the uterus are unique compared with patterns in the brain, mammary gland, and kidney. In addition, uterine stretch seems to be required for dramatic parturition-associated changes in uterine oxytocin receptor gene expression. These findings suggest that myometrial cell-specific transcriptional factors regulate oxytocin receptor gene expression.

IV. SUMMARY

There have been major advances in the understanding of the regulation and physiological functions of contractile proteins in myometrium in recent years. Phosphorylation of the regulatory light chain of myosin by Ca^{2+}/CaM-dependent MLCK plays a pivotal role in activation. The simple view that contractile force in smooth muscle is proportionate to $[Ca^{2+}]_i$ and myosin light chain phosphorylation has been modified as additional experiments have provided insights into the mechanisms of regulation

of the contractile elements. It is apparent that, although $[Ca^{2+}]_i$ is undoubtedly the master mediator of regulation, additional pathways act to modulate the regulatory components, particularly during pregnancy. The sensitivity of myosin light chain phosphorylation to $[Ca^{2+}]_i$ can be shifted by second messengers modulating the activities of MLCK and myosin phosphatase. MLCK is phosphorylated, which desensitizes its activation by Ca^{2+}/CaM; protein phosphatase activity toward myosin is also regulated by phosphorylation and dephosphorylation of regulatory subunits or cytosolic inhibitors. The dependence of force on myosin phosphorylation is established in the steady state of tonic contractions; however, in uterine smooth muscle, transient increases and decreases in light chain phosphorylation parallel cyclic increases in contractile force. Pregnancy can shift the relationship between regulatory light chain phosphorylation and force development, indicating that the number of cross-bridges can be altered independent of myosin light chain phosphorylation. The physiologic importance and relative contributions of other regulatory components for uterine smooth muscle function *in vivo* are not entirely clear. Moreover, the role of these mechanisms in various hormonal states and pregnancy remains to be defined. The uterus exhibits physiologic properties unique from other smooth muscle types characterized by unique ligand receptors, electrical properties, and Ca^{2+} homeostatic mechanisms. In addition, there is growing appreciation for differences in contractile protein contents and differing patterns of expressed contractile protein isoforms in the uterus during pregnancy. The future holds exciting new information that will increase understanding of the regulatory processes in uterine contractility.

Glossary

G-protein Any of a class of guanine nucleotide-binding proteins associated with the cytoplasmic face of the plasma membrane of mammalian cells; proteins involved in transmitting signals from certain types of hormone and neurotransmitter receptors to intracellular pathways.

protein kinase An enzyme that phosphorylates proteins, specifically phosphorylating the amino acids serine, threonine, and tyrosine.

sarcoplasmic reticulum A membranous organelle system of muscle cells, composed of vesicular and tubular components, that stores calcium ions involved in muscle contraction.

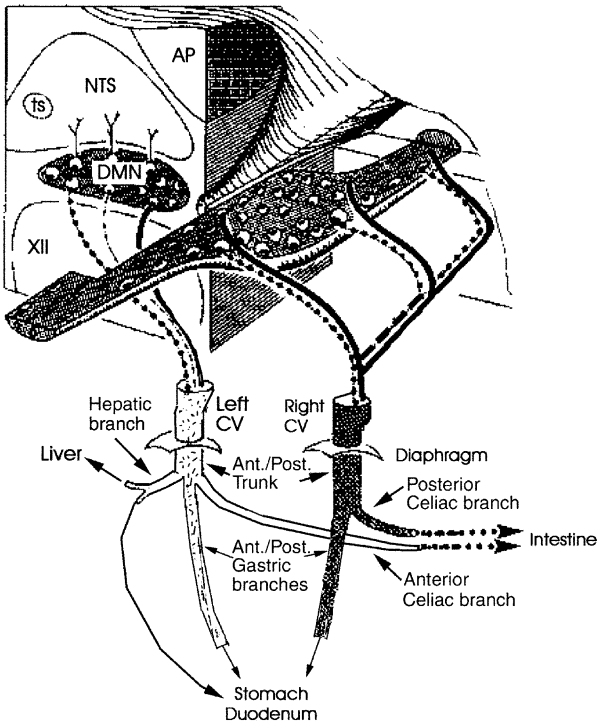

FIGURE 1 Rostrocaudal schematic representation of DMN neurons providing vagal innervation of the stomach through the gastric and hepatic branches. Dendritic projections of DMN motoneurons into the nucleus tractus solitarius are also shown. AP, area postrema; CV, cervical vagus; NTS, nucleus tractus solitarius. Reprinted with permission from Powley, T. L., Berthoud, H.-R., Prechtl, J. C. and Fox, A. E. (1991). Fibers of the vagus regulating gastrointestinal function. *In* "Brain–Gut Interactions" (Y. Taché and D. Wingate, eds.), pp. 73–82. Copyright CRC Press, Boca Raton, Florida.

the lowest threshold for synaptic activation, DMN neurons projecting to the fundus have smaller and shorter after-hyperpolarization and a higher frequency of action potential firing than neurons projecting to the cecum through the vagal celiac branch. Within the medial column, there is also a site-specific organization of neurons. Those projecting to the fundus are more laterally located and those innervating the antrum/pylorus are more medially positioned.

Neurons in the DMN also display dendritic fields that are spread in the horizontal plane with each column harboring spatial separation. Of particular significance are the dendrites of DMN neurons that extend to the overlying nucleus tractus solitarius (NTS) with the highest density in the subnucleus gelatinosus of the dorsal medial NTS, just rostral to the obex where gastric vagal afferent fibers project. This wiring provides the anatomic basis for gastric vago-vagal reflexes whereby signaling from gastric vagal afferent endings in the dorsal medial NTS feed back onto DMN neurons to modulate vagal outflow to the stomach and thereby regulate gastric functions.

Immunohistochemistry combined with retrograde tracing studies revealed that the neurochemical phenotypes of DMN neurons projecting to the stomach are mainly cholinergic. In addition, nitric oxide (NO), a recognized neuronal messenger molecule detected by NO synthase (NOS), is present in 12% of medial neurons of the caudal DMN projecting to the fundus. Nitric oxide innervation may play an important role in vagally mediated gastric reflex relaxation.

C. Projections to the DMN from Brain Nuclei Involved in Regulating Gastric Functions

DMN neurons receive direct neural input from many brain nuclei. Tracing studies revealed that the parvocellular part of the paraventricular nucleus of the hypothalamus (PVN), the central amygdala, the locus coeruleus, and the bed nucleus stria terminalis are an interconnected continuum of "prevagal neurons" that send direct projections to influence DMN neurons. In the medulla, the DMN receives direct projections from a number of NTS neurons as well as from specific nuclei located in the ventral regions, namely, the raphe pallidus (Rpa), the raphe obscurus (Rob), and the parapyramidal regions (PPR). The biochemical coding of identified neurons projecting from the PVN to the dorsal vagal complex (DVC) includes a large number of peptides such as bombesin-like peptide, somatostatin, enkephalins, corticotropin-releasing factor (CRF), neuropeptide Y, vasopressin, and oxytocin.

Consistent with these anatomical circuits for regulatory process, the activation of these specific hypothalamic, limbic, pontine, and medullary neurons influences the neuronal activity of DVC neurons and results in the vagal-dependent alterations of gastric motor and secretory function. In addition, peptides shown to project from the PVN to the DVC, such as bombesin, CRF, and somatostatin, when applied directly into the DVC alter gastric function through vagal pathways.

D. Vagal Efferent Innervation of the Stomach

The vagal preganglionic projections originating from DMN neurons end in the enteric nervous system, predominantly in the myenteric plexus located between the circular and the longitudinal muscular

layers. The prevailing concept is that, due to their small number, vagal efferent fibers provide parasympathetic input to the gut through projections to selected "mother cells/command enteric neurons." However, this concept has been recently challenged. There is now convincing evidence that vagal efferent terminals encircle or make putative contacts with all the ganglia in the myenteric plexus and, to a lesser extent, in the submucosal plexus of the stomach. Electrophysiological probing is also consistent with the notion that a high percentage of gastric myenteric neurons receive direct synaptic fast excitatory postsynaptic potential input from the vagus nerve. Therefore, the current understanding of an interface between vagal efferent fibers and myenteric neurons supports the existence of a dense network of direct interactions between the extrinsic and the enteric nervous systems.

The neurochemical phenotypes of gastric myenteric neurons receiving vagal efferent input encompass serotonin (5-HT)-, vasoactive intestinal peptide (VIP)-, NOS-, gastrin-releasing peptide (GRP)-, and GRP/VIP-containing neurons. Moreover, 60–70% of myenteric neurons in the stomach are cholinergic and surrounded by cholinergic positive fibers, showing the importance of vagal efferent cholinergic/nicotonic input to postganglionic cholinergic myenteric neurons innervating the muscular and mucosal layers of the stomach.

III. BRAIN MEDULLARY THYROTROPIN-RELEASING HORMONE AND VAGAL REGULATION OF GASTRIC FUNCTIONS

The combined use of neuroanatomical, electrophysiological, and pharmacological techniques provided increasingly detailed understanding on the role of medullary thyrotropin-releasing hormone (TRH) in the vagal regulation of gastric function. These studies greatly expanded initial observations from the 1980s that injection of TRH into the cerebrospinal fluid (CSF) at the level of the cisterna magna induced a vagal-dependent stimulation of gastric acid secretion in rats. Currently, TRH-containing projections to the DVC are the only brain peptidergic circuit known to have physiological relevance in the central vagal stimulation of gastric function.

A. Neuroanatomical and Electrophysiological Evidence

Tracing studies revealed that neurons in the Rpa, Rob, and PPR are the exclusive source of the TRH fibers innervating the DVC. Immunoelectron microscopy showed that TRH immunoreactive fibers make direct synaptic contacts with dendrites of DMN neurons projecting to the stomach. Likewise, in humans, TRH immunoreactive fibers represent the most prominent neuronal network compared with that of 12 other neuropeptides investigated. In addition, there is a strong anatomical relationship between TRH nerve terminals in the DVC and the localization of TRH receptors. Earlier studies pointed out that the highest concentration of TRH-binding sites occurs within the medial DMN where gastric preganglionic motor neurons are located and in the subnucleus gelatinosus of the NTS where gastric vagal afferents project. This was further confirmed by the mapping of TRH receptor gene distribution after the cloning of TRH receptor subtype 1 and subtype 2 (TRH_1 and TRH_2). TRH_1 mRNA, but not TRH_2 mRNA, is highly expressed in DMN and NTS neurons. Electrophysiological reports demonstrated that TRH directly stimulates the firing rates of DMN neurons by increasing the inward cationic current and reducing the calcium-dependent after-hyperpolarizing current. TRH also indirectly activates DMN neurons by inhibiting the activity of the NTS neurons that are responsive to gastric distention. Indeed, electrophysiological evidence shows that distention of the stomach and/or duodenum increased the firing rate of the majority of NTS neurons and decreased the firing rate of most DMN neurons, suggesting suppressive input onto DMN neurons from gastric distention-responsive NTS neurons. The activation of DMN neurons by central injection of TRH stimulates vagal efferent outflow to the stomach as monitored electrophysiologically in the cervical vagus as well as in the gastric vagal branch. It also induces a widespread activation of myenteric neurons in the gastric corpus and antrum as shown by Fos expression, a marker of neuronal activation.

B. Gastric Responses to Central TRH-Induced Vagal Stimulation

TRH injected into the CSF of the cisterna magna or brain ventricle or directly into the DMN results in a vagal-dependent and atropine-sensitive stimulation of gastric secretions (acid, pepsin, mucus, histamine, prostaglandin, NO, serotonin, and gastrin), gastric motor function (motility, transit), and gastric mucosal blood flow. The gastric acid secretion in response to central TRH results from the activation of cholinergic postganglionic neurons, which directly stimulate parietal cell secretion through interaction

with muscarinic receptors localized on these cells. In addition, the vagally mediated increase of gastric histamine release also stimulates the parietal cells. The gastric hyperemia in response to a maximally effective dose of TRH injected intracisternally is mediated by the cholinergic activation of peripheral NO pathways. This increase in blood flow is independent of the release of established vasoactive substances, such as histamine, calcitonin gene-related peptide (CGRP), VIP, and prostaglandins (Fig. 2).

By contrast, under conditions of submaximal increase of vagal efferent activity, induced by low doses of TRH injected into the cisterna magna, the gastric acid response is largely blunted or abolished. This is related to the action of vagally released anti-acid secretory transmitters, namely, prostaglandins, CGRP, and 5-HT. However, despite this minimal acid response, there is a robust gastric hyperemia resulting from the vagal cholinergic-dependent activation of capsaicin-sensitive CGRP/NO vasodilatory pathways without the involvement of prostaglandins. These observations support the notion that various transmitters are released in the stomach by central vagal cholinergic stimulation. Their interplay varies with the degree of vagal activation and contributes to the differential patterns of gastric responses elicited by low or high levels of vagal efferent drive (Fig. 2).

C. Roles of Endogenous Medullary TRH in the Vagal Regulation of Gastric Functions

The use of specific TRH antibody and TRH_1 receptor antisense oligodeoxynucleotides as well as the monitoring of changes in medullary TRH gene expression provided valuable approaches to examine the physiological role of endogenous medullary TRH in the absence of selective TRH receptor antagonists. There is now convincing evidence that this peptide participates in the central vagal stimulation of gastric function during the digestive process, specific stress conditions, and thyroid-related endocrine alterations.

The cephalic phase of gastric acid secretion is mediated by centrally driven vagal-dependent pathways as initially demonstrated by Pavlov's pioneering studies in dogs. Medullary TRH plays an important role in the cephalic phase of gastric acid secretion as shown by the dampening of the gastric acid response to sham feeding by pretreatment into the cisterna

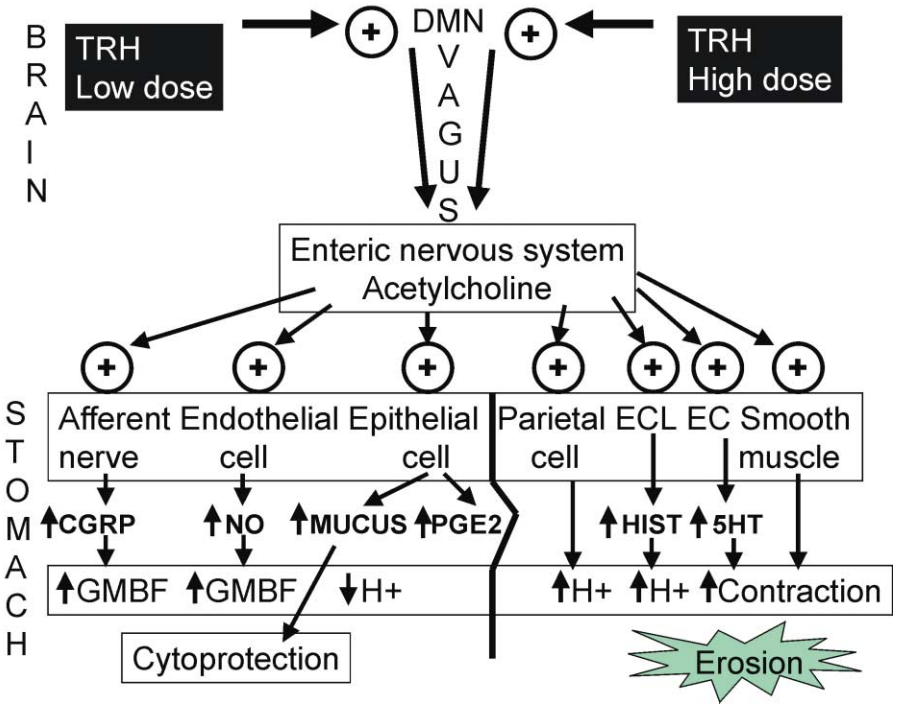

FIGURE 2 Summary of experimental studies showing the gastroprotective and ulcerogenic actions of central vagal stimulation induced by low and high doses of TRH, respectively, and related transmitters involved in the dual gastric responses. CGRP, calcitonin gene-related peptide; EC, enterochromaffin cells; ECL, enterochromaffin-like cells; GMBF, gastric mucosal blood flow; HIST, histamine; NO, nitric oxide.

magna with antisense oligodeoxynucleotides targeted to the TRH_1 receptor. Another established role of the vagus was in the modulation of the gastric mucosa to withstand damaging agents such as strong acid or ethanol. Low doses of TRH injected into the cisterna magna or DVC confer gastric protection against ethanol-induced mucosal lesions. The gastric protection is brought about by medullary TRH inducing a vagal cholinergic-dependent release of gastric prostaglandins and NO, as well as the activation of a local effector function of capsaicin-sensitive splanchnic afferents containing CGRP and related gastric hyperemia (Fig. 2). Likewise, the endogenous release of TRH in the DVC induced by the activation of TRH cell bodies in the Rpa is also gastroprotective. Other phenomena, such as the vagal-dependent adaptive gastric protection whereby a mild gastric irritant reduced the damaging effect of a strong irritant, are also mediated by TRH in the brain medulla. In view of these findings, the cephalic phase of gastric secretion, which results in a mild vagal stimulation, may have beneficial effects on the gastric mucosa by triggering these mucosal protective mechanisms. Conversely, a deficient cephalic phase (nongustatory appreciation) may facilitate the damaging effect of ulcerogenic stimuli due to the reduction or absence of vagally recruited protective mechanisms.

By contrast, a high and sustained level of vagal activation is known to cause gastric hemorrhagic erosions. There is now evidence that intracisternal injection of a maximal acid secretory dose of TRH and maximal chemical stimulation of TRH-synthesizing neurons in the Rpa also result in the development of gastric erosions through the activation of vagal cholinergic pathways. Moreover, this gastric erosive response is potentiated when gastric prostaglandins, also released under these conditions of vagal stimulation, are blocked by an inhibitor of prostaglandin synthesis. Acute exposure of fasted rats to cold (an experimental model known since the 1960s to reliably induce vagal-dependent stimulation of gastric acid secretion, motility, and gastric lesions) is now clearly linked with the activation of medullary TRH pathways. Acute cold exposure increased TRH gene expression in the medullar nuclei selectively in the Rpa, Rob, and the PPR along with Fos expression, which is indicative of cell activation and gene transcription. TRH antibody injected into the cisterna magna reduced cold exposure-induced vagal-dependent gastric acid secretion and mucosal lesion formation. Antisense oligodeoxynucleotides targeted to the TRH_1 receptor, given centrally, prevented acute cold exposure-induced vagal cholinergic acceleration of gastric emptying. Collectively, these findings highlighted the dual role of medullary TRH, which, depending upon the differential level of activity, confers to the gastric mucosa a vagal cholinergic-mediated prevalence of protective or erosive mechanisms.

Another important role of medullary TRH is related to the alterations of autonomic activity linked with diseased thyroid states. Indeed, the synthesis of TRH gene expression in the Rpa, Rob, and PPR neurons is regulated by the feedback inhibition of thyroid hormones as established for TRH neurons located in the PVN. There is recent evidence that hypothyroidism significantly increased Fos expression in TRH-synthesizing neurons as well as TRH mRNA expression in the Rpa, Rob, and PPR neurons. Conversely, hyperthyroidism reduced TRH gene expression in these neurons. The localization of thyroid hormone receptors in these medullary nuclei indicates that the feedback regulation of TRH gene expression is mediated by a direct action of thyroid hormone on TRH neurons. The alterations of TRH neuroanatomical circuitry by hypo/hyperthyroidism along with the established effects of TRH to stimulate vagal outflow provide new insight into the understanding of autonomic disorders associated with altered thyroid states. Functional studies support the notion that hypothyroidism associated with increased TRH gene expression in raphe neurons is also linked with increased vagal drive to the viscera.

D. Modulation of Medullary TRH Action by Other Brain Peptides

There is growing evidence that TRH excitatory action on DMN neurons occurs in concert with other modulatory influences exerted by other neuropeptides or neurotransmitters innervating the DVC. Neuroanatomical support for this interaction came with the co-localization of TRH with substance P (SP) and 5-HT immunoreactivity in neurons of the Rpa, Rob, and PPR projecting to the DVC. These substances modulate the activities of the vagal preganglionic motor neurons as they are co-released with TRH in the DVC. In particular, SP immunoreactive fibers innervate the entire lengths of the DMN and the NTS in rats and humans. Retrograde labeling studies identified DMN neurons projecting to the stomach located at the rostral level of the obex that are in contact with terminals containing SP fibers. In addition, gastric-projecting preganglionic vagal motor neurons expressed neurokinin-1 (NK_1) receptor. The biological consequence of activation of NK_1 receptors in the DMN is the reduction of

the gastric secretory and motor responses to exogenous or endogenous TRH. Therefore, co-released SP with TRH in the DVC dampens the excitatory action of TRH in the DMN. By contrast, 5-HT, which is also co-localized with TRH in medullary raphe nuclei and PPR projecting into the DVC, potentiates TRH stimulatory action through 5-HT_2 receptors within the DVC. A number of brain peptides co-injected with TRH into the DMN have been reported to inhibit the vagal-dependent stimulation of gastric function by TRH. These include interleukin-1, opioid peptides, adrenomedulin, CGRP, bombesin, and calcitonin, providing pharmacological evidence of their central action to influence vagal outflow to the gut.

IV. BRAIN BOMBESIN-LIKE PEPTIDES AND VAGAL INHIBITION OF GASTRIC FUNCTIONS

Thirty years ago, Erspamer *et al.* isolated the 14-amino-acid peptide bombesin from extracts prepared from the skin of the European frog, *Bombina bombina*. Earlier studies showed that bombesin-like immunoreactivity (-LI) was widely distributed in the brain and that central injection of bombesin exerted potent centrally mediated actions on thermoregulation, glucoregulation, and gastric function in rats. In addition, other reports showed the presence of bombesin-LI in the gut of rodents that fostered research to identify a mammalian bombesin counterpart. This resulted in the late 1970s in the characterization of a 27-amino-acid peptide displaying strong homology with the carboxyl-terminus of bombesin and potent gastrin-releasing activity and was accordingly named gastrin-releasing peptide. With these observations, bombesin/GRP was added to the list of peptides co-existing and acting both in the brain and in the gut, giving support to the emerging concept of the peptidergic brain–gut axis.

A. Neuroanatomical Evidence

The neuroanatomical substrate role for the bombesin-LI terminal fields in the modulation of vagal outflow to the stomach came from the identification by retrograde tracing of bombesin-LI in cell bodies within the medial parvocellular part of the PVN projecting to the DVC. These projections constitute an important source of bombesin-LI terminals in the DVC with the strongest labeling in the medial NTS. A similar distribution of bombesin-LI in the rat DVC was confirmed with an N-terminal antibody selective for GRP and bombesin gene expression by *in situ* hybridization. Ultrastructural analysis identified a large number of bombesin-LI-labeled nerve terminals making mostly axo-dendritic synaptic contact on medium and small dendrites in the DMN and medial NTS. These data indicated that bombesin action was directly exerted on postsynaptyic neurons. Autoradiographic studies also revealed a high to moderate density of binding sites for ^{125}I-[Tyr^4]bombesin in the caudal NTS.

B. Biological Role

Bombesin was the first peptide shown to act in the brain to inhibit gastric function. The peptide administered into the cisterna magna induced a potent, dose-related, and long-lasting inhibition of acid secretion in several mammalian species including the rabbit, cat, dog, and rodents. The specificity and potency of bombesin action were established as 30 unrelated natural neuropeptides tested under the same conditions in rats and dogs were found to be inactive or less potent.

Consistent with bombesin action being mediated by altering vagal outflow to the stomach, bombesin-responsive hindbrain nuclei include the DVC. When microinjected at low doses (0.6–6.2 pmol), bombesin inhibited the gastric acid and contractile responses to the TRH analogue RX 77368 co-injected into the DVC. In addition, the delayed gastric emptying induced by central injection of bombesin was completely prevented by ganglionic blockade and vagotomy but not adrenalectomy in rats and dogs. The dose ranges at which central injection of bombesin delayed gastric emptying also correlated well with those inhibiting vagal outflow as monitored by electrophysiological recording of gastric vagal efferent discharges.

The biological actions of bombesin-like peptides are mediated by their binding to high-affinity receptors. Four members of the bombesin receptor family have been cloned: the mammalian neuromedin B-preferring receptor (neuromedin B receptor), the GRP-preferring receptor (GRP receptor), the bombesin subtype 3 (bombesin-3), and the amphibian bombesin subtype 4 (bombesin-4) receptors. The receptor subtype involved in bombesin anti-secretory action is unlikely to involve the neuromedin B receptor since neuromedin B injected into the CSF did not influence gastric acid secretion. The pharmacological characterization of bombesin-3 receptor showed that litorin, ranatensin, and bombesin have a low affinity and that [Phe^{13}]bombesin has no affinity

for this subtype. Since these peptides also act centrally to inhibit acid secretion, this rules out a possible mediation through bombesin-3 receptor. Therefore, it is likely that the GRP receptor is involved in bombesin action. The bombesin/GRP receptor antagonist *N*-acetyl-$GRP_{20-26}-O-CH_3$ injected at a 52:1 antagonist:agonist ratio blocked intracisternal bombesin-induced anti-secretory action.

Taken together, these neuroanatomical and functional studies support an inhibitory action of bombesin-LI peptides in the DVC to regulate gastric function through vagal pathways. Additional actions of bombesin are also exerted at sites influencing sympathetic activity and the activation of this pathway contributes to the potent centrally mediated antisecretory effect of bombesin injected intracisternally or into the rostroventral medulla. The elucidation of the physiological importance of bombesin-like peptide-induced regulation of gastric function through vagal pathways will be forthcoming with the development of more selective and specific GRP receptor antagonists and/or the use of GRP receptor subtype gene knockout mice.

V. BRAIN CRF RECEPTORS AND VAGAL INHIBITION OF GASTRIC MOTOR RESPONSE TO STRESS

The characterization of the 41-amino-acid peptide CRF in the 1980s and, more recently, of the CRF-related family members urocortin, urocortin II, and urocortin III, as well as the cloning of CRF receptor subtypes 1 (CRF_1) and 2 (CRF_2) and the development of specific CRF_1/CRF_2 receptor antagonists provided key tools to unravel the neurochemical basis of the stress response. Evidence has emerged that the activation of brain CRF receptors triggers almost the entire repertoire of behavioral, neuroendocrine, autonomic, immunological, and visceral responses characteristic of stress in rodents and primates. In particular, the activation of brain CRF receptors modulates autonomic outflow and plays a role in stress-related autonomic alterations of gut function.

A. Activation of Brain CRF Receptors and Vagal Inhibition of Gastric Motor Function

Several reports consistently established that CRF and related peptides injected into the CSF act in the brain to inhibit gastric emptying of a solid or liquid meal and gastric contractility in rats and dogs. CRF and related peptides also act in the brain to inhibit gastric acid secretion and somatostatin release. These actions are mediated through modulation of vagal pathways. Brain sites responsive to CRF to inhibit gastric motor function are located in nuclei established to influence parasympathetic outflow to the viscera, namely, the PVN and DVC. In particular, CRF microinjected into the DVC blocked exogenous or endogenous TRH-induced vagal stimulation of gastric function. Functional mapping of brain neuronal activity using Fos expression also showed that central injection of CRF inhibits cold exposure-induced activation of DMN neurons and increases NTS neuronal activity. Moreover, direct electrophysiological recording of gastric vagal efferent discharges showed that intracisternal injection of CRF and related peptides inhibits gastric vagal efferent discharges. Finally, vagotomy prevented intracisternal CRF-induced inhibition of gastric motor function.

CRF actions in the medulla to decrease vagal outflow to the stomach may be primarily mediated by the CRF_2 receptor. This is supported by functional studies showing that selective CRF_2 receptor antagonists blocked central CRF- or urocortin-induced inhibition of gastric motor function. In addition, mapping studies of the distribution of CRF receptor gene expression in the medulla showed the presence of CRF_2 receptors particularly in the NTS. The network of CRF immunoreactive fibers in the NTS suggests that CRF may act through activation of NTS inhibitory input to the DMN preganglionic neurons.

B. Role of Brain CRF Receptors in Stress-Related Alterations of Gastric Motor Function

Activation of brain CRF receptors plays a role in the vagally mediated alterations of gastric function evoked by stress. Delayed gastric emptying is a common pattern of response to exposure to various acute stressors such as operant avoidance, water avoidance, radiation, handling, acoustic stimulation, hemorrhage, abdominal or cranial surgery, tail shock, trunk clamping, wrap restraint at room temperature, swimming, and anesthetic exposure in experimental animals (mice, rats, guinea pigs, dogs, and/or monkeys). Likewise, in healthy subjects, anger, fear, labyrinthine stimulation, painful stimuli, preoperative anxiety, or intense exercise results in a slowing of gastric transit.

Various CRF receptor antagonists injected into the CSF or the PVN at doses preventing the biological actions of centrally injected CRF blocked the delayed gastric emptying resulting from exposure to various forms of acute stress. These include those elicited by

immunological agents (intravenous or intracisternal injection of interleukin-1β), physico-psychological factors (partial restraint, forced swimming), exogenous chemical stimulation (short anesthetic), and body injury (abdominal or cranial surgery or peritoneal irritation). These findings provide new venues for understanding brain pathways contributing to gastric stasis in response to an acute stress including the underlying mechanisms of postoperative ileus. It is also noteworthy that the intercommunications between the immune and hypothalamic CRF systems impact the central regulation of gastric motor function.

VI. VAGAL INHIBITION OF GASTRIC FUNCTION BY POSTPRANDIAL RELEASE OF THE GUT PEPTIDE, PEPTIDE YY

Peripherally originating gut peptides can enter the brain and act in specific brain nuclei outside the blood–brain barrier to regulate gastric functions. Recent studies have established that peptide YY (PYY) is a representative peptide with this mechanism of action. PYY is a 36-amino-acid hormone that was originally isolated from the pig intestine and localized in the open-ended L-type endocrine cells of the terminal ileum and colon in the rat, dog, and human. PYY is released postprandially via extramural neural or endocrine mechanisms that originate in the foregut and by intralumenal nutrients. However, the basal release of PYY seems to be partly regulated by tonic vagal activity. PYY_{1-36} and PYY_{3-36} are the two molecular forms of PYY that are abundant in the blood. Circulating PYY displays a profound inhibitory action on gastric emptying and acid secretion. Recent studies have revealed two important mechanisms involved in the inhibitory action of PYY on gastric acid secretion, one of which is its central action on vagally mediated regulation of gastric functions.

A. Peripheral PYY Is a Potent Inhibitor of Vagally Mediated Gastric Acid Secretion

Intravenous infusion of PYY at doses reproducing circulating levels induced by food ingestion inhibits gastric acid secretion in several experimental animals and in humans irrespective of acid secretion being stimulated by peripheral (pentagastrin and liver extract) or central vagal (insulin, baclofen, and TRH) mechanisms. However, earlier observations indicated that PYY was more potent at inhibiting gastric acid secretion induced by central–vagal secretagogues than peripheral secretagogues. It was first speculated that PYY acts by inhibiting acetylcholine release from vagal nerve fibers rather than by inhibiting the action of acetylcholine on the parietal cell. This viewpoint was further supported by studies in rats showing that administration of PYY had no effect on bethanechol-induced acid output, but inhibited baclofen-induced acid output. Baclofen is a γ-aminobutyric acid receptor agonist that stimulates gastric acid output through atropine-sensitive and vagally mediated pathways. The demonstration that vagotomy markedly impaired the anti-secretory potency of peripherally infused PYY indicated that PYY inhibitory action on gastric acid secretion required the integrity of vagal innervation.

B. Neuroanatomical Basis for PYY Action in the DVC

Recent studies revealed that PYY acts in the medullary DVC particularly at the level of the area postrema (AP) located close to the surface of the fourth ventricle (Fig. 1) and portions of the NTS are defined as circumventricular organs where the blood–brain barrier is incomplete. These regions can therefore act as portals of entry for circulating peptide hormones. PYY-binding sites are present in the AP and DVC. Specific binding sites for both ^{125}I-[Leu^{31}Pro^{34}]PYY (Y_1 agonist) and ^{125}I-PYY_{3-36} (Y_2 agonist) have been detected in the NTS and AP. A recent study revealed that Y_1, Y_2, and Y_4 receptor subtype mRNAs are located in the AP, NTS, and the DMN with a high level of expression in the AP and DMN. Labeled PYY, injected intravenously at doses that produce a blood concentration of PYY within the range observed after a meal is consumed, binds specifically to the region of the rat brainstem containing the DVC. Likewise, peripheral injection of PYY activates NTS and AP cells as shown by Fos expression. Collectively these data provide neuroanatomical evidence supporting a receptor-mediated action of PYY in the brain medulla.

C. Central Action of Peripheral PYY in Inhibiting Gastric Function

The centrally mediated action of peripheral PYY in inhibiting vagally stimulated gastric acid secretion was observed in studies using immunoneutralization with a PYY polyclonal antibody. PYY infused intravenously inhibited in a dose-dependent manner the acid response to TRH analogue injected intracisternally. PYY or the Y_2 agonist PYY_{3-36} injected intracisternally reproduced the anti-secretory effect observed

after peripheral administration of the peptides. In addition, intravenous injection of PYY antibody that shows a 35% cross reaction with PYY_{3-36} by radioimmunoassay completely prevented the inhibitory effect of intravenous infusion of PYY. When injected intracisternally, the PYY antibody reversed not only the inhibition of gastric acid secretion induced by centrally administered PYY but also the inhibition elicited by PYY infused peripherally. These results strongly indicated that peripheral PYY acts within the area of the AP/NTS outside of the blood–brain barrier to inhibit central-vagally stimulated gastric acid secretion. The role of Y_2 receptors in mediating the anti-secretory action of PYY is further supported by the strong expression of Y_2 receptor mRNA in the AP and NTS. The central action of circulating PYY released postprandially to suppress vagally stimulated gastric response induced by TRH may have relevance in the dampening of the cephalic phase of gastric secretion in response to a meal.

VII. SUMMARY

Brain medullary TRH is a physiologically important stimulant of vagal efferent discharges to the stomach and thereby stimulates gastric secretory and motor functions and blood flow. Medullary TRH also regulates the gastric mucosal resistance against injury with a dual action, protective or ulcerogenic in relation to the intensity of the vagal activity. The central action of this peptide is to function in the course of normal physiological digestive activities, in particular during the cephalic phase of the gastric response to a meal. Impaired thyroid levels feed back on the regulation of medullary TRH gene expression and impact on autonomic regulation of the viscera through TRH–vagal pathway. Within the brain, several selective nuclei send inputs to the DVC neurons and modulate the action of TRH through the release of peptides and transmitters. There is evidence that TRH action is modulated by inhibitory actions of medullary SP and PVN–DVC projections containing bombesin-LI, whereas medullary 5-HT potentiates TRH excitatory action in the DVC. In addition, postprandially released gut peptides, such as PYY, may impact on the cephalic phase of gastric secretion through a direct action on the medullary area outside of the blood–brain barrier.

New information is emerging about the stress-related inhibition of gastric motor function through the activation of brain CRF receptors, which suppressed vagal outflow to the stomach. The brain–gut peptidergic interaction is part of the mechanisms through which digestive function is coordinated and adjusted in response to internal and external environmental changes.

Glossary

dorsal vagal complex Association of two medullary nuclei: the dorsal motor nucleus of the vagus and the nucleus tractus solitarius. The dorsal motor nucleus contains cell bodies with axons that form the vagal innervation of the gut. The nucleus tractus solitarius contains cell bodies of interneurons and of neurons projecting to other brain areas as well as terminal fibers of vagal afferents originating from cell bodies in the nodose ganglia; fibers from cell bodies located in the other parts of the brain (central amygdala, hypothalamus) are also present in the nucleus tractus solitarius.

enteric nervous system Network of neuronal cells and fibers embedded within the gut wall that serve as a relay for signals to and from the brain or spinal cord. This network can respond to stimuli from various sensory receptors and generate changes in neuronal activity independent of the central nervous system.

hypothalamus A region in the forebrain that contains control centers for homeostatic regulation of pituitary hormone secretions, behavior, and visceral functions.

peptides Molecules composed of small numbers of amino acids (fewer than 100).

thyrotropin-releasing hormone (TRH) A tripeptide amide originally isolated from the hypothalamus and expressed in many extrahypothalamic brain nuclei, especially the medulla. Hypothalamic TRH regulates thyroid function by releasing pituitary thyrotropin hormone, whereas medullary TRH regulates autonomic function by acting as an excitatory neurotransmitter on autonomic regulatory neurons.

vagus nerve The 10th cranial nerve that emerges from the brainstem and passes through the neck and thorax to the abdomen, innervating visceral organs including the heart, lungs, and digestive organs; it plays a major role in the parasympathetic regulation of gut functions.

Vascular Endothelial Growth Factor B (VEGF-B)

ULF ERIKSSON AND XURI LI
Ludwig Institute for Cancer Research, Stockholm

Vascular endothelial growth factor (VEGF)-B was found serendipitously as a partial mouse cDNA clone encoding a VEGF-related peptide. The partial cDNA was then used to isolate full-length mouse and human cDNA clones from mouse and human cDNA libraries.

I. DISCOVERY

A full-length cDNA that encoded a homologue of vascular endothelial growth factor (VEGF) was discovered, and in analogy with the nomenclature of the related platelet-derived growth factors (PDGFs), the new protein was denoted VEGF-B. Independently, other researchers found the same gene when attempting to identify the locus involved in multiple endocrine neoplasia type 1 (MEN1). The protein encoded by this gene was designated VEGF-related factor and was later excluded from being involved in MEN1.

II. PROTEIN STRUCTURE

Two isoforms of mouse and human VEGF-B have been identified. Both isoforms are secreted proteins and have 167 (VEGF-B_{167}) and 186 (VEGF-B_{186}) amino acid residues, respectively. The isoforms have an identical amino-terminal domain of 115 amino acid residues, excluding the signal sequence, whereas the two different carboxyl-terminal domains are not related to each other. The highly conserved pattern of eight cysteine residues found in VEGFs and PDGFs, involved in intra- and intermolecular disulfide bonding, was present in the common amino-terminal domain. Both human and mouse VEGF-B isoforms

lack the consensus sequence for N-linked glycosylation (-Asn-Xxx-Thr/Ser-), unlike the structurally related factors of the PDGF/VEGF family. However, VEGF-B_{186} is O-glycosylated in the unique carboxyl-terminal domain, which is rich in serine and threonine residues. Pairwise comparisons of the amino acid sequences showed that mouse VEGF-B_{167} is ≈43% identical to mouse $VEGF_{164}$, ≈30% identical to human placenta growth factor (PlGF), and ≈20% identical to mouse PDGF-A and PDGF-B.

The two VEGF-B isoforms are produced as disulfide-linked homodimers and under reducing conditions the molecular mass of secreted VEGF-B_{167} is 21 kDa. The secreted O-glycosylated VEGF-B_{186} isoform has an apparent molecular mass of 32 kDa, and the unmodified intracellular form of VEGF-B_{186} has a molecular mass of 26 kDa.

The different carboxyl-terminal domains of the two isoforms of VEGF-B affect their biochemical and cell biological properties. The highly hydrophilic carboxyl-terminal domain of VEGF-B_{167} is related to the corresponding region in several isoforms of VEGF, with several conserved cysteine residues and stretches of basic amino acid residues. VEGF-B_{167} will remain cell-associated upon secretion by binding to pericellular heparan sulfate proteoglycans. The cell association is likely to occur via its unique basic carboxyl-terminal region, as noted for the highly basic splice variants of VEGF.

The carboxyl-terminal domain of the VEGF-B_{186} isoform is rather hydrophobic with several conserved alanine, proline, serine, and threonine amino acid residues, and its characteristics contrast with those of the hydrophilic and basic carboxyl-terminal domain in VEGF-B_{167}. The amino acid sequence of the carboxyl-terminus of this isoform has no significant similarity with other known amino acid sequences. On secretion, VEGF-B_{186} does not remain cell-associated. Instead, it is proteolytically processed, and the processing regulates the biological properties of the growth factor.

Both isoforms of VEGF-B form disulfide-linked heterodimers with VEGF when co-expressed in transfected cells, but it has not been established whether naturally occurring VEGF·VEGF-B heterodimers exist. It is known that VEGF forms naturally occurring heterodimers with PlGF, and such heterodimers display functional properties distinct from those of both VEGF and PlGF homodimers. Similarly, VEGF·VEGF-B heterodimers may have unique functional properties.

Heterodimers of VEGF-B_{167}·VEGF remain cell-associated, whereas homodimers of $VEGF_{165}$ are secreted from cells in a soluble form. In contrast, heterodimers of VEGF-B_{186} and VEGF are freely secreted. Thus, VEGF-B_{167} determines the release of heterodimers from cells, and heterodimerization of VEGF with either of the two isoforms of VEGF-B might therefore control the release and bioavailability of VEGF·VEGF-B heterodimers. Whether the VEGF-B polypeptides act as homodimers, as heterodimers with VEGF, or as both is not known.

The ability of VEGF-B isoforms to affect the release of VEGF·VEGF-B heterodimers from the producing cells is intriguing since the two factors are co-expressed in many tissues, most prominently in heart and muscle.

III. GENE STRUCTURE AND REGULATION

The human VEGF-B gene is localized to chromosome 11q13, close to the MEN1 locus. The mouse and human genes for VEGF-B are almost identical and both span approximately 4 kb of DNA. The genes are composed of seven exons and their exon–intron organization is similar to that of the VEGF and PlGF genes. The common amino-terminal domain in the two isoforms of VEGF-B is encoded by exons 1–5, and differential use of the remaining three exons gives rise to the two isoforms. The transcript for VEGF-B_{167} is generated by exons 1–5, exon 6b, and exon 7. In contrast, the transcript encoding VEGF-B_{186} is generated by the use of an alternative splice acceptor site in exon 6, leading to an insertion of 101 bp (exon 6a) that introduces a frameshift mutation and termination of the coding region in exon 6b (Fig. 1). In VEGF and PlGF, several isoforms are encoded by the use of alternative splice acceptor sites and different combinations of exons in the 3′-regions of the genes, but the corresponding transcripts are translated using the same reading frame. The use of partially overlapping but different reading frames is rare among higher eukaryotes, but is frequently used by different viruses.

The expression of the two isoforms of VEGF-B appears to be strictly regulated. In most adult and embryonic tissues, the transcript encoding VEGF-B_{167} accounts for more than 80% of the total level of expression of VEGF-B. However, in several primary tumors and tumor cell lines, the expression of transcripts encoding VEGF-B_{186} is up-regulated. The differential expression of VEGF-B isoforms would contribute to a genetically controlled mechanism involved in the release of VEGF·VEGF-B heterodimers in co-expressing tissues.

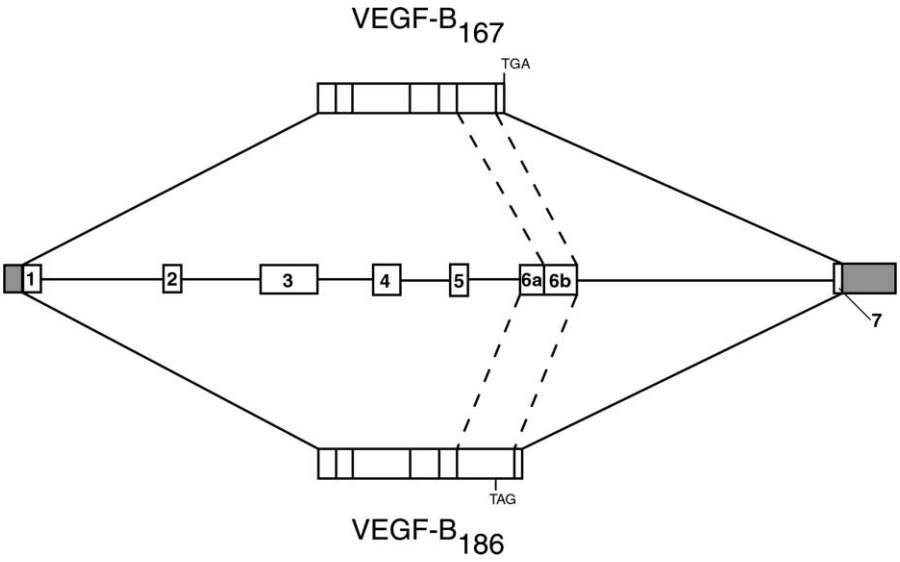

FIGURE 1 Schematic structure of the gene encoding VEGF-B. The genomic region harboring the seven coding exons spans approximately 4 kb. Alternative use of the splice acceptor site in exon 6 generates the transcripts for the two VEGF-B isoforms. Translation terminates in exon 7 in VEF-B_{167} and in exon 6b in VEGF-B_{186}.

The gene for VEGF-B does not contain binding sites for hypoxia-inducible factors, and accordingly, VEGF-B mRNA expression is not regulated by hypoxia, unlike VEGF expression. Instead, the expression levels of VEGF-B are remarkably stable and not influenced by a variety of other stimuli including several growth factors and cytokines.

IV. TISSUE DISTRIBUTION

In adult mouse and human tissues, VEGF-B is abundantly expressed as a 1.4 kb mRNA in heart, brain, skeletal muscle, and kidney, and lower levels are present in most other tissues. VEGF-B and VEGF mRNAs are co-expressed in many tissues, such as heart, skeletal muscle, pancreas, and prostate, generating the possibility that VEGF-VEGF-B heterodimers may occur *in vivo*.

VEGF-B is expressed during embryonic development and is widely distributed. It is prominently expressed in the developing cardiac myocytes and less abundantly expressed in several other tissues, including developing muscle, bone, pancreas, adrenal, and the smooth muscle cell layer of several larger vessels. On embryonic day (E) 11.5–12.5, VEGF-B was strongly expressed in the developing heart. Later, on E14, VEGF-B was expressed in most tissues of the embryo, although most prominently in heart, spinal cord, and cerebral cortex. On E17, VEGF-B expression was concentrated in the heart, brown fat, and spinal cord. Throughout embryonic development, no expression of VEGF-B was detected in endothelial cells. Based on the expression pattern, VEGF-B was suggested to have a role in vascularization of the heart, skeletal muscles, and other tissues and act via paracrine interactions between endothelial cells and surrounding tissue cells.

V. RECEPTORS

Two receptors have been identified for the two isoforms of VEGF-B, the vascular endothelial growth factor receptor (VEGFR)-1 and the co-receptor neuropilin-1 (NP-1). VEGFR-1 is a cell surface receptor tyrosine kinase containing seven immunoglobulin-like domains in the extracellular portion and an intracellular tyrosine kinase domain. In addition to VEGF-B, VEGFR-1 is a receptor for VEGF and PlGF. VEGF-B and PlGF form a subgroup of VEGFR-1-specific ligands since VEGF also binds to VEGFR-2, the main mitogenic VEGF receptor. The first three immunoglobulin-like domains are sufficient for VEGF-B binding, and the binding site is identical to, or at least overlaps, the binding site for VEGF and PlGF. VEGFR-1 binds to the common growth factor domains present in both VEGF-B isoforms. The receptor is expressed on the endothelium of blood vessels during embryonic development and in adult tissues, and it is also expressed by monocytes, macrophages, and certain stem cell populations. Targeted deletion of VEGFR-1 has shown that it is crucial for vascular development during embryogenesis.

Embryos homozygous for VEGFR-1 deletion die at E9–11 due to extensive accumulation of endothelial cells in the developing vessels. In contrast, embryos with a deletion of the intracellular tyrosine kinase domain of VEGFR-1 are viable. These data suggest that the extracellular ligand-binding portion of the receptor is sufficient to support normal development of the vasculature.

NP-1, the second receptor for VEGF-B, is also an isoform-specific co-receptor for some isoforms of VEGF and PlGF and is a receptor for semaphorin-s/collapsins involved in axonal guidance. In addition to its neuronal expression, NP-1 is present in the endothelial cells of blood vessels and in mesenchymal cells surrounding the blood vessels during embryonic development, as well as in certain other nonneuronal tissues. Embryos with targeted deletion of NP-1 die of cardiovascular failure at E10.5–12.5, and overexpression of NP-1 under the β-actin promoter is lethal due to severe anomalies of both the nervous system and the cardiovascular system.

NP-1 binds to both VEGF-B isoforms via the carboxy-terminal domains. In VEGF-B_{167}, the interaction is mediated by the heparin-binding exon 6B-encoded domain, which is homologous to the NP-1-binding domain of $VEGF_{165}$. VEGF-B_{186}, the non-heparin-binding isoform, binds to NP-1 following proteolytic cleavage of the unique carboxy-terminal domain that unmasks the binding epitope. The binding epitope has been mapped to the first 12 amino acid residues of the carboxy-terminal domain.

VI. BIOLOGICAL ACTIVITIES AND PATHOLOGY

VEGF-B is poorly, if at all, mitogenic for endothelial cells. This property accompanies the weak ligand-induced activation of VEGFR-1. Initially, it was reported that conditioned medium from cells transfected with an expression vector generating VEGF-B_{167} stimulated DNA synthesis in primary cultures of endothelial cells. However, at least part of this mitogenic activity is probably contributed by the formation of VEGF·VEGF-B heterodimers as most *in vitro* grown cell lines express VEGF endogenously.

The poor mitogenic effect of VEGF-B on endothelial cells seen *in vitro* is also reflected in *in vivo* studies. Transgenic mice overexpressing VEGF-B under strong promoters show no obvious vascular phenotypes, and mice carrying a targeted deletion in the VEGF-B gene develop normally. No gross abnormalities can be seen in such mice, even in organs in which normal expression of VEGF-B is high, such as heart, muscle, and kidney. These results have shown that VEGF-B is not required for embryonic angiogenesis. Similar results have been shown in mice deficient in PlGF, the functional homologue of VEGF-B, suggesting that neither VEGFR-1-specific ligand is a critical regulator of embryonic vessel development. This is in contrast to the essential role of VEGF in vasculogenesis and angiogenesis.

VEGF-B is expressed in most tumors and tumor-derived cell lines analyzed. Given its poor mitogenic capacity on endothelial cells, VEGF-B is unlikely to directly control the growth of the tumor vasculature like VEGF. Instead, the effects of VEGF-B may be indirect and related to the recruitment of stem cells, progenitor cells, and inflammatory cells to the tumors (see below).

Recent results have suggested that the receptor for VEGF-B, VEGFR-1, is important in the recruitment and mobilization of hematopoietic stem cells and endothelial progenitors from the bone marrow. Such cells are likely to have important functions in therapeutic angiogenesis whereby new vessels are generated or existing vessels are remodeled in ischemic tissues to allow increased blood flow. Furthermore, these cells also contribute to pathological vessel growth in several diseases, including cancer and retinopathies, and contribute to inflammatory conditions, such as atherosclerosis and arthritis. VEGF-B is also able to induce an endothelial cell phenotype of mesenchymal stem cells from the bone marrow. Given that expression of VEGF-B is widespread, and rather abundant in some tissues, a role of VEGF-B in stem cell biology and inflammation is likely.

VII. FUTURE DIRECTIONS

The exciting finding that VEGFR-1 and its ligands control the recruitment and mobilization of hematopoietic stem cells and endothelial progenitor cells and the differentiation of mesenchymal stem cells suggests that they provide important tools for the therapeutic modulation of vessel growth in cardiovascular disease, cancer, retinopathies, inflammation, atherosclerosis, and hematopoiesis. Clearly, more extensive studies of these molecules, and particularly VEGF-B, in various experimental models are warranted.

Vascular Endothelial Growth Factor D (VEGF-D)

MARC G. ACHEN AND STEVEN A. STACKER
Ludwig Institute for Cancer Research, Melbourne

Vascular endothelial growth factor D (VEGF-D) is a member of the VEGF family of growth factors. These growth factors are secreted glycoproteins that contain a cysteine knot motif. Human VEGF-D is mitogenic for vascular endothelial cells *in vitro* and can induce the growth of both blood vessels and lymphatic vessels *in vivo*. VEGF-D is expressed at many sites in the developing embryo including lung and kidney mesenchyme, skin, liver, heart, and limb buds, likely playing a role in inducing the growth of blood and lymphatic vessels in these regions. In adult tissues, VEGF-D is expressed in the vascular smooth muscle of blood vessels, where it may play a role in the repair of blood vessels after vascular damage.

I. DISCOVERY AND ALTERNATIVE NAMES

Vascular endothelial growth factor D (VEGF-D) is the most recently discovered mammalian member of the VEGF family of growth factors, which consists of the secreted glycoproteins VEGF (VEGF-A), VEGF-B, VEGF-C, VEGF-D, placenta growth factor, and VEGF-like molecules encoded by viruses and present in snake venoms. VEGF family members form part of a structural superfamily of growth factors containing a cysteine knot motif in which six conserved cysteine residues contribute to a three-dimensional fold involving an unusual clustering of three cysteine bridges intertwined to resemble a knot. VEGF-D was originally reported as c-*fos*-induced growth factor because it was identified as a protein that was down-regulated in fibroblasts deficient in c-*fos*. Subsequently, the protein was renamed VEGF-D when its capacity to bind and activate VEGF receptors was

demonstrated. VEGF-D is most closely related to VEGF-C (these proteins share 48% amino acid identity throughout the entire molecule and 61% identity within the central VEGF homology domain); similarities in the structure, proteolytic processing, and receptor binding of these two growth factors indicate that they form a subfamily within the VEGF family.

II. PROTEIN STRUCTURE

Human VEGF-D and mouse VEGF-D are 354 and 358 amino acids in length, respectively (including the signal sequence for protein secretion), are 87% identical in amino acid sequence, and contain three potential N-linked glycosylation sites. VEGF-D is initially synthesized as a precursor protein containing N- and C-terminal propeptides in addition to a central VEGF homology domain (VHD) (Fig. 1). The VHD contains the known receptor-binding regions and shares homology with all VEGF family members. The free N-terminal propeptide has an apparent molecular weight of approximately 10 kDa as assessed by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) under reducing conditions, whereas the VHD is approximately 21 kDa and the C-terminal propeptide is approximately 29 kDa. The C-terminal propeptide contains numerous cysteine residues, many of which are arranged in motifs resembling those of the Balbiani ring 3 protein (BR3P) ($CysX_{10}CysXCysXCys$). Approximately 50 of these motifs are found in BR3P, a cysteine-rich protein synthesized in the larval salivary glands of the midge *Chironomus tentans*. It has been speculated that the cysteine residues in the C-terminal propeptide of VEGF-D may have a role in intermolecular interactions (as is the case for the BR3P motifs), possibly modulating the bioavailability, localization, or biological half-life of the growth factor.

Two distinct isoforms of mouse VEGF-D, VEGF-D_{358} and VEGF-D_{326}, which differ in the structure of the C-terminal propeptide, have been reported. Alternative use of an RNA splice donor site in exon 6 of the mouse *VEGF-D* gene produces the two different protein isoforms. The two isoforms are both expressed in a wide range of adult mouse tissues and embryonic stages of development. Both isoforms are proteolytically processed in a fashion similar to human VEGF-D to generate a range of secreted derivatives (Section III). The isoforms are differently glycosylated when expressed *in vitro*. Hence, RNA splicing, protein glycosylation, and proteolysis are mechanisms for generating structural diversity of mouse VEGF-D. Multiple isoforms of human VEGF-D, generated by alternative RNA splicing, have not been reported.

III. BIOSYNTHESIS

Studies carried out with VEGF-D *in vitro* demonstrated that the N- and C-terminal propeptides are proteolytically cleaved from the VHD in a step-wise

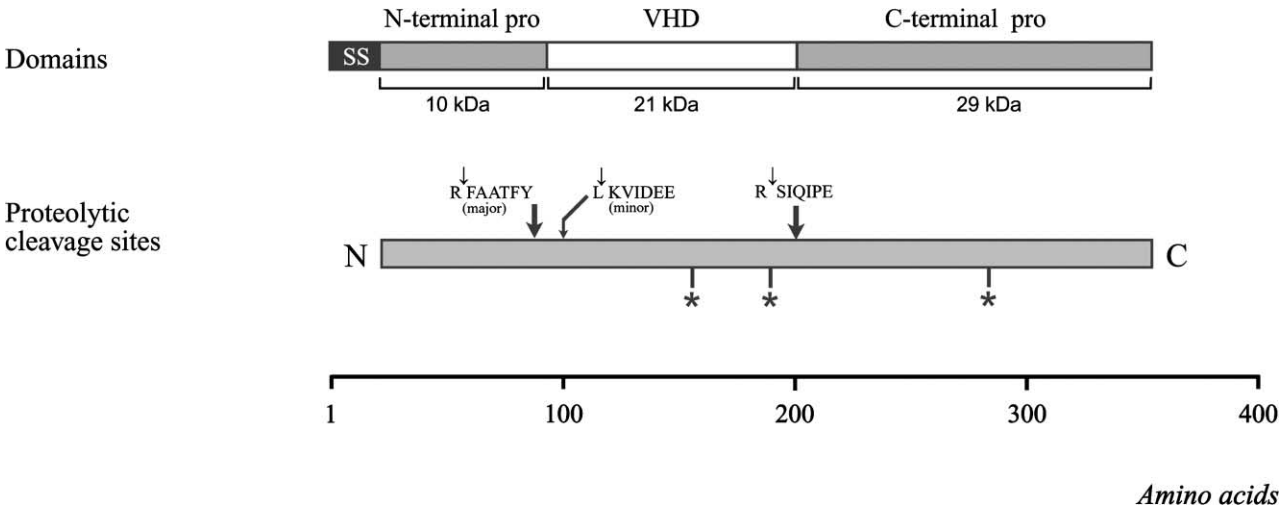

FIGURE 1 Schematic representation of the domain structure of human VEGF-D. SS denotes signal sequence for protein secretion and pro denotes propeptide. Proteolytic cleavage sites are indicated by arrows and potential N-linked glycosylation sites by asterisks. Apparent molecular weights, indicated under the domains, were determined by SDS–PAGE under reducing conditions.

fashion after secretion from the cell to ultimately generate a mature form consisting of dimers of the VHD (Fig. 2A). The VHD dimers are assumed to be anti-parallel in nature based on the three-dimensional structure of VEGF, and the association between them is predominantly noncovalent. Proteolytic processing at the N-terminus of the VHD occurs at multiple sites in a region that appears to be prone to proteolysis, whereas cleavage at the C-terminus occurs at a unique site (Fig. 1) that is located at the same position in VEGF-C. Expression of VEGF-D in mammalian cells *in vitro* leads to the production of a mixture of unprocessed, partially processed, and fully processed forms that accumulate in the cell culture medium. Predominant forms observed by SDS–PAGE are the free N-terminal propeptide (~10 kDa), the free C-terminal propeptide (~29 kDa), the free VHD (~21 kDa), the VHD linked to the N-terminal propeptide (~31 kDa), and full-length material (~58 kDa). Analysis of VEGF-D purified from mouse lung demonstrated that this growth factor is proteolytically processed *in vivo*.

IV. RECEPTORS

The receptors for human VEGF-D identified thus far are VEGFR-2 (also known as KDR in human and Flk1 in mouse) and VEGFR-3 (also known as Flt4) (Fig. 2B). These are cell surface receptor tyrosine kinases that are closely related in structure, contain seven Ig-like domains in their extracellular regions, and are bound, cross-linked, and activated by VEGF-D. VEGFR-2 is localized on the endothelium of blood vessels during embryonic development but is generally down-regulated in adult tissues. In contrast, VEGFR-3 is localized on lymphatic endothelium in adult tissues. During embryogenesis, VEGFR-3 is initially expressed on a wide range of vessels but subsequently becomes restricted to developing veins and then to the lymphatics. An extensive range of

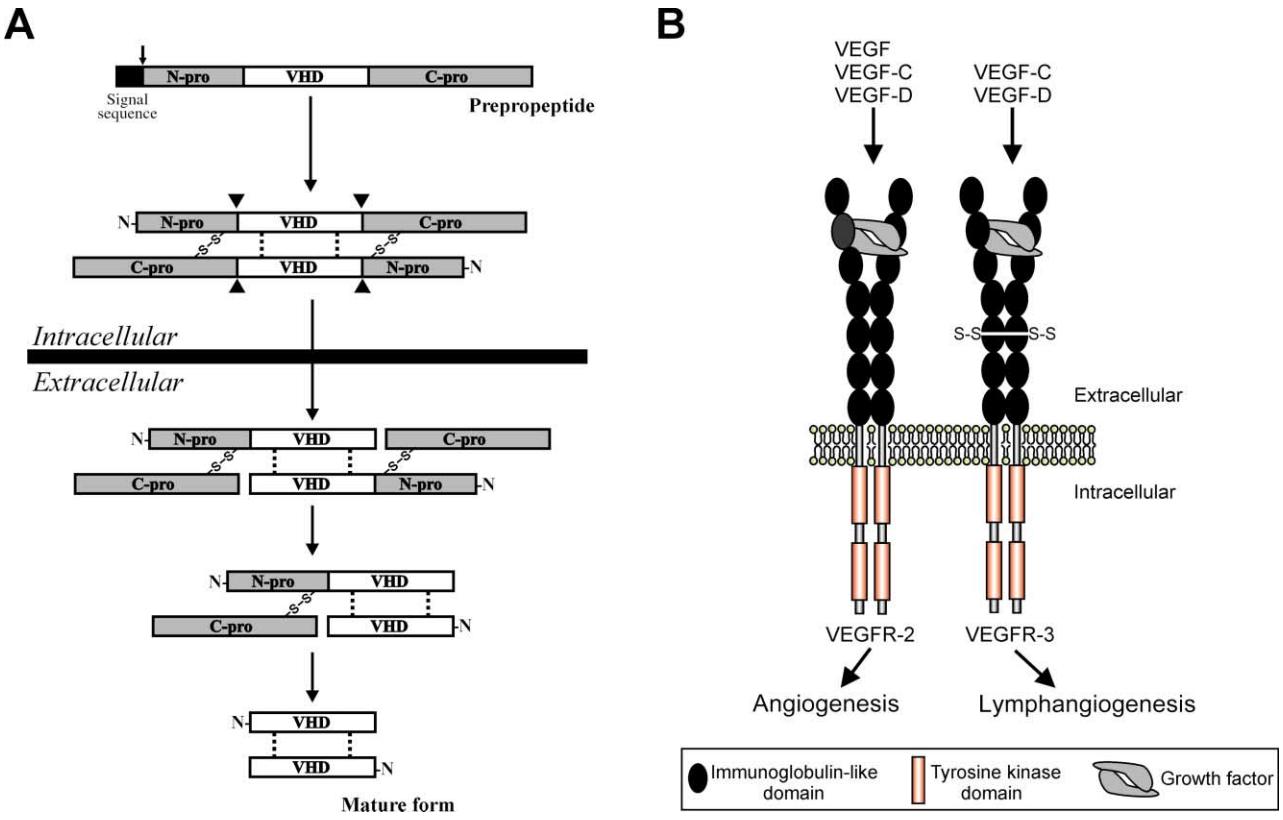

FIGURE 2 Model for biosynthesis of VEGF-D (A) and schematic representation of receptor interactions (B). (A) Stepwise proteolytic processing gives rise to a mature form consisting of dimers of the VHD. Arrowheads indicate sites of proteolytic cleavage; -S-S-, disulfide bridges; N-Pro, the N-terminal propeptide; C-pro, the C-terminal propeptide; dotted lines, noncovalent interactions. (B) Mammalian VEGF family members dimerize VEGFR-2 and VEGFR-3 to induce angiogenesis and lymphangiogenesis, respectively.

in vivo studies have indicated that VEGFR-2 signals for angiogenesis, whereas VEGFR-3 signals for lymphangiogenesis.

