With regard to the EGF family of growth factors, it is now clear that the EGF relatives TGF-α and neuregulins (NRGs) are produced in hypothalamic astrocytes and stimulate GnRH secretion indirectly, using an astrocyte-to-astrocyte mode of action. To exert this stimulatory effect, they bind to erbB receptors located on the cell membrane of astroglial cells (instead of GnRH neurons) and induce the release of bioactive substances, such as PGE2, that act directly on GnRH neurons to elicit GnRH secretion. TGF-α is recognized by erbB-1 receptors, which are required for normal sexual development. Studies in rodents have shown that if these receptors are blocked in the median eminence, or if their function is diminished by a genetic mutation, female puberty is delayed. Conversely, transgenic mice carrying a molecularly modified TGF-α-producing gene and rats carrying intrahypothalamic grafts of cells genetically engineered to secrete TGF-α, show accelerated sexual development. The results of the latter study led to the notion that activation of a discrete subset of astrocytes near GnRH neurons may suffice to induce an appropriate pattern of GnRH secretion able to set in motion the pubertal process. In support of this concept is the finding that, in humans, some puberty-inducing hypothalamic tumors known as hamartomas contain astroglial cells rich in TGF-α and its receptors.

As indicated above, the hypothalamus of developing female rats also produces NRGs, a group of

TGF-α-related proteins, and two of the three erbB receptors mediating NRG signaling, erbB-2 and erbB-4. Experiments using cell lines have shown that whereas NRGs bind to erbB-4 receptors, erbB-2 functions as an auxiliary subunit, recruited by erbB-4 receptors upon ligand binding. A similar set of interactions occurs in the developing hypothalamus. During female sexual development, the hypothalamic content of erbB-2 and erbB-4 mRNA begins to increase by the end of the juvenile period, when circulating sex steroid levels are still low, suggesting that the increase is independent of an augmentation in gonadal output of sex steroids. The presence of the co-receptor erbB-2 appears to be critical for the timely initiation of female puberty because *in vivo* disruption of erbB-2 synthesis results in delay puberty in female rats. The physiological importance of both the TGF-α- and the NRG-dependent signaling systems for the timely initiation of puberty and subsequent reproductive performance has been demonstrated by recent studies using a genetic approach to disrupt the functional competence of each ligand–receptor complex. Thus, mice carrying a mutated erbB-4 receptor able to block the signaling capability of the intact receptor specifically in astrocytes show delayed female sexual development and compromised fertility, without alterations in erbB-1 function. Breeding these animals to mice carrying a defective erbB-1 receptor aggravated the defect by further delaying the onset of puberty and seriously compromising fertility. As a measure of this defect, litters born to double-mutant mothers were 1–3 pups in size, in marked contrast to the 8–12 pups per litter observed in normal wild-type animals.

IV. THE NEURONAL CONTROL OF NEUROENDOCRINE GLIAL FUNCTION

An important issue that hitherto had not been resolved is the identity of potential neuron-to-astrocyte communication pathways capable of regulating erbB-dependent astrocytic signaling. Recent studies have implicated excitatory amino acids as participants of one of these communication pathways. Hypothalamic astrocytes contain two classes of glutamate recognition molecules known as metabotropic and α-amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA) receptors. They also express several proteins required for these receptors to convey intracellular signals in response to glutamate binding. Upon stimulation with the appropriate receptor ligand, astrocytes respond with functional changes, including mobilization of erbB receptors to the cell surface and association of TGF-α and NRGs with their respective receptors on the cell membrane. As a consequence of this association, erbB receptors are phosphorylated, indicating that excitatory amino acids acting via AMPA and metabotropic receptors activate erbB receptors indirectly by facilitating their interaction with their TGF-α and NRG ligands. These results complement and expand earlier findings showing that activation of AMPA and metabotropic receptors in astrocytes causes PGE2 release, which in turn increases glial glutamate release. Because astrocytic glutamate released in response to PGE2 triggers calcium fluxes in neighboring neurons, it has been postulated that this cell–cell signaling pathway is required for astrocytes to regulate synaptic transmission in the central nervous system. Thus, communication between astrocytes and neuronal networks that use amino acids for neurotransmission appears to represent a fundamental mechanism employed by the neuroendocrine brain to control the advent and progression of mammalian sexual maturation.

Activation of erbB-mediated signaling may also represent one of the centrally originated, gonad-independent components that controls the initiation of puberty. Because erbB-1 ligands are able to activate estrogen-dependent events in the absence of estrogen, they could act in key hypothalamic regions to initiate such events before steroid production begins to increase at puberty and, thus, provide—in the absence of changes in gonadal output—one of the initial stimuli underlying the initiation of the pubertal process.

V. PRESUMPTIVE UPSTREAM CONTROLLING GENES

Preceding, and likely controlling, the activation of the aforementioned cell–cell communication pathways, there appears to exist an "upstream" layer of specific regulators of gene transcription that, operating within specific cellular subsets of the hypothalamus, unleash the primary events leading to the pubertal increase in central drive. Two of these upstream regulators, known as Oct-2 and TTF-1/Nk-2.1, have been implicated in this process.

In the postnatal brain, the Oct-2 gene is expressed in several neuronal hypothalamic nuclei, but Oct-2 proteins are more abundant in cultured astrocytes than in neurons, indicating that Oct-2 gene products may play an important role in regulating the transcriptional activity of astroglial genes. One of

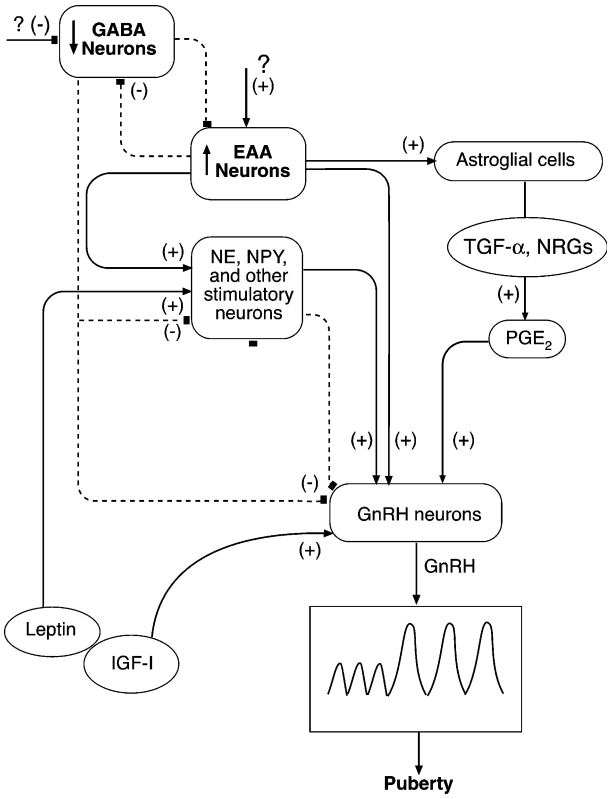

FIGURE 1 The central events underlying the initiation of puberty. An increase in episodic GnRH secretion is activated by an integrative mechanism involving both neuron-to neuron and glia-to-neuron communication processes. The neuron-to-neuron (transsynaptic) component involves the simultaneous activation of excitatory transsynaptic inputs and a reduction in inhibitory inputs to GnRH neurons. The main excitatory transsynaptic input affecting GnRH release is postulated to be provided by neurons that use excitatory amino acids (EAA) as neurotransmitters. Norepinephrine (NE) and Neuropeptide Y (NPY)-containing neurons provide a complementary facilitatory input to the GnRH neuronal network. The chief inhibitory neuronal input restraining GnRH release is provided by GABAergic neurons (GABA). The glia-to-neuron component of the process involves the production of the epidermal growth factor (EGF)-related peptides, TGF-α and neuregulins (NRGs), by astroglial cells, and the stimulatory effect of these peptides on the glial production of neuroactive substances, such as prostaglandin E2, which act directly on GnRH neurons to elicit GnRH secretion. Current evidence suggests that an increase in EAA neurotransmission (↑, EAA neurons) may be predominantly responsible for the pubertal activation of pulsatile GnRH secretion in the rat, whereas a decrease in an inhibitory GABAergic tone (↓, GABA neurons) may be a primary transsynaptic event underlying the process in the rhesus monkey. Evidence collected in rodents indicates that excitatory amino acids can act directly on GnRH neurons to enhance GnRH release (+), and on GABA neurons to inhibit (−) GABA neurotransmission. It is also possible, however, that a primary decrease in GABA release triggers the pubertal increase in EAA neurotransmission. EAA acting on astroglial cells appear to facilitate the glial production of TGF-α/NRGs. While the decrease in GABA transmission begins to relieve GnRH neurons from GABAergic inhibitory control, the increased production of EGF-related glial peptides stimulates the formation of prostaglandin E2, which acts directly on GnRH neurons to elicit GnRH release, amplifying the stimulatory effect of EAA and magnifying the loss of GABAergic inhibitory control. Upon the initiation of these changes, a further increase in EAA stimulation and a further decrease in GABAergic inhibitory tone lead to activation of NE and NPY neuronal systems. Both NE and NPY would then contribute to the progression of the pubertal process by stimulating GnRH secretion. There is also evidence that an inhibitory NPY influence on GnRH release is lifted at the end of juvenile development and, thus, contributes to the initiation of the pubertal process. The metabolic signals leptin and IGF-I further the process along by stimulating GnRH secretion either directly (IGF-I) or via functionally connected neuronal networks (leptin). The resulting increase in pulsatile GnRH secretion then results in the initiation of puberty [↓ = (−) = inhibition; ↑ = (+) = stimulation]. Modified with permission from Ojeda and Bilger (1999), *In* "Neuroendocrinology in Physiology and Medicine" (P. M. Conn and M. E. Freeman, eds.), pp. 197–224. Humana Press.

the astroglial genes regulated by Oct-2 is TGF1. Its promoter contains a DNA sequence recognized by Oct-2 and is activated by Oct-2. Oct-2 appears to be important for the pubertal increase in hypothalamic TGF-α gene expression and for the initiation of puberty itself, because—like TGF-α—hypothalamic Oct-2 mRNA levels increase during juvenile development preceding the pubertal augmentation of steroid secretion. More importantly, blockade of Oct-2 synthesis results in reduced astrocytic TGF-α synthesis and delayed age at first ovulation, indicating that an intact Oct-2-initiated pathway involving TGF-α as a downstream regulated gene is required for the timely acquisition of female sexual maturity. Puberty-advancing lesions of the hypothalamus activate Oct-2 expression in astrocytes near the lesion site, further supporting this notion.

In addition to increasing Oct-2 gene expression in astrocytes, these lesion increased TTF-1 mRNA in neurons. Like Oct-2, the hypothalamic content of TTF-1 mRNA increases transiently before the initiation of normal puberty—also before the occurrence of any discernible change in gonadal steroid secretion. After birth, the hypothalamic expression of TTF-1 is limited to discrete cellular subsets, which include selected glial cells and neurons. The most prominent glial site of expression is in the median eminence of the hypothalamus, where it co-localizes

with erbB-2. The most salient site of neuronal expression is in a group of hypothalamic neurons that produce enkephalins, a family of inhibitory peptides. TTF-1 is also expressed to some extent in GnRH neurons. TTF-1 activates erbB-2 and GnRH gene expression, but it inhibits expression of the enkephalin gene, via binding to specific DNA sites present in the controlling (promoter) region of these genes. These findings have led to the hypothesis that TTF-1 is a controlling gene able to coordinate the (1) activation of hypothalamic cells required for the initiation of the pubertal process (such as GnRH neurons and erbB-2-containing glial cells of the median eminence) and (2) the repression of neuronal systems (such as enkephalinergic neurons) that may inhibit the initiation of puberty.

VI. SUMMARY AND CONCLUSIONS

Clear evidence now exists indicating that the activation of GnRH secretion at puberty requires the concerted activation of both transsynaptic and astroglial regulatory systems (Fig. 1). The neuronal networks most critically involved in this process are those that utilize excitatory and inhibitory amino acids as neurotransmitters. Astroglial cells, on the other hand, contribute by producing cell–cell signaling molecules able to regulate neuronal function. Although in several brain regions the interaction of excitatory and inhibitory neuronal networks appear to follow the rules of a glutamate-to-GABA hierarchy, it is still unclear which of these two neurotransmitter systems initiates the transsynaptic cascade of events leading to the pubertal activation of GnRH secretion. Among the various cell–cell signaling molecules produced by astroglial cells, the TGF-α and EGF families of growth factors have been identified as central components of the communication pathway used by hypothalamic glial cells to facilitate GnRH release. Although IGF-I is also produced in astrocytes and facilitates the onset of puberty via stimulation of GnRH release, it does not appear to exert these effects upon release from hypothalamic astrocytes, but instead is produced by a peripheral source and reaches the hypothalamus via the bloodstream. In addition to the aforementioned glia-to-neuron signaling complexes, there is a neuron-to-glia communication pathway employed by neurons that use glutamate for neurotransmission and mediated by the coordinated activation of different glutamate receptors. Activation of these receptors on astrocytes sets in motion events that lead to activation of a different type of receptor, those that mediate the actions of TGF-α and neuregulins on glial cells. Finally, two genes have been implicated as members of the upstream regulatory hierarchy controlling some of the cellular events underlying the synchronized changes in neuronal/glial function that initiate puberty. The importance of neuronal and glial plasticity in the pubertal process remains to be established and should be the subject of extensive investigation in years to come.

Glossary

astrocytes Nonneuronal, glial cells (from the Greek, meaning glue). They are required for the integration of cell–cell communication within the nervous system, regulation of synaptic transmission, facilitation of neuronal activity, generation of neurons, and production of growth factors needed for the integrity of neuronal function.

gonadotropin-releasing hormone The neuropeptide that controls pituitary secretion of gonadotropic hormones and that is produced by a specialized subset of neuroendocrine neurons of the hypothalamus. It is also known as luteinizing hormone-releasing hormone.

transsynaptic The mode of communication between neurons, which convey information to one another via chemical signals released into specialized points of contact known as synapses.

upstream Describes events that control and/or initiate subsequent events in a regulatory pathway.

Gonadotropin-Releasing Hormone Neuron

ALLAN E. HERBISON
University of Otago, New Zealand

The brain integrates multiple internal homeostatic and external factors to control reproductive functioning. The neural network responsible for this critical function ultimately uses a small group of 1000–2000 gonadotropin-releasing hormone (GnRH) neurons to control directly the secretion of gonadotropins from the pituitary gland. The release of the GnRH decapeptide from nerve terminals located in the median eminence into the pituitary portal system is episodic in nature and responsible for the pulsatile profile of the circulating gonadotropins. Furthermore, the changes in gonadotropin pulse amplitude and frequency that occur across the female ovarian cycle, or in response to various stressors, are thought to arise principally from alterations in the pattern of GnRH release. Thus, knowledge of the GnRH neuron and how it secretes GnRH is critical to our understanding of how the brain controls fertility. This article focuses on recent advances obtained in our understanding of the cellular properties of the GnRH neuron in mammalian species.

I. TOPOGRAPHY AND MORPHOLOGY

Remarkably, in all mammals examined to date, the gonadotropin-releasing hormone (GnRH) neurons responsible for regulating reproduction are not created in the brain but, instead, arise from the olfactory placode located within the nose. During midgestation, the GnRH neurons migrate along the axons of olfactory neurons to pass through the nose and enter the brain, whereupon they turn ventrally and proceed to the medial septum and hypothalamus. This pattern of migration is remarkable not only in the distance covered by the GnRH neurons but also in terms of the multiple different environments they must navigate to reach their final destination. Kallmann's syndrome, with the predominant features of infertility and anosmia, represents one such example of failed GnRH neuron migration in which these cells do not pass from the nose into the brain in humans.

One consequence of the extraordinary migratory development of the GnRH neurons is that the cell bodies of the GnRH neurons come to reside in a scattered manner along the entire midline migratory pathway within the postnatal brain (Fig. 1). Although this phenomenon is found in all species, differences

the pulsatile infusion of the decapeptide can restore gonadotropin secretions in GnRH-deficient subjects, continuous administration of GnRH fails to sustain gonadotropin release. The pulsatile GnRH release pattern is thus considered a critical feature of the cascade of hormone secretions that constitute the reproductive axis. Those neurons and their processes that function to release the neuropeptide GnRH in this rhythmic manner are collectively referred to as the GnRH pulse generator.

At least one form of GnRH regulates reproduction in all vertebrate species. Thus far, at least nine different molecular forms of the decapeptide have been identified in lower vertebrates, and at least two different GnRH molecules, GnRH-I and GnRH-II, are expressed in many mammals. Two distinct genes encode the latter two GnRH molecules, and their expression patterns in the brains of primates and other animals are clearly dissimilar. With regard to function, much is known of the biology of GnRH-I, but little is known of the biological importance of GnRH-II. The hypophyseotropic functions of GnRH-I have been extensively studied in the years following its identification, and it is generally held that it serves as the predominant GnRH governing the reproductive axis in mammals. The neuroendocrine and behavioral functions of GnRH-II and other GnRH molecules are much less clear; although their distribution suggests a role in neuromodulation, this remains unproven. Thus, this article will focus largely on the anatomy, molecular and cellular biology, and physiology of GnRH-I neurons, and the appellation "GnRH" will henceforth be used synonymously with "GnRH-I," referring to the GnRH decapeptide: pyroGlu^{1}-His^{2}-Trp^{3}-Ser^{4}-Tyr^{5}-Gly^{6}-Leu^{7}-Arg^{8}-Pro^{9}-Gly^{10}amide.

II. ANATOMY OF GnRH NEURONS

During embryogenesis, GnRH neurons originate from the olfactory epithelium and migrate along the nasal septum and terminal nerve to enter the basal forebrain. In most, if not all, animals the relatively small population of GnRH perikarya (e.g., 800 neurons in mice) assumes its final distribution along a medial septal, preoptic, and hypothalamic tissue continuum prior to birth. The number of GnRH neurons appears to remain constant throughout postnatal life, although the cytological appearance (e.g., smooth versus spiny contours) and the degree of glial ensheathment have been suggested to change during postnatal stages of development. The GnRH neuron in the mature animal is typically fusiform in shape and is relatively unremarkable at the ultrastructural level. Diminished or absent dendritic arborizations, as well as a minimum of synaptic contacts, are perhaps the most consistent features of GnRH neurons. This has been taken as presumptive evidence that only a limited number of afferent synaptic signals contribute to the integrative activity that occurs within GnRH neurons. Thus, nonsynaptic signals (neural or endocrine) and/or autoregulatory activity may predominate in the cell signal integration that controls spontaneous and regulated pulsatile GnRH secretion. A significant proportion of GnRH neurons co-express the structurally unrelated neuropeptide galanin, and this GnRH neuronal product has been suggested to play a role in the autoregulation of GnRH neurosecretion.

In rodents, the topography of GnRH is characterized by a scattered but stereotyped distribution pattern that typically forms an "inverted V" pattern at more rostral tissue levels, including the diagonal band of Broca, organum vasculosum of the lamina terminalis (OVLT), and preoptic nuclei. The distributions of GnRH neurons in monkeys, sheep, and guinea pigs additionally include subsets of GnRH perikarya that reside more caudally within the mediobasal hypothalamus. Although some GnRH neurons extend processes that make synaptic contacts with other neurons in the basal forebrain, it is clear that the majority of the GnRH neurons extend axons toward and within the lateral median eminence and form neurovascular junctions with fenestrated microcapillaries of the primary portal plexus. It is within this neurohemal organ that GnRH neurosecretion into the hypophyseal portal vasculature takes place and from which GnRH molecules are conveyed to a secondary plexus within the anterior pituitary gland.