Both VEGFR-2 and VEGFR-3 are crucial for vascular development during embryogenesis. Embryos homozygous for *VEGFR-2* gene inactivation, which die at approximately 9 days post coitum (dpc), lack both hematopoietic precursor cells and endothelial cells, indicating that this receptor plays a crucial role in early vasculogenesis. In contrast, VEGFR-3 is not required for vasculogenesis as mouse embryos lacking this receptor have both hematopoietic and endothelial cells; however, large vessels become abnormally organized with defective lumens, leading to fluid accumulation in the pericardial cavity and cardiovascular failure at 9.5 dpc. On the basis of these findings, it has been proposed that VEGFR-3 is required for the maturation of primary vascular networks into larger blood vessels. As the *VEGFR-3* mutant mice die before the lymphatic vessels emerge, it may be necessary to generate conditional knockout *VEGFR-3* mice in order to test the role of VEGFR-3 in the development of the lymphatic vasculature.

Unexpectedly, mouse VEGF-D, in contrast to human VEGF-D, fails to bind mouse VEGFR-2 but activates VEGFR-3. Mutation of amino acids in mouse VEGF-D to those in the human homologue indicated that residues important for the VEGFR-2 interaction are clustered at, or are near, the receptor-binding surface predicted from the structure of VEGF. The different receptor-binding specificities of mouse and human VEGF-D indicate that this growth factor may have different biological functions in mouse and human.

Analyses of the interaction of human VEGF-D with immobilized receptor extracellular domains revealed that proteolytic processing modulates VEGF-D function as the mature form of human VEGF-D binds VEGF-2 and VEGFR-3 with 290- and 40-fold greater affinity, respectively, than does unprocessed VEGF-D. Therefore, proteolytic processing is essential for generation of VEGF-D, which binds these receptors with high affinity. VEGF-D activates both VEGFR-2 and VEGFR-3 as the treatment of cells expressing these receptors with VEGF-D induces the phosphorylation of tyrosine residues on these receptors.

V. BIOLOGICAL ACTIVITIES

Human VEGF-D is mitogenic for vascular endothelial cells *in vitro* and can induce both angiogenesis and lymphangiogenesis *in vivo*, although the predominant response to this growth factor depends on the timing and location of its application. For example, VEGF-D was demonstrated to be angiogenic in the adult rabbit cornea and in a mouse tumor model. When expressed during embryonic development in the epidermis of mouse skin, under the control of the *keratin-14* gene promoter, VEGF-D induced lymphatic hyperplasia/lymphangiogenesis, but not angiogenesis, in the underlying dermis. The biological response induced by VEGF-D, be it angiogenesis or lymphangiogenesis, most likely depends on the proximity of blood vessels and lymphatic vessels expressing VEGFR-2 and/or VEGFR-3 to the site of application of the growth factor. VEGF-D also induced lymphangiogenesis in a mouse tumor model. Importantly, the tumor lymphangiogenesis induced by VEGF-D promoted metastatic spread via the lymphatics, suggesting that the route of metastatic spread of a tumor is dependent on the capacity of tumor-derived growth factors to induce angiogenesis and/or lymphangiogenesis.

Some members of the VEGF family, such as VEGF and VEGF-C, potently induce a rapid and transient increase in the permeability of microvessels to macromolecules. However, the mature form of human VEGF-D did not exhibit any activity in the Miles vascular permeability assay. This suggests that VEGF-D is unlikely to induce edema in a therapeutic setting and that activation of VEGFR-2 alone may not be sufficient to induce vascular permeability.

VI. GENE STRUCTURE AND REGULATION

The gene encoding human VEGF-D consists of seven exons, is approximately 50 kb in size, and is located on the X chromosome at position Xp22.1. The mouse *VEGF-D* gene is similar in structure and is also located on the X chromosome. The *VEGF-D* gene is highly homologous to that for VEGF-C, further illustrating the relatedness of these two growth factors. It is clear that the genes for VEGF-D and VEGF-C arose from duplication of a common ancestor gene. Although it is known that c-*fos* induces *VEGF-D* gene expression, few studies have addressed the regulation of this gene. VEGF-D gene expression is induced by cell–cell contact mediated by cadherin-11, but unlike VEGF-C, VEGF-D is not up-regulated by interleukin-1β, tumor necrosis factor α, or serum. Distinct mechanisms of gene regulation occur among VEGF family members to enable independent expression during blood and lymphatic vessel growth and development.

The mechanism by which the transcripts for mouse VEGF-D_{358} and VEGF-D_{326} are generated can be explained by the structure of exon 6 of the mouse *VEGF-D* gene. The VEGF-D_{358} transcript is generated by a splice event from within exon 6 to the beginning of exon 7. In contrast, the transcript for VEGF-D_{326} arises when this splice event does not occur. Therefore, the 3′ region of exon 6 is represented in the VEGF-D_{326} transcript but not in the VEGF-D_{358} transcript. Such alternative splicing events have not been reported for the human *VEGF-D* gene.

VII. TISSUE DISTRIBUTION

VEGF-D is expressed at many sites in the developing embryo including lung and kidney mesenchyme, skin, liver, heart, and limb buds. As this growth factor can induce both angiogenesis and lymphangiogenesis, it is likely that it plays a role in attracting the growth of blood and lymphatic vessels into these regions of the embryo during development. In adult tissues, VEGF-D is localized in the vascular smooth muscle of blood vessels. Although VEGFR-2 is not strongly expressed on the endothelium of blood vessels in adult tissues, it can be up-regulated in response to various forms of vascular stress or damage. As VEGF-D is an activating ligand for VEGFR-2, the VEGF-D produced by vascular smooth muscle may play a role in repair of blood vessels after vascular damage.

VIII. PATHOLOGY

VEGF-D is expressed in a range of human tumors including malignant melanoma, glioma, and breast and lung carcinomas. In non-small-cell lung carcinoma, VEGF-D was detected in tumor cells and the endothelium of nearby vessels. Furthermore, mRNA for VEGF-D was detected in the tumor cells but not in the endothelium, indicating that VEGF-D is produced by tumor cells and accumulates in nearby endothelium due to receptor-mediated uptake. These findings suggest a paracrine model by which VEGF-D derived from tumor cells promotes tumor angiogenesis and lymphangiogenesis. Direct demonstration of such a role was established by studies of VEGF-D action in a mouse tumor model that indicated that this growth factor can induce tumor angiogenesis, lymphangiogenesis, and metastatic spread via lymphatic vessels. Therefore, VEGF-D may be a useful target for anti-cancer therapy designed to block metastatic spread via the lymphatics.

IX. FUTURE DIRECTIONS

Recent studies of VEGF-D action in tumor models suggest that inhibition of VEGF-D may be of use to block metastatic spread. Neutralizing monoclonal antibodies, peptidomimetic inhibitors of receptor binding, and small-molecule inhibitors of the catalytic domains of VEGFR-2 and VEGFR-3 must be carefully tested in animal models of tumor development to establish the utility of targeting the signaling pathways in which VEGF-D is involved. Other possible clinical utilities for VEGF-D include induction of endothelial cell mitogenesis for prevention of restenosis, induction of collateral vessel formation for treatment of diseases involving ischemia, and induction of lymphangiogenesis/lymphatic hyperplasia for treatment of primary and secondary lymphedema. Testing the utility of VEGF-D in these clinical contexts is a matter of high priority.

Glossary

angiogenesis Growth of blood vessels.
lymphangiogenesis Growth of lymphatic vessels.
lymphatic system An open-ended network of vessels that collect fluid from tissue spaces and ultimately drain it into the venous system.
lymphedema Swelling of tissue due to accumulation of lymphatic fluid.
vasculogenesis *De novo* formation of blood vessels from mesodermal precursors.

Vasoactive Intestinal Peptide (VIP)

BAHRİ KARAÇAY AND M. SUE O'DORISIO

University of Iowa College of Medicine

Vasoactive intestinal peptide is a 28-amino-acid hormone belonging to the secretin/glucagon superfamily of peptides. Through receptor-specific interactions, vasoactive intestinal peptide activates signal transduction pathways that confer vasodilatory effects throughout the body. In its roles as neurotransmitter, hormone, and cytokine, this peptide also plays a role in oncologic disease; further studies may lead to important therapeutic applications.

I. VASOACTIVE INTESTINAL PEPTIDE

A. Discovery of VIP

Vasoactive intestinal peptide (VIP), first discovered in porcine duodenum, was initially considered to be a gastrointestinal hormone. The peptide was named for its profound and long-lasting vasodilatory effects in laboratory animals. This initial identification, however, belies a much broader function of VIP in the central and peripheral nervous systems as well as in the immune system. Today we know that VIP functions as a neurotransmitter, a hormone, and a cytokine through neuroendocrine and neuroimmune axes. VIP regulates intestinal water and electrolyte secretion; vaginal fluid secretion; pituitary hormone, neuronal growth factor, and lymphocyte cytokine release; and glycogenolysis in the liver and cerebral cortex. Through its vasodilatory effect, VIP modulates the vascular reactivity for penile erection, influences cervical and vaginal blood flow, and induces bronchodilation. One or more of these functions is essential to the role of VIP in oocyte maturation, neurogenesis, neuroprotection, and immune homeostasis.

B. Structure of the Peptide

VIP is a 28-amino-acid peptide with structural similarity to other gastrointestinal hormones, including secretin, glucagon, pituitary adenylate cyclase-activating polypeptides (PACAP-37 and PACAP-38), gastric inhibitory peptide (GIP), growth hormone-releasing hormone (GHRH), peptide histidine isoleucine (PHI; in pigs and rodents), and peptide histidine methionine (PHM; in humans) (Fig. 1). Thus, VIP belongs to the secretin/glucagon superfamily of peptides. The sequence is identical in human, porcine, bovine, sheep, goat, rabbit, rat, and mouse VIP, suggesting strict amino acid conservation during evolution.

C. Structure of the VIP Gene

The approximately 9-kb gene encoding human VIP is located on chromosome 6q24. The VIP gene consists of six introns and seven exons. Exon sizes vary from 89 to 165 bp. Isolation and sequence determination of the cDNA for human VIP reveal that the messenger RNA encodes a second peptide, PHM (PHI in rodents). PHM is encoded by exon four and VIP is encoded by exon five (Fig. 2). The prepro-VIP consists of 170 amino acids; during proteolytic

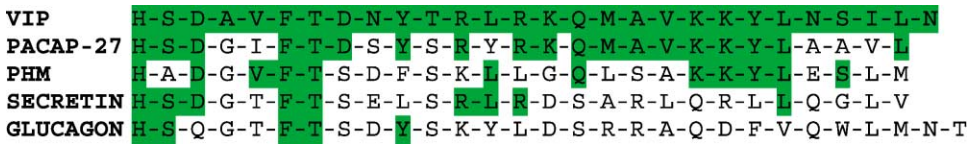

FIGURE 1 Structures of the secretin/glucagon family of peptides. VIP, Vasoactive intestinal peptide; PACAP, pituitary adenylate cyclase-activating peptide; PHM, peptide histidine methionine. Areas of amino acid sequence homologies with VIP are shaded. PACAP-27, PHM, secretin, and glucagon share 68, 44, 37, and 20% amino acid homology with VIP, respectively.

cleavage, five peptides are formed: prepro-VIP(22–79) (N-terminal flanking peptide), peptide histidine isoleucine/methionine (PHI/PHM)(81–107), prepro-VIP (111–122) (bridging peptide), VIP(125–152), and prepro-VIP(156–170) (C-terminal flanking peptide). Alternative splicing generates a C-terminally extended PHM, a peptide designated as PHV-42 that has been shown to be a potent smooth muscle relaxer (Fig. 2). The amino acid homology between VIP and PHM (37%) is less than the degree of similarity between VIP and PACAP (68%). The evolutionary process leading to the generation of different precursors for secretin/glucagon superfamily members probably includes serial gene duplication accompanied by exon loss events. The fact that two different peptides (VIP and PHM) are encoded by the same messenger RNA suggests cosynthesis of the two peptides in the same tissue. However, colocalization is not always found in the same cells in the brain. The differential regulation of these two peptides may be due to differences at translational or posttranslational levels.

D. Regulation of Gene Expression

Cell-type-specific expression of the human VIP gene requires several cis-acting sequences located at the 5′ flanking region of VIP. Among these, a 425-bp tissue-specifier element (TSE) located between −4.6 and −4.0 kb and a region with multiple positive- and negative-acting elements, along with a cyclic adenosine monophosphate (cAMP) response element located between −1.55 kb and −904 bp, play important roles in regulation of VIP gene expression (Fig. 2). The ubiquitously expressed POU-homeodomain proteins Oct-1 and Oct-2 as well as AP-2/Ets transcription factors physically interact with the TSE and play a central role in regulation of VIP gene expression. Accurate spatial expression of the

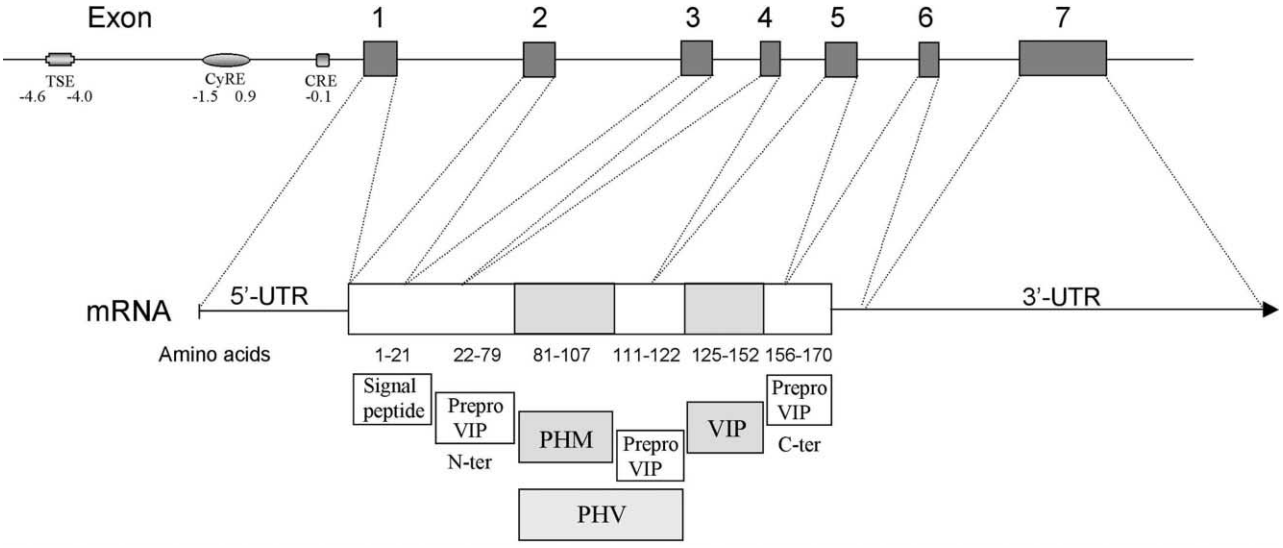

FIGURE 2 Schematic representation of the human VIP gene structure, mRNA transcript, and peptide products. The VIP gene is approximately 9 kb in size and is located on human chromosome 6q24. Exon sizes vary from 89 to 165 bp. PHM, Peptide histidine methionine; PHV, peptide histidine valine; VIP, vasoactive intestinal peptide; TSE, tissue-specifier element; CyRE, cytokine response element; CRE, cyclic AMP response element; UTR, untranslated region.

VIP gene requires combinatorial effects of the cis-elements within the TSE and the proximal 1.55-kb 5′ flanking sequence. The proximal promoter region contains cis-acting elements such as E-boxes, MEF-2-like motifs, and a cytokine-responsive element. Interactions between the TSE and proximal promoter elements lead to either transcriptional repression or activation of VIP gene expression in different cell lineages, resulting in varying levels of VIP message in different cell types.

The spatial expression pattern of VIP is remarkably well conserved between rodents and human genes. Consistent with this, analysis of 5′ flanking regions of mouse and human VIP genes demonstrates a high level of conservation (80%) immediately upstream of the transcription initiation site that also includes the cAMP response element (Fig. 2). A higher level of conservation (91%) has been found between human and mouse genes within a 210-bp fragment located more than 1.1 kb upstream from the transcription start site; this sequence contains cis-acting elements such as PEA-3 and NGF–IL-6. Studies aimed at determining whether 5′ flanking sequences of the VIP gene could recapitulate the endogenous gene expression have demonstrated that a 5.2-kb promoter region of the human VIP gene is able to direct reporter gene expression to the small intestine of transgenic mice. In a later study, a 2-kb promoter fragment was shown to direct the expression of a reporter gene to tissues in a pattern similar to the endogenous VIP gene expression profile. However, the transgene expression was also detected in smooth muscle and Schwann cells, in which endogenous VIP mRNA is rare. When a 16.5-kb upstream sequence of the mouse VIP gene was fused to β-galactosidase, reporter gene expression was targeted to neurons in the esophagus, stomach, small intestine, and colon, where endogenous VIP is present. However, this reporter gene was not expressed in brain, including the regions that contain high levels of VIP such as the cerebral cortex, thalamus, hippocampus, amygdala, and suprachiasmatic nucleus. These results demonstrate that gene regulation at the level of transcription is of fundamental importance for VIP gene expression, but the results also suggest that additional studies are necessary to provide a better understanding of *in vivo* regulation of VIP gene expression. Recent studies demonstrate that VIP gene expression is also regulated at the posttranscriptional level; elements that regulate RNA stability are localized at the 3′ untranslated region of the VIP message. The presence of different sizes of VIP mRNA with varied half-lives, along with competition studies employing heterologous RNA stability elements, suggest an important role for tissue-specific posttranscriptional regulation of VIP levels (Fig. 2). The multiple levels of control of VIP gene expression provide a highly specific spatial expression pattern.

II. VIP EXPRESSION DURING DEVELOPMENT

Developmental regulation of the VIP gene has not been studied in great detail. Although samples from different species have been used, most of the data regarding VIP expression have been obtained from rats. Early studies demonstrated no VIP expression in the central nervous system (CNS) of rats until birth, when a rapid increase in expression is observed. However, later studies employing *in situ* hybridization and histochemistry detected VIP message as early as embryonic day 14 (E14) in the hindbrain of a mouse. This may be due to the increased sensitivity of the method used, or to the interspecies differences between mice and rats. After birth, rat VIP mRNA increases in most brain regions until the level and distribution reach the expression profile of the adult. In the cortex, however, VIP message level increases until postnatal day 14 but decreases after postnatal day 21 until it reaches adult levels, suggesting that VIP may be involved in the development of the cortex. VIP is expressed earlier in the peripheral nervous system than in the CNS. *In situ* hybridization detects VIP message in the embryonic body in E14 rat embryos. By E16, VIP message is detectable in the sphenopalatine ganglion, aorta, and intestine. Contrary to late appearance of VIP message in the CNS during development, binding sites for VIP appear earlier (E13 in rats and E9 in mice). VIP binding sites are particularly abundant in brain regions where rapid cell division takes place, such as neuroepithelial regions of the brain or the intermediate medial thalamus. The observation that maternal VIP levels peak during midgestation raises the possibility that maternal VIP may be involved in early embryonic development, when embryonic VIP binding sites are apparent but embryonic VIP is still undetectable.

In the adult central nervous system, VIP is expressed in the cerebral cortex, hypothalamus, amygdala, hippocampus, and corpus striatum at high levels. Potentiation of cAMP levels in the cortex results in promotion of glycogenolysis. Localization of binding sites for VIP in cortex by *in vitro* autoradiography suggests that VIP may function in the energy metabolism of the cortex. Processes of some VIP-containing neurons penetrate the cortical surface, enter the pial membranes, and make contacts

with cerebral blood vessels. VIP binding sites are abundant throughout the cortex, with the highest binding in layers of the cortex exhibiting greatest dendritic arborization of VIP neurons (layers I, II, IV, and VI). *In situ* hybridization reveals vasoactive intestinal peptide receptor 1 (VPAC1) message in the cortex of rat, suggesting that VPAC1 may mediate the effects of VIP in cerebral cortex. VIP neurons are also present in the hippocampal formation and send their axons to nearby pyramidal and granule cells, where VIP receptors are expressed. These neurons receive input from the γ-aminobutyric acid (GABA)-ergic septohippocampal pathway and diagonal band. *In vitro* binding studies localize VIP binding throughout the hippocampal formation, with higher levels in the molecular layer of the dentate gyrus. Thus, VIP may play a role in the regulation of electrical activity in the hippocampal formation.

Within the hypothalamus, the suprachiasmatic nucleus (SCN) has the highest density of VIP neurons and VIP binding sites. Both VIP peptide and message levels vary over the day/night cycle, with peak levels occurring at night. Microinjection of VIP or PACAP into the rodent SCN shifts the circadian pace maker whereas VIP antagonists and oligonucleotides disrupt the circadian cycle. Overexpression of VPAC2 in the SCN alters the circadian phenotype of mice, leading to a quicker resynchronization in transgenic mice compared to wild-type animals. VPAC2-overexpressing mice also exhibit a shorter circadian period in constant darkness. Some early studies focused on VIP regulation of prolactin release from the anterior pituitary. Subsequent studies have reported a role for VIP as an important modulator of other pituitary hormones, such as adrenocorticotropic hormone (ACTH), growth hormone, and luteinizing hormone (LH). VIP may also regulate anterior pituitary GABA concentrations.

III. VIP RECEPTORS

A. Receptor Subtypes

VIP binds with high affinity to specific G-protein-coupled receptors with seven transmembrane domains. Two receptor subtypes with different affinities for VIP have been isolated and designated as vasoactive intestinal peptide receptors 1 and 2 (VPAC1 and VPAC2) (Table 1). VPAC1 was first isolated from rat lung. The human homologue has also been cloned and expressed in different cell lines. VPAC1 consists of 457 amino acids with an estimated molecular mass of 52 kDa. Murine VPAC1 has 93 and 83% identity with previously cloned rat and human counterparts, respectively. The powerful fluorometric quantitative polymerase chain reaction (PCR) assay has demonstrated that expression of VPAC1 is highest in the small intestine and colon of the mouse, followed by the liver and the brain. VPAC1 message was also detected in thymus, spleen, lung, kidney, gonads, adrenal gland, spinal cord, and heart. Human, mouse, and rat VPAC1 genes map to syntenic regions of human chromosome 3p21.33–p21.31, the distal region of mouse chromosome 9, and to rat chromosome 8q32.

A second high-affinity VIP receptor has been cloned from rat olfactory bulb and designated as VPAC2. VPAC2 has 438 amino acids with an estimated molecular mass of 47 kDa. The VPAC2 gene

TABLE 1 Receptor-Specific Agonists and Antagonists for VPAC1 and VPAC2

Ligand	IC_{50}		Activity
	VPAC1	VPAC2	
VIP	1 n*M*[a]	3–4 n*M*[a]	VPAC1 agonist, VPAC2 agonist
[Lys^{15}, Arg^{16}, Leu^{27}]VIP$_{(1-7)}$GRF$_{(8-27)}$-NH$_2$	1 n*M*	—	VPAC1 agonist
[Arg^{16}]chicken secretin	2 n*M*	—	VPAC1 agonist
[Acetyl-His^{1}, D-Phe^{2}, lys^{15}, Arg^{16}]VIP$_{(3-7)}$GRF$_{(8-27)}$-NH$_2$	1–10 n*M*	3 μ*M*	VPAC1 antagonist
RO25-1392	—	10 n*M*	VPAC2 agonist
RO25-1553	—	1 n*M*	VPAC2 agonist
PACAP-27	1 n*M*	10 n*M*	VPAC1 agonist, VPAC2 agonist
PACAP-38	30 n*M*	2 n*M*	VPAC1 agonist, VPAC2 agonist
Secretin	1.5 μ*M*	—	VPAC1 agonist
GRF	—	5–30 μ*M*	VPAC2 agonist
VIPhyb	0.5 μ*M*		VPAC1 agonist
VIP$_{(10-28)}$	1 μ*M*	—	VPAC1 antagonist

[a]Value is K_d instead of IC_{50}.

was mapped to human chromosome 7q36.3. Northern blot analysis shows that the rat VPAC2 gene is expressed in lung, stomach, and intestine, with lower levels in telencephalon, diencephalon, brain stem, cerebellum, and olfactory bulb. VPAC2 message is also detected in rat thymus, spleen, pancreas, adrenal gland, heart, placenta, and pituitary. The two receptors have similar affinities for VIP (Table 1) when expressed in cell lines, with an IC_{50} of 1 and 3 n*M* for VPAC1 and VPAC2, respectively. Both receptors also recognize the related peptide PACAP. VPAC1 has similar affinity for PACAP-27 and PACAP-38 (IC_{50}, 1 n*M*), but VPAC2 has different affinities for PACAP-27 and PACAP-38 (IC_{50}, 10 and 2 n*M*, respectively). A PACAP-selective receptor (PAC1) has been isolated, cloned, and shown to have a strong affinity for both PACAP-27 and PACAP-38 (IC_{50}, 1 n*M*), but has 1000-fold less affinity for VIP (IC_{50}, 1 μ*M*).

B. Receptor Pharmacology

Long-term goals to use VIP analogues for the treatment of cancer, immune disorders, nerve degeneration, and impotence have been hampered by a lack of receptor-specific agonists and antagonists. Similarly, basic research into understanding the biological functions of VIP and its receptors would be facilitated by the availability of specific agonists and antagonists. However, few synthetic VPAC1- and VPAC2-specific agonist or antagonists have yet been designed. Molecular cloning of VIP receptors has facilitated functional testing of several newly developed compounds. These potential peptide agonists and antagonists have been examined for their ability to mimic or inhibit the physiological actions of VIP (Table 1).

Stearyl-Nle-VIP (SNV) is a VIP analogue designed by the addition of a fatty acid moiety to VIP; this enables penetration of the analogue through membranes while maintaining binding and functional activity. SNV also contains a norleucine at position 17, which increases the stability of the molecule against oxidation and increases its lipophilicity. SNV is 100-fold more potent than VIP in providing neuroprotection to cerebellar granule neurons. SNV binds both VPAC1 and VPAC2 with similar affinities as compared to VIP (Table 1). This peptide has also been shown to be effective in potentiation of sexual performance in a variety of impotence models in rats. Toxicological studies in animals indicate that SNV is safe, making it a possible candidate for clinical studies.

Two VPAC1-specific agonists have been described. The VIP/GRF hybrid [Lys^{15},Arg^{16}, Leu^{27}]-$VIP_{(1-7)}GRF_{(8-27)}$-NH_2 has an IC_{50} value of 1 n*M* for VPAC1 but does not bind to the GRF receptor. [Arg^{16}]chicken secretin is an agonist at both VPAC1 and secretin receptors, but can be used as a highly selective VPAC1 agonist in tissues, such as brain, that do not express the secretin receptor. [Acetyl-His^1, D-Phe^2,lys^{15},Arg^{16}]$VIP_{(3-7)}GRF_{(8-27)}$-NH_2 acts as a selective VPAC1 antagonist (IC_{50}, 1–10 n*M*). IC_{50} values of ^{125}I-labeled VIP binding inhibition by this antagonist, also known as PG 97-269, were 10 and 2 n*M* for rat and human VPAC1, compared to 2 and 3 μ*M* for rat and human VPAC2.

RO25-1553, a VPAC2-specific agonist, was designed with a lactam ring that is introduced within the VIP peptide between positions 21 and 25. It exhibits a high potency and long duration of action. It is a selective agonist for VPAC2, having an affinity for this receptor (IC_{50}, 1 n*M*) that is 1000-fold higher than for the VPAC1 receptor (IC_{50}, 1 μ*M*). It exhibits anti-inflammatory effects using the VPAC2 signal transduction pathway in lipopolysaccharide (LPS)-stimulated human monocytes, leading to inhibition of tumor necrosis factor α (TNFα) and interleukin-12 (IL-12) synthesis.

A VIP cyclic analogue RO25-1392 is also highly potent and specific for VPAC2 (300-fold greater affinity than for VPAC1). It increases the intracellular concentration of calcium and cAMP. It also downregulates VPAC2 expression when tested on Chinese hamster ovary cells stably expressing recombinant human VPAC1 or VPAC2. Several VIP antagonists have also been developed using VIP or a peptide from the same family as part of their structure, including [4-Cl-D-Phe^6,Leu^7]VIP, $VIP_{(10-28)}$, $neurotensin_{(6-11)}$-$VIP_{(7-28)}$ (also designated VHA), stearyl-Nle^{17}-hybrid antagonist (SNH), and [Ac-Tyr^1, D-Phe^2]-growth hormone-releasing factor(1–29) amide. VHA inhibits VIP-mediated cAMP formation or VIP-associated maintenance of neuronal survival in spinal cord cultures. A new derivative of this antagonist yields the stearyl-VIP-hybrid antagonist, stearyl-Nle^{17}-$neurotensin_{(6-11)}$-$VIP_{(7-28)}$; it has been shown to be 100-fold more potent in producing neuronal death than the parent VHA molecule and also a growth inhibitor in lung cancer. Although several candidate compounds have been developed within the past few years, the need for specific agonists and antagonists for each VIP receptor remains unfulfilled.

Despite the lack of extensive studies, endogenous peptide fragments of natural VIP, such as $VIP_{(4-28)}$ or

$VIP_{(10-28)}$, may play roles as agonist or antagonist, providing another level of regulation for the VIP–VPAC signal transduction pathway.

IV. MECHANISM OF VIP ACTION (SIGNAL TRANSDUCTION PATHWAY)

An increase in the intracellular concentrations of cyclic 3′, 5′-adenosine monophosphate is generated by activation of a membrane-associated enzyme, adenylate cyclase, that is stimulated on binding of VIP to either VPAC1 or VPAC2 (Fig. 3). VIP binding to its receptors has been shown to elevate cellular cAMP levels through a guanosine triphosphate (GTP)-regulated coupling of the receptor to a stimulatory guanine nucleotide-binding (G_s) protein. In turn, cAMP binds cooperatively to two sites on the regulatory subunit of protein kinase A (PKA). This binding results in release of the active catalytic subunit that phosphorylates its substrate (the serine in the context X-Arg-Arg-X-Ser-X), present in a number of cytoplasmic and nuclear proteins such as cAMP response element binding (CREB) protein or CREMτ. Activated PKA modulates the function of transcription factors that bind to cis-acting elements present in the promoter regions of cAMP-induced

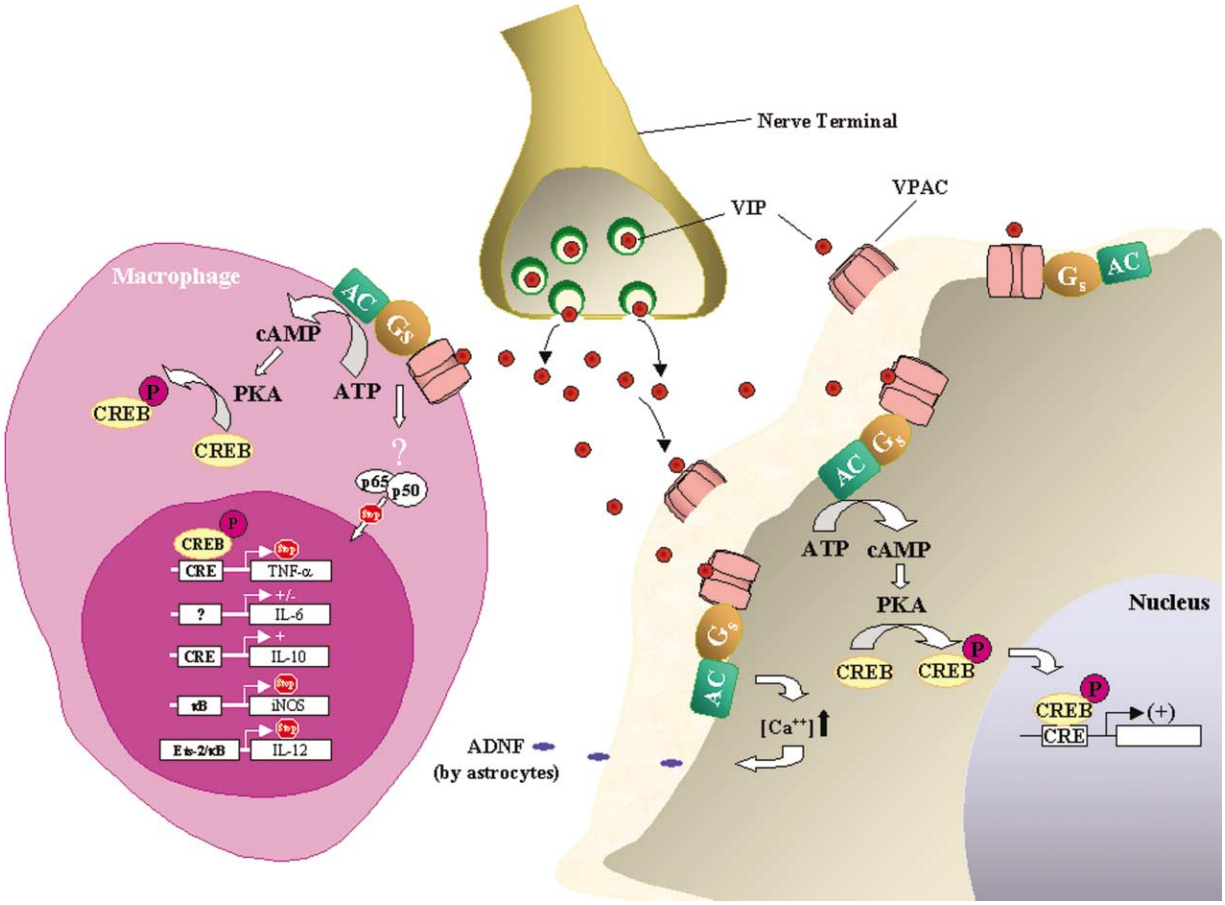

FIGURE 3 Signal transduction pathway activated by vasoactive intestinal peptide (VIP) binding to receptor VPAC1 or VPAC2. Binding of VIP initiates VPAC1 or VPAC2 association with membrane-bound G-protein (G_s), activating adenylate cyclase (AC) and generating cAMP, which, in turn, binds to a regulatory subunit in protein kinase A (PKA). The active catalytic subunit of PKA is then released to phosphorylate its substrate, cAMP response element (CRE) binding protein (CREB). Phospho-CREB binds to cis-acting elements present in the promoter regions of cAMP-induced genes. Through this signal transduction pathway, VIP stimulates synthesis and secretion of neuroprotective molecules such as the cytokine interleukin-1α (IL-1α), activity-dependent neurotropic factor (ADNF), and activity-dependent neuroprotective protein (ADNP) from astrocytes. In macrophages, VIP inhibits the production of proinflammatory factors tumor necrosis factor α (TNFα), IL-6, IL-12, and nitric oxide (iNO) and stimulates the production of the anti-inflammatory cytokine IL-10. A cAMP-independent pathway of VIP is involved in the nuclear factor κB (NF-κB; p65/p50), the inactivation of which affects the transcription of the TNFα, IL-12, and iNOS genes.

genes. Most of the cAMP-responsive genes have one or more copies of cAMP response elements (CREs) within their promoters. The consensus CRE is constituted by the palindromic sequence TGACGTCA (Fig. 3). CRE binding protein, a member of the basic region/leucine zipper (bZip) transcription factor family and the first to be cloned, also binds to CRE. CREB cloning has been followed by cloning of many other proteins that have the characteristic bZip domains. Although heterodimerization is possible among the members, some specific combinations are more common than others. Certain CRE binding factors, such as ATF-2, ATF-3, and ATF-4, can heterodimerize with the bZip oncogenes Fos and Jun, allowing the cAMP/PKA pathway to interact with the diacylglycerol/protein kinase C pathways. Depending on the CRE binding factors, this pathway may result in the activation or repression of the expression of downstream genes.

In some neuronal preparations, inositol phosphate production and protein kinase C activation has been observed, suggesting that VIP signal transduction may follow alternative pathways in addition to adenylate cyclase. After VIP binds to its receptor, the peptide is rapidly internalized by receptor-mediated endocytosis. Most of the receptors are recycled and move back to the cell surface, although some are degraded in lysosomes. VIP peptide is cleaved and inactivated by tissue neutral endopeptidase 24.11, which is widely distributed in the peripheral circulation. VIP is also susceptible to trypsin and plasma-catalyzed cleavage.

V. BIOLOGICAL EFFECTS OF VIP

A. VIP in the Nervous System

VIP acts as a neurotransmitter in the nervous system; its presence and synthesis in neurons, its release from the nerve terminals in response to electrical stimulation, its target tissue response after neuronal stimulation, and its enzymatic degradation after binding to VPAC1 or VPAC2 are all characteristics of a true neurotransmitter. Furthermore, electrophysiological studies demonstrate that VIP can affect membrane potential and can act in concert with other neurotransmitters to modulate electrical responses. The effects of VIP on electrical activity can be either excitatory or inhibitory in the same brain region, suggesting that VIP modulates effects of other neuroactive substances. In early studies carried out on isolated spinal cords, VIP led to depolarization of the dorsal root terminals and motoneurons. However, VIP had both inhibitory and excitatory actions on neurons from preoptic, septal, and midbrain regions. VIP enhanced both the inhibitory effects of GABA and excitatory responses to acetylcholine. Although VIP binding to VPAC1 or VPAC2 has been shown to increase the cAMP levels in many cell types, the slow depolarization and decreased membrane resistance of retinal horizontal neurons on VIP treatment are not replicated by analogues of cAMP or forskolin (a lipophilic agent that causes an increase in intracellular cAMP levels). These results suggest that effects of VIP can be mediated through other signal transduction pathways or, alternatively, may be indirect. VIP shares some of the functional characteristics of neurotropins, which play fundamental roles in the nervous system, including neuroprotective neurotropins that are expressed after neural injury. VIP modulates cell proliferation, differentiation, neurite outgrowth, and neuronal survival. Early studies on the ability of VIP to prevent cell death associated with tetrodotoxin demonstrated that VIP stimulates secretion of neuroprotective molecules such as cytokine IL-1α, a serine protease inhibitor (protease nexin I), and an extracellular stress protein, activity-dependent neurotropic factor (ADNF), from astrocytes (Fig. 3). Hence, many of the neurotropic and neuroprotective effects of the VIP have been attributed to the secretagogue action of the peptide. The survival-promoting action of VIP is mediated indirectly through nonneuronal astroglia via induction of glial cell neuroprotective proteins. Stimulation of high-affinity VIP receptors on astroglia results in the release of several neurotropic substances, including cytokines, protease nexin I, ADNF, and activity-dependent neuroprotective protein (ADNP). The active sites of ADNF and ADNP (ADNF-9 and NAP, respectively) have been shown to be effective in femtomolar concentrations. The neurotropic action of VIP occurs at very low peptide concentrations (0.1 n*M*) and appears to be correlated with mobilization of calcium and the translocation of specific isoenzymes of protein kinase C. On the other hand, cAMP increases are associated with neurotropic effects in developing sympathetic nervous system.

B. VIP in Immunomodulation

The endocrine and immune systems are linked through a communication system that utilizes cytokines and neuropeptides. Studies employing immunohistochemistry and flow cytometry demonstrate that VIP is present in all lymphoid organs and in several lymphocyte subpopulations, including T and

B lymphocytes, and splenic lymphocytes. VIP is released by peptidergic nerve fibers that innervate primary and secondary lymphoid organs in mammalian species. VPAC1 and VPAC2 receptors have been detected in rodent and human immune systems by autoradiography. These receptors have been also detected in established cell lines of immune origin. Studies in rodents and humans demonstrate that VPAC1 and VPAC2 genes are differentially distributed and regulated in the immune system. Murine VPAC1 is expressed in stimulated and unstimulated thymocytes and in splenic CD4 and CD8 T cells. In contrast, VPAC2 is expressed on splenic T-cell subpopulations only following stimulation. Resting and LPS-stimulated murine B cells do not express either VIP receptor. VPAC1 is constitutively expressed in resting human T cells and monocytes. VPAC2 is expressed at very low levels in resting human T cells but is not detectable in resting monocytes. *In vitro* stimulation of T cells with soluble anti-CD3 plus phorbol myristic acid (PMA) induces a T-cell activation-dependent down-regulation of VPAC1.

In vitro studies have demonstrated that secretion of VIP is enhanced in mitogen-stimulated cell suspensions from different murine lymphoid organs. VIP secretion is also stimulated by corticosteroids and proinflammatory cytokines (IL-1, IL-6, and TNFα) produced by activated murine macrophages. VIP plays a role in modulation of the immune response through its effect on the expression of various key cytokines. VIP inhibits the production of proinflammatory factors TNFα, IL-6, IL-12, and nitric oxide and stimulates the production of anti-inflammatory cytokine IL-10 (Fig. 3). VIP may have inhibitory (inflammatory or endotoxemia models) or stimulatory (unstimulated macrophages or after low LPS doses) effects on IL-6 production, depending on the conditions. These results support the role of VIP as an immune homeostasis mediator. VIP has been shown to suppress collagen-induced arthritis in mice and to correct the associated cytokine imbalance. T_H1 and T_H2 cells are responsible for phagocyte-mediated host defense and phagocyte-independent host defense, respectively, and have relatively restricted cytokine production profile and effector functions. Enhancement of T_H2 function and suppression of T_H1 cells have been proposed as a therapeutic approach for rheumatoid arthritis. VIP suppresses T_H1 cell function and differentiation but enhances T_H2 function, as revealed by decreased interferon γ (IFNγ) and increased IL-4 production, respectively. VPAC1 was shown to be the major mediator of the anti-inflammatory effect of VIP.

VIP message is also detected within granulomas of murine schistosomiasis and expression is localized to granuloma T cells. In murine schistosomiasis, VIP invokes IL-5 release from granuloma T cells. Furthermore, VIP suppresses mitogen- and antigen-induced T-cell proliferation, possibly by inhibiting IL-2 production. The granuloma T cells express both VPAC1 and VPAC2 receptors. VIP also inhibits activation-induced cell death (AICD) *in vivo* and *in vitro* in peripheral T cells and T-cell hybridomas. The effect is dose dependent and is mediated through VPAC1 and VPAC2 receptors. A functional study has demonstrated that inhibition of AICD is achieved through inhibition of activation-induced FasL expression at protein and mRNA levels. VIP has also been shown to increase the survival of thymocytes against glucocorticoid-induced apoptosis, and this action of VIP is mediated by VPAC1. Phenotypic analysis shows that VIP, PACAP-27, and PACAP-38 protect predominantly CD4 + CD8 + thymocytes from glucocorticoid-induced apoptosis.

C. VIP in Pulmonary and Cardiac Systems

Many systemic and pulmonary blood vessels are innervated by VIP immunoreactive nerve fibers that cause vascular smooth muscle dilation. VIP activation of adenylate cyclase has been observed in cerebral, heart, and coronary vessels and in the portal vein, aorta, mesenteric artery, and ovarian artery of mice. The vasodilatory effect of VIP in different species and tissues is not only due to increased cAMP but also to activation of lipoxygenase, nitric oxide synthase, or the guanylate cyclase and cyclooxygenase pathways. In some species, VIP effects may involve hyperpolarization of the vascular smooth muscle membrane, which reduces calcium influx and intracellular Ca^{2+} concentration. The relative contribution of these various mediators to the vasodilatory effects of VIP is not known; however, interaction between different mediators may modulate VIP action. A possible example of this interaction is seen in gastrointestinal smooth muscle, in which relaxation is stimulated by both cAMP- and cGMP-dependent pathways. The effects of VIP on coronary arteries have been studied in isolated vascular tissue, in intact hearts, and *in vivo* in rodents as well as humans; VIP is shown to have a significant dilatory effect in each species. VIP has a stronger vasodilatory effect on arteries than on veins, possibly due to higher receptor density on the arteries. In ventricular myocytes, VIP binding to its receptor results in increased levels of cAMP, which can stimulate protein kinase A activity. This, in turn,

enhances calcium channel phosphorylation and L-type calcium currents, leading to increased intracellular calcium concentration. As a result, cardiac myocyte tension rate and extent of contraction are enhanced. An increase in cAMP can also lead to sequestration of intracellular calcium via decreased troponin affinity for calcium, which subsequently enhances the rate and extent of myocyte relaxation. In this manner, VIP can increase cardiac myocyte contraction and relaxation. *In vivo* studies have also demonstrated that both administered and endogenous VIP can increase coronary blood flow. The vasodilatory effect of VIP is not limited to coronary arteries; similar effects have been observed in cerebral arteries as well as vessels of the eyes, thyroid, and pancreas. A vasodilatory effect of VIP was also confirmed by using a monoclonal anti-VIP antibody that significantly attenuated VIP-induced vasodilation in the *in situ* hamster cheek pouch.

VIP is present in nerves innervating the airway smooth muscles and pulmonary and nasal vessels. VIP produces prolonged relaxation of airway smooth muscles and mimics the electrophysiological changes produced by noncholinergic, nonadrenergic nerve stimulation. VIP has been shown to prevent lung injury and to improve survival in different experimental models of acute respiratory distress syndrome. Protective effects of VIP include inhibition of transcription factor nuclear factor κB (NF-κB) activation (Fig. 3) and inhibition of caspase activity coupled with an increase in antiapoptotic Bcl-2 protein. Both receptor subtypes, VPAC1 and VPAC2, are expressed by several lung cell lines. VPAC2 is expressed in airway epithelial, glandular, and immune cells of the lung but not in airway and vascular smooth muscles. The absence of VPAC2 mRNA in vascular and airway smooth muscle myocytes along with presence of high-affinity VIP binding in the lung suggest that the effects of VIP on vasodilation and bronchodilation are mediated by VPAC1 in the lung.

D. VIP in the Gastrointestinal System

VIP nerves have been demonstrated in the esophageal wall, mostly in the circular muscle layer. More VIP-containing neurons are located near the sphincter region. Both *in vitro* and *in vivo* studies show that VIP has a relaxing affect on the lower esophageal sphincter, the sphincter of Oddi, and the anal sphincter. In the stomach as well as the small and large intestines, VIP is involved in relaxation of smooth muscles. VIP is a major peptide with relaxant activity and is considered a transmitter of inhibitory motor neurons of the gut. The relaxation-inducing effect of VIP has also been demonstrated using VIP antiserum, which blocks this effect. VIP stimulates the secretion of ductal pancreatic and biliary bicarbonate and water and simultaneously inhibits gastric acid and pepsinogen secretion as well as absorption from the intestinal lumen. VIP also stimulates enzyme secretion from pancreatic acinar cells and regulates chloride secretion. All layers of the gut contain VIP fibers. VIP nerve fibers are most dense in the lamina propria, where they associate with blood vessels and come into contact with the surface epithelium. VIP acts on neurons and muscle cells to regenerate nitric oxide (NO). VIP inhibits the growth of certain colonic adenocarcinoma cell lines and both VIP and VPAC1 expression are elevated during the enterocytic differentiation of a colonic adenocarcinoma cell line *in vitro*.

E. VIP in Oncology

In 1958, Verner and Morrison described a clinical syndrome that included the triad of pancreatic islet cell tumors, severe watery diarrhea, and hypokalemia. In 1973, Bloom and colleagues made the association between Verner–Morrison syndrome and vasoactive intestinal peptide. They reported that patients with this syndrome also had elevated plasma levels of VIP. These VIP-secreting tumors of the pancreas are also known as VIPomas, watery diarrhea/hypokalemia/hypochlorhydria syndrome, or pancreatic cholera syndrome. VIP is the major mediator of the diarrhea, as demonstrated by a rapid fall in VIP levels and cessation of diarrhea after tumor removal as well as the demonstration that intravenous injection of VIP in normal subjects can induce diarrhea. Some patients develop hypotension resulting from peripheral vasodilation, and severe hypertension may develop after tumor removal; hypotension is also induced by intravenous administration of VIP. These features are compatible with the known cardiovascular effect of VIP. A recent 15-year retrospective review of patients with VIPoma showed that VIP-secreting tumors are usually metastatic at the time of diagnosis. However, survival of the patients with VIPoma has improved due to supportive treatment and the use of chemotherapy.

In approximately 20% of the VIPoma cases, the tumor is too small to localize with computerized tomography (CT) scanning. However, all of these patients receive symptomatic relief of the watery diarrhea. However, in a recent Verner–Morrison

syndrome case study, octreotide, an analog of somatostatin, was shown to be effective in reducing the serum VIP level of the patient and in decreasing water loss, but both CT scan and octreoscan failed to detect the tumor. The tumor was detectable in the pancreatic tail using ^{123}I-labeled VIP scintigraphy. Surgical resection of the tumor resulted in complete remission of the syndrome. Recent data also indicate that ^{123}I-labeled VIP receptor scintigraphy is clinically useful for the *in vivo* localization of adenocarcinomas, liver metastases, and certain endocrine tumors of the gastrointestinal tract. Although ^{123}I-labeled VIP receptor scintigraphy is a highly promising method for imaging, the high uptake of the peptide by the lung does not allow therapeutic use of VIP labeled with isotopes such as ^{131}I or ^{90}Y. Thus, related compounds with different binding profiles, such as ^{99m}Tc-labeled VIP conjugates, have been developed and currently are undergoing testing for clinical use. Further scintigraphic studies with patients need to be carried out using newly designed VIP-based radioligands with high specific activity.

In a study to evaluate whether VIP can be used as a tumor marker, serum levels of VIP were evaluated in a total of 135 patients; 45 patients had metastatic colorectal cancer, 45 suffered from metastatic pancreatic cancer, and 45 healthy volunteers served as controls. As opposed to pancreatic cancer and healthy controls, patients with metastatic colorectal cancer had elevated serum VIP levels that were statistically significant ($p < 0.0001$). Several pediatric tumors, including neuroblastoma, primitive neuroectodermal tumors (PNET), and tumors of the Ewing's sarcoma/peripheral PNET family, express either VIP or VIP receptors. High levels of expression of VIP and VIP receptors are a favorable prognostic factor in neuroblastoma, a tumor of neuroectodermal origin. Patients with high levels of VIP and associated diarrhea have a more favorable prognosis. VIP can also slow the rate of proliferation and induce *in vitro* differentiation of neuroblastoma cells. Both medulloblastoma (infratentorial PNET) and supratentorial PNET (tumors derived from neuroepithelial precursors) express VIP receptors as demonstrated by reverse transcriptase (RT) and PCR, high-affinity binding of ^{125}I-labeled VIP on quantitative autoradiography, and in competitive binding assays. VIP also inhibits tumor cell proliferation in a dose-dependent manner in PNET cell lines.

VIP inhibits proliferation of small-cell lung carcinoma cells (SCLCs) in culture and dramatically suppresses the growth of SCLC tumor cell implants in athymic nude mice. The effect of VIP is mediated by a cAMP-dependent mechanism. High-affinity VIP binding sites are also detected in several breast cancer cell lines as well as breast cancer biopsy specimens as revealed by ^{125}I-labeled VIP. Several breast cancer cell lines make and secrete immunoreactive VIP; cAMP levels are elevated in these cell lines following VIP treatment. Furthermore, VIPhyb, a VIP antagonist, inhibits breast cancer growth *in vitro* and *in vivo*. Retinoic acid treatment of breast carcinoma cell lines leads to the down-regulation of the VPAC1 receptor.

VI. CONCLUSION AND PERSPECTIVES

The previously unknown role and contribution of VIP to certain biological processes have been discovered within the past few years. During the preparation of this article, for example, a possible role for VIP in autism was reported. In the first study, in which neuropeptide and neurotropin concentrations were determined, plasma concentrations of VIP were found to be higher at birth in children with autism or mental retardation without autism than in healthy control children. The roles of VIP in brain development and its functions as neurotransmitter and neuromodulator warrant more research on its role in autism.

Anti-inflammatory effects of VIP in the immune system have also recently been documented. These studies have led to the use of VIP in the treatment of inflammatory collagen-induced arthritis in mice, suggesting a new therapeutic approach for rheumatoid arthritis. VIP inhibits the production of proinflammatory factors TNFα IL-6, IL-12, and nitric oxide, and stimulates the production of anti-inflammatory cytokine IL-10.

Receptor targeting with radiolabeled peptides is rapidly developing in nuclear oncology. These naturally occurring peptides are clinically useful diagnostic imaging agents and have future implications for the treatment of tumors expressing target receptors. Radiolabeled VIP and VIP analogues are being developed and evaluated for clinical application because of observations that most human carcinomas express VIP receptors as measured by *in vitro* receptor autoradiography. The application of radiolabeled VIP (^{123}I-labeled VIP) is generally safe and scintigraphy results can be obtained within 2–4 h after injection of the peptide.

Availability of genomic and cDNA sequences for VIP peptide and its receptors will facilitate the disruption of corresponding genes in mice using homologous recombination techniques, thus uncovering the biological processes in which VIP is involved

as well as the relative contributions of each receptor for VIP action. Together with the development of receptor-specific analogues, these studies should lead to development of alternative therapies that will take advantage of manipulating VIP-initiated signal transduction pathways. Although use of native VIP as a drug is limited due to its susceptibility to endopeptidases and its limited passage across biological membranes, several VIP analogues have been developed to overcome this problem and are under investigation for their possible use.

Vasoactive intestinal peptide clearly functions in multiple ways, including neurotransmission; neuromodulation, immunomodulation, bronchodilation, vasodilation, smooth muscle relaxation, and modulation of reproduction. One peptide that can fulfill multiple roles as a cytokine, neurotransmitter, and hormone must be a physiologic VIP, a "very important peptide."

Glossary

agonist Peptide, hormone, or drug that binds to a specific receptor and activates its signal transduction cascade.

antagonist Peptide, hormone, or drug that binds to a specific receptor and blocks its signal transduction cascade.

autoradiography Visualization of radioactively labeled molecules on X-ray film.

complementary DNA Nucleic acid synthesized by reverse transcription of RNA; cDNA is complementary to the RNA template.

G-proteins Guanine nucleotide-binding trimeric proteins that reside in the plasma membrane and transduce a signal from a receptor–ligand complex to the signal transduction cascade.

IC_{50} Concentration of ligand that inhibits by 50% the binding of a homologous radiolabeled ligand to a specific receptor.

K_d Concentration of ligand that inhibits by 50% the binding of an identical radiolabeled ligand to a specific receptor.

signal transduction Process by which a ligand–receptor interaction activates a cascade of biochemical reactions, leading to a change in cellular activity.

T_H1 A T helper lymphocyte that makes interleukin-2 and interferon γ, promoting a cellular immune response.

T_H2 A T helper lymphocyte that makes interleukin-4, -5, -9, and -10, promoting humoral or allergic responses.

transfection Introduction of new genetic material into a cell.

transgenic Describes animals that are generated by insertion of new DNA into the germ line via DNA microinjection into the one-cell-stage embryo.

Vasopressin (AVP)

WILLIAM E. ARMSTRONG
University of Tennessee College of Medicine

Vasopressin, also called antidiuretic hormone because of its actions on the kidney, is formed with an arginine at position 8 in all mammals but pigs. Arginine vasopressin is a 9-amino-acid polypeptide hormone that is synthesized in and released from mammalian hypothalamic neurosecretory cells. It functions in blood pressure regulation and water reabsorption by the kidneys.

I. INTRODUCTION

Arginine vasopressin (AVP) and the closely related peptide oxytocin (OT) were the first pituitary hormones for which the amino acid structures were characterized (Fig. 1). Each hormone consists of 9 amino acids with an NH_2 terminus; the amino acids form a ring via disulfide bonds at the two cysteine residues. These hormones are similar to peptides serving related functions in fishes, birds, and amphibians. In pigs, vasopressin is formed with a lysine substituted for arginine at position 8.

The production of neurohypophyseal hormones in brain tissue first was established by Ernst Bargmann and the Scharrers, who utilized Gomori-positive histochemistry (which reveals sulfide-rich elements) to demonstrate the axonal pathway from the hypothalamus to the neurohypophysis. These early studies have been confirmed and expanded with more advanced biochemical and immunohistochemical studies. AVP is synthesized in neurons of the supraoptic nuclei (SON) and paraventricular hypothalamic nuclei (PVN) of the central nervous system (CNS) (Fig. 2). Synthesis begins with a preprohormone complex containing a signal peptide; the latter is cleaved and the remaining protein is glycosylated to a prohormone in the Golgi apparatus. The prohormone is packaged into large (150–200 nm) neurosecretory vesicles, which are axonally transported to the neural lobe of the pituitary gland for release into the general circulation. The prohormone contains AVP, a large protein called neurophysin, and a 39-amino-acid glycopeptide (absent in the OT complex). These products are separated by several enzymes within the neurosecretory granules during axonal transport and are released as separate products. There is no generally accepted peripheral function for neurophysin or the glycopeptide, although each may have some biological activity. A natural "knockout" for the AVP gene, the Brattleboro rat, is characterized by a single base deletion. The Brattleboro rat has extreme polydipsia and polyuria and has been a model for diabetes insipidus.

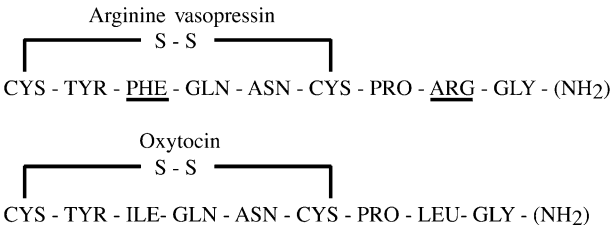

FIGURE 1 The amino acid sequences for arginine vasopressin and oxytocin. The nonapeptides share all but two amino acids, with substitutions at positions 3 and 8. Note the cysteine ring formed by disulfide bonds.

Although in most situations AVP and OT are found in separate cells, many neurons can synthesize both peptides, as shown by extensive colocalization of mRNA when amplification procedures are employed. During enhanced hormone release, the amount of colocalization may be increased for OT and AVP as well as for other peptides, although in lesser quantities (e.g., neuropeptide Y), found in the same neurons. Synthesis is at least partly regulated by the stimuli that evoke AVP release. For example, osmotic stimulation increases transcription of AVP and mRNA abundance and increases the length of the RNA poly(A) tail. Transcription of AVP mRNA appears to be regulated in part by immediate-early genes such as c-*fos*, but other regulators, such as the cAMP response element binding protein, are

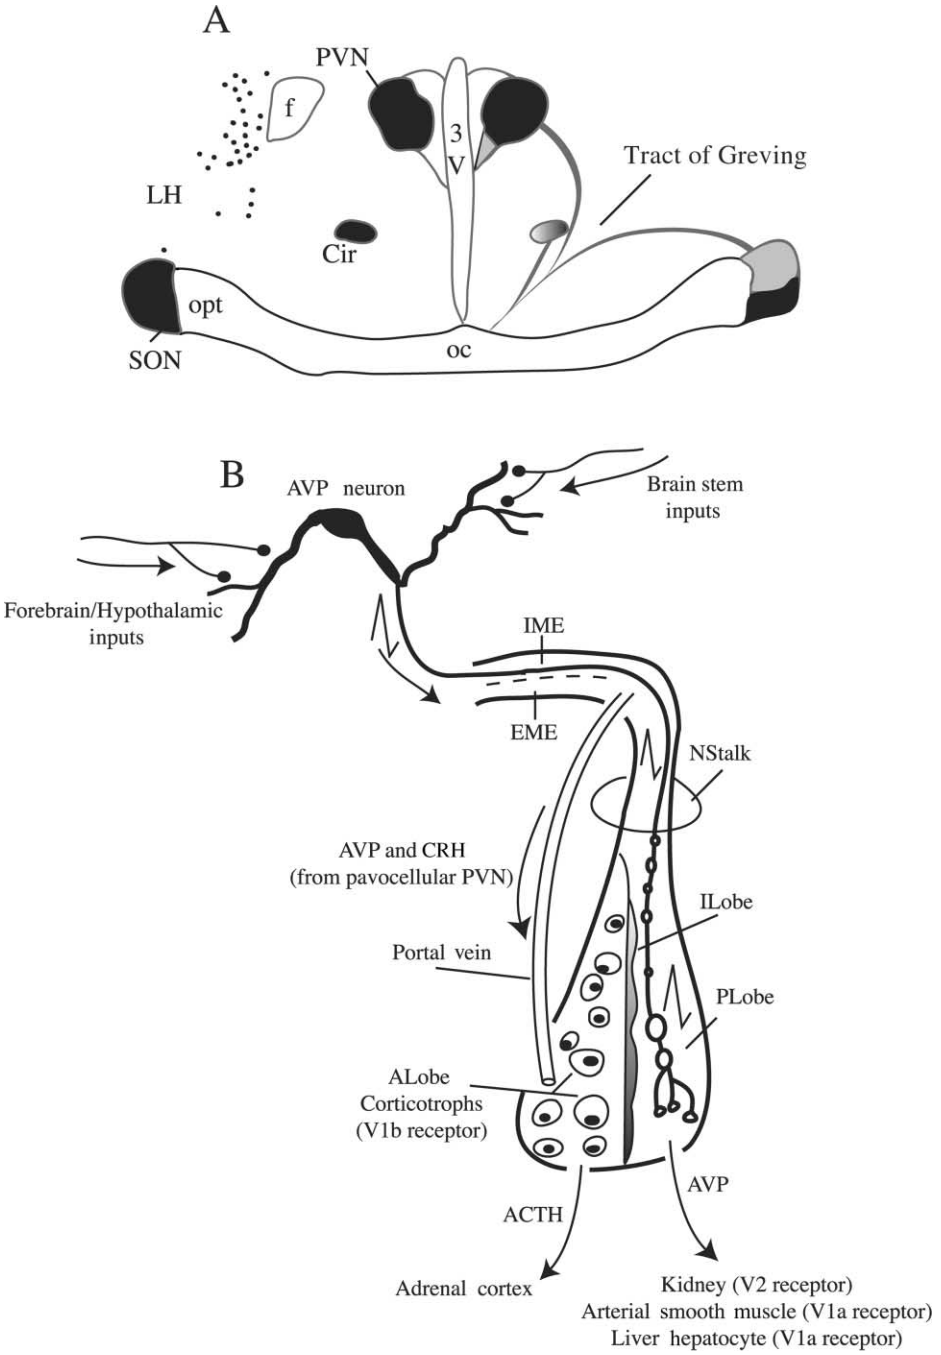

FIGURE 2 Anatomical location and connectivity of arginine vasopressin (AVP) neurons. (A) Drawing of a coronal section through the rat hypothalamus, illustrating the location of AVP and oxytocin neurons and schematizing their projection toward the pituitary. On the left, paraventricular hypothalamic nuclei (PVN) and supraoptic nuclei (SON) fiber tracts are named. On the right, AVP neuronal clusters are shown in black and oxytocin clusters are in gray. In addition to the PVN and SON, accessory neurosecretory nuclei are shown. At this plane, there are scattered neurons in the lateral hypothalamus (LH), and a cluster called the nucleus circularis (Cir). The axons from all nuclei collect in the tract of Greving, which eventually leads to the internal layer of the median eminence before projecting into the posterior (neural) lobe of pituitary. Abbreviations: f, fornix; oc, optic chiasm; opt, optic tract; 3V, third ventricle. (B) Schematic representation of an AVP neuron and its axonal projection to the posterior lobe of the pituitary. The neuron has a sparse dendritic tree but receives important brain stem synapses that relay vascular reflex signals; from the forebrain and rostral hypothalamus, synapses relay osmotic, vascular, and other stimuli. The single axon projects into the internal layer of

involved. These factors can be activated by neurotransmitter actions and/or increases in intracellular ($[Ca^{2+}]_i$).

II. NEUROANATOMICAL LOCALIZATION AND CONNECTIONS OF AVP NEURONS

For neurohypophyseal release, the neurons synthesizing AVP are located in the SON, PVN, and a few accessory magnocellular nuclei (Fig. 2). Neurons in these regions send axons arching through the lateral hypothalamus (tract of Greving) to collect along the midline of the ventral hypothalamus in the internal lamina of the median eminence. These axons lead into the neural stalk and terminate in the posterior (or neural) lobe of the pituitary gland in varicosities, largely 1–2 μm in diameter, near fenestrated capillaries. Larger swellings (5–15 μm) called Herring bodies are more visible with histochemical stains but typically do not form endings per se. Herring bodies serve to store hormone but can also release it with prolonged stimulation. In addition to axon terminals and a dense capillary bed, the neural lobe contains a large number of modified astrocytes, called pituicytes, which have an intimate morphological relationship with the terminals. Pituicyte processes normally separate terminals from capillaries and can engulf terminals. The processes recede during periods of great hormone demand.

Magnocellular PVN and SON neurons have a relatively simple morphology (Fig. 2). A typical neuron has an egg-shaped somata 25–30 μm in diameter, two to three short dendrites with few branches, and a single axon arising from the soma or primary dendrite. A few axons may branch and form local connections (not shown in Fig. 2). This simple morphology computes to a relatively small surface area and, electrically speaking, a large input resistance. Thus, even distal synaptic inputs may reach the soma and exert significant control over the membrane potential and spike initiation. The dendrites are varicose, moderately spinous, and also contain AVP. Varicosities dot the axons along their course and form the classic "string of pearls" described in original Gomori-positive material.

Within the SON and PVN, AVP and OT neurons cluster into separate regions. In many species, a large cluster of AVP neurons characterizes the lateral wing of the PVN. Although all mammals, including humans, have a mix of OT and VP neurons in both the PVN and SON, the distribution and proportions vary widely across species. SON and PVN somata and dendrites receive a variety of synaptic inputs. Quantitatively, the most numerous synaptic terminals contain the excitatory amino acid glutamate or the inhibitory amino acid γ-aminobutyric acid (GABA). All of the sources of these two transmitters are not known, but two important contributors are the median preoptic nucleus and organum vasculosum of the lamina terminalis (OVLT), two areas known to participate in osmoregulation. Another strong forebrain input comes from the subfornical nucleus, also involved in water regulation. Although accounting for a minority of synapses, noradrenergic and other inputs arising from the ventrolateral medulla and nucleus of the solitary tract have great importance for cardiovascular functions. Additional inputs to the SON and/or the PVN include the locus coeruleus, the parabrachial nucleus, the bed nucleus of the stria terminalis, adjacent hypothalamic nuclei, and midbrain and/or hypothalamic dopaminergic neurons. Neurochemically, AVP neurons receive a rich variety of peptidergic and other neuromodulators, many of which colocalize with glutamate or GABA.

AVP also is found in other CNS neurons and synaptic terminals. Within the PVN, a parvocellular group of neurons synthesizes both AVP and corticotropin-releasing hormone (CRH). These neurons control the release of adrenocorticotropic hormone (ACTH) from the anterior pituitary via projections to the portal vascular plexus of the external layer of the median eminence (Fig. 2). The suprachiasmatic nucleus contains AVP neurons involved in circadian rhythms. The bed nucleus of the stria terminalis and

the median eminence and into the neural stalk before arborizing in the posterior lobe. AVP-containing vesicles are present in the many varicosities along the axon, the largest of which are called Herring bodies. The axons terminate near fenestrated capillaries, where released hormone enters the bloodstream. Action potentials from the neuron drive release at the terminals. The external layer of the median eminence also contains AVP terminals from axons of parvocellular PVN neurons that colocalize with corticotropin-releasing hormone (not shown). These neurons release these two hormones into the external layer of the median eminence, where portal veins carry the products into the anterior lobe of the pituitary. Abbreviations: ALobe, anterior lobe (adenohypophysis) of the pituitary; ACTH, adrenocorticotropic hormone; EME, external layer of the median eminence; ILobe, intermediate lobe of the pituitary; IME, internal layer of the median eminence; NStalk, neural stalk; PLobe, posterior (neural) lobe of the pituitary gland.

medial amygdaloid nucleus have widespread outputs; AVP neurons in these nuclei are highly responsive to gonadal steroids. The central effects of AVP on a variety of neuronal functions are well documented.

III. AVP ACTIONS AND RECEPTORS

The pressor effects of AVP were discovered over 100 years ago. Shortly thereafter, the antidiuretic effects of AVP in kidney were appreciated, and, more recently, effects of AVP in liver, brain, anterior pituitary, and testis have been demonstrated. The receptors for AVP, now cloned, fall into three main classes: V1a, V1b, and V2 receptors. Along with the OT receptor, all are part of the G-protein-coupled superfamily. V1a receptors are coupled to G-proteins ($G_{q/11}$, G_i). Activation leads to increased phospholipases, production of inositol 1,4,5-trisphosphate and diacylglycerol, the activation protein kinase C, and the mobilization of intracellular calcium. V1a receptors also can increase $[Ca^{2+}]_i$ via extracellular influx by coupling to voltage-gated Ca^{2+} channels (primarily L type). For vascular smooth muscle, V1a activation results in contraction and an increase in arterial blood pressure, and activation has a mitogenic effect as well. Because of the wide vascular distribution, V1a receptors can be found in most tissues, including the medullary vessels in the kidney. In the liver, AVP activation of V1a receptors on hepatocytes leads to gluconeogenesis and glycogenolysis. In the brain, V1a receptors are found on a variety of neurons, including autoreceptors on AVP cells, and on the pituicytes of the neural lobe. Although sensitivity to AVP can vary, even across vascular beds, AVP typically activates V1a receptors with K_d values in the low nanomolar or high picomolar range. Occupation of a divalent binding site on the receptor, preferentially by Mg^{2+}, increases the affinity of AVP for the receptor.

The V1b receptor population is dense on corticotrophs of the anterior pituitary. Like V1a activation, yet with distinct intracellular pathways, V1b occupation leads to increased $[Ca^{2+}]_i$. Although the details of these messaging signaling differences are not fully known (e.g., cAMP may be increased with strong V1b activation), V1b receptors have a different pharmacological profile compared to V1a receptors, with a lower affinity for various V1a antagonists. V1b activation on corticotrophs leads to release of ACTH. AVP expression is low (even undetectable) in parvocellular PVN neurons but increases during stress or in the absence of negative glucocorticoid feedback (as with adrenalectomy). Because of the potency differences, AVP may normally serve as a cofactor augmenting the response of colocalized CRH. Like the V1a receptors, V1b receptors are found on neurons as well as in other tissues.

V2 receptors are the classic renal receptors and are concentrated on the collecting ducts and distal tubules of the kidney medulla. Activation of V2 receptors leads to a G-protein (G_s) stimulation of adenylyl cyclase, an increase in cyclic adenosine monophosphate (cAMP), activation of protein kinase A, and insertion of new water (aquaporin-2) channels. These new channels enhance reabsorption of water in the collecting ducts and tubules, producing concentrated urine. The affinity of AVP for the V2 receptor is in the low picomolar range.

IV. STIMULI FOR AVP RELEASE

Increased plasma osmolality, decreased blood volume, and hypotension are the most effective and well-studied stimuli for the release of AVP. A low release threshold and the exquisite sensitivity of the kidney suggest that small osmolality perturbations near basal levels ($\sim$285 mOsm/kg H_2O) are finely controlled by AVP release (Fig. 3). The osmotic threshold for release is 1–3% in a well-hydrated subject, which can lead to an antidiuresis from the release of just a few picomoles of AVP. Suprathreshold stimulation results in a linear relationship between plasma osmolality of AVP release. Although a purely osmotic stimulus is apparently sufficient for AVP release, Na^+ is the most abundant and effective physiological osmotic particle, and brain Na^+ detection is a part of the normal response to hypertonicity. Release of AVP is triggered locally with the SON and PVN by these same stimuli. Locally released AVP can feed back on the neurons to modulate their electrical activity (see later).

The hypothesis first proffered by Verney some 60 years ago, that brain osmoreceptors were located near the SON, has been confirmed in a variety of studies and species. Indeed, the SON neurons are osmoreceptive. The mechanism is demonstrated to be a volume-dependent modulation of stretch-inactivated, nonselective cationic channels (SICs). Membrane stretching associated with hypotonic cell swelling decreases SIC channel openings. Cell shrinkage increases them, provoking membrane depolarization. Furthermore, extracellular Na^+ increases the permeability of SIC channels, and prolonged hypertonicity has been shown to increase Na^+ channel density in SON neurons. However, the intrinsic osmoreceptivity of the AVP neuron is insufficient to account for the full activation of SON neurons and

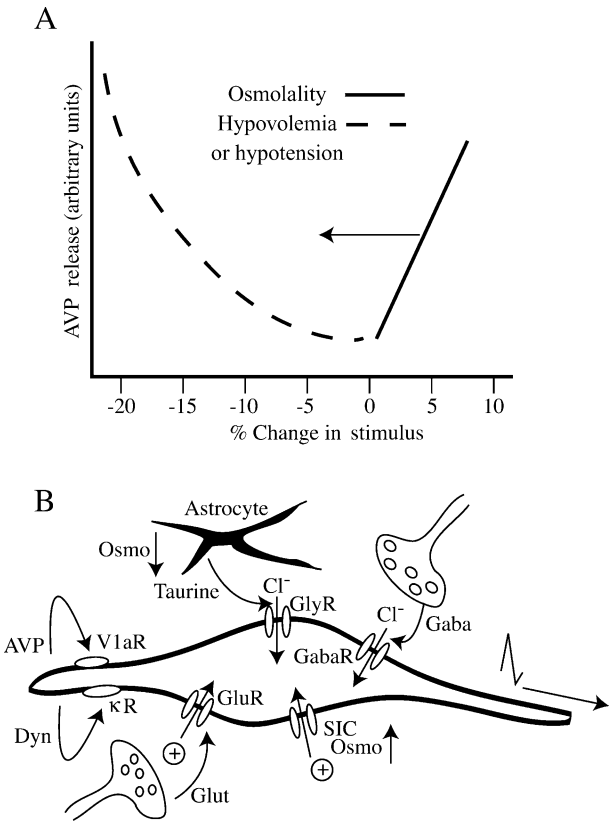

FIGURE 3 Integration of vascular and osmotic signals by arginine vasopressin (AVP) neurons. (A) Schematic diagram illustrating the responsiveness of AVP neurons to both vascular (dashed line) and osmotic (solid line) stimuli. AVP release is linearly related to changes in osmotic pressure above threshold and is more sensitive to this than to vascular stimuli. Vascular stimuli are exponentially related to release, but ultimately can cause release of larger quantities of AVP compared to hypertonicity. The arrow shows that the osmotic curve is displaced to the left in the presence of hypovolemia/hypotension, such that release in response to osmotic stimuli is enhanced. (B) Neural, glial, and osmotic signals are integrated by AVP neurons and lead to changes in action potential activity. Osmotic stimuli have two effects: first, increased osmolality (Osmo)/Na^+ concentration opens stretch-inactivated cation (SIC) channels directly on the AVP cell, depolarizing it; second, decreases in osmolality increase the release of taurine from astrocytes in the supraoptic nuclei. Taurine increases Cl^- influx through glycine receptors (GlyR). Thus, during hypertonicity, the neuron is released from this inhibitory stimulus in addition to being depolarized directly. Excitatory and inhibitory transmitters (and many modulators not shown) impinge on the AVP neuron. Some carry information from cardiovascular receptors, transducing blood volume and pressure signals, others carry information from additional osmoreceptive neurons. Increased activity is associated with increased somato-dendritic release of AVP and the colocalized peptide, dynorphin (Dyn). AVP acts on V1a receptors to increase intracellular [Ca^{2+}] and to modulate neuronal activity. Dynorphin acts on κ receptors (κR), but the exact second messengers and/or channels modulated are not known. However, dynorphin decreases the depolarizing afterpotential and inhibits burst length. Abbreviations: Gaba, γ-aminobutyric acid; GabaR, γ-aminobutyric acid receptor; Glut, glutamate; GluR, glutamate receptor; V1aR, V1a subclass of AVP receptor.

AVP release. Additional osmosensitive elements are located along the lamina terminalis of the hypothalamus, in the OVLT and median preoptic nucleus. Direct osmoreceptivity has been demonstrated in excitatory OVLT neurons projecting to the SON. Activation of these neurons increases the frequency of glutamate-mediated excitatory postsynaptic potentials and contributes strongly to SON activation. Indeed, damage to the ventral wall of the lamina terminalis strongly impairs osmoregulation and can be associated with chronic hypernatremia in humans. Astrocytes invested within the SON are also osmosensitive and release the inhibitory amino acid taurine during hypotonicity. Thus, intrinsic SON and glial cell osmoreceptivity, as well as the activity of osmosensitivity afferent inputs, all participate in the fully integrated response of AVP neurons (Fig. 3).

Dehydration incurs hypovolemia and hypertonicity. Plasma volume deficits as low as 5%, induced with hemorrhage or isotonic fluid withdrawal, stimulate AVP release in the absence of any change in osmolality (Fig. 3). For AVP release, purely volemic stimuli are transduced in the thoracic vasculature, primarily by atrial stretch receptors. Unloading these receptors results in strong neuronal activation of the SON via brain stem nuclei such as the nucleus of the solitary tract, the ventrolateral medulla, and the parabrachial nucleus. Osmotic and volemic signals clearly interact, because small changes in blood volume result in a stronger osmotic response. Conversely, osmotic dilution will blunt the response to hypovolemia. The integration of these signals likely occurs in the hypothalamus, if not the SON. Hypovolemia also triggers the release of renin, which leads to a pressor response from angiotension II (AII). By stimulating AII receptors in the subfornical organ, AII can augment AVP release via a strong projection from this organ to the SON.

Hypotension often accompanies hypovolemia and it can be difficult to separate the stimuli. Hypotensive stimuli are primarily transduced by arterial receptors in the carotid sinus and aortic arch and reach the SON via related, but not identical, brain stem neurons, as for hypovolemia. In some animal models,

hypovolemia induces AVP release only when there is an associated drop in arterial pressure, and this response is dependent on nerve activity from sinoaortic receptors. Nevertheless, considerable data suggest that volume and pressure signals are separately transduced, if often integrated. In humans, the release of 1–2 pmol of AVP can be triggered by a reduction in arterial pressure by ~5%, and further reductions are exponentially related to AVP release, resulting in a large release (~100 pmol) with reductions near 40%. Receptor activation need not depend on total blood or water loss, however, because shifts in regional blood pools induced by temperature or body position are effective at altering AVP release. Like volume stimuli, hypotension also enhances the response to increased osmolality (Fig. 3).

Although V1a receptors with high affinity are densely distributed on hepatocytes, the physiological role of AVP in the regulation of blood glucose is questionable. Pronounced hypoglycemia is a trigger for AVP release, but the levels of AVP required to increase plasma glucose are thought to be high for day-to-day regulation.

V. ELECTROPHYSIOLOGY OF AVP NEURONS

The pioneering studies of Harris and Douglas showed clearly that Ca^{2+}-dependent stimulus-secretion coupling, much like that observed at the neuromuscular junction, characterizes neurohypophyseal hormone release. It is now widely appreciated that release of AVP from the neural lobe is a function of both the pattern and the rate of action potential activity originating in SON and PVN neurons. Action potentials depolarize the axon terminals and increase Ca^{2+} influx, which triggers the exocytosis of AVP-containing vesicles.

Hypotension, hypovolemia, and hyperosmolality all trigger a stereotypic electrical response from AVP neurons. This response consists of a phasic, bursting pattern of activity (Fig. 4). In normal animals, very few neurons exhibit this pattern. With even moderate dehydration, the majority of AVP neurons adopt this pattern. Stimulation of phasic neurons increases the firing rate within bursts and can increase burst length. Phasic activity is clearly the most efficient means of releasing AVP (Fig. 5). Studies directly using the action potential distribution of bursts to stimulate the axons electrically in the neural lobe have shown that this pattern is superior to continuous trains of stimuli at the same mean frequency for releasing AVP. The maximally efficient frequency is ~13 Hz. Efficiency is related both to the high frequency of discharge at the beginning of each burst (facilitation) and to the recovery from fatigue during interburst intervals. Recovery during these silent intervals maximizes Ca^{2+} uptake into the terminals for successive bursts.

Although phasic activity is instigated and controlled by the peripheral stimuli known to release AVP, the mechanisms for this activity are intrinsic properties of the AVP neuron and can be observed in synaptically uncoupled neurons. Phasic activity is voltage dependent, with a threshold from −60 to −50 mV. Thus, peripheral stimuli must depolarize the neuron to this range before the activity can commence, regardless of whether isolated action potentials occur. With depolarization, action potentials open voltage-gated Ca^{2+} channels and induce a Ca^{2+}-dependent depolarizing afterpotential (DAP) (Fig. 4). The DAP summates with repetitive firing and forms a plateau potential on which a long (10- to 60-s) discharge is maintained. The current underlying the DAP appears to result from the reduction in a resting K^+ conductance, although inward cationic currents participate. SON neurons contain many other conductances that could shape the activity of the burst, the best studied of which are low- and high-threshold Ca^{2+} currents, a Ca^{2+}-dependent K^+ current that gates the firing rate, voltage-gated K^+ currents that influence the firing rate and spike width, and voltage-gated, nonselective cation currents, such as I_H.

Recent data of great interest concern an autoinhibitory feedback mechanism controlling burst length. AVP neurons also synthesize the opiate peptide dynorphin and package it within AVP dense core vesicles. Both dynorphin and AVP are released locally during neuronal activity. Dynorphin acts on κ opioid receptors on AVP neurons and serves to inhibit phasic bursting. At least one mechanism for this inhibitory effect is a direct inhibition of the DAP. Thus, accumulative release of dynorphin during spike activity may eventually terminate the burst.

The V1a (and possibly V1b or related variant) receptors are located on the membrane of AVP neurons, just as OT receptors have been found on OT neurons. Activation of these receptors increases $[Ca^{2+}]_i$ and also modulates AVP neuronal activity. The precise effect (i.e., inhibitory or excitatory) varies with the ongoing level of activity, so as to reinforce the most efficient firing rate for AVP release.

VI. SUMMARY

Arginine vasopressin released from the posterior pituitary is synthesized within a preprohormone complex by large neurons in SON and PVN of the

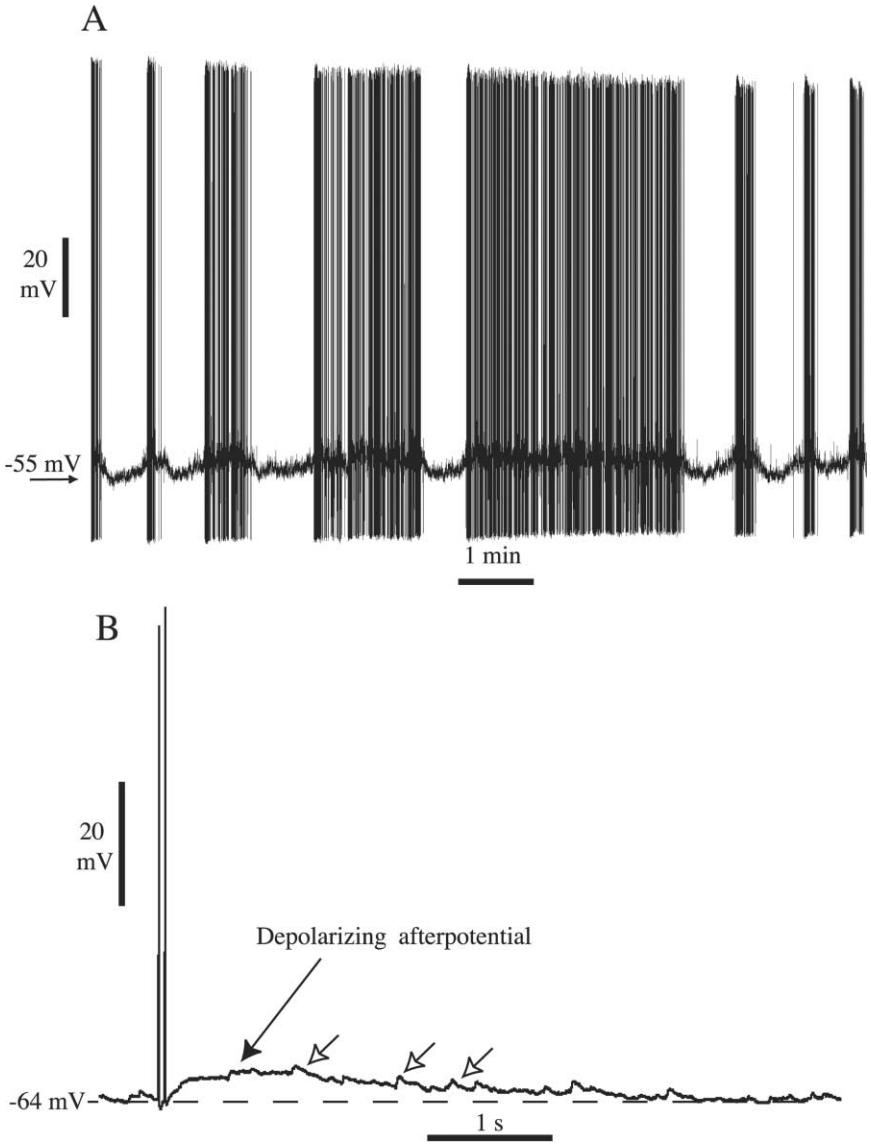

FIGURE 4 (A) Example of a phasically bursting AVP neuron from a whole-cell recording in a hypothalamic slice from an adult rat. Note the periods of action potential activity associated with membrane depolarizations, interrupted by silent periods when the membrane is hyperpolarized. (Recording courtesy of Chunyan Li). (B) The depolarizing afterpotential implicated in phasic activity is shown following two action potentials evoked with current injection. At this more hyperpolarized potential, a depolarizing afterpotential can be evoked, but the resulting depolarization does not reach spike threshold. Note the excitatory synaptic potentials (open arrowheads).

mammalian hypothalamus. After axonal transport to the neurohypophysis, the hormone is released into the peripheral circulation by stimuli such as dehydration, hypovolemia, and hypotension. At least three cloned AVP receptors are present. V1a receptors are found primarily on vascular smooth muscle and act to transduce muscle contraction. V1b receptors are found on pituitary corticotrophs and their activation leads to ACTH release. V2 receptors are found in the kidney, where they mediate antidiuresis. AVP neurons are osmoreceptive.

Glossary

anterior pituitary lobe Also called the adenohypophysis, this region contains numerous hormone-secreting cells under humoral control from hypothalamic inhibitory and excitatory factors.

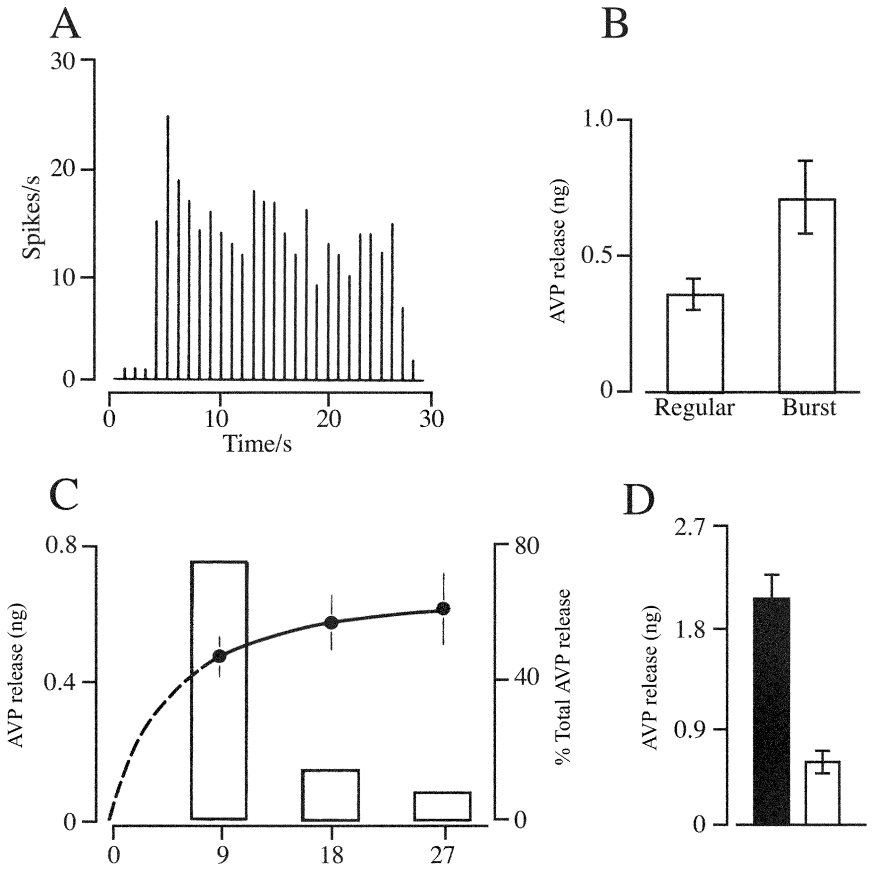

FIGURE 5 The relationship between phasic bursting activity and arginine vasopressin (AVP) release in isolated neural lobes. (A) Rate meter of a burst recorded in an AVP neuron. This burst was used to program the electrical stimulation of isolated neural lobes. The burst contained 348 spikes, lasted 26.7 s, and had a mean firing rate of 13 Hz. Note that firing rate is higher at the beginning of the burst. (B) Total AVP release evoked in isolated neural lobes is much greater with the burst as compared to when lobes are stimulated at the same frequency, with the same number of pulses, in a regular manner (i.e., the interpulse interval was constant). (C) Groups of neural lobes were stimulated with the AVP burst for the first 9 s, the first 18 s, or the complete burst. The black circles show the AVP release from each group. The bars show the amount of AVP attributable to each 9-s period as a percentage of the total amount released. Release is high in the beginning of the burst, when frequency is higher, and low in the final 18 s of the burst. The efficiency is likewise highest in the first 9 s, when each pulse evoked an average of 3.3 pg AVP, compared with 0.7 and 0.6 pg AVP, respectively, in the second and third 9-s periods. (D) Neural lobes were stimulated with four successive bursts that were either separated by 21-s silent intervals (filled bar) or were administered without silent periods (open bar). Release is higher when recovery from fatigue is allowed during the silent periods. Modified from Cazalis *et al.* (1985).

median eminence Collection of neurosecretory axons along middle, ventral, and posterior portions of the hypothalamus; connects the brain with the pituitary gland.

neurohypophysis Posterior (neural) and intermediate lobes of the mammalian pituitary gland.

oxytocin Polypeptide hormone closely related to vasopressin. Composed of 9 amino acids, oxytocin is synthesized in and released from neurosecretory cells in the hypothalamus of mammals; promotes uterine contractions, salt excretion, and milk ejection.

posterior (neural) pituitary lobe Houses vasopressin- and oxytocin-containing axon terminals, fenestrated capillaries, and a large population of astrocyte-like cells, the pituicytes.

supraoptic and paraventricular nuclei Clusters of neurons in the mammalian hypothalamus with axons that project to the neurohypophysis; synthesize vasopressin and oxytocin.

vasopressin Polypeptide hormone composed of 9 amino acids. Synthesized and released from neurosecretory cells in the hypothalamus of mammals, vasopressin increases blood pressure and promotes water reabsorption from the kidneys.

Vitamin D

ANTHONY W. NORMAN
University of California, Riverside

Vitamin D is essential for life in higher animals. Classically, vitamin D has been shown to be one of the most important biological regulators of calcium homeostasis. This important biological effect is only achieved as a consequence of the conversion of vitamin D into a family of daughter metabolites, including the two key kidney-produced metabolites 1α,25$(OH)_2$-vitamin D_3 [1α,25$(OH)_2D_3$] and 24R,25$(OH)_2$-vitamin D_3 [24R,25$(OH)_2D_3$]. 1α,25$(OH)_2D_3$, is a steroid hormone and there is increasing evidence that 24R,25$(OH)_2D_3$ is also a steroid hormone.

I. VITAMIN OR HORMONE?

The first scientific description of the bone disease rickets, which is the hallmark of vitamin D deficiency, was provided in written scientific treatises as early as 1645. The major breakthrough in understanding the causative factors of rickets was the development of nutrition as an experimental science and the appreciation of the existence of vitamins. Considering the fact that the biologically active form of vitamin D is now known to be a steroid hormone, it is somewhat

ironic that vitamin D, through a historical accident, became classified as a vitamin. In 1919–1920, Sir Edward Mellanby, while working with dogs raised exclusively indoors (in the absence of sunlight or ultraviolet light), devised a diet that allowed him to unequivocally establish that rickets was caused by a deficiency of a trace lipid component present in the dog's diet. In 1921, he wrote, "The action of fats in rickets is due to a vitamin or accessory food factor which they contain, probably identical with the fat-soluble vitamin." Furthermore, he established that cod liver oil was an excellent anti-rachitic agent. This ultimately led to the anti-rachitic factor being classified as a vitamin or as an essential dietary trace component that prevents rickets. However, in 1924 it was discovered that a precursor of vitamin D that could be converted into vitamin D by exposure to sunlight or ultraviolet light was present in skin. Thus, the substance known as vitamin D is correctly termed "a vitamin" only when there is a deficiency of sunlight exposure.

The modern era of vitamin D began in 1965–1970 with the discovery and chemical characterization of a metabolite of vitamin D, namely, 1α,25$(OH)_2$-vitamin D_3 [1α,25$(OH)_2D_3$] and its nuclear receptor, VDR. It is now accepted that vitamin D is a precursor of 1α,25$(OH)_2D_3$, which generates biological responses as a steroid hormone.

II. CHEMISTRY

Vitamin D_3 is the naturally occurring form of vitamin D and is produced from 7-dehydro-cholesterol. Vitamin D_2 is a synthetic form of vitamin D that is produced by irradiation of the yeast steroid, ergosterol. The structures of vitamin D_3 (cholecalciferol) and its provitamin 7-dehydrocholesterol are presented in Fig. 1. Vitamin D is a generic term and indicates a molecule of the general structure shown for rings A, B, C, and D with differing side chain structures. The A-, B-, C-, and D-ring structure is derived from the cyclopentanoperhydrophenanthrene ring structure for steroids. Technically, the steroid vitamin D is classified as a seco-steroid. Seco-steroids are those in which one of the rings has been broken; in vitamin D, the 9,10 carbon–carbon bond of ring B is broken, and it is indicated by the inclusion of "9,10-seco" in the official nomenclature. Vitamin D (synonym calciferol) is named according to the revised rules of the International Union of Pure and Applied Chemists (IUPAC). Because vitamin D is derived from a steroid, the structure retains its numbering from the parent compound cholesterol (see Fig. 1). Asymmetric centers are designated by using the R,S notation; the configuration of the double bonds is indicated as E for "eingang" or *trans* and Z for "zuzammen" or *cis*. Thus, the official name of vitamin D_3 is 9,10-seco(5Z,7E)-5,7,10(19)cholestatriene-3β-ol. Vitamin D_3 is currently the form of calciferol that is used for food supplementation, particularly of milk, in the United States. Vitamin D_2 differs from D_3 by virtue of the presence of a 22-ene and 24-methyl group in the side chain. Historically, vitamin D_2 was used in the years 1940–1960 as a food supplement to supply vitamin D activity. The official name of vitamin D_2 is 9,10-seco(5Z,7E)-5,7,10(19),22-ergostatetraene-3β-ol.

III. PHOTOBIOLOGY

Vitamin D_3 can be produced photochemically by the action of sunlight or ultraviolet light on the precursor sterol 7-dehydrocholesterol, which is present in the epidermis or skin of most higher animals (see Fig. 2). The chief structural prerequisite of a provitamin D is that it be a sterol with a Δ5-7 diene double bond system in ring B (see Fig. 1). The conjugated double bond system in this specific location of the molecule allows the absorption of light quanta (energy) at certain wavelengths in the ultraviolet (uv) range; this can readily be provided in most geographical locations by natural sunlight. This initiates a complex series of transformations (partially summarized in Fig. 2) that ultimately results in the transformation into vitamin D_3. Thus, it is important to appreciate that vitamin D_3 can be endogenously produced and that as long as the animal (or human) has access on a regular basis to sunlight there is no dietary requirement for this vitamin.

IV. VITAMIN D ENDOCRINE SYSTEM

Vitamin D_3 is not known to have any intrinsic biological activity itself. It is only after vitamin D_3 is metabolized, first into 25(OH)-vitamin D_3 [25-$(OH)D_3$] in the liver and then into 1α,25$(OH)_2D_3$ and 24R,25$(OH)_2D_3$ by the kidney, that biologically active molecules are produced. *In toto*, some 37 vitamin D_3 metabolites have been isolated and chemically characterized. Fig. 3 illustrates the concept of the vitamin D endocrine system. The elements of the vitamin D endocrine system include the following: (1) in the skin, photoconversion of 7-dehydrocholesterol to vitamin D_3 or dietary intake of vitamin D_3; (2) conversion vitamin D_3 by the liver to 25$(OH)D_3$, which is the major form of vitamin D

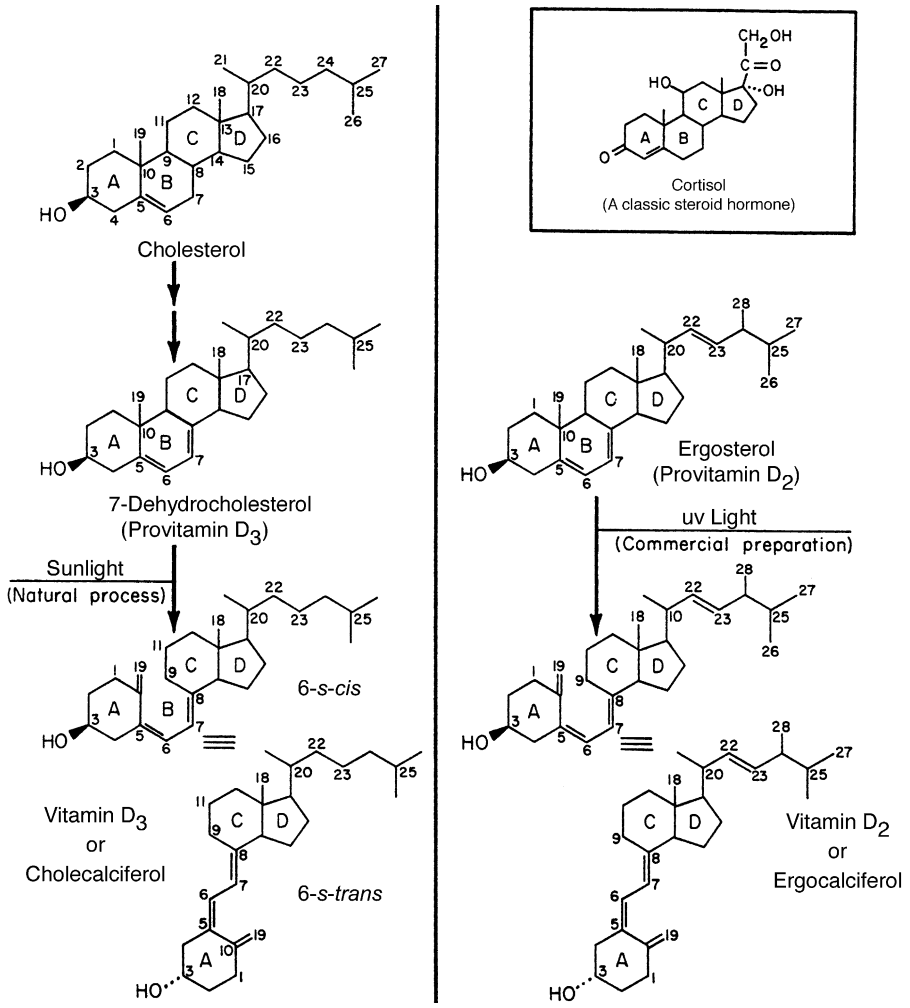

FIGURE 1 Structural relationship of vitamin D_3 (cholecalciferol) and vitamin D_2 (ergocalciferol) with their respective provitamins (7-dehydrocholesterol and ergosterol), cholesterol, and a classic steroid hormone, cortisol (see inset box). The two structural representations presented at the bottom for both vitamin D_3 and vitamin D_2 result from the conformational flexibility in the B ring that allows 180° rotation about the 6,7 single carbon bond. This rotation generates a population of conformers that are represented by the 6-*s-cis* and the 6-*s-trans* orientations indicated in the figure. Vitamin D_3 is the naturally occurring form of the vitamin; it is produced from 7-dehydrocholesterol, which is present in the skin, by the action of sunlight or ultraviolet light. Vitamin D_2 is produced commercially by the irradiation of the sterol ergosterol with ultraviolet light.

circulating in the blood compartment; (3) conversion of 25(OH)D_3 by the kidney (functioning as an endocrine gland) to produce the two principal dihydroxylated metabolites, 1α,25$(OH)_2D_3$ and 24R,25$(OH)_2D_3$; (4) systemic transport of the dihydroxylated metabolites 24R,25$(OH)_2D_3$ and 1α,25$(OH)_2D_3$ to distal target organs; (5) binding of the steroid hormone 1,25$(OH)_2D_3$ to either a nuclear receptor or a membrane receptor at the target organs followed by the subsequent generation of appropriate biological responses. An additional key component in the operation of the vitamin D endocrine system is the plasma vitamin D-binding protein (DBP), which carries vitamin D_3 and all its metabolites to their various target organs.

The three enzymes responsible for the conversion of vitamin D_3 into its two key daughter metabolites include the hepatic vitamin D_3-25-hydroxylase and the two kidney enzymes, 25(OH)D_3-1α-hydroxylase and 25(OH)D_3-24R-hydroxylase. All three enzymes have been demonstrated to be cytochrome P450 mixed-function oxidases. Both renal enzymes are localized in mitochondria of the proximal tubules of the kidney. The 25(OH)D_3-1α-hydroxylase has been

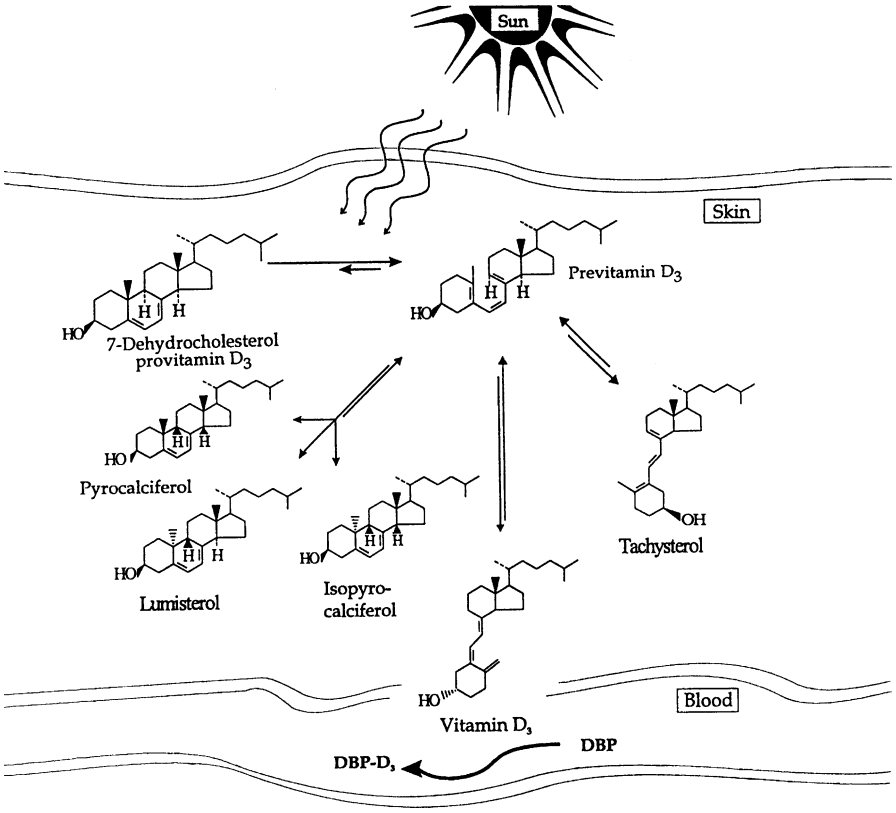

FIGURE 2 Photochemical pathway of production of vitamin D_3 (calciferol) from 7-dehydrocholesterol. The starting point is the irradiation of a provitamin D, which contains the mandatory $\Delta^{5,7}$-conjugated double bonds; in the skin, this is 7-dehydrocholesterol. After absorption of a quantum of light from sunlight (ultraviolet B), the activated molecule can return to the ground state and generate at least six distinct products. The four steroids that do not have a broken 9,10 carbon bond (provitamin D, lumisterol, pyrocalciferol, and isopyrocalciferol) represent the four diastereomers with either an α- or a β-orientation of the methyl group on carbon 10 and the hydrogen on carbon 9. The three seco-steroid products, vitamin D_3, previtamin D, and tachysterol, have the three conjugated double bonds at different positions. In the skin, the principal product is previtamin D, which then undergoes a 1,7-sigmatropic hydrogen transfer from C-19 to C-9, yielding the final vitamin D. Vitamin D can be drawn as either a *6-s-trans* representation (this figure) or a *6-s-cis* representation (Fig. 1), depending upon the state of rotation about the 6,7 single bond. The resulting vitamin D_3, which is formed in the skin, is removed by binding to the plasma transport protein, the vitamin D-binding protein (DBP), present in the capillary bed of the dermis. The DBP-D_3 then enters the general circulatory system.

cloned and the specific site of mutations that result in the appearance in patients of vitamin D-resistant rickets type I (VDRR-I) has been identified. These patients lack the ability to produce $1\alpha,25(OH)_2D_3$ and thus express the phenotype of vitamin D deficiency. In addition, $25(OH)D_3$-24R-hydrodroxylase and vitamin D_3-25-hydroxylase have been cloned.

The most important point of regulation of the vitamin D endocrine system occurs through the stringent control of the activity of the renal $25(OH)D_3$-1α-hydroxylase. In this way, the production of the hormone $1\alpha,25(OH)_2D_3$ can be modulated according to the calcium needs and other endocrine needs of the organism. The chief regulatory factors are $1\alpha,25(OH)_2D_3$ itself, parathyroid hormone (PTH), and the serum concentrations of calcium and phosphate. The secretion of PTH is inversely proportional to the serum Ca^{2+} concentration and increased secretion of PTH will result in stimulation of the renal $25(OH)D_3$-1α-hydroxylase and a concomitant increase in the serum concentration of $1\alpha,25(OH)_2D_3$. Probably the most important determinant of 1α-hydroxylase is the vitamin D status of the animal. When the circulating concentration of $1\alpha,25(OH)_2D_3$ is low, a lowered serum Ca^{2+} results and production of $1\alpha,25(OH)_2D_3$ by the kidney is high; when the circulating concentration of $1\alpha,25(OH)_2D_3$ is high, the output of $1\alpha,25(OH)_2D_3$ by the kidney is sharply reduced.

A. Mode of Action of 1α,25(OH)$_2$

1α,25(OH)$_2$D$_3$ produces a wide spectrum of biological responses through interaction with both its nuclear receptor to regulate gene transcription and a second receptor associated with the cellular membrane that mediates the generation of a variety of rapid signal transduction processes (see Fig. 2).

1. Genomic Responses of 1α,25(OH)$_2$D$_3$

The genomic responses to 1α,25(OH)$_2$D$_3$ are a consequence of the stereospecific interaction of this steroid hormone with its nuclear vitamin D receptor, the VDR. The VDR is a protein of 50 kDa that binds 1α,25(OH)$_2$D$_3$ with high affinity; the $K_d \approx 0.5$ nM. The VDR is not able to bind the parent vitamin D, whereas 25(OH)D$_3$ and 1α (OH)D$_3$ only bind 0.1–0.3% as well as 1α,25(OH)$_2$D$_3$. The primary amino acid sequence of the VDR, like all nuclear receptors for steroid hormones, is divided into five functional domains: these include regions (from the N-terminal to the COOH-terminal) involved in nuclear localization, DNA binding, heterodimerization with other nuclear proteins, ligand binding, and transcriptional activation.

The process of nuclear receptor-mediated regulation of gene transcription is exquisitely dependent upon the complementary relationship between the unoccupied receptor and its cognate ligand. Thus, the unoccupied receptor is largely unable to engage in a productive fashion with the transcriptional machinery to effect meaningful regulation of gene transcription. It is only after the ligand-receptor complex has formed, resulting in conformational changes in the receptor protein, that a functional receptor protein is generated. Thus, acquisition of a detailed understanding of the complementarity of the ligand shape with that of the interior surface of the nuclear VDR receptor ligand-binding domain is believed to be the key to understanding not only the structural basis of receptor action and its formation of heterodimers and interactions with co-activators, but also to designing new drug forms of the various hormones, including 1α,25(OH)$_2$D$_3$.

The protein receptors for all steroid hormones (estrogen, progesterone, testosterone, cortisol, and aldosterone) and the protein receptors for 1α,25(OH)$_2$D$_3$, retinoic acid, and thyroid hormone are all members of the same gene superfamily; accordingly, there is a high level of conservation in their amino acid sequences, particularly in their DNA- and ligand-binding domains. The X-ray crystallographic structures of the ligand-binding domains (LBDs) of the thyroid hormone receptor, the retinoic acid receptor, the estrogen receptor, and the progesterone receptor have all been determined with their respective ligands bound. Also, the crystal structure of the nuclear receptor for vitamin D bound to its natural ligand 1α,25(OH)$_2$D$_3$ has been determined at a 1.8 Å resolution. The VDR LBD structure, as well as that of the other nuclear receptors, consists of 12 α-helices that are arranged to create a three-layer sandwich that completely encompasses the ligand 1α,25(OH)$_2$D$_3$ in a hydrophobic core. The secondary and tertiary structural features of this family of receptor proteins were found to be remarkably similar.

An animal model in which the gene for the VDR has been deleted (termed a gene knockout or KO) has been engineered by targeted disruption of both the first and the second zinc-fingers of the DNA-binding domain of the VDR. This VDR KO displays the phenotype of vitamin D-dependent rickets type II (VDDR-II). Despite the widespread tissue distribution of the VDR (see Fig. 2), the resultant animals were phenotypically normal at birth, indicating that there is biological redundancy with respect to most of the functions of this receptor. The most surprising observation was that all of the VDR KO mice developed alopecia (hair loss) by 7 weeks. In addition, the male and female VDR KO mice were infertile.

2. Rapid Responses of 1α,25(OH)$_2$D$_3$

The "rapid" responses mediated by 1α,25(OH)$_2$D$_3$ (see Fig. 3) are postulated to be mediated through interaction of 1α,25(OH)$_2$D$_3$ with a second protein receptor located on the external membrane of the cell. Rapid responses stimulated by 1α,25(OH)$_2$D$_3$ include the following: transcaltachia [the rapid stimulation by 1α,25(OH)$_2$D$_3$ of intestinal Ca^{2+} absorption], the opening of voltage-gated Ca^{2+} and Cl^- channels, rapid uptake of $^{45}Ca^{2+}$ into (ROS, rat osteosarcoma 17/2.8) osteoblast cells, enhancement of the concentration of phospholipid second messengers in the intestine, activation of protein kinase C, tyrosine kinases, and mitogen-activated protein kinase.

3. 24R,25(OH)$_2$D$_3$ Biological Properties

In comparison to 1α,25(OH)$_2$D$_3$, the biological actions of 24R,25(OH)$_2$D$_3$ have been relatively less studied. One key question that has attracted attention is whether 1α,25(OH)$_2$D$_3$ acting alone can generate *all* the biological responses that are attributed to the parent vitamin D$_3$ or whether a second vitamin D$_3$ metabolite may be required for some responses.

Evidence supports the view that the combined presence of both 1α,25$(OH)_2D_3$ and 24R,25$(OH)_2D_3$ is necessary to generate the complete spectrum of biological responses attributable to the parent vitamin D_3. Current research on 24R,25$(OH)_2D_3$ focuses on elucidating its actions in cartilage and bone cells.

V. NUTRITIONAL REQUIREMENTS

A. Recommended Dietary Allowance (RDA)

The World Health Organization has responsibility for defining the "International Unit" of vitamin D_3. Their most recent definition, provided in 1950, stated that "the International Unit of vitamin D recommended for adoption is the vitamin D activity of 0.025 μg of the international standard preparation of crystalline vitamin D_3." Thus, 1.0 IU of vitamin D_3 is 0.025 μg, which is equivalent to 65.0 pmol. With the discovery of the conversion of vitamin D_3 to other active seco-steroids, particularly 1α,25$(OH)_2D_3$, it was recommended that 1.0 Unit of 1α,25$(OH)_2D_3$ be set equivalent in molar terms to that of the parent vitamin D_3. Thus, 1.0 Unit of 1α,25$(OH)_2D_3$ has been operationally defined to be equivalent to 65 pmol.

The vitamin D requirement for healthy adults has never been precisely defined. Since vitamin D_3 is produced in the skin after exposure to sunlight, the human does not have a requirement for vitamin D when sufficient sunlight is available. The tendencies of humans to wear clothes, to live in cities where tall buildings block adequate sunlight from reaching the ground, to live indoors, to use synthetic sunscreens that block ultraviolet rays, and to live in geographical regions of the world that do not receive adequate sunlight all contribute to the inability of the skin to biosynthesize sufficient amounts of vitamin D_3. Thus, vitamin D does become an important essential nutritional factor in the absence of sunlight. It is known that a substantial proportion of the U.S. population is exposed to suboptimal levels of sunlight. This is particularly true during the winter months. Under these conditions, vitamin D becomes a true vitamin, which dictates that it must be supplied in the diet on a regular basis.

The current "adequate intake" allowance of vitamin D recommended in 1998 by the United States Food and Nutrition Board of the Institute of Medicine is 200 IU/day (5 μg/day) for infants, children, and adult males and females up to age 51. For adults ages 51–70, the adequate indicated level is set at 400 IU/day (10 μg/day). For adults >70 years of age, the adequate indicated level is set at 600 IU (15 μg/day). The adequate allowance for pregnancy and lactation is set at 200 IU/day (5 μg/day). These recommendations are all summarized in a 1998 publication from the Food and Nutrition Board of the Institute of Medicine.

In the United States, adequate amounts of vitamin D can readily be obtained from the diet and/or from casual exposure to sunlight. The uv exposure can be as little as three times per week exposure of the face and hands to ambient sunlight for 20 min. However, in some parts of the world where food is not routinely fortified and sunlight is often limited during some periods of the year, obtaining adequate amounts of vitamin D becomes more of a problem. As a result, the incidence of the bone disease rickets in these countries is higher than in the United States.

1. Food Sources of Vitamin D

Animal products constitute the bulk source of vitamin D that occurs naturally in unfortified foods. Salt water fish, such as herring, salmon, and sardines, and fish liver oils are good sources of vitamin D_3. Small quantities of vitamin D_3 are also derived from eggs, veal, beef, butter, and vegetable oils, whereas plants, fruits, and nuts are extremely poor sources of vitamin D. In the United States, fortification of foods such as milk (both fresh and evaporated), margarine and butter, cereals, and chocolate mixes help in meeting the RDA recommendations. Because only fluid milk is fortified with vitamin D, other dairy products (cheese, yogurt, etc.) do not provide the vitamin.

B. Excess and Toxicity

1. Vitamin D

Excessive amounts of vitamin D are not normally available from usual dietary sources and thus reports

FIGURE 3 Summary of the vitamin D endocrine system. The kidney is the principal endocrine gland that produces in a regulated fashion small amounts of both 1α,25$(OH)_2D_3$ and 24R,25$(OH)_2D_3$. During pregnancy, these same two metabolites are also produced by the placenta. Target organs for the steroid hormone 1α,25$(OH)_2D_3$ by definition contain the nuclear receptor 1α,25$(OH)_2D_3$ (VDR). Also, 1α,25$(OH)_2D_3$ produces selected biological responses via a rapid signal transduction process. The biological roles of 24R,25$(OH)_2D_3$ are believed to occur in the bone and cartilage.

of vitamin D intoxication are rare. However, there is always the possibility that vitamin D intoxication may occur in individuals who are taking excessive amounts of supplemental vitamins. In 1993, there was one report of vitamin D intoxication occurring from drinking milk that had been fortified with inappropriately high levels of vitamin D_3. Symptoms of vitamin D intoxication include hypercalcemia, hypercalciuria, anorexia, nausea, vomiting, thirst, polyuria, muscular weakness, joint pains, diffuse demineralization of bones, and general disorientation. If allowed to go unchecked, death will eventually occur. The extent of toxicity has been shown in some instances to be related to the level of dietary intake of calcium.

The biological basis for intoxication resulting from the inappropriate intake of the parent vitamin D_3 is believed to occur from the unrestrained conversion by the liver of the vitamin D_3 to $25(OH)D_3$; this is a largely unregulated metabolic step. The vitamin D intoxication is thought to occur as a result of high plasma levels of 25(OH)D rather than high plasma levels of $1\alpha,25(OH)_2D_3$. Patients suffering from hypervitaminosis D have been shown to exhibit a 15-fold increase in plasma 25(OH)D concentration compared to normal individuals; however, their $1\alpha,25(OH)_2D$ levels are not substantially altered. It has also been shown that large concentrations of $25(OH)D_3$ can mimic the actions of $1\alpha,25(OH)_2D_3$ at the level of the VDR, which can lead to a massive stimulation of intestinal Ca^{2+} absorption and bone Ca^{2+} resorption and ultimately the occurrence of soft tissue calcification and kidney stones. The use of pamidronate, a bisphosphonate inhibitor of bone resorption, has been proposed to reduce the hypercalcemia secondary to acute vitamin D intoxication.

VI. DISEASE STATES

Figure 4 describes human disease states related to vitamin D and the vitamin D endocrine system. Conceptually, human clinical disorders related to vitamin D can be considered as those arising because of the following: (1) altered availability of vitamin D; (2) altered conversion of vitamin D_3 to $25(OH)D_3$; (3) altered conversion of $25(OH)D_3$ to $1\alpha,25(OH)_2D_3$ and/or $24R,25(OH)_2D_3$; (4) variations in end organ responsiveness to $1\alpha,25(OH)_2D_3$ or possibly $24R,25(OH)_2D_3$; and (5) other conditions of uncertain relation to vitamin D. Thus, the clinician/nutritionist/biochemist is faced with a problem, in a diagnostic sense, of identifying parameters of hypersensitivity, antagonism, or resistance (including genetic aberrations) to vitamin D or one of the other of its metabolites as well as identifying perturbations of metabolism that result in problems in production and/or delivery of the hormonally active form, $1\alpha,25(OH)_2D_3$.

A. Vitamin D Deficiency and Rickets

The classic deficiency state resulting from a dietary absence of vitamin D or lack of ultraviolet (sunlight)

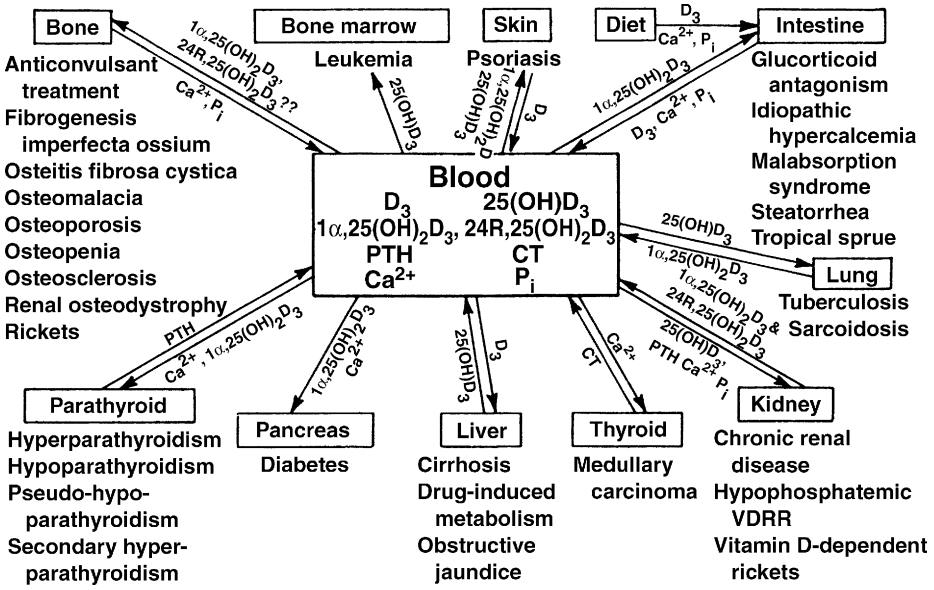

FIGURE 4 Human disease states related to vitamin D and its endocrine system.

exposure is the bone disease rickets (in children) or osteomalacia (in adults). The clinical features of rickets and osteolmalacia depend on the age of onset. The classical skeletal disorder of rickets includes deformity of the bones, especially the knees, wrists, and ankles, as well as associated changes in the costochondrial joint functions, which have been termed by some as the rachitic rosary. If rickets develops in the first 6 months, infants may suffer from convulsions or develop tetany due to a low blood calcium level (usually <7 mg/100 ml; normal blood calcium levels are 9–10.5 mg/100 ml) but may have only minor skeletal changes. After 6 months, bone pain as well as tetany is likely to be present. Since osteomalacia occurs after growth and development of the skeleton are complete (i.e., the adult stage of life), its main symptoms are muscular weakness and bone pain with little bone deformity.

A characteristic feature of bone osteomalacia and rickets is the failure of the organic matrix of bone (osteoid) to calcify. This leads to the appearance of excessive quantities of uncalcified osteoid. In addition, there is often a high serum level of alkaline phosphatase, a fact that is often used to assist in the clinical diagnosis of osteomalacia. Also, low serum levels of $25(OH)D_3$ have been found to be diagnostic for the presence of rickets or osteomalacia. The normal serum level of $25(OH)D_3$ is 25–35 ng/ml. When the serum $25(OH)D_3$ level is below 5 ng/ml, the individual is classified as being vitamin D-deficient. When the serum $25(OH)D_3$ level is below 10 ng/ml, the individual is "at risk" for development of vitamin D deficiency.

The nutritional availability of vitamin D is particularly important both in the newborn and young child and in the elderly. Thus, circumstances of deprivation of sunlight through seasonal variation (winter) or skin pigmentation in Africans or African Americans or certain cultural groups, including Muslims, associated with clothing that covers the entire body and face, can lead to the onset of clinical rickets or osteomalacia, characterized by low serum $25(OH)D_3$ levels. Accordingly, the nursing infant can be at risk for rickets if her/his mother is vitamin D-deficient.

VII. SUMMARY

Current evidence substantiates the concept that the classical biological actions of the nutritionally important fat-soluble vitamin D in mediating calcium homeostasis are supported by a complex vitamin D endocrine system that coordinates the conversion of vitamin D_3 into $1\alpha,25(OH)_2D_3$ and $24R,25(OH)_2D_3$. It is now clear that the vitamin D endocrine system embraces many more target tissues than simply the intestine, bone, and kidney. Notable additions to this list include the pancreas, pituitary, breast tissue, placenta, hematopoietic cells, skin, and cancer cells of various origins. Key advances in understanding the mode of action of $1\alpha,25(OH)_2D_3$ have been made by a thorough study of nuclear receptors as well as emerging studies describing a membrane receptor for this steroid hormone. Integral to these observations are efforts to define the signal transduction systems that are subservient to the nuclear and membrane receptors for $1\alpha,25(OH)_2D_3$ and to obtain a thorough study of the tissue distribution and subcellular localization of the gene products induced by this steroid hormone. There are clinical applications for $1\alpha,25(OH)_2D_3$ or related analogues for treatment of the bone diseases of renal osteodystrophy and osteoporosis, psoriasis, and hypoparathyroidism. Other clinical targets for $1\alpha,25(OH)_2D_3$ currently under investigation include its use in leukemia and breast, prostate, and colon cancer as well as its use as an immunosuppressive agent.

Glossary

endocrine system The integrated interaction between an endocrine gland (source of a hormone) and target cells (location of the hormone's receptor) to generate in a regulated fashion the selective biological responses for that system.

hormone Any of several chemical classes of compounds produced in regulated quantities by an endocrine gland that acts as a chemical messenger, usually delivered through the circulatory system to a target cell, which by definition possesses a receptor for that hormone so that a specific biological response may be generated.

photochemical reaction A chemical reaction mediated or enhanced by some wavelength of light.

receptor A protein molecule that binds very specifically to its cognate hormone to generate a receptor–hormone complex that initiates a cellular signal transduction process resulting in a biological response.

Recommended Dietary Allowance (RDA) Recommendations for the amounts of various dietary nutrients (e.g., vitamins and minerals) required to maintain human health.

rickets A bone disease in infants and children characterized by a reduction of bone calcium content that results from a dietary deficiency of vitamin D or lack of adequate exposure to sunlight.

steroid A member of the lipid class of compounds that is composed of a four-ring structure, the cyclopentanoperhydro-phenanthrene nucleus, and is the basic

structural component of steroid hormone families such as estrogens, progestogens, androgens, mineralocorticoids, and glucocorticoids.

vitamin Any of a group of essential organic substances provided in trace amounts in food components to effect the normal function of a cellular metabolic process.

Vitamin D and Cartilage

BARBARA D. BOYAN[*,**], VICTOR L. SYLVIA[*], DAVID D. DEAN[*], AND ZVI SCHWARTZ[*,**,†]

[*]*University of Texas Health Science Center at San Antonio* • [**] *Georgia Institute of Technology and Emory University, Atlanta* • [†]*Hebrew University Hadassah, Jerusalem*

Two metabolites of vitamin D, $1\alpha,25$-dihydroxy vitamin D_3 ($1\alpha,25(OH)_2D_3$) and 24R,25-dihydroxy vitamin D_3 ($24R,25(OH)_2D_3$) regulate growth plate physiology. The effects of each metabolite are limited to different subsets of cells in specific zones of the growth plate; different mechanisms of action are used by the metabolites to exert their effects in their target cells.

I. INTRODUCTION

Cartilage is one of the primary target tissues for vitamin D action. During embryonic development, a cartilage anlage provides the form of the skeleton. Mineralization of the cartilage must occur before it can serve as a structural support for bone formation, ultimately being replaced by bone marrow. At the ends of the long bones of the skeleton, at cranial sutures, at the scapula, and at the mandibular condyle, the embryonic cartilage forms a specialized tissue called the growth plate. This tissue remains in postfetal life and provides the mechanism for continued bone growth.