A second GnRH axon terminal field is present within the OVLT, where GnRH neurovascular junctions are also evident. The functions of this ostensible GnRH neurosecretory site remain unknown. Axon terminals have also been found to extend through the ependymal lining of the ventral third ventricle, the septal lateral ventricle, the subfornical organ, and the cerebral aqueduct. The release of GnRH from these terminals into the cerebrospinal fluid has been inferred, and its functional importance in the regulation of pituitary function or behavior has been debated. Additional GnRH terminal fields of much smaller proportions have been characterized and include olfactory tissues, portions of pyriform cortex, medial, and cortical amygdalar nuclei, stria terminalis, ventral hippocampus, and subiculum. Several GnRH axons also course from the level of

the medial septum and reach as far caudally as the midbrain central gray, where they have been implicated in the modulation of lordotic behavior in female rats.

III. MOLECULAR BIOLOGY OF GnRH

The paucity and scattered topography of GnRH neurons hampered early molecular biological investigations of the neurohormone. These technical barriers were largely overcome following the development of immortalized hypothalamic GnRH neurons, including the GT1-1 and GT1-7 cells, as well as the GN10 and GN11 cell lines. Much information has since been obtained on the regulation of GnRH transcription, translation, processing, and secretion in a homogenous GnRH cell context *in vitro*.

The 5′-flanking sequences of the mouse, rat, and human GnRH gene contain a neuron-specific enhancer and dual promoters, each region being critical for transcription of the gene. The 300 bp enhancer is situated 1.8 kb upstream of the transcriptional start site and it confers a 50-fold activation of GnRH gene transcription. It contains sites that bind proteins important for neuron-specific expression of the gene, including POU-homeodomain (sharing a domain common to Pit-Oct-Unc families of transcription factors) and GATA (binding GATA nucleotide sequence) factors. In the human GnRH gene, the 5′-flanking region contains two transcriptional start sites at +1 and −579, each associated with respective promoter sequences. The proximal (or downstream) promoter for the proximal start site is active in hypothalamic GnRH neurons, whereas the distal promoter is fully active in cells derived from other reproductive tissues, including the placenta. The existence of dual promoters in the 5′-flanking region of the GnRH gene appears to be a conserved feature of GnRH genes across mammalian species.

Several neuroendocrine signals have been shown to regulate the transcriptional activity of the proximal GnRH gene promoter. Estrogen, progesterone, glucocorticoids, and retinoic acid are among the steroid hormones that have been shown to either directly or indirectly influence GnRH gene transcription, depending upon species and cell context. The negative and positive effects of estrogen and progesterone have received the greatest attention, with studies guided by the possibility that transcriptional regulation of the GnRH gene may mediate the negative and positive feedback actions of these steroids on GnRH release *in vivo*. Current evidence indicates that a negative estrogen-response element is localized in the proximal promoter region (−171 to −126), although the estrogen receptor does not bind to this region. An indirect regulatory mechanism has therefore been inferred. Progesterone has also been found to repress GnRH promoter activity through a region that encompasses the estrogen-response element. Three putative nonconsensus binding elements for the progesterone receptor (PR) are present within this region of the GnRH promoter. Glucocorticoids have also been found to suppress GnRH gene transcription. In the mouse GnRH gene, one response element is known to directly interact with the glucocorticoid receptor (GR) and a second binds the POU-homeodomain factor Oct-1, which in turn binds the GR. Both regions can confer negative regulation of the mouse GnRH gene promoter. GnRH promoters of various species have also been found to be regulated by signals within growth factor- and G-protein-coupled receptor-mediated pathways. Among these are signals conveyed via protein kinase C, insulin-like growth factor-I (IGF-I), bFGF, corticotropin-releasing hormone receptors, human chorionic gonadotropin/LH receptors, and GnRH receptors.

The coding region of the GnRH gene includes sequences distributed across four exons. Transcription and RNA processing yield a GnRH mRNA that encodes a 92-amino-acid prepro-GnRH protein, and the GnRH decapeptide and gonadotropin-releasing hormone-associated peptide are ultimately derived from the posttranslational proteolytic cleavage of this precursor molecule. The posttranslational processing of the molecule, including its C-terminal amidation, likely takes place within the nascent secretory granule and during axonal transport to the axon terminal. The GnRH secretory process involves a Ca^{2+}-dependent exocytotic mechanism, which is in turn directed by intermittent volleys of action potentials that invade the GnRH terminals and are coupled to both the entry of extracellular Ca^{2+} into the cell and the mobilization of intracellular Ca^{2+} stores.

A variety of neural and endocrine signals are known to regulate the rate and pattern of pulsatile GnRH release. In general, these inputs can be categorized as those that impact the amplitude of GnRH release or those that impact the frequency of GnRH pulse generation. Potential mechanisms for the regulation of GnRH amplitude include modulation of GnRH gene transcription, translation, posttranslational processing, intracellular transport, and stimulus-secretion coupling; the last process includes the enhancement or diminishment of cell signaling leading to the elevation of intracellular Ca^{2+} and the exocytotic release of the GnRH

decapeptide. Frequency modulation is likely dependent on inputs that alter the electrophysiological excitability of the GnRH neuronal membrane. Although the mechanisms that mediate such effects are not well known, the alteration of GnRH pulse frequency is most likely manifest as changes in the rate of a basic pulse-generating mechanism that is largely an intrinsic function of GnRH neuronal networks.

IV. THE GnRH PULSE GENERATOR

The GnRH release process is almost invariably pulsatile, and in virtually all female and male mammals studied this pulsatile release pattern has been found to be critically important in sustaining gonadotropin secretions. The cellular mechanisms that govern the pulsatile GnRH release process, however, remain poorly understood. Electrophysiological correlates of pulse generator activity have been characterized using mediobasal hypothalamic, multiunit recordings in monkeys, sheep, goats, and rats. Although these studies have not allowed for microanatomical mapping of pulsing cells and/or circuitries, they have provided a functional definition of the GnRH pulse generator: a set of neurons that periodically fire a high-frequency volley of action potentials that eventuate in the neurosecretion of a GnRH pulse into the hypophyseal portal vessels. Beyond this definition, the electrophysiological studies have also underscored the existence of at least two important elements of the GnRH pulse-generating process—a pulse initiation mechanism and a mechanism for electrophysiological synchronization among GnRH neurosecretory cells.

The simplest model for pulsatility holds that pacemaking activity occurs within one or more GnRH neurons themselves and that the activities of "slave" GnRH neurons are entrained to the rhythm of the dominant pacemaker within the population. This idea is supported by the observations that GnRH release from immortalized GT1 cells in culture is pulsatile. Observations of pulsatile GnRH release from isolated guinea pig mediobasal hypothalamus and rat preoptic–mediobasal hypothalamic tissues *in vitro* have also been documented, and these findings, too, support the idea of intrinsic GnRH pulsatility, since GnRH perikarya in these species are contained within these respective tissues. Studies of cultured GnRH neurons, however, have not provided evidence that any specific GnRH neuron operates as a dominant pacemaker within a population of cells. Thus, a variation of the foregoing model of pulsatility (pseudo-pacemaking) holds that any neuron within the pulsing network can initiate a pulse and that the pulsatile rhythm follows from the continued repetition of (1) random activation of a GnRH neuron within the interconnected GnRH network; (2) stimulation of other neurons in the network by the excited cell; (3) a refractory period, during which no neurons fire; and (4) activation of another neuron in the network. This stochastic model has been strongly supported by studies of Ca^{2+} elevations in cultured GnRH neurons.

Some mechanism must also operate to synchronize the pulsatile release activity among GnRH neurons. Synchronicity may be achieved through intercellular signaling via GnRH–GnRH synaptic contacts or gap junctions. Some GnRH immunopositive terminals have been demonstrated in apposition to GnRH perikarya, and recent evidence suggests that GnRH receptors are expressed in GnRH neurons. Other work suggests that a volume transmission mechanism, perhaps involving nitric oxide, could mediate synchronization among GnRH neurons.

V. NEUROENDOCRINE REGULATION OF THE GnRH PULSE GENERATOR

Physiological regulation of the reproductive axis commonly occurs through GnRH pulse frequency modulation. Regulation of GnRH pulse frequency appears to be important in initiating prolonged changes in the activity of the reproductive axis, such as those occurring in puberty, during seasonal transitions in the reproductive state, and following gonadectomy. Frequency regulation also appears to mediate inhibitory responses of the reproductive axis to prolonged exercise and food restriction. The cellular mechanisms that mediate GnRH pulse frequency modulation are not currently understood. Based on the pseudo-pacemaking model of pulsatility, however, it may be assumed that any stimulus that tends to depolarize the membrane potential of a pulse-generating neuron would increase its likelihood of reaching the firing threshold in response to a stimulus. Conversely, any condition that tends to hyperpolarize the membrane would decrease the likelihood of a cell reaching the firing threshold in response to a stimulus. These expectations would apply regardless of the nature of the stimulus, viz. whether or not the cell is autoexcitatory or excited by another cell. Thus, if a significant portion of the entire pulsing neuronal network is rendered more or less excitable (more or less depolarized), the probability

of any cell initiating a pulse at a given time following a preceding pulse would be increased or decreased, accordingly. It follows that any overall change in the probability of excitation in a pulsing network would produce a commensurate change in average interpulse interval and, hence, in GnRH pulse frequency.

How then is a given level of cell excitability manifest in an individual GnRH neuron, and how may it be altered? One likely mechanism depends upon the activity of ion channels, particularly those selective for K^+, which conduct hyperpolarizing currents that can prevent or retard depolarization toward firing threshold. Patch-clamp studies, using both whole-cell and perforated-patch configurations, have shown that immortalized GnRH neurons express several types of K^+ channels, including a K^+ inward rectifier (K^+_{ir}) and four outward K^+ channels: a delayed rectifier, a 4-AP-sensitive "A-type" channel, a 4-AP and TEA-insensitive channel, and a large-conductance Ca^{2+}-activated K^+ (BK) channel. A K^+_{ir} channel has been shown to be active in embryonic GnRH neurons, as well as in GT1 cells; it has been postulated that it is these channels that may be regulated to produce changes in GnRH neuronal excitability.

VI. NEUROENDOCRINE REGULATION OF GnRH RELEASE DURING THE OVULATORY CYCLE

During the ovulatory cycles of rats, monkeys, and other spontaneous ovulators, gonadotropin secretions maintained at low levels, principally through the negative feedback actions of the gonadal steroids, estrogen and progesterone, and protein hormones, such as inhibin. These homeostatic negative feedback actions are exerted via integrated actions on the GnRH pulse generator and pituitary gonadotropes (see Fig. 1). At midcycle, however, the sustained negative feedback regulation of GnRH and gonadotropin secretion is interrupted by the induction of the preovulatory gonadotropin surge. A rising tide of estrogen, secreted by the ripening follicle(s), evokes a primary surge of LH and FSH that in turn triggers ovulation. A major unresolved issue in the study of reproductive neuroendocrinology is the clarification of the mechanisms by which low levels of estrogen and progesterone may, on the one hand, exert homeostatic negative feedback actions on the GnRH pulse generator, while high levels of these steroids, on the other hand, exert positive feedback actions that culminate in the release of GnRH and LH surges.

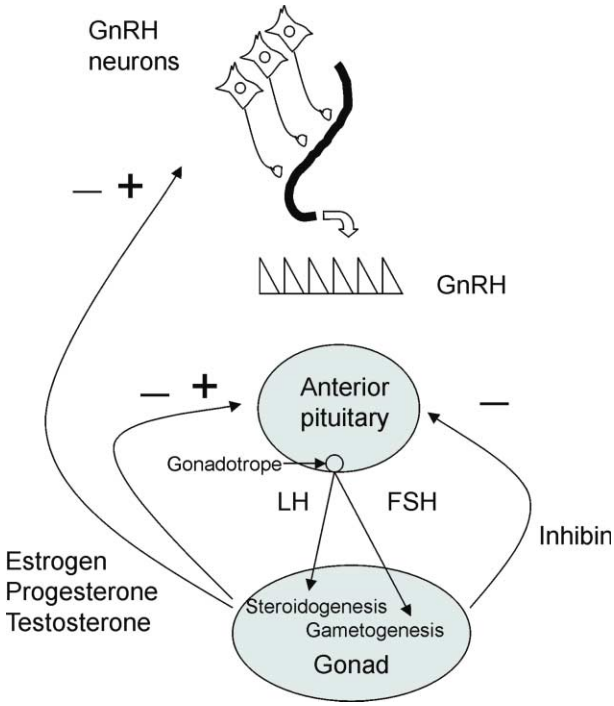

FIGURE 1 Schematic diagram of hormonal signals in the hypothalamic–pituitary–gonadal axis. The "GnRH pulse generator," consisting of GnRH neurons and possibly other neuronal elements, governs the neurosecretion of pulsatile GnRH into the hypophyseal portal vessels. After delivery to the anterior pituitary gland, GnRH molecules bind GnRH receptors on the plasma membranes of gonadotropes and stimulate the synthesis and secretion of the gonadotropins, LH and FSH. At the gonads in both sexes, LH stimulates steroidogenesis and FSH supports gametogenesis. Steroids and protein hormones (e.g., inhibin) can exert homeostatic negative feedback actions within the hypothalamus to retard the activity of the GnRH pulse generator and at the anterior pituitary to suppress responsiveness to GnRH stimulation. In females, high levels of estrogen produced during the preovulatory period exert a positive feedback action, culminating in the release of preovulatory GnRH and gonadotropin surges.

VII. PREOVULATORY GnRH SURGES

Preovulatory GnRH surges have been identified in rats, sheep, and monkeys and indirect measurements suggest that they may occur in women. In rats, where the necessity of this neurosecretory trigger in stimulating LH surges is unambiguous, a proestrous surge of GnRH in this species appears to be composed of a 2 to 4 h increase in the overall amount of GnRH released. Detailed analyses of GnRH release patterns during surges suggest that GnRH pulse amplitude, as well as a basal GnRH secretory component, may be acutely increased as a major portion of this surge release. An example of an estrogen-induced

GnRH surge, and its associated LH surge in the peripheral plasma, is depicted in Fig. 2. Mechanisms by which estrogen may exert these positive feedback actions include increased GnRH gene expression, activation of synaptic inputs to pulsing GnRH neurons, alterations in neurotransmitter receptor synthesis, and/or alterations in the expression of postreceptor signaling molecules. In some female mammals, notably many rodents, the release of GnRH surges is timed to occur during a restricted period on the afternoon preceding estrus. This mechanism has likely evolved to ensure that ovulation occurs in temporal association with the onset of behavioral estrus and that both processes occur during the nocturnal period of wakefulness for these species. Classical work showed that a daily neuronal signal, conveyed from the biological clock resident in the suprachiasmatic nucleus to GnRH surge-producing circuitries, directs the release of GnRH surges during the specified period on the afternoon of proestrus. Estrogen's actions appear to be important in coupling the daily neuronal signal to the GnRH surge release process. This coupling action is most evident in animals treated with prolonged, high levels of estrogen, in which daily afternoon GnRH and LH surges occur on successive days of treatment. Recent work suggests that estrogen couples the daily neural signal to the GnRH surge release mechanism via induction of transcription factors in estrogen-responsive neurons, which may thereafter be activated by neural signals for the surge. One such estrogen-induced transcriptional regulator may be the intracellular progesterone receptor. Evidence supporting this idea includes the observations that estrogen treatments fail to produce surges in progesterone receptor knockout mice.

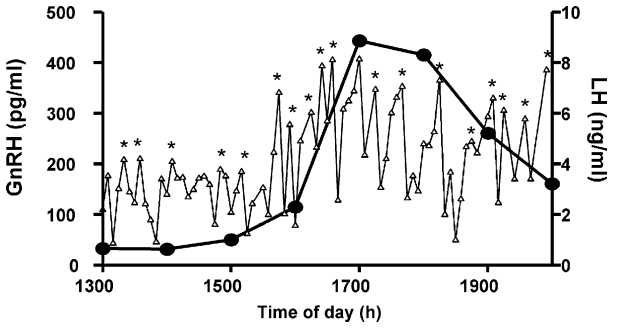

FIGURE 2 Estrogen-induced GnRH and LH surge in an individual ovariectomized rat. A microdialysis procedure was used to monitor GnRH release in the median eminence of a rat that was acutely ovariectomized on the afternoon of diestrus and treated at the same time with 30 μg estradiol benzoate. Experiments were performed on the following day of presumptive proestrus. Radioimmunoassay of GnRH in microdialysates revealed an afternoon surge of GnRH that was accompanied by a surge of LH in the peripheral plasma. Open triangles indicate GnRH levels. Filled circles indicate LH levels. Asterisks represent significant pulses as determined by statistical analysis. Data are from Chappell *et al.* (2000). *Endocrinology* **141**, 1477–1485.

The cellular targets of estrogen's positive feedback actions on GnRH release have been extensively studied, and much remains to be clarified about this important signaling process. Three possible mechanisms of action have received the most attention in neuroendocrine investigation. One is a direct action of the steroid on GnRH neurons, whereby estrogen may directly alter gene transcription or cellular excitation. Early immunohistochemical analyses cast doubt on this scenario, as few if any GnRH neurons were found to express steroid receptors. More recent studies have resurrected this idea, however, as a small but significant portion of GnRH neurons have been found to express both the estrogen receptor-β (ER-β) mRNA and the ER-β protein. A second hypothesis holds that estrogen induces alterations in the glial ensheathment of GnRH neuronal projections and thereby affects changes in the rate and/or pattern of GnRH neurosecretion from neurovascular terminals in the lateral median eminence. Correlative immunohistochemical and ultrastructural microscopy studies have provided evidence supporting this idea; however, a causal link has yet to be established.

A third model for estrogen's positive feedback actions invokes the possibility that estrogen-receptive, non-GnRH interneurons mediate the positive feedback actions of estrogen on GnRH neurosecretion. Most investigators agree that the most important neural locus for the transduction of estrogen's positive feedback actions is a relatively discrete, sexually dimorphic region within the preoptic area, referred to as the anteroventral periventricular nucleus (AVPv). Although this area is replete with estrogen receptors, it contains a relatively small number of GnRH neurons. Lesions of this nucleus render female animals acyclic and unresponsive to estrogen's positive feedback actions. Thus, one prevailing model for the positive feedback actions of estrogen holds that non-GnRH, ER-expressing neurons in the AVPv transduce estrogen positive feedback signals and that these neurons thereafter convey first- or multi-order afferent signals to GnRH neurons for the initiation of GnRH surge release. Estrogen's actions in these transducer interneurons may include the induction of PRs, which may in turn be activated

by neural signals emanating from the biological clock (via ligand-independent mechanisms) as well as by progesterone (via ligand-dependent mechanisms) secreted during the onset of the LH surge. The neurotransmitter phenotypes of AVPv neurons that may participate in this positive feedback circuitry include calcitonin gene-related peptide, dopamine, dynorphin, enkephalin, galanin, γ-aminobutyric acid (GABA), neurotensin, and substance P. Other estrogen-responsive cells situated outside of this area, such as noradrenergic or neuropeptide Y-producing neurons in the mediobasal hypothalamus or brainstem A2 cell group, may convey estrogen positive feedback signals via axo-axonic contacts within the median eminence.

VIII. HOMEOSTATIC INHIBITION OF GnRH RELEASE

In the absence of the gonads, GnRH pulse generation in adult animals can occur at frequencies that approach one pulse per 10 min. In all normal physiological situations, however, the frequency and amplitude of GnRH pulses are continuously subject to feedback regulation by gonadal hormones. In male animals, the major feedback mechanism is mediated by testicular androgens. The GnRH pulses evoke LH pulses, which stimulate episodic testosterone secretion. Testosterone and its metabolites, estrogen and dihydrotestosterone, exert negative feedback influences at the hypothalamic level through the restraint of GnRH pulse generator activity. Inhibition is also maintained at the pituitary level through suppression of gonadotropin responses to GnRH pulses. In females, the negative feedback actions of estrogen and progesterone (as well as inhibin and other gonadal peptides) are also of primary importance in restraining GnRH pulse generation and in suppressing the responsiveness of the pituitary gland. Although the relative influence of the two ovarian steroids may vary among species and in different circumstances, it is likely that the appropriate homeostatic control over basal GnRH pulsatility requires the actions of both steroid hormones. There is some evidence to suggest that GnRH estrogen's negative feedback actions are principally manifest as a suppression of GnRH pulse amplitude and progesterone may primarily exert its effects on GnRH pulse frequency.

The sites and mechanisms of estrogen and progesterone negative feedback actions remain less well characterized than those mediating positive feedback. Some evidence suggests that the inhibitory effects of estrogen are exerted at neural loci that are at least partially dissociable from those that mediate positive feedback effects. That there are some conditions, e.g., in progesterone receptor deletion mutant mice, in which positive feedback is absent but negative feedback actions prevail suggests that the cellular mechanisms that mediate the two actions are distinct and separable. The involvement of multiple mechanisms in either or both feedback modes is also a consideration. The actions of estrogen, for example, may be transduced by both intracellular, ER-mediated genomic actions and nongenomic membrane effects of the steroid. The nongenomic effects of estrogen have been indicated by the observations that nanomolar concentrations of 17β-estradiol rapidly and directly hyperpolarized GnRH neurons in the guinea pig. The inhibitory actions of estrogen and progesterone may also be exerted through multiple intracellular routes; although some steroid effects may be exerted through direct actions on the GnRH neuron, there are other suggestions in the literature that negative feedback actions may be exerted indirectly, through the stimulation of inhibitory transmitter turnover or inhibition of stimulatory transmitter release. The strongest cases to be made in this regard are for GABAergic and endorphinergic neurons, which both express steroid receptors and release transmitters known to inhibit GnRH release.

IX. ENVIRONMENTAL AND SOMATIC SIGNALS REGULATING GnRH NEUROSECRETION

Neurosecretion of GnRH is also regulated by numerous physiological signals from nongonadal sources. These include sensory stimuli, information retrieved from memory, and circulating hormonal and metabolic factors. Perhaps the best studied of these regulatory inputs are photoperiodic stimuli. In seasonally breeding animals, day length is registered through photic pathways that ultimately regulate the pattern of pineal melatonin secretions. Changes in the duration of pineal melatonin secretion, in turn, activate or depress GnRH pulse generation and thereby sustain or depress activity in the reproductive axis. In hamsters, long days are photostimulatory for the reproductive axis, and these responses are presumably mediated by activation and inhibition of the GnRH pulse generator, respectively. In sheep, exposure to short days leads to a stimulation of GnRH pulsatility, whereas long days are photoinhibitory; this mechanism dictates the birth of young in the spring, when the chances of survival are maximal.

There are numerous other examples of reproductively relevant sensory cues that prompt adaptive alterations in GnRH pulse amplitude or frequency. GnRH pulses are acutely stimulated in ewes following visual exposure to rams, coitus induces an ovulatory GnRH surge in rabbits through activation of the sensory pathways leading from the cervix to the hypothalamus, and pheromonal cues from male mice are critically important for the release of GnRH surges in female mice. In all of these circumstances, reflex pathways convey information regarding the presence of a sexual partner, and the GnRH pulse generator is activated to prepare the gonads for fertilization.

Chronic and acute stress can also alter the pattern of pulsatility, often in an inhibitory manner so as to favor the expenditure of metabolic energy on adaptive stress responses rather than on reproduction. Metabolic and hormonal cues, such as glucose, leptin, insulin, IGFs, thyroid hormones, or glucocorticoids, can also be important in mediating the adaptive physiological responses of the GnRH pulse generator. Food deprivation, for example, is a state that is not compatible with reproductive success; it is not surprising, then, that it is accompanied by suppression of the GnRH pulse generator in many species. Again, this regulatory mechanism may spare energy stores from being depleted during attempts to reproduce under adverse environmental conditions. In disease states, GnRH pulsatility may also be suppressed. Immune stress and inflammation responses may be accompanied by suppression of the GnRH pulse generator, possibly through the actions of cytokines that are known to be produced under these conditions.

X. SUMMARY

The GnRH neuronal system functions as the final common pathway through which the brain regulates the activity of the reproductive axis. The physiological importance of the decapeptide can be easily appreciated by observing the drastic reproductive consequences of impaired GnRH secretion or action: near total reduction of LH secretion and reduced FSH secretion, greatly diminished steroidogenesis, anovulation in females, the absence of normal reproductive development, and a state of infertility in both sexes that prevails until GnRH stimulation of the pituitary gland is restored. The release of GnRH occurs in a pulsatile manner, providing an intermittent signal to pituitary gonadotropes that is necessary to sustain continued responsiveness to the decapeptide. The cellular mechanisms that function to produce this pulsatile GnRH release pattern remain ill-defined, but are proving amenable to study via homogenous tumor-derived cell lines and new transgenic animal models. Advanced genetic and molecular approaches are also opening up new pathways toward an understanding of the cellular and molecular pathways that mediate neural and endocrine regulatory inputs to the GnRH pulse generator, which remain a major focus of attention in the field of neuroendocrinology.

Glossary

GnRH pulse generator The cellular and molecular mechanisms that produce and sustain pulsatile gonadotropin-releasing hormone neurosecretion; these mechanisms are incompletely understood.

gonadotropin-releasing hormone A decapeptide that is synthesized in neurons of the basal forebrain, released into the hypophyseal portal vasculature, and conveyed to the anterior pituitary gland, where it stimulates the synthesis and secretion of the gonadotropins luteinizing hormone and follicle-stimulating hormone; it is also referred to as luteinizing hormone-releasing hormone.

hypothalamic–hypophyseal portal vessels The specialized vasculature that forms a plexus in the median eminence of the hypothalamus and collects into larger vessels that extend into the hypophysis (pituitary gland); a major function of this vascular network is to convey substances that undergo neurosecretion from neurovascular junctions in the median eminence to the anterior pituitary gland, where these factors, such as gonadotropin-releasing hormone, can regulate hormone secretions.

median eminence The neural tissue at the base of the medial hypothalamus that contains neurovascular junctions, from which releasing factors, such as gonadotropin-releasing hormone, are secreted into the hypothalamic–hypophyseal portal vessels.

pulsatile neurosecretion Rhythmic releases of neurohormone pulses from neurovascular junctions in the median eminence into the hypothalamic–hypophyseal portal vessels.

Gonadotropin-Releasing Hormone and Puberty

SERGIO R. OJEDA, VINCENT PREVOT, SABINE HEGER, AND BARBARA DZIEDZIC

Oregon National Primate Research Center

Gonadotropin-releasing hormone (GnRH), when it is released from the hypothalamus, acts on specialized hormone-producing cells in the pituitary, stimulating the secretion and synthesis of the luteinizing hormone and follicle-stimulating hormone. Once released into the bloodstream these hormones stimulate the gonads to secrete peptidergic and steroid hormones, which promote the growth of secondary sex organs and the development of traits of sexual dimorphism. The activation of GnRH secretion at puberty is not determined by a single mode of transsynaptic communication but instead requires the activation of both transsynaptic and astroglial regulatory systems.

I. INTRODUCTION

Puberty is initiated by events that take place within the central nervous system and that are set in motion even in the absence of the gonads. These events ultimately result in an increase in the release of gonadotropin-releasing hormone (GnRH) from a handful of specialized neurons located in a ventral region of the brain known as the hypothalamus. These neurons send their secretory axons to a region of the hypothalamus termed the median eminence, where they release GnRH into blood vessels that link the hypothalamus to the pituitary gland. Upon reaching the pituitary gland, GnRH acts on specialized hormone-producing cells known as gonadotrophs to stimulate the secretion and synthesis of gonadotropins. These hormones, known as luteinizing hormone (LH) and follicle-stimulating hormone (FSH), are released into the bloodstream and reach the gonads, where they stimulate the secretion of sex steroids and peptidergic hormones. In turn, steroid hormones promote the growth of the secondary sex organs and elicit the appearance of sexual dimorphism (such as fat distribution, muscle mass, breast development, and tone of voice).

It is now clear that the initial signals leading to the pubertal activation of GnRH secretion do not reside within the GnRH neuronal network itself but instead occur in neuronal and astroglial systems functionally connected to GnRH neurons. Some authors have postulated that the primary change in neuronal activity underlying the initiation of puberty is a loss of transsynaptic inhibitory inputs to GnRH neurons. According to this concept, a "central restraint" of puberty—imposed by neurons that utilize the amino acid γ-amino butyric acid (GABA) for neurotransmission—would operate at full capacity during juvenile development, preventing GnRH secretion from increasing prematurely. Other authors postulate that the pubertal activation of GnRH secretion is instead caused by an increase in excitatory inputs and that the main excitatory neurotransmitter system involved in this activation is composed of neurons that utilize the amino acid glutamate for transsynaptic communication. In addition to this dual neuronal

occur in the locations along this pathway at which the majority of GnRH neurons stop their migration; in the rat, sheep, and mouse (Fig. 1), the great majority of GnRH neurons are found in the medial septum and rostral hypothalamus, whereas, in the primate, about half of the GnRH neurons end up in the mediobasal hypothalamus at the caudal extreme of the migratory pathway. The consequences of these neurons of being resident in one of several different areas of the medial septum and hypothalamus are not yet established, despite the observation that GnRH neurons located throughout the "GnRH neuron continuum" extend axons to the median eminence and are presumably all involved in the regulation of gonadotropin secretion.

In addition to the median eminence, a very substantial projection of GnRH fibers passes to the organum vasculosum of the lamina terminalis (Fig. 1), a brain region outside the blood–brain barrier. The role of this projection is completely unknown. Smaller numbers of GnRH fibers are encountered in other forebrain and brainstem regions where they may conceivably have roles in the coordination of gonadotropin hormone secretion with other facets of reproductive physiology. Whether individual GnRH neurons project to multiple locations within the brain has not yet been established. It is also unclear whether GnRH neurons located in different parts of the GnRH neuron continuum project to extrahypothalamic regions in a selective manner.

In many species, the cell body of the GnRH neuron exhibits a predominantly bipolar morphology with an orientation that reflects its embryonic migratory pathway. In other species, such as the sheep, the orientation and scattered distribution are maintained but the GnRH neurons display a variety of different morphologies. The significance of these different morphologies is unknown. Similarly, the functional relevance of bipolar GnRH neurons that exhibit either smooth or spiny contours, when assessed following GnRH immunocytochemistry, has not yet been established. Although GnRH perikarya are, for the most part, scattered along the GnRH neuron continuum, not all of the cells are completely isolated from one another, and clusters of adjacent GnRH neurons can be observed. A very small number of GnRH neurons are known to form

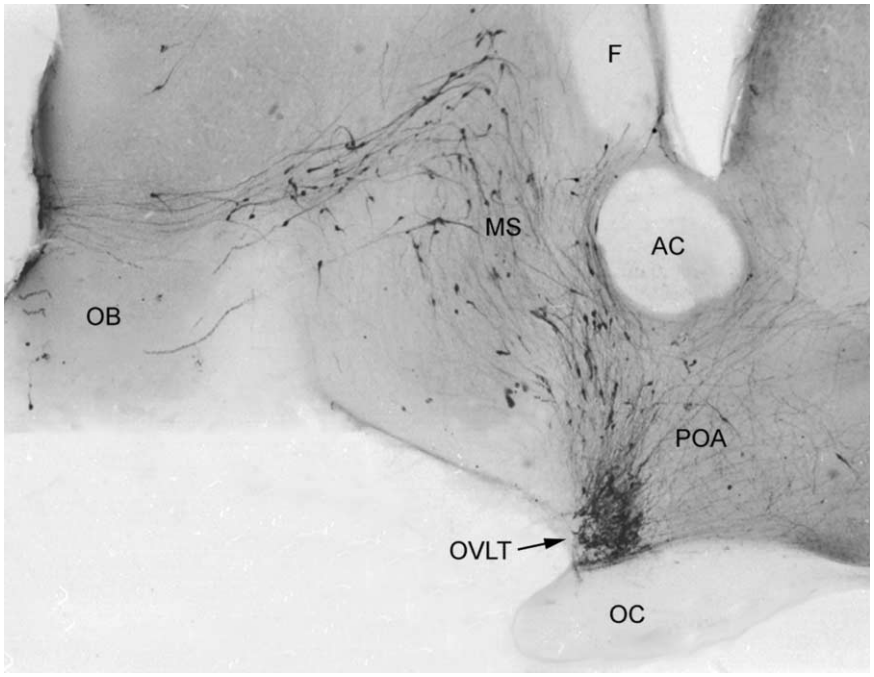

FIGURE 1 Low-power photomicrograph of a midline parasagittal section of the adult mouse brain immunostained for GnRH (front of the brain to the left). Note that the cell bodies of the GnRH neurons are found scattered along their embryonic route of migration from the olfactory bulbs (OB) through the medial septum (MS) into the preoptic area (POA) and hypothalamus (right). The median eminence, where most GnRH neurons extend axons, is not shown and would be to the far right. The other major projection site for the GnRH neurons is the organum vasculosum of the lamina terminalis (OVLT). AC, anterior commissure; F, fornix; OC, optic chiasm.

cytoplasmic bridges with one another. Nevertheless, the overriding morphological and topographical features of the GnRH neuron are its relatively simple shape and its scattered distribution over a wide area within the basal forebrain.

II. ELECTROPHYSIOLOGICAL PROPERTIES

The GnRH neurons secrete GnRH in a pulsatile manner to regulate gonadal function. As such, two of the most important features of the GnRH neuron that require explanation are (1) how they generate an episodic pattern of activity and (2) considering their dispersed topography, how this activity is synchronized among the GnRH neuronal population. Providing the answers to these questions has proven to be extremely difficult, and multiple different experimental strategies have been employed.

Because the GnRH neurons are not clustered together in a single brain region, it is currently impossible to identify them *in vivo* and undertake single-cell recordings. However, by targeting multiunit electrodes to the mediobasal hypothalamus, in the vicinity of the GnRH axons passing to the median eminence, a good correlation has been found between electrical activity in this region and pulsatile luteinizing hormone (LH) secretion *in vivo*. Although this has proven useful, the phenomenon is observed clearly only in ovariectomized animals, where GnRH pulsatility is at its most frequent. Furthermore, the identity and nature of this multiunit activity have not been defined and it is unclear whether this activity represents electrical activity in the GnRH neurons. Another strategy for examining electrical properties of the GnRH neuron has been that of making recordings from immortalized GnRH-secreting cell lines, such as the GT1 cells. Although these studies have demonstrated that GT1 cells have autonomous pulsatile activity and identified the presence of multiple neuron-specific channels and signaling pathways, the properties of an immortalized cell line *in vitro* are very unlikely to represent those of the native GnRH neuron within the brain. The use of organotypic explant cultures derived from the embryonic nose has provided a better model for the investigation of native GnRH neurons, and studies here have also suggested that GnRH neurons may have an inherent episodic nature. However, once again, it may be dangerous to interpret these results in terms of the GnRH neuron *in vivo*.

The most useful strategy for determining the electrical properties of the native GnRH neurons in the postnatal brain has come about through the acute brain slice approach. In this procedure, the electrical activity of native GnRH neurons can be recorded in their normal environment although the cells have usually had their axons, and possibly distal dendrites, cut off. The identification of the GnRH neuron in the brain slice preparation has remained troublesome due to their scattered topography but progress has been made through the "blind" recording of cells with a bipolar morphology and then determining whether they are GnRH neurons (or not) by postidentification GnRH immunocytochemistry or single-cell reverse transcriptase-polymerase chain reaction (RT-PCR). A further refinement to this technique has been to create transgenic rodents in which the GnRH promoter is used to direct the expression of molecules that can be visualized, such as green fluorescent protein, specifically to the GnRH neurons. This then enables GnRH neurons to be preidentified by examination of the brain slice under a fluorescence microscope. Although some uncertainties exist with this approach, it remains the most rapid method available for collecting electrophysiological data on GnRH neurons *in situ*.

Studies using the brain slice approach have now shown that, despite their unusual origins, the GnRH neurons exhibit conductances and general membrane properties similar to those of most other neurons in the brain. These include the identification of a variety of potassium (I_A, I_{IR}, and I_K) and calcium (high- and low-voltage-activated) channels as well as tetrodotoxin-sensitive sodium channels in spontaneously firing GnRH neurons. A little disappointingly, no clear electrophysiological "fingerprint" for the GnRH neuron has arisen as yet. However, one clear feature of the GnRH neurons that has emerged is the marked degree of heterogeneity present in their electrical behavior. Firing rates and patterns vary considerably and range from complete silence, through intermittent bursting, to continuous steady firing. Furthermore, the presence of different calcium and potassium channels is also variable within the GnRH neuronal population and, apparently, irrespective of their morphology or location within the GnRH neuron continuum. The same phenomenon of marked heterogeneity has been found in the expression of "activity-dependent" immediate-early genes by the GnRH neuronal population. Although some of the phenomena observed to date may be explained by technical considerations, it is apparent that the GnRH neurons do not exhibit nearly as homogenous an electrophysiological profile as other neuroendocrine populations involved in pulsatile

pituitary hormone release, such as the magnocellular oxytocin or vasopressin neurons.

In terms of understanding the key issue of GnRH pulsatility and its origins, much has yet to be learned. Work involving the GT1 cells and organotypic embryonic GnRH neurons suggests that individual GnRH neurons may exhibit inherent pulsatility on an approximately 30 min periodicity. The electrical recordings made from GnRH neurons *in situ* have not yet confirmed or refuted this hypothesis. Although there is evidence that some GnRH neurons can exhibit bursting behavior, this is very variable in duration and timing, and its relationship to the pulsatile release of GnRH *in vivo* is unclear. Intriguingly, it appears that the electrical activity of the GnRH neuron is not altered markedly when evaluated before and after puberty. Clearly, this does not correlate with the marked increase in gonadotropin release that occurs at puberty in mammals and, interestingly, suggests that the absolute firing rate of individual GnRH neurons may not be strongly related to the release of GnRH from nerve terminals in the median eminence. Whether this results from a technical artifact, such as the cutting of critical inputs to GnRH neurons in the slice preparation, or provides us with a unique insight into the mechanisms underlying pulsatile GnRH secretion is unknown at this point. Although comprehensive data are currently lacking from GnRH neurons *in situ* within the mature brain, current data favor the likelihood that GnRH neurons do possess inherent pulsatile activity but that this needs to be entrained by external influences upon the cell.