Cartilage cells in the growth plate proceed through a lineage cascade that culminates in the calcification of the tissue (Fig. 1). Chondrocytes in the resting zone, also called the reserve zone, of the growth plate are surrounded by an extracellular matrix that is rich in type II collagen and sulfated

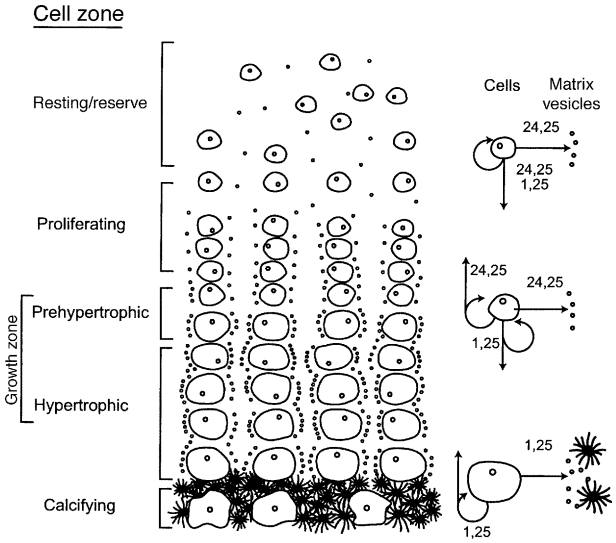

FIGURE 1 Growth plate cartilage. Cells progress through their lineage in a linear fashion in time and space. Vitamin D metabolites $1,25(OH)_2D_3$ (1,25) and $24,25(OH)_2D_3$ (24,25) produced by the chondrocytes act back on the cells in an autocrine manner or on adjacent chondrocytes in a paracrine manner. In addition, they act on matrix vesicles in the extracellular matrix.

glycosaminoglycans in the form of proteoglycan aggregates. This region of the growth plate cushions the tissue from mechanical load. Upon signals that are not yet understood, chondrocytes at the base of the resting zone align in columns and undergo a set number of divisions. Once proliferation is complete, the phenotype of the cartilage cells is altered. The cells are described as being in the zone of maturation or the prehypertrophic cell zone. There are many features of this zone that are not well understood but it appears to be a staging ground for the rapid increase in cell size that characterizes the zone of hypertrophy. This increase in size is primarily in the longitudinal direction and is accompanied by rapid turnover of extracellular matrix, particularly the breakdown of type II collagen and proteoglycan aggregate. In addition, the cells produce increased numbers of extracellular matrix vesicles that contain matrix-processing enzymes and serve as focal points for initial calcification of the tissue. Many of the chondrocytes in this zone are apoptotic. At the base of the hypertrophic cell zone, calcification of the cartilage is complete. This is accompanied by vascular invasion and migration of mesenchymal cells that ultimately differentiate into osteoblasts and marrow stromal cells, resulting in bone and bone marrow formation. A similar sequence of events is recapitulated during fracture repair and during the process of osteoinduction.

In the absence of vitamin D, mineralization of the growth plate fails to occur. As a consequence, the hypertrophic cell zone increases in length since proliferation continues at its normal rate. Because the hypertrophic zone is weak structurally, it cannot withstand weight-bearing loads. As a result, a condition known as rickets develops, in which there is characteristic bowing of the long bones.

In experimental animals, rickets can be cured rapidly by injection with either 25-hydroxy vitasmin D_3 ($25(OH)D_3$) or metabolites of vitamin D that are hydroxylated on the 1-carbon, such as $1\alpha,25(OH)_2D_3$. This effect is due to the rapid release of Ca^{2+} into the extracellular matrix of the cells. Other studies have shown that rickets in rats that are deficient in vitamin D as well as phosphate can be cured by systemic injection of $24R,25(OH)_2D_3$ or local injection of this metabolite into the bone. Since this metabolite is not associated with Ca^{2+} transport, these observations suggest either that the $24R,25(OH)_2D_3$ is further metabolized to 1,24,25-trihydroxy vitamin D_3 ($1,24,25(OH)_3D_3$) in the tissue or that $24R,25(OH)_2D_3$ also regulates growth plate chondrocytes directly, affecting other aspects of cell physiology that contribute to the development of the rachitic syndrome.

Vitamin D is also an important regulator of growth plate physiology in vitamin D replete animals. When vitamin D replete adolescent rats are given radiolabeled $25(OH)D_3$, both $1,25(OH)_2D_3$ and $24,25(OH)_2D_3$ are concentrated in the growth plate to a greater extent than in kidney or serum. This supports the hypothesis that these vitamin D metabolites have functions in the growth plate in addition to calcium ion transport. There are numerous studies that indicate this to be the case and these are reviewed below.

The sensitivity of growth plate cartilage to vitamin D and the fact that this tissue contains a single cell type that transits its lineage cascade in a linear manner that can be visualized under a dissecting microscope have made this tissue an excellent model for studying the mechanisms of action of this hormone. The development of techniques for the culture of growth plate chondrocytes has enabled investigators to identify specific subpopulations of cells that respond to $24R,25(OH)_2D_3$ and $1\alpha,25(OH)_2D_3$. These studies have also led to rapid advances in our understanding of the mechanisms involved.

II. ROLE OF 1α,25(OH)$_2$D$_3$

Growth plate chondrocytes contain nuclear receptors for 1α,25(OH)$_2$D$_3$ and respond to this vitamin D metabolite via traditional nuclear receptor-mediated mechanisms. In addition to the rapid release of Ca^{2+} ions after treatment with 1α,25(OH)$_2$D$_3$, there are a number of other changes that occur in the growth plate in response to this metabolite. 1α,25(OH)$_2$D$_3$ causes an increase in alkaline phosphatase activity in the hypertrophic zone of the growth plate, as well as an increase in phospholipase A$_2$ activity. This results in the increased production of lysophospholipids. Other aspects of phospholipid metabolism are affected as well, including the specific breakdown of phospholipids not associated with the nucleation of hydroxyapatite crystals in the extracellular matrix. Moreover, the activity of various matrix-processing enzymes is increased. These observations indicate that the primary functions of 1α,25(OH)$_2$D$_3$ are to prepare the matrix for calcification and to ensure that the mineral ions necessary for calcium phosphate formation are present in sufficient quantity. This hypothesis is supported by the fact that many of the effects described above involve matrix vesicles, which are extracellular organelles produced by the chondrocytes that contain matrix-processing enzymes and serve as foci for initial mineral formation.

Studies examining the effects of 1α,25(OH)$_2$D$_3$ on growth plate chondrocytes in culture show that this metabolite inhibits the proliferation of both resting zone and growth zone (prehypertrophic and upper hypertrophic cell zones) cells. However, the effects of this metabolite on differentiation are limited to cells from the growth zone. In confluent cultures of rat costochondral growth plate chondrocytes grown in the presence of serum, 1α,25(OH)$_2$D$_3$ increases the production of prostaglandin E1 (PGE1) and PGE2, stimulates the activity of matrix vesicle alkaline phosphatase and phospholipase A$_2$, and increases the activity of matrix metalloproteinases in these extracellular organelles. In contrast, cultures of chick epiphyseal growth plate chondrocytes grown under serum-free conditions respond to 1α,25(OH)$_2$D$_3$ with a decrease in cellular alkaline phosphatase activity. Whether these differences are due to the species, the presence of serum, or the tissue from which the cells were derived, cells versus matrix vesicles, or the experimental design is not known.

1α,25(OH)$_2$D$_3$ also modulates growth plate physiology indirectly by regulating the storage and activation of transforming growth factor-β (TGF-β) in the extracellular matrix of prehypertrophic and hypertrophic chondrocytes (Fig. 2). Synthesis of latent TGF-β-binding protein by growth zone chondrocytes is regulated by 1α,25(OH)$_2$D$_3$ both *in vivo* and *in vitro*. 1α,25(OH)$_2$D$_3$ also acts directly on matrix vesicle membranes, increasing phospholipase A$_2$ activity and releasing enzymes that can activate latent TGF-β1. It is now known that 1α,25(OH)$_2$D$_3$ is involved in the release of active stromelysin-1, also called matrix metalloproteinase-3, from matrix vesicles and that this enzyme is responsible for the release of latent TGF-β1 from the matrix and its subsequent activation. Interestingly, TGF-β1 regulates the metabolism of 25(OH)D$_3$ in the growth plate, thereby completing the regulatory feedback loop.

III. ROLE OF 24R,25(OH)$_2$D$_3$

A role for 24R,25(OH)$_2$D$_3$ in the growth plate has been controversial. Rickets can be treated by direct injection of this metabolite into the growth plate, but the possibility exists that this is due to conversion of 24R,25(OH)$_2$D$_3$ to 1,24,25(OH)$_3$D$_3$. In experiments using difluorinated analogues of 24,25(OH)$_2$D$_3$ that prevented further metabolism to 1,24,25(OH)$_3$D$_3$, rapid healing of rickets did not occur, leading to the assumption that 24R,25(OH)$_2$D$_3$ had no active function in the tissue. However, there were a number of studies using rat mandibular condyle organ cultures as an experimental model that argued to the contrary. In addition, the effects of systemically administered 24R,25(OH)$_2$D$_3$ on matrix-processing enzymes in rachitic rat epiphyseal growth plates are very different from the effects of 1α,25(OH)$_2$D$_3$, supporting the contention that they are not due to further metabolism of the metabolite on the 1-carbon. Moreover, specific binding of radiolabeled 24,25(OH)$_2$D$_3$ was found in the growth plate by autoradiography, indicating that receptors for this metabolite are present. Although a nuclear receptor for this vitamin D metabolite has not been purified to homogeneity, recent studies indicate that membrane receptors specific for 24R,25(OH)$_2$D$_3$ exist.

Cell culture studies confirm that 24R,25(OH)$_2$D$_3$ directly affects rat costochondral growth plate chondrocytes, but the response to this metabolite is primarily seen in cells from the resting zone. 24R,25(OH)$_2$D$_3$ stimulates matrix vesicle alkaline phosphatase activity, but it inhibits phospholipase A$_2$ activity and decreases the production of PGE1 and PGE2. The activity of matrix-processing enzymes in matrix vesicles is also decreased. 24R,25(OH)$_2$D$_3$ stimulates the synthesis of latent TGF-β-binding protein by resting zone cells both *in vivo* and *in vitro*,

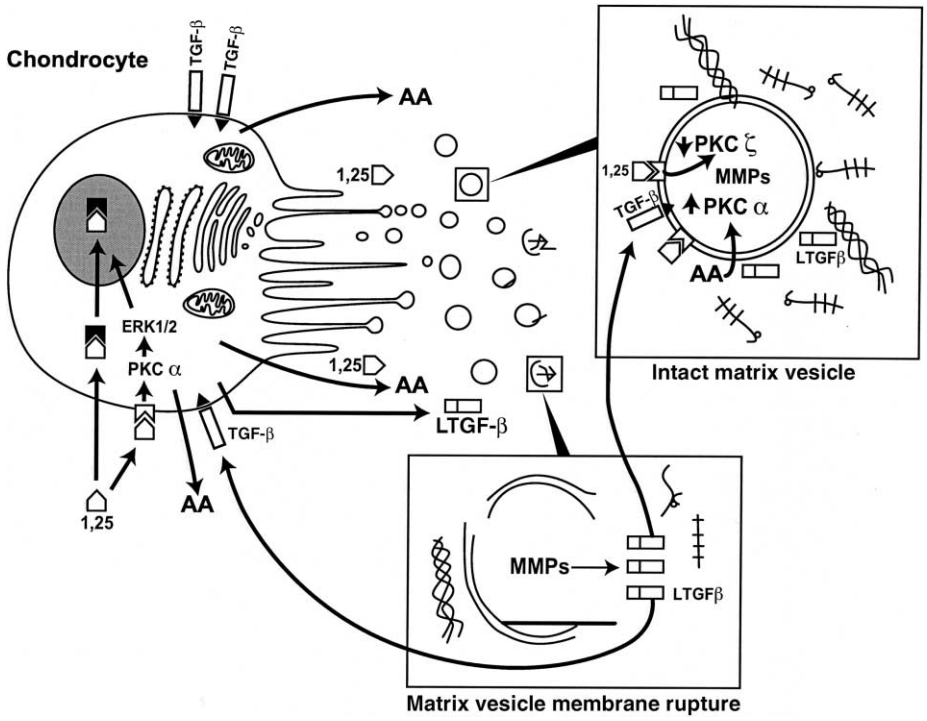

FIGURE 2 Growth plate chondrocytes secrete $1,25(OH)_2D_3$ (1,25) into the extracellular matrix, where it acts directly on matrix vesicles via membrane-associated receptors (1,25-mVDR), decreasing protein kinase C ζ (PKC ζ) activity. Alkaline phosphatase and phospholipase A_2 activities are also increased, leading to increased local phosphate concentration, calcium phosphate crystal formation (line on inner surface of matrix vesicle membrane), and destabilization of the membrane. The mineral within the matrix vesicle provides calcification initiation sites. Matrix-processing enzymes are released into the matrix, causing proteoglycan degradation and facilitating further calcification. Matrix vesicle stromelysin-1 releases and activates latent TGF-β1 stored in the matrix. TGF-β1 can then act back on the cell. Secreted $1,25(OH)_2D_3$ also binds to the 1,25-mVDR on the cell membrane, causing activation of PKC and MAP kinase, ultimately leading to new gene expression. $1,25(OH)_2D_3$ binds to the 1,25-nVDR as well, also contributing to genomic regulation of the cells. Phospholipase A_2 is activated by $1,25(OH)_2D_3$, releasing arachidonic acid, which can participate in the cell response and act on matrix vesicle PKC as well.

but this metabolite is not involved in the activation of latent TGF-β. These observations all suggest that $24R,25(OH)_2D_3$ modulates the differentiation of the cells, but down-regulates matrix turnover that leads to calcification of the matrix. This is supported by the fact that $24R,25(OH)_2D_3$ causes uptake rather than release of Ca^{2+}.

However, these results do not explain how injection of $24R,25(OH)_2D_3$ into a rachitic growth plate can lead to repair of a rachitic lesion. It is now known that $24R,25(OH)_2D_3$ induces resting zone cells to acquire a growth zone phenotype. Short-term exposure to $24R,25(OH)_2D_3$ increases the proliferation of resting zone cells, and this is accompanied by an increase in the levels of stathmin. Prolonged exposure to $24R,25(OH)_2D_3$ causes a decrease in proliferation. Responsiveness to the metabolite is also reduced, and the cells become responsive to $1\alpha,25(OH)_2D_3$. In addition, $24R,25(OH)_2D_3$ regulates the expression and activity of 1-hydroxylase, leading to production of $1,25(OH)_2D_3$ and potentially to production of $1,24,25(OH)_3D_3$.

IV. METABOLISM OF $25(OH)D_3$

The fact that growth plate cartilage has the ability to metabolize $25(OH)D_3$ has been known for some time. Recent studies using the rat costochondral cartilage cell model have enabled us to examine the mechanisms involved. Resting zone and growth zone chondrocytes constitutively produce $1,25(OH)_2D_3$ and $24,25(OH)_2D_3$ at levels that are comparable to kidney cells, with production of $1,25(OH)_2D_3$ being greater than production of $24,25(OH)_2D_3$. This correlates with mRNA levels for 1-hydroxylase

(Cyp27B1) and 24-hydroxylase (Cyp24), as well as with constitutive activities of these enzymes. The metabolism of $25(OH)D_3$ is regulated in a cell-specific manner. In resting zone cells, the production of $1,25(OH)_2D_3$ is regulated by TGF-β1 within 1 h and by dexamethasone within 24 h. Production of $24,25(OH)_2D_3$ is regulated by TGF-β1 within 24 h, suggesting that it may be due to the earlier increase in $1,25(OH)_2D_3$. This is in fact the case. TGF-β1 stimulates an increase in 24-hydroxylase gene expression and activity, whereas expression of 1-hydroxylase is decreased. In contrast to its effects on $25(OH)D_3$ metabolism in resting zone cells, TGF-β1 has no effect on the production of either $1,25(OH)_2D_3$ or $24,25(OH)_2D_3$ in growth zone cell cultures. $24R,25(OH)_2D_3$ decreases 24-hydroxylase and 1-hydroxylase activity in resting zone cells, but affects neither hydroxylase in growth zone cells. $1\alpha,25(OH)_2D_3$ increases 24-hydroxylase activity and $24,25(OH)_2D_3$ production in growth zone cells but has no effect on 1-hydroxylase activity.

These complex interrelationships indicate that the secreted hormones can act back on the cells that produce them. The 24-hydroxylase gene Cyp24 has a $1\alpha,25(OH)_2D_3$-response element in its promoter, but to date there have been no reports of a $1\alpha,25(OH)_2D_3$-response element in the promoter of the Cyp27B1 gene. Recent studies indicate that both promoters contain activator protein 1 (AP-1) sites, and AP-1 is sensitive to mitogen-activated protein (MAP) kinase, which is activated by $24R,25(OH)_2D_3$ in resting zone cells and by $1\alpha,25(OH)_2D_3$ in growth zone cells. These observations suggest that the secreted metabolites may modulate their own metabolism through mechanisms that are independent of the nuclear vitamin D receptor (1,25-nVDR) or that augment the actions of the 1,25-nVDR.

V. MEMBRANE-MEDIATED ACTIONS

Rat costochondral growth plate chondrocytes produce $1,25(OH)_2D_3$ and $24,25(OH)_2D_3$ at levels that correspond to those at which biological effects are observed in cell culture, 10^{-8} and 10^{-7} M, respectively. This also corresponds to the amount of radiolabeled $1,25(OH)_2D_3$ and $24,25(OH)_2D_3$ found in the growth plates of vitamin D replete rats treated with radiolabeled $25(OH)D_3$. These observations indicate that locally produced metabolites are important in the physiology of the cells and suggest that they act in an autocrine or paracrine manner. In fact, $1\alpha,25(OH)_2D_3$ and $24R,25(OH)_2D_3$ act directly on the cells via mechanisms involving activation of protein kinase C α (PKC α) by specific membrane-associated receptors (1,25-mVDR; 24, 25-mVDR). Both resting zone cells and growth zone cells possess both types of membrane receptors, yet the effects of $1\alpha,25(OH)_2D_3$ are limited to growth zone cells and the effects of $24R,25(OH)_2D_3$ are limited to resting zone cells. It is now known that distinctly different mechanisms are responsible for the action of the metabolites in their target cells.

$1\alpha,25(OH)_2D_3$ causes a rapid increase in arachidonic acid release via cytosolic phospholipase A_2. The arachidonic acid acts as a co-factor, activating PKC α directly. It also serves as a substrate for constitutive cyclooxygenase 1 (COX-1), resulting in increased prostaglandin production. Inhibition of COX-1 inhibits the action of $1\alpha,25(OH)_2D_3$ on PKC as well as the membrane-mediated effects of $1\alpha,25\ (OH)_2D_3$ on the physiology of the cell. PGE2 produced as a consequence of $1\alpha,25(OH)_2D_3$ action on growth zone cells acts on its own prostaglandin E type 1 (EP1) receptors, increasing PKC through a protein kinase A-dependent mechanism. $1\alpha,25(OH)_2D_3$ also activates phosphatidylinositol-specific phospholipase C-β, leading to the formation of diacylglycerol and inositol 1,4,5-trisphosphate (IP_3). Diacylglycerol binds to cytosolic PKC α and activates the translocation of the enzyme to the plasma membrane, thereby increasing the plasma membrane enzyme activity. The released IP_3 activates the release of Ca^{2+} from the endoplasmic reticulum, which is also a co-factor for PKC α. These effects of $1\alpha,25(OH)_2D_3$ on PKC are mediated by the 1,25-mVDR.

$24R,25(OH)_2D_3$ also activates PKC α, but it can do so only in resting zone cells. $24R,25(OH)_2D_3$ causes a rapid decrease in arachidonic acid release, followed by an increase in release after 15 min. Production of prostaglandin is also reduced. The action of PGE2 on its EP1 receptor inhibits PKC activity in these cells, so reduction of PGE2 has the effect of reducing the inhibition, in essence contributing to the stimulatory effect of $24R,25(OH)_2D_3$ on the enzyme. $24R,25(OH)_2D_3$ also causes an increase in diacylglycerol production but there is no corresponding increase in IP_3. Instead, the diacylglycerol is a result of the activation of phospholipase D. Moreover, translocation of PKC α to the plasma membrane does not occur.

Many of the physiological effects of $1\alpha,25(OH)_2D_3$ on growth zone cells and of $24R,25(OH)_2D_3$ on resting zone cells are mediated, at least in part, by the activation of PKC α. Some of these effects do not require new gene expression,

but other effects clearly have a genomic component. For $1\alpha,25(OH)_2D_3$, the 1,25-nVDR is likely to play a role. However, an equivalent receptor for $24R,25(OH)_2D_3$ has not been isolated, raising the possibility that any genomic response may be mediated through other mechanisms, such as the 24,25-mVDR. In other systems, MAP kinase has been shown to mediate the downstream effects of the PKC α-dependent signaling pathway. This appears to be the case in cartilage as well. $1\alpha,25(OH)_2D_3$ activates the extracellular signal-related kinase 1/2 (ERK1/2) family of MAP kinases at the same time that peak activation of PKC α is observed. Similarly, $24R,25(OH)_2D_3$ activates ERK1/2 MAP kinase at the time that peak increases in PKC α occur in resting zone cells.

These experiments explain how $1\alpha,25(OH)_2D_3$ and $24R,25(OH)_2D_3$ exert their membrane-mediated effects in the chondrocytes but they do not explain how secreted metabolites can elicit one set of responses in the cells but another set of responses in matrix vesicles. Matrix vesicles are produced by resting zone and growth zone chondrocytes under genetic control. $1\alpha,25(OH)_2D_3$ increases PKC activity in matrix vesicles produced by growth zone cells by increasing the synthesis of protein kinase ζ (PKC ζ). Similarly, $24R,25(OH)_2D_3$ increases PKC activity in matrix vesicles produced by resting zone cells by increasing the synthesis of PKC ζ. Thus, one mechanism for discriminating the effects of the vitamin D metabolites on matrix vesicles versus cells is by differential segregation of PKC isoforms; PKC α predominates in the cell and PKC ζ predominates in the matrix vesicle. In addition, when matrix vesicles are incubated directly with the vitamin D metabolites, the responsive isoform is PKC ζ rather than PKC α, and activity is decreased rather than increased. These effects are mediated by the membrane receptors for each metabolite and are by definition nongenomic because matrix vesicles lack DNA and RNA. In addition to the direct regulation of PKC ζ by $1\alpha,25(OH)_2D_3$ and $24R,25(OH)_2D_3$, matrix vesicle PKC is regulated by arachidonic acid, causing an increase in enzyme activity. Since arachidonic acid is a co-factor for PKC α, which is also present in the matrix vesicles, it is likely that this is the affected isoform. Arachidonic acid is released by growth zone chondrocytes as a consequence of the action of $1\alpha,25(OH)_2D_3$ on phospholipase A_2, providing another membrane-mediated mechanism by which the cell can transmit signals to the extracellular organelles and regulate their activity nongenomically.

VI. SUMMARY

This article has described how two metabolites of vitamin D, $1\alpha,25(OH)_2D_3$ and $24R,25(OH)_2D_3$, regulate the physiology of growth plate cartilage. Each metabolite exerts its effects primarily on a subset of the cells as the chondrocytes mature through the endochondral lineage cascade. Some of the responses are mediated through traditional 1,25-nVDR mechanisms, resulting in new gene expression and protein synthesis. Other responses involve the action of membrane-associated receptors for each metabolite, and these too can result in gene expression through the PKC α signaling pathway and MAP kinase activation. $1\alpha,25(OH)_2D_3$ and $24R,25(OH)_2D_3$ also exert direct effects on extracellular organelles via their respective membrane receptors, thereby modulating matrix maturation, growth factor activation, and calcification.

Vitamin D and Human Nutrition

NORMAN H. BELL

Medical University of South Carolina

Vitamin D is an essential fat-soluble vitamin that is acquired from dietary sources or by dermal synthesis in response to exposure to sunlight. Nutritional deficiency of vitamin D causes rickets in infants and children and osteomalacia in adults; it may also be a contributing factor in the development of osteoporosis and fractures in the elderly. Treatment with vitamin D can correct and prevent these bone diseases.

I. INTRODUCTION

Vitamin D, an essential fat-soluble vitamin, is derived from the diet as vitamin D_2 (irradiated ergosterol) or by dermal synthesis from 7-dehydrocholesterol as vitamin D_3 in response to solar ultraviolet light and body heat. Vitamin D itself is biologically inactive and must undergo hydroxylation in the liver to form 25-hydroxyvitamin D [25(OH)D] and in the kidney to form 1,25-dihydroxyvitamin D [1,25$(OH)_2$D], by vitamin D 25-hydroxylase and 25(OH)D-1α-hydroxylase, respectively. The metabolites of vitamin D_2 and D_3 have similar biologic activity, although those of vitamin D_2 are less toxic. 24-Hydroxylase is the rate-limiting enzyme for degradation of 25(OH)D and 1,25$(OH)_2$D and is genomically induced by 1,25$(OH)_2$D.

Nutritional deficiency of vitamin D leads to rickets in infants and children and to osteomalacia in adults and can be a contributing factor to the development of osteoporosis and fractures in older adults. These bone diseases can be corrected and prevented by treatment with vitamin D. Dark-skinned individuals who reside in areas of limited sunlight exposure are at particular risk for developing vitamin D deficiency and its consequences. This occurs because melanin pigment in skin absorbs

the photons of light energy and prevents activation of 7-dehydrocholesterol to eventually form vitamin D_3. Vitamin D deficiency is prevalent worldwide, especially in underdeveloped countries where foods are not fortified.

II. RICKETS

Deficiency of vitamin D is the major cause of rickets in infants and children and results from inadequate exposure to sunlight or intake of dietary vitamin D. Except for oily fishes and fortified foods, the normal diet provides little in the way of vitamin D so that adequate dermal exposure to sunlight or supplementation of vitamin D is essential to prevent rickets. In human milk, the concentrations of vitamin D and 25(OH)D are not adequate to meet daily requirements. Thus, rickets occurs in breast-fed infants who are not given vitamin D supplements, in infants before they are able to walk and be outdoors, in children living at extremes of latitude, and in children who have diminished exposure of skin as a consequence of excess clothing and lack of exposure to sunlight. African American infants with dark skin are at particular risk. In underdeveloped countries in the Middle East, for example, vitamin D deficiency is prevalent in Arab adults and children who reside near the equator because of avoidance of sunlight, wearing of clothes and veils that cover the body, lack of vitamin D supplements, and consumption of nonfortified foods and diets that are low in calcium or high in inhibitors of calcium absorption. Vitamin D deficiency also occurs in vegetarians and those who consume macrobiotic diets, regardless of where they live.

Deficiency of vitamin D leads to decrease in serum 25(OH)D and $1,25(OH)_2D$ and the intestinal absorption of calcium that in turn causes hypocalcemia, secondary hyperparathyroidism, and hypophosphatemia and results in diminished mineralization of the skeleton (Fig. 1). A decrease in serum 25(OH)D is the hallmark of vitamin D deficiency.

Children with rickets may have muscle weakness, stridor (a harsh, high-pitched respiratory sound), a waddling gait, impaired growth, and fractures and may have cataracts, seizures, tetany sometimes associated with carpopedal spasm, and a positive Chvostek sign as a consequence of hypocalcemia and tetany. Dental problems include delayed tooth eruption, defects in tooth structure, and increased incidence of caries. Patients are prone to develop pneumonia. It is not clear whether this is caused by immune deficiency as a consequence of vitamin D deficiency or myopathy resulting in poor clearing of bronchopulmonary secretions. Myopathy may include left ventricular myocardial dysfunction. These abnormalities are all corrected by vitamin D and adequate calcium intake.

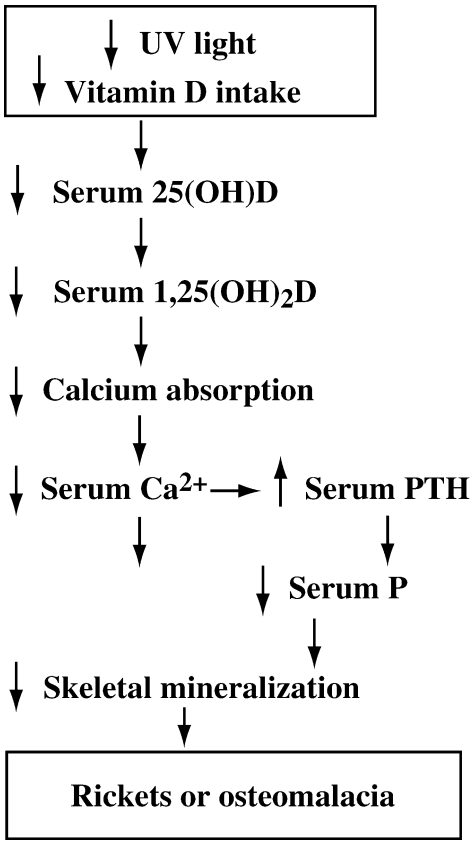

FIGURE 1 Pathogenesis of rickets and osteomalacia.

The rate of growth of different bones varies with age. Since skeletal deformities develop at sites of rapid growth, skeletal changes of rickets vary with age and may indicate the age of onset of the disease. With rapid growth in neonates, the skull is particularly affected. Softening of the cranium or craniotabes may occur with parietal flattening, frontal bossing, and widened sutures. Rapid growth of the arms and rib cage in early childhood is associated with widening of the forearm at the wrist and thickening of the costochondral junctions that results in the rachitic rosary. There may be forward projection of the breastbone or "pigeon chest" and scoliosis or kyphosis of the spine. Indentations of the lower ribs at the site of attachment of the diaphragm may occur and are called Harrison's groove. With rapid growth of long bones, bowing of the lower extremities, genu varus (bowleg) or valgus (knock-knee), may result because of weight-bearing. Deformities of the pelvis

may also occur and may severely compromise weight-bearing. Secondary hyperparathyroidism may cause resorption of the phalanges and distal ends of long bones, such as the clavicles and humeri.

Biochemical findings include low serum 25(OH)D, calcium, and phosphorus and elevated serum immunoreactive parathyroid hormone (PTH) and alkaline phosphatase. Serum $1,25(OH)_2D$ may be low, normal, or increased depending on the degree of 25(OH)D deficiency and secondary hyperparathyroidism. When present, increases in serum $1,25(OH)_2D$ induce 24-hydroxylase, enhance degradation of 25(OH)D and $1,25(OH)_2D$, and hasten the development of vitamin D deficiency.

III. OSTEOMALACIA

Osteomalacia caused by nutritional deficiency of vitamin D occurs primarily in Asian Indians and Pakistanis, more commonly in those who live far from the equator and have limited exposure to sunlight. Inadequate intake of vitamin D, increased skin pigmentation, practice of purdah by women in which veils are worn during pregnancy, parturition, and lactation, and consumption of a vegetarian diet are contributing factors.

Patients with osteomalacia may be asymptomatic or have muscle weakness and diffuse skeletal pain in the lower back, hip, or sites of fractures. Decreased skeletal density is the most common X-ray finding. Looser zones or pseudo-fractures may occur and are typically bilateral and symmetrical. Common sites are axillary margins of the scapulae, lower ribs, superior and inferior pubic rami, inner margins and neck of the proximal femora, and posterior margins of the proximal ulnae. Bone resorption caused by secondary hyperparathyroidism is sometimes the most prominent radiographic finding.

In patients with osteomalacia, bone density determined by dual-photon absorptiometry is reduced and bone scans show increased uptake of technetium-99m pyrophosphate by long bones and wrists and prominence of the calvaria and mandible. Beading of the costochondral junctions may occur and increased tracer uptake by the sternum and its margins produces the so-called "tie sternum." Pseudo-fractures appear as hot spots.

IV. OSTEOPOROSIS

Vitamin D deficiency is often present in older men and women. Decreased dermal production of 7-dehydrocholesterol, the precursor of vitamin D_3, decreased exposure intake of vitamin D, decreased exposure to sunlight, down-regulation of the vitamin D receptor in the small intestine, and decreased production of 25(OH)D and $1,25(OH)_2D$ are contributing factors. Older individuals may be house-bound as well. In addition to vitamin D, calcium intake is often inadequate in older men and women.

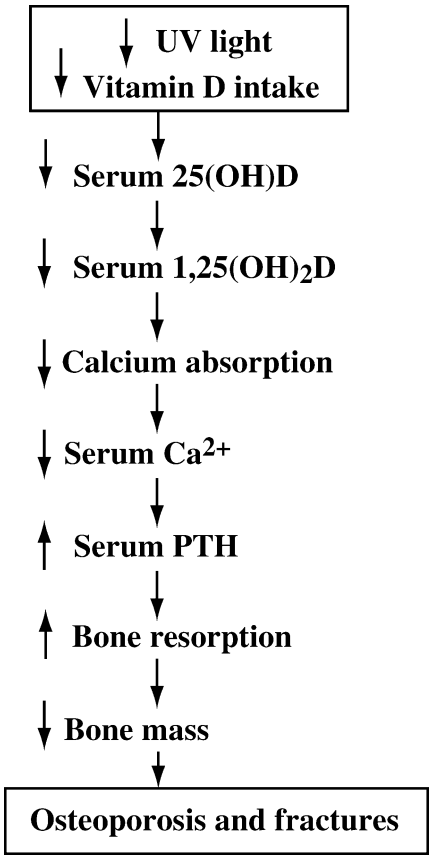

FIGURE 2 Pathogenesis of osteoporosis.

Deficiency of vitamin D leads to decrease in serum 25(OH)D and $1,25(OH)_2D$, the intestinal absorption of calcium that in turn causes hypocalcemia, secondary hyperparathyroidism, increased bone resorption, bone loss, osteoporosis, and fractures (Fig. 2).

V. TREATMENT

The most recent recommended daily intakes of vitamin D and calcium by the National Academy of Science are listed in Table 1; values for vitamin D range from 200 IU per day in children to 600 IU per day in older individuals. The normal range for serum 25(OH)D is between 10 and 60 ng/ml. However, an increase in circulating PTH is the most sensitive

TABLE I Recommendations for Daily Intake of Calcium and Vitamin D

Age (years)	Calcium (mg)	Vitamin D (IU)[a]
4–8	800	200
9–18	1300	200
19–50	1000	200
51–65	1200	400
>65	1200	600

[a] 1 IU equals 15 ng.

indicator of vitamin D deficiency, and the lowest value for serum 25(OH)D at which there is a plateau of circulating immunoreactive PTH ranges from approximately 30 to 40 ng/ml. In a recent study, serum 25(OH)D (28 to 50 ng/ml) and serum and urinary calcium remained in the normal range in normal men and women given 4000 IU per day for 2 to 5 months. Furthermore, a comprehensive review of the literature indicated that serum 25(OH)D does not begin to increase abnormally and cause hypercalcemia until a daily dose of more than 10,000 IU is administered. Thus, there is a wide margin of safety between therapeutic and toxic doses of vitamin D.

In patients with rickets or osteomalacia, the goals of treatment are to correct and prevent the effects of hypocalcemia, cataracts, seizures, and skeletal effects of secondary hyperparathyroidism, to prevent and correct the skeletal deformities of rickets and osteomalacia, to prevent hypercalcemia, hypercalciuria, and their consequences, and to produce normal growth and development of the skeleton in children.

Vitamin D deficiency is treated with vitamin D. Although 400 IU per day of the vitamin is an adequate maintenance dose, the initial dose should be larger, perhaps 1200 IU per day.

Stoss therapy with an intramuscular dose of 150,000 IU of vitamin D or more is recommended by some. Excess vitamin D produces intoxication that is associated with hypercalcemia and hypercalciuria; it is caused by increased circulating 25(OH)D and is produced by daily doses in excess of 10,000 IU. Serum $1,25(OH)_2D$ is usually in the normal range. Available evidence indicates that hypercalcemia does not occur at doses of 10,000 IU per day of vitamin D or less. Vitamin D intoxication is treated by discontinuing the vitamin D, by forcing fluids, and, if necessary, by treatment with dexamethasone or hydrocortisone.

Although it is well documented that elderly subjects may be deficient in vitamin D, that vitamin D deficiency can lead to secondary hyperparathyroidism, increased bone resorption, and increased bone loss, and that the incidence of fractures can be reduced by treatment with vitamin D and calcium, results of studies in which $25(OH)D_3$ and calcium were given separately to men and women show that calcium is more effective than $25(OH)D_3$ at increasing bone mineral density. The recommended intake for calcium in individuals over the age of 65 years is 1200 mg per day.

VI. SUMMARY

Vitamin D deficiency is prevalent especially in underdeveloped countries where foods are not fortified with vitamin D. Breast-fed infants, particularly African American infants, are at risk for rickets if they are not given vitamin D or exposed to sunlight. Asian Indians and Pakistanis are at risk for developing rickets and osteomalacia especially when they have limited access to sunlight and vitamin D. Aging men and women are prone to vitamin D deficiency, osteoporosis, and fractures and can be treated with calcium and vitamin D. Recent evidence indicates that daily doses of vitamin D as high as 4000 IU are well tolerated and do not increase serum 25(OH)D or serum or urinary calcium abnormally.

Glossary

carpopedal spasm Spasm of the wrist and foot produced by hypocalcemia and tetany.

Chvostek's sign A spasm of the facial muscles in response to tapping of the facial nerve that is caused by hypocalcemia and tetany.

craniotabes Caused by softening of the cranium and associated with parietal flattening of the sides of the skull, frontal bossing or exaggeration of the curvature of the forehead, and widened sutures or sites of attachment of bones to one another.

kyphosis Enhanced curvature of the spine as seen from the side, or hunchback.

osteomalacia A bone disease that occurs in adults as a result of vitamin D deficiency and that is caused by abnormal mineralization of the skeleton and weak bone that is prone to bend and fracture.

osteoporosis A bone disease that is characterized by decreased bone mass and alterations in microarchitecture, resulting in increased skeletal fragility and risk of fracture.

pigeon chest The forward projection of the breastbone that occurs with rickets.

pseudo-fracture A thickening of periosteum or bone surface and formation of new bone over what appears to be a fracture on X ray. It is usually found at the site of a

pulsating artery and may result from softening of bone and arterial pulsation.

rachitic rosary Caused by thickening of the costochondral junctions of the ribs.

rickets A bone disease that occurs in children as a result of vitamin D deficiency and is caused by abnormal mineralization of the skeleton and weak bone that is prone to bend and fracture. Rapid growth of the arms and rib cage in early childhood is associated with widening of the forearm at the wrist and scoliosis or kyphosis of the spine. Indentations of the lower ribs at the site of attachment of the diaphragm may occur and are called Harrison's groove.

scoliosis A lateral curvature of the spine.

Vitamin D-Binding Protein

IVY HURWITZ AND NANCY E. COOKE
University of Pennsylvania

Vitamin D-binding protein (DBP) plays a major role in the binding, solubilization, and serum transport of the principal vitamin D metabolites 25-hydroxyvitamin D_3, the major circulating metabolite, and 1,25-dihydroxyvitamin D_3, the more biologically active metabolite. However, circulating DBP concentrations are approximately 20-fold higher than that of total vitamin D metabolites. This large excess is unusual among other serum carrier proteins, suggesting other roles for this protein.

I. INTRODUCTION

Vitamin D-binding protein (DBP), also referred to as group-specific component of serum or Gc-globulin, was initially identified by its polymorphic migration pattern on serum electrophoresis. Although its function remained relatively unknown at that time, its highly polymorphic nature allowed DBP to play a

to fracture. In the case of rickets, a number of additional skeletal abnormalities are found, including bowing of the long bones, joint pain and swelling, bone pain, and abnormalities of the teeth. In severe vitamin D insufficiency, infants with rickets may show delayed development and even respiratory failure if thoracic cage development is impaired sufficiently to restrict breathing.

II. NORMAL VITAMIN D PHYSIOLOGY

A. Synthesis

Calcium is absorbed in the upper small intestine under the control of the active vitamin D hormone, 1,25-dihydroxyvitamin D_3 [1,25$(OH)_2D_3$], also known as calcitriol (in this article these terms are used interchangeably). There are two forms of vitamin D: vitamin D_2 (ergocalciferol), of plant origin, and vitamin D_3 (cholecalciferol), of animal origin. Vitamin D_3 can be synthesized in the skin with the aid of sunlight or it is ingested in the diet. The distribution of vitamin D_3 in food is quite restricted, being substantial mainly in oily fish. Because dietary vitamin D is so limited, in some countries various foods (milk, cereals, etc.) have been fortified with either vitamin D_2 or vitamin D_3 in order to avoid widespread vitamin D deficiency. Even in countries with standard vitamin D fortification programs, however, nutritional sources of vitamin D may be limited and exposure to sunlight is critical for adequate endogenous production of vitamin D_3.

As outlined in Fig. 1, vitamin D is ingested in the diet or is endogenously manufactured following exposure to ultraviolet rays of sunlight, which causes conversion of the precursor 7-dehydrocholesterol to vitamin D_3 in the skin. Vitamin D_3 is subsequently converted to the active hormone by a two-step process, first by 25-hydroxylation in the liver to 25-hydroxyvitamin D_3 and then by 1-hydroxylation in the kidney to 1,25-dihydroxyvitamin D_3. 1,25-Dihydroxyvitamin D_3 then acts via the intranuclear vitamin D receptor (VDR) to regulate target genes, in a pathway similar to those of other steroid hormones. The target genes are involved in regulation of calcium and phosphate delivery to the bone-forming sites to mineralize osteoid.

Any step in the pathway of calcitriol synthesis or action that is defective can result in rickets/osteomalacia. The usual causes of rickets/osteomalacia are shown in Fig. 1 and are detailed in Table 1. The most common cause of rickets/osteomalacia worldwide is nutritional vitamin D deficiency, combined with insufficient synthesis in the skin. This can be caused by inadequate dietary consumption of vitamin D and/or by malabsorption of vitamin D in the gastrointestinal tract, coupled with inadequate sunlight exposure. Because vitamin D supplementation

Autosomal dominant hypophosphatemic rickets (ADHR)
Miscellaneous causes
Acidosis
Phosphate depletion
Renal tubular disorders

of milk or other dietary products reduces nutritional causes of rickets/osteomalacia in the United States and in other developed countries, other etiologies are becoming more important. Other causes of rickets/osteomalacia include the inability to synthesize calcitriol due to renal failure or due to a genetic defect in 1α-hydroxylase, the key enzyme involved in calcitriol synthesis. Abnormalities that cause excess loss of phosphate include genetic defects or tumors that produce phosphaturia. Finally, mutations in the vitamin D receptor, the protein that mediates calcitriol actions in the intestine and other target tissues, can cause rickets in children.

B. Regulation of Calcium and Phosphate Homeostasis

Control of calcium levels in the serum is tightly regulated by the interplay of calcitriol and parathyroid hormone (PTH). As depicted in Fig. 2, serum calcium concentration is monitored by the calcium-sensing receptor present in the parathyroid glands and possibly also in the kidney and other sites. PTH synthesis is negatively regulated by calcium and by calcitriol. When the calcium concentration falls, the PTH level rises in an attempt to restore serum calcium to normal. The actions of PTH on the skeleton increase bone resorption whereas the actions of PTH on the kidney reduce the level of calcium excretion. Both processes help to maintain serum calcium within the normal range. Importantly, the actions of PTH on the kidney also result in increased activation of the 1α-hydroxylase enzyme, which augments conversion of circulating 25-hydroxyvitamin D_3 to the active hormone calcitriol. The increased concentration of calcitriol activates intestinal cells to increase calcium absorption along the length of the intestine. These combined actions restore the circulating calcium concentration to normal. Elevated levels of PTH return to normal in response both to normalization of serum calcium and to feedback inhibition of PTH production by a direct action of calcitriol on the parathyroid glands.

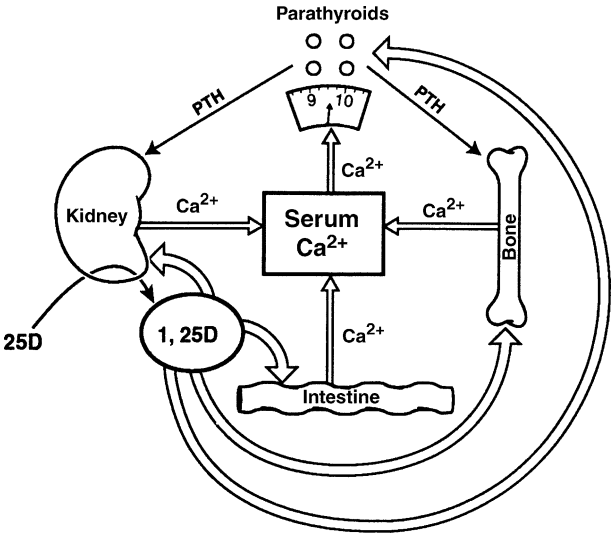

FIGURE 2 Regulation of serum Ca^{2+} levels. The control of calcium levels in the blood is tightly regulated by vitamin D and parathyroid hormone (PTH). Gastrointestinal absorption of calcium from the diet is controlled by the activity of 1,25-dihydroxyvitamin D_3 (1,25D). The active form of vitamin D is synthesized in the kidney by 1α-hydroxylation of circulating 25-hydroxyvitamin D_3 (25D). 1,25-Dihydroxyvitamin D_3 also acts on bone to resorb calcium and on the parathyroid glands to suppress PTH. The calcium-sensing receptor in the parathyroids detects the concentration of serum calcium. When calcium levels begin to fall, PTH secretion is increased, which acts on the kidney to stimulate 1α-hydroxylase activity and increase 1,25-dihydroxyvitamin D_3 synthesis. PTH also acts on bone and kidney to elevate serum calcium levels. Reproduced from Feldman *et al.* (2001), with permission from Elsevier Science.

Control of phosphate levels is in part controlled by vitamin D but, importantly, is also regulated by other systems that are incompletely understood. Calcitriol increases both calcium and phosphate absorption from the intestine. PTH, although it increases calcium reabsorption in the kidney, inhibits phosphate reabsorption, causing phosphaturia. Renal phosphate transport is controlled by sodium phosphate cotransporter type IIa (NPT2), which is responsible for the bulk of phosphate reabsorption in the proximal tubule of the kidney. It is postulated that there is a phosphate-regulating hormone, phosphatonin, that regulates NPT2. Recent data suggest that fibroblast growth factor 23 (FGF 23) may be the phosphate-regulating molecule. Abnormalities of phosphatonin balance contribute to several causes of rickets/osteomalacia (see Section IV,A).

C. The Vitamin D Receptor

Although called a vitamin, 1,25-dihydroxyvitamin D_3 is actually a member of the steroid hormone family. 1,25-Dihydroxyvitamin D_3 regulates calcium metabolism and promotes other physiologic actions through the vitamin D receptor, a member of the steroid/thyroid/retinoid receptor gene superfamily. These receptors regulate gene transcription by acting as ligand-activated transcription factors (see Fig. 3). Members of this receptor family share a modular structure comprising an N-terminal transactivation domain of variable length, a DNA-binding domain

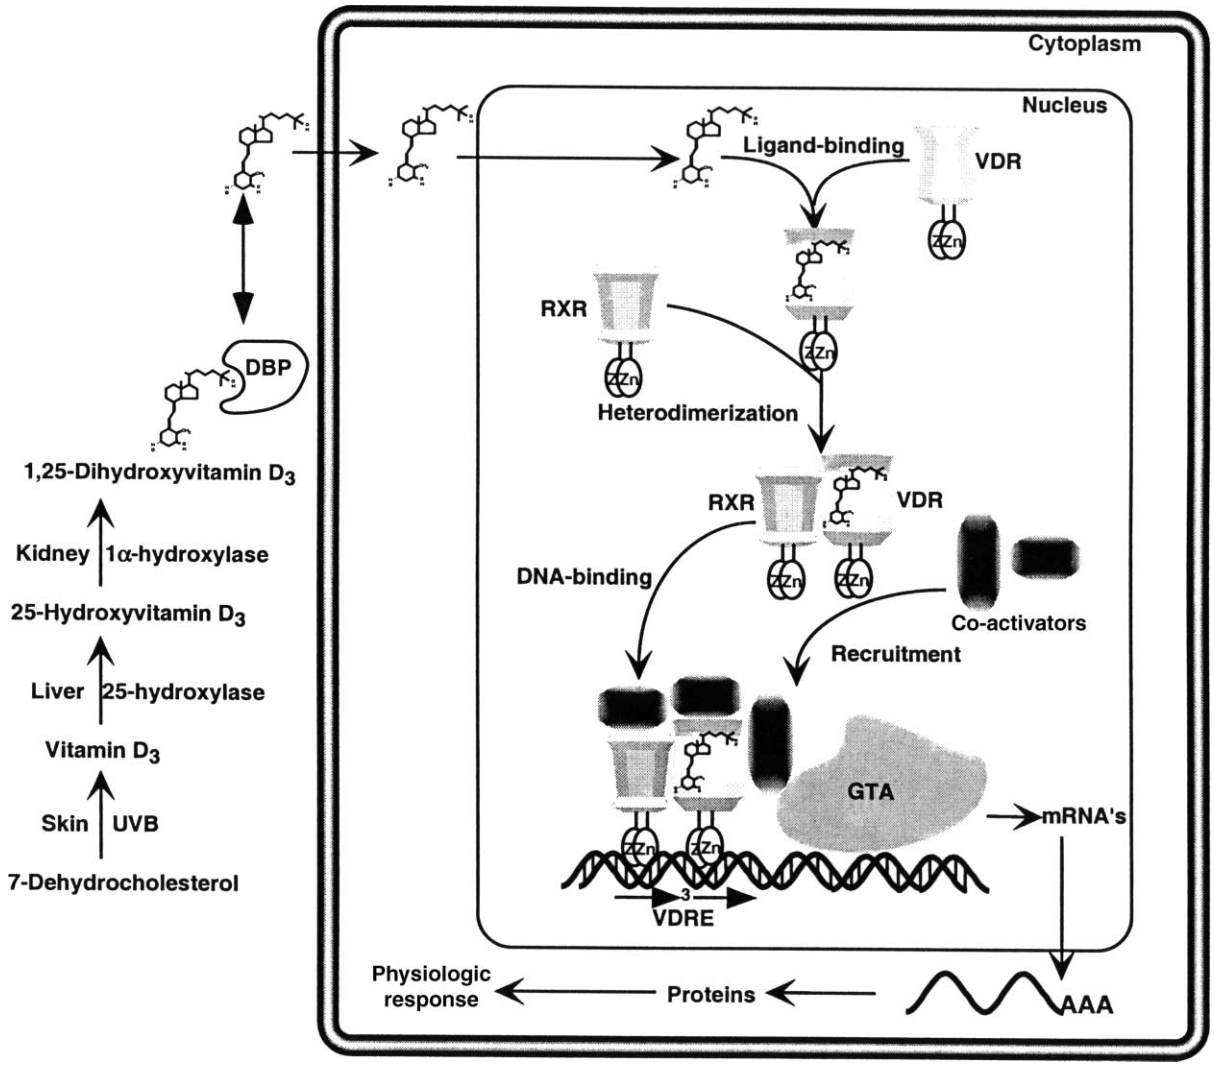

FIGURE 3 Mechanism of 1,25-dihydroxyvitamin D_3 action on target cells. After conversion of 7-dehydrocholesterol in the skin by ultraviolet B (UVB) light, the active form of vitamin D, 1,25-dihydroxyvitamin D_3, is synthesized by sequential hydroxylation steps in the liver and kidney. Once in the circulation, some of 1,25-dihydroxyvitamin D_3 is bound by the vitamin D-binding protein (DBP), and a small amount remains free. The free 1,25-dihydroxyvitamin D_3 enters the cell and binds to the vitamin D receptor (VDR). The occupied VDR heterodimerizes with the retinoid X receptor (RXR) and binds to vitamin D response elements (VDREs) on target genes. Binding to DNA is carried out by the two zinc (Zn) finger DNA-binding domains of the VDR. Co-activators are recruited to the VDR-RXR complex, allowing the general transcription apparatus (GTA) to initiate gene transcription. Reproduced from Malloy, P. J., Pike, J. W., and Feldman, D. (1999). The vitamin D receptor and the syndrome of hereditary 1, 25-dihydroxyvitamin D-resistant rickets. *Endocr. Rev.* **20**, 156–188. Copyright The Endocrine Society.

(DBD) that enables interaction of the receptor proteins with hormone response elements in promoter regions of target genes, and a C-terminal ligand-binding domain (LBD). In addition, a highly conserved region at the C-terminus of the LBD, defined as the activation function-2 domain (AF-2), regulates transcription. Like other steroid receptors, the VDR LBD binds specifically to its cognate ligand, calcitriol, triggering a series of molecular events leading to the activation of vitamin D-responsive genes. Regulation of specific gene transcription by the VDR requires its binding as a heterodimer with the retinoid X receptor (RXR). RXR heterodimerizes with a number of other receptors in the steroid/thyroid/retinoid gene superfamily, including thyroid receptor, retinoic acid receptor, and the peroxisome

proliferator-activating receptor. Initiation of gene transcription also involves the recruitment of co-activator proteins that act as bridging factors linking the VDR to the preinitiation complexes and RNA polymerase II. Co-activators include a family of closely related p160 proteins such as SRC-1/NcoA1, TIF2/GRIP1/NcoA2/SRC-2, and pCIP/Rac3/ACTR/AIB1/SRC-3. Other co-activators include a group of proteins collectively called vitamin D receptor-interacting proteins (DRIPs). These co-activator proteins associate with nuclear receptors in a ligand-dependent manner to enhance transactivation of target genes.

D. Mechanism of Action

How do cells respond to calcitriol? A simplified model of calcitriol action is shown in Fig. 3. After the hormone is produced and secreted by the kidney, it is transported in the blood either bound to vitamin D-binding protein (DBP) or in the free state. The free hormone is lipid-soluble and readily gains entry into cells by permeating the lipid bilayer of the cell membrane. Cells that respond to calcitriol have VDRs located in the cell nuclear compartment, where they are loosely associated with the RXR. Once inside the cell, calcitriol encounters the VDR and binds in the ligand-binding pocket in the LBD. Calcitriol binding causes the VDR to bind more tightly to the RXR and to interact with vitamin D response elements (VDREs) on target genes. When calcitriol occupies the ligand-binding pocket, helix H12 in the VDR LBD swings into position, locking the hormone inside the binding domain and at the same time forming a new surface interface for interaction with co-activators. The co-activators that are recruited by the VDR, such as steroid receptor co-activator-1 (SRC-1), are then able to remodel the chromatin so that assembly of the transcriptional apparatus can take place. The VDR can then recruit the DRIP complex and begin activating gene transcription.

III. VITAMIN D DEFICIENCY, RICKETS AND OSTEOMALACIA

A. Nutritional Deficiency

Vitamin D deficiency causes a constellation of metabolic abnormalities that combine to cause osteomalacia or rickets. The insufficiency of vitamin D, if severe, can result in diminished intestinal calcium absorption and hypocalcemia. The calcium-sensing receptor present in the parathyroid gland detects the low serum calcium level. This leads to an increase in PTH synthesis and results in secondary hyperparathyroidism. The elevated levels of PTH allow correction of the hypocalcemia by three actions on bone and kidney. One action is aimed at stimulating renal 1α-hydroxylase activity to cause increased renal production of calcitriol. However, for increased production of calcitriol, this step requires adequate vitamin D_3 and 25-hydroxyvitamin D_3 substrate, which is inadequate in vitamin D deficiency. A second PTH action on bone is to increase bone resorption, thus increasing calcium and phosphate flux from bone to serum. A third PTH action is to increase renal calcium reabsorption and decrease calciuria. However, PTH, while decreasing calciuria, increases phosphaturia, thus reducing the availability of this mineral component for bone mineralization. The overall result of vitamin D deficiency is hypocalcemia, secondary hyperparathyroidism, and defective mineralization of osteoid, leading to the development of osteomalacia.

It is clear that adequate calcium and vitamin D_3 are required for bone health. The vitamin D_3 requirement is estimated to be 400 international units (IU) per day, although elderly subjects may require 600 IU or more. Most infants and children in the United States have adequate vitamin D intake because of vitamin D supplementation of milk. During adolescence, when consumption of milk and dairy products diminishes, decreased dietary vitamin D may adversely affect calcium absorption and thereby lead to impaired skeletal health. Vitamin D insufficiency in the elderly population greatly increases their risk for both osteoporosis and osteomalacia. This problem is more severe in countries that do not supplement milk or other foods with vitamin D and where sunlight exposure may be inadequate.

Except for oily fish, most dietary components lack substantial levels of vitamin D_3. In the United States, milk is ostensibly fortified with 400 IU of vitamin D_3 per quart, although amounts vary. For the many individuals who do not include in their diet adequate amounts of milk or dairy products, exposure to ultraviolet radiation from sunlight is necessary to achieve normal vitamin D status. Endogenous vitamin D production occurs in the skin, which contains a vitamin D_3 precursor, 7-dehydrocholesterol; this compound undergoes photolysis on exposure to solar irradiation and is converted to vitamin D. Thus, inadequate dietary intake and inadequate sun exposure lead to vitamin D insufficiency. This problem is exacerbated by several modern trends, including avoidance of dairy products to control weight or high

cholesterol and avoidance of sunlight to reduce the risk of skin cancer. Also, many elderly individuals have limited mobility and do not have the opportunity for adequate sunlight exposure. These circumstances have led to a substantial increase in the frequency of osteomalacic bone disease and fractures in the elderly, especially among the nursing home population. In wintertime, the problem of reduced sunlight further diminishes vitamin D_3 synthesis and worsens the tendency toward vitamin D_3 insufficiency. Races of people with dark skin have further difficulty with adequate vitamin D_3 synthesis, because the melanin in the skin is a natural sunscreen that reduces the penetration of ultraviolet rays into the layers of the dermis where vitamin D_3 is formed.

Deficient dietary calcium intake may also cause osteomalacia or exacerbate the problem of vitamin D insufficiency. There exists a spectrum of etiologies ranging from pure vitamin D deficiency with normal calcium to adequate vitamin D sufficiency with inadequate calcium. Worldwide, many cases of osteomalacia are due to vitamin D insufficiency combined with relative calcium insufficiency. Certain dietary habits common in selected populations may exacerbate vitamin D insufficiency by inhibiting vitamin D absorption or by increasing the metabolic clearance of 25-hydroxyvitamin D_3. The consumption of chapattis, an East Asian bread made from wheat flour with high phytate levels, impairs both calcium and vitamin D absorption. Thus, inadequate sunlight exposure and dietary habits combine in a variety of situations—e.g., because of customs, life-style choices (vegetarianism, high-fiber diets), or economic, age-related, and geographic circumstance (living at high altitude, calcium-deficient diets)—to exacerbate vitamin D insufficiency, thus determining the risk and severity of osteomalacic bone disease.

B. Gastrointestinal Problems and Malabsorption of Vitamin D

In parts of the world where there are no programs to fortify foodstuffs with vitamin D, the diet of much of the population is estimated to contribute only one-quarter to one-third of the daily requirement of vitamin D. In such populations, therefore, gastrointestinal malabsorption may worsen the vitamin D insufficiency, but is not often the sole cause of osteomalacia. Some gastrointestinal problems are associated with increased metabolic clearance of vitamin D metabolites, compounding the malabsorption problem. Gastrointestinal diseases associated with osteomalacia include celiac disease (gluten enteropathy), cirrhosis, biliary obstruction, pancreatic insufficiency, inflammatory bowel disease, and post-gastrectomy or jejuno-ileal bypass surgery. Patients receiving total parenteral nutrition (TPN), usually because of chronic bowel disease, develop osteomalacia due to inadequate mineral or vitamin D supplementation. Anticonvulsant therapy increases the metabolic clearance of vitamin D metabolites, requiring vitamin D supplementation.

C. Renal Osteodystrophy

Renal failure is associated with complex abnormalities of vitamin D and calcium metabolism. Phosphate retention due to inadequate kidney function causes hypocalcemia by complexing calcium and inhibiting renal 1α-hydroxylase activity, and therefore diminishing calcitriol synthesis. Also, as kidneys shrink and renal functional tissue declines, 1α-hydroxylase activity is further diminished, leading to deficiency of calcitriol production. These changes also lead to secondary hyperparathyroidism, compounding the bone abnormality. The constellation of hypocalcemia, secondary hyperparathyroidism, and calcitriol deficiency causes osteomalacia and renal osteodystrophy. Recognition of this sequence of events has led to important changes in the medical management of renal failure in an attempt to prevent the development of renal osteodystrophy. Two major therapeutic measures include the use of phosphate binders to minimize and/or prevent the development of elevated phosphate concentration and its consequent hypocalcemia, and supplementation with calcitriol to avoid deficiency of active vitamin D.

D. Tumor-Induced Osteomalacia

Some small mesenchymal tumors (hemangiopericytomas, fibromas, angiosarcomas, etc.) can cause phosphaturia and hypophosphatemia, leading to osteomalacia. The syndrome is known as tumor-induced osteomalacia (TIO), or oncogenic osteomalacia. The mechanism involves the synthesis and secretion of excessive amounts of a phosphaturic factor. Currently, the major candidate for this role is FGF 23. How FGF 23 causes phosphaturia is still not completely understood. However, recent findings from the study of X-linked hypophosphatemia and autosomal dominant hypophosphatemic rickets have shed light on TIO and on the mechanisms for all three phosphaturic entities. The tumors causing TIO originally were thought to be benign and of mesenchymal origin, but malignant tumors have also been reported to cause the syndrome. Often the tumors are small and

difficult to locate. The levels of calcitriol are inappropriately low (hypophosphatemia should stimulate calcitriol production) and so the tumor product is also thought to interfere with renal 1α-hydroxylation. The osteomalacia responds to treatment with large phosphate supplements, which restore phosphate levels to normal. The syndrome can be cured by successfully removing the tumor.

IV. HEREDITARY RICKETS

A comparison of hereditary causes of rickets is shown in Table 2.

A. Hypophosphatemic Rickets

1. X-Linked Hypophosphatemic Rickets

X-Linked hypophosphatemia (XLH), an X-linked dominant disorder caused by renal phosphate wasting, results in severe skeletal abnormalities and growth retardation. The primary mechanism, defective phosphate reabsorption in the renal proximal tubule, impairs phosphate reabsorption. The clinical presentation is usually not apparent until 6–12 months of age and ranges from mild abnormalities of the bones to severe rickets and osteomalacia. Children exhibit rachitic bone deformities, including enlargement of the wrists and knees and bowing of the lower extremities. Defects in tooth development and premature cranial synostoses may also be present. Low or inappropriately normal circulating levels of calcitriol are found despite the hypophosphatemia. The low serum phosphate normally causes an increase in 1α-hydroxylase activity and enhanced calcitriol production, suggesting that XLH may also result in abnormal regulation of 1α-hydroxylase.

The gene causing XLH has been cloned; it is a phosphate-regulating gene with homologies to endopeptidases and is located on the X-chromosome, thus it has been named *PHEX*. The *PHEX* gene is homologous to a family of endopeptidases that includes endothelin-converting enzyme-1 and neutral endopeptidase. The *PHEX* gene encodes a 749-amino-acid membrane-bound protein that is expressed in bone, adult ovary, lung, and fetal liver. A number of genetic defects in the *PHEX* gene have been found in patients with XLH. Because many of the mutations are inactivating mutations, the X-linked dominant expression of the disorder is likely the result of the loss of a single functioning allele (haploinsufficiency) coded by the X-chromosome rather than the result of a dominant negative effect.

2. Autosomal Dominant Hypophosphatemic Rickets

Autosomal dominant hypophosphatemic rickets (ADHR), an autosomal dominant disorder caused by phosphate wasting, has findings commonly seen in other phosphate wasting disorders. Patients have short stature, bone pain, rickets, and osteomalacia. The patients also have inappropriately normal serum calcitriol concentrations.

The gene causing ADHR has been cloned; recent data have suggested that fibroblast growth factor 23 is the phosphate-regulating molecule, thus the ADHR gene has been named *FGF23*. The *FGF23* gene encodes a member of the fibroblast growth factor family, a 251-amino-acid protein that is expressed in heart, lymph node, thymus, and liver. Three unique mutations have been found in the *FGF23* gene in patients with ADHR. These mutations affect two arginine residues located in a consensus proteolytic cleavage site. The mutations prevent degradation of *FGF-23* and thus result in enhanced or prolonged action leading to phosphate wasting and the syndrome of ADHR.