In much the same way as the difficulty in obtaining good electrophysiological data on native GnRH neurons has prevented any definitive knowledge about GnRH neuron pulsatility, the nature of GnRH neuron synchronization remains obscure. It has not yet been established whether a pulse of LH arises from the activation of all GnRH neurons projecting to the median eminence or just a subpopulation or, even then, whether the same subpopulation of GnRH neurons is activated for each pulse. Nevertheless, it is reasonable to assume that a degree of synchronization must exist among some GnRH neurons. The potential mechanisms underlying synchronization are numerous. However, its seems unlikely that this occurs through direct electrical communication at the level of the cell body. Not only are nearly all GnRH cell bodies remote from one another, but no evidence of functional dye-coupling has been found in mouse GnRH neurons to support the presence of gap junctions in native GnRH neurons. Instead, the scattered distribution of these cells favors the existence of neurochemical intermediates that coordinate the GnRH neurons. This may exist in the form of diffusible molecules, such as nitric oxide, or more classically, as synaptic-released neurotransmitters from neurons within the GnRH neuronal network. The potential for GnRH neurons to communicate with one another through collateral innervation using GnRH itself as a neurotransmitter has long been suggested, but definitive proof for a role in pulsatility has not been forthcoming. Thus, although the need for synchronization among the GnRH neurons is likely, the underlying mechanisms remain unknown.

III. SYNAPTIC AND HORMONAL INPUTS

The ability to regulate the pulsatile release of GnRH through the ovarian cycle and in response to factors such as stress and nutrition is critical for reproductive homeostasis. As such, it is important that the electrical activity of the GnRH neurons can be altered by the neural network responsible for regulating fertility. This may occur at the level of the GnRH cell bodies or at their nerve terminals located in the median eminence.

Currently, there is little evidence for the presence of synapses on GnRH nerve terminals. However, there is substantial *in vitro* evidence showing that a wide range of neurotransmitters and neuropeptides can influence GnRH secretion from the median eminence. This suggests that the nerve terminals are a site of regulation but that this may occur through nonsynaptic mechanisms. For example, "volume transmission" may exist whereby neurochemicals are released from nearby nerve terminals and diffuse a short distance through the extracellular matrix to influence the GnRH terminals. Although this would not provide specific targeting of any signal to the GnRH nerve terminals, the expression of specific receptors by GnRH nerve terminals may provide a degree of selectivity. The molecules capable of influencing GnRH secretion in this way may also arise from nonneuronal sources, such as glial and endothelial cells in the vicinity of the GnRH nerve terminals.

In contrast to the GnRH nerve terminal, there is good evidence for the presence of synapses on GnRH perikarya. However, a common observation has been that there are relatively few synapses on GnRH cell bodies and proximal dendrites compared with neighboring non-GnRH neurons. Although the innervation density of distal dendrites has not yet been

examined, these data have suggested that the direct regulation of GnRH neurons at the level of the cell body may be undertaken by a relatively small number of afferent neurons. Importantly, the perikarya of GnRH neurons in the female rat and sheep have been shown to have twice as many synapses as GnRH neurons in males. Thus, sexually dimorphic afferent inputs to the GnRH neuron may underlie some of the marked sex differences that exist in the regulation of GnRH secretion in mammals.

An important goal has been to establish the identity of these primary afferents to the GnRH cell body, and electron microscopic experiments have identified the presence of a wide variety of different neurotransmitters and neuropeptides within nerve terminals synapsing on GnRH perikarya (Fig. 2). In association with *in vivo* data showing that these compounds alter LH secretion when infused into the brain, these findings have resulted in a perplexing situation whereby each of a large number of different neurotransmitters has been postulated to provide a small but direct input regulating the activity of the GnRH neuron. Furthermore, dual-labeling studies have provided ample evidence for the heterogeneous expression of various neurotransmitter receptors by GnRH neurons, once again adding the issue of heterogeneity to the problem of understanding the neural regulation of these cells.

Electrophysiological experiments in the mouse have now begun to provide a functional hierarchy for these multiple putative inputs to the GnRH cell body. Recent studies have shown that the great majority of postsynaptic currents in GnRH neurons originate from the actions of GABA or glutamate and that 100% of GnRH neurons respond to these two amino acids. The effects of GABA are mediated principally by the $GABA_A$ receptor, although $GABA_B$ may also have a role in other species, whereas both *N*-methyl-D-aspartate (NMDA) and AMPA (α-amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid) receptors are responsible for the excitatory effects of glutamate (Fig. 2). Experiments using single-cell RT-PCR have further been able to profile the $GABA_A$ receptor subunit messenger RNAs expressed by GnRH neurons in the mouse. These studies clearly indicate that, like most forebrain neurons, the amino acid neurotransmitters GABA and glutamate are the most important in terms of the ongoing regulation of GnRH neuron activity. The effects of the various putative neuropeptide regulators of GnRH neurons have yet to be examined in detail although GnRH neurons in the guinea pig have been

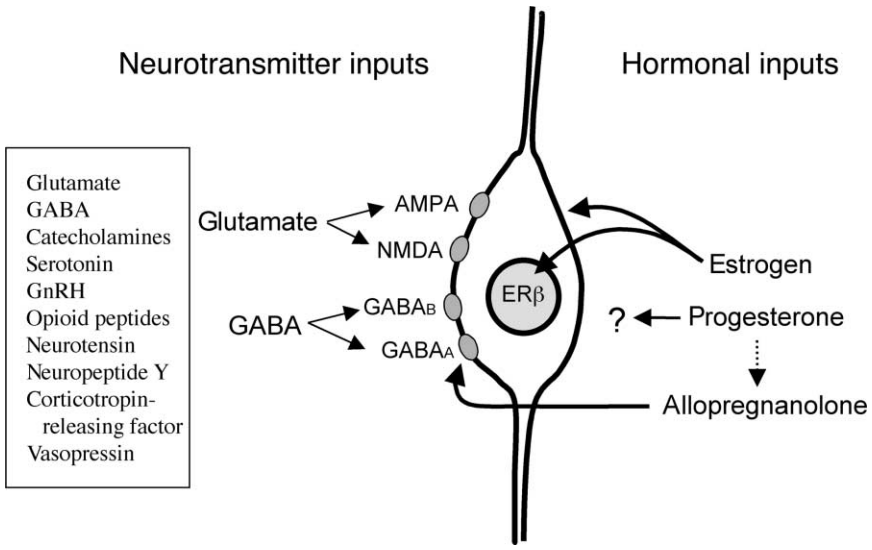

FIGURE 2 Schematic diagram depicting established synaptic and hormonal inputs that impinge directly upon mammalian GnRH neurons. Neurotransmitters that have been identified in terminals synapsing on GnRH neurons by electron microscopy are indicated in the box (left). The amino acids glutamate and GABA have been shown by electrophysiology to mediate most ongoing postsynaptic activity in mouse GnRH neurons through AMPA and NMDA and through $GABA_A$ as well as $GABA_B$ receptors, respectively. Estrogen may exert both direct membrane and classical transcriptional influences (through estrogen receptor β) on GnRH neurons. Progesterone's ability to influence GnRH neurons directly is not clear but, following its rapid conversion to allopregnanolone in the brain, can enhance the inhibitory action of GABA through the $GABA_A$ receptor.

shown to express functional μ opiate receptors. Some of the neuropeptides may be found to subserve distinct functional roles in the regulation of GnRH neuron activity and secretion.

Whereas the synchronization and regulation of GnRH neurons are very likely to be dependent upon other neurons within the GnRH network, there is a possibility that one important influence upon the GnRH neurons occurs in a direct manner. Gonadal steroids act as important "feedback molecules" that relay information on the status of the ovaries and testes to the GnRH neuron. In the female, estrogen and progesterone can exert stimulatory (positive feedback) or inhibitory (negative feedback) actions upon GnRH biosynthesis and GnRH secretion. The initial site of positive feedback appears to occur remotely from the GnRH neurons in several species and must therefore require intermediary cells to transmit the information to the GnRH neurons, but some of the inhibitory effects may occur directly. Recent studies have demonstrated that GnRH neurons express estrogen receptor β (ER-β), thus providing a direct route through which estrogen can regulate gene expression in these cells (Fig. 2). The genes potentially regulated by estrogen in GnRH neurons are not firmly established but might conceivably include those regulating neurotransmitter and ion channel function.

Increasing evidence indicates that gonadal steroids may also exert rapid nonclassical, direct actions upon GnRH neurons. Studies in the guinea pig have shown that estrogen can exert rapid inhibitory effects on the membrane of GnRH neurons that involve the modulation of potassium channels. Although no evidence has yet been found for a direct effect of progesterone itself on GnRH neurons, electrophysiological studies in the mouse have shown that allopregnanolone, which is rapidly synthesized from progesterone in the brain, acts to allosterically enhance the activity of $GABA_A$ receptors expressed by GnRH neurons (Fig. 2). Thus, both estrogen and progesterone may contribute to negative feedback in a direct manner by direct actions at the GnRH cell membrane. The mechanisms through which androgens may influence GnRH neurons are not known. These studies indicate that the important regulatory influence of gonadal steroids on the GnRH neurons may occur through direct membrane actions or ERβ-mediated transcriptional events, as well as following the gonadal steroid modulation of glial or other neuronal elements within the GnRH network.

IV. SUMMARY

The GnRH neurons are a critical element of the neural network controlling fertility. As a consequence of their unique embryonic origin within the olfactory placode, these neurons undertake an extraordinary migration through the nose and into the brain during embryogenesis. The resultant scattered distribution of the GnRH cell bodies within the septum and hypothalamus has greatly hindered the investigation of this phenotype but new approaches, particularly the use of GnRH promoter transgenics, are providing rewarding avenues for elucidating their properties. One recurring phenomenon encountered when investigating these cells is the marked degree of heterogeneity that exists at essentially all levels within the GnRH neuronal phenotype. The functional significance of this heterogeneity remains to be established. Although key issues such as the nature of pulsatility and synchronization within the GnRH population *in vivo* also remain unresolved, the amino acid neurotransmitters glutamate and GABA have now been identified as central molecules regulating the excitability of GnRH neurons. In addition, the important regulatory influence of gonadal steroids on the GnRH neuron appears likely to occur in part through both direct membrane and classical genomic mechanisms.

Glossary

gonadotropin-releasing hormone A decapeptide released by a specific population of hypothalamic neurons to regulate the secretory activity of pituitary gonadotrophs. Also known as luteinizing hormone-releasing hormone.

neural network A group of interconnected neurons and associated glial cells that perform a specific brain function.

organotypic culture An *in vitro* experimental tissue preparation in which the organization of the (brain) cells resembles their *in vivo* organization.

reverse transcriptase-polymerase chain reaction A method through which RNA is transcribed into complementary DNA and then the amounts of a specific cDNA are amplified in an exponential manner to enable detection. This approach can be used to determine the mRNAs expressed by single neurons.

Gonadotropin-Releasing Hormone Ontogeny

OLINE K. RØNNEKLEIV* AND ROBERT B. NORGREN, JR.†

**Oregon Health and Sciences University* • *†University of Nebraska Medical Center*

Gonadotropin-releasing hormone (GnRH) neuronal cell bodies are diffusely located in the brain, primarily in the preoptic region and basal hypothalamus. Axons from this network of neurons project to the median eminence and secrete GnRH into the portal vessels of the anterior pituitary gland. GnRH acts on the pituitary gonadotropes to control the secretion of luteinizing hormone and follicle-stimulating hormone. GnRH neurons are unique in their development and also undergo critical functional changes related to two important events in human development: puberty and menopause. This article, however, will focus on early events in the development of GnRH neurons, specifically their differentiation and migration.

I. INTRODUCTION

Early in gestation, gonadotropin-releasing hormone (GnRH) neurons originate outside the brain in the nasal (olfactory) placode and migrate along olfactory, vomeronasal, or terminal nerves into the telencephalon. Once in the telencephalon, GnRH neurons migrate to their final destination, primarily the hypothalamus. The cellular substrates and molecular cues that guide GnRH neuronal migration have been extensively investigated because of specific interest in the development of this critical component of the reproductive system. In addition, this is an ideal model for the general study of neuronal migration due to easy identification of migrating GnRH neurons in some species of birds and mammals.

II. DEVELOPMENT OF TERMINAL, VOMERONASAL, AND OLFACTORY NERVES AND GnRH NEURONS

The nasal placode (nasal epithelium) gives rise to the olfactory, vomeronasal, and terminal nerves. The olfactory sensory neurons located in the olfactory epithelium (OE) project to the olfactory bulb. This projection mediates the sensation of smell. Sensory neurons in the vomeronasal organ (VNO), located at the base of the nasal septum (Fig. 1), project to the accessory olfactory bulb in most vertebrates, with the exception of birds. The VNO is a chemoreceptive structure that is thought to mediate pheromone-stimulated reproductive behavior in mammals. In the human, this structure develops from the medial nasal mucosa at approximately gestational days 50–60, but almost completely degenerates by approximately day 80 of gestation (Fig. 1). It has long been known that neurons migrate out of the nasal placode and vomeronasal organ early in development and form neuronal clusters that connect the VNO to the brain. These clusters of neurons and their fiber projections are termed the terminal nerve. The cell

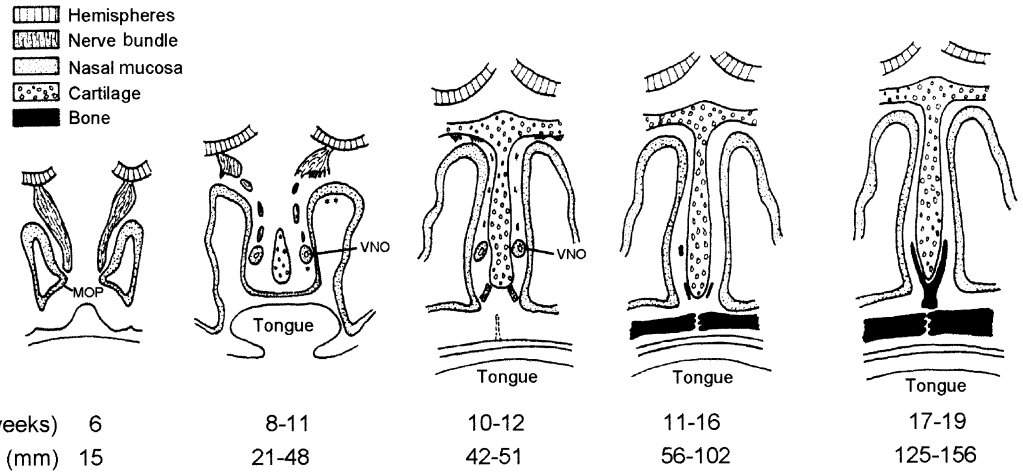

FIGURE 1 Stages of development of the human nasal cavity, evaluated on frontal sections of the nose from fetal ages 6–19 weeks. MOP, medial olfactory pit; VNO, vomeronasal organ; CR, crown rump. Adapted from Kjaer, I., and Fisher Hansen, B. (1996). The human vomeronasal organ: Prenatal developmental stages and distribution of luteinizing hormone-releasing hormone. *Eur. J. Oral Sci.* **104**, 34–40, with permission from Blackwell Publishing.

bodies of the terminal nerve, which are found at various locations along the VNO projection pathway, are referred to as the ganglia of the terminal nerve. The terminal nerve, which is distinct from the vomeronasal nerve, sends projections to a number of forebrain regions including the septum and preoptic area (POA).

The presence of GnRH-containing neurons within the peripheral and central parts of the terminal nerve was first described in mammals in the early 1980s. This led to the idea that the terminal nerve might be an additional source of GnRH besides the POA-basal hypothalamus (BH) population of neurons. However, in the late 1980s, based on studies of GnRH distribution in amphibians, it was proposed that GnRH neurons are derived embryologically from the terminal nerve, which originates in the nasal placode and VNO during development. Shortly thereafter, experimental evidence was obtained showing that GnRH neurons originating in the nasal (olfactory) placode migrate along vomeronasal and terminal nerves to reach the brain. This phenomenon has now been described in teleost fish, amphibians, birds, rodents, monkeys, and humans.

III. DIFFERENTIATION OF GnRH NEURONS

The exact location of the source of GnRH neurons is controversial. Most investigators have suggested that these cells originate in the medial olfactory epithelium, which is where they are first observed during development. However, evidence has been put forth that they may arise in the respiratory epithelium or in the border zone between the olfactory epithelium and the respiratory epithelium. The olfactory and the respiratory epithelia are both derived from the nasal placodes, which are bilateral ectodermal thickenings on the ventrolateral sides of the head. In contrast to the respiratory epithelium, the composition of the developing OE has been studied extensively and a wealth of transcription factors that may be involved in the induction and differentiation of the various cell types are expressed in the OE during early development. Some of these factors, such as Olf-1, GATA-4, and nestin, are also transiently expressed in GnRH neurons. However, their specific roles in GnRH neuronal development are unknown. Experiments with null mutant mice suggest that the transcription factor activator protein 2 alpha, which is normally expressed by the respiratory epithelium, appears to prevent GnRH differentiation in this tissue. The origin of other cell types, such as those containing γ-aminobutyric acid (GABA), somatostatin, neuropeptide Y, tyrosine hydroxylase, and galanin, that migrate within the vomeronasal or terminal nerves remains to be determined.

IV. GnRH NEURONAL MIGRATION

GnRH in some species, such as the rhesus monkey, the mouse, and the chicken, is expressed at the earliest stages of migration, i.e., as neurons leave the olfactory epithelium or VNO. Therefore, in these species, it is possible to describe the migration

pathway using immunohistochemistry or *in situ* hybridization. Thus, it has been established that GnRH neurons migrate from the medial olfactory epithelium in close association with vomeronasal (mammals) or olfactory (chicken) nerves to the rostral telencephalon, where the future accessory olfactory and olfactory bulbs will form. During migration in the nasal cavity, GnRH cells form "tracks" that extend from olfactory areas to the forebrain (Fig. 2). As the fetus develops, the number of GnRH cells within the nasal area greatly decreases and the number within the brain increases. The period for development and migration is specific for each species that has been studied.

Thus, during development in mice starting at approximately embryonic day 11.5, GnRH cells migrate from the olfactory epithelium into the brain and then migrate caudally to reach their final destination by embryonic day 16.5 of a 20-day gestation period. In rhesus monkey, GnRH immunoreactive cells are detected within the medial olfactory epithelium and in nerve bundles of the nasal septum on days 32–36 of a 165-day gestation. During this period, GnRH cells are not found in the brain, but GnRH fibers extend from the nasal area into the brain and bilaterally along the ventral surface of the brain from the olfactory region rostrally to the basal hypothalamus caudally (Fig. 2). By day 38 of gestation, GnRH cells are also localized in the olfactory region of the brain. With increasing fetal age, there is a gradual caudal extension of GnRH cells, and the cells appear in the basal hypothalamus at approximately 47 days of gestation with an adult-like distribution by days 55–60 (Fig. 2). More limited information about GnRH neuronal migration is known in human, in which GnRH cells are present in the medial olfactory epithelium, nasal septum, and rostral forebrain at approximately day 42 of gestation.

GnRH cells migrate through the nasal septum and into the forebrain via the vomero-nasal and terminal nerves in mammals or via the medial part of the olfactory nerve in birds. After entering the brain, GnRH neurons appear to reach the septal–preoptic area and basal hypothalamus by routes that vary depending on the species. In mice the route appears to be associated with peripherin-containing axonal fiber pathways. In primates, a few "pioneer" GnRH neurons appear to lead the remainder "follower" GnRH neurons as they migrate out of the placode. Thus, GnRH neurons track along neurites of other GnRH neurons in what is termed neurophilic migration. The majority of GnRH neurons appear to follow the path laid by GnRH fibers through a

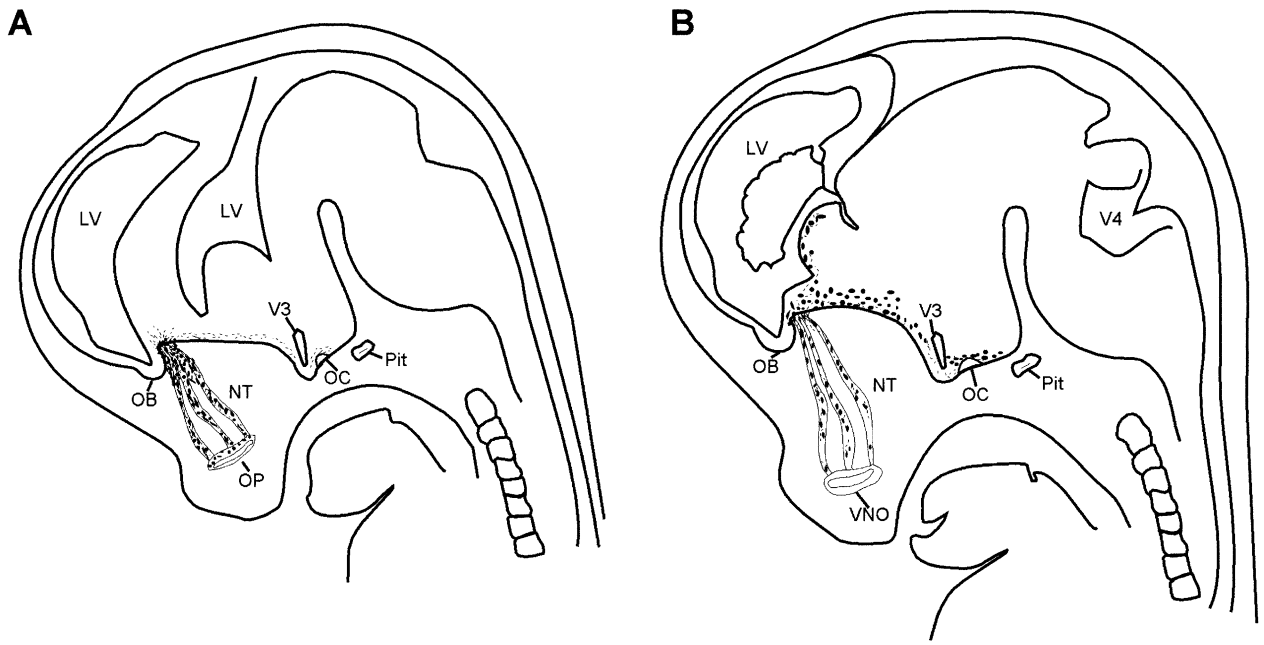

FIGURE 2 Schematic drawings of the primate head at approximately 36 (A) and 50 (B) days of gestation, illustrating GnRH neuronal migration pathways. The large dots represent GnRH neurons, and the thin, stippled lines represent GnRH fibers. LV, lateral ventricle; NT, terminal nerve; OB, olfactory bulb; OC, optic chiasm; OP, olfactory placode; Pit, pituitary; V3, third ventricle; V4, fourth ventricle; VNO, vomeronasal organ.

ventral GnRH fiber path to the POA and basal hypothalamus. However, a portion of the migrating cells travel dorsally accompanied by GnRH fibers in the septal area, along periventricular regions of the lateral ventricles and interventricular foramen to hypothalamic regions. The guiding mechanism(s) of GnRH neuronal migration along a ventral and dorsal path is currently unknown.

There is widespread agreement that most neuroendocrine GnRH neurons originate in structures derived from the nasal placode. However, there is substantial evidence that there are other populations of GnRH neurons that do not appear to be derived from the nasal placode. These nonolfactory GnRH neurons are found in the striatum, thalamus, lateral septum, bed nucleus of the stria terminalis, and midbrain. Most likely, these neurons originate in the subventricular zone of the forebrain. They are substantial in number (at least 10,000 in primates), but their functions are unknown.

V. FACTORS CONTROLLING GnRH NEURONAL MIGRATION

Several lines of evidence indicate that vomeronasal and terminal nerve axons are critical in guiding the GnRH neurons to the brain. First, in Kallmann's syndrome patients, who are anosmic and hypogonadal, olfactory, vomeronasal, and terminal nerves extend toward the brain but do not enter the telencephalon. GnRH neurons are produced and migrate within the nasal area but do not enter the brain. Instead, they remain outside the brain in the nasal cavity and within the dural layers of the meninges on the dorsal surface of the cribriform plate. Second, experimental studies in chicken embryos have demonstrated that GnRH neurons follow misdirected olfactory nerve axons to ectopic locations, including the pons, a region in which GnRH neurons are normally never found.

The dependence of GnRH neurons on nasal area nerves to gain entrance to the brain raises two questions: First, what are the molecular cues that guide olfactory, vomeronasal, and terminal nerve axons into the brain? And second, what is the molecular mechanism by which GnRH neurons maintain their close association with these nerve axons? The search for important guidance and adhesion molecules has led to many descriptive studies demonstrating that a variety of molecules are expressed along the GnRH neuronal migration pathway. Experimental evidence that these molecules are necessary for GnRH neuronal migration is much more limited.

The cloning of the KAL1 gene, which is mutated in Kallmann's syndrome, provides one obvious candidate for olfactory and vomeronasal nerve ingrowth to the brain. The KAL1 protein is predicted to be a secreted extracellular matrix protein with several fibronectin type III repeats, which occur in many neural cell adhesion molecules. Interestingly, studies in chick and humans are not in agreement regarding the expression profile of KAL1 mRNA in the developing olfactory bulb. However, in both species, KAL1 has been found not to be expressed in the nasal cavity along the path of migrating GnRH neurons. Detailed studies in chicken have demonstrated that olfactory neurons, GnRH neurons, and the mesenchymal tissue through which these neurons migrate do not express the KAL1 gene. Studies of human fetal brains, although more limited, similarly provide evidence that KAL1 is not expressed along the olfactory and GnRH migratory paths. In both species, the KAL1 gene is expressed in the olfactory bulb, which has led to the hypothesis that the genetic defect underlying Kallmann's syndrome is a disruption of the movement of nerve fibers from the nose to the brain. The failure to discover a mouse KAL1 homologue has prevented the production of null mutant experimental animals thus far. These problems have slowed the progress of developing models to explore the mechanism by which KAL1 facilitates GnRH migration.

A number of other molecules have been suggested to mediate GnRH neuronal migration in association with vomeronasal nerve axons. Neural cell adhesion molecule (NCAM) is strongly expressed in the olfactory and vomeronasal nerves during development; it is possibly expressed in migrating GnRH neurons, although this is controversial. Since NCAM is a well-studied homophilic adhesion molecule, it has been suggested that it may mediate GnRH neuronal migration. However, NCAM null mutant mice do not exhibit any deficits in either olfactory nerve ingrowth or GnRH neuronal migration. This suggests that NCAM is not necessary for GnRH neuronal migration, perhaps due to functional redundancy in that its role may be taken over by other cellular components. Also, a number of other factors may in certain circumstances be induced to direct migration of these neurons that are so critical for maintaining species survival.

The neurotransmitter GABA has been found to influence GnRH neuronal migration both *in vitro* and *in vivo* and multiple effects of GABA agonists and

antagonists have been demonstrated. Within the nasal compartment, a subset of GnRH neurons express GABA, and treatment with $GABA_A$ agonists inhibits GnRH migration out of this area. Therefore, it is reasonable to suggest that GABA is involved in regulating the rate of GnRH neuronal migration from the nasal area to the brain. Interestingly, it has been shown in a number of species that migrating GnRH neurons normally "rest" for 1–3 days at the CNS border before entering the brain. The specific molecular mechanism, including a role for GABA in this delaying process, needs to be elucidated. The most striking result of GABA modulation is the disorganization of migrating GnRH neurons in the brain after the $GABA_A$ receptor is blocked with bicuculline. After such treatment, the GnRH neurons and the peripherin-containing fibers along which GnRH neurons are believed to migrate become disassociated. Thus, there is good evidence that GABA may be involved in GnRH migration; however, it is likely that additional molecules remain to be identified.

VI. SUMMARY

Since the discovery in the late 1980s that GnRH neurons migrate into the brain in association with olfactory and vomeronasal nerves, significant progress has been made in understanding the development of these neurons. In normal intact animals, GnRH neurons are first observed in the olfactory placode. Therefore, the assumption has been that GnRH progenitors originate in the olfactory epithelium. However, various experimental manipulations have provided evidence that GnRH neurons may develop in the border zone between the respiratory epithelia and the chemosensory epithelia. Future studies are needed to solve this issue. GnRH neurons are dependent on vomeronasal or terminal nerves to reach the brain, in a process that may involve both NCAM and GABA, and most likely a number of currently unknown factors are also involved. The KAL1 protein is necessary for olfactory nerve and GnRH neuronal entry to the brain by an unknown mechanism. Once in the brain, GnRH neurons are no longer attached to large nerve bundles; they disperse and find their species-specific location within septal and hypothalamic areas. Not much is known about the mechanism of GnRH migration within the brain, although the expression of GABA receptors in GnRH neurons may be important for the accuracy of migration.

Glossary

activating enhancer binding protein 2 α A transcription factor that is important in embryogenesis and is expressed in the developing respiratory epithelium.

fibronectin type III repeats Repeat sequences found in the Kallmann gene; they were first detected in fibronectin, an extracellular matrix adhesion molecule, and also occur in many neural cell adhesion molecules. The function of these repeats is not well understood, but their presence seems to be important for axonal outgrowth.

GATA-4 A transcription factor that is expressed in cells, including developing GnRH cells, in the olfactory epithelium.

Kallmann's syndrome A genetic disorder associated with an X chromosome deletion at Xp22.3, resulting in anosmia and hypogonadism due to failure of olfactory nerve ingrowth and GnRH neuronal migration during embryonic development

nasal (olfactory) placode Thickening of nasal ectoderm bilaterally; the precursor of the olfactory and vomeronasal epithelia.

nestin An intermediate neurofilament found in proliferating neural precursor cells. Nestin mRNA and protein are temporarily expressed in developing GnRH neurons.

neural cell adhesion molecule A large cell surface glycoprotein along which neurons may migrate.

neurophilic neuronal migration Movement of neurons that occurs via the preferential adherence of the neurons to the surface of apposing axons.

Olf-1 A transcription factor that is expressed in cells, including developing GnRH cells, in the olfactory epithelium.

terminal nerve A ganglionated cranial nerve that is in part embedded within the olfactory nerves in the nasal area, enters the brain caudal to the olfactory bulbs, and has projections to the septal and preoptic areas of the brain.

vomeronasal organ Chemosensory organ that sends projections to the accessory olfactory bulbs and transmits pheromone-related stimuli to the brain.

Gonadotropin-Releasing Hormone Pharmacology: Agonists and Antagonists

JEAN RIVIER* AND P. MICHAEL CONN†

The Salk Institute, La Jolla • †Oregon National Primate Research Center

The roles of endogenous peptides acting as regulatory molecules present potential strategies for diagnosis and pharmacologic intervention in a broad range of physiologic and pathophysiologic processes. Antagonists to these endogenous peptides are recognized as potential therapeutic agents in an ever-increasing number of disease states. In most cases, however, it is difficult to realize the therapeutic potential of a naturally occurring peptide because of short duration of action, multiple pharmacologic activities due to multiple sites of action, or low bioavailability within the bounds of convenient routes of administration. Peptide analogues are therefore designed to fulfill the needs that are either not satisfied or only partially satisfied by the parent compounds. Analogues with higher affinity for their receptor and higher resistance to biodegradation may be more potent and longer acting than the native peptides. This article examines the design of peptide gonadotropin-releasing hormone agonists and antagonists and nonpeptide antagonists, as well as their mechanisms of action and clinical significance.

I. INTRODUCTION

The structure of gonadotropin-releasing hormone (GnRH; pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2) was first disclosed at the Endocrine Society meeting on June 24, 1971, by Andrew V. Schally, preceded by the submission of three reports that were published a few weeks after this meeting. In the first report, Schally and co-workers described the isolation and properties of the follicle-stimulating hormone (FSH) and luteinizing hormone (LH)-releasing hormone; in the second, the proposed structure of the

porcine LH- and FSH-releasing hormone was given, and in the third, they confirmed the structure of porcine GnRH by conventional sequential analysis. This pioneering work in peptide isolation, sequencing, and synthesis was recognized in 1977 when Schally shared the Nobel Prize in Medicine with Roger Guillemin and Rosalyn Yalow. The structure of mammalian GnRH was confirmed by the total synthesis, isolation, and characterization of ovine GnRH. At present, 14 different members of the GnRH family have been fully characterized (Table 1). Except for 2 of these structures (guinea pig with a tyrosine at position 2 and lamprey I with a tyrosine at position 3), they all share six amino acids (four at the N-terminus including the posttranslationally modified pyroglutamic acid derived from glutamine and two at the C-terminus including the posttranslationally modified primary amide derived from a glycine residue followed by two basic residues in the precursor).

Competitive antagonists of several regulatory peptides (GnRH, vasopressin, parathyroid hormone, corticotropin-releasing factor, vasoactive intestinal peptide, and bombesin, among others) have been developed and shown to be useful for the elucidation of their mode(s) of action and ultimately for therapeutic applications. Development of orally active peptides is a high priority of pharmacologists, and preliminary results would indicate that both resistance to enzymatic degradation and small molecular size may play an important role for diffusion into the bloodstream after oral administration, and solubility in the physiological milieu may be important for controlled release after formulation in cases of parenteral administration.

This article reviews the design of peptide GnRH agonists and antagonists, nonpeptide antagonists, what is known of their mechanism of action, and some highlights of their clinical significance. Early structure–activity relationship (SAR) studies for both agonists and antagonists were described by Karten and Rivier in 1986. Patent and scientific literature of nonpeptide antagonists was reviewed recently.

II. PEPTIDE AGONISTS

A. Structure–Activity Relationships

The original premise for the design of GnRH agonists was both academic and pragmatic. Academically, it was important to understand the structural basis of GnRH agonists and this could be determined through SAR studies and physicochemical measurements such as NMR. Pragmatically, it was hypothesized that the LH-releasing and ovulation-inducing effects of GnRH observed in laboratory animals could be applied to the treatment of male and female infertility. However, the GnRH molecule is very flexible in solution and crystals could not be obtained, therefore jeopardizing efforts to generate structure-based models of the bioactive conformation of GnRH. Additionally, the half-life of GnRH is very short, and more potent and long-acting analogues were thought to be necessary for practical clinical utility.

Tunicate II (t-II)	—	—	—	—	Leu	Cys	His	Ala	—	—

[a]Only amino acids that are different from the sequence of mammalian GnRH are indicated.

Two major discoveries, the deletion of the C-terminal glycine amide and its substitution by an ethylamide and the introduction of a D residue at position 6, are the basis for the generation of long-acting, very potent agonists, also called superagonists. Ironically, these superagonists have antireproductive effects.

An abbreviated list of agonists used clinically in the past 25 years is shown in Table 2. Although the *in vitro* potency of these analogues varied considerably, their *in vivo* efficacy is comparable.

B. Mode of Action

The mechanism of action of these agonists can be divided into two types. First, short-acting compounds, given in pulses or on a single occasion, can be used to stimulate the receptor or test functioning of the axis. Long-acting agents (given to maintain elevated levels of the peptide) result in a refractory status due to loss of receptor and loss of receptor–effector coupling. The result is diminished release of gonadotropins and, therefore, steroids. This is a valuable therapeutic approach to steroid-dependent cancers. This latter type is dependent on metabolically stable analogues useful to maintain serum levels.

C. Indications

GnRH and long-acting GnRH agonists are currently being used for the management of the human disorders male and female infertility, precocious puberty, endometriosis, prostate cancer, uterine bleeding and leiomyoma, cryptorchidism, and others, and they are also used as protection during chemotherapy.

III. PEPTIDE ANTAGONISTS

A. Structure–Activity Relationships

The original premise for the design of GnRH antagonists was both academic and pragmatic. Academically, it was important to be able to block LH and FSH release in order to assess the physiological role of GnRH. Pragmatically, it was hypothesized that the LH-releasing and ovulation-inducing effects of GnRH observed in laboratory animals could be blocked with a competitive antagonist, thus opening new contraceptive avenues.

The design for potent GnRH peptide antagonists with adequate solubility, high affinity for the GnRH receptor, low potency in releasing histamine, and long duration of action was achieved following what is herein referred to as a "conventional approach" to the design of GnRH antagonists. Incremental increases in potency and duration of action were obtained mostly by intuition and trial and error. Several observations are now recognized as having played a critical role in the design of those antagonists that reached the clinic (see Table 3). Among these, substitution of Arg by ILys yielded analogues with considerably reduced histamine-releasing activity and substitution of the E-substituted lysines (L and D, respectively) at positions 5 and 6 by amino phenylalanines resulted in analogues with extended duration of action. Finally, optimization of the substituents on the ω-amino function of Aph^5 and Aph^6 yielded FE200486, currently under development.

With regard to the pharmacological properties of the analogues described in Table 3, ganirelix, abarelix, azaline B, cetrorelix, and FE200486 have very similar binding affinities and relative potencies. Additionally, some of them are more potent than others with regard to their ability to release histamine. They are listed in Table 3 in order of decreasing potency. For the safest analogues, the highest dose administered does not cause release of histamine to the full extent available in the assay.