TABLE 2 Comparison of Genetic Causes of Rickets[a]

Component	1α-Hydroxylase deficiency	HVDRR	XLH	ADHR
Gene	*CYP27B1*	*VDR*	*PHEX*	*FGF23*
$1,25(OH)_2D_3$	Low	High	(Normal)	(Normal)
PTH	High	High	Normal	Normal
Calcium	Low	Low	Normal	Normal
Phosphate	Low	Low	Low	Low
Alopecia	No	Yes	No	No

[a] 1α-Hydroxylase deficiency, causes vitamin D-dependent rickets, type I; HVDRR, hereditary vitamin D-resistant rickets; XLH, X-linked hypophosphatemic rickets; ADHR, autosomal dominant hypophosphatemic rickets; (normal) indicates inappropriately normal relative to decreased serum phosphate concentration.

3. Mechanism of Phosphate Loss in XLH, ADHR, and TIO

How are *PHEX* and *FGF23* involved in the pathophysiology of XLH, ADHR, and TIO? One current hypothesis is that under conditions of normal phosphate regulation the *PHEX*-encoded enzyme regulates the bioavailability of the *FGF23*-encoded protein, the putative phosphatonin molecule. As *FGF23* product is secreted from cells, some of it is degraded to inactive metabolites by the membrane-bound *PHEX* endopeptidase. The remaining active *FGF23* product enters the circulation and interacts with a receptor protein on the renal tubule cells. Binding transmits a signal to down-regulate the activity of the sodium-dependent phosphate cotransporter (NPT2) in the kidney and to decrease phosphate reabsorption. In XLH patients, the mutant *PHEX* protein or lack thereof is unable to degrade the *FGF23* protein. This leads to excess amounts of *FGF23* protein in the circulation. As a result, the signal to down-regulate NPT2 activity is magnified, leading to renal phosphate wasting. In ADHR, on the other hand, mutations in *FGF23* prevent the proteolytic processing step by the *PHEX* product and therefore there is an overabundance of active *FGF23* protein, which then leads to down-regulation of NPT2 activity, which causes phosphate wasting. In TIO, tumors overexpress *FGF23* protein, and elevated secretion by the tumors also leads to phosphate wasting and osteomalacia in this condition.

B. 1α-Hydroxylase Deficiency

This disease was originally known as vitamin D-dependent rickets type I (VDDR-I). Other names include pseudo-vitamin D deficiency type I and pseudo-vitamin D deficiency rickets (PDDR). We prefer to refer to the entity as 1α-hydroxylase deficiency because it has been shown to be caused by mutations in the cytochrome P450 enzyme, 25-hydroxyvitamin D 1α-hydroxylase (1α-hydroxylase). The human 1α-hydroxylase gene (*CYP27B1*) is located on chromosome 12. A number of mutations that disrupt 1α-hydroxylase activity are found scattered throughout the entire region of the *CYP27B1* gene. 1α-Hydroxylase deficiency is a rare autosomal recessive disease that is manifested at an early age. Patients exhibit hypocalcemia, elevated levels of PTH and alkaline phosphatase, and low levels of urine calcium. Affected children present with hypotonia, muscle weakness, growth failure, and rickets. Tetany and convulsions may occur with severe hypocalcemia. Patients have normal serum concentrations of 25-hydroxyvitamin D_3 but low levels of $1,25(OH)_2D_3$ due to the defective synthesis of $1,25(OH)_2D_3$. PTH infusion does not increase circulating $1,25(OH)_2D_3$ levels, consistent with a defect in 1α-hydroxylase activity. Very large doses of vitamin D_3 or 25-hydroxyvitamin D_3 are required for adequate treatment of 1α-hydroxylase deficiency; often, daily vitamin D doses of 20,000 to over 100,000 IU are needed. On the other hand, modest doses of $1,25(OH)_2D_3$ (0.25–2 μg/day) tend to be sufficient to restore calcium to normal and to heal the rickets. Because mutations in 1α-hydroxylase block $1,25(OH)_2D_3$ synthesis, this latter treatment bypasses the defect and reverses the abnormalities caused by the disease.

C. Hereditary 1,25-Dihydroxyvitamin D_3-Resistant Rickets

Hereditary 1,25-dihydroxyvitamin D_3-resistant rickets (HVDRR) is known as vitamin D-dependent rickets type II (VDDR-II), or pseudo-vitamin D deficiency type II. This rare genetic disease arises as a result of mutations in the VDR; HVDRR is an autosomal recessive disease characterized by early-onset rickets, hypocalcemia, secondary hyperparathyroidism, and normal or elevated serum $1,25(OH)_2D$ levels. Parents of children with HVDRR usually have a history of consanguinity and have no evidence of bone disease. In many cases, the affected child exhibits total body alopecia, lacking all body hair, including eyelids and eyelashes. The alopecia, which usually occurs within the first year after birth, provides evidence for the HVDRR syndrome.

Several missense mutations have been identified in the VDR DBD. These usually occur in highly conserved amino acids. In a few families, nonsense mutations that result in premature termination of the VDR have also been found. Some premature termination signals result from mutations that cause exon skipping or affect RNA splicing. A number of missense mutations in the VDR LBD have also been identified. In one case, an arginine at codon 274 was mutated to leucine, which affected $1,25(OH)_2D_3$ binding. Arginine 274 is the contact point for the 1-hydroxyl group of $1,25(OH)_2D_3$ in the ligand-binding pocket of the VDR. In a second case, histidine was mutated to glutamine at codon 305, which caused a 5- to 10-fold reduction in $1,25(OH)_2D_3$ binding and a similar reduction in gene transactivation. Histidine 305 is the residue that makes contact with the 25-hydroxyl group of $1,25(OH)_2D_3$. Some mutations also disrupt RXR heterodimeriztion with the VDR. An arginine to

cysteine mutation at codon 391 interfered with RXR binding but did not affect $1,25(OH)_2D_3$ binding, whereas another mutation, phenylalanine to cysteine at codon 251, affected both $1,25(OH)_2D_3$ binding and RXR heterodimeriztion. Interestingly, there has been one case of HVDRR in which no mutations were found in the VDR. The patient exhibited all the signs of HVDRR, including alopecia. This case highlights the fact that proteins other than VDR are involved in $1,25(OH)_2D_3$ signaling and that defects in these proteins may also cause the HVDRR syndrome. Genetic defects in co-activators may also be the molecular basis for other steroid hormone-resistant syndromes.

Some children with HVDRR respond to large doses of calcitriol, which can overcome the VDR ligand-binding defects, whereas others respond to large doses of calcium and calcitriol. However, in cases in which the VDR is completely inactivated, the patients are unresponsive to large doses of vitamin D derivatives or oral calcium supplements. Successful treatment of these children has been achieved by chronic intravenous administration of calcium infusions, given nightly over a period of many months. This treatment bypasses the intestinal defect in calcium absorption and over time is able to correct the hypocalcemia. The treatment eventually results in normalization of serum calcium levels, correction of secondary hyperparathyroidism, and normal mineralization of bone and healing of rickets, as evidenced on X-rays. Clinical improvement can be sustained if adequate serum calcium and phosphorus concentrations are maintained. Although intravenous calcium may have been required to render the child normocalcemic, the benefits can sometimes be maintained thereafter by oral calcium. However, alopecia, if present, does not improve as a consequence of the treatment.

V. SUMMARY

Many forms of rickets/osteomalacia are due to genetic defects in the synthesis or action of calcitriol or to conditions that cause phosphate loss. Recent improvements in our understanding of the molecular mechanisms by which these defects cause rickets or osteomalacia have led to improved diagnostic and treatment strategies. However, the commonest cause of rickets/osteomalacia worldwide is deficiency of vitamin D. Fortification of dietary foodstuffs or provision of vitamin D_3 supplements to individuals at risk would greatly reduce the impact of this devastating disease of the skeleton.

Glossary

1α-hydroxylase Cytochrome P450 enzyme that converts 25-hydroxyvitamin D_3 to 1,25-dihydroxyvitamin D_3 by catalyzing the addition of a hydroxyl group at the C-1 position.

osteomalacia Bone disease in which mineralization of the collagen matrix of bone is defective, causing softening of the bones and susceptibility to fracture.

osteoporosis Bone disease causing increased susceptibility to fracture; although the bones have a normal content of mineral and matrix, bone loss causes porosity and fragility.

PHEX Gene on the X chromosome that encodes a membrane-bound protein with endopeptidase activity; mutations have been found in the disease X-linked hypophosphatemia.

rickets Osteomalacic disease in a growing child; caused by inadequate mineralization of bone and cartilage, resulting in bowing of the weight-bearing bones of the extremities, joint swelling, pain in bones and joints, and other skeletal problems due to softening of the bones.

vitamin D receptor Member of the steroid/retinoid/thyroid superfamily of nuclear receptors; mediates 1,25-dihydroxyvitamin D_3 actions to regulate gene expression in target cells.

Vitamin D-Dependent Calbindins (CaBP)

ANGELA PORTA, PUNEET DHAWAN, KRISTEN GENGARO, YAN LIU, XIAORONG PENG, AND SYLVIA CHRISTAKOS

University of Medicine and Dentistry of New Jersey

Calbindin-D_{9k} and calbindin-D_{28k} are intracellular calcium-binding proteins that are present in many different tissues whose production is stimulated by the steroid hormone $1\alpha,25(OH)_2D_3$. The calbindins serve different functions and are regulated by several steroids as well as by factors that affect signal transduction pathways. Understanding their functions and activities may lead to therapeutic intervention in disorders of calcium metabolism and bone development.

I. INTRODUCTION

Increased synthesis in the intestine and kidney of the calcium-binding protein, calbindin, the first identified molecular target of vitamin D action, is one of the most pronounced effects of vitamin D known. There are two major subclasses of calbindin: calbindin-D_{9k} (a 9000-Da protein that is present in highest concentrations in mammalian intestine and in mouse and neonatal rat kidney, placenta, and uterus) and calbindin-D_{28k} (a 28,000-Da protein that is highly conserved in evolution and is present in highest concentrations in avian intestine and mammalian and avian kidney, brain, and pancreas). There is no amino acid sequence homology between calbindin-D_{9k} and calbindin-D_{28k}. The calbindins belong to a family of intracellular proteins that bind calcium with high affinity. Other members of this family include calmodulin, parvalbumin, troponin C, calretinin, calcineurin, the myosin light chains, and S100α and S100β. A characteristic of all of these proteins is the EF-hand structural motif. The EF-hand domain is an octahedral calcium-binding structure formed by a helix–loop–helix conformation of the polypeptide chain. The loop contains the side chain oxygens necessary for binding the calcium cation, and within one protein, amino acid linker sequences connect multiple EF hands. Calbindin-D_{28k} contains six EF hands but only four are functional and bind calcium. Calbindin-D_{9k} contains two EF hands and both bind calcium. Studies related to the distribution of calbindin and its cellular colocalization with the vitamin D receptor have resulted in key advances in our understanding of the diversity of the vitamin D endocrine system (Table 1). The focus here is on the localization, proposed functional significance, and regulation of these calcium-binding proteins. Insights obtained by studying these proteins allow an understanding of the multiple actions of the vitamin D endocrine system.

(e.g., psoriasis), and inducer of cell differentiation (e.g., cancer).

This article discusses the effect of $1,25(OH)_2D_3$ in three important tissues wherein differentiation is essential, namely, in cancer tissues, skin, and tissues of the immune system.

II. CANCER

A wide variety of malignant cells and tissues possess nuclear receptors for $1,25(OH)_2D_3$. Several laboratories have demonstrated that immature mouse myeloid cells, upon treatment with $1,25(OH)_2D_3$, differentiate toward more mature macrophage-like cells that are characterized by a decreased growth rate. The same effect was later observed in human leukemia cell lines such as HL-60 and U937. These cells acquire the morphology of monocytes, are able to perform phagocytosis, and possess differentiation-specific characteristics [such as expression of nonspecific esterases, production of superoxides, and expression of surface markers (e.g., CD14, CD11b)]. The anti-proliferative and prodifferentiating effects of $1,25(OH)_2D_3$ are not limited to leukemia cells but are also seen in a wide variety of other cancer cells possessing the vitamin D_3 receptor such as melanoma, breast cancer, colon cancer, and prostate cancer.

The molecular mechanisms responsible for cell growth arrest and terminal differentiation are still unclear. It has been demonstrated that $1,25(OH)_2D_3$-treated cancer cells accumulate in the G1 phase of the cell cycle. The regulation of cell cycle genes could be a possible explanation for the anti-proliferative effects of $1,25(OH)_2D_3$. Table 1 gives an overview of genes regulated by $1,25(OH)_2D_3$ at the transcriptional level in cancer cells. $1,25(OH)_2D_3$ increases the expression level of the cell cycle inhibitory proteins p21 and p27 in a wide variety of cancer cell lines such as leukemia, prostate cancer, and breast cancer cells. The promoter region of p21 even contains a vitamin D-response element (VDRE), suggesting that p21 is a direct target of $1,25(OH)_2D_3$. However, treatment of MCF-7 breast cancer cells with $1,25(OH)_2D_3$ and antibodies neutralizing transforming growth factor-β (TGF-β) completely abrogates $1,25(OH)_2D_3$-induced up-regulation, whereas the growth inhibitory effect was only partially reversed. Moreover, a recent report questions the inhibitory function of p21 in $1,25(OH)_2D_3$-induced growth reduction as an *in vitro* and *in vivo* down-regulation of p21 was observed in squamous cell carcinoma after treatment with $1,25(OH)_2D$. The cyclin-dependent kinase (cdk) inhibitors p15 and p18 are up-regulated in myeloid U937 cells following treatment with $1,25(OH)_2D_3$. Cell cycle arrest and differentiation in these cells are preceded by a proliferative burst and a transient increase in cyclin D1, A, and E protein levels. The activity of cdk2 and cdk6, involved in the transition from G1 to S, is reduced following treatment with $1,25(OH)_2D_3$ and may contribute to the observed growth inhibitory effect.

Incubation of HL-60 cells with $1,25(OH)_2D_3$ increases cdk5 activity, which is thought to facilitate the G1 to S phase transition in cells approaching replicative quiescence and to enhance concomitant monocytic differentiation. In addition to cell cycle genes, other genes such as proto-oncogenes and tumor suppressor genes are also regulated by $1,25(OH)_2D_3$ (Table 1). It is not always clear whether this modulation represents a direct effect of $1,25(OH)_2D_3$ or is

TABLE 2 Anti-Tumor Effects of $1,25(OH)_2D_3$ in Different Animal Models of Cancer

Administration	Tumor model	Anti-tumor effect
Oral	Colon cancer	Reduction of tumor incidence
Intraperitoneal	Head and neck squamous cell carcinoma	Suppression of tumor growth
Intraperitoneal	Lymphoma	Increase in survival time
Intraperitoneal	Liver cancer	Suppression of tumor growth
Intravesical	Bladder cancer	Reduction of tumor incidence
Hepatic arterial infusion	Liver cancer	Suppression of tumor growth

Note: Data are from studies published in 2000–2001.

rather a consequence of its overall effect on proliferation and differentiation. Suppression of c-*myc* transcription in HL-60 cells following treatment with $1,25(OH)_2D_3$ is thought to be mediated by binding of the nuclear phosphoprotein HOXB4 to the promoter region of the gene. A rapid up-regulation of the proto-oncogene c-*fos* has been reported in several cell lines treated with $1,25(OH)_2D_3$. This up-regulation is thought to be a direct effect of $1,25(OH)_2D_3$ mediated by a VDRE in the promoter region of the gene. Exposure of HL-60 cells to $1,25(OH)_2D_3$ induces the expression of c-*fms*, which is the receptor for macrophage colony-stimulating factor, concomitantly with the induction of the monocytic phenotype.

Enhanced expression of some tumor suppressor genes was reported in breast cancer cells after incubation with $1,25(OH)_2D_3$. The cell surface adhesion molecule E-cadherin and the breast cancer susceptibility gene BRCA1 are up-regulated following treatment with $1,25(OH)_2D_3$. Recently, it was demonstrated that $1,25(OH)_2D_3$ promotes the differentiation of colon carcinoma cells by the induction of E-cadherin and the inhibition of β-catenin signaling.

Another mechanism by which $1,25(OH)_2D_3$ and its analogues inhibit cell growth is the induction of programmed cell death (apoptosis) in various cancer cells including breast, colon, and prostate cancer cells. A whole set of genes involved in the cascade of apoptosis are influenced by $1,25(OH)_2D_3$. However, some contradictory reports have been published on the role of apoptotic cell death in the growth inhibition caused by this compound.

The *in vitro* studies showing the anti-proliferative and prodifferentiating effects of $1,25(OH)_2D_3$ on cancer cells have been confirmed *in vivo* in different animal models (Table 2). Indeed, the tumor incidence or tumor growth was reduced in different cancers such as colon, liver, or bladder cancer. To overcome the calcemic side effects of $1,25(OH)_2D_3$ (hypercalciuria, hypercalcemia, and increased bone resorption), attempts were made to generate chemically modified $1,25(OH)_2D_3$ molecules (analogues) that retain the beneficial anti-proliferative and prodifferentiating effects but not the unwanted calcemic side effects. Some of these potent analogues with beneficial effects on tumor growth in animals are now being further investigated in clinical trials (Table 3). These drugs can be used not only as monotherapy but also as adjuvant therapy in combination with chemotherapeutics or hormone therapy. The combined agents may act in concert and produce additional or synergistic effects on cell proliferation and differentiation but also allow dose reduction, thereby decreasing adverse side effects.

III. SKIN

The skin occupies a central position in the vitamin D endocrine system: it is not only the site of synthesis of vitamin D_3, as cutaneous cells are also capable of converting vitamin D_3 to its active form, $1,25-(OH)_2D_3$. Moreover, they contain the VDR, rendering them responsive to the actions of $1,25(OH)_2D_3$. The exact physiological function of vitamin D in the skin is still elusive. However, humans or mice with a dysfunctional VDR display a postnatal alopecia, which cannot be cured by normalization of calcium levels by dietary means. These findings firmly indicate that the VDR is directly implicated in hair follicle biology. In this context, recent mechanistic studies refer to a ligand-independent role for VDR–retinoic acid X receptor dimers in anagen initiation in the epithelial (keratinocyte) component of the hair follicle apparatus.

Whereas almost every cutaneous cell type contains the VDR (Table 4), the epidermal keratinocyte is generally considered the main vitamin D target cell in the skin. $1,25(OH)_2D_3$ at pharmacological concentrations is a potent inducer of keratinocyte growth arrest and differentiation. These properties were the basis for the successful application of $1,25(OH)_2D_3$ analogues in the treatment of hyperproliferative skin

TABLE 3 Clinical Trials with $1,25(OH)_2D_3$ and Analogues

Compound	Administration	Tumor	Effects
$1,25(OH)_2D_3$	Oral	Hormone refractory metastatic prostate cancer	No toxicity; no reduction of tumor mass
$1,25(OH)_2D_3$	Oral	Myelodysplastic syndrome	Clinical response in 70% of patients; no toxicity
$1,25(OH)_2D_3$	Oral	Myelodysplastic syndrome	No clinical effect
Calcipotriol	Topical	Breast cancer	Reduction of tumor diameter in 20% of patients
EB 1089	Oral	Advanced breast and colon cancer	Stabilization of the disease in 17% of patients
$1,25(OH)_2D_3$ + docetaxel	Oral	Androgen-independent prostate cancer	Reduction in PSA; limited or no toxicity
$1\alpha(OH)D_3$ + surgery + chemotherapy + radiotherapy	Oral	Glioblastomas and anaplastic astrocytomas	Progressive and durable tumor regression in 20% of patients; no toxicity

Note: EB 1089, 22,24-diene-24,26,27-trihomo-$1\alpha,25(OH)_2D_3$.

diseases such as psoriasis and certain forms of ichthyosis. The $1,25(OH)_2D_3$-dependent growth arrest and differentiation in keratinocytes are likely to be based on a similar mechanism of action as described for cancer cells: $1,25(OH)_2D_3$-treated keratinocytes fail to progress from the G_1 to the S phase of the cell cycle due to induction of the negative cell cycle regulators p21 and p27 and suppression of the proto-oncogene c-myc. Induction of autocrine or paracrine growth regulators such as transforming growth factor-β, tumor necrosis factor α (TNFα), and parathyroid hormone-related peptide may also contribute to the anti-mitotic $1,25(OH)_2D_3$ effect in epidermal cells. $1,25(OH)_2D_3$-dependent keratinocyte differentiation is accompanied by induction of cornified envelope precursors such as involucrin and its cross-linking enzyme transglutaminase type I. There is also a stimulatory effect on stratification by translocation of E-cadherin to assembling adherens junctions, which will further enhance the prodifferentiative actions of $1,25(OH)_2D_3$.

Low concentrations of $1,25(OH)_2D_3$ exert mitogenic activity rather than a growth-inhibiting effect on keratinocytes, especially in cells that are committed to differentiate. Increased proliferation is also observed following application of $1,25(OH)_2D_3$ compounds to normal mouse or human skin. In contrast, hyperproliferative epidermis (in psoriasis or induced by application of mitogens) responds to $1,25(OH)_2D_3$ derivatives with growth arrest. These data indicate that $1,25(OH)_2D_3$ exerts a normalizing rather than an unidirectional anti-proliferative effect on epidermal growth.

Skin fibroblasts also respond to $1,25(OH)_2D_3$ treatment with normalization of their growth rate and collagen production. Therefore, $1,25(OH)_2D_3$ compounds can be therapeutically used for diseases with excessive fibroblast activity (scleroderma) or insufficient fibroblast activity (skin atrophy). $1,25(OH)_2D_3$ stimulates the production of melanin in melanocytes, a feature that can be applied in the treatment of vitiligo. Despite the obvious role for the VDR in hair biology, no application of $1,25(OH)_2D_3$ analogues in hair disorders is yet available; however, animal models open promising perspectives for the prevention of chemotherapy-induced alopecia.

TABLE 4 Vitamin D Target Cells in the Skin with Effects of $1,25(OH)_2D_3$ and Clinical Application of $1,25(OH)_2D_3$ Analogues

Target cell	Effect of $1,25(OH)_2D_3$	Clinical use
Keratinocyte	Regulation of growth and differentiation	Psoriasis; hyperproliferative ichthyosis
Fibroblast	Regulation of growth and collagen production	Scleroderma; skin atrophy
Hair follicle cell	Hair cycle regulation	Alopecia (chemotheraphy)?
Melanocyte	Stimulation of melanogenesis	Vitiligo

IV. IMMUNE SYSTEM

The detection of VDRs in almost all cells of the immune system, especially antigen-presenting cells (macrophages and dendritic cells) and activated T lymphocytes, led to the investigation of a potential for $1,25(OH)_2D_3$ as an immunomodulator. Application of the molecule *in vitro* and *in vivo* has led to interesting observations, confirming a role for $1,25(OH)_2D_3$ and its analogues in the immune system. Not only is the VDR present in all cells of the immune system, activated macrophages are able to synthesize and secrete $1,25(OH)_2D_3$. These cells indeed express the enzyme $25(OH)D_3$-1α-hydroxylase, as could recently be demonstrated at the molecular level by reverse transcription-polymerase chain reaction (RT-PCR) in activated macrophages. Although cloning and sequencing of the mRNA clearly demonstrated this enzyme to be identical to the known renal form, its regulation seems to be under completely different control. The macrophage enzyme mainly runs through immune signals, with interferon-γ (IFN-γ) being a powerful stimulator. In macrophages, no clear down-regulation of the enzyme by $1,25(OH)_2D_3$ could be observed, explaining the hypercalcemia occurring in situations of macrophage overactivation such as tuberculosis or sarcoidosis. The secretion of classical macrophage products such as cytokines [interleukin-1 (IL-1), TNFα, and IL-12] precedes the transcription of the enzyme and as a consequence the secretion of $1,25(OH)_2D_3$. Therefore, its timing is compatible with that of a suppressive signal, allowing first an activation and further recruitment of the other members of the immune system, followed by inhibiting signals, such as prostaglandin E2 (PGE2), to limit the extent of the reaction (Fig. 1).

As a true immunomodulator, $1,25(OH)_2D_3$ not only interacts with T cells but also targets the central cell in the immune cascade, the antigen-presenting cell.

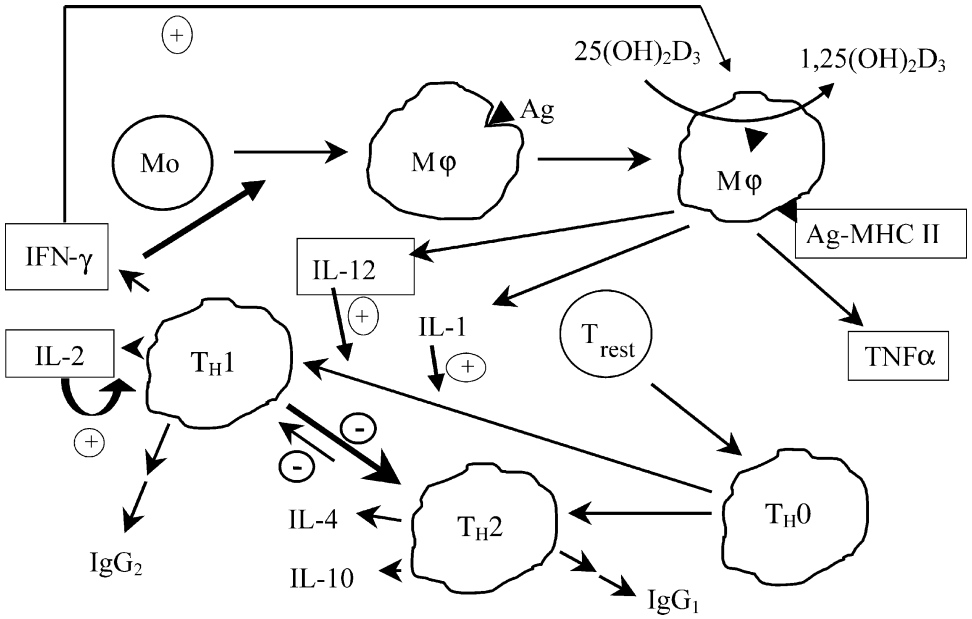

FIGURE 1 Regulation of the immune response by $1,25(OH)_2D_3$. Upon contact with an antigen (Ag), e.g., a bacterial component, blood monocytes (Mo) or dendritic cells will become activated (Mφ) and present this antigen in the context of MHC class II molecules to the rest of the immune system. Moreover, by secretion of chemokines and activating cytokines [e.g., interleukin-12 (IL-12), tumor necrosis factor α (TNFα)], these activated cells will recruit T lymphocytes (CD4 cells) and activate them, depending on the cytokine environment, into T helper 1 (T_H1) or T_H2 cells. T_H1 cells, which produce mainly interferon-γ (IFN-γ) and IL-2, will further activate the macrophage and close a positive feedback loop, leading to amplification of the immune response. $1,25(OH)_2D_3$ and its analogues can modulate the immune response via several mechanisms. $1,25(OH)_2D_3$ inhibits IL-12 production and down-regulates co-stimulatory molecule expression by dendritic cells, thus inhibiting the development of T_H1 cells along the T_H1 pathway and favoring the induction of $CD4^+CD25^+$ regulatory T cells. $1,25(OH)_2D_3$ also exerts direct effects on T cells by inhibiting IL-2 and IFN-γ production and by inducing, in particular, T_H2 cells in target tissues. In addition, $1,25(OH)_2D_3$ inhibits the recruitment of T_H1 cells to sites of inflammation. Macrophages (Mφ) can synthesize $1,25(OH)_2D_3$ and this may also contribute to the regulation of the immune response.

Here, $1,25(OH)_2D_3$ stimulates the differentiation of monocytes toward "good" phagocytosis and killing of bacteria. Differentiation of monocytes into dendritic cells and further differentiation of these cells from immature to mature dendritic cells is almost completely inhibited by $1,25(OH)_2D_3$. Incubation of monocytes with $1,25(OH)_2D_3$ *in vitro* results in a cell type totally different from classical dendritic cells, but also different from monocytes. CD14 is highly expressed on the surface, but human leukocyte antigen class II proteins and B7.2 proteins are down-regulated. Antigen-presenting cells are not able to promote an immune response, since they are not able to properly stimulate T cells to proliferation or cytokine secretion. On the other hand, these cells have also not differentiated into macrophages, since they are unable to perform chemotaxis or phagocytosis of bacteria. Also, the crucial signals secreted by antigen-presenting cells for the recruitment and activation of T cells are directly influenced by $1,25(OH)_2D_3$. A key cytokine in the immune system, IL-12 is clearly inhibited by $1,25(OH)_2D_3$ and its analogues. This monocyte-produced substance is the major determinant of the direction in which the immune system will be activated. IL-12 stimulates the development of CD4 T helper 1 (T_H1) cells and inhibits the development of CD4 T_H2 lymphocytes. T_H1 lymphocytes secrete mainly IL-2 and IFN-γ and are considered to be the most important cells in graft rejection and autoimmunity. T_H2 cells secrete IL-4, IL-5, and IL-10 and are considered to be regulator cells. The observation of clear inhibition of IL-12 by $1,25(OH)_2D_3$ and its analogues (*in vitro* by enzyme-linked immunosorbent assay or by intracellular fluorescence-activated cell sorting (FACS) analysis or *in vivo* by RT-PCR) is essential in understanding the observed effects of these substances *in vitro* on T-cell proliferation and cytokine production and *in vivo* on graft survival and autoimmunity prevention (Table 5). By inhibiting IL-12 secretion, $1,25(OH)_2D_3$ directly interferes with the heart of the immune cascade and shifts the reaction toward a T_H2 profile. $1,25(OH)_2D_3$ also influences the secretion of other cytokines secreted by monocyte-derived cells: the suppressive PGE2 is stimulated and the monocyte recruiter granulocyte/macrophage colony-stimulating factor is suppressed. Several T-cell cytokines, especially the T_H1 type, are also direct targets for $1,25(OH)_2D_3$ and its analogues. $1,25(OH)_2D_3$-mediated inhibition of IL-2 secretion occurs through impairment of nuclear factor of activated T cells (NFAT) complex formation, since the receptor complex itself binds to the distal NFAT-binding site in the human IL-2 promoter. Another key T-cell cytokine that by itself further stimulates antigen presentation, IFN-γ, is directly (via a VDRE) down-regulated by $1,25(OH)_2D_3$. Moreover, progressive deletion analysis of the IFN-γ promoter revealed that negative regulation by $1,25(OH)_2D_3$ is also present at the level of an upstream region containing an enhancer element. Finally, it was recently demonstrated that $1,25(OH)_2D_3$ also directly stimulates IL-4 production by T_H2 cells. The combination of these effects on dendritic cell phenotype and cytokine secretion, with the direct effects on T-cell cytokine profile, results in the differentiation of T cells toward a T_H2 profile. This profile is beneficial in achieving prolonged organ graft survival and in prevention of organ-specific autoimmune diseases such as multiple sclerosis or type 1 diabetes.

TABLE 5 Beneficial Effects of $1,25(OH)_2D_3$ and its Analogues in Animal Models of Autoimmunity and Transplantation

Autoimmunity
Autoimmune diabetes
Chemically induced diabetes mellitus
Collagen-induced arthritis
Experimental allergic encephalomyelitis
Experimental autoimmune thyroiditis
Heyman nephritis
Lupus nephritis
Mercuric chloride-induced glomerulonephritis
Transplantation
Aorta
Bone marrow
Heart
Kidney
Liver
Pancreatic islets
Skin
Small bowel

The fact that $1,25(OH)_2D_3$ and its analogues influence the immune system, not by pure immunosuppression, but by immunomodulation through induction of immune shifts and regulator cells, makes these products very appealing for clinical use, especially in the treatment and prevention of autoimmune diseases (Table 5). In autoimmune diabetes in the non-obese diabetic (NOD) mouse, up-regulation of regulator cells and a shift from T_H1 toward T_H2 locally in the pancreas and islet grafts of treated mice could be observed, and other effects on the immune system have also been described, the most important being a restoration of defective apoptosis sensitivity in lymphocytes, leading to better elimination of potentially dangerous autoimmune effector cells.

This increase in immunocyte apoptosis in NOD mice by $1,25(OH)_2D_3$ and its analogues has been reported to occur following different apoptosis-inducing signals and could explain why an early short-term treatment with these products, before the onset of autoimmunity, can lead to long-term protection and a restoration of tolerance.

Finally, clear additive and even synergistic effects were observed between $1,25(OH)_2D_3$ or its analogues and other more classical immunomodulators such as cyclosporin A and sirolimus (rapamycin). These effects were observed *in vitro* and could be confirmed *in vivo* in models of autoimmunity (diabetes and experimental allergic encephalomyelitis) and in graft destruction (Table 5).

In conclusion, these data suggest a physiological role for $1,25(OH)_2D_3$ in the immune system as an inhibiting signal secreted by activated macrophages and received by activated T cells, thus limiting the immune reaction (Fig. 1). Analysis of the VDR knockout mouse model, however, confirms that all immune effects of $1,25(OH)_2D_3$ are mediated through the VDR but demonstrate that $1,25(OH)_2D_3$ is possibly a redundant signal in the immune system.

V. SUMMARY

The combined presence of $25(OH)D_3$-1α-hydroxylase and the VDR in several nonclassical tissues introduced the concept of a paracrine role for $1,25(OH)_2D_3$ outside that of calcium and bone metabolism. Moreover, the fact that $1,25(OH)_2D_3$ was found to be capable of regulating cell differentiation and proliferation of normal (keratinocytes and immune cells) and malignant cells (leukemia, breast, prostate, and colon cancer cells) gave new perspectives on this molecule. The efforts made by companies and laboratories worldwide to develop analogues of $1,25(OH)_2D_3$ with reduced calcemic effects opened therapeutic applications for these compounds as inhibitors of cell proliferation (e.g., treatment of psoriasis or cancer), as inducers of cell differentiation (e.g., treatment of cancer), and as immune modulators (e.g., treatment of autoimmune diseases or prevention of graft rejection). Moreover, the synergistic effects of $1,25(OH)_2D_3$ analogues with retinoids, anti-estrogens, conventional chemotherapeutics, and classical immunomodulators may result in better response rates for the treatment of cancer and immune disorders. However, more research and clinical trials are needed to select the best $1,25(OH)_2D_3$ analogue for each application.

Glossary

alopecia Hair loss that can occur in patches (alopecia areata) or globally. Causes range from hormones to autoimmunity.

anagen The growth phase of the growth cycle of mature hair follicles; anagen is followed by regression (catagen), rest (telogen), and shedding (exogen).

apoptosis Programmed cell death; cells undergoing apoptosis are cleared from the system silently without the initiation of inflammation.

autoimmune diseases Disorders initiated by the activation of autoreactive T cells that result in the destruction of tissues and cells by the body's own immune system.

cornified envelope Proteinaceous reinforced structure beneath the plasma membrane in differentiated keratinocytes consisting of cross-linked precursor proteins.

epidermis Outer epithelial layer of the skin consisting mainly of cells called keratinocytes.

ichthyosis Skin disease in which the skin is very dry and exhibits fish-like scales.

$1,25(OH)_2D_3$ The dihydroxylated, biologically active form of vitamin D. It is a central hormone in calcium homeostasis and bone metabolism, but has also a number of other functions and notably powerful immunomodulatory properties.

vitamin D receptor (VDR) A member of the superfamily of nuclear receptors for steroid hormones, thyroid hormone, and retinoic acid. The VDR functions as a $1,25(OH)_2D_3$-activated transcription factor that ultimately influences the rate of RNA polymerase II-mediated transcription. VDRs are present not only in cells typically involved in calcium and bone metabolism, but also in other cell types, such as cells of the immune system.

vitamin D A vitamin/hormone with a central role in calcium and bone metabolism; it can be absorbed from the diet or can be synthesized by the skin via stimulation by ultraviolet light. Deficiency of vitamin D leads to a disorder known as rickets or osteomalacia.

vitamin D analogues Chemically modified molecules derived from $1,25(OH)_2D_3$. Modifications have been made throughout the molecule, to obtain analogues with the desired properties. More than 1000 different vitamin D analogues have been synthesized worldwide.

Vitamin D Metabolism

HELEN L. HENRY

University of California, Riverside

Vitamin D_3 is produced in the skin through the action of ultraviolet light and is subsequently hydroxylated in the liver and then in the kidney to form 1α,25-dihydroxyvitamin D_3, the biologically active form of vitamin D. The biochemical reactions that occur in vitamin D metabolism, the enzymes that catalyze these reactions, and the genes that encode these enzymes are discussed in this article. In addition, the factors that regulate the pathways of vitamin D metabolism are examined.

I. INTRODUCTION

Ultraviolet light and heat bring about the conversion of 7-dehydrocholesterol to vitamin D_3 in the skin of vertebrates on exposure to sunlight (Fig. 1). In the liver, vitamin D_3 is hydroxylated at carbon 25 on the side chain to form 25-hydroxyvitamin D_3 [25(OH)D_3], the major circulating vitamin D_3 metabolite. 25(OH)D_3 serves as the substrate for the production in the kidney of the biologically active steroid hormone, 1α,25-dihydroxyvitamin D_3 [1α,25-(OH)$_2D_3$] and of 24R,25-dihydroxyvitamin D_3 [24R,25(OH)$_2D_3$]. The cytochrome P450-dependent enzymes that catalyze these three reactions are

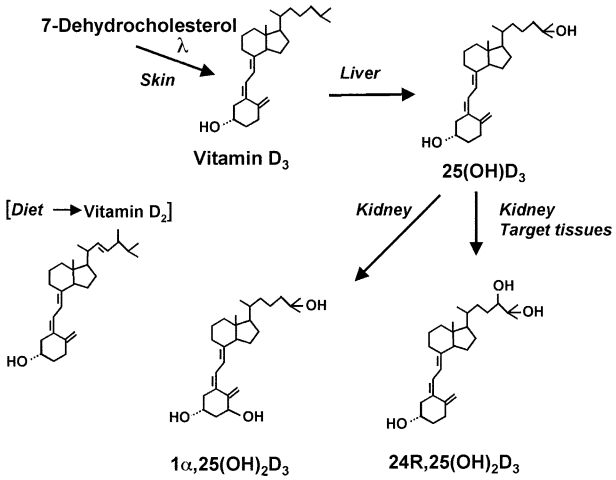

FIGURE 1 Metabolism of vitamin D. Following its production in the skin through the action of ultraviolet light, vitamin D_3 is hydroxylated in the liver by 25-hydroxylase (CYP27A) and then in the kidney by 25(OH)D_3-1α-hydroxylase (CYP27B) to form 1α,25(OH)$_2D_3$, the steroid hormonally active form of vitamin D. 25(OH)D_3 is also hydroxylated in the kidney and in 1α,25(OH)$_2D_3$ target tissues at carbon 24 by the 24R-hydroxylase (CYP24). Vitamin D_2, which is derived from and differs only in the side chain from vitamin D_3, which is derived from ergosterol, can undergo the same activation steps to 1α,25(OH)$_2D_2$.

the vitamin D3-25-hydroxylase (CYP27A1), 25(OH)-D_3-1α-hydroxylase (CYP27B1), and 25(OH)D_3-24R-hydroxylase (CYP24), each of which is discussed in more detail below.

The side chain of both 25(OH)D_3 and 1α,25(OH)$_2D_3$ is subject to further metabolism, as shown in Fig. 2. Following 24R-hydroxylation, the same cytochrome P450 catalyzes further hydroxylation, oxidation, and cleavage of four carbons from the side chain; another pathway leads to the formation of 26,23-lactone derivative.

Vitamin D_2 (Fig. 1) is derived from the plant sterol ergosterol and is used as a dietary supplement for humans and domesticated animals. In humans, it is considered to be metabolized to 1α,25(OH)$_2D_2$ in a manner that is qualitatively and quantitatively similar to that of vitamin D_3. However, the presence of the double bond between carbons 22 and 23 and the methyl group attached to carbon 24 impedes the side chain metabolism of the vitamin D metabolites derived from ergosterol.

The enzymes that catalyze the transformations of vitamin D and its metabolites are cytochrome P450-dependent mixed-function oxidases or steroid hydroxylases. In general, these enzymes depend on a source of electrons to reduce molecular oxygen and either one (for microsomal enzymes) or two (for mitochondrial enzymes) accessory proteins to transport the electrons to the specific cytochrome P450 responsible for the stereospecific hydroxylation of the substrate.

II. VITAMIN D_3-25-HYDROXYLASE

The most abundant circulating form (15–60 ng/ml) of vitamin D_3 is the 25-hydroxylated derivative, 25(OH)D_3, which is formed in the liver by the mixed-function oxidase, vitamin D_3-25-hydroxylase. Although other tissues, such as the kidney and intestine, are capable of catalyzing this reaction, the liver makes by far the largest and physiologically most significant contribution to the circulating levels of the prohormone, 25(OH)D_3.

The experimental evidence for the subcellular localization of 25-hydroxylase activity depends on the species under investigation. For example, in rats and rabbits, activity has been reported in both microsomes and mitochondria and both subcellular forms have been purified to homogeneity. In humans, only a mitochondrial form of 25-hydroxylase activity has been demonstrated; on this basis, as well as the fact that in rats microsomes contain fivefold less activity than do mitochondria, some authors have questioned the physiological significance of the microsomal 25-hydroxylase activity and most recent investigations have focused on the mitochondrial enzyme.

The mammalian mitochondrial vitamin D_3-25-hydroxylase that has been cloned is CYP27A1, which also catalyzes the hydroxylation of carbons 26 and 27 of cholesterol, during steps in the formation of bile acids. CYP27A1 cDNA expressed in *Escherichia coli* hydroxylates vitamin D_3 at several positions on the side chain in addition to carbon 25 and carbon

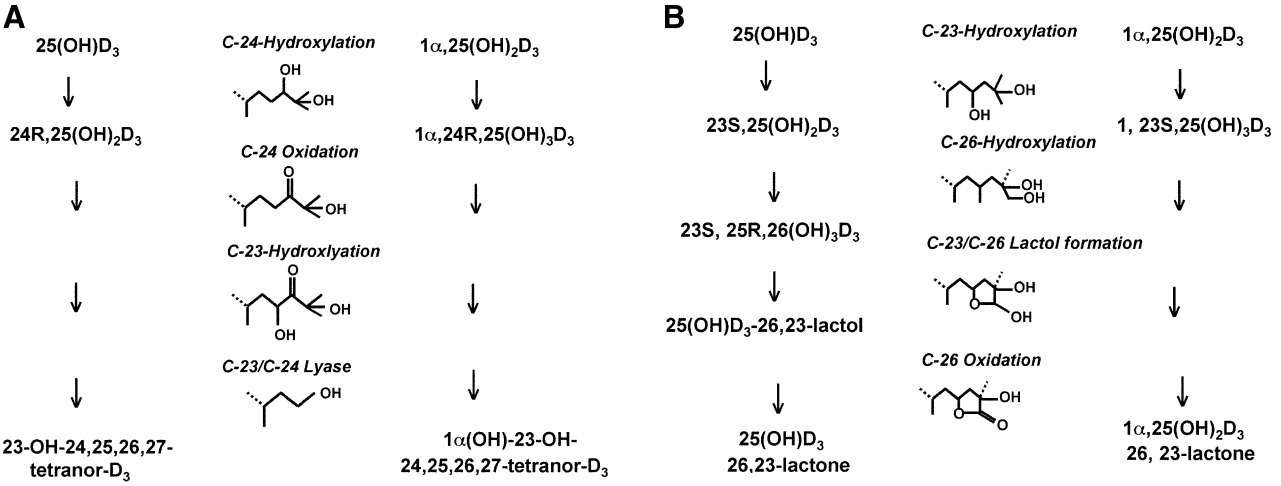

FIGURE 2 Metabolism of the vitamin D side chain. (A) The reactions carried out by CYP24 leading to the cleavage of four carbons. In the kidney, a significant amount of 24R,25(OH)$_2D_3$ is released prior to the subsequent oxidation steps. The complete C-24 oxidation pathway occurs in most target tissues of 1α,25(OH)$_2D_3$. (B) The C-23 oxidation pathway leading to the formation of the C-23/C-26 lactone derivatives. As indicated, both pathways can operate on substrates with or without the hydroxylation at carbon 1 in the A ring.

1. Whether CYP27A is the only enzyme responsible for the formation of 25-hydroxylated vitamin D derivatives, however, is brought into question by lack of evidence that it forms 25(OH)D_2, the predominant circulating derivative of vitamin D_2, as efficiently as it forms 25(OH)D_3.

III. 25(OH)D_3-1α-HYDROXYLASE

It has been appreciated for three decades that the kidney is the major site of production of circulating 1α,25$(OH)_2$D (20–60 pg/ml), although, as discussed below, other tissues and cell types, notably skin, placenta, and cells of hematopoietic lineage, have been shown to produce 1α,25$(OH)_2D_3$ from 25(OH)D_3. In the kidney and in other tissues in which subcellular localization has been investigated, 1α-hydroxylase activity is exclusively mitochondrial.

cDNA sequences for the rat, mouse, pig, and human enzymes show that the primary structure of the 1α-hydroxylase is most similar to that of CYP27A1; therefore, it has been designated CYP27B1. The CYP27B1 gene, which is located on mouse chromosome 10 and human chromosome 12, is composed of nine exons and appears to be present in a single copy.

Although studies in vitamin D-deficient animals suggest that 1α-hydroxylase enzymatic activity is localized in the proximal tubule of the renal nephron, recent *in situ* hybridization and immunohistochemical studies of normal human kidney indicate that the enzyme and its message are more highly expressed in the distal portions of the nephron. It is likely that differential localization of the enzyme along the nephron under different conditions of vitamin D status reflects the dual autocrine/paracrine and endocrine roles of the kidney in calcium homeostasis.

Although the belief that the kidney is the principal site of 1α,25$(OH)_2D_3$ production is supported by studies in uremic animals as well as by clinical experience with patients with chronic renal failure, there is also evidence for the extrarenal production of 1α,25$(OH)_2D_3$. The most studied of these include keratinocytes and skin *in vivo*, various placental preparations, and the cells of the hematopoietic system. 1α-Hydroxylase activity in these cell latter types is not regulated by those components of the calcium homeostatic system described below for the renal 1α-hydroxylase but rather by immune cell regulators such as interferon-γ and lipopolysaccharide. It is thought that these occurrences of extrarenal 1α-hydroxylase activity serve autocrine/paracrine functions.

IV. 25(OH)D_3/1α,25$(OH)_2D_3$-24R-HYDROXYLASE

Whereas the 1α-hydroxylase has but one naturally occurring substrate, the 24R-hydroxylase has two. The same enzyme catalyzes the 24-hydroxylation and subsequent side chain modification of both 25(OH)D_3 and 1α,25$(OH)_2D_3$ (Fig. 2). Depending on the enzyme preparation and assay conditions used, the affinity of the enzyme for 25(OH)D_3 is either much greater than or much less than that for 1α,25$(OH)_2D_3$. Given the fact that circulating levels of 25(OH)D_3 are approximately three orders of magnitude greater than those of 1α,25$(OH)_2D_3$ and that the turnover number is greater for 25(OH)D_3 than for 1α,25$(OH)_2D_3$, there is, in the whole animal, considerable capacity to produce 24R, 25$(OH)_2D_3$.

The cDNA encoding CYP24 has been cloned from rat, mouse, pig, and human kidneys. Expression studies in *E. coli* have shown that all of the reactions depicted in Fig. 2, C-24-hydroxylation, C-24 oxidation, C-23-hydroxylation, and C-23/C-24 cleavage, are catalyzed by a single cytochrome P450.

The 24R-hydroxylase gene, which contains 12 exons, has been localized to human chromosome 20 and mouse chromosome 2. The promoter region of the rat gene contains two vitamin D-response elements that are likely involved in the induction of the 24-hydroxylase by 1α,25$(OH)_2D_3$ (see below).

Although first identified and characterized in the kidney, where it is notable for its regulation that is reciprocal to that of the 1α-hydroxylase, the 24R-hydroxylase is actually very widespread, occurring in all target tissues that contain the receptor for 1α,25$(OH)_2D_3$, VDR. In fact, the inducibility of the 24R-hydroxylase by 1α,25$(OH)_2D_3$ is often taken as *prima facie* evidence of a cell being a target of 1α,25$(OH)_2D_3$ action. Like the 1α-hydroxylase, the 24R-hydroxylase is exclusively mitochondrial.

Although there is no controversy regarding the fundamental importance of the 1α-hydroxylase in the production of a biologically important steroid hormone, 1α,25$(OH)_2D_3$, the biological significance of the 24R-hydroxylase is less clear-cut. It is undoubtedly important to the inactivation and catabolism of 1α,25$(OH)_2D_3$ in the target cells in which is it induced by this steroid through the nuclear actions of the VDR. A 24R-hydroxylase knockout mouse has been produced in which observed deficiencies in bone metabolism were attributed not to the absence of 24R,25$(OH)_2D_3$ but to excess 1α,25$(OH)_2D_3$ resulting from its impaired catabolism.

On the other hand, the fact that substantial amounts of 24R,25$(OH)_2D_3$ are produced by the kidney along with evidence that 24R,25$(OH)_2D_3$ may have biological actions distinct from those attributable to 1α,25$(OH)_2D_3$ leaves open the possibility of an endocrine role for the kidney in the production of 24R,25$(OH)_2D_3$ as well as 1α,25$(OH)_2D_3$.

V. REGULATION OF VITAMIN D METABOLISM

The overall pathway leading to the production of the hormonally active 1α,25$(OH)_2D_3$ begins with the availability of vitamin D either from production in the skin or from the diet. If the supply of the parent vitamin is limited, deficiency of 1α,25$(OH)_2D_3$ will result in bone abnormalities. There is no documented physiologically significant regulation of the 25-hydroxylation of vitamin D by the liver, and in fact, circulating levels of 25$(OH)D_3$ are widely used to assess vitamin D status.

A. Kidney

The production of 1α,25$(OH)_2D_3$ by the kidney is tightly regulated by factors that generally have the opposite effects on the production of 24R,25$(OH)_2D_3$. The most thoroughly studied of these factors, and probably the most important in normal physiological circumstances, are the prevailing levels of 1α,25-$(OH)_2D_3$ itself and of parathyroid hormone (PTH). As depicted in Fig. 3, 1α,25$(OH)_2D_3$ inhibits its own synthesis and increases that of 24R,25$(OH)_2D_3$. The effect of 1α,25$(OH)_2D_3$ on 24R-hydroxylase is primarily if not exclusively mediated through increased mRNA levels, but the mechanism by which 1α,25$(OH)_2D_3$ reduces the 1α-hydroxylase is not as clear.

The second important physiological regulator of the renal hydroxylation of 25$(OH)D_3$ is PTH, which increases the synthesis of 1α,25$(OH)_2D_3$ and decreases that of 24R,25$(OH)_2D_3$. Low dietary calcium has the same effects on the two hydroxylase activities, which are probably mediated through increased PTH secretion. Intracellular signaling systems involved in mediating the effects of PTH on the two hydroxylases include cyclic AMP-dependent protein kinase as well as protein kinase C. The steady-state level of mRNA encoding CYP27B (1α-hydroxylase) is increased and that for CYP24 is decreased by PTH, but whether the entire effect of the peptide hormone on the activity of the two hydroxylases can be accounted for by alterations in mRNA levels has not been established.

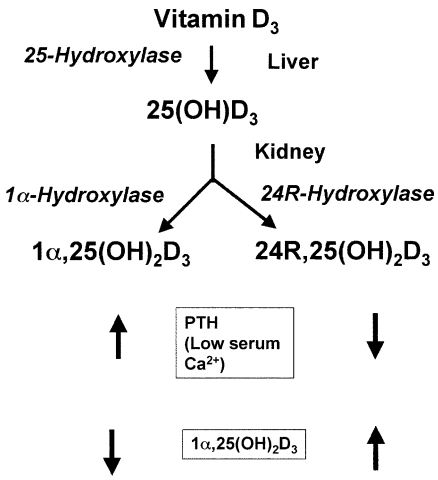

FIGURE 3 Regulation of vitamin D metabolism. The hydroxylation of vitamin D in the liver is not regulated in physiological circumstances so that the circulating levels of 25$(OH)D_3$ are a reflection of vitamin D status. In the kidney, 1α-hydroxylation and 24R-hydroxylation of 25$(OH)D_3$ are regulated in a reciprocal fashion by 1α,25$(OH)_2D_3$ and by PTH.

Changes in the levels of other hormones have been reported to influence the amounts of 1α,25$(OH)_2D_3$ and/or 24R,25$(OH)_2D_3$ produced by the kidney. These include calcitonin, glucocorticoids, growth hormone, and sex steroids. The direction and magnitude of the effects of these hormones on 1α-hydroxylase and 24R-hydroxylase activities are variable, depending on the animal model under investigation. It is likely that although the effects of these hormones on vitamin D metabolism may be important in certain special endocrine circumstances, they are of less significance than 1α,25$(OH)_2D_3$ and PTH in the normal homeostatic control of the renal hydroxylation of 25$(OH)D_3$.

B. Bone and Intestine

Studies of the regulation of the mRNA for 24R-hydroxylase in bone and intestine have shown that, as in the kidney, these are increased by 1α,25$(OH)_2D_3$. However, as shown in Fig. 4, the effects of PTH and activation of protein kinase C on 24R-hydroxylase mRNA are tissue specific.

VI. OTHER PATHWAYS OF VITAMIN D METABOLISM

A. C-23 Oxidation

As shown in Fig. 2, the side chain of either 25$(OH)D_3$ or 1α,25$(OH)_2D_3$ can undergo hydroxylation at

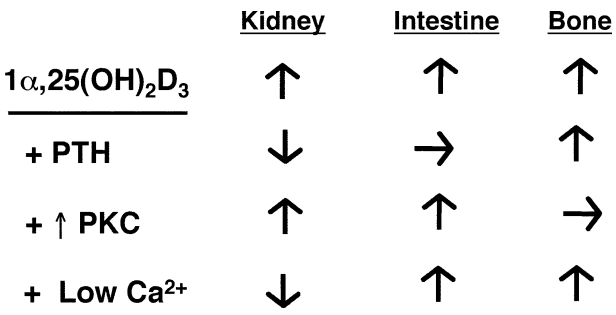

FIGURE 4 Tissue-specific regulation of 24R-hydroxylase mRNA. In all three tissues, $1\alpha,25(OH)_2D_3$ is required to induce the 24-hydroxylase from basal levels. Once induced, the 24R-hydroxylase is modulated differentially by PTH, activation of protein kinase C, and low dietary calcium in the three tissues.

carbon 23, leading to the formation of the 23(S), 25(R)-26,23-lactone derivatives. Human CYP24, expressed in *E. coli,* is capable of catalyzing all of these reactions with both substrates, but other enzymes may be involved *in vivo*. In terms of their contribution to the catabolism of $1\alpha,25(OH)_2D_3$ and $25(OH)D_3$, there is considerable species variation in the utilization of the C-23 and C-24 oxidation pathways. For example, rats and mice use the C-24 pathway almost exclusively, whereas C-23 derivatives predominate in the guinea pig.

B. 3-Epimerization

The formation of 3-epi-$1\alpha,25(OH)_2D_3$ has been reported in human keratinocytes, bone cells, and parathyroid cells. Although metabolites of this compound have been reported to possess biological activity, the physiological importance of this pathway has not been established.

Glossary

cytochrome P450 In eukaryotes, a family of microsomal and mitochondrial heme-containing proteins (named for their characteristic absorption of light of 450 nm when carbon monoxide is bound) that reduce molecular oxygen, one atom of which is incorporated stereospecifically into the substrate as a hydroxyl group; those that use endogenous steroids for substrates are sometimes called steroid hydroxylases and many catalyze steps subsequent to the initial hydroxylation.

prohormone A precursor (either peptide or steroid) to an active hormone that is produced in significant amounts as an intermediate in the pathway of production of the active hormone.

protein kinase C A family of serine/threonine protein kinases that are activated by Ca^{2+} and/or phospholipids in response to extracellular signals.

VDR The specific target tissue receptor for 1α,25dihydroxyvitamin D_3, the steroid hormone form of vitamin D.

vitamin D-response element The specific vitamin D receptor-binding DNA sequence in the promoter regions of genes whose transcription is altered by 1α,25-dihydroxyvitamin D_3.

Vitamin D: Nuclear Receptor for 1,25(OH)$_2$D$_3$

J. Wesley Pike and Nirupama K. Shevde
University of Wisconsin

The biological actions of 1,25-dihydroxyvitamin D_3 [1,25(OH)$_2$D$_3$] in tissues and cells are orchestrated within the nucleus through complex changes in gene expression. These changes lead to cell-specific alterations in the level of proteins that regulate the cell cycle, modulate differentiated cell function, or regulate subsequent levels of gene expression through their additional actions on genes or cells. Most, if not all, of the molecular actions of 1,25(OH)$_2$D$_3$ in the nucleus are mediated by a receptor protein termed the vitamin D receptor (VDR). This receptor is a specific member of a large gene family of transcription factors that function to mediate the actions of all the known steroid hormones, among them the estrogens and androgens, progesterone, the glucocorticoids, and thyroid hormone. As discussed in this article, the structural features of the VDR are well adapted to this functional role in regulating gene expression.

I. INTRODUCTION

Vitamin D_3, derived from 7-dehydrocholesterol through the actions of heat and ultraviolet light, undergoes further enzymatic activation first to 25-hydroxyvitamin D_3 in the liver and then to 1,25-dihydroxyvitamin D_3 [1,25(OH)$_2$D$_3$] in the kidney. This final metabolic conversion, which is highly regulated by parathyroid hormone as well as a variety of additional hormones and circulating factors, leads to what is now considered to be the active form of vitamin D_3. By virtue of its small size, lipophilic nature, and mechanism of action, 1,25(OH)$_2$D$_3$ is not considered to be a vitamin but rather a steroid hormone.

The classical role of 1,25(OH)$_2$D$_3$ is to regulate mineral homeostasis, achieved in part through regulatory actions on the parathyroid gland and through coordinate actions on intestine, kidney, and bone. Accordingly, the discovery of the vitamin D receptor (VDR) was initially made through investigations in those tissues. Currently, however, the VDR is found in a wide variety of cells and tissues, including those of skin, liver, pancreas, muscle, breast, prostate, adrenal, and thyroid and in cells of mesenchymal and hematopoietic origin. Although the VDR in these tissues is derived from the same chromosomal gene, its role in cellular function is pleiotropic and not necessarily involved in the control of mineral balance. Indeed, one of its most basic functions appears to be that of regulating cellular proliferation and differentiation, an activity that may be found associated with most steroid and adrenal hormones. This regulatory feature is likely a fundamental component of all biological responses to 1,25(OH)$_2$D$_3$, including those that involve mineral homeostasis.

II. STRUCTURAL ORGANIZATION OF THE VDR

Evidence for the existence of a receptor for 1,25(OH)$_2$D$_3$ predated the discovery of the hormone itself and supported the idea that the mechanism of action of vitamin D might be similar to that of other steroids. Over the ensuing years, research revealed numerous biochemical features of the VDR. These characteristics included the ability of the receptor to bind its ligand, 1,25(OH)$_2$D$_3$, with very high affinity

TABLE 1 Overview of Nonclassical $1,25(OH)_2D_3$ Target Tissues

Cardiovascular tissue and muscle	Other endocrine organs
Cardiac myocytes	Adrenals
Skeletal muscle	Pancreatic beta cells

	Variety of cancers

[a]Site of a key hormonal role for $1,25(OH)_2D_3$/VDR in regulating the Ca^{2+} homeostatic endocrine system.

[b]Although these tissues are not "classical" sites of plasma calcium regulation, regulation of Ca^{2+} translocation is likely to be a principal function of $1,25(OH)_2D_3$/VDR therein.

DNA response element sequence in gel-shift studies. Collectively, studies using all of these approaches provide a large body of complementary data about the receptors and their putative sites of action.

III. $1,25(OH)_2D_3$ FUNCTIONS IN NONCLASSICAL TARGETS: COMMONALITIES AND GENERALITIES

Many effects have been described for $1,25(OH)_2D_3$ actions in nonclassical targets (Table 3). Although some of these effects (e.g., effects on signal transduction pathways, Ca^{2+} buffering, and growth regulation) parallel events known to occur in classical targets in the regulation of plasma Ca^{2+} homeostasis, tissue-specific effects also occur, and knowledge of their existence will likely continue to grow. Moreover, in contrast to many other effects, $1,25(OH)_2D_3$ induction of the vitamin D-related calbindins—which is typical of the traditional Ca^{2+}-translocating tissues—does not occur in many of the nonclassical targets.

TABLE 2 Types of Analyses Used to Define New VDR Targets

Approach	Example
Biochemical	[^{3}H]-$1,25(OH)_2D_3$ binding studies and Scatchard analysis
	Sucrose density-gradient analysis
	DNA cellulose chromatography
	Immunoblotting
Histological	Autoradiography
	Immunohisto/cytochemistry
Molecular	Northern analysis
	Gel shift

The hormonal effects of $1,25(OH)_2D_3$ in its targets involve two separate, but likely interdependent, mechanisms, termed "genomic" and "nongenomic" processes. Genomic actions are those in which the nuclear VDR regulates gene transcription at the DNA level. Interestingly, although this is the classical mechanism of action of the vitamin D endocrine system, specific details (e.g., the identity of the regulated genes) are not well delineated in most nontraditional targets. Nongenomic actions of $1,25(OH)_2D_3$ are those mediated principally through actions at/on the cellular membrane. Although several laboratories have exerted considerable effort to identify the putative membrane receptors for $1,25(OH)_2D_3$, details of the molecular structures are not yet available. In other steroid receptor systems, there may be multiple membrane receptor forms—some with identity to the nuclear receptor forms and some with totally different molecular origins. It is hoped that it will soon be known whether this interesting pattern of diversity of membrane receptor forms also holds for the vitamin D hormone. Despite both the lack of definition of the precise membrane effectors and the relatively recent focus on membrane-related events, a plethora of data exist defining apparent nongenomic signal transduction mechanisms of $1,25(OH)_2D_3$ in these systems. It is important to note that many signal transduction pathways have been implicated in the nongenomic actions of $1,25(OH)_2D_3$, sometimes occurring in different tissues but sometimes all within one tissue (e.g., skeletal muscle). Moreover, it is increasingly clear that these pathways are all intimately intertwined, and thus often affect one another in the response process.

$1,25(OH)_2D_3$ exerts important tissue- and development-specific effects on growth and differentiation. Its hormonal effects are important both in regulating normal growth processes and in clinically relevant conditions such as cancer (e.g., breast or prostate) and in tissue regeneration processes. In many tissues (e.g., cells of the hematolymphopoietic lineage),

TABLE 3 Examples of $1,25(OH)_2D_3$ Effects in Nonclassical Targets

Mechanism	Tissue
Regulation of intracellular signaling pathways	Many
Proliferation/differentiation	Many
Protection against cellular damage (including Ca^{2+} buffering)	A growing list that includes the CNS, heart, and pancreas
Hormone secretion	Pancreas, ovary?
Regulation of $1,25(OH)_2D_3$ responsiveness	
24-Hydroxylase	Universal
VDR levels	Pancreas and skin (not heart, testis, or lung)
Calbindin levels	Rare

growth inhibition correlates with specific effects to induce differentiation.

A. Cytoprotective Effects of $1,25(OH)_2D_3$

$1,25(OH)_2D_3$ exerts important cytoprotective effects in a number of targets, especially by increasing antioxidant activity or by attenuating increases in free intracellular Ca^{2+} ($[Ca^{2+}]_i$). Thus, the hormone protects against damage from a long list of toxins and carcinogens known to act principally via release of free radicals. Buffering of $[Ca^{2+}]_i$ may occur through several mechanisms, including, for example, increased Ca^{2+} channel activity or increases in Ca^{2+}-binding proteins such as calbindin-D_{28k}.