What is most striking is that the duration of action after subcutaneous injection in mannitol (Table 3) is unpredictable on the basis of the primary structure although very reproducible from one assay to the next. The reason for that behavior of the peptides

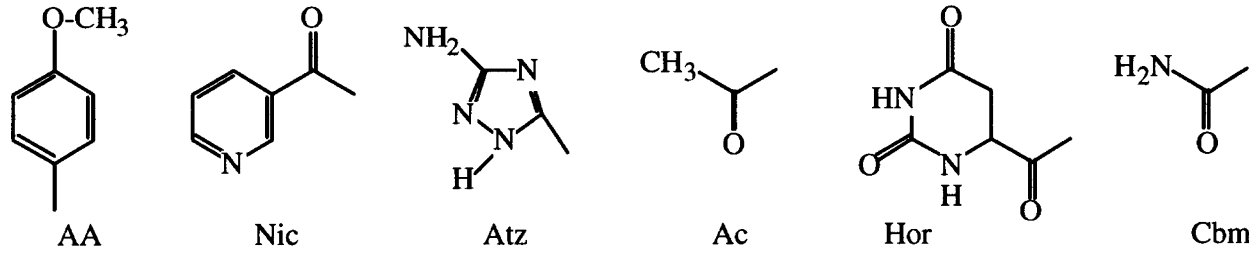
TABLE 2 GnRH Agonists in the Clinic

Compound	Accepted designation	Company/sponsor
[DLeu^6,Pro^9-NHEt]GnRH	Leuprorelin (Leuprolide)	TAP Pharmaceuticals
[DSer(tBu)^6,Aza-Gly^{10}]GnRH	ICI 118630	ICI Pharmaceuticals
[DSer(tBu)^6,Pro^9-NHEt]GnRH	Buserelin	Hoechst (Aventis)
[DHis(Bzl)^6,Pro^9-NHEt]GnRH	Histrelin	Ortho
[DTrp^6]GnRH	Tryptorelin	Debiopharm
[DTrp^6,Pro^9-NHEt]GnRH	Deslorelin	Salk Institute
[DTrp^6,N-MeLeu^7,Pro^9-NHEt]GnRH	Lutrelin	Wyeth
[D2Nal^6]GnRH	Nafarelin	Syntax Research

TABLE 3 Selected Structures of GnRH Antagonists in the Clinic

Structure	Name	Duration
Ac-Δ^3Pro-DFpa-DTrp-Ser-Tyr-DTrp-Leu-Arg-Pro-Gly-NH_2	4F antagonist	Short
Ac-DNal-DFpa-DTrp-Ser-Tyr-DArg-Leu-Arg-Pro-Gly-NH_2	"Nal-Arg" antagonist	Short
Ac-DNal-DCpa-DPal-Ser-Arg-DGlu(AA)-Leu-Arg-Pro-DAla-NH_2	"Nal-Glu" antagonist	Short
Ac-DNal-DCpa-DPal-Ser-Tyr-DCit-Leu-Arg-Pro-DAla-NH_2	Cetrorelix	Long
Ac-DNal-DCpa-DPal-Ser-Tyr-DHArg(Et_2)-Leu-HArg(Et_2)-Pro-DAla-NH_2	Ganirelix	Intermediate
Ac-DNal-DCpa-DPal-Ser-Tyr-DHci-Leu-ILys-Pro-DAla-NH_2	Antarelix/Teverelix	
Ac-DNal-DCpa-DPal-Ser-*N*-MeTyr-DAsn-Leu-ILys-Pro-Dala-NH_2	Abarelix	Very short
Ac-DNal-DCpa-DPal-Ser-Lys(Nic)-DLys(Nic)-Leu-ILys-Pro-DAla-NH_2	Antide	
Ac-DNal-DCpa-DPal-Ser-Aph(Atz)-DAph(Atz)-Leu-ILys-Pro-Dala-NH_2	Azaline B	Long
Ac-DNal-DCpa-DPal-Ser-Aph(Ac)-DAph(Ac)-Leu-ILys-Pro-DAla-NH_2	Acycline	Long
Ac-DNal-DCpa-DPal-Ser-Aph(LHor)-DAph(Cbm)-Leu-ILys-Pro-DAla-NH_2	FE200486	Very long

Note. Chemical structures of substituents shown in parentheses:



Definition of duration of action in castrated male rat assay (50 μg injection of antagonist is administered sc in 100 μl of mannitol): Very long = over 80% inhibition of LH release at 96 h; Long = over 80% at 72 h but not at 96 h; Intermediate = over 80% at 48 h but not at 72 h; Short = over 80% at 24 h but not 48 h; Very short = no inhibition at 24 h.

seems to lie in their ability to form gels at the site of administration.

B. Mode of Action

Antagonists function by blocking the binding site of the GnRH receptor, thus preventing the (endogenous) agonist from occupying the site. At present, no alteration in the membrane receptor or activation of its effector coupling has been ascribed to antagonists. Much of the challenge of producing useful antagonists has been in minimizing histamine-releasing activity and, at the level of formulation, to achieve long duration of action.

C. Indications

Abarelix is often a useful depot formulation that can be administered on days 1, 15, 29, and 57 and every 28 days thereafter. Because it is the first GnRH antagonist used for a major indication in which chronic administration is a must, the commercial success of this antagonist compared to that of the established superagonist preparations will be important in vindicating those of us who saw in those molecules an opportunity to avoid the undesirable "flare" and to obtain a more profound and prompt inhibition of gonadotropin than is observed with superagonists. This was demonstrated exactly 10 years ago when Pavlou and his colleagues showed that the combined administration of the GnRH antagonist (Nal-Glu) and testosterone replacement in men results in reversible azoospermia without loss of libido, a condition that cannot be attained with the administration of any dose of an agonist. In fact, Broqua *et al.* presented data that emphasized the difference in the efficacy of agonists versus that of antagonists on the growth of the androgen-dependent prostate tumor Dunning R-3327H.

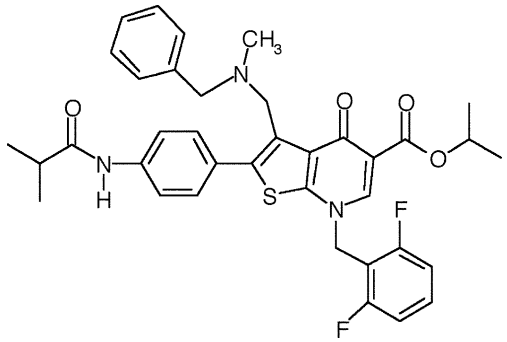


FIGURE 1 Structure of T98475.

The authors concluded that a rapid and complete suppression of plasma testosterone levels was necessary to stop the progression of the Dunning R-3327H rat prostatic tumor growth and therefore that the anti-tumoral activity of FE200486 makes it a promising candidate for prostate cancer treatment.

GnRH antagonists are currently being used for *in vitro* fertilization and are being considered for the same indications as those for which superagonists are promoted. It is believed that GnRH antagonists will replace the superagonists because of the absence of a stimulatory phase (i.e., immediate inhibition) and the observation that antagonists have a more profound effect on gonadotropin inhibition than the superagonists, an effect that is equal to castration in the male, suggesting additional uses such as contraception (suppression of ovulation and spermatogenesis).

IV. NONPEPTIDE ANTAGONISTS

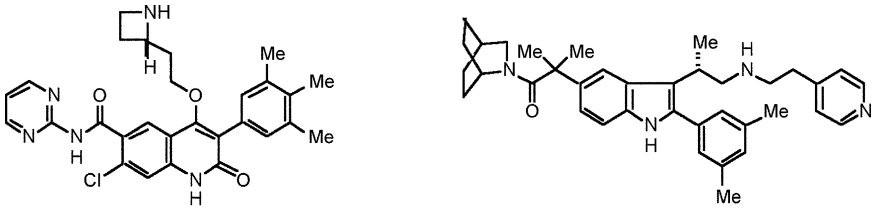
Development of orally active peptides is still in its infancy because of limitations due to gut adsorption, distribution, metabolism, and elimination (ADME).

With the availability of the cloned GnRH receptor, high-throughput screening programs for small nonpeptide molecules were initiated mainly by the pharmaceutical industry. Although there are several patents covering such molecules, only two groups have disclosed their most promising structures in the scientific literature. With an affinity of 0.2 nM on cloned human receptor-bearing cell lines, T98475 was described as having good oral bioavailability (see Fig. 1).

More recently, De Vita *et al.*, at Merck, initiated a program to develop nonpeptide GnRH antagonists by screening their compound collection for binding to the rat GnRH receptor. Leads were identified that ultimately produced the potent and selective GnRH antagonists represented by examples Q2 and In2 (Fig. 2).

The oral bioavailability (F) and pharmacokinetic properties of In2 were suitable for characterization of *in vivo* efficacy (rat $F = 8\%$, $t_{1/2} = 1.0$ h). In the castrated male rat, In2 reduced plasma LH when administered orally at doses of 5 and 10 mg/kg. The duration of effect in the 10 mg/kg experiment was approximately 12 h. This analogue was also reported to be active in the male rhesus macaque.

In short, inhibitory effects obtained *in vivo* with peptide GnRH antagonists are now also obtained with small nonpeptide molecules that bind to the GnRH receptor. Interestingly, these molecules are species specific in that they will bind with different affinities, for example, to rat, monkey, dog, or human GnRH receptors. This raises the question as to whether nonpeptide GnRH antagonists bind to the GnRH receptor at the same site(s) as do peptide antagonists. Additionally, this brings to light the fact that in order to carry out mandatory toxicology before administration to human, nonpeptide antagonists may have to have approximately the same affinity for both laboratory animal and human



Q2

^{h}GnRH binding IC_{50} = 0.4 nM
^{h}GnRH PI turnover IC_{50} = 1.0 nM

In2

^{h}GnRH binding IC_{50} = 0.6 nM
^{h}GnRH PI turnover IC_{50} = 3.4 nM

FIGURE 2 Merck nonpeptide GnRH antagonists. h, human.

receptors before the toxicology studies can be validated. This condition may limit the number of nonpeptide antagonist families that can be selected for development. However, nonpeptide antagonists are here to stay and, as with the GnRH peptide antagonists, further refinement of structures may be needed for improved ADME.

In conclusion, attractive physicochemical properties of new antagonists have been identified and new proprietary formulations of water-soluble (>50 mg/ml) and safe GnRH antagonists effective for about 1 month have been tested successfully in human. The question therefore is not whether a peptide antagonist will gain drug status but rather for which indication(s) it will be used. Also, nonpeptide GnRH antagonists may rapidly enter the market. It is unlikely that these will be used for the same indications as the current long-acting depot preparations that were developed to address prostate cancer (and the like); in comparison with peptide injectables, such compounds may be more versatile (allowing short- and long-term administration), better received (because of oral activity), and more economical as a result of improved ADME.

Glossary

agonist A molecule that binds to a receptor and activates it.
analogue A molecule that is chemically similar to another.
antagonist A molecule that binds to a receptor and does not activate it but blocks agonists from binding.
gonadotropin-releasing hormone A hypothalamic peptide that is released into the portal system and stimulates the release of luteinizing hormone and follicle-stimulating hormone from the pituitary.
indication A disease state that is improved by a particular treatment.
peptidomimetic A nonpeptide structure designed to be recognized by a receptor and modeled by comparison to peptide structures.

different families of G-protein-coupled receptors were distinguished.

The amino acid sequences are similar among receptors within the same family, especially within the transmembrane domains. However, despite sharing a seven-transmembrane structure, the receptors in different families have no sequence similarity. The largest family by far is the Class A or rhodopsin-like receptor family, which contains several thousand members in mammals. Included in this family are receptors for light, calcium, odorants, small molecules (amino acids, neurotransmitters, peptides), and proteins (see Table 1). It should be noted that a given intercellular signaling chemical may interact with many types of receptors. For example, acetylcholine activates several rhodopsin-like G-protein-coupled receptors, originally identified pharmacologically as the muscarinic receptors. In addition, acetylcholine is the neurotransmitter that activates the nicotinic receptors, which are multisubunit receptor–channel complexes having no structural relationship to G-protein-coupled receptors.

Class B receptors include mainly receptors for peptides, such as secretin, vasoactive intestinal polypeptide, pituitary adenylate cyclase-activating peptide, glucagons, and corticotropin-releasing factor. Class C includes the G-protein-coupled receptors for the neurotransmitters glutamate and γ-aminobutyric acid (GABA). Several additional receptor families can be distinguished, including Class D receptors for pheromones, Class E receptors for adenosine 3′,5′-cyclic monophosphate (cAMP), and an additional class for the frizzled and smoothened receptors involved in the development of cellular polarity.

III. GENERAL STRUCTURAL FEATURES

As shown in Fig. 1, all G-protein-coupled receptors have an extracellular amino-terminus, seven transmembrane domains that form the transmembrane core, three extracellular loops, three intracellular loops, and a carboxy-terminal segment. The membrane topology results in the segregation of secondary modifications to different receptor segments. For example, the amino-terminus can be modified by the attachment of polysaccharides (glycosylation), which may influence receptor stability. The carboxy-terminus segment may be modified by the attachment of palmitate to a cysteine residue (palmitoylation) that anchors this receptor domain to the membrane and results in a fourth cytoplasmic loop. Each of the seven-transmembrane domains is generally composed of 20–27 amino acids. On the other hand, amino-terminal segments (7–595 amino acids), loops

TABLE 1 G-Protein-Coupled Receptor Families

Receptor family	Ligand type	Examples
Class A: Rhodopsin-like	Amine	Acetylcholine (muscarinic), adrenoceptors (α and β), dopamine, histamine, serotonin
	Peptide	Angiotensin, bombesin, bradykinin, chemokine, interleukin-8, endothelin, somatostatin, galanin-like
	Hormone protein	Follicle-stimulating hormone, luteinizing hormone/choriogonadotropic hormone, thyrotropin
	(Rhod)opsin	Rhodopsin
	Olfactory	Several types
	Prostanoid	Prostaglandin, prostacyclin, thromboxane
	Nucleotide-like	Adenosine, purinoceptors
	Cannabis	Cannabinoid receptors
	Platelet-activating factor	Platelet-activating factor receptor
	Gonadotropin-releasing hormone	Gonadotropin-releasing hormone receptor
Class B: Secretin-like	Calcitonin	Calcitonin receptor
	Corticotropin-releasing factor	Corticotropin-releasing factor receptor
	Glucagon	Glucagon receptor
	Parathyroid hormone	Parathyroid hormone receptor
Class C: Metabotropic glutamate	Glutamate	Metabotropic glutamate receptors
	γ-aminobutyric acid	$GABA_B$ receptors
Class D: Fungal pheromone	Fungal pheromone	Fungal pheromone STE2-like
Class E: cAMP receptors	cAMP	cAMP receptor in *Dictyostelium*

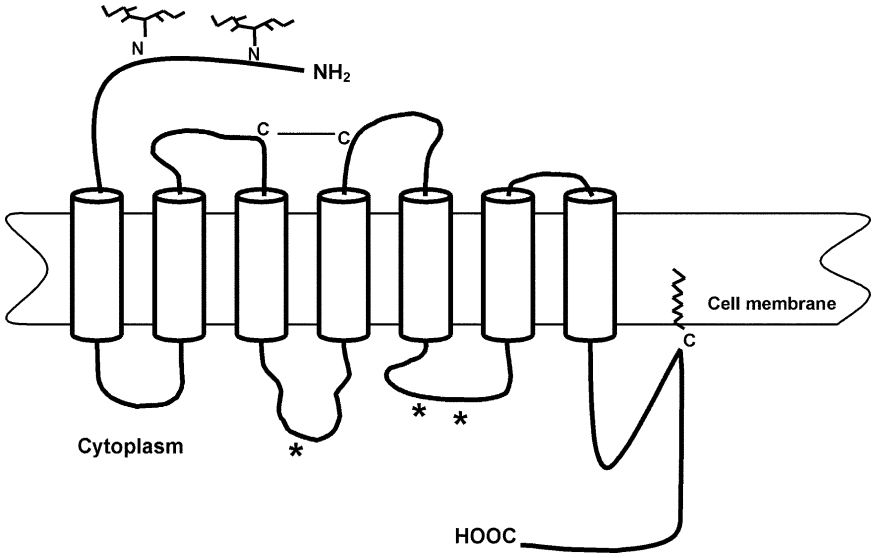

FIGURE 1 Two-dimensional model of a typical rhodopsin-like G-protein-coupled receptor showing some of the major structural features. The general structure of seven alpha-helical transmembrane domains is shown as cylinders connected by three extracellular and three intracellular loops. The amino-terminus usually contains asparagine (N)-linked glycosylation sites. Most receptors in this family have a cysteine (C) disulfide bridge between extracellular loops 2 and 3 and a conserved palmitoylation site in the carboxy-terminus, as shown. Potential regulatory phosphorylation sites are indicated by asterisks.

(5–230 amino acids), and carboxy-terminal segments (12–359 amino acids) vary considerably in size, an indication of their diverse structure and functions.

The seven transmembrane segments of rhodopsin are arranged as a closed loop in a clockwise direction from helix 1 to helix 7 when viewed from the intracellular surface. The orientation of the transmembrane segments imposes a stereo and geometric specificity on a ligand's entry into and binding to the transmembrane core. In this arrangement, the core is primarily composed of helices 1, 2, 3, 5, 6, and perhaps 7, whereas helices 1 and 4 are located peripherally (see Fig. 2).

The high-resolution three-dimensional structure of rhodopsin crystals provided the first detailed view of the three-dimensional structure of the transmembrane core. The structure of rhodopsin indicated that the transmembrane core does not have a vacant pocket, channel, or tunnel structure, as suggested earlier. Although the transmembrane core has hydrophilic, polar side chains, there are only a limited number ($\sim$10) of associated water molecules in the crystal structure. An extensive network of hydrogen bond interactions connects residues within the same transmembrane segments and between different segments.

Disulfide bonds play a major role in the structure and stability of G-protein-coupled receptors. Two conserved Cys residues in extracellular loops 1 and 2 are known to be linked by a disulfide bond. This bond appears to be required for proper assembly of most receptors, as its disruption interferes with either the expression or the function of various Class A receptors.

A. Glycosylation

In common with most membrane proteins, G-protein-coupled receptors are usually modified by the attachment of oligosaccharides. Most Class A receptors contain at least one glycosylation site in the amino-terminal domain. However, some receptors, such as the α_{2B}-adrenoceptor, do not have any sites for glycosylation. Oligosaccharides are linked to the side chain of asparagine residues (N-linked glycosylation) in a multistep process.

The contribution of glycosylation to receptor function differs for individual receptors. Glycosylation is important for the expression and stability of the gonadotropin-releasing hormone receptor and the vasopressin V_{1A} receptor. Likewise, glycan chains are essential for correct folding and membrane insertion of the thyroid-stimulating hormone and follicle-stimulating hormone receptors. For some receptors, including receptors for somatostatin, β_2-adrenergic, thyroid-stimulating hormone, and

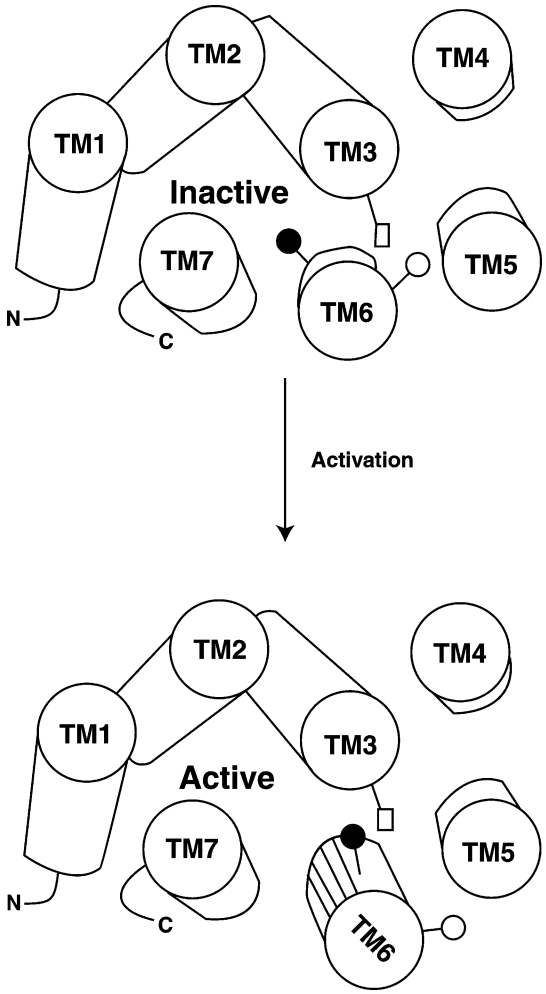

FIGURE 2 Three-dimensional schematic showing the arrangement of the transmembrane domains of an inactive and active Class A receptor as viewed from the inside of the cell. Selected side chains are shown to reveal the rotation and helix movements that occur during receptor activation.

gastrin-releasing peptide, glycosylation has been found to be important for proper receptor function, either ligand binding or receptor G-protein coupling. In other receptors, however, glycosylation has no known function. This latter group includes receptors for oxytocin, histamine H_2, muscarinic acetylcholine M_2, NK_1, bombesin BB_1, adenosine A_{2A}, and angiotensin. Thus, although N-linked glycosylation of receptors is an almost universal phenomenon, its effects on the properties of specific receptors may be variable.