B. Regulation of Vitamin D-Related Responses

In many tissues, $1,25(OH)_2D_3$ alters processes that contribute to the ability of the molecule to regulate its own responsiveness within the tissue. $1,25(OH)_2D_3$ treatment almost universally up-regulates 24-hydroxylase activity, which is an early step in $1,25(OH)_2D_3$ clearance pathways. In more tissue-specific patterns, such treatment also regulates VDR levels and 1α-hydroxylase activity. In the latter case, up-regulation of tissue 1α-hydroxylase activity is thought to provide a local enhancement of the hormonal action with minimal effects on plasma calcium levels. Uncontrolled elevation of this paracrine system may be responsible for the hypercalcemia associated with some diseases such as sarcoidosis. There are also emerging reports of other cellular proteins (e.g., a heat-shock 70-related protein and the Ca^{2+}-binding protein calreticulin) that interfere with genomic actions of the VDR, and their regulation by $1,25(OH)_2D_3$ may be a feedback mechanism to turn off $1,25(OH)_2D_3$ responsiveness.

IV. $1,25(OH)_2D_3$ FUNCTIONS IN NONCLASSICAL TARGETS: TISSUE-SPECIFIC EFFECTS

A. Skeletal Muscle: a Tissue with Well-Delineated Nongenomic Effects of $1,25(OH)_2D_3$

Vitamin D deficiency has long been known to be associated with a generalized muscle weakness, which can lead to muscle atrophy and which is reversed by vitamin D treatment. It now appears that there are both nongenomic and genomic mechanisms through which $1,25(OH)_2D_3$ regulates skeletal muscle function. In a long and elegant series of studies, the research team of Boland and de Boland has delineated the nongenomic mechanisms induced by $1,25(OH)_2D_3$, principally using models from chick skeletal muscle. Their studies define a system in which there is an intricate interplay between numerous intracellular signaling pathways, which likely also interact with the nuclear VDR mechanisms. In this system, $1,25(OH)_2D_3$ treatment results in rapid activation of phospholipase C, producing inositol 1,4,5-trisphosphate ($InsP_3$) and diacylglycerol (DAG). These effectors result in an increase in $[Ca^{2+}]_i$ levels, with an initial release (1 min) from internal stores and then a sustained phase (up to 5 min) of uptake through both L-type and store-operated Ca^{2+} channels. These effects parallel, but are not dependent on, increases in adenylyl cyclase and protein kinase A activities. However, the increases in $[Ca^{2+}]_i$ are dependent on activation of calmodulin, protein kinase C, and tyrosine kinase pathways. In fact, the relationship between $1,25(OH)_2D_3$ stimulation and activation of tyrosine kinases is complex in this system. $1,25(OH)_2D_3$ induces tyrosine kinase cascades, which result in increased phosphorylation of tyrosine residues in several proteins, including, in particular, phospholipase C-γ (which increases $[Ca^{2+}]_i$ from internal stores and by uptake through Ca^{2+} channels),

the mitogen-activated protein kinases (MAPKs) ERK1 and ERK2, and c-myc. The $1,25(OH)_2D_3$ effect on MAPK activation is dependent on $[Ca^{2+}]_i$ and protein kinase C (PKC). In addition, $1,25(OH)_2D_3$ treatment increases Src kinase activity and decreases its tyrosine phosphorylation, and also causes increases in the levels of a VDR–Src kinase complex that is associated with elevated tyrosine phosphorylation of the VDR. The function of this tyrosine-phosphorylated VDR–Src kinase complex and its relationship to nuclear actions of the VDR have not yet been established. In rat skeletal muscle, $1,25(OH)_2D_3$ also activates phospholipase D, which results in a second phase of DAG release from phosphatidylcholine. This activation step is dependent on elevated $[Ca^{2+}]_i$ and G-protein activity, but its contributions to the $1,25(OH)_2D_3$ effects in this system have not been fully delineated.

The rapid $1,25(OH)_2D_3$ effects, via tyrosine kinase cascades, on the growth-related MAPK activity and the mitogenic effects of c-myc highlight the concept of cross-talk between the nongenomic pathways activated by $1,25(OH)_2D_3$ and nuclear actions of the VDR. The effects of $1,25(OH)_2D_3$ on growth and differentiation in this system are complex and depend on the developmental state. For example, in undifferentiated chick embryo myoblasts, there is stimulation of DNA synthesis and inhibition of myogenesis. As cultures form more differentiated myotubes, the $1,25(OH)_2D_3$ effects result in inhibition of DNA synthesis and an increase in differentiation as defined by increased synthesis of biochemical markers typical of differentiated muscle. Moreover, PKC α activation was associated with the proliferation phase, whereas its activity was decreased during the differentiation stage.

B. CNS: Neuroprotective Roles of $1,25(OH)_2D_3$

Numerous sites throughout the central nervous system contain VDRs, but the effects of VDRs are not well understood in each of these sites. The cerebellum contains high levels of the vitamin D-related calbindin-D_{28k}, where its expression is not altered by $1,25(OH)_2D_3$/vitamin D status. Nevertheless, there is evidence for roles of $1,25(OH)_2D_3$ in the brain under a variety of conditions. For example, changes in VDR distribution patterns in the central nervous system (CNS) during development suggest possible roles in this process. In cerebral cortex, $1,25(OH)_2D_3$ treatment alters the levels of some enzyme activities (e.g., acetylcholinesterase, citrate synthase, and acyl phosphatase), but not others (e.g., cytochrome *c* oxidase and acid phosphatase).

Chronic treatment with $1,25(OH)_2D_3$ has been reported to provide neuroprotective roles in models of both aging and stroke. The rationale for the aging studies comes in part from putative links between altered calcium homeostasis and the development of Alzheimer's disease. Consistent with this hypothesis, when rats are treated chronically with $1,25(OH)_2D_3$, there is an increase in neuronal density in the hippocampus, wherein a loss of neurons is considered a reliable biomarker for aging. In the cerebral artery ligation model of stroke, $1,25(OH)_2D_3$ pretreatment decreases ischemic brain injury concomitant with elevated levels of plasma calcium. In this model, $1,25(OH)_2D_3$ treatment also increases levels of glial cell-derived neurotropic factor in the cortex, which has been associated with reduced cerebral infarction in this model. $1,25(OH)_2D_3$ pretreatment in culture models also protects dopaminergic neurons against cytotoxic effects of numerous insults, including reactive oxygen species, glutamate, specific dopaminergic toxins, or elevated Ca^{2+} entry induced by Ca^{2+} ionophores. Mechanistic studies have indicated that these $1,25(OH)_2D_3$ protective effects may be via direct actions on neurons, in that physiological doses of $1,25(OH)_2D_3$ can reduce the damage to hippocampal neurons *in vitro* that results from excess/inappropriate neurotransmitter release and the resulting sustained excitation. Similar doses of $1,25(OH)_2D_3$ also reduce L-type Ca^{2+} channel levels by effects at the mRNA level, suggesting that the resulting decrease in Ca^{2+} entry into the cell may play a role in the neuroprotective effect. Another clue to the neuroprotective role of $1,25(OH)_2D_3$ comes from a study in which $1,25(OH)_2D_3$ treatment increased the activity of γ-glutamyl transferase, an enzyme that has been implicated in scavenging reactive oxygen species, particularly in pericytes and peripheral astrocytes in rat brain.

CNS inflammatory disease can be associated with excess production of inducible nitric oxide synthase (iNOS). In mice with clinical signs of experimental allergic encephalitis, $1,25(OH)_2D_3$ treatment reduces CNS iNOS levels in a region- and cell-specific pattern and results in improvement of the clinical signs of the disease. Subsequent studies have documented loss of paralysis, decreased white matter and meningeal inflammation, and decreased CNS macrophage accumulation after $1,25(OH)_2D_3$ treatment. These results suggest that $1,25(OH)_2D_3$ provides a protective role in iNOS-associated CNS diseases. Although these $1,25(OH)_2D_3$ effects may relate more

to immunomodulatory effects rather than direct neuronal actions, the beneficial effects of $1,25(OH)_2D_3$ treatment in this experimental model of multiple sclerosis are particularly interesting in light of prior suggestions that multiple sclerosis in humans may correlate with diminished activity of the vitamin D endocrine system.

C. Pancreas: Nongenomic and Cytoprotective Effects of $1,25(OH)_2D_3$

There is evidence indicating that insulin secretion and synthesis are impaired in vitamin D deficiency and are restored with $1,25(OH)_2D_3$ treatment. The defects have been shown to relate to the loss of $1,25(OH)_2D_3$ effects on several signal transduction pathways important in effecting glucose-signaled insulin secretion in pancreatic beta cells, including those involved in regulating $[Ca^{2+}]_i$, phospholipase C, PKC, and adenylyl cyclase. These insulinotropic effects of $1,25(OH)_2D_3$ are likely mediated through nongenomic mechanisms, as evidenced in part by their inhibition by a membrane-specific $1,25(OH)_2D_3$ antagonist [$1\beta,25(OH)_2D_3$]. In addition, $1,25(OH)_2D_3$ stimulates the production of a number of specific, but as yet unidentified, proteins in islet cells by a mechanism that seems to involve genomic pathways. These observations may also be important in clinical situations associated with transient defects in glucose signaling. For example, in patients with gestational diabetes, $1,25(OH)_2D_3$ treatment reduces plasma glucose levels, possibly by increasing insulin sensitivity.

Unlike most of the other nonclassical $1,25(OH)_2D_3$ targets, in addition to nuclear VDRs, pancreatic beta cells (and alpha cells in some species) contain the vitamin D-related calbindin-D_{28k}, and it is regulated by $1,25(OH)_2D_3$ in the beta cells. However, studies designed to identify a role for calbindin-D_{28k} in $1,25(OH)_2D_3$ effects on insulin secretion have thus far produced negative results. Pancreatic tissue damage, induced experimentally, for example, by oxidative stress, can result in islet cell destruction by cytokine-induced pathways. In this model of beta cell destruction and diabetes onset or islet allograft rejection, $1,25(OH)_2D_3$ exposure reduces several markers of oxidative stress and decreases immune/-cytokine activation, suggesting that the hormone can exert a protective effect against immune destruction in these systems. In another model of diabetes in the nonobese diabetic (NOD) mouse, $1,25(OH)_2D_3$ prevents the development of diabetes by a mechanism that results in reduced resistance to apoptotic signals in NOD thymocytes and thus disrupts the autoimmune response.

D. Cardiac Myocytes, Including the Atrial Endocrine Myocytes

There are complex effects of vitamin D deficiency, $1,25(OH)_2D_3$ supplementation, and vitamin D or $1,25(OH)_2D_3$ excess in the heart. The complexity derives in part from the attendant changes in parathyroid hormone (PTH) and plasma or tissue calcium. For example, low $1,25(OH)_2D_3$ levels may play a role in the cardiac disease associated with chronic renal failure (Table 4), and vitamin D

TABLE 4 Possible Vitamin D Effects on the Cardiovascular System

	Vitamin D/ $1,25(OH)_2D_3$ levels[b]

supplementation in these patients results in improved cardiac function. However, the therapeutic improvement may also be due to indirect effects of $1,25(OH)_2D_3$ replacement on other physiological parameters, because impaired vitamin D status may also alter cardiovascular-related systems, including vascular smooth muscle and blood pressure, or other components of calcium homeostasis, in particular PTH and calcium levels (Table 4).

VDR sites have been described in cardiac muscle, with some concentration in atrial natriuretic peptide (ANP)-producing cells of the atria. $1,25(OH)_2D_3$ effects in cardiac tissues, as in many nontraditional targets, are independent of traditional $1,25(OH)_2D_3$ effects such as induction of calcium-binding proteins or changes in VDR levels. $1,25(OH)_2D_3$ stimulation in these systems does include nongenomic, and perhaps genomic as well, effects on Ca^{2+} uptake pathways, as well as developmental roles and genomic effects on ANP production. In nongenomic pathways in cardiac muscle, adenylyl cyclase and G-proteins are involved in $1,25(OH)_2D_3$-induced Ca^{2+} uptake through L-type Ca^{2+} channels and this effect is accompanied by cyclic adenosine monophosphate (cAMP)/protein kinase A (PKA)-dependent increases in microsomal protein phosphorylation.

Vitamin D deficiency results in reduced cardiac contractility, an effect reversed by $1,25(OH)_2D_3$. These effects on contractility are probably mediated at many levels: specific effects of $1,25(OH)_2D_3$ treatment include altered myocyte numbers, altered myosin isoenzyme patterns, and altered activity of many metabolic enzymes in the heart. In neonatal ventricular myocytes, $1,25(OH)_2D_3$ has complex effects on maturation and growth. It inhibits differentiation by a mechanism that may involve PKC. $1,25(OH)_2D_3$ inhibits proliferation by blocking entry into the cell cycle S phase, though there are conflicting reports on whether it also induces hypertrophy. These growth effects are paralleled by events *in vivo*, whereby vitamin D deficiency induces morphological changes in the heart that reflect cardiac myocyte hyperplasia and are accompanied by elevated c-myc levels. Also, in hearts of rat pups from mothers fed diets with low levels of vitamin D, there is evidence of slowed cardiac development. In contrast, excess vitamin D can result in protease-induced cardionecrosis, accompanied by damage to the cardiac contractile apparatus. In the ANP-producing endocrine myocytes of the atria, $1,25(OH)_2D_3$ inhibits ANP synthesis (decreased mRNA) and release, and these genomic effects are Ca^{2+} independent.

E. Vascular Smooth Muscle

$1,25(OH)_2D_3$ also seems to play a role in maintaining normal function of vascular smooth muscle by effects on a number of important processes. For example, the cardiovascular defects due to impaired vitamin D status in renal failure also include effects on smooth muscle elements (Table 4). Most $1,25(OH)_2D_3$ effects described to date in vascular smooth muscle seem to be mediated by genomic pathways, in contrast to the presence therein of well-described membrane-linked (nongenomic) effects of estrogen in these systems.

Recent studies of $1,25(OH)_2D_3$ effects in vascular smooth muscle have indicated that the responses differ in different areas of the vascular tree. In rat mesenteric resistance vessels, $1,25(OH)_2D_3$ treatment *in vivo* prior to vessel isolation increases contractile force and the force response to stress hormones. These long-term effects in more distal vessels seem to reflect a genomic effect of the hormone, but do not involve effects on myosin expression. Conversely, in the aorta, $1,25(OH)_2D_3$ treatment increases the expression of myosin light and heavy chains. When the mesenteric vessels are cultured, they lose the force response to stress (e.g., norepinephrine exposure) and this loss parallels altered patterns of myosin heavy chain expression. These detrimental effects are prevented by $1,25(OH)_2D_3$ treatment. Consistent with $1,25(OH)_2D_3$ effects on vascular contractility, $1,25(OH)_2D_3$ treatment increases blood pressure in *in vivo* models, likely via a genomic mechanism.

Soft tissue calcification, particularly in kidney and heart, is a serious consequence of the hypercalcemia caused by $1,25(OH)_2D_3$/vitamin D excess. Studies of vascular calcification have shown that $1,25(OH)_2D_3$ treatment increases *in vitro* calcification of cultured vascular smooth muscle cells, apparently by inhibiting expression of PTH-related peptide (PTHrP) (which inhibits calcification) and by stimulating expression and activity of procalcification proteins such as alkaline phosphatase and osteopontin.

F. Endocrine and Reproductive Tissues

$1,25(OH)_2D_3$ alters the function of a number of endocrine tissues. It increases thyrotropin-releasing hormone (TRH)-stimulated thyroid-stimulating hormone (TSH) and prolactin secretion in the pituitary. It has a wide range of effects in thyroid C cells, including inhibiting calcitonin gene expression and altering cell structure. It affects the synthetic pathways for adrenal catecholamines by regulating a

number of the key enzymatic steps. Moreover, it is required for normal gonad function and estrogen synthesis in both males and females.

In many tissues, $1,25(OH)_2D_3$ exerts its activities through alterations in cAMP pathways. For example, in rat FRTL-5 thyroid cells, $1,25(OH)_2D_3$ regulates (reduces) TSH/cAMP signaling and affects basal cAMP levels. Inhibition of TSH-induced cAMP production is associated with a reduction in TSH-induced growth and iodide uptake in these thyroid-derived cells. TSH receptor levels and the levels of the G-protein $G_{\alpha s}$, which transduces the TSH receptor response to cAMP, are not affected. Conversely, $1,25(OH)_2D_3$ treatment specifically increases the levels of the inhibitory G-protein $G_{\alpha i2}$, but not $G_{\alpha i1}$ or $G_{\alpha i3}$. Because there is evidence of $1,25(OH)_2D_3$ effects beyond the cAMP effects, its effect on PKA subunits has also been also assessed, with a rather complex result. $1,25(OH)_2D_3$ treatment increases levels of the PKA regulatory subunit RIIβ. Additional studies have confirmed that the post-cAMP $1,25(OH)_2D_3$ inhibition in this system is due to the resultant increase in the relative levels of the PKA subunit tetrameric complex $RII\beta_2C_2$, which thus decreases the relative levels of the alternate tetrameric form $RI\alpha_2C_2$, because PKA I is the predominant effector in this system. These effects of attenuating the cAMP response pathway at several steps are long term and thus are likely to be genomic effects of $1,25(OH)_2D_3$.

Many reproductive tissues, including testis, epididymis, and uterus, contain modest VDR levels. However, the levels of these VDR sites and of the vitamin D-related calbindins are not regulated by $1,25(OH)_2D_3$ in these tissues. In the uterus, for example, they are estrogen regulated. Moreover, although there are least modest effects (the degree seems to vary among animal models) of vitamin D deficiency on reproduction in males and females, it is possible that the attendant hypocalcemia is responsible for at least some of these effects.

When male and female rats are treated neonatally with $1,25(OH)_2D_3$, there are important changes in their sexual behavior as adults, suggesting that $1,25(OH)_2D_3$ may interfere in sexual imprinting and normal sex steroid receptor actions. Similarly, male pups from mothers exposed to $1,25(OH)_2D_3$ during pregnancy exhibit enlarged prostates but no change in seminal vesicle size. Moreover, there is a high rate of sudden death in these uncastrated male pups at puberty. Thus, there seem to be tissue-specific effects of $1,25(OH)_2D_3$ on development and genetic imprinting in the prostate.

When parameters of the calcium homeostatic endocrine system were assessed in women with fertility problems (especially arrest of follicular development) due to polycystic ovarian disease, despite normocalcemia in all of the patients, a subset exhibited relatively low $25(OH)D_3$ levels and some had elevated PTH levels. Vitamin D and calcium repletion resulted in two pregnancies and the return to normal menstrual cycles for several women. These observations were interpreted as indicating that abnormal calcium homeostasis may contribute to polycystic ovarian disease and/or the problems in follicular development associated with the disease.

In mammary glands, VDR levels vary from puberty to maturation and during pregnancy and lactation. The calcium-supplemented VDR knockout mouse has been used as a model to assess possible effects of $1,25(OH)_2D_3$/VDR on mammary gland development. In this system, the initial stage of development, ductal branching after puberty, is seen to be normal. However, later stages of branching and ductal development show some degree of undifferentiation, suggesting roles for $1,25(OH)_2D_3$/VDR in normal differentiation in this system. Moreover, these observations may explain part of the correlation of reduced activity of the vitamin D endocrine system and mammary tumor development, in that undifferentiated structures are a target of agents that cause cancer transformation in this system.

G. Lung

In the adult rat lung, there are low levels of VDRs and the calbindin-D_{9k}, but regulation of both proteins is $1,25(OH)_2D_3$ independent. In the near-term fetal (but not neonatal) rat lung, type II alveolar cells express VDRs and respond to $1,25(OH)_2D_3$ treatment with increased phospholipase activity, including synthesis and release of disaturated phosphatidylcholine and improved surfactant release and advancement of other maturation processes. In contrast, fetal lung fibroblasts do not express VDRs, but do exhibit 1α-hydroxylase activity, which can produce $1,25(OH)_2D_3$. These observations suggest that there is a paracrine $1,25(OH)_2D_3$ response system in the fetal lung for communication between epithelial and mesangial cells; this system may be involved in achieving the degree of lung maturation that is necessary to reduce the respiratory distress syndrome of premature birth.

H. Liver

Chronic liver disease is often associated with vitamin D depletion. Alternatively, $1,25(OH)_2D_3$ treatment induces the activity of a number of metabolic enzymes in the liver and reduces the hepatic damage from some toxins. Moreover, the liver has long served as a system for studies of nongenomic $1,25(OH)_2D_3$ effects.

Impaired calcium metabolism has been shown to interfere in hepatic regeneration processes—for example, after partial hepatectomy. Studies of $1,25(OH)_2D_3$ and calcium effects on specific markers of hepatic regeneration [e.g., mRNAs for hepatocyte growth factor and transforming growth factor-α (TGF-α)] and cell cycle regulators (e.g., cyclin D1 and cyclin A) indicate that both factors are important in optimal liver regeneration and that impaired regrowth occurs through molecular changes that reduce G1 transit efficiency in the cell cycle. In fetal rat hepatocytes, $1,25(OH)_2D_3$ treatment potently inhibits synthesis of α-fetoprotein and corticosteroid-binding globulin (CBG). $1,25(OH)_2D_3$ inhibition of CBG synthesis is much more potent than are the effects of activators of the retinoic acid receptor (RAR) or retinoic acid X receptor (RXR) and is not affected by the stimulation of CBG synthesis by the thyroid hormone triiodothyronine (T_3).

Studies of the antioxidant role of $1,25(OH)_2D_3$ in the liver show that vitamin D supplementation in the rat is more potent than vitamin E supplementation with respect to changes in a number of antioxidant activities, underscoring the notion that many of the cytoprotective effects of $1,25(OH)_2D_3$ may be mediated through antioxidant effects. More recent studies indicate that chronic $1,25(OH)_2D_3$ treatment inhibits hepatocyte damage following injection of the carcinogen diethylnitrosamine, likely by inhibiting lipid peroxidation, which in turn protects cell membranes from damage induced by free radicals.

V. $1,25(OH)_2D_3$/VDR INHIBITS BREAST AND PROSTATE CANCER GROWTH

VDR sites have been described in both breast and prostate epithelial cells. Reports of growth inhibitory $1,25(OH)_2D_3$ effects (particularly in cell models) in cancers from a number of tissues soon followed. These antiproliferative effects led to the hypothesis that $1,25(OH)_2D_3$ might be useful in treatment of a variety of cancers. To date, there is an active interest in these treatments and their mechanisms, but the issue is, of course, complicated by the hypercalcemic effect of $1,25(OH)_2D_3$ treatment. Thus, a number of pharmaceutical companies are actively seeking to develop noncalcemic analogues of the hormone.

In breast cancer, VDR is expressed in most breast cancer cell lines and in about 80% of human tumors. VDR levels in breast cancer do not correlate to sex steroid receptor levels nor to the stage of tumor development, and there is not always a good correlation between VDR levels in breast cancer models and the ability of $1,25(OH)_2D_3$ to inhibit tumor/cell growth. $1,25(OH)_2D_3$ inhibition of breast cancer cell growth includes both antiproliferative (altered cell cycle proteins) and pro-apoptotic effects.

In prostate cancers, the presence of VDR is required for the $1,25(OH)_2D_3$ effects, but there is not a good correlation of VDR levels and $1,25(OH)_2D_3$ responsiveness across cell models. Thus, other factors must contribute to $1,25(OH)_2D_3$ responsiveness in these systems. Recent studies have indicated that inhibition of 24-hydroxylase activity in VDR-containing but relatively $1,25(OH)_2D_3$-insensitive cells restores $1,25(OH)_2D_3$ sensitivity, suggesting that enhanced $1,25(OH)_2D_3$ clearance can contribute to the differences in apparent VDR responsiveness. Nevertheless, studies to date implicate only genomic mechanisms in the growth inhibitory effects of $1,25(OH)_2D_3$ in prostate cancer cells. Specific effects of $1,25(OH)_2D_3$ in these systems include alterations in the cell cycle (although the details differ among cell types), increases in the prostate cell differentiation marker prostate-specific antigen (PSA), and reduced activity of several growth factors. However, in most cases, the details of the $1,25(OH)_2D_3$ effects are not yet well understood. The ability of $1,25(OH)_2D_3$ to induce androgen receptor levels in these systems has led to the suggestion that it may also be useful to restore sensitivity to therapy in patients who have developed anti-androgen resistance. Finally, a small clinical trial of the effectiveness of $1,25(OH)_2D_3$ treatment in patients with prostate cancer has demonstrated that $1,25(OH)_2D_3$ treatment does slow prostate cancer growth *in vivo*, although hypercalcemia is a problem, as expected.

VI. SUMMARY

There are numerous effects of $1,25(OH)_2D_3$ in nonclassical target tissues, including both somewhat general effects on cell/tissue function and tissue-specific effects. The initial impetus for studying $1,25(OH)_2D_3$ effects in many of these tissues was

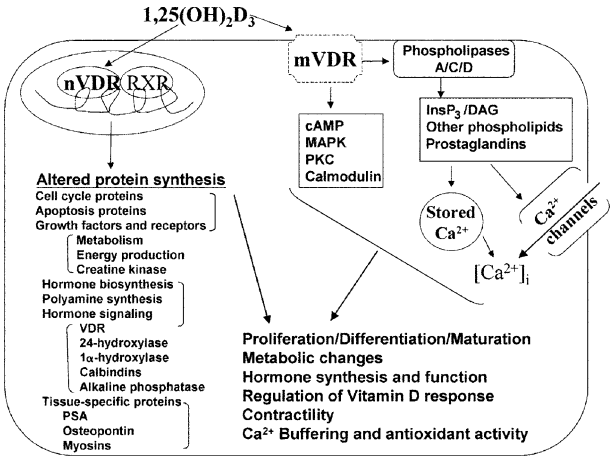

FIGURE 1 A schematic diagram showing the range of $1,25(OH)_2D_3$ effects in nonclassical target tissues. Left: A summary of many of the proteins/processes regulated at the transcriptional level by the nuclear vitamin D receptor (nVDR). Right: A summary of some of the intracellular signaling processes affected through the putative membrane VDR (mVDR) and systems they may affect. Abbreviations: RXR, retinoic acid X receptor; cAMP, cyclic adenosine monophosphate; MAPK, mitogen-activated protein kinase; $InsP_3$, inositol 1,4,5-trisphosphate; DAG, diacylglycerol; PSA, prostate-specific antigen.

the finding of significant (albeit perhaps low) levels of VDR sites in the tissues. The initially described VDR sites in these tissues were likely the traditional nuclear VDRs, which regulate cell function at the level of gene transcription (Fig. 1). However, in many of these tissues, many effects of $1,25(OH)_2D_3$ may be mediated by the as yet uncharacterized membrane VDR sites via a plethora of intracellular signal transduction pathways (Fig. 1). Defining the gene targets of the traditional nuclear VDR sites in these tissues, as well as characterizing the membrane VDR sites and their targets, are exciting directions for future studies.

Glossary

calbindin Vitamin D-regulated calcium-binding protein (two forms, with molecular masses of 9 and 28 kDa) strongly induced by $1,25(OH)_2D_3$ in classical target tissues.

classical $1,25(OH)_2D_3$ target tissues The earliest identified $1,25(OH)_2D_3$/vitamin D targets, such as kidney, bone, and intestine, in which the predominant hormonal effect is Ca^{2+} translocation.

1α-hydroxylase The final enzyme in the biosynthetic pathway that produces the active hormone $1,25(OH)_2D_3$.

24-hydroxylase The initial enzyme in the clearance pathway for $1,25(OH)_2D_3$.

membrane vitamin D receptor Newly hypothesized membrane receptor of as-yet unknown structure that seems to mediate some actions of $1,25(OH)_2D_3$ through well-known membrane receptor-induced signal transduction pathways.

nonclassical $1,25(OH)_2D_3$ target tissues A number of tissues other than those in the earliest studies describing vitamin D receptor and $1,25(OH)_2D_3$ effects.

nuclear vitamin D receptor The traditional $1,25(OH)_2D_3$/vitamin D receptor that exerts its actions as a $1,25(OH)_2D_3$-activated nuclear transcription factor.

Wnt Protein Family

BENJAMIN N. R. CHEYETTE* AND RANDALL T. MOON†

University of California, San Francisco • †University of Washington

Wnts are a family of secreted signaling proteins. Wnt signaling is critical during animal development, contributing to the regulation of cell fate specification, cell morphology, cell proliferation, cell migration, cell polarity, and tissue patterning. Misregulation of Wnt signaling is a likely etiologic factor in human disease and has been strongly implicated in oncogenesis.

I. HISTORY AND BIOLOGICAL SIGNIFICANCE

The manner in which Wnt signaling was discovered reflects its biological importance across animal species. Mutations in the *wingless* (*wg*) gene of the fruit fly *Drosophila melanogaster* lead to a spectrum of developmental phenotypes. Null mutations cause severe segmental patterning defects that are lethal during embryogenesis. Some hypomorphic mutations are viable—the first mutation identified produces adult flies without wings, which gave the *Drosophila* gene its name. The *int-1* proto-oncogene was separately discovered as a target of the mouse mammary tumor virus (MMTV), a retrovirus that does not carry its own oncogene, but induces carcinomas in the mammary glands of susceptible mice by activating a host gene at its DNA integration site (int). The discovery that *Drosophila wg* and mouse *int-1* are orthologues and are part of a large evolutionarily conserved group of genes in multicellular animals led to the contracted family name "*Wnt*."

A. Cancer

The initial identification of *Wnt1/int-1* as a proto-oncogene has been extended by further investigation. Alteration in the Wnt/β-catenin signaling pathway is now a well-established etiologic agent in tumorigenesis. The evidence is most striking for two downstream intracellular signaling components: the gene product of the *adenomatous polyposis coli* (*APC*) locus and the β-catenin protein. APC is a negative regulator of the canonical Wnt/β-catenin pathway that is mutated in the majority (>80%) of sporadically occurring colorectal adenomas and carcinomas. In addition, mutations in this gene are responsible for the genetic disease familial adenomatous polyposis, characterized by the proliferation of initially benign colonic polyps that predispose afflicted individuals to intestinal cancer. Similarly, mutations in β-catenin, the transcription cofactor that is activated by canonical Wnt signaling, have been described in a wide array of different cancer types. Mutations in other Wnt pathway components have likewise been associated with cell transformation *in vitro* and with the pathogenesis of an array of cancer types *in vivo* (Table 1).

B. Other Diseases

Given the prevalence and biological significance of Wnt signaling, it should not be surprising that it has

major role in population genetics and forensic medicine. The multifunctionality of DBP has now been recognized. In addition to transporting vitamin D metabolites, DBP is proposed to be involved in the transport of fatty acids, to function as a plasma actin scavenger following tissue damage, and to play a role in complement C5a-mediated chemotaxis, and DBP may be involved in the activation of macrophages.

II. REGULATION AND EXPRESSION OF DBP

DBP is a member of the albumin (ALB), α-fetoprotein (AFP), and α-albumin/afamin (AFM) gene family that is encoded on human chromosome 4. Initial studies have sublocalized the DBP gene to 4q11–q13, and refined mapping of this region has demonstrated that these four related genes are linked in the following order: centromere–3′-DBP-5′–5′-ALB-3′–5′-AFP-3′–5′-AFM-3′–telomere. Despite this linkage and the high degree of sequence and structural similarities among DBP, ALB, AFP, and AFM, the multifunctionality of DBP is a unique characteristic.

The human DBP gene itself is composed of 13 exons and spans over 42 kb from the transcription initiation site to the polyadenylation site. The cDNA structure of DBP was initially reported for humans and was subsequently determined for rat, mouse, rabbit, turtle, and chicken. Turtle DBP occupies a unique niche because it also binds thyroxine. Thus far, DBP appears to be limited to vertebrate species; a search of the *Drosophila melanogaster* genome database revealed no sequence homologues to DBP.

Human DBP mRNA encodes a 458-amino-acid secreted protein following cleavage of its 16-amino-acid signal sequence. DBP is a monomeric protein, migrating at approximately 58 kDa (Table 1). Its exact size is dependent on its glycosylation state. Like other members of the ALB family, DBP is cysteine rich. In the case of DBP, all 28 cysteine residues are present in the disulfide form and define a signature modular structure of three internally repeated peptide domains. Biochemical binding studies initially identified a vitamin D sterol-binding domain near the amino-terminus and an actin-binding domain closer to the carboxyl-terminus. The X-ray crystallographic details of DBP structure including its vitamin D- and actin-binding domains have recently become available. DBP has significant similarity to the α-helical structure of ALB, but the overall three-dimensional orientation of DBP's three internal peptide domains is quite dissimilar and is responsible for its binding properties. The helices of domain I in the N-terminus form an open vitamin D-binding cleft, accessible to solvent and lined with hydrophobic residues. Such a cleft cannot be formed in ALB, and this binding cleft is dissimilar to the internal and closed vitamin D-binding pocket in the nuclear vitamin D receptor molecule. The unique organization of DBP's three internal domains compared to ALB is central to its unique ability to bind G-actin. DBP clamps onto G-actin by narrowing the distance between domain I on one side and domains II and III on the other side, by virtue of a hinge at glycine 227. Thus, a very large binding interface is formed by the overall fold of DBP; this may account for the high-affinity association between DBP and actin. Human DBP expression is detected by the end of the first trimester and reaches normal adult circulation levels (4–8 μM) by term. Estimations from kinetic studies suggest that the daily production rate of DBP is approximately 10 mg/kg. The plasma half-life of DBP is 2.5 to 3 days, whereupon it is recycled by megalin or degraded completely in various tissues. The expression of DBP appears to undergo hormonal and growth factor regulation. Modest increases in DBP expression have been reported during pregnancy and in subjects receiving estrogen. In the Hep3B hepatoma cell line, interleukin-6 and dexamethasone were shown to increase DBP mRNA by approximately twofold and transforming growth factor-β decreased DBP mRNA

TABLE 1 Features of DBP

General properties	
Size	58 kDa
Plasma concentration	4–8 μM
Plasma half-life	2.5–3 days
Daily production rate	~10 mg/kg
Vitamin D-binding abilities	
Plasma capacity	2.4 mg/liter
Affinity	
$25(OH)D_3$	$K_a = 5 \times 10^8\ M^{-1}$
$1,25(OH)_2D_3$	$K_a = 4 \times 10^7\ M^{-1}$
Actin-binding abilities	
Plasma capacity	270 mg/liter
Affinity	$K_a = 2 \times 10^9\ M^{-1}$
Macrophage and osteoclast activation abilities	
DBP "activation"	By β-galactosidase and sialidase
Macrophage effects	Increased superoxide production, increased phagocytic activities
Osteoclast effects	Increased osteoclastogenesis
Chemotactic abilities	
C5a enhancement	Binding of DBP to leukocytes
DBP leukocyte-binding site	Chondroitin sulfate proteoglycans
Affinity	Low affinity, nonselective

in a dose-dependent fashion by up to fivefold. Decreased DBP titers have also been reported in plasma from patients with advanced liver or kidney disease.

DBP is expressed at low levels in a variety of tissues, but most serum DBP is derived from the liver. Tissue-specific regulation of DBP has been postulated to be dependent on the relative abundance of two transcription factors, hepatocyte nuclear factor 1α (HNF1α) and HNF1β. These two closely related homeodomain-containing transcription factors bind to DNA as either homodimers or heterodimers. The DBP proximal promoter has three functional HNF1-binding sites. In this model, HNF1α homodimers stimulate a high level of DBP expression in the liver. In the kidney, the increased expression of HNF1β, and therefore formation of heterodimers, results in reduced DBP expression. In this situation, HNF1β functions as a *trans*-dominant inhibitor of HNF1α-mediated enhancing activity. The unique role of HNF1 in DBP expression is supported by the observation that DBP expression is reduced by 50% in the livers of HNF1 null mice. These observations would suggest that the net expression of the DBP gene reflects a balance between the two major HNF1 isoforms. Recently, mutations in human HNF1α and HNF1β have been identified to be the cause of some cases of maturity onset diabetes of the young (MODY). Whether or not DBP expression is affected in individuals with these MODY mutations remains undetermined.

III. DBP POLYMORPHISMS

The 3 most common allelic variants of DBP differ based on four single-nucleotide polymorphisms at codons 152, 311, 416, and 420. These protein variants are known as Gc*1F, Gc*1S, or Gc*2, where F and S refers to relative fast or slow migration rate following gel electrophoresis. The gene products of each variant allele differ from one another by amino acid substitution and/or by polysaccharide attachment. In addition to these 3 common alleles, there are over 124 rare variant alleles described to date, thus making DBP one of the most polymorphic proteins known. The geographical occurrences of some of these variants have been correlated with patterns of human migration and are therefore of anthropological interest. The affinities for vitamin D metabolites by several of these DBP isoforms have been determined, and for the most part, it was found that variants with higher isoelectric points have slightly lower ligand affinity. Any biological implications of these minor changes in binding affinity remain to be identified.

In the late 1980s, there was much controversy linking the expression of different DBP variants with susceptibility to human immunodeficiency virus infection. These initial reports were later proven to be erroneous by many investigators. Multiple studies have also been conducted over the years in an attempt to link the DBP variants to susceptibility or resistance to a variety of diseases such as multiple sclerosis, chronic obstructive pulmonary disease, pulmonary tuberculosis, and even schizophrenia. To date, no conclusive correlation has been reported in any of these cases. More recently, several attempts have been made to link DBP with the occurrence of diabetes. A higher prevalence of the Gc*1S-Gc*2 genotype was observed in type 2 diabetes in Japan. This genotype was also associated with higher fasting insulin levels and a higher index of insulin resistance in nondiabetic Japanese. In this population and in Dogrib Indians, the lowest fasting insulin levels were seen in individuals harboring the Gc*1F-Gc*1F genotype. Interestingly, a difference in response to the oral glucose tolerance test was also observed in nondiabetic Pima Indians with this genotype, suggesting a link between the prediabetic state and DBP genotype. Conversely, in a mixed population study of nondiabetic Hispanic Americans and Caucasians, this Gc*1F-Gc*1F genotype was associated with high fasting glucose levels. Studies in Caucasian populations would suggest that there is no association between DBP genetic variants and disease. These conflicting data may reflect the ethnic diversity in the populations sampled. Nonetheless, it is most unlikely that polymorphisms within the DBP gene are directly related to the diabetic trait.

IV. DBP FUNCTIONS

A. Sterol Binding

Under normal physiological conditions, most circulating vitamin D metabolites are protein bound. DBP binds 88% of serum 25-dihydroxyvitamin D_3 [25(OH)D_3] ($K_a = 5 \times 10^8\ M^{-1}$) and 85% of serum 1,25-dihydroxyvitamin D_3 [1,25$(OH)_2D_3$] ($K_a = 4{\times}10^7\ M^1$), leaving 0.40% "free" and the remainder associated with other serum proteins. Because DBP is in significant molar excess over vitamin D, only approximately 5% of the total circulating DBP actually carries vitamin D metabolites. This large molar excess of serum DBP has been hypothesized to play a role in protecting against

vitamin D intoxication by buffering the levels of free vitamin D metabolites. But work using a DBP-deficient (Dbp-null) mouse model had challenged the validity of this idea. Dbp-null mice were generated at the expected Mendelian frequency from intercrosses of Dbp heterozygous animals. These animals are of normal size and appearance. There is no evidence for impairment of fertility in either males or females because intercrosses between Dbp-null animals resulted in normal-sized litters. This conclusion was surprising because extensive population studies had failed to identify a human DBP-null allele. The successful generation of the Dbp-null mice clearly demonstrated that DBP is not essential for viability.

The major role of DBP appears to be in sterol transport. *Dbp*-null mice on normal diets demonstrate only a modest decrease in serum levels of $25(OH)D_3$ and $1,25(OH)_2D_3$, and show no evidence of biological vitamin D deficiency, clearly indicating that free hormone levels are still physiologically adequate. However, when subjected to a vitamin D-deficient diet for 4 to 6 weeks, end-organ effects of vitamin D deficiency become apparent in these animals, suggesting that normal DBP levels offer a degree of protection against short-term, dietary-induced vitamin D deficiency.

To test the buffering capacity of DBP *in vivo*, sublethal doses of vitamin D were administered to *Dbp*-null and wildtype animals. Vitamin D toxicity is manifested by hypercalcemia, bone resorption, and calcification of soft tissues. Surprisingly, *Dbp*-null mice were less susceptible to hypercalcemia and the secondary soft-tissue calcifications of vitamin D toxicity than the wild-type controls. This protection may have arisen secondary to an accelerated clearance of $25(OH)D_3$ from serum and a rapid urinary excretion in the absence of DBP. A partial explanation for this paradoxical phenomenon was provided by the recent hypothesis that megalin in the proximal renal tubule may function to recycle DBP and $25(OH)D_3$.

Megalin/gp330 is a transmembrane protein with a large extracellular domain, a single transmembrane domain, and a short cytoplasmic tail. This protein belongs to the low-density lipoprotein (LDL) receptor family. Megalin is expressed in the proximal brush border surfaces of the kidney epithelium where it appears to function as an endocytic DBP receptor for the reabsorption of apo–DBP and DBP–$25(OH)D_3$ complexes from the glomerular filtrate into the proximal tubular cells (Fig. 1). Here, $25(OH)D_3$ is metabolized to the physiologically active $1,25(OH)_2D_3$. In the absence of DBP, renal uptake and activation of $25(OH)D_3$ via the megalin endocytic recycling pathway would also be absent, thereby resulting in increased $25(OH)D_3$ excretion in

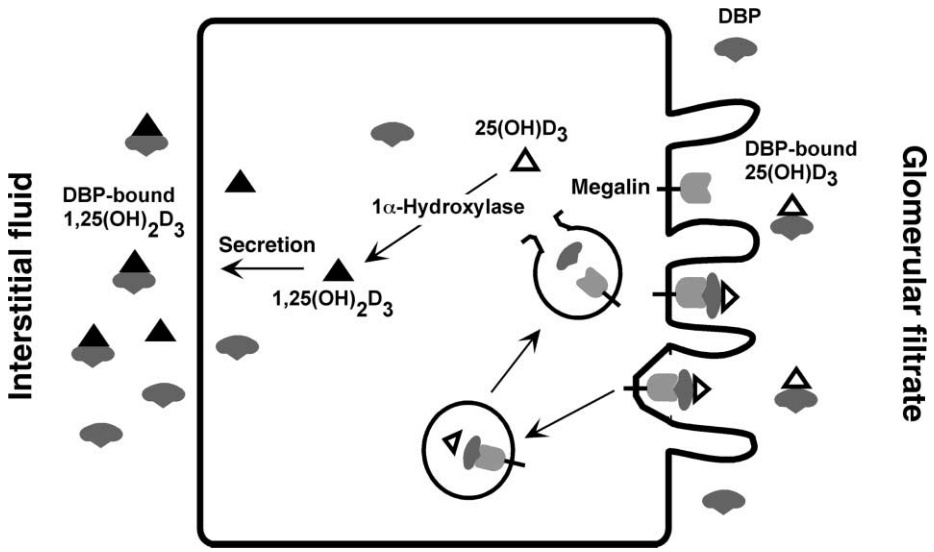

FIGURE 1 Receptor-mediated endocytosis and activation of $25(OH)D_3$ by megalin. DBP-bound $25(OH)D_3$ interacts with megalin located at the brush border surface of the proximal tubule. This complex enters the cell by endocytosis and $25(OH)D_3$ is released and undergoes metabolic activation by 1α-hydroxylase. This active form of vitamin D, $1,25(OH)_2D_3$, is secreted back into the interstitial fluid, where it is rebound by DBP and delivered to target organs. Adapted from White *et al.* (2000). The multifunctional properties and characteristics of vitamin D-binding protein, *Trends in Endocrinology and Metabolism,* **11,** 320–327, with permission from Elsevier Science.

the urine and contributing to the observed resistance to vitamin D toxicity in the *Dbp*-null mice.

Like other members of the LDL receptor family, megalin exhibits broad ligand specificity. Megalin has been demonstrated to bind apolipoproteins, aminoglycosides, receptor-associated protein, and a variety of growth factors as well as DBP. A megalin-deficient mouse model has been generated to further elucidate the significance of this protein. A large percentage of megalin-deficient mice die perinatally from holosprosencephaly. Animals that do survive to adulthood demonstrate severe growth retardation, bone formation defects, and reduced bone density with scalloped bone surfaces. These animals also demonstrate tubular resorption deficiencies and excrete low-molecular-weight plasma proteins in their urine including DBP and albumin, reminiscent of patients with Fanconi syndrome. The loss of plasma carrier proteins such as DBP is concomitant with the loss of $25(OH)D_3$. The disturbances in bone metabolism in the megalin knockout animals as a consequence of vitamin D deficiency have therefore been attributed to the urinary wasting of DBP–$25(OH)D_3$ complexes. These studies may overemphasize the physiological role of megalin-mediated $25(OH)D_3$ in reclamation from the urine. Unlike the megalin knockout mice, *Dbp*-null mice are physiologically normal and show no evidence of biological vitamin D deficiency. This clearly indicates that in the absence of DBP, uptake and activation of $25(OH)D_3$ occur via a pathway that is independent of the proposed DBP–megalin endocytic recycling route. Thus, the role of megalin in vitamin D metabolism and its linkage to DBP recycling remains unclear.

B. Actin Scavenger Activity

DBP is part of an "actin scavenger system" that functions by sequestering G-actin from the circulation for subsequent disposal (Fig. 2). DBP binds monomeric actin (G-actin) with very high affinity ($K_a = 2 \times 10^9\ M^{-1}$). This interaction occurs independent of sterol binding, and all three common polymorphic forms of DBP appear to have equal avidity for binding to G-actin.

The function of DBP in actin scavenging appears to be interrelated with the function of the protein gelsolin (GSN). Serum GSN functions mainly as a nonenzymatic fibrous actin (F-actin) severing molecule but has been demonstrated to also bind G-actin in the absence of DBP. As the G-actin monomers dissociate from the pointed ends of the severed actin

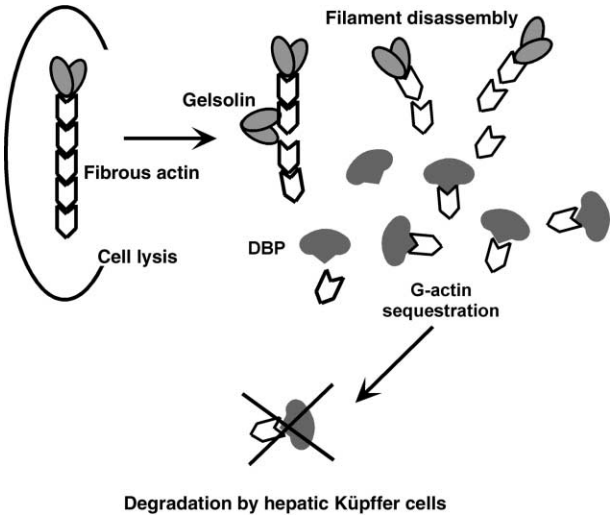

FIGURE 2 DBP and serum gelsolin (GSN) act in concert to prevent actin toxicity following tissue injury. When released from the cell, fibrous actin is disassembled by GSN. Monomeric actin released by this reaction is sequestered by DBP and to some extent by GSN. The bound actin is subsequently cleared from the circulation.

polymer, they are rapidly bound by DBP and cleared from the circulation by Küpffer cells in the liver. The coordinated action of DBP and GSN has been demonstrated to inhibit actin-stimulated platelet aggregation. It is hypothesized that these two serum proteins function in concert to clear free actin from the circulation, thereby preventing the consequences of actin toxicity in the host. For example, G-actin is released into the circulation following tissue injury. If left unattended, G-actin will rapidly polymerize into F-actin, resulting in microemboli that may further damage the microvasculature. DBP–actin and GSN–actin complexes have been reported in the circulation of patients with a wide range of serious illnesses including hepatitis, acute lung injury, septic shock, severe trauma, and pregnancy. The levels of these complexes are also increased following tissue ischemia, inflammation, or injury. Clinical studies have recently described DBP as an acute-phase reactant after major surgery. Studies of rats injected with increasing concentrations of G-actin demonstrate progressive binding followed by saturation of DBP by G-actin. Saturation is then followed by the observation of new F-actin polymers and the appearance of emboli in the microcirculation of the lungs and hearts of these animals, resulting in death. In humans, marked decreases in total DBP followed by increased levels of DBP–actin complexes were reported in patients suffering from multiple organ

failure and trauma. Saturation of the DBP–actin scavenger system has been correlated with poor patient survival rates. Although decreases in hepatic DBP production may be due to initial liver damage, the increase in DBP–actin complexes is likely the result of the sequestration of the free actin released from the failing or damaged organs by circulating DBP. Depletion of the circulating pool of DBP often precedes death in these settings.

C. Macrophage Activation and Osteoclastogenesis

Studies suggest that during inflammation DBP is transformed by sequential deglycosylation by two membrane-bound galactosidases into a potent macrophage-activating factor known as DBP–MAF. Increases in superoxide production and phagocytotic activities have been reported in macrophages activated by DBP–MAF *ex vivo*. These activated macrophages have been reported to successfully eradicate Ehrlich ascites tumors in mice. DBP–MAF has also been demonstrated to be an osteoclast activator in rat studies. Because osteoclast progenitor cells are blood-borne cells of the monocyte–macrophage lineage, this connection between macrophage activation and osteoclastogenesis is not totally surprising.

The structural requirements of DBP that relate to its bone resorbing activities were recently examined. It was demonstrated that DBP–MAF activates osteoclasts *ex vivo* in a dose-dependent manner. This activation occurs in the presence or absence of sterol binding to DBP. Furthermore, the study demonstrated that glycosylation of DBP is imperative for its ostesoclast-activating activities. Unglycosylated *Escherichia coli*-expressed recombinant DBP failed to activate osteoclasts, whereas glycosylated DBP expressed in a baculovirus system demonstrated significant osteoclast-activating function. Although it was not demonstrated in this study, it is likely that initial DBP glycosylation is also critical for macrophage activation by the scheme described previously.

The abnormal macrophages of several osteopetrotic mice and rats have been studied in detail. These animal models generally exhibit varying degrees of immunological as well as bone disorders. Analysis of B cells from two different strains of osteopetrotic mice (*mi/mi* and *op/op*) and one osteopetrotic rat (*op*) demonstrated that they lack β-galactosidase activities. This galactosidase has been shown to work in concert with sialidase, found on T cells, to deglycosylate DBP to its purported DBP–MAF active form. Treatment of the *op*rat from birth with DBP–MAF resulted in the reversal of the macrophage defect and partially ameliorated bony abnormalities. These results indicated a role for DBP in osteoclastogenesis. However, *Dbp*-null mice do not display bony defects and do not show a defect in macrophage recruitment or activation or in mounting an immune response to microorganisms requiring activated macrophages as the first line of defense. These observations would suggest that DBP–MAF generation is nonessential *in vivo* and that alternative pathways must exist for each of the activities attributed to DBP–MAF.

In vitro experiments demonstrated that whereas the Gc*1 human DBP protein requires sequential treatment by β-galactosidase (B cells) and sialidase (T cells) for activation to DBP–MAF, the Gc*2 DBP protein is predicted to be activated by β-galactosidase alone. A site located between amino acids 416 and 420 in domain III of DBP is thought to be the O-linked glycosylation site for *N*-acetylagalactosamine (GalNAc). Galactose and sialic acid residues are attached to this sugar molecule in the Gc*1 DBP proteins, creating a branched structure. Early work on human DBP has in fact demonstrated that a contributing factor to the difference in electrophoretic mobility between the Gc*1F and the Gc*1S DBP isoforms is related to the number of sialic acid residues attached to this sugar moiety. Treatment of Gc*1F with sialidase results in its migration to the position of GC*1S. Upon activation, the terminal structure of the DBP–MAF derived from the Gc*1 proteins appears to be GalNAc-threonine. The situation for Gc*2 human DBP is unclear. It is proposed that the polysaccharide chain for this isoform of DBP is linear in that it lacks sialic acid. Removal of the terminal galactose by β-galactoside would result in a DBP–MAF structure as described above. However, only a very small percentage of Gc*2 human DBP appears to be O-glycosylated, suggesting that the glycosylation site might be at amino acid 420. A single nucleotide polymorphism (A to C) at this codon results in an amino acid change from threonine (Gc*1) to lysine (Gc*2). The lysine residue cannot be glycosylated. If this were the case, then Gc*2 homozygous individuals would be incapable of utilizing the macrophage activation pathway. Recently, threonine 418 was suggested to be the putative Gc*2 glycosylation site. Evidence supporting this idea, however, is lacking. Further biochemical studies in this area are clearly required.

D. Chemotaxis Enhancing Activity

DBP has been demonstrated to interact with a variety of different cell types. When bound to the surface of leukocytes, DBP plays an essential role in augmenting the chemotactic effect of complement factor C5a for neutrophils, monocytes, and fibroblasts *ex vivo*. DBP has been isolated from bronchoalveolar lavage fluid from patients with chronic obstructive pulmonary disease and adult respiratory distress syndrome, suggesting that it may indeed be a critical player in the inflammatory and chemotactic response to lung injury.

The chemotactic activity of DBP is dependent on its binding to chondroitin sulfate proteoglycans on the cell surface of neutrophils. Unlike DBP's interaction with vitamin D and actin, binding to these cell surface molecules is nonselective and of rather low affinity. Recently, it was reported that binding of DBP to neutrophils plateaus with time, possibly reflecting a steady state between binding and shedding of DBP on the plasma membrane. Inhibition of serine proteases with phenylmethylsulfonyl fluoride appears to disrupt this balance and allows for the accumulation of DBP on the plasma membrane of these cells. By a process of elimination, it was discovered that only inhibitors of neutrophil elastase prevented the loss of membrane-bound DBP-binding activity. A decrease in C5a chemotactic activities was correlated with the loss of DBP from the cell surfaces. Taken together, these results would suggest that neutrophil elastase plays a regulatory role in DBP-mediated C5a chemotactic activities. The exact mechanism by which DBP mediates its co-chemotactic response to C5a remains to be elucidated.

V. SUMMARY

DBP is a multifunctional protein that plays a critical role in regulating the bioavailability of $25(OH)D_3$. New data implicate DBP as a ligand for the endocytic recycling receptor, megalin. The folding of DBP's three internal structural domains results in a large, high-affinity G-actin-binding interface. Serum DBP's actin-binding function is postulated to work in concert with serum gelsolin as part of an actin scavenger system that prevents actin toxicity in the host following tissue injury. From an immunological standpoint, DBP is a co-factor for C5a-mediated chemotaxis and appears to be involved in macrophage and osteoclast activation in *ex vivo* experiments. Many of the mechanisms underlying the different roles played by DBP remain obscure. Future studies using the *Dbp*-null mouse model may provide long-awaited answers.

Glossary

F-actin (filamentous actin) Protein that results from the self-assembly of G-actin into head-to-tail polymers. This assembly is regulated by a large class of actin-binding proteins.

G-actin (globular actin) The major protein of the microfilament system in eukaryotic cells.

gelsolin A calcium- and polyphosphoinositide-regulated F-actin severing and capping protein found in both cytosol and serum.

megalin A multifunctional, transmembrane clearance receptor of the low-density lipoprotein family that mediates the uptake and lysosomal degradation of numerous ligands, particularly in renal proximal tubular cells.

vitamin D-binding protein An abundant serum protein of the albumin family that functions to bind and solubilize vitamin D sterols for transport to target tissues and for storage; it is also an extracellular G-actin-binding and sequestration protein.

Vitamin D: Biological Effects of 1α,25(OH)$_2$D$_3$ in Bone

TATSUO SUDA

Saitama Medical School, Japan

Vitamin D, in concert with parathyroid hormone and calcitonin, plays a critical role in regulating serum calcium homeostasis. A metabolite of vitamin D$_3$, 1α,25(OH)$_2$D$_3$, stimulates osteoblastic bone formation and mineralization at least in an indirect manner, by stimulating the intestinal absorption of calcium. 1α,25(OH)$_2$D$_3$ also stimulates osteoclastic bone resorption by inducing osteoclast differentiation factor (ODF) receptor activator of NF-κB ligand (RANKL) in osteoblasts.

I. INTRODUCTION

It is well known that, in healthy animals and humans, serum calcium levels are tightly regulated and are maintained at 9 to 10 mg/dl. Intestine, bone, and kidney are the three major organs involved in calcium homeostasis. Vitamin D plays a major role in regulating serum calcium homeostasis in concert with parathyroid hormone (PTH) and calcitonin. Most of the biological effects generated by vitamin D are produced by its metabolite 1α,25-dihydroxyvitamin D$_3$ [1α,25(OH)$_2$D$_3$]. Vitamin D receptors (VDRs), which bind 1α,25(OH)$_2$D$_3$, have been reported to be present in these three organs. In bone, VDRs are located preferentially in osteoblasts. In addition, vitamin D-deficient animals and humans exhibit severe rickets and osteomalacia. From these results, it was postulated that vitamin D directly stimulates bone formation, in particular, bone mineralization.

In 1997, Kato and his associates in Japan succeeded in generating mice deficient in VDR by gene targeting. They showed that in VDR null mutant mice [VDR (−/−)], no appreciable defects in development and growth were observed before weaning, irrespective of the reduced expression of vitamin D target genes. After weaning, however, mutant mice failed to thrive, and alopecia, hypocalcemia, and infertility resulted (Fig. 1a). Both bone formation and mineralization were severely impaired as a typical feature of type II vitamin D-dependent rickets. Most of the null mutant mice died within 15 to 25 weeks after birth due to severe hypocalcemia (Fig. 1b). Unexpectedly, when these null mutant mice were fed a rescue diet containing high levels of calcium, they developed normally even at 50 weeks, but severe alopecia remained (Fig. 1, inset). Bone formation and mineralization in the null mutant mice maintained on

TABLE 1 Distribution of Calbindin

Calbindin-D_{9k}	Calbindin-D_{28k}
Mammalian intestine	Avian intestine
Mouse and neonatal rat kidney	Avian, reptilian, amphibian, and mammalian kidney (mouse, rat, bovine, and human kidney)
Rat and mouse yolk sac	Hen eggshell gland (uterus)
Rat uterus	Mouse reproductive tissues (uterus, oviduct, and ovary)
Rat and mouse placenta	Avian and mammalian beta cells of the pancreas
	Alpha cells of the rat pancreas
Rat growth cartilage	Rat growth cartilage
Ameloblasts and osteoblasts of rodent teeth	Ameloblasts and osteoblasts of rodent teeth; mouse osteoblasts
Rat lung	Brain (avian, reptilian, amphibian, molluskan, fish, and mammalian brain)

II. LOCALIZATION AND FUNCTIONAL SIGNIFICANCE

A. Intestine

One of the most important findings in the vitamin D field was the discovery by Robert Wasserman and Alan Taylor in 1966 of the 28,000-Da vitamin D-dependent calcium-binding protein in avian intestine. The intestinal calbindins (both avian and mammalian) are present in high concentrations in the intestine (0.15 m*M* or more) and are found in the highest concentration in the duodenum (specifically, in the cytosol of the columnar epithelial cells). Early studies in chicks established a strong correlation between the level of calbindin and an increase in intestinal calcium transport. The active form of vitamin D, 1,25-dihydroxyvitamin D_3 [$1,25(OH)_2D_3$] affects overall intestinal calcium absorption in three phases: (1) the transfer of calcium across the lumenal brush-border membrane, (2) the transfer of calcium across the cell interior, and (3) the energy-requiring extrusion of calcium from the basolateral membrane. A vitamin D-dependent apical calcium channel has recently been identified in $1,25(OH)_2D_3$-responsive epithelia (proximal duodenum and distal tubule of the kidney), suggesting a mechanism of calcium entry in the first phase of the transcellular process. It is thought that $1,25(OH)_2D_3$ functions in the second phase of the calcium absorptive process by interacting with the intestinal vitamin D receptor (VDR) to induce the genomic production of calbindin. Intestinal calbindin is thought to facilitate the diffusion of calcium in the absorptive cells toward the basolateral membrane. Indeed, in VDR knockout mice (VDR-ablated mice that have been generated by gene targeting), the major defect is in intestinal calcium absorption, which is accompanied by a 50% reduction in intestinal calbindin-D_{9k}. It has also been suggested that calbindin can act in the second phase as a cytosolic calcium buffer to prevent toxic levels of calcium from accumulating in the intestinal cell. In the third phase, calbindin is thought to stimulate calcium extrusion indirectly by increasing the local concentration of calcium adjacent to the basolateral plasma membrane calcium ATPase (PMCA).

B. Kidney

In the kidney, relatively high levels of calbindin (2–7 μg/mg protein) are present, specifically in the distal nephron (distal convoluted tubule, connecting tubule, and cortical collecting duct). The vitamin D receptor is localized predominantly in the distal nephron, the site of localization of both calbindin-D_{9k} and calbindin-D_{28k}, which are induced by vitamin D. Similar to intestinal calcium absorption, regulation by $1,25(OH)_2D_3$ of calcium transport in the distal nephron is thought to involve a transcellular process. Calcium enters through the apical plasma membrane, diffuses through the cytosol, and is actively extruded across the opposing basolateral membrane. A model of distal tubule renal calcium transport, involving calbindin, has been proposed. Calbindin-D_{28k} has been reported to increase the influx of calcium at the apical membrane. Whether calbindin-D_{28k} affects the activity of the recently identified apical calcium channel in the distal tubule, which has been reported to be up-regulated by vitamin D, is not yet known. Calbindin-D_{28k} may then act as a diffusional carrier of calcium through the cytosol to the basolateral membrane. In addition, renal calbindin-D_{28k} may also act to lower cytosolic calcium levels, preventing the accumulation of toxic levels of calcium. In the vicinity of the basolateral

membrane, the calbindin-D_{9k} protein binds the calcium and stimulates the extrusion of calcium via the PMCA (a calbindin-D_{9k} binding domain has been identified in the PMCA). Thus, in the mouse distal nephron and the perinatal rat distal nephron, which contain both calbindin-D_{9k} and calbindin-D_{28k}, these proteins have different functions. The different functions of these proteins suggest mechanisms by which $1,25(OH)_2D_3$ (which induces the calbindins) may function to enhance calcium reabsorption in the distal nephron. Future studies utilizing calbindin-D_{9k} knockout mice as well as calbindin-D_{9k} and calbindin-D_{28k} double-knockout mice should provide additional insights about both intestinal and renal calcium transport. In addition, studies exploring the relationship of $1,25(OH)_2D_3$ and calbindin to the apical calcium channels will further define their respective roles in calcium transport.

C. Bone

Previous studies using immunocytochemical analyses have indicated that calbindin-D_{9k} and calbindin-D_{28k} are found in chondrocytes of growth plate cartilage in rats and in ameloblasts and osteoblasts of rodent teeth. It has been suggested that the calbindins may be involved in the movement of intracellular calcium in the chondrocyte. It has also been suggested that elevated expression of the calbindins may characterize cells involved in the elaboration of mineralized tissues and bone. In a recent study, calbindin-D_{28k} was found to be expressed at low levels in several osteoblastic cell lines and at much higher levels in primary cultures of murine osteoblastic cells. Transient transfection of calbindin-D_{28k} in MC3T3-E1 osteoblastic cells protected against tumor necrosis factor α (TNFα)-induced apoptotic cell death. Extracts from the TNFα-treated cells expressing high levels of calbindin-D_{28k} as well as purified calbindin-D_{28k} inhibited the activity of caspase 3, a protease known to be an important mediator of apoptosis. These findings are novel because they demonstrate that calbindin-D_{28k} is unique among the family of calcium-binding proteins in its ability to interact with and consequently inhibit caspase, thereby preventing apoptotic cell death in osteoblasts, independent of its calcium-binding capabilities. Thus far, calbindin-D_{28k} is the only other known natural inhibitor of caspase besides the inhibitor of apoptosis proteins (IAPs). A further understanding of the mechanisms whereby calbindin-D_{28k} attenuates apoptosis, including which regions of calbindin-D_{28k} are involved in caspase 3 inhibition, will have important implications for the prevention of degeneration in bone cells (as well as in other cells) and therefore could prove important for the therapeutic intervention of many diseases, including osteoporosis.