For most G-protein-coupled receptors, glycosylation of at least one site contributes to normal expression or function.

B. Palmitoylation

Covalent lipid modifications anchor numerous signaling proteins to the cytoplasmic face of the plasma membrane. These modifications mediate protein–membrane and protein–protein interactions and are often essential for receptor function. Protein fatty acylation occurs through either amide linkages (N-acylation) or thioester linkages (S-acylation). N-Acylation occurs on the amino-terminal glycine residue following removal of the initiator methionine by a methionyl-aminopeptidase. S-acylation occurs on cysteine residues through a thioester linkage in a wide variety of sequence contexts. Palmitate is the most commonly used S-linked fatty acid; thus, this posttranslational process is usually referred to as protein palmitoylation. However, other fatty acids can be incorporated into cellular proteins by a thioester linkage, including myristate, stearate, and arachidonate.

Palmitoylation is a posttranslational modification that is limited to a small subset of cellular proteins among which proteins involved in signal transduction are prevalent. This thioesterification of cysteine residues by palmitate distinguishes itself from other lipid modifications by its reversibility. The palmitoylation state of several proteins has been shown to be dynamically regulated. In particular, biological regulation of the palmitoylation state of the G-proteins and of their cognate receptors has been demonstrated.

Many G-protein-coupled receptors have been shown to be palmitoylated at cysteine residues in the intracellular carboxy-terminal tail, and these include the rhodopsin receptor, β_2- and α_2-adrenoceptors, luteinizing hormone/chorionic gonadotropin receptors, endothelin ET_A and ET_B receptors, and the vasopressin V_2 receptor. The serotonin 5-HT_{1A} and 5-HT_{1B}, dopamine D_1 and D_2, and metabotropic glutamate $mGlu_4$ receptors have also been reported to be palmitoylated.

Evidence suggests that palmitoylation serves to enhance the association of cytosolic proteins with the membrane. In this regard, palmitoylation of seven-transmembrane receptors anchor the carboxy-terminal tail to the plasma membrane, yielding a fourth intracellular loop. Biologically regulated changes in the palmitoylation state of either receptors or G-proteins may have important functional consequences and for some receptors, such as the endothelin receptor, have been shown to contribute to coupling to the mitogen-activated protein kinase cascade. The palmitoylation state of the receptor

may also govern receptor internalization by regulating the accessibility of receptor to the arrestin-mediated internalization pathway.

C. Phosphorylation

Regulatory processes collectively known as receptor desensitization usually attenuate the signal transduction pathways regulated by G-protein-coupled receptors. Thus, within milliseconds to minutes of agonist exposure, cells can diminish or virtually eliminate their agonist-evoked responses, via a process that involves phosphorylation of the receptors at one or more intracellular domains. After longer exposure to the agonist, receptor down-regulation also occurs, a process that includes receptor internalization (endocytosis) from the cell surface, protein degradation, and decreased receptor expression.

Two general types of phosphorylation-mediated receptor desensitization can be distinguished, homologous desensitization and heterologous desensitization. Homologous desensitization refers to the process in which the desensitization of the receptor results only from agonist-mediated activation of the same receptor. Heterologous desensitization refers to a process in which activation of one type of receptor can activate signal transduction leading to the desensitization of a different receptor.

The mechanisms underlying homologous and heterologous desensitization differ. Homologous desensitization is mediated by a unique class of serine/threonine protein kinases called G-protein-coupled receptor kinases (GRKs). Six different mammalian GRKs which differ in their tissue expression and receptor specificity, have been identified. Whereas GRKs usually phosphorylate only active-state, agonist-occupied receptors, second-messenger-activated kinases, such as protein kinase A or protein kinase C, may phosphorylate receptors that are not themselves being activated. Thus, heterologous desensitization may be caused by any cellular signaling that leads to activation of second-messenger-activated protein kinases that then phosphorylate sites on a particular receptor.

Phosphorylation of several receptors by GRKs leads to the receptor associating with a member of the arrestin family proteins. The association of arrestin with the receptor interferes with G-protein coupling and promotes internalization. Paradoxically, for some receptors, the arrestin interaction that attenuates G-protein coupling actually promotes the activation of mitogen-activated protein kinase pathways. Phosphorylation of receptors by signaling-activated protein kinases, such as protein kinase A, desensitizes the receptor because it causes a decreased efficiency in the activation of G-proteins.

IV. BINDING SITE STRUCTURE

The various G-protein-coupled receptors manifest a remarkable diversity in the molecular mechanisms that they have developed for interacting with agonists. This evolutionary divergence on the shared seven-transmembrane template reflects the dual needs to maintain an efficient machinery for transmembrane signaling and to recognize specific activating signals as different as a photon of light and a 40 kDa protein.

A. Photoreceptors: Rhodopsin

Photoreceptors have a retinal chromophore, which is attached through formation of a Schiff's base between the aldehyde moiety of retinal and the ϵ-amine of lysine in the seventh transmembrane helix of the receptor. The protonated Schiff base is paired with a conserved glutamate present at the boundary between the third transmembrane domain and the first extracellular loop. Light absorption causes isomerization of the retinal chromophore from 11-*cis* to all-*trans*, disrupting the salt bridge between lysine and glutamate and activating the receptor.

B. Biogenic Amine Receptors

The biogenic amines acetylcholine, serotonin, adrenaline, noradrenaline, dopamine, and histamine activate their receptors by entering the transmembrane core. The binding site of these agonists lies approximately one-third of the way through the membrane. The amine nitrogen of these agonists forms an ionic interaction with an aspartate side chain in the third transmembrane helix of the receptor. This residue is a determinant for ligand binding but not for signal generation. The aromatic ring of most of these agonists interacts with a pocket in the fifth and sixth transmembrane domains to trigger receptor activation.

C. Peptide Receptors

Peptide hormone receptors such as the formyl receptor, the thyrotropin-releasing hormone receptor, and the gonadotropin-releasing hormone receptor form a complex with the peptide through interactions involving both the extracellular domains and the transmembrane helix core.

D. Protease-Activated Receptor

The ligands for these receptors are proteases, which activate their receptors by cleavage at specific amino-terminal domain sites. For example, the thrombin receptor has a specific site that is recognized by thrombin and cleaved. This results in the thrombin receptor having a new amino-terminus, which then functions as a tethered ligand that autoactivates the receptor.

E. Glycoprotein Hormone Receptors

The glycoprotein hormones, which include luteinizing hormone, follicle-stimulating hormone, chorionic gonadotropin, and thyroid-stimulating hormone, are the largest (30–40 kDa) and most complex G-protein-coupled receptor agonists. These hormones are heterodimers that consist of a common α-subunit and a hormone-specific β-subunit. Their receptors have a unique structure generated by fusing proteins from two gene families, the leucine-rich repeat glycoprotein family, which forms the amino-terminus, and the heptahelical Class A G-protein-coupled receptor family, which forms the transmembrane core. The high-affinity binding site of these receptors is contained within the large (350–400 residues) amino-terminal domain and the site of activation lies within the membrane-associated transmembrane core.

V. ACTIVATION MECHANISM

When associated with an extracellular agonist, G-protein-coupled receptors undergo a conformational change that promotes the interaction and activation of the intracellular G-protein. The conserved amino acid side chains of the Class A receptors contribute to a network of interhelical interactions that subserve the shared requirement of these proteins to undergo conformational rearrangements during activation. Activation results from triggering a molecular switch within the receptor. An arginine located at the cytoplasmic side of the transmembrane segment 3 of all Class A G-protein-coupled receptors contributes to the conformational changes underlying receptor activation. Class A receptors activate their G-proteins via a rigid body movement and rotation of the helices, in which the transmembrane helices move as units (Fig. 2). The activation entails a displacement and rotation of helix 6 relative to helix 5. The movement of the helices then exposes the intracellular sites required for interaction with and activation of the G-proteins.

VI. G-PROTEIN INTERACTIONS

G-proteins are heterotrimeric signaling proteins, consisting of an α-subunit, a β-subunit, and a γ-subunit. In the inactive state, the three subunits are associated and the α-subunit contains the nucleotide guanosine diphosphate in a nucleotide-binding site. Activation of a G-protein-coupled receptor causes a conformational change in the G-protein, which leads to guanosine triphosphate replacing guanosine diphosphate in the nucleotide site of the α-subunit and the dissociation of the α-subunit from the β-/γ-subunits. Both the α-subunit and the β-/γ-subunits can then interact with intracellular effector proteins to induce changes in signal transduction. The α-subunit has an enzymatic phosphatase activity for guanosine triphosphate. When the guanosine triphosphate is hydrolyzed to guanosine diphosphate, the α- and β-/γ-subunits reassociate, terminating the signaling.

The major specificity of G-proteins derives from the α-subunit. For example, an active G_s α-subunit induces an increase in adenylate cyclase activity, which in turn generates the intracellular signaling molecule cAMP. An active G_q subunit stimulates phospholipase C activity, ultimately promoting a release of calcium from intracellular stores and an activation of protein kinase C. The physiological effects induced by activation of a G-protein-coupled receptor are determined, in part, by the particular G-protein to which it couples. G-protein-coupled receptors preferentially activate a specific type of G-protein, such as G_s. However, many receptors have been found to be capable of activating more than one type of G-protein. The G-protein coupling preference displayed by an individual G-protein-coupled receptor is relative rather than absolute.

Given the structural conservation of G-protein-coupled receptors and heterotrimeric G-proteins, it is likely that the overall geometry of different receptor/G-protein complexes is generally conserved. Surprisingly, within a G-protein-coupled receptor family, the amino acids that are responsible for determining the G-protein coupling preferences show little relationship among receptors that display similar G-protein coupling profiles. Furthermore, receptors in different structural classes that have no sequence homology may couple to the same set of G-proteins. In the case of the agonist-binding site, amino acid similarities among receptors binding related agonists can be readily identified, such as an aspartate in the third transmembrane helix that interacts with biogenic amine agonists. The absence of evidence for a similar conservation pattern among

the sites in different receptors involved in specifying the interaction with a particular G-protein, such as G_s, suggests that the structural basis for G-protein coupling specificity results from convergent evolution.

A. Receptor Domains Involved in G-Protein Coupling

The selectivity of G-protein recognition is determined by multiple intracellular receptor regions. The most important regions are located in the second intracellular loop and in the amino-terminal and carboxy-terminal segments of the third intracellular loop. The intracellular domains act in a cooperative fashion to dictate proper G-protein recognition and efficient G-protein activation.

B. Effects of Posttranslational Modifications on Receptor/G-Protein Selectivity

The selectivity of receptor/G-protein coupling may also be regulated by receptor phosphorylation. Activation of β_2-adrenergic receptors leads to a pronounced increase in intracellular cAMP levels via activation of G_s (followed by activation of protein kinase A) and to the stimulation of mitogen-activated protein kinases through a pathway involving G_i-proteins. Studies with mutant β_2-adrenergic receptors lacking protein kinase A phosphorylation sites have shown that receptor-mediated activation of G_i-proteins is dependent on phosphorylation of the β_2-adrenergic receptor by protein kinase A. As protein kinase A phosphorylation decreases the efficiency of binding of β_2-adrenergic receptor to G_s, phosphorylation represents a switch mechanism for regulating the G-protein selectivity of the β_2-adrenergic receptor.

Many G-protein-coupled receptors have a conserved cysteine in their carboxy-terminus that may be modified by covalent attachment of palmitic acid. For some receptors, such as the endothelin receptor, this palmitoylation has been implicated in G-protein coupling selectivity.

VII. MODIFYING PROTEINS

The function of specific G-protein-coupled receptors may be profoundly influenced by interactions between the receptor and specific proteins. A class of transmembrane proteins called receptor activity-modifying proteins (RAMPs) modulate the expression and/or function of several calcitonin-related G-protein-coupled receptors.

The calcitonin family of peptides comprises five known members: calcitonin (CT), amylin, two calcitonin gene-related peptides (CGRP1 and CGRP2), and adrenomedullin (ADM). CT, CGRP, ADM, and amylin have high-affinity receptors identified in tissue. The first RAMP, RAMP1, was discovered through attempts to clone the CGRP receptor. Human RAMP1 is a 148-amino-acid protein with a large extracellular amino-terminal domain, a single transmembrane-spanning domain, and a short cytoplasmic domain. RAMP1 is closely related to two other RAMPs. The RAMPs interact with specific receptors and have three potential effects: assisting in shuttling the receptor to the plasma membrane, altering receptor glycosylation, and altering the pharmacological specificity of the receptor. The calcitonin receptor-like receptor (CRLR) requires the presence of a RAMP to be transported to the cell surface plasma membrane. RAMP1 also alters the terminal glycosylation of CRLR. These effects of RAMP1 are direct, as the CRLR and RAMP1 are associated with each other.

VIII. RECEPTOR DIMERIZATION

Many G-protein-coupled receptors function as dimers. Several G-protein-coupled receptors form heterodimers not only with closely related receptor subtypes but also with dissimilar G-protein-coupled receptors and even with members of other protein classes. Dimerization can affect receptor trafficking and G-protein coupling.

Receptor dimers may be present under basal conditions or may be generated following agonist stimulation. There are three patterns of dimerization: (1) dimers are detected under basal conditions and no change in their amount is observed upon agonist exposure; this pattern has been observed with the muscarinic M_3 receptor; (2) dimers are detected under basal conditions but agonists modulate the levels of the dimers, a pattern observed for the δ opioid receptor; and (3) dimerization requires the presence of agonist.

A. Homodimerization

Many G-protein-coupled receptors have been shown to form homodimers. Indeed, the presence of receptor dimers may be the natural state of G-protein-coupled receptors. The presence of homodimers was originally suggested by the pattern observed with protein

electrophoresis. Resonance energy transfer techniques have shown that receptor dimers are present in living cells.

B. Heterodimerization

Heterodimerization provides a combinatorial mechanism that increases the population of distinct functional receptors. The first G-protein-coupled receptor recognized to form a heterodimer was the $GABA_B$ receptor. Each subunit of the dimer, the $GABA_{B(1)}$ and $GABA_{B(2)}$ proteins, is nonfunctional in the absence of a partner. Without $GABA_{B(2)}$, $GABA_{B(1)}$ is retained in the endoplasmic reticulum. $GABA_{B(2)}$ serves to chaperone $GABA_{B(1)}$ to the cell membrane and also contributes to coupling the complex to G-proteins and downstream effectors.

Heterodimerization of related receptors has also been found between κ and δ opioid receptors and between μ and δ opioid receptors, which influences receptor internalization and pharmacology. Heterodimerization also occurs with serotonin $5\text{-}HT_{1D}$ and $5\text{-}HT_{1B}$ and with somatostatin SST_5 and SST_1 receptors.

In addition, heterodimerization occurs between more distantly related G-protein-coupled receptors. Somatostatin SST_5 and dopamine D_2 dopamine receptors can interact in the presence of agonist and function as a single signaling unit. Heterodimerization between dopamine D_1 and adenosine A_1 receptors and between angiotensin AT_1 and bradykinin B_2 receptors also occurs.

IX. RECEPTOR MUTATIONS AND DISEASES

A large number of diseases result from mutations of G-protein-coupled receptors. The mechanisms by which receptor mutations lead to diseases include changes in the levels of receptor expression, in receptor signaling, in receptor desensitization, and in receptor specificity.

A. Loss-of-Function Mutations

Mutations that lead to a loss of receptor function underlie a large number hereditary diseases. Loss-of-function mutations usually behave as recessive genetic traits. Representative examples are described.

Color blindness was the first disorder found to be caused by a defective G-protein-coupled receptor. The color-sensitive opsins, located in the retinal cone, are activated by light of a particular wavelength and couple to a specialized G-protein, cone transducin (G_t). A variety of mutations in cone opsin genes ranging from a single base change to large deletions have been correlated with loss of vision color. Mutations in the gene encoding the corresponding photoreceptor of retinal rod cells, rhodopsin, are responsible for autosomal dominant and recessive forms of retinitis pigmentosa, a degenerative disease of the retina.

B. Constitutively Activated Mutations

Several naturally occurring mutations that cause constitutive activation of G-protein-coupled receptors have been identified. These mutations cause the receptor to be more likely to spontaneously assume the active state, even when no agonist is present, and thus to autonomously generate cellular signaling. The pathogenesis of these disorders results from the spontaneous signaling that occurs.

One type of retinitis pigmentosa is caused by mutations of the visual receptor rhodopsin that lead to a high level of spontaneous signaling. Interestingly, a mutation of rhodopsin that causes only a slight increase in spontaneous receptor signaling does not lead to degeneration of the retina but causes persistent desensitization of retinal cell signaling. This interferes with the ability of the retinal cells to adapt to low light levels and causes congenital night blindness. Activating mutations of the thyrotropin receptors have been identified in hyperfunctioning thyroid adenomas. A mutation of the luteinizing hormone receptor that causes increased spontaneous activity has been found to cause hereditary precocious puberty.

C. Receptor Specificity

Diseases that result from a loss in receptor specificity have been identified. The thyrotropin-stimulating hormone receptor and luteinizing hormone/chorionic gonadotropin receptor are two Class A glycoprotein hormone receptors that have a high selectivity for their respective agonists. A hereditary mutation of the thyrotropin-stimulating hormone receptor has been identified that leads to a reduced ability to distinguish between thyrotropin-stimulating hormone and chorionic gonadotropin. During pregnancy, the elevated levels of chorionic gonadotropin levels cause an aberrant stimulation of the thyrotropin-stimulating hormone receptor. This mutation underlies the clinical disease familial gestational hyperthyroidism in which women become hyperthyroid only during pregnancy.

X. SUMMARY

The remarkable heptahelical structure of the G-protein-coupled receptors has provided an adaptable template for the intercellular signaling of higher organisms. The signaling specificity of these receptors has been exploited both by evolution and by the pharmaceutical chemist. Receptor diversity is accomplished by the presence of a huge number of distinct receptor genes and is further augmented by combinatorial interactions of different receptors to form receptors with novel properties. The importance of the proper functioning of this signaling system for human health is indicated by the large number of diseases associated with function-altering receptor mutations. The G-protein-coupled receptor is a micromachine for facilitating the intercellular transfer of information required for homeostasis and survival that has proven versatile and efficient.

Glossary

α-helix A basic structural element of proteins consisting of a continuous coil that contains 3.6 amino acids per turn.

agonist A chemical that specifically interacts with and activates a receptor by stabilizing the active conformation. The effects of agonists can be prevented by chemicals called antagonists or inverse agonists, which are usually synthetic compounds that interact with the receptor but oppose its activation.

clone A purified, specific DNA sequence, such as the sequence that provides the template for synthesis of a particular receptor.

conformation A particular structure or three-dimensional state that can be assumed by a chemical, such as a receptor protein. Receptor proteins can exist in several conformations and a given receptor molecule can transition between these conformations.

dimerization The association of two receptor molecules to form a bimolecular complex.