D. Pancreas

The pancreas was the first nonclassical target tissue reported to contain vitamin D receptors. Immunocytochemical and autoradiographic studies have indicated that receptors for $1,25(OH)_2D_3$ and calbindin-D_{28k} are both present in the pancreatic beta cell. In chicks and rats, pancreatic calbindin-D_{28k} has been reported to be responsive to $1,25(OH)_2D_3$. In the rat, calbindin-D_{28k} is localized in alpha as well as beta cells of the pancreatic islet. Because $1,25(OH)_2D_3$ receptors are not present in a cells, it has been suggest that beta cell calbindin-D_{28k}, but not alpha cell calbindin, may be regulated by $1,25(OH)_2D_3$. Recent studies using calbindin-D_{28k} null mutant (knockout) mice and beta cell lines have shown that calbindin-D_{28k} can modulate depolarization-stimulated insulin release. These findings suggest that calbindin-D_{28k} can control the rate of insulin release by regulation of intracellular calcium. In addition to modulation of insulin release, more recent studies have indicated that cytokine-mediated destruction of pancreatic beta cells, a cause of insulin-dependent diabetes, can be inhibited by calbindin-D_{28k}. In beta cells transfected with the calbindin-D_{28k} gene, cytokine-mediated stimulation of free radical formation is inhibited. It has been suggested that calbindin-D_{28k}, by stabilizing cellular calcium, could prevent calcium-mediated mitochondrial damage and consequent generation of free radicals. These findings have important therapeutic implications for the prevention of autoimmune destruction of beta cells in type 1 diabetes.

E. Nervous Tissue

In brain tissue, calbindin-D_{28k} is present in most neuronal cell groups and fiber tracts but it is not regulated by $1,25(OH)_2D_3$; i.e., calbindin-D_{28k} is expressed constitutively. Neurons containing calbindin-D_{28k} are found in the cerebral cortex, hippocampus, amygdala, pyriform region, thalamus, and hypothalamus. The highest concentration of calbindin-D_{28k} is in the cerebellum (1–2% of the total soluble protein), where it is specifically localized in the Purkinje cells. The phenotype of the calbindin-D_{28k} knockout mouse (the calbindin-D_{28k} gene is specifically ablated by gene targeting) is impaired motor

coordination. This phenotype may be the result of abnormal cerebellar activity because of altered depolarization-induced calcium transients in the Purkinje cells in the absence of calbindin. It has been suggested that calbindin-D_{28k}, by regulating depolarization-induced potentials, may also be involved in the control of hormone secretion from hypothalamic neuroendocrine neurons. In addition, specific neuronal sensory cells (cochlear and vestibular hair cells in the inner ear, cone but not rod photoreceptor cells of the avian and mammalian retina, and photoreceptor cells of pineal transducers) contain calbindin-D_{28k}. Thus, calbindin-D_{28k} in these cells is involved in mechanisms of signal transduction.

In the nervous system, besides affecting induced calcium transients and signal transduction mechanisms, calbindin-D_{28k} protects neurons against calcium-mediated neurotoxicity. Studies using hippocampal cells in culture showed a direct relationship between calbindin-positive neurons and protection against damage induced by glutamate or calcium ionophore. Correlative evidence between decreases in neuronal calbindin and neurodegeneration have been reported in studies of chronic neurological diseases (Parkinson's, Alzheimer's, and Huntington's diseases), epilepsy, aging, and ischemic injury. Direct evidence of a protective role of neuronal calbindin-D_{28k} against a variety of insults, including exposure to glucocorticoid, cyclic adenosine monophosphate (cAMP), immunoglobulin G (IgG) from amyotrophic lateral sclerosis patients, and hypoglycemia, has been shown in primary neuronal cells in culture or in neuronal cell lines in which the calbindin-D_{28k} gene has been transfected, resulting in overexpression of calbindin.

Overexpression of calbindin in neural cells is also found to suppress the proapoptotic actions of mutant presenilin 1 (PS-1). Mutant PS-1 is causally linked to approximately 50% of the cases of early-onset familial Alzheimer's disease. Mutant PS-1 sensitizes cells to apoptosis induced by amyloid β-peptide (Aβ), the cleavage product of the amyloid precursor protein and the major component of plaques in Alzheimer's disease. It has been suggested that Aβ damages neurons by a mechanism involving oxidative stress and disruption of calcium homeostasis. Calbindin-D_{28k} protected against the proapoptotic action of mutant PS-1 by attenuating the increase in intracellular calcium and preventing the impairment of mitochondrial function. Thus, calbindin-D_{28k} in the nervous system (as well as in osteoblasts and pancreatic beta cells) has an important role in protecting against cell death. A further understanding of the mechanisms whereby calbindin-D_{28k} protects against apoptotic cell death may have important therapeutic implications for the prevention of cellular degeneration.

F. Placenta, Yolk Sac, and Uterus

Immunocytochemical and/or biochemical studies have indicated the presence of calbindin-D_{9k} in bovine placenta, in the placenta and yolk sac of rats and mice, and in the endometrium and myometrium of pregnant and nonpregnant rat uterus and in the uterine epithelium of pregnant rats. In placenta and yolk sac, calbindin-D_{9k} increases in late gestation (when fetal mineralization occurs), suggesting a role for calbindin-D_{9k} in the transport of calcium to the fetus. Calbindin-D_{28k} is not present in rat reproductive tissues. However the 28,000 M_r calbindin is present in the uterus of the laying hen and in mouse reproductive tissues (endometrium and glandular epithelium of mouse uterus, mouse oviduct epithelium, and primary follicles of mouse ovary). Calbindin-D_{28k} in these tissues is not affected by $1,25(OH)_2D_3$. However, calbindin-D_{9k} and calbindin-D_{28k} in rat and chick uterus, respectively, are up-regulated by estradiol. The presence of calbindin in epithelial cells of the uterus and oviduct suggests a role for calbindin in transepithelial calcium transport. The presence of calbindin in the myometrium suggests the involvement of calbindin in intracellular calcium regulation that may affect the frequency and strength of uterine contractions.

A. Calbindin-D_{28k}

1. Genomic Organization

The structure of the chicken calbindin-D_{28k} gene has been elucidated. The size of the gene is 18.5 kb; it consists of 11 exons and 10 introns. The coding regions in the mouse and chicken calbindin-D_{28k} gene share 77% sequence homology.

2. Regulation by $1,25(OH)_2D_3$

Regulation of the calbindin-D_{28k} gene is a complex phenomenon. Its induction by $1,25(OH)_2D_3$ in avian intestine and in avian and mammalian kidney is well known. In response to $1,25(OH)_2D_3$ treatment, the expression of the calbindin-D_{28k} gene is induced by a small early increase in calbindin-D_{28k} transcription followed by a sustained accumulation of mRNA long after $1,25(OH)_2D_3$ treatment, suggesting stabilization of calbindin-D_{28k} mRNA by

$1,25(OH)_2D_3$. Similar observations have been made for chicken intestinal and rat renal calbindin-D_{28k}. A putative vitamin D response element (VDRE) has been found in the promoter of the chicken calbindin-D_{28k} gene and a VDRE that responds to $1,25(OH)_2D_3$ has been identified in the promoter of the mouse calbindin-D_{28k} gene. The putative VDRE in the chicken promoter is relatively inactive and the response of the mouse calbindin-D_{28k} promoter to $1,25(OH)_2D_3$ is modest (maximal fivefold response). The modest response reflects the *in vivo* findings of a small transcriptional response. There is increasing evidence that the large induction of calbindin-D_{28k} mRNA in both chick intestine and mouse kidney is due primarily to posttranscriptional mechanisms. In addition, in VDR-ablated mice, only a minor reduction in basal levels of renal calbindin-D_{28k} is observed. However, the response of renal calbindin-D_{28k} to injection of $1,25(OH)_2D_3$ is compromised. Thus, the regulation of calbindin-D_{28k} mRNA by $1,25(OH)_2D_3$ appears to be more complex than the conventional genomic mechanism of steroid hormone action, which involves steroid receptor binding to specific DNA sequences and transcriptional activation. Regulation of calbindin-D_{28k} by $1,25(OH)_2D_3$ may involve other factors and is mostly posttranscriptional.

3. Regulation of Calbindin-D_{28k} by Factors Other Than $1,25(OH)_2D_3$

In the intestine of vitamin D-treated chicks, glucocorticoids inhibit the levels of calbindin-D_{28k} protein and mRNA, resulting in a decrease in intestinal calcium absorption. Although a putative glucocorticoid-responsive element has been identified by sequence homology in the chicken calbindin-D_{28k} promoter, it is not yet known whether the effect of glucocorticoids is an indirect or a direct effect on the calbindin gene. The complexity of calbindin-D_{28k} gene regulation is also indicated in studies showing a modulation by calcium of calbindin-D_{28k} gene expression in avian intestine as well as in avian and mammalian kidney.

In the central nervous system, calbindin-D_{28k} is not regulated by $1,25(OH)_2D_3$. Various other factors that affect signal transduction pathways, including neurotropin-3, brain-derived neurotropic factor, insulin-like growth factor-I, fibroblast growth factor, and tumor necrosis factors, have all been reported to induce neuronal calbindin-D_{28k}. Because neurotropic factors can protect against cytotoxicity, the induction of calbindin-D_{28k} by these factors may be one mechanism involved in calbindin's neuroprotective role. In addition to factors that affect signal transduction pathways, neuronal calbindin is also regulated by corticosterone and retinoic acid. Corticosterone has been shown to up-regulate calbindin-D_{28k} in the hippocampus. Because corticosterone causes cell death in non-calbindin-D_{28k}-containing areas of the hippocampus, the induction of calbindin may be a compensatory mechanism to promote neuronal survival. Retinoic acid has also been reported to induce calbindin-D_{28k} in medulloblastoma cells that are derived from the cerebellum and express a neuronal phenotype. Because retinoic acid has profound effects on embryogenesis, it is possible that retinoic acid may have a role in the induction of calbindin in the developing nervous system. Thus, although neuronal calbindin-D_{28k} is unresponsive to $1,25(OH)_2D_3$, it can be regulated by neurotropic factors as well as by other steroids.

As previously discussed, calbindin-D_{28k} is present in the avian eggshell gland as well as in mouse ovary, uterus, and oviduct. In these tissues, calbindin is not regulated by $1,25(OH)_2D_3$ but rather by estradiol. Analysis of the mouse calbindin-D_{28k} promoter indicates that multiple imperfect half-palindromic estrogen-responsive elements (between -1075 and -702 and between -175 and -78) contribute to the induction by estradiol.

B. Calbindin-D_{9k}

1. Genomic Organization

The size of the calbindin-D_{9k} gene is 2.5 kb. The calbindin-D_{9k} gene contains three exons interrupted by two introns. The first exon contains almost the entire 5′ noncoding region. The second exon codes for the first calcium-binding site. The third exon codes for the second calcium-binding site and the 3′ untranslated region.

2. Regulation of Calbindin-D_{9k} by $1,25(OH)_2D_3$

Similar to the regulation of calbindin-D_{28k}, calbindin-D_{9k} is regulated by $1,25(OH)_2D_3$ by a small, rapid transcriptional stimulation followed by a posttranscriptional effect, accounting for the sustained increase of calbindin-D_{9k} mRNA. Unlike renal calbindin-D_{28k}, in VDR-ablated mice there is a marked inhibition of both basal and $1,25(OH)_2D_3$-induced calbindin-D_{9k} mRNA levels. These findings suggest that basal levels of intestinal calbindin-D_{9k} mRNA are more sensitive to control by VDR-mediated mechanisms than are basal levels of renal calbindin-D_{28k} mRNA. In addition, recent studies using transgenic

mice indicate that 4580 base pairs of the 5′ regulatory sequence of the calbindin-D_{9k} gene are needed for intestine-specific expression as well as for the responsiveness to $1,25(OH)_2D_3$. The proximal promoter of the calbindin-D_{9k} gene, from -117 to $+400$, and a distal element located at -3500, together, but not separately, confer the $1,25(OH)_2D_3$-induced transcriptional response. In addition, an intestine-specific transcription factor, caudal homeobox-2 (Cdx-2), binds to a Cdx-2-binding site in the distal element of the calbindin-D_{9k} promoter and plays a crucial role in the transcription of the calbindin-D_{9k} gene in the intestine.

3. Regulation of Calbindin-D_{9k} by Other Steroids

In the intestine, calbindin-D_{9k} expression is inhibited by glucocorticoids. This decrease may be involved in the reported decrease by glucocorticoids in intestinal calcium absorption. It is not yet known whether the mechanism of the effect of glucocorticoids on calbindin-D_{9k} expression is direct or indirect.

In the uterus, calbindin-D_{9k} expression is unaffected by $1,25(OH)_2D_3$ but rather is under strong estrogen control. An imperfect estrogen response element (ERE) that binds the estrogen receptor (ER) has been identified in the first 5′ splice site of the rat calbindin-D_{9k} gene. Because the ERE has been found to contribute only weak estrogen induction, it has been suggested that the ER may cooperate with other transcription factors or co-activators to result in efficient transcriptional activation of the calbindin-D_{9k} gene.

IV. SUMMARY

Calbindin-D_{9k} and calbindin-D_{28k} were previously thought to be exclusively vitamin D-dependent proteins. It is now evident that these proteins are present in many different tissues, that they serve different functions, and that they are regulated by several steroids as well as by factors that affect signal transduction pathways. In future studies the generation of calbindin-D_{9k} null mutant mice as well as increasingly refined cellular and molecular approaches will provide new insights into the mechanism of action of the calbindins, including the role of calbindin in intestinal calcium absorption, in calcium reabsorption in the distal nephron, and in protection against cell death.

Glossary

apoptosis Biological process of programmed cell death that occurs in normal physiology as well as in response to adverse conditions.

calbindin-D_{9k} A 9000-Da calcium-binding protein that is present in highest concentrations in mammalian intestine, in mouse and neonatal rat kidney, and in placenta and uterus.

calbindin-D_{28k} A 28,000-Da calcium-binding protein present in highest concentrations in avian intestine and mammalian and avian kidney, brain, and pancreas.

1,25-dihydroxyvitamin D_3 Active steroid hormone form of vitamin D, which is synthesized in the kidney.

vitamin D receptor Member of the steroid/nuclear receptor superfamily; binds 1,25-dihydroxyvitamin D_3 and to specific DNA sequences and activates or represses the transcription of specific target genes.

Vitamin D: 24,25-Dihydroxyvitamin D

ANTHONY W. NORMAN AND HELEN L. HENRY
University of California, Riverside

24,25-Dihydroxyvitamin D_3 [24*R*,25$(OH)_2D_3$] and 1α,25-dihydroxyvitamin D_3 are the two major dihydroxylated vitamin D metabolites circulating in the blood. Although both forms are produced from the parent vitamin D_3, it appears that the less well-studied 24*R*,25$(OH)_2D_3$ form plays distinct biological roles.

I. INTRODUCTION

In comparison to 1α,25$(OH)_2D_3$, the biological actions of 24*R*,25$(OH)_2D_3$ have been relatively less studied. Although it is clear that 24*R*,25$(OH)_2D_3$ is produced by the same enzyme system that inactivates 1α,25$(OH)_2D_3$ in its target cells, there is substantial evidence that the important biological activities of 24*R*,25$(OH)_2D_3$ and 1α,25$(OH)_2D_3$ are distinctly different. One key question that has attracted attention is whether 1α,25$(OH)_2D_3$ acting alone can generate all of the biological responses that are attributed to the parent vitamin D_3, or whether, for some responses, a second vitamin D_3 metabolite is required. There is evidence to support the view that the presence of both 1α,25$(OH)_2D_3$ and 24*R*,25$(OH)_2D_3$ is required to generate the complete spectrum of biological responses attributable to the parent vitamin D_3. The purpose of this article is to summarize results from biological systems in which 24*R*,25$(OH)_2D_3$ has been shown to produce biological effects.

II. PRODUCTION OF 24*R*,25$(OH)_2D_3$

The 25$(OH)D_3$/1α,25$(OH)_2D_3$-24*R*-hydroxylase (24*R*-hydroxylase) is induced by and responsible for the inactivation and catabolism of 1α,25$(OH)_2D_3$ in its target cells. In addition, 24*R*-hydroxylase in the kidney utilizes 25$(OH)D_3$ as substrate to produce significant amounts (2–5 ng/ml) of circulating 24*R*,25$(OH)_2D_3$.

A mouse knockout (KO) of 25$(OH)D_3$-24*R*-hydroxylase has been generated. The newborn mice are viable but develop significant bone abnormalities. Although these deficiencies have been attributed to elevated levels of plasma 1α,25$(OH)_2D_3$ rather than to a deficiency of 24*R*,25$(OH)_2D_3$, there is experimental evidence that 24*R*,25$(OH)_2D_3$ has biological activity in its own right.

III. BIOLOGICAL EFFECTS OF 24*R*,25$(OH)_2D_3$

A. Parathyroid Gland Regression

In vitamin D-deficient hypocalcemic animals, the parathyroid glands undergo marked hypertrophy and hyperplasia. The first suggestion that 24*R*,25$(OH)_2D_3$ could generate biological responses when 1α,25$(OH)_2D_3$ given alone did not elicit responses was obtained by measuring regression of hypertrophied parathyroid glands typically present in vitamin D-deficient, hypocalcemic chicks. Coadministration of physiological concentrations of 24*R*,25$(OH)_2D_3$ and 1α,25$(OH)_2D_3$ resulted in significant reduction in parathyroid gland size, whereas 1α,25$(OH)_2D_3$ alone was ineffective in reducing parathyroid gland size. Concomitantly with these observations, several studies reported on the effects of 24*R*,25$(OH)_2D_3$ on parathyroid (PTH) secretion in animal systems and in patients with renal osteodystrophy.

a high-calcium diet were completely reestablished. From these results, it can be concluded that the stimulating effect of 1α,25(OH)$_2$D$_3$ on bone formation and mineralization is indirect, occurring through the stimulation of intestinal absorption of calcium by vitamin D.

II. DISCOVERY OF BONE MINERAL MOBILIZATION ACTIVITY OF VITAMIN D

It appears to be paradoxical, but vitamin D functions in the process of calcium mobilization from calcified bone, making calcium available to the extracellular fluid upon demand by the calcium homeostatic system. This important observation was first reported by Carlsson in 1952. He showed that when hypocalcemic rats fed a vitamin D-deficient, low-calcium diet were orally given 100 IU (2.5 μg) of vitamin D$_3$, their serum calcium was increased from 5 to 8 mg/dl 3 days after administration (Fig. 2a). Parathyroidectomy (PTX) 2 h prior to vitamin D$_3$ administration abolished the increase in serum calcium levels (Fig. 2a). Since the diet did not contain any appreciable amounts of calcium, he concluded that vitamin D stimulates mineral mobilization from calcified bone to blood in concert with PTH.

The metabolite of vitamin D$_3$ responsible for bone mobilization is 1α,25(OH)$_2$D$_3$. Using an *in vitro* organ culture system, in 1972 Raisz *et al.* reported that 1α,25(OH)$_2$D$_3$ and 25(OH)D$_3$ increase the release of ^{45}Ca from prelabeled bone into the culture medium. They also showed that 1α,25(OH)$_2$D$_3$ is about 80 times more potent than 25(OH)D$_3$ in increasing the ^{45}Ca release from prelabeled bone (Fig. 2b). From these results, they concluded that the metabolite of vitamin D$_3$ which stimulates bone mineral mobilization is indeed 1α,25(OH)$_2$D$_3$.

In 1981, Abe *et al.* discovered the cell differentiation-inducing activity of 1α,25(OH)$_2$D$_3$ using mouse and human myeloid leukemic cells. HL-60 is a human promyelocytic leukemia cell line established from a leukemia patient, and the cells can be induced to differentiate into granulocytes by retinoic acid and monocyte–macrophages by 1α,25(OH)$_2$D$_3$. 1α,25(OH)$_2$D$_3$ was a potent and selective inducer of differentiation of HL-60 cells into macrophages. Furthermore, 1α,25(OH)$_2$D$_3$ directly induced the fusion of alveolar macrophages at a very high rate. Approximately 80% of the macrophages fused to form multinucleated giant cells by stimulating the differentiation and fusion of macrophages. However, the multinucleated giant cells formed from alveolar macrophages in response to 1α,25(OH)$_2$D$_3$ did not satisfy the criteria of osteoclasts.

III. ESTABLISHMENT OF A MOUSE CO-CULTURE SYSTEM TO EXAMINE OSTEOCLASTOGENESIS

It is well recognized that osteoclasts are derived from hematopoietic cells of the monocyte–macrophage lineage. Hematopoietic monocytic cells are present in almost all tissues, whereas osteoclasts, the cells responsible for bone resorption, are present only in

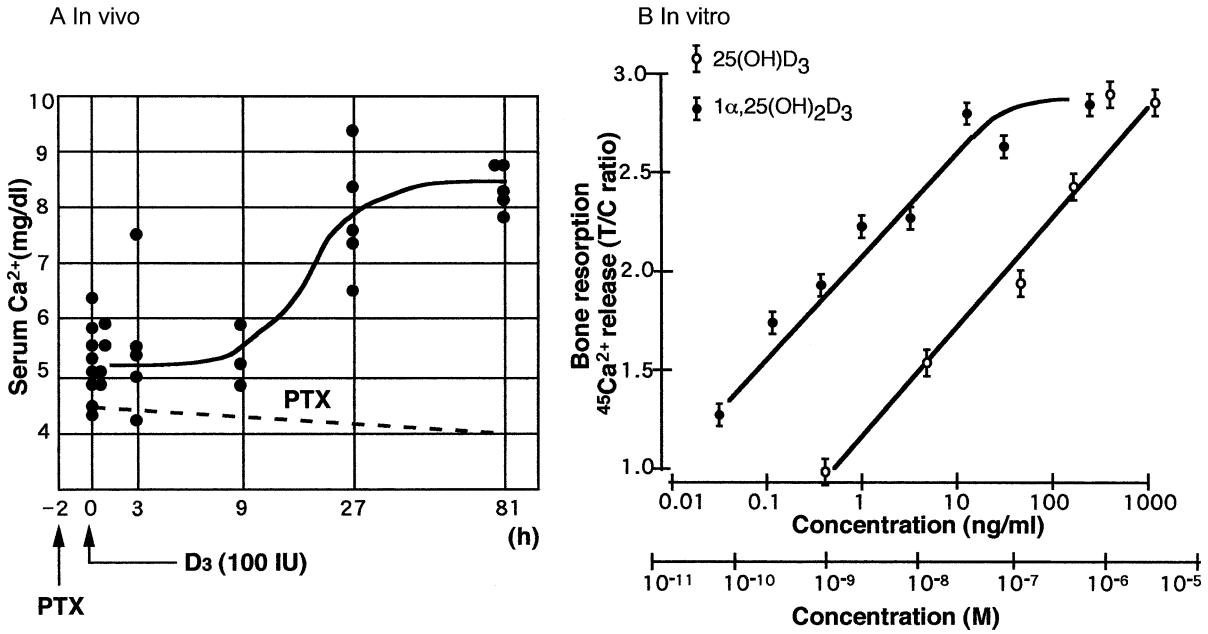

FIGURE 2 (A) Discovery of bone mineral mobilization activity of vitamin D *in vivo*. PTX, parathyroidectomy. Reprinted from Carlsson (1952), with permission from Blackwell Publishing Ltd. (B) The comparison of the *in vitro* activity to increase the release of ^{45}Ca from prelabeled bone between 25(OH)D$_3$ and 1α,25(OH)$_2$D$_3$. Reprinted from Raisz *et al.* (1972), *Science* **175**, 768–769. Copyright 1972 American Association for the Advancement of Science.

bone. This led to the speculation that some local factors or local mechanisms are involved in this tissue-specific localization of osteoclasts in bone. Special attention was given to the role of osteoblasts in osteoclast development, since osteoblasts are present only in bone. The process of osteoclast development consists of several steps, including proliferation, differentiation, fusion, and activation.

In 1988, Takahashi *et al.* established an efficient mouse co-culture system to recruit osteoclasts. Osteoblastic cells were isolated from mouse calvaria, and spleen cells were used as hematopoietic osteoclast progenitors. They were either separately cultured or co-cultured together with or without 10^{-8} M 1α,25(OH)$_2$D$_3$. When osteoblastic cells alone or spleen cells alone were cultured, no osteoclasts were formed even in the presence of 1α,25(OH)$_2$D$_3$. In contrast, numerous multinucleated osteoclasts were formed when spleen cells and osteoblastic cells were co-cultured in the presence of 1α,25(OH)$_2$D$_3$. Cell-to-cell contact between spleen cells and osteoblastic cells appeared to be important for osteoclast formation, since no osteoclasts were formed when spleen cells and osteoblastic cells were co-cultured but separated by a membrane filter even in the presence of 1α,25(OH)$_2$D$_3$. From these results, it was hypothesized that the direct contact of spleen cells and osteoblastic cells is essential for osteoclast differentiation, suggesting the requirement of a membrane-associated factor for osteoclast formation. Spleen cells represented osteoclast progenitors, in other words, "the seeds," and osteoblastic cells represented supporting cells that provide a suitable microenvironment for osteoclast formation in bone, in other words, "the farm."

After extensive studies, it was found that not only 1α,25(OH)$_2$D$_3$ but also PTH, IL-1, PGE2, IL-6, and IL-11 similarly stimulated osteoclast formation in mouse co-cultures (Fig. 3). The target cells of these bone-resorbing factors were osteoblastic cells but not hematopoietic osteoclast precursors. These bone-resorbing factors were classified into three diverse signaling pathways mediated by the VDR, cAMP, and gp130 (Fig. 3). These three signals appeared to stimulate osteoclast differentiation independently, since osteoclasts were formed both in VDR null mutant mice and in gp130 knockout mice. In other words, there is a redundancy in bone-resorbing factors to recruit osteoclasts. It was proposed that the "osteoclast differentiation factor" (ODF) is commonly induced on the plasma membrane of osteoblastic cells in response to these bone-resorbing factors (Fig. 3). Osteoclast precursors having ODF receptors recognize ODF by cell-to-cell contact and

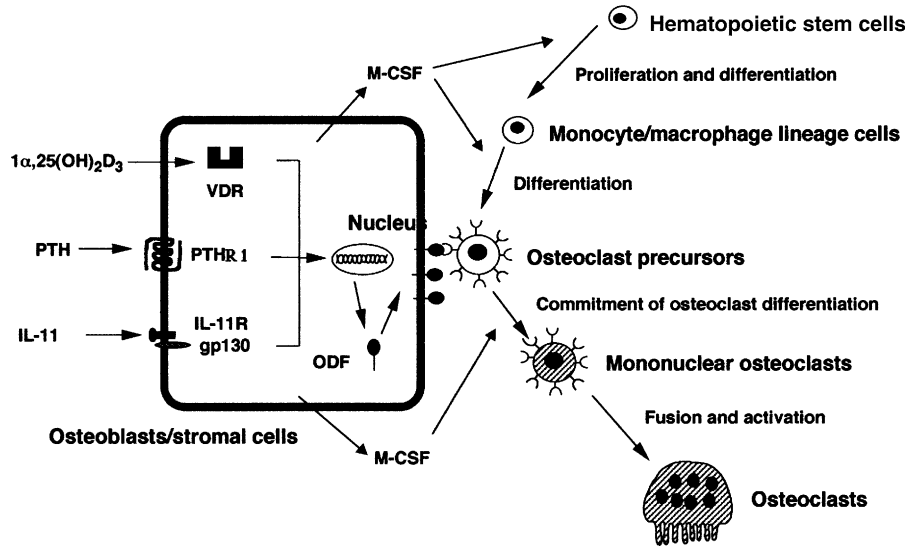

FIGURE 3 A hypothetical concept of osteoclast differentiation, proposing the requirement of a membrane-associated factor, osteoclast differentiation factor (ODF), in osteoblasts/stromal cells for osteoclastogenesis.

differentiate into osteoclasts. Macrophage-colony stimulating factor (MCSF, also called colony stimulating factor-1, CSF-1) appeared to play an important role in the proliferation and differentiation of osteoclast progenitors, since M-CSF-deficient op/op mutant mice showed severe osteopetrosis with the complete absence of osteoclasts.

IV. MOLECULAR MECHANISM OF OSTEOCLASTOGENESIS

In 1997, the research groups of Amgen and Snow Brand Milk Products independently succeeded in the molecular cloning of a factor that strongly inhibits osteoclastogenesis. Amgen named it "osteoprotegerin" (OPG) and Snow Brand named it "osteoclastogenesis inhibitory factor" (OCIF). OPG and OCIF were the same molecule, which belongs to the TNF receptor family. OPG/OCIF lacked the membrane-bound domain, indicating that OPG/OCIF is a soluble receptor. It was speculated that OPG/OCIF could compete with the ODF receptor for the binding of ODF.

Using radioactive OCIF, the molecular cloning of a membrane-associated factor responsible for osteoclastogenesis was finally accomplished. The Amgen group also succeeded in the molecular cloning of such a factor. Amgen named it OPG ligand (OPGL), which was identical to ODF. Figure 4 schematically shows the molecular mechanism of osteoclast formation. All bone-resorbing factors such as 1α,25(OH)$_2$D$_3$, PGE2, PTH, and IL-11 act on osteoblastic cells to induce ODF. ODF recognizes osteoclast progenitors having an ODF receptor by a mechanism involving cell-to-cell contact. M-CSF is also an essential factor for osteoclast differentiation and is produced by osteoblastic cells in bone. Osteoclast progenitors differentiate into osteoclasts by binding to ODF. When OPG/OCIF covers ODF, osteoclast progenitors having the ODF receptor are unable to bind ODF; thus, osteoclast formation is inhibited.

The molecular cloning of ODF revealed that this molecule was identical to "receptor activator of NF-κB ligand" (RANKL), "TNF-related activation-induced cytokine" (TRANCE), and OPGL, all of which were independently identified by different research groups as a novel member of the TNF ligand family. ODF, OPGL, TRANCE, and RANKL are the same molecule, and it is important in the

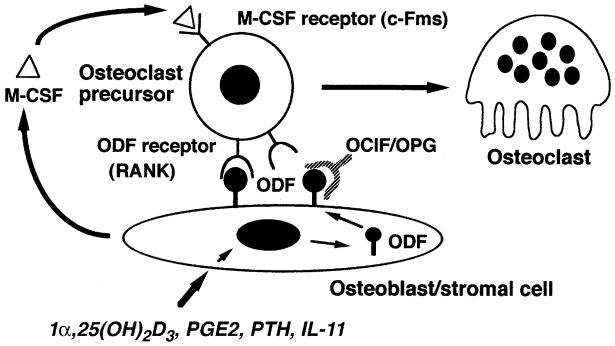

FIGURE 4 The molecular mechanism of osteoclast formation from its precursors supported by osteoblasts/stromal cells.

development of T cells and dendritic cells as well as the development of osteoclasts. "Receptor activator of NF-κB" (RANK), which has been cloned as a receptor of RANKL, is the transmembrane signaling receptor for ODF as well. OPG/OCIF is a soluble receptor for ODF and it appears to function as a decoy receptor.

ODF is involved not only in osteoclast differentiation but also in osteoclast activation. The lifetime of osteoclasts can be divided into three steps: the first step is proliferation and differentiation, the second step involves survival and fusion, and the third step is the activation of osteoclasts. Proliferation and differentiation of osteoclasts essentially require ODF together with M-CSF. The survival and fusion of osteoclasts are induced by either ODF or M-CSF. Activation of osteoclasts is induced by ODF but not by M-CSF. Thus, ODF appears to be involved throughout the lifetime of osteoclasts.

V. ROLE OF 1α,25(OH)$_2$D$_3$ IN MAINTAINING SERUM CALCIUM HOMEOSTASIS

It should, however, be recognized that physiological plasma levels of 1α,25(OH)$_2$D$_3$ do not stimulate osteoclastic bone resorption *in vivo*; only pharmacological or toxic doses of 1α,25(OH)$_2$D$_3$ are capable of stimulating it. Figure 5 shows the difference in dose levels of 1α,25(OH)$_2$D$_3$ required to stimulate intestinal calcium transport activity and bone mineral mobilization activity. In this particular experiment, the intestinal calcium transport activity was measured by the everted gut sac method (serosal/mucosal ^{45}Ca ratio) in vitamin D-deficient rats after administration of graded doses of 1α,25(OH)$_2$D$_3$. The bone mineral mobilization activity was monitored by determining serum calcium levels in rats fed a vitamin D-deficient, low-calcium diet after administration of graded doses of 1α,25(OH)$_2$D$_3$. Physiological dose levels (0.1–0.25 μg/rat) of 1α,25(OH)$_2$D$_3$ greatly increased intestinal calcium transport activity but did not increase serum levels of calcium appreciably. Approximately 10 to 50 times higher dose levels of 1α,25(OH)$_2$D$_3$ were required to induce bone mineral mobilization activity. In our co-culture system, 10^{-8} M 1α,25(OH)$_2$D$_3$ was required to generate osteoclasts *in vitro*, a level that was 50 to 100 times higher than the serum concentration of 1α,25(OH)$_2$D$_3$ in healthy subjects. Thus, it may be concluded that physiological concentrations of 1α,25(OH)$_2$D$_3$ are not capable of inducing bone mineral mobilization and that pharmacological or toxic levels of 1α,25(OH)$_2$D$_3$ are required for inducing bone resorption.

VI. SUMMARY

Physiological doses of vitamin D preferentially stimulate intestinal calcium absorption, which in

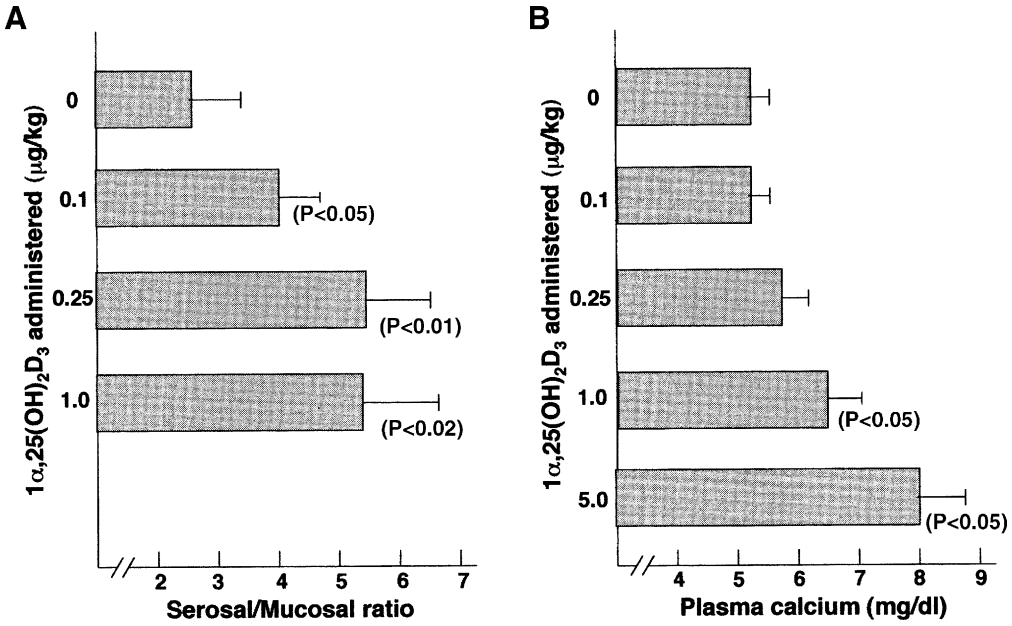

FIGURE 5 Differences in the dose levels of 1α,25(OH)$_2$D$_3$ required to stimulate intestinal calcium transport activity (A) and bone mineral mobilization activity (B).

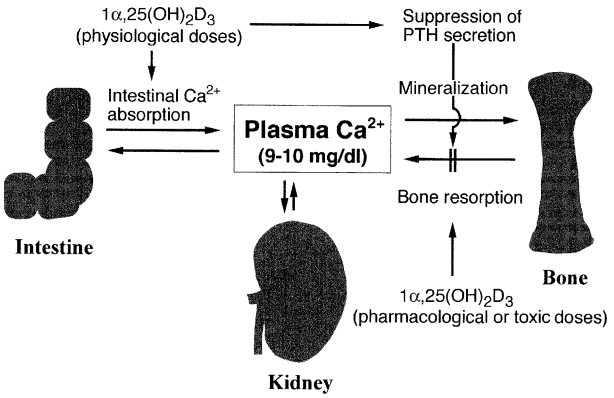

FIGURE 6 The role of 1α,25(OH)$_2$D$_3$ in maintaining plasma calcium homeostasis.

turn stimulates bone mineralization (Fig. 6). The recent findings of VDR knockout mice and of those mice fed a rescue diet containing high levels of calcium indicate that the stimulating effect of vitamin D on bone formation and mineralization is indirect, occurring through the stimulation of intestinal absorption of calcium by this vitamin. In contrast, osteoclastic bone resorption can be induced by vitamin D directly but only by pharmacological or toxic doses (Fig. 6). Physiological doses of vitamin D never stimulate bone resorption.

It is interesting that osteoclast formation requires cell-to-cell contact with osteoblastic cells, which generates ODF/RANKL as a membrane-associated factor in response to several bone-resorbing factors including vitamin D. In normal bone remodeling, bone formation by osteoblasts always occurs in a programmed manner accurately and quantitatively just after bone resorption by osteoclasts. Thus, it is possible that cell-to-cell contact between osteoclast progenitors and osteoblastic cells may leave some template for bone formation in osteoblasts/stromal cells. This possibility must be proved by future experiments.

Glossary

osteoblasts The cells responsible for bone formation, which derive from mesenchymal progenitors and synthesize bone matrix proteins containing type III collagen and other noncollagenous proteins such as osteocalcin, osteopontin, osteonectin, and bone sialoproteins.

osteoclast differentiation factor (ODF) The factor responsible for osteoclast formation and activation, which belongs to the tumor necrosis factor (TNF) ligand family. ODF consists of 316 amino acid residues and is also called receptor activator of NF-κB ligand (RANKL).

osteoclasts The cells responsible for bone resorption, which originate from hematopoietic cells of the monocyte–macrophage lineage and which are present only in bone.

osteoprotegerin (OPG) The decoy receptor of ODF/RANKL, which belongs to the TNF receptor family. OPG is also called osteoclastogenesis inhibitory factor (OCIF). OPG/OCIF is a soluble receptor having no membrane-associated domain.

receptor activator of NF-κB (RANK) The receptor of ODF/RANKL, which belongs to the TNF receptor family.

VDR The specific receptor for the hormonal form of vitamin D$_3$, 1α,25(OH)$_2$D$_3$, in target tissues.

Vitamin D: Biological Effects of $1,25(OH)_2D_3$ in the Intestine and the Kidney

JOOST G. J. HOENDEROP, CAREL H. VAN OS, AND RENÉ J. M. BINDELS

University of Nijmegen, The Netherlands

Calcitriol or 1,25-dihydroxyvitamin D_3 [$1,25-(OH)_2D_3$] is essential for the development and maintenance of bone. This hormone plays a crucial role in Ca^{2+} and P_i homeostasis and exerts its biological actions on the intestine and kidney; the absorbing activity of these target organs ultimately determines the mineral balance for the entire body. $1,25(OH)_2D_3$ has strong stimulatory effects on Ca^{2+} transport proteins; thus, transepithelial Ca^{2+} transport in the small intestine and kidney is dependent on vitamin D. Less is known regarding the transport of P_i in the kidney and intestine. However, it is well established that vitamin D stimulates Na^+-dependent P_i transport in the small intestine, although the molecular mechanism responsible has not yet been elucidated.

I. INTRODUCTION

Calcitriol or 1,25-dihydroxyvitamin D_3 [$1,25(OH)_2D_3$] plays a critical role in Ca^{2+} and phosphate (P_i) homeostasis and is essential for the development and maintenance of bone. The intestine and kidney are main target organs for the action of this hormone. The absorbing activity of intestine and kidney determines the net intake and excretion of minerals for the entire body and, therefore, the mineral balance. In normal adults, the renal excretion of Ca^{2+} and P_i is critically balanced by gastrointestinal absorption. On the other hand, the distribution of Ca^{2+} within the body is determined by exchanges of Ca^{2+} between interstitium and bone. These pathways are primarily regulated by vitamin D metabolites and parathyroid hormone (PTH). Alterations in these regulatory processes are present in many physiological and pathophysiological states.

The biological actions of calcitriol on the target organs are mediated by both genomic and rapid posttranscriptional mechanisms. The genomic response is linked to the nuclear vitamin D receptor (VDR). Upon binding $1,25(OH)_2D_3$, the VDR undergoes a conformational change and forms a complex with a retinoid X receptor (RXR). The VDR/RXR complex binds to DNA elements in the promoter regions of target genes described as vitamin D-response elements (VDREs). Binding to the VDREs may control the rate of gene transcription. The rapid response is believed to utilize another signal transduction pathway that is likely linked to a putative cell membrane receptor for $1,25(OH)_2D_3$, but its physiological role is still not well understood.

II. BIOLOGICAL EFFECTS IN THE INTESTINE

The most critical role of $1,25(OH)_2D_3$ in the gut is to regulate the absorption of Ca^{2+} and P_i during variations in dietary intake and body demand. The most obvious stimulatory effect of $1,25(OH)_2D_3$ in this tissue takes place in the proximal small intestine and is mediated by VDR-controlled genomic actions.

A. Calcium Absorption

There is ample evidence that vitamin D is an important determinant of intestinal Ca^{2+} absorption. For instance, in vitamin D deficiency, intestinal Ca^{2+} absorption is low, resulting in an increased risk of developing negative Ca^{2+} balance and bone loss. Conversely, plasma levels of $1,25(OH)_2D_3$ are increased as a primary response to low dietary Ca^{2+} intake and increased Ca^{2+} requirements during growth, pregnancy, and lactation, affecting primarily the rate of active Ca^{2+} absorption in duodenum. During transcellular Ca^{2+} transport, Ca^{2+} ions pass across the lumenal brush-border membrane, then transverse through the cytosol, and exit against an electrochemical gradient across the basolateral membrane. The epithelial Ca^{2+} channel, ECaC (or Ca^{2+} transporter, CaT), the vitamin D-dependent Ca^{2+}-binding protein, calbindin-D_{9K}, and the plasma membrane Ca^{2+}-ATPase, PMCA, represent the major Ca^{2+} transporters that mediate this three-step process in the small intestine. $1,25(OH)_2D_3$ stimulates this vectorial Ca^{2+} transport primarily via a genomic action and the contribution of each individual transporter to the overall stimulatory action of $1,25(OH)_2D_3$ has been elucidated in several studies.

The molecular identity of the Ca^{2+} entry mechanism across the lumenal brush-border membrane has recently been established. By an expression cloning strategy, the epithelial calcium channels ECaC1 and ECaC2 (also known as CaT1) were identified. These highly homologous channels represent a new class of Ca^{2+}-selective channels, which are predominantly expressed in $1,25(OH)_2D_3$-responsive epithelia such as small intestine, kidney, and placenta. Analysis of the 5′ upstream region of the human ECaC1 gene revealed putative VDREs at a distance of approximately 1.5–0.5 kb from the transcription initiation site, which supports the previous findings that ECaC1 is a target gene for $1,25(OH)_2D_3$. The role of the VDREs in $1,25(OH)_2D_3$-mediated ECaC1 gene transcription remains to be established. However, it is likely that $1,25(OH)_2D_3$ regulates the transcription of these Ca^{2+} channels. Surprisingly, in two initial studies no significant effect of $1,25(OH)_2D_3$ on the expression of these channels could be found, thus far for unexplained reasons. Northern blot analysis did not reveal vitamin D-dependent regulation of ECaC2 expression in the duodenum of rats and no significant relationship was shown between human ECaC2 expression in duodenal samples and serum $1,25(OH)_2D_3$ levels of healthy volunteers. The first indication that ECaC in the intestine is regulated by vitamin D was recently shown in animal studies. A single pharmacological dose of $1,25(OH)_2D_3$ in wild-type mice stimulated the duodenal level of ECaC1 mRNA by a factor of 1.6 and that of ECaC2 mRNA by more than sixfold. In a study from two independent groups, using mice strains in which the VDR was inactivated, it was further investigated whether these channels are indeed prime targets for hormonal regulation by $1,25(OH)_2D_3$. These mice display a phenotype similar to that observed in hereditary hypocalcemic vitamin D-resistant rickets, namely, rickets, hypocalcemia, and hypophosphatemia. This phenotype could be rescued by high dietary Ca^{2+} intake, confirming that the intestinal absorption of Ca^{2+} is critical in $1,25(OH)_2D_3$ action on Ca^{2+} homeostasis. ECaC1 and ECaC2 mRNA levels were considerably and consistently down-regulated in the duodenum of these VDR-knockout mice on a normal Ca^{2+} diet. Similar studies were performed in mice homozygous for the disrupted Na^+–P_i co-transporter (Npt2) gene. These hypophosphatemic mice exhibit hypercalcemia and hypercalciuria resulting from duodenal Ca^{2+} hyperabsorption, secondary to elevated serum $1,25(OH)_2D_3$ levels. In these mutants, the duodenal expression of ECaC1 and ECaC2 mRNAs is higher than in wild-type littermates, suggesting that the corresponding proteins are involved in mediating the increase in duodenal Ca^{2+} absorption. Finally, the expression of ECaC2 is rapidly up-regulated by $1,25(OH)_2D_3$ and precedes vitamin D-stimulated Ca^{2+} transport in Caco-2 cells, a human intestinal cell line. Taken together, these results suggest that the expression of these novel duodenal epithelial Ca^{2+} channels is strongly vitamin D-dependent.

There is ample evidence that calbindin-D_{9K} is highly responsive to $1,25(OH)_2D_3$. In animal models and cell lines, it has been documented that $1,25(OH)_2D_3$ stimulates the expression of calbindin-D_{9K} on both mRNA and protein levels, involving a genomic pathway. This results in an increase in the capacity of diffusional flow of Ca^{2+} ions through the cytosol. The linear correlation between the intestinal content of calbindin-D_{9K} and the rate of active Ca^{2+}

transport in the intestine underscores the important role of calbindin-D_{9K} in active Ca^{2+} absorption. The molecular basis for regulating the calbindin-D_{9K} gene by $1,25(OH)_2D_3$ is not completely understood since the previously identified VDREs in the promoter region seem not to be responsible for the stimulatory effect.

PMCA is ubiquitously expressed in Ca^{2+} transporting epithelia and is encoded by four distinct genes (PMCA1–4) that can be further posttranscriptionally modified. PMCA1b is the only isoform predominantly expressed in small intestine and kidney. It has been shown experimentally that in variable circumstances the extrusion capacity of PMCA is more than adequate, suggesting that the Ca^{2+} exit step is not necessarily a prime target for regulation by $1,25(OH)_2D_3$. This could perhaps explain the difficulty in observing a consistent stimulatory effect of $1,25(OH)_2D_3$ on PMCA. In VDR knockout mice strains, the expression of PMCA1b is not altered in duodenal samples, whereas in $1,25(OH)_2D_3$ repletion studies performed in chicken, rat, and mice, an increase in intestinal PMCA1b expression was observed.

The overall conclusion is that the stimulatory effect of $1,25(OH)_2D_3$ on intestinal Ca^{2+} absorption results primarily from an increased expression of ECaC and calbindin-D_{9K}. Thus, during periods of high Ca^{2+} demand, the activity of ECaC is increased in the brush-border membrane of the enterocyte via a $1,25(OH)_2D_3$-dependent genomic mechanism. The concomitant increase in the cytosolic content of calbindin-D_{9K} serves two important physiological functions. It guarantees sufficient buffering and inactivation of Ca^{2+} ions in the close vicinity of the channel to prevent a Ca^{2+}-induced inactivation of channel activity and accelerates the transfer of Ca^{2+} to the basolateral extrusion pumps. In this way, $1,25(OH)_2D_3$ can efficiently promote high rates of transcellular Ca^{2+} absorption in the small intestine.

B. Phosphate Absorption

The intestinal P_i absorption process occurs both by a Na^+-independent, nonsaturable pathway and by an active, Na^+-dependent mechanism present mainly in duodenum and jejunum. This latter process is subject to chronic regulation by $1,25(OH)_2D_3$. Ample studies have demonstrated that the stimulatory effect of $1,25(OH)_2D_3$ occurs through an increased rate of Na^+–P_i co-transport present in the brush-border membrane, but the molecular details have not been elucidated. To date, three different families of Na^+–P_i co-transporters have been identified, but the physiological role of these transporters in intestinal P_i absorption remains to be firmly established. The so-called NaP_i type IIb co-transporter is expressed in the small intestine and is located in the apical membrane. The abundance of this transporter is up-regulated by $1,25(OH)_2D_3$, but a concomitant increase in mRNA levels was not observed in adult animals. This suggests that posttranscriptional mechanisms are involved in Na^+-dependent P_i co-transporter activity, contributing to the observed $1,25(OH)_2D_3$-induced stimulation of P_i absorption. Little is known about the molecular mechanisms responsible for the extrusion of P_i across the intestinal basolateral membrane into the circulation. Future work, in which all apical and basolateral P_i transporters will be identified, must be completed before a comprehensive molecular description of $1,25(OH)_2D_3$ action on intestinal P_i absorption can be provided.

III. BIOLOGICAL EFFECTS IN THE KIDNEY

Renal tubular reabsorption of Ca^{2+} and P_i is a key element in overall mineral homeostasis and also involves hormone-regulated active transport mechanisms. The molecular identification of the responsible Ca^{2+} and P_i transporters provided tools to study the regulation of tubular transport function at the cellular and organ levels and will ultimately disclose the full-delineated mechanisms involved in vitamin D-controlled mineral excretion.

A. Calcium Reabsorption

The distal part of the nephron is the main site of hormone-regulated transcellular Ca^{2+} transport, which is at the cellular level realized by a three-step process similar to that described for the intestine. However, there are distinctive differences between intestinal and renal active Ca^{2+} transport. For instance, renal Ca^{2+} reabsorption is tightly controlled by PTH, but this calciotropic hormone has no direct effect on intestinal Ca^{2+} absorption. The kidney contains a 28 kDa calbindin to facilitate the cellular Ca^{2+} flow, but thus far only mouse, bovine, and rat also contain calbindin-D_{9K}. In addition, the kidney utilizes primarily the Na^+–Ca^{2+} exchanger to extrude Ca^{2+}.

Although there has been some controversy concerning the role of $1,25(OH)_2D_3$ in renal Ca^{2+} transport and the mechanisms behind $1,25(OH)_2D_3$ responsiveness, there is now accumulating evidence that this seco-steroid stimulates transcellular Ca^{2+}

transport in the distal part of the nephron. In a primary culture of rabbit distal tubular cells, $1,25(OH)_2D_3$ increases transcellular Ca^{2+} transport in a dose-dependent manner. In addition, extensive immunohistochemical and *in situ* hybridization studies revealed that the VDR is expressed in both proximal and distal segments but is highly enriched in the distal part of the nephron, a site known to be primarily involved in active transcellular Ca^{2+} transport.

Comparable to the intestine, ECaC1 is the postulated gatekeeper of transepithelial Ca^{2+} transport in the kidney and is, therefore, a candidate target for the action of $1,25(OH)_2D_3$. The first indication that ECaC1 is indeed controlled by $1,25(OH)_2D_3$ came from a vitamin D-deficient rat model. In kidneys of these depleted animals, ECaC1 mRNA and protein levels were significantly reduced. Repletion with $1,25(OH)_2D_3$ completely restored the abundance of ECaC1, which was accompanied by a normalization of the plasma Ca^{2+} concentration. This suggests a crucial function of this Ca^{2+} influx channel in renal Ca^{2+} handling.

The vitamin D-induced stimulation of ECaC in this rat model was accompanied by a comparable enhancement of calbindin-D_{28K}, confirming the established vitamin D dependence of this calcium-binding protein. In kidneys obtained from VDR knockout mice, the expression of calbindin-D_{9K} was virtually abolished at both the mRNA and protein levels, whereas calbindin-D_{28K} was only modestly decreased. Another mouse model for the study of vitamin D-dependent processes was established by ablation of the 25-hydroxyvitamin D 1α-hydroxylase gene [1α(OH)ase]. The synthesis of $1,25(OH)_2D_3$ from its precursor 25-hydroxyvitamin D is catalyzed by the mitochondrial cytochrome P450 enzyme 25-hydroxyvitamin D 1α-hydroxylase D, which is primarily expressed in the kidney. The $1,25(OH)_2D_3$ dependency was confirmed by the marked reduction in mRNA levels encoding renal calbindin-D_{9K} and calbindin-D_{28K} in the 1α(OH)ase null mice relative to wild-type littermates. These data clearly demonstrate that in mouse kidney, calbindin-D_{9K} and calbindin-D_{28K} are regulated by the VDR-mediated action of $1,25(OH)_2D_3$.

The physiological implication of the concomitant increase in ECaC1 and calbindin-D levels is similar to the findings for the intestine, where the expression of ECaC2 and calbindin-D_{9K} is closely coupled to vitamin D dependency of Ca^{2+} absorption. Together with the fact that both calcium transport proteins are co-expressed in the same tissues, these findings suggest an obligatory functional coupling between ECaC and calbindin-D in order to mediate vitamin D-dependent Ca^{2+} transport.

The effect of $1,25(OH)_2D_3$ on the basolateral extrusion systems, NCX (Na^+–Ca^{2+} exchanger) and PMCA, is less clear and remains controversial. Although NCX plays a dominant role in the extrusion process, many studies failed to establish a direct regulation by vitamin D. Exposure of $1,25(OH)_2D_3$ to primary cultures of rabbit connecting tubules did not noticeably alter NCX expression. Surprisingly, a single pharmacological dose of $1,25(OH)_2D_3$ significantly reduced the expression of NCX in mouse kidney. As in small intestine, $1,25(OH)_2D_3$ upregulates PMCA1b protein expression and activity in kidney distal tubules and derived cell lines. Furthermore, $1,25(OH)_2D_3$ enhanced PMCA1b mRNA stability. However, other reports in which primary cultures of renal cells or mice exposed to $1,25(OH)_2D_3$ were used as model systems failed to show significant regulation of PMCA1b expression levels. Conversely, runoff reporter gene assays using 1.7 kb of the human PMCA1 promoter expressed in distal tubular cell lines demonstrated mRNA downregulation by $1,25(OH)_2D_3$. Taken together, a consistent stimulatory effect of $1,25(OH)_2D_3$ on the Ca^{2+} extrusion mechanisms in the kidney remains to be established.

B. Phosphate Reabsorption

The reabsorption of P_i in the proximal tubule plays a primary role in overall P_i homeostasis and involves an active P_i transport mechanism. Vitamin D has been suggested to enhance the proximal tubular P_i reabsorption in rats. It is, however, difficult to distinguish between direct and indirect effects since the vitamin D status is closely associated with plasma Ca^{2+} and PTH concentrations. In contrast to the small intestine where $1,25(OH)_2D_3$ has a direct effect on lumenal Na^+-dependent P_i uptake, it remains, therefore, unclear whether $1,25(OH)_2D_3$ directly regulates proximal tubular P_i reabsorption.

The cellular scheme for the P_i reabsorption process includes three different Na^+–P_i co-transporters, namely, type I, type Iia, and type III; the type I and type Iia transporters are localized along the apical membrane, whereas type III is expressed in the basolateral membrane. A single study demonstrated that NaP_i-type IIa mRNA and protein were markedly decreased in the juxtamedullary cortex of vitamin D-deficient rats, but not in the superficial cortex. Luciferase reporter studies in COS7 cells, expressing the human VDR, confirmed the existence of a

TABLE I The Expression Level of Ca^{2+} and P_i Transporters during $1,25(OH)_2D_3$-Stimulated Transport in Small Intestine and Kidney

functional VDRE approximately 2 kb upstream from the transcription initiation site of the NaP_i-type IIa gene. At present, sufficient data are not available to postulate a direct role of $1,25(OH)_2D_3$ on proximal P_i reabsorption in general and on the individual P_i transporters in particular.

IV. SUMMARY

Recently, detailed insights in the vitamin D action on Ca^{2+} and P_i homeostasis were obtained from several animal models including vitamin D-depleted rats and knockout mice in which the VDR and 1α(OH)ase genes were inactivated. The delineated effects on the individual Ca^{2+} and P_i transporters are summarized in Table 1. In general, $1,25(OH)_2D_3$ has profound stimulatory effects on the Ca^{2+} transport proteins, explaining the vitamin D dependency of transepithelial Ca^{2+} transport in small intestine and kidney. The situation is less clear for renal and intestinal P_i handling. Only in the small intestine it is well established that vitamin D stimulates Na^+-dependent P_i transport, but the elucidation of the molecular mechanism awaits future investigations.

Glossary

calbindin-D Vitamin D-dependent Ca^{2+}-binding proteins consisting of a 28 kDa protein (calbindin-D_{28K}) and a 9 kDa protein (calbindin-D_{9K}) that bind Ca^{2+} with high affinity and facilitate diffusion of cytosolic Ca^{2+}.

ECaC Epithelial calcium channels that were identified in kidney and small intestine as ECaC1 and ECaC2 (also known as CaT1), respectively, and are the gatekeepers in active Ca^{2+} (re)absorption.

NaPi Sodium–phosphate co-transporters that mediate the movement of extracellular phosphate into cells driven by the existing Na^+ gradient. To date, three different families, named types I, II, and III, have been identified.

NCX Na^+–Ca^{2+} exchanger present in the plasma membrane and the kidney; it is primarily responsible for the basolateral extrusion of Ca^{2+} in the distal tubular cells.

1α(OH)ase knockout mice A mouse strain in which the key enzyme 25(OH)D-1α-hydroxylase has been inactivated, mimicking the genetic disorder vitamin D-dependent rickets type I, also known as pseudo-vitamin D-deficiency rickets.

PMCA Plasma membrane Ca^{2+} ATPase that mediates the extrusion of Ca^{2+} across the basolateral membrane. To date, four different genes have been identified; PMCA1b is the predominant isoform expressed in the small intestine and the distal part of the nephron.

VDR knockout mice A mouse strain in which the vitamin D receptor has been inactivated, mimicking the autosomal recessive disorder hypocalcemic vitamin D-resistant rickets.

Vitamin D Deficiency, Rickets and Osteomalacia

DAVID FELDMAN AND PETER J. MALLOY
Stanford University

The complex interplay of 1,25-dihydroxyvitamin D_3 (calcitriol) and parathyroid hormone regulates mineral metabolism and proper delivery of minerals to the skeleton. Supply of adequate calcium and phosphate to bone-forming sites is critical for synthesizing normal bone and for preventing rickets or osteomalacia. A defect in any step in the pathway of synthesis or action of 1,25-dihydroxyvitamin D_3 can cause these diseases.

I. INTRODUCTION

Bone is a complex, living tissue composed of a mineralized protein matrix that forms a hard and rigid skeletal framework. Osteoblasts are the bone-forming cells that secrete the malleable collagen matrix that is eventually mineralized with hydroxyapatite, a calcium phosphate crystal. Bone is constantly turning over; osteoclast-mediated resorption in specific areas of bone is coupled to bone formation carried out by osteoblasts. In order to maintain normal mineralization of newly formed bone, adequate calcium and phosphate must be delivered to the osteoblasts at bone-forming sites. To meet this mineral requirement for normal bone formation and turnover requires the ingestion of adequate calcium and phosphate in the diet and the presence of adequate amounts of vitamin D, the hormone responsible for regulating mineral absorption from the gastrointestinal tract. If calcium or phosphate delivery to the bone-forming site is inadequate, undermineralized bone is formed. This process is called osteomalacia. If osteomalacia develops during childhood, while active bone growth is underway, the undermineralization of both bone and cartilage leads to rickets. This involves failure or delay of mineralization in the growth plates and joints as well as in other skeletal sites.

Undermineralized bone is characterized by excess osteoid, the collagenous bone matrix, relative to mineral. Normally, most osteoid is rapidly mineralized and only a small rim of unmineralized matrix can be found on bone trabeculae. However, in rickets or osteomalacia, the level of unmineralized osteoid is increased. Initially, osteoid surface and volume are increased, but osteoid thickness and lag times (delay in mineralizing osteoid) are normal. In more severe cases, osteoid thickness exceeds 15 μm and mineralization lag time exceeds 100 days. In the most florid cases, no mineralization is detected. The strength of unmineralized osteoid is greatly diminished compared to normally mineralized bone, leading to metabolic bone disease and increased susceptibility

B. Chick Egg Hatchability

Long-term studies of White Leghorn hens that received only exogenous vitamin D metabolites from the day of hatching have shown that 24*R*,25$(OH)_2D_3$ is required in combination with 1α,25$(OH)_2D_3$ for the normal hatchability of the fertilized eggs. In a follow-up study of Japanese quail, only the naturally occurring 24*R*,25$(OH)_2D_3$ [i.e. not the artificial 24*S*,25$(OH)D_3$] in combination with 1α,25$(OH)_2D_3$ supported normal egg hatchability.

C. Fracture Healing

In an *in vivo* model of fracture healing in the chick, the renal 24*R*-hydroxylase activity increases three-fold approximately 1 week following imposition of a tibial fracture; this is accompanied by a similar increase in the levels of circulating 24*R*,25$(OH)_2D_3$. When the degree of fracture healing as reflected in bone strength is measured, 24*R*,25$(OH)_2D_3$, but not 24*S*,25$(OH)D_3$, when given in combination with 1α,25$(OH)_2D_3$ (a dose that is ineffective by itself), results in bone strength equivalent to that seen in control animals receiving 25$(OH)D_3$.

Based on these observations, it is possible to envision the existence of an endocrine system linking a bone fracture to the kidney 25$(OH)D_3$-24*R*-hydroxylase, resulting in the subsequent elevation of the serum 24*R*,25$(OH)_2D_3$ levels. The increased availability of this steroid hormone allows occupancy of the proposed vitamin D receptor ($VDR_{mem\ 24,25}$), which then initiates, in collaboration with 1α,25-$(OH)_2D_3$, appropriate transduction signals that orchestrate the competent healing of the fracture (see Fig. 1).

D. Cartilage Cells

24*R*,25$(OH)_2D_3$ has biological effects distinct from those of 1α,25$(OH)_2D_3$ on a subset of cells in growth plate cartilage. One hallmark of a steroid hormone is that it is preferentially accumulated by its target cells *in vivo* on a high-affinity receptor that tightly binds the hormone and effectively removes it from the blood compartment. This standard has been achieved for 24*R*,25$(OH)_2D_3$ in relation to growth plate cartilage cells of the rat. These cells selectively accumulate tritiated 24*R*,25$(OH)_2D_3$ that is been administered *in vivo* to rats.

IV. RECEPTORS FOR 24*R*,25$(OH)_2D_3$

Unlike 1α,25$(OH)_2D_3$, which has a widely distributed nuclear receptor that mediates an array of biological responses, the seco steroid 24*R*, 25$(OH)_2D_3$ likely produces biological responses in a more limited

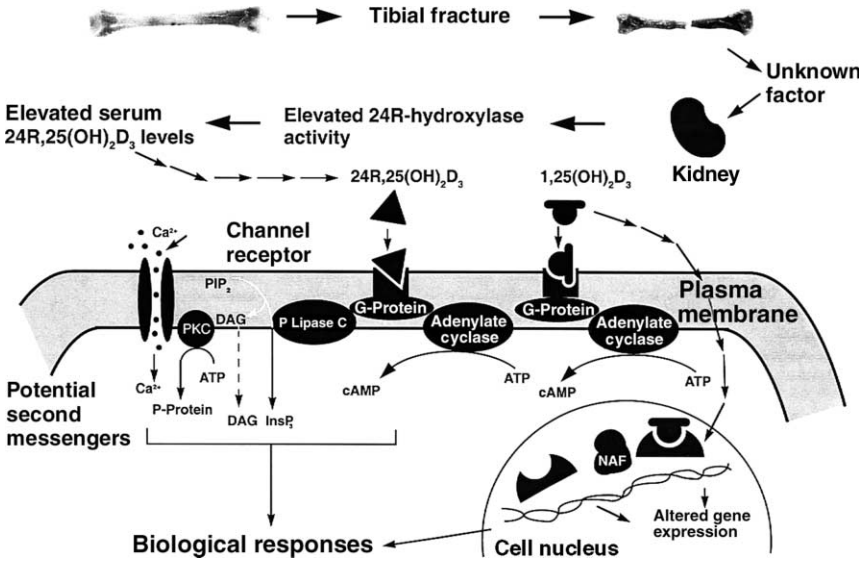

FIGURE 1 Proposed mode of action of 24*R*,25$(OH)_2D_3$ for the process of fracture healing. After imposition of a bone fracture, an unknown factor is produced and delivered systemically to the kidney proximal tubule, leading to a significant increase in the activity of the 25$(OH)D_3$-24*R*-hydroxylase. The resultant elevation of the plasma level of 24*R*,25$(OH)_2D_3$ leads to occupation of membrane vitamin D receptors believed to be present in the fracture-healing callus, and thereby initiating signal transduction processes and contributing to the process of fracture healing. PKC, Protein kinase C; DAG, diacylglycerol; $InsP_3$, inositol 1,4,5-trisphosphate; NAF, nuclear activation factor.

TABLE 1 Biological Responses Attributed to 24*R*,25(OH)$_2$ Vitamin D$_3$

Organ cell system	Response studied
Parathyroid gland	Regression of hypertrophied glands; inhibition of PTH secretion
Egg hatchability	Required in combination with 1α,25(OH)$_2$D$_3$ for normal egg hatchability
Bone	Healing of rachitic lesions with increased bone strength; healing of fractures with increased bone strength
Chondrocytes (resting zone)	Activation of protein kinase C; inhibition of prostaglandin E2 production; increased activity of phospholipase C

sphere, consisting of cartilage and bone cells and possibly parathyroid hormone-secreting cells. Table 1 summarizes the biological responses that have been reported to be mediated by 24*R*,25(OH)$_2$D$_3$.

The stereospecificity at the C-24*R* position of 24*R*,25(OH)$_2$D$_3$ vs 24*S*,25(OH)D$_3$, for the effects described for parathyroid glands, egg hatchability, and bone fracture healing, suggests the existence of a receptor that can distinguish between the two compounds. The search for 24*R*,25(OH)$_2$D$_3$-specific receptors is an active area of current investigation. Thus far, there has been no evidence for the existence of a nuclear receptor, but preliminary evidence suggests that there is a membrane-associated receptor-binding protein ($K_d \approx 18 \pm 1.9$ n*M*) for 24*R*,25- (OH)$_2$D$_3$ in the chick fracture-healing callus. The binding of [^{3}H]1α,25(OH)$_2$D$_3$ to the callus membrane receptor-binding protein is specific in that it is competed for only by nonradioactive 24*R*,25- (OH)$_2$D$_3$, and not by 24*S*,25(OH)D$_3$, 1α,25(OH)$_2$- D$_3$, or 25(OH)D$_3$. Evidence has also been obtained that growth zones cartilage cells of bone and osteoblasts have a membrane receptor for 24*R*,25(OH)$_2$D$_3$.

The first mechanistic insight into the signal transduction pathways activated by 24*R*,25-(OH)$_2$D$_3$ in cartilage resting zone cartilage cells includes activation of protein kinase C (PKC) via effects on phospholipase A$_2$, as well as possible effects on increasing the activity of phospholipase C.

V. SUMMARY

Results from a number of studies support a role for 24*R*,25(OH)$_2$D$_3$ in the parathyroid gland and in hatching of the avian embryo. Current evidence also supports the concept that 24*R*,25(OH)$_2$D$_3$, acting through its receptor, plays an important role in bone fracture healing and in the maturation of growth plate cartilage cells. Biochemical details of these proposed receptors and further details on the signal transduction pathways that they activate might emerge in future studies.

Glossary

endocrine system Network of endocrine glands (sources of a hormones) and target cells (locations of the hormones receptors) involved in integrated interactions that generate regulated, selective biological responses necessary to maintain the system viability.

hormone Any of several chemical classes of compounds produced in regulated quantities by an endocrine gland; acts as a chemical messenger, usually delivered through the circulatory system to a target cell, which, by definition, possesses a receptor for that hormone so that a specific biological response is generated.

receptor Protein molecule that binds very specifically to its cognate hormone; binding generates a receptor–hormone complex that initiates a cellular signal transduction process, resulting in one or more biological responses.

steroid Member of the lipid class of compounds; composed of the cyclopentano-perhydro-phenanthrene nucleus, a four-ring structure that is the basic structural component of steroid hormone families such as estrogens, progestogens, androgens, mineralocorticoids, and glucocorticoids.

vitamins Essential organic substances present in trace amounts in food; effect the normal cellular metabolic processes.

Vitamin D Effects on Cell Differentiation and Proliferation

CHANTAL MATHIEU, ANNEMIEKE VERSTUYF, SIEGFRIED SEGAERT, AND ROGER BOUILLON
Katholieke Universiteit Leuven, Belgium

1α,25-dihydroxyvitamin D_3 [1α,25$(OH)_2D_3$] exerts its effects via the vitamin D receptor (VDR), which belongs to the steroid/thyroid hormone receptor superfamily, leading to gene regulation mediating various biological responses. Within the past two decades, the receptor has been shown to be present not only in classical target tissues such as bone, kidney, and intestine but also in many other nonclassical tissues, e.g., in the immune system (T and B cells, macrophages, and monocytes), in the reproductive system (uterus, testis, ovary, prostate, placenta, and mammary glands), in the endocrine system (pancreas, pituitary, thyroid, and adrenal cortex), in muscles (skeletal muscle, smooth muscle, and heart muscle), in brain, in skin, and in liver.

I. INTRODUCTION

In addition to the almost universal presence of vitamin D receptors (VDRs), some cell types (e.g., keratinocytes, monocytes, bone, and placenta) are capable of metabolizing 25-hydroxyvitamin D_3 to 1,25$(OH)_2D_3$ by the enzyme 1α-hydroxylase. The combined presence of 25$(OH)D_3$-1α-hydroxylase and the specific receptor in several tissues introduced the idea of a paracrine role for 1,25$(OH)_2D_3$. Moreover, it has been demonstrated that 1,25$(OH)_2D_3$ can induce differentiation and inhibit proliferation of normal and malignant cells. In addition to the treatment of bone disorders with 1,25$(OH)_2D_3$, these newly discovered functions of 1,25$(OH)_2D_3$ open new therapeutic applications as an immune modulator (e.g., for the treatment of autoimmune diseases or prevention of graft rejection), inhibitor of cell proliferation

and selectivity and, perhaps just as importantly, to bind to DNA. Both were features consistent with those of a protein capable of mediating vitamin D-dependent gene expression. It was the molecular cloning of the VDR, however, that led to new insights into receptor structure and function and which enabled the tremendous progress that has been made recently in understanding how hormones such as $1,25(OH)_2D_3$ function to regulate gene expression.

A. General Organization of Steroid Receptors

The general structural organization of the VDR and other members of the steroid receptor family is illustrated in Fig. 1a. As can be seen, the typical hormone receptor is composed of an amino-terminal domain, a more centrally located DNA-binding domain (DBD), which is the hallmark of the nuclear receptor family, a linker region, and a large carboxy-terminal ligand-binding domain (LBD) that is capable of binding not only hormonal ligands but also additional transcriptional co-regulators that are directly responsible for the activation (or repression) of gene expression. Receptors that contain large amino-terminal extensions can also modulate gene expression through this region. As seen in Fig. 1b, the overall structure of the VDR is generally similar with the exception that its amino-terminal domain is somewhat abbreviated relative to that of other receptor family members. As a consequence, the VDR relies heavily on the activation region found within the carboxy-terminal LBD. The key structural elements of the VDR (as well as other family members) are, therefore, the DNA-binding domain, which specifies the genes that are to be regulated, and

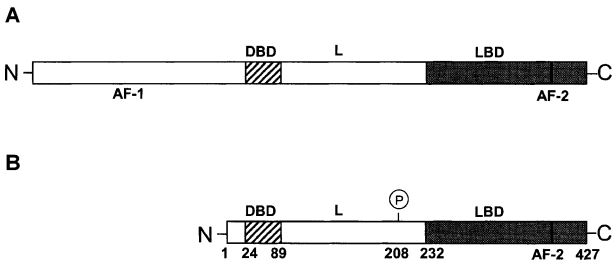

FIGURE 1 General structural organization of members of the nuclear receptor gene family. (A) Organization of a prototypical steroid receptor. the carboxy-terminal domain, which mediates the transcriptional regulatory process following binding and activation by $1,25(OH)_2D_3$ or other steroidal ligands.

B. The DNA-Binding Domain of the VDR

The DBD of the VDR and the nuclear receptor family consists of two similar modules, each composed of a zinc-coordinated finger structure (Fig. 2). Each zinc atom is coordinated in a tetrahedral fashion through four highly conserved cysteine residues that serve to stabilize the finger structure itself. Although the two zinc modules of the VDR appear to be highly related structurally, topologically they are not equivalent as a result of differing chirality of the residues in each module that coordinate the zinc atom. More importantly, the function of each of these modules in DNA binding is known to be substantially different. Whereas the amino-terminal module functions to direct specific DNA binding in the major groove of the DNA-binding site, the carboxy-terminal module serves as a dimerization interface for interaction with DNA-binding protein partners. Recent studies have led to the elucidation of the three-dimensional structure of the DNA-binding domain of several nuclear receptors while bound to DNA.

C. The Ligand-Binding Domain of the VDR

The LBD of the VDR is responsible for the receptor's functional activity. This region contains both a dimerization domain that permits essential interaction with the retinoid X receptor (RXR), a key DNA-binding protein partner, and an activation domain that directs the recruitment of co-regulatory proteins such as steroid receptor co-activator-1 (SRC-1), glucocorticoid receptor-interacting protein (GRIP), and D receptor-interacting protein 205 ($DRIP_{205}$). These factors as well as others mediate linkage to large

protein machines responsible for altering chromatin structure and facilitating recruitment of RNA polymerase II, both of which are integral to the modulation of gene expression. Most importantly, however, the structural integrity and functional activity of both of these protein-interacting domains within the VDR are under the control of $1,25(OH)_2D_3$. This tight regulatory capacity of the hormone is achieved by its ability to occupy a small pocket within the receptor and to induce significant conformational changes necessary for activity. Thus, the limited functional capabilities of a very small molecule such as $1,25(OH)_2D_3$ are expanded through its interaction with a much larger macromolecule to confer multifunctional cellular capabilities. Recent efforts have resulted in determination of the three-dimensional structure of the LBD of the VDR. The crystal structure both confirms previous biochemical and molecular studies of VDR and provides new avenues of research aimed at understanding the structure and function of this important molecule.

III. REGULATION OF GENE EXPRESSION THROUGH DNA BINDING

The vitamin D hormone is known to regulate a host of genes, a few of which are indicated in Table 1. Perhaps the first to be identified was the chicken vitamin D-dependent calbindin gene, whose product is involved in facilitating intestinal calcium absorption. More recently, gene targets include the 25-hydroxyvitamin D_3-24-hydroxylase, osteocalcin, osteopontin, and p21. An initial understanding of how $1,25(OH)_2D_3$ and its receptor might regulate gene expression was derived initially from studies of the human osteocalcin gene. Accordingly, a hexanucleotide repeat DNA sequence separated by 3 bp that represented a specific binding and transcriptional activation site (vitamin D-response element or VDRE) for the VDR was discovered upstream of the start site of transcription within the human osteocalcin gene promoter. This element as well a similar sequence found in the rat osteocalcin gene provided a first glimpse at a binding site for the VDR within a $1,25(OH)_2D_3$-regulated gene. The sequences of these VDREs as well as several additional ones that were discovered in the mouse osteopontin gene, mouse calbindin -D-28K, rat calbindin D-9K, the rat and human 25-hydroxyvitamin D_3-24-hydroxylase genes (two apparent VDREs), and the human p21 gene are documented in Table 1.

IV. THE VDR FUNCTIONS AS A HETERODIMER

The duplicated nature of the VDRE in the osteocalcin gene and other gene promoters suggested that VDR might bind as a homodimer to DNA identical to that for other steroid receptors. Despite this precedent, the VDR was surprisingly found to bind to VDREs as a heterodimer with a previously identified protein, termed the RXR (Fig. 3). This interaction requires a protein dimerization surface within the DBD of both VDR and RXR as well as one located within the carboxy-terminus of both proteins. Additional studies indicate that the VDR/RXR interaction with DNA exhibits polarity. As seen in Fig. 3, RXR binds to the 5′ or upstream promoter half-site of the VDRE and the VDR occupies the downstream site. There are three RXR isotypes that can interact with the VDR, thereby increasing the potential complexity of gene regulation. Interestingly, each of these forms also interacts with other nuclear receptors, including the thyroid hormone receptor and the retinoic acid receptor. Thus, all receptors that utilize RXR as a common partner in a single cell likely compete for this protein during transcriptional activation.

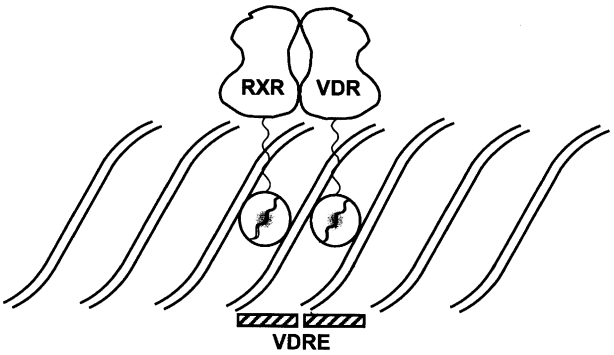

FIGURE 3 Heterodimeric binding of the VDR to a VDRE in a hormone-sensitive gene promoter. RXR, retinoid X receptor; VDR, vitamin D receptor.

V. ROLE OF $1,25(OH)_2D_3$ IN VDR ACTIVATION

$1,25(OH)_2D_3$ induces conformational changes in the VDR that lead to significant rearrangements within the receptor, particularly those that form important protein-interacting surfaces. Although these changes have not been visualized directly within the VDR using X-ray crystallography, as has been accomplished for certain steroid receptors, three-dimensional modeling studies based upon similarity in receptor structure strongly support such hormone-induced rearrangements. A variety of biochemical and cellular assays also support in an indirect fashion these conformational changes. For example, ligand binding significantly enhances VDR stability and induces strong resistance to proteolytic degradation *in vitro*. It is now known that the molecular changes that are induced by $1,25(OH)_2D_3$ within the VDR have a functional consequence, namely, to promote the dimerization of VDR with its RXR partner. Indeed, initial studies suggested that the affinity of the VDR for RXR increased almost 10-fold for its protein partner when $1,25(OH)_2D_3$ was present. Since these interactions occurred in the absence of VDRE DNA, it suggests that the initial event in vitamin D-dependent gene activation is the formation of a functional receptor module composed of ligand-occupied VDR and RXR. Formation of this complex is followed by VDRE binding. It is now clear that the conformational changes induced by $1,25(OH)_2D_3$ also lead to the formation of a new surface or surfaces capable of binding directly to members of at least several different classes of co-modulatory proteins. These proteins are essential to the complex transcriptional regulatory process. Thus, a host of latent activities within receptors such as VDR are uncovered when hormonal ligand is present converting the VDR into a transcriptionally active protein.

VI. VDR RECRUITMENT OF TRANSCRIPTIONAL CO-REGULATORS

Early working models of steroid receptor action placed the receptor in contact with the general transcriptional apparatus, thus directly modulating transcription. Transcriptional regulation is considerably more complicated than originally envisioned, however. Complex sets of molecular machinery capable of modifying chromatin structure and recruiting RNA polymerase II are involved in facilitating transcription and different sets promote transrepression. Thus, $1,25(OH)_2D_3$ functions to target this machinery to the promoters of vitamin D-sensitive genes. These targeting events are mediated by the VDR, first through its interaction with selective sequences of DNA and then through its ability to sequentially recruit additional regulatory complexes.

A. p160 Co-activators and Acetylation

Activation of gene expression requires numerous alterations in chromatin architecture. Thus, protein machines that are initially recruited by steroid receptors to hormonally responsive promoters contain histone acetyltransferases (HATs) capable of modifying lysine residues on histones and increasing transcription factor accessibility to DNA (Fig. 4). HATs exhibit different specificities for lysine residues on histones, providing a likely explanation why multiple proteins within the complex contain residual acetylating capabilities. Direct linkage between the receptor and these large protein complexes is provided in part by several proteins termed p160 co-activators, which contain HAT activity as well. SRC-1 represents the prototypic member. The primary interaction surface or docking site on the VDR that mediates receptor/SRC-1 interaction is designated activation function-2 (AF-2). The formation of this binding site is highly dependent upon the presence of hormone, which alters the placement of several of the approximately 12 α-helices in the receptor LBD and completely rearranges the position of α-helix 12. The p160 co-activators (as well as other proteins that bind to AF-2) interact with the receptor in turn through a specific leucine-charged helix termed the nuclear receptor box that contains central core residues of the pattern LXXLL. The VDR together with the RXR also interacts in a ligand-dependent manner with SRC-1 and other members of

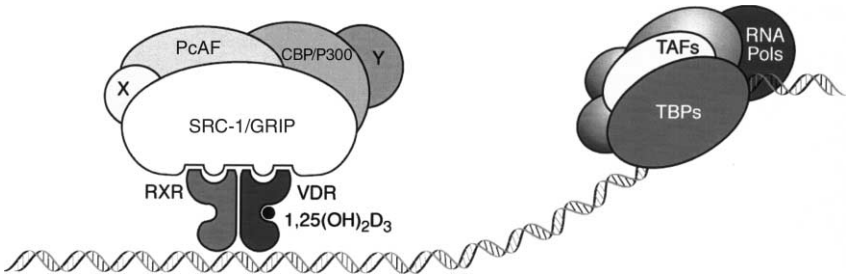

FIGURE 4 Arrangement of the SRC-1/GRIP complex following recruitment to a $1,25(OH)_2D_3$-sensitive gene promoter. SRC-1 or GRIP binding to hormone-activated VDR and its silent partner RXR leads to the subsequent recruitment of additional transcription factors including CBP/p300 (CREB-binding protein/p300, where CREB denotes Ca^{2+}/cyclic AMP-response element-binding protein), P/CAF (p300/CBP-associated factor), and perhaps other unknown proteins (X and Y). This complex mediates transactivation though modification of chromatin-associated histone residues and through direct contacts with specific TAFs (transcription activating factor). RNA pols, RNA polymerase II; TBP, TATA box-binding protein.

the p160 co-activators, thus initiating the recruitment of machinery essential for the initial phase of the transcriptional activation process. Since the co-activator family of genes exhibits little specificity for individual receptors, it is likely that selectivity for the different co-activators that are found within a cell may be promoter context dependent. Despite this, it is clear that the recruitment of these HAT-containing complexes and additional proteins capable of chromatin modification are essential to the process of transactivation.

B. Co-repressor Complexes and Deacetylation

Steroid receptors also function to suppress transcriptional activity. Not surprisingly, repression requires the recruitment of complexes that remove acetyl residues from histones, thereby producing a transcriptionally resistant form of chromatin. These proteins are histone deacetylases (HDACs). Nuclear receptors recruit such HDACs to specific chromatin templates indirectly via proteins such as nuclear receptor co-repressor (N-CoR) and silencing mediator for retinoic acid and thyroid hormone (SMRT). Although the interaction site within the nuclear receptor for these repressors is also located at AF-2, the leucine-charged LXXLL motif within the nuclear co-repression is somewhat altered to a slightly different configuration. Both N-CoR and SMRT also interact with the VDR following activation by $1,25(OH)_2D_3$, presumably to decrease the ability of the receptor to activate transcription. Interestingly, several receptors including the thyroid hormone and retinoic acid receptors suppress gene expression in the absence of hormone. In these cases, N-CoR and SMRT are recruited to the promoter via receptors that are not bound to their respective hormonal ligands.

C. The DRIP Complex

The DRIP complex, a fundamentally different molecular machine, also interacts with the VDR. The DRIP complex is composed of 10 or more proteins, none of which appear to contain either HAT or HDAC activity. The DRIP complex interacts not only with other members of the nuclear receptor family such as estrogen receptor, but with certain basal transcription factors as well. Recruitment of DRIP is achieved by the VDR through $DRIP_{205}$, a protein that contains several LXXLL motifs that interact with $1,25(OH)_2D_3$-activated VDR at AF-2. Although the function of the DRIP complex is not precisely understood at present, it may be involved in mediating the recruitment of RNA polymerase II to the DNA template.

The discovery that transcriptional regulation by nuclear receptors is mediated by downstream co-regulatory factors highlights the complexity of gene regulation. The diversity of these co-regulators is enormous. In addition to those mentioned, additional factors that provide synergistic regulation, that link nuclear receptors to unrelated transcription factors, and that enable mechanisms whereby receptors are degraded have been identified. Imposing these additional sets of factors into the steroid receptor functional pathway provides important ways in which a cell can modulate receptor action and integrate its actions with other incoming signals important for survival and function.

VII. HEREDITARY RESISTANCE TO $1,25(OH)_2D_3$

The central importance of the VDR to $1,25(OH)_2D_3$ action is emphasized through studies of the human syndrome of hereditary $1,25(OH)_2D_3$-resistant rickets. Early studies suggested that this genetic disease was due to defects in vitamin D signal transduction and experiments in cells from patients with the disease eventually implicated the VDR in this resistance pathway. However, it was cloning and structural and sequence analyses of the chromosomal gene for the VDR that enabled direct analysis of the VDR gene from patients with hereditary resistance. These efforts led to the discovery of a series of different mutations within the VDR that compromised its ability to function. Accordingly, mutations were found in the DBD as well as in the LBD. The former led to an inability of the receptor to bind to DNA, whereas the latter resulted in a receptor unable to bind $1,25(OH)_2D_3$ or to interact with its RXR dimerization partner. Additional mutations continue to be found. Each of these alterations in VDR structure results in the loss of transcriptional activity and leads to significant defects in the skeleton as a result of altered calcium and phosphorus homeostasis. Genetic ablation of the VDR gene in mice has revealed many of the skeletal features found in the human and now provides an excellent animal model with which to study $1,25(OH)_2D_3$ and VDR function.

VIII. SUMMARY

$1,25(OH)_2D_3$ is a steroid-like hormone that functions to regulate mineral homeostasis and other biological events in higher organisms. This regulation is achieved in target tissues through selective control of gene expression, a process that is mediated by the VDR. The VDR is an intracellular receptor protein that belongs to the steroid receptor family of transcription factors and whose functional activities are activated by $1,25(OH)_2D_3$. Functional activities include selective VDR/RXR binding to DNA sequences or VDREs followed by VDR-mediated recruitment of additional protein complexes essential to the transcriptional regulatory process. Significant details associated with this highly intricate regulatory step are now beginning to emerge. The importance of the VDR in the biological actions of vitamin D is seen in humans with genetic abnormalities in the VDR as well as in animals in which the VDR has been genetically ablated. It is likely that a fuller understanding of the mechanism of action of the vitamin D hormone and its receptor will be forthcoming during the next few years.

Glossary

activation function A domain located within the ligand-binding region of steroid receptors that interacts with co-regulators, thus modulating transcription.

co-regulators Transcription factors that are recruited to active gene promoters via DNA-binding proteins such as the vitamin D receptor.

hereditary A human syndrome of generalized resistance to 1,25-dihydroxyvitamin D_3 due to inherited mutations in the vitamin D receptor.

histone modification Acetylation or deacetylation of lysine residues within DNA-bound histones that alter chromatin structure and transcription factor accessibility.

retinoid X receptor A member of the steroid receptor gene family that functions as a heterodimeric DNA-binding partner for the vitamin D receptor.

steroid or nuclear receptor gene family A large family of eukaryotic genes whose protein products both function as receptors for steroid and thyroid hormones, retinoic acid, and 1,25-dihydroxyvitamin D_3 and modulate transcription.

target genes Genes that can be regulated by a specific hormone because their promoters contain regulatory elements that can interact with the hormone's receptor.

vitamin D receptor A specific protein that binds 1,25-dihydroxyvitamin D_3 and mediates the actions of this hormone in target tissues.

vitamin D-response element A specific DNA-binding site for the vitamin D receptor that is located within the promoter region of a gene that is regulated by 1,25-dihydroxyvitamin D_3.

Vitamin D Receptors and Actions in Nonclassical Target Tissues

MARIAN R. WALTERS
Tulane Medical School, New Orleans

Intestine, kidney, and bone tissues have long been known to have receptors for vitamin D. Vitamin D receptors are now known to exist in many other tissues, including those of skeletal and vascular smooth muscles, central nervous system components, the heart, endocrine and reproductive organs, the lungs, and the liver. 1,25-Dihdroxyvitamin D_3 interacts specifically with receptors in these tissues; the effects of these interactions are mediated by many intracellular signaling pathways. Genetic characterizations of the receptors and activation pathways hold promise in further understanding the roles of vitamin D in health and disease.

I. INTRODUCTION

Traditional studies of vitamin D receptors (VDRs) and their actions have focused on plasma calcium-regulating vitamin D targets such as intestine, kidney, and bone. However, in 1979, putative VDR sites were first described in "nonclassical" tissues—for example, in tissues as diverse as the pancreas, pituitary gland, and uterus. Thus began a new era in which the concept of the actions of the hormonal form of vitamin D, 1,25-dihydroxyvitamin D_3 [1,25(OH)$_2$D$_3$], changed from its being considered solely a hormone that regulates plasma calcium homeostasis to understanding that it plays roles in numerous cellular processes, including proliferation/differentiation, hormonal secretion, and neuroprotection.

II. RANGE OF 1,25(OH)$_2$D$_3$ TARGETS AND ACTIONS

As detailed in Table 1, vitamin D receptors have now been described in numerous targets, including many cells of the immune system, cardiovascular tissues, skeletal muscle, reproductive and other endocrine sites, central nervous system, and a host of other tissues. Evidence for the presence of VDR sites in these tissues has come from a variety of experimental approaches (Table 2). Moreover, through the years, increasingly sophisticated approaches have been used to probe for the presence of VDRs in putative new target tissues. For example, a recent immunoblotting study has demonstrated the presence of VDRs in tissue extracts from the hippocampus, with more specific localization demonstrated by immunocytochemistry in the neuronal and glial cells in pyramidal and granule cell layers, including CA1, CA2, CA3, and the dentate gyrus. More functional studies have indicated that hippocampal extracts contain a VDR-like species capable of binding to the specific osteopontin VDR

TABLE 1 Wnt Signaling Molecules[a] in Human Cancer

Wnts	sFRPs	CK2	Axin	APC	β-Catenin
Breast cancer (WNT1, WNT5a)	Breast cancer	Breast cancer	Liver cancer	Colorectal cancer (spontaneous)	Colorectal cancer; liver cancer; ovarian cancer
Leukemia (WNT16)				Familial ademomatous polyposis (genetic precancerous condition)	pancreatic cancer; prostatic cancer; skin cancer (melanoma); stomach cancer; uterine cancer

[a]See text (Sections V and VI) for full molecule names and roles in Wnt signal transduction.

been linked to many other diseases besides cancer. A rare childhood disorder of bone formation, osteoporosis–pseudoglioma syndrome, is caused by a genetic disruption in canonical Wnt signaling. Disruptions in Wnt signaling have been proposed to underlie an assortment of other diseases as well. This is an area of understandably intense scientific and biomedical interest (Table 2).

C. Vertebrate Development

The first clue to a role for Wnt/β-catenin signaling in vertebrate development came from overexpression studies in the classical embryonic system, the frog *Xenopus laevis*. When Wnt1 is ectopically expressed in cells that would normally contribute to the ventral embryo (i.e., the future belly), they instead adopt a dorsal and anterior fate (i.e., they become the future head). This induction of a "secondary dorsal axis" produces a striking phenotype: two-headed tadpoles. The ability of ectopic Wnt1 to induce a secondary dorsal axis derives from the participation of the canonical Wnt/β-catenin signaling pathway in the natural process of dorsal cell fate specification early in vertebrate embryogenesis. However, it remains unclear whether an endogenous intercellular Wnt signal, or only the downstream intracellular signaling cascade, is normally responsible for dorsal fate determination. Further developmental analyses in vertebrates have included both overexpression and loss-of-function studies in *Xenopus*, zebrafish, and mice and have established the importance of Wnt signaling in an array of processes in early development (Table 3).

D. Invertebrate Development

In *Drosophila*, the contribution of wg signaling to developmental tissue patterning has been intensely investigated in several processes, especially the segmentation of the embryonic cuticle and the compartmentalization of the wing epithelial primordium

TABLE 2 Wnt Signaling Molecules[a] Implicated in Human Disease

Wnt signaling (general)	Wnt4	sFRP	Fz	LRP5	Dvl	GSK3	β-Catenin
Polycystic kidney disease (Polycystin-1 activates canonical Wnt signaling pathway)	Injury-induced renal fibrosis; wound healing	Heart failure	Ulcerative colitis	Osteoporosis-pseudoglioma syndrome (genetic syndrome of defective bone formation)	Ulcerative colitis; schizophrenia (mouse knockout model)	Familial Alzheimer's disease (through interaction with presenilin-1); schizophrenia (reduced levels in prefrontal cortex); bipolar disorder (enzymatic activity reduced by therapeutic agents)	Familial Alzheimer's disease (through interaction with presenilin-1)

[a]See text (Sections V and VI) for full molecule names and roles in Wnt signal transduction.

TABLE 3 Some Wnt Signaling Developmental Activities across Species

	Caenorhabditis elegans (nematode)	*Drosophila melanogaster* (fruit fly)	*Xenopus laevis* (frog)	*Danio rerio* (zebrafish)	*Mus musculus* (mouse)
Canonical	Embryonic polarity; mesoderms vs endodermal specification through asymmetric cell divisions (note: this pathway may be noncanonical)	Embryonic segmentation & wing disc compartmentalization	Embryonic axis specification & specification of axial vs somitic mesoderm	Patterning of neural ectoderm, mesoderm at gastrulation; specification of neural crest derivatives; specification & patterning of rostral midbrain/hindbrain; specification & patterning of head cartilage & tail	Embryonic axis specification, specification of caudal structures, specification of neural crest derivatives, specification & patterning of rostral midbrain/hindbrain, specification & proliferation; specification & patterning of urogenital system, differentiation of hair shaft precursors, placental development, osteogenesis, angiogenesis, adipogenesis
Noncanonical	Cell migration?	Wing hair orientation; compound eye facet orientation	Cell movements (convergent extension) during gastrulation	Cell movements (convergent extension) during gastrulation	Limb outgrowth?

(wing disc). In the embryonic cuticle, a band of cells positioned at the posterior border of a future parasegmental boundary first expresses wg. Secreted wg activates expression of the engrailed (en) transcription factor in adjacent cells on the other (anterior) side of the parasegmental boundary. The en transcription factor activates the expression of a second secreted signaling molecule, hedgehog (hh), in the anterior cells. Hedgehog secreted by the anterior cells signals back across the future parasegmental boundary to the original wg-secreting cells, stabilizing their wg expression. The result is an intercellular positive-feedback loop that establishes each parasegmental boundary with cells expressing wg on the anterior border and cells expressing en/hh on the posterior border. In the wing disc, wg secreted by cells at the future dorsal–ventral boundary similarly helps pattern the surrounding tissue by inducing the expression of different genes in neighboring cells on both sides.

E. NONCANONICAL SIGNALING

Genetic studies in *Drosophila* unexpectedly uncovered a completely different class of tissue patterning events that shares some (but not all) of the same genes implicated in the patterning of the embryonic segments and the wing disc. This "planar cell polarity" (PCP) pathway establishes the transverse orientation of cells making up an epithelial sheet. Examples of planar cell polarity in *Drosophila* include the orientation of facets making up the compound eye or the direction in which bristles point on the animal's back. During development, a subclass of wg receptors activate a distinct group of intracellular signaling molecules to regulate planar cell polarity. Because PCP signaling uses wg receptors but a different downstream signal transduction cascade than canonical wg signaling, it represents a separate "noncanonical" wg signaling pathway in *Drosophila* (see Section VI). A noncanonical signaling pathway has also been identified in vertebrates, where it is involved in coordinating major cell movements such as those of gastrulation. However, the correspondence between PCP signaling in *Drosophila* and noncanonical signaling in vertebrates remains ambiguous (see Section VI). Some of the more important and well-studied developmental events regulated by Wnt signaling in vertebrates and invertebrates are summarized in Table 3.

II. THE Wnt PROTEIN FAMILY: STRUCTURE AND BIOCHEMISTRY

There are a total of 7 related *Wnt* genes in the *Drosophila* genome and 19 in the human genome (some with multiple isoforms) that generally have close orthologues in mice (Fig. 1). Orthologous Wnt gene products (proteins with the same function in different species) are often very highly conserved. For example, the mouse and human Wnt1 proteins are 99% identical, differing at only 4 amino acid residues within a cleavable secretory signal sequence at the amino-terminus. More distantly related Wnt family members can share less than 30% identity. The length of vertebrate Wnt protein precursors varies from approximately 100 amino acids to over 400 amino acids. All Wnt proteins contain a cleavable amino-terminal signal peptide that targets them for secretion, a conserved cysteine-rich composition, and multiple N-linked glycosylation sites. Wnt proteins synthesized *in vivo* are glycosylated. Once outside the cell, mature Wnt glycoproteins associate with extracellular matrix and bind to heparin sulfate proteoglycans (HSPGs). Genetic studies in *Drosophila* have demonstrated the importance of HSPGs in stabilizing extracellular wg protein and in regulating its distribution. The importance of proteoglycans for intact Wnt signaling *in vivo* has been confirmed independently in vertebrates. In *Drosophila*, non-wg-producing cells endocytose wg that has been secreted by neighboring cells. Genetic studies have demonstrated that this endocytic activity is important both for facilitating wg signaling and for regulating its distribution.

In *Drosophila* and in vertebrates, it is clear that Wnt proteins often act over a relatively short range: on cells located within a few cell diameters of the secretory source. More controversial is whether Wnt proteins may also act over longer distances. The morphogen hypothesis, which predicts that some signaling molecules specify distinct cellular identities along a concentration gradient, remains contested in the field of developmental biology. Nonetheless, some of the strongest experimental evidence in favor of a morphogen concerns the action of wg in the *Drosophila* wing disc.

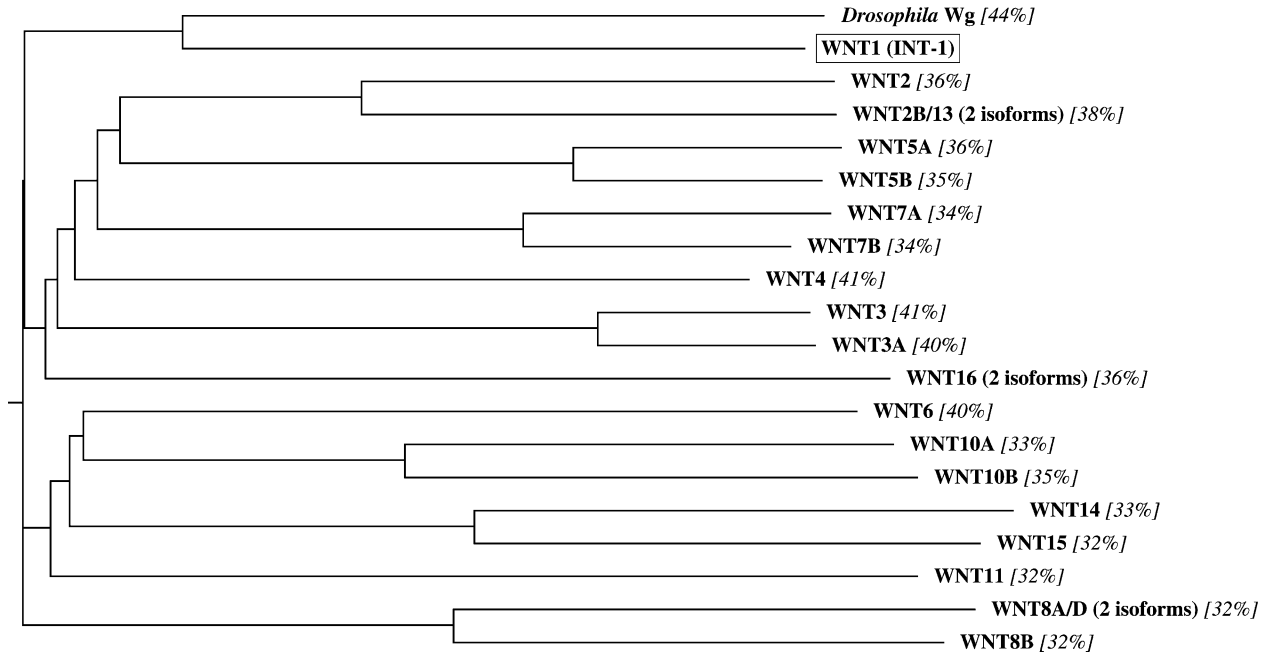

FIGURE 1 A sequence relatedness tree among the 19 human WNT gene products. *Drosophila* wg is included for comparison. The percentage of amino acid residues in each protein that are identical to WNT1 (boxed) is indicated. WNT1/INT-1 was chosen as the index sequence for comparison purposes purely for historical reasons (it is not evolutionarily ancestral to the other WNTs). This tree is based on overall identity among predicted Wnt gene products and is *not* meant to convey absolute evolutionary relationships. Horizontal distance from a node correlates with the degree of sequence divergence; vertical distance is arbitrary. Sequences were obtained from the protein database of the National Center for Biotechnology Information and compared using the default matrix settings of MacVector 6.5.3 (Oxford Molecular Group).

In addition to intercellular signaling, autocrine signaling by Wnt proteins (self-activation by a Wnt-secreting cell) may be important, both as a feedback mechanism during normal biological processes and in disease pathogenesis. Tumors induced by MMTV are clonal—suggesting that once the virus activates the *Wnt1* gene in a single mouse mammary gland cell, Wnt secretion stimulates uncontrolled proliferation by that cell and possibly other oncogenic changes as well. Similarly, some tissue culture cell lines transfected either with a *Wnt* gene or with DNA from MMTV-induced tumors become transformed and clonally tumorigenic. In *Drosophila*, there is evidence that autocrine signaling through wg occurs and activates a downstream signaling cascade that is genetically partly distinct from paracrine wg signaling.

It has been proposed that the vertebrate *Wnt* genes can be subdivided into functional classes based on whether they activate the canonical or noncanonical signaling pathways. However, recent studies have shown that in *Xenopus*, the developmental response to a Wnt of one proposed class can be switched to that of the other class by co-expressing a specific Wnt receptor. In the developing *Drosophila* eye and wing, the response to wg is influenced by the relative abundance and ligand affinity of the wg receptor proteins expressed in the target tissue. Synthesis of the available data from vertebrates and *Drosophila* suggests that the response to a specific Wnt signal *in vivo* is likely to be influenced both by the particular Wnt protein secreted and by the different receptor types (and downstream intracellular signaling molecules) present in the target tissue.

III. RECEPTOR STRUCTURE AND BIOCHEMISTRY

There are two types of cell-surface molecules that are known to be necessary for Wnt/β-catenin signal transduction in responsive cells: the Frizzled (Fz) receptor family and a subclass of the low-density-lipoprotein-related protein (LRP) receptor family.

A. Fz

Fz proteins constitute a family of seven-transmembrane domain receptors with a cysteine-rich extracellular domain. As a class, Fzs are structurally related to the superfamily of trimeric G-protein-coupled receptors (GPCRs). There are 4 *Fz* genes in *Drosophila* and 10 in humans, with close orthologues in mice. As a class, Fz proteins participate in both canonical and noncanonical signaling, but individual Fz receptors may differ in their basal (minus ligand) ability to activate signaling of each type, suggesting that structural differences among the Fz proteins contribute to functional specificity. There is contradictory evidence regarding the importance of the Fz extracellular domain for this specificity, but it is clear that the carboxyl-terminal tail and intracellular loops contribute. In other fields, there is mounting evidence that many seven-transmembrane domain proteins exist and act as multimers on the cell surface. In the case of the Fz receptors, there is no direct functional evidence for this, but crystallization studies have revealed a conserved dimerization interface in the extracellular cysteine-rich domain.

B. LRP

LRP5 and *LRP6* are closely related genes in humans and mice that are structurally distinct from other *LRP* family members. A single *Drosophila* orthologue exists and is called *arrow*. The proteins are single-transmembrane domain receptors with an extracellular domain composed of four amino-terminal epidermal growth factor-like repeats and three low-density-lipoprotein (LDL) receptor type A repeats. They have a relatively short proline-rich intracellular domain. Genetic evidence in *Drosophila* and loss-of-function and overexpression evidence in vertebrates support the conclusion that arrow and LRP5/6 are essential Wnt co-receptors with the Fz proteins. Based on initial genetic and mutational analyses in humans and mice, LRP5 is likely to be partly functionally redundant with LRP6. Unlike the Fz proteins, evidence from both vertebrates and *Drosophila* supports a role for these proteins only in the canonical Wnt signaling pathway, not in noncanonical signaling.

In *Drosophila*, arrow is essential for all aspects of canonical wg signaling, as demonstrated by the observation that the phenotype of an *arrow* null mutation closely resembles that of a *wg* null mutation. Similarly, an *LRP6* mutation in mice causes defects that are a combination of those seen with mutations in canonical mouse *Wnt* genes, whereas overexpression of LRP6 in vertebrates causes ectopic canonical pathway activation. The extracellular domain of LRP6 binds Wnt and interacts with the extracellular domain of Fz in a Wnt-dependent manner, whereas LRP5 activates canonical Wnt signaling when ectopically expressed in mammalian fibroblasts and interacts with canonical pathway cytoplasmic signaling components (see Section V).

IV. CYTOPLASMIC SIGNAL TRANSDUCTION PROTEINS

It remains unclear how signals from the Wnt receptors at the cell surface are coupled to distinct downstream cytoplasmic signal transduction cascades. However, at least two types of proteins have been proposed to functionally link the receptors to downstream effectors in both canonical and PCP signaling: heterotrimeric G-proteins and the Dishevelled (Dvl) family of cytoplasmic proteins.

A. G-Proteins

The topological resemblance of the Fz proteins to other seven-transmembrane receptors that couple to heterotrimeric G-proteins begs the question of whether Fz proteins signal through G-proteins as well. Positive evidence that G-proteins might be involved in Fz-mediated signal transduction has only recently begun to accumulate and at this time is restricted to overexpression studies in vertebrate systems and some antisense (loss-of-function) evidence in tissue culture cells. For example, stimulation of mammalian tissue culture cells by expressing one of the Wnt/Fz combinations implicated in canonical signaling can be blocked by pertussis toxin and other G-protein inhibitors. In *Xenopus* embryos, ectopic expression of a regulator of G-protein signaling (RGS) protein antagonizes canonical signaling and causes defects resembling those caused by ectopic expression of other Wnt pathway inhibitors.

Similarly, overexpression of Wnt5a in mammalian tissue culture cells, zebrafish, and *Xenopus* embryos activates a noncanonical signaling pathway that is selectively blocked by several G-protein inhibitors, including pertussis toxin. Work with chimeric Fz receptors containing the extracellular and transmembrane domains of the β_2-adrenergic receptor suggests that G-proteins may couple to the intracellular domain of Fz proteins. These experiments implicate $G_{\alpha o}$ and $G_{\alpha q}$ for Fz receptors activating canonical signaling and $G_{\alpha o}$ and $G_{\alpha t2}$ for Fz receptors activating noncanonical signaling. It should be noted here that the noncanonical pathway measured in these experiments is the Wnt/calcium pathway, which may or may not be distinct from PCP signaling in *Drosophila* (see Section VI). To date, neither a Wnt/calcium pathway nor a genetic requirement for heterotrimeric G-proteins has been described for wg signaling in *Drosophila*. Accordingly, it remains unclear whether G-proteins couple to Fz receptors to transduce all Wnt signals.

B. Dvl

A well-established component of both canonical and PCP signaling is the cytoplasmic molecule Dvl. There are three Dvl paralogues each in mice and humans and a single gene (*dsh*) in *Drosophila*. All Dvl family members share three well-conserved domains (DIX, PDZ, and DEP, in order from amino-terminus to carboxyl-terminus). The domains have been shown through mutational analyses in both vertebrates and in *Drosophila* to mediate different aspects of Wnt signaling: the DIX and PDZ domains are most critical for canonical Wnt signaling, whereas the PDZ and DEP domains are most important for PCP signaling. These domains have no known intrinsic enzymatic activity, but instead act as protein–protein interaction interfaces. Consequently, Dvl is considered to be a regulative adapter or scaffold protein that brings together cytoplasmic signaling components in response to events at the cell membrane. In most cell types, Dvl proteins display a predominantly cytoplasmic, punctate distribution, though a more diffuse nuclear component has also been described. In *Xenopus* embryos, overexpression of Fz protein can cause a redistribution of Dvl to the inner cell membrane. Whether translocation of Dvl to the membrane is an important component of physiological Wnt signaling is somewhat unclear, and there are no reliable data that Dvl actually interacts with Fz. There is evidence from both *Drosophila* and vertebrates that activation of Wnt signaling is accompanied by phosphorylation of Dvl. Exactly how signals are transduced from the transmembrane Wnt receptors to Dvl, whether through heterotrimeric G-proteins or some other mechanism, remains an area of intense experimental investigation.

V. THE CANONICAL Wnt/β-CATENIN PATHWAY

The canonical Wnt/β-catenin pathway is typified in vertebrates by responses to a subclass of the vertebrate Wnt proteins and Fz receptors and to LRP5 or LRP6; in *Drosophila* it is typified by wg, DFz2, and arrow. The central feature of this pathway is a multiprotein complex (degradation complex) that controls cytoplasmic concentration levels of the multifunctional protein β-catenin. β-Catenin plays a structural role at the inner cell membrane of adherens junctions, but also acts as a transcriptional coactivator in the nucleus. The concentration of soluble β-catenin in the cytoplasm, and therefore in the nucleus, is primarily determined by its rate of

degradation through ubiquitination-dependent targeting to the proteosomal pathway. Glycogen synthase kinase-3 (GSK3 in vertebrates, zeste-white/shaggy in *Drosophila*) regulates this process by phosphorylating β-catenin, targeting it for degradation. In addition to GSK3 itself, other components of the degradation complex include Dvl, Axin, and APC. Whereas Dvl is a Wnt pathway activator, GSK3, Axin, and APC are all inhibitors. Axin and APC help to stabilize the activity of GSK3, thereby keeping β-catenin levels low and Wnt target gene transcription turned off in the absence of a Wnt signal (Fig. 2A).

During Wnt signaling, several molecular events that change the composition of the degradation complex occur. It remains unclear whether any of these events are directly mediated by the transmembrane receptor or associated proteins. As mentioned in Section V, in response to canonical Wnt signaling, Dvl becomes phosphorylated. Several different kinases, including casein kinase I (CK1), casein kinase 2 (CK2), and the Par1 kinase from *Drosophila*, have been implicated in this process and in Wnt-pathway activation, but which of these is most important *in vivo* remains unclear. Another protein called GSK3-binding protein (GBP or FRAT) binds both GSK3 and Dvl in response to canonical signaling, possibly preventing the continued association of GSK3 with other members of the degradation complex. There is also evidence that binding of a Wnt protein to LRP5 causes the translocation of Axin from the degradation complex to the inner cell membrane, followed by Axin degradation. Regardless of which of these molecular events is the key to cytoplasmic transduction of the Wnt signal, the net effect is to destabilize and/or inhibit the degradation

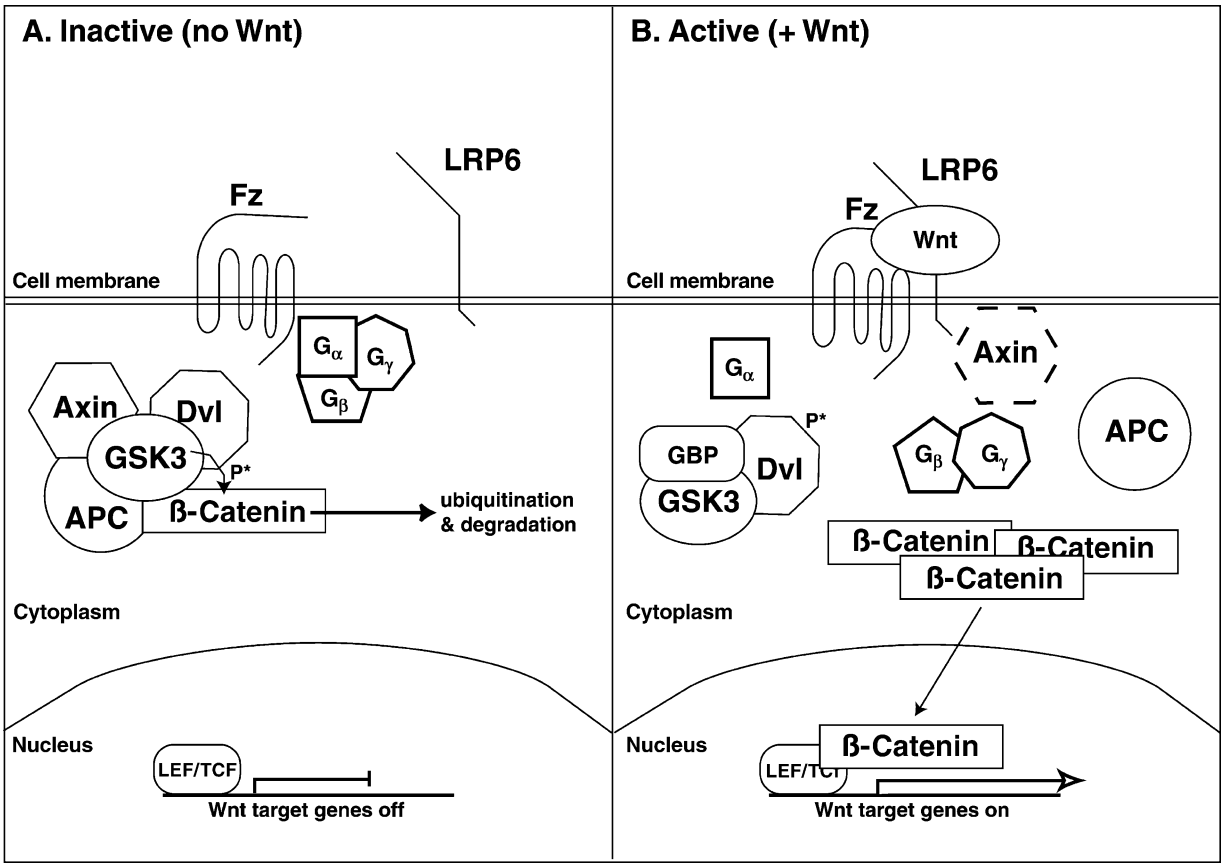

FIGURE 2 The canonical Wnt signaling pathway. (A) Inactive (no Wnt). (B) Active (+ Wnt). Activation of a Fz/LRP6 receptor by a Wnt causes the phosphorylation of Dvl, translocation of Axin to the membrane, and association of GSK3 with GBP. The net effect of these changes is to down-regulate the phosphorylation-dependent degradation of β-catenin in the cytoplasm. β-Catenin accumulates and translocates into the nucleus where it acts as a transcriptional co-activator with members of the LEF/TCF gene family. There is evidence that heterotrimeric G-proteins may couple to the Fz receptor upstream of Dvl in this pathway, but this remains controversial (see text).

complex and thereby to prevent phosphorylation of β-catenin by GSK3. As a result, soluble β-catenin—no longer phosphorylated, ubiquitinated, and degraded—accumulates and translocates to the nucleus. In the nucleus, β-catenin acts with members of the LEF/TCF family of transcription factors to regulate the expression of Wnt target genes (Fig. 2B).

In addition to the well-established canonical pathway members mentioned above and depicted in Figs. 2A and 2B, several other cytoplasmic inhibitors of canonical Wnt/β-catenin signaling that generally share the ability to bind Dvl have been identified in recent years. These include the *Drosophila* gene *naked cuticle* (*nkd*) and the vertebrate proteins Idax and Dapper (Dpr). Both nkd and Dpr have been demonstrated to play crucial roles in the development of *Drosophila* and *Xenopus*, respectively. There are also several secreted extracellular inhibitors of canonical Wnt/β-catenin signaling that are biologically important for development and disease. These include cerberus (cer) and secreted Frizzled-related proteins (sFRPs), which bind Wnt and therefore act as general Wnt inhibitors; Dickkopf (dkk), which binds to LRP6 and is therefore specific for canonical signaling; and Wnt inhibitory factor-1 (WIF-1), which resembles the LRP extracellular domain but whose exact mechanism of action is unknown.

VI. NONCANONICAL PATHWAYS: PLANAR CELL POLARITY AND Wnt/CALCIUM SIGNALING

Noncanonical Wnt signaling in *Drosophila* is defined by the planar cell polarity pathway mediated by the Fz receptor (which has redundant activity with DFz2 in the canonical pathway). Despite the fact that wg has been shown to bind to Fz and is often assumed to be the PCP effector, there is as yet no absolutely conclusive *in vivo* evidence that the endogenous ligand for Fz during PCP signaling is wg. The PCP pathway downstream of Fz has been defined on the basis of a combination of genetic and molecular data. As with the canonical Wnt pathway, the *Drosophila* Dvl homologue, dsh, is one of the most upstream cytoplasmic components of PCP signaling, although the requirement for the domains of dsh differ in the two pathways (see Section IV). As with canonical Wnt signaling, several dsh-interacting proteins that participate in PCP signaling have been identified, including the putative calcium-sensitive protein nkd and the Formin homology protein Daam1, which also binds the small GTPase RhoA. PCP signaling through dsh activates RhoA, which in turn activates a cascade of signaling proteins through the Jun-N-terminal kinase (JNK). The JNK cascade can alter gene expression through activation of the AP-1 transcription factor in the nucleus; the significance of this for PCP signaling is unknown. RhoA also activates the *Drosophila* Rho-associated kinase (Drok), which causes cytoskeletal changes by phosphorylating the nonmuscle myosin regulatory light chain and possibly other proteins (Fig. 3A).

Aside from the *Drosophila* PCP pathway molecules that fit into the signaling pathway described above, several other genetically identified components play roles that are not yet understood at a biochemical level. Although arrow/LRP6 is not required for PCP signaling through Fz, at least three other transmembrane proteins that could act as coreceptors or independently of Fz proteins have been implicated in PCP signaling: flamingo (fmi), a seven-transmembrane domain protein; strabismus (stbm or vang), a three-transmembrane domain protein; and fuzzy (fy), a four-transmembrane domain protein. Also implicated is the membrane-associated daschous (ds) protein, a member of the cadherin superfamily. Cytoplasmic proteins that play a role include the gene products of *prickle* (*pk*), *inturned* (*in*), and *multiple wing-hair* (*mwh*). How these proteins connect to other components of the *Drosophila* PCP pathway is not yet understood, but the noncanonical signaling function of at least some of them is conserved in vertebrate cells. For example, vertebrate Stbm and the DEP domain of Dvl have been demonstrated to participate in JNK cascade activation in mammalian cells.

In vertebrates, noncanonical Wnt/calcium signaling antagonizes canonical Wnt/β-catenin signaling and is typified by embryonic responses to Wnt5a and Wnt11. Based on studies primarily in zebrafish and *Xenopus*, these responses include an IP_3-mediated rapid increase of intracellular calcium, followed by activation of protein kinase C (PKC) and calcium/calmodulin-regulated kinase II (CamKII) (Fig. 3B). As mentioned in Section IV, there is considerable evidence that initial signaling downstream of Fz in the Wnt/calcium signaling pathway occurs through heterotrimeric G-proteins. Studies in mammalian cultured cells and in *Xenopus* embryos have demonstrated that Wnt5a activates the JNK cascade, providing a possible link between the vertebrate Wnt/calcium signaling pathway and the *Drosophila* PCP pathway. Furthermore, activators of the Wnt/calcium pathway (e.g., Wnt5a) and activators of PCP

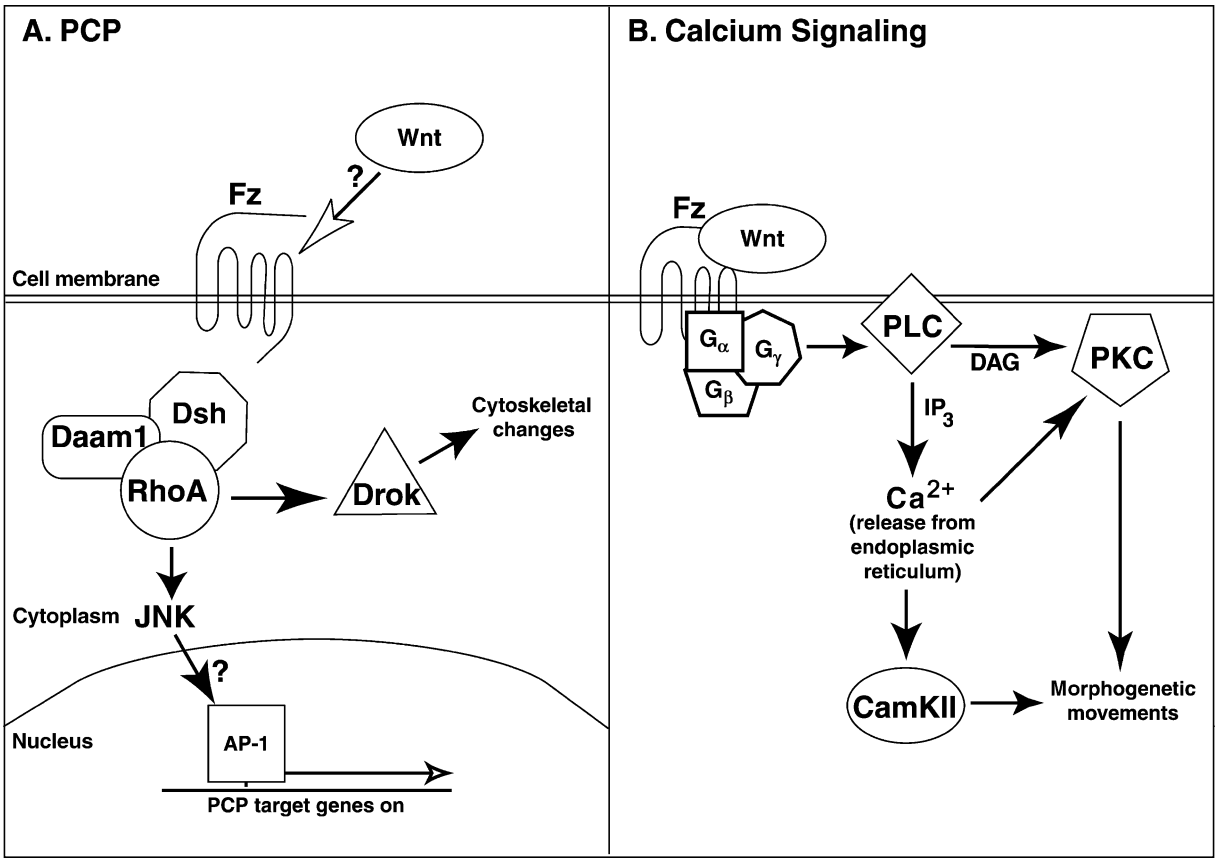

FIGURE 3 The noncanonical Wnt signaling pathways. (A) PCP signaling in *Drosophila*. Signaling through a Fz receptor activates dsh (the *Drosophila* Dvl homologue) through an unknown mechanism. dsh, with the dsh/RhoA-binding protein Daam1, activates RhoA. RhoA has multiple signaling outputs, which include the JNK cascade, which can regulate gene expression, and Drok, which is a component of cytoskeletal regulation. Multiple molecules not shown here, including several membrane-associated proteins, have been implicated genetically (see text). (B) Wnt/calcium signaling pathway in vertebrates. Signaling through some Wnt proteins such as Wnt5a activate heterotrimeric G-proteins and cause a transient increase in intracellular calcium, probably by acting through the second messengers inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG), released through membrane phospholipid hydrolysis by phospholipase C (PLC). Calcium (and DAG) activate protein kinase C (PKC) and calcium/calmodulin-regulated kinase II (CamKII). It is possible that the noncanonical pathways presented in A and B are alternate facets of a single conserved noncanonical Wnt pathway (see text).

signaling (e.g., Stbm and Nkd) similarly affect convergent extension movements during gastrulation in zebrafish and in *Xenopus*. One attractive hypothesis is that the Wnt/calcium signaling pathway and the PCP pathway are two aspects of the same molecular cascade. The reason that this is unclear is that the Wnt/calcium signaling pathway represents cellularly defined signaling events in frog and fish embryos, whereas the PCP pathway represents genetically defined signaling molecules in *Drosophila*. It is plausible but unproven that both are part of a single evolutionarily conserved noncanonical pathway. Resolution of this issue awaits the results of ongoing experimental studies in *Drosophila*, *Xenopus*, and zebrafish and the investigation of whether Wnt/calcium signaling occurs in mammalian cultured cells.

VII. SUMMARY: BEYOND DEVELOPMENT AND CANCER

The *Wnt* genes, first identified as a single developmental mutation in fruit flies and as a proto-oncogene in a mouse model of cancer, are now established as critically important, evolutionarily conserved intercellular signaling molecules. Although general mechanisms of Wnt signal transduction have been determined, many details remain to be experimentally

elucidated. Current studies of cross talk between canonical and noncanonical signaling pathways, as well as of the concordance between these pathways in different biological contexts, are expected to yield exciting new conceptual advances.

In addition to its fundamental importance in developmental patterning events, cell fate determination, cell movements, cell morphology, cell polarity, cell proliferation, and neoplasia, there is emerging evidence that Wnt signaling contributes significantly to disease processes ranging from scar formation to heart failure to neuropsychiatric disorders. Further research into the role of Wnt signaling in these processes offers both the promise of fascinating scientific insights into basic biological processes and the hope of revolutionary therapeutic innovations that may one day alleviate human suffering.

Glossary

canonical Wnt/β-catenin pathway The Wnt signaling pathway as first elucidated in *Drosophila* wing development, *Drosophila* embryonic segmentation, vertebrate axis specification, and mammalian tumorigenesis, which modulates gene activity through the regulated degradation of β-catenin.

noncanonical pathway Signaling by a Wnt or a Wnt receptor that occurs in a β-catenin-independent manner.

planar cell polarity pathway The noncanonical pathway in *Drosophila melanogaster* composed of genes affecting the transverse orientation of cells in an epithelial sheet.

Wnt/calcium pathway A proposed noncanonical pathway, best described in frog and fish embryos.