G-protein A signaling molecule that is activated by G-protein-coupled receptors. When active, it is associated with guanosine triphosphate.

hormone A chemical compound that is produced by an endocrine cell and that is delivered, usually via the circulatory system, to a distant target cell, where it interacts with a specific receptor protein to induce a particular biological response.

mutation A natural or laboratory-generated change in the DNA sequence of a particular gene. If the mutation alters the coding sequence of a receptor, it causes a corresponding change in the amino acid sequence for that receptor and may thereby alter the receptor's function. Naturally occurring receptor mutations may cause diseases by altering receptor function or level of expression. Site-directed receptor mutagenesis is a research tool in which alteration of specific amino acids is used to elucidate their role in receptor structure and function.

neurotransmitter A small chemical that provides signaling between neurons. It is released by a neuron and interacts with a receptor in an adjacent neuron to elicit a specific response.

peptide Two or more amino acids bound by covalent bonds. Many hormones are peptides.

receptor A cellular protein that interacts with a specific agonist and serves to initiate a molecular chain of events that converts the arrival of the agonist into a particular biological response in the cell.

signal transduction The process through which an extracellular signal, such as a hormone or neurotransmitter, is converted into a cellular response.

transmembrane domain The segment of a membrane protein that passes through the membrane. The transmembrane domain is often composed of an abundance of lipid-preferring (hydrophobic) amino acids that form an α-helix.

When injected into mice or humans, G-CSF stimulates a dose-dependent increase in circulating levels of neutrophils and is the most potent cytokine to do so. The increase begins rapidly (within 4–5 h), reaches a plateau by 5–10 days, and is sustained until injections cease. With cessation of G-CSF administration, neutrophil levels return to normal within 1–2 days. Somewhat surprisingly, G-CSF also stimulates a dramatic increase in circulating levels of all hematopoietic progenitor cells and stem cells (several hundred-fold), peaking at day 5–6 then declining. These increases arise in part through mobilization of cells from the bone marrow into the blood but also through increased production of progenitor and mature cells.

G-CSF is also the major regulator of neutrophil production under steady-state conditions. Mice in which either the G-CSF gene or the G-CSF receptor gene had been deleted by homologous recombination in embryonic stem cells displayed only approximately 20% of the normal levels of circulating neutrophils and only approximately half the number of progenitor and maturing cells within this lineage in the bone marrow. These mice were also deficient in mobilizing stem cells from the bone marrow to the blood in response to some other stem cell-mobilizing factors, such as the chemokine interleukin-8 and the chemotherapeutic agent cyclophosphamide, but not to others, such as the Flt3 ligand. Although these mice were still able to respond to infections by near normal elevation of neutrophils (suggesting that G-CSF is not essential for this process), they nevertheless were less effective in clearing the infections, perhaps reflecting the other actions of G-CSF on neutrophil functions.

III. PROTEIN STRUCTURE

Human G-CSF is synthesized as a 204-amino-acid precursor protein with the first 30 amino acids (the leader sequence) being cleaved during secretion from the producer cells (macrophages, endothelial cells, and fibroblasts). It is glycosylated with the attachment of sugar residues to a single threonine residue (Thr-133) (called O-glycosylation) and contains two disulfide bonds linking cysteines 36–42 and 64–74. The molecular weight of the mature protein is 18,627 (excluding the sugar chain). The sugar chain is not required for biological activity but increases the solubility and stability of the protein.

G-CSF folds into a three-dimensional conformation that is conserved among many different cytokines. It consists of a four α-helical bundle with relatively long helical lengths forming two antiparallel pairs (helices A with D and B with C). There is an additional small helix (E) in the loop between the A and the B helices (see Fig. 1). At least one major site of interaction of G-CSF with its receptor is the face presented by the A and C helices, with Glu-19 being particularly important. A second site of interaction has been postulated to involve residues on the E helix with the immunoglobulin-like domain of the receptor.

IV. GENE STRUCTURE

The human G-CSF gene is on chromosome 17 and consists of five exons. The mouse G-CSF gene is on chromosome 11 and has an identical intron–exon structure. The major mRNA transcript in both cases is approximately 1500 nucleotides long and, in humans, there is a second minor transcript that contains an additional 9 nucleotides or 3 amino acids as a result of the use of an alternative splice donor sequence within intron 2. The alternative G-CSF thus encoded contains 3 additional amino acids (ValSer-Glu) after amino acid 35 and has a reduced biological activity.

Control of G-CSF expression occurs at both the transcriptional and the posttranscriptional levels. Like the mRNA of many other cytokines, G-CSF mRNA contains an AU-rich 3′-untranslated region that confers instability on the mRNA. This sequence

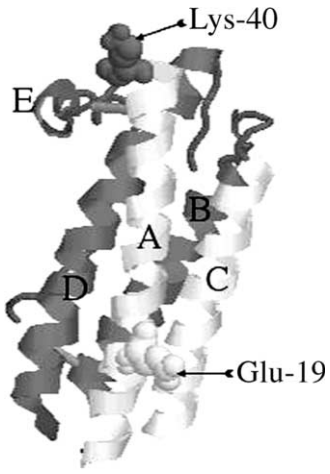

FIGURE 1 The structure of human G-CSF as determined by X-ray crystallography. The main body of the molecule is made up of four antiparallel α-helices labeled as ribbons A–D in the figure (N-terminal) to (C-terminal). The short fifth helix is labeled E. The main receptor interaction site on the A–C helical face centered around Glu-19 is shown with CPK sphere models of the side chains, and the proposed interaction site with the immunoglobulin domain of the receptor, centered around Lys-40, is similarly shown. Disulfide bonds are shown as cylinders joining two helices.

is thought to bind specific proteins or ribonucleoproteins in a regulatable manner so that the mRNA can exist in a short or longer half-life form depending on extracellular signals. Inductive stimuli, such as bacterial lipopolysaccharides (LPSs), tumor necrosis factor (TNF), or interleukin-1 (IL-1), stabilize the G-CSF mRNA through this mechanism. The region 300 bp upstream of the transcriptional initiation site of the G-CSF gene is sufficient for both constitutive and inducible (in response to LPS, TNF, and IL-1) transcription of G-CSF in macrophages. Three *cis* regulatory elements (GPE1–3) have been identified involving nuclear factor κB (NF-κB)/NF-IL-6-binding sites, octamer-binding sites, and unidentified binding sites with the first two appearing to be the most important for LPS and TNF/IL-1-inducible transcription in macrophages, endothelial cells, and fibroblasts.

V. G-CSF RECEPTOR

Specific receptors for G-CSF are expressed on all cells of the neutrophilic granulocyte series from blast cells to mature neutrophils. These cells generally display a few hundred receptors per cell but some monocytes also express lower numbers of receptors. Other hematopoietic cells do not express G-CSF receptors but some nonhematopoietic cells, including placental trophoblasts and endothelial cells, also express G-CSF receptors. The function of G-CSF receptors in these latter cells is currently unclear.

The G-CSF receptor was identified by expression cloning and shown to belong to the type I cytokine receptor family characterized by the presence in the extracellular domain of a paired fibronectin III module called the cytokine recognition domain (CRD). It also contains an N-terminal immunoglobulin (Ig) domain and three additional fibronectin III domains prior to the transmembrane domain.

Somewhat surprisingly, the three-dimensional structure of G-CSF bound to a truncated G-CSF receptor containing only the CRD domain revealed a 2:2 complex rather than the 1:2 complex previously determined for the related growth hormone:growth hormone receptor complex (Fig. 2). Residues on the A and C helices of G-CSF (particularly Glu-19) interact in a hydrogen bond network with loops from both the N and the C subdomains of the CRD of one receptor chain (particularly Tyr-172 and Arg-287, respectively). The N-terminal residues of G-CSF (particularly Ser-7 and Gln-11) also interact with the C subdomain of the CRD of the other receptor chain (particularly Phe-259 and His-260, respectively), thus

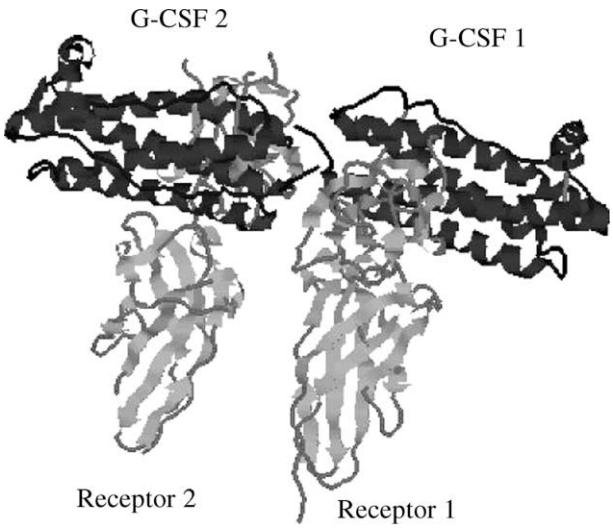

FIGURE 2 The structure of the 2:2 G-CSF:G-CSF receptor complex as determined by X-ray crystallography. The two G-CSF molecules are shown as darker molecules with essentially the same structure as in Fig. 1, and the two receptor molecules are shown as the lighter colored molecules. The receptor fragments used in this study contained only the CRD domain and lacked the immunoglobulin domain. The β-strands of the two subdomains of each receptor are shown as arrows with each G-CSF molecule making contact with both receptor chains.

linking the two 1:1 complexes. This structure does not explain the importance of the Ig domains of the G-CSF receptor that has been noted in other studies but it is possible that these interact with other residues on G-CSF (previously called site I, which includes Lys-40 and Phe-144).

The cytoplasmic domain of the G-CSF receptor also contains conserved sequence elements typical of type I cytokine receptors including the box 1 and box 2 elements. Accordingly, activation of Janus tyrosine kinases (JAKs), tyrosine phosphorylation of the receptor, and activation of the signal transducers and activators of transcription (STATs) are thought to be critical for G-CSF-induced intracellular signaling. Other signaling pathways, including the Ras/MAP kinase and phosphatidyl inositol 3-kinase pathways, are also stimulated by G-CSF. Whereas only the membrane proximal regions of the receptor are required to signal cell proliferation, there is evidence that C-terminal regions are required for cellular differentiation in some cell lines and for feedback inhibition of G-CSF signaling. Interestingly, some patients with severe congenital neutropenias that develop into preleukemic myelodysplastic syndromes acquire mutations in the C-terminal part of the receptor cytoplasmic domain.

VI. CLINICAL USES

The ability of G-CSF to elevate circulating neutrophils in mice and humans led to its application initially in patients receiving cytotoxic chemotherapy for malignancy. Neutropenia is a significant side effect of many chemotherapy regimens and may limit the benefits that patients accrue from treatment. G-CSF was tested in clinical trials for its ability to prevent or reduce severe neutropenia and its complications. Randomized trials demonstrated that, when commenced after chemotherapy, G-CSF accelerates the recovery of neutrophil numbers and reduces the duration of severe neutropenia when patients are at high risk of infections. As a direct consequence of this accelerated neutrophil recovery, G-CSF administration also reduced the incidence of inflammation of the oral mucosa, the need for antibacterial and antifungal antibiotics, and the duration of hospitalization. The benefits were shown to be more significant when more intensive chemotherapy was used and greatest after myeloablative chemo-radiotherapy and autologous bone marrow transplantation. G-CSF has been used to support chemotherapy in routine clinical practice for more than 10 years now, and specific indications for its use have been refined. Evidence-based guidelines for its cost-effective use have been published by the American Society of Clinical Oncology. G-CSF is used routinely to support chemotherapy of moderate intensity in patients with curable malignancies including lymphoma, leukemia, and breast cancer.

A second major clinical use for G-CSF is the mobilization of hematopoietic stem cells from the bone marrow into the blood. In early clinical studies, it was noted that the numbers of all types of CFCs and stem cells in the blood were elevated dramatically (about 100-fold) 4–7 days after the beginning of G-CSF treatment. These blood stem cells proved easier to collect in large numbers than bone marrow stem cells and they also were proved to reconstitute the hematopoietic system significantly faster than bone marrow when infused following myeloablative chemo-radiotherapy. In particular, platelet recovery was accelerated by 5–10 days. For patients undergoing autologous transplantation, blood stem cells are collected after mobilization either with G-CSF given alone or, more commonly, with G-CSF given during the recovery phase after chemotherapy when the number of stem cells in the blood may be increased 1000-fold over steady state. Patients undergoing allogeneic hematopoietic stem cell transplantation receive cells from normal donors. G-CSF administration to volunteer donors for patients undergoing allogeneic transplantation has been shown to be safe and effective. G-CSF-mobilized blood stem cells now have replaced bone marrow as the standard source of hematopoietic stem cells for both autologous and allogeneic bone marrow transplantation.

G-CSF has also found clinical utility in the treatment of patients with neutropenia unassociated with chemotherapy, such as severe congenital neutropenia, cyclic neutropenia, aplastic anemia, and some myelodysplastic syndromes. In particular, patients with severe congenital neutropenia have benefited substantially. Regular use of G-CSF in these settings increases the neutrophil counts toward normal, allowing previously refractory infections to resolve and preventing mouth ulceration, fevers, and recurrent infections.

The observation that serum levels of G-CSF are markedly increased during infection led to initial speculation that treatment with G-CSF may hasten the recovery of noncancer patients with serious bacterial or fungal infections. However, G-CSF administration does not accelerate the recovery of patients from pneumonia or septic shock, and G-CSF is not indicated in these conditions. Similar results were observed when this strategy was tested in patients with chemotherapy-induced neutropenia and indicate that the major benefit of G-CSF in chemotherapy patients is the previously mentioned reduction in the duration of severe neutropenia and consequent reduction in the risk of developing an infection. For neutropenic patients with life-threatening infections, transfusions of neutrophils may be beneficial. G-CSF is used to increase the number of neutrophils in the blood of donors by three- to fivefold, facilitating the efficient collection of these short-lived cells for immediate infusion into patients.

G-CSF is usually given by subcutaneous injection once per day to accelerate neutrophil recovery and either once or twice per day to mobilize stem cells into the blood. For patients requiring chronic treatment with G-CSF, administration once or twice a week is often sufficient. The side effects experienced by patients receiving G-CSF are generally mild and well tolerated. The most common are lethargy, headache, and bone pain. Bone pain is most common in patients who continue G-CSF after their neutrophil counts have recovered and in normal donors. It reflects an expansion of bone marrow tissue within the medullary cavity and a dramatic increase in local blood flow that accompanies this expansion. In volunteer donors, the only life-threatening complication is splenic rupture and this is a rare

occurrence. In patients with acute myeloid leukemia, the presence of G-CSF receptors on leukemic cells raised the theoretical concern that G-CSF administration may accelerate the progression of the leukemia. This concern has not been borne out in clinical trials and short-term use of G-CSF is not thought to cause or promote leukemia. However, for patients with the preleukemic condition severe chronic neutropenia, prolonged G-CSF treatment is associated with an increased risk of the development of acute leukemia. This risk is offset by the marked improvement in the quality of life that these patients experience with G-CSF treatment. For the vast majority of people receiving G-CSF, it is a safe and highly effective therapeutic agent.

Glossary

bone marrow transplantation The transplantation of a patient's own bone marrow (autologous) or bone marrow from a different donor (allogeneic) into a patient to provide a source of hematopoietic stem cells from which the entire hematopoietic system can be reconstituted after high-dose chemotherapy or radiotherapy.

chemotherapy and radiotherapy The use of toxic chemicals or radiation to attempt to kill (usually) cancer cells in patients. Side effects usually include the killing of normal hematopoietic cells (myelotoxicity), leading to infections, and the killing of intestinal and hair precursor cells, leading to vomiting and hair loss, respectively. Myeloablative chemotherapy is high-dose chemotherapy that permanently destroys the hematopoietic system and would prove fatal without bone marrow transplantation.

colony-forming cell The progenitor cell (blast cell) that can multiply and differentiate in semisolid cultures to form the differentiated cells that constitute a colony.

colony-stimulating factor A generic term for a family of proteins that stimulate the production of hematopoietic cell colonies from single-cell suspensions in semisolid medium such as agar or methylcellulose.

differentiation The process of morphological and functional maturation that occurs in cells as they progress from a blast cell stage to the mature cell (e.g., granulocyte).

granulocyte A white blood cell containing granules in the cytoplasm that is involved in attacking bacterial infections. There are three types, depending on the type of granules, called neutrophils, eosinophils, and basophils. The term granulocyte is sometimes used to mean only neutrophils, e.g., in the case of granulocyte colony-stimulating factor.

granulocyte colony-stimulating factor (G-CSF) receptor The protein displayed on the surface of cells that specifically recognizes, interacts with, and responds to G-CSF.

neutropenia A reduction in the normal circulating numbers of neutrophilic granulocytes from 4000–10,000/μl to 1000/μl or less. The reduction can be due to genetic diseases (congenital neutropenias) or to the myelotoxic effects of chemotherapeutic drugs.

signal transduction The series of molecular events occurring after G-CSF binds to its receptor, leading to the appropriate cellular responses. Signal transduction usually involves receptor modification, binding of intermediary signaling molecules, and activation of transcription factors, leading to the expression of specific genes.

eosinophil survival due to the production of GM-CSF by local lung epithelial cells. The priming of granulocytes for enhanced effector cell function is important to boost the innate immune response and facilitate phenomena central to inflammation such as adhesion to blood vessel wall, migration into tissues in response to chemotactic stimuli, and enhanced phagocytosis, degranulation, release of oxygen radicals, and cytotoxic activity. Although GM-CSF is an effective stimulus of all these functions, there is a hierarchy in terms of the concentrations of GM-CSF required. Cell survival is the function that requires the least amount of GM-CSF and hence receptor occupancy, highlighting the importance of this function and perhaps reflecting differences in signaling pathways according to the "strength" (level of receptor occupancy) of the signal.

GM-CSF also participates in the acquired immune response through its ability to up-regulate class II expression and stimulate dendritic cells. Interstitial myeloid dendritic cells can be generated *in vitro* by stimulating monocytes specifically with GM-CSF and interleukin-4. Similarly, both interstitial and Langerhans dendritic cells (found in the skin) can be uniquely generated *in vitro* by stimulating $CD34^+$ hematopoietic stem cells with GM-CSF and tumor necrosis factor α (TNFα). Such cells are dedicated to antigen uptake and processing and are unusually adept at stimulating naive T cells. The immunomodulatory properties of GM-CSF to enhance dendritic cell functions are currently being exploited in (1) vaccination strategies to prevent infection and (2) anti-cancer therapy.

In addition to its direct effect on hematopoietic and immune cells, GM-CSF exerts a synergistic effect in the presence of other cytokines. One example is with IL-4 in the production of dendritic cells. Another one is with stem cell factor or c-kit ligand, a cytokine that is a poor proliferative stimulus by itself but which, in combination with GM-CSF, has a strong proliferative effect on hematopoietic cells. Most of these *in vitro* effects of GM-CSF are recapitulated *in vivo* following the injection of GM-CSF in mice and humans. *In vivo* administration of GM-CSF results in increased numbers of circulating neutrophils, eosinophils, monocytes, and multipotent hematopoietic cells and increased numbers and activation of tissue macrophages, including alveolar macrophages. It also enhances dendritic cell maturation, proliferation, and migration and the proliferation and function of pulmonary type II alveolar epithelial cells. In the bone marrow, GM-CSF alters the kinetics of myeloid progenitor cells, causing rapid entry of cells into the cell cycle and decreasing cell cycle time by as much as 33%. There is also a synergistic response *in vivo* when GM-CSF is combined with other cytokines (such as erythropoietin and thrombopoietin) to stimulate multilineage hematopoietic recovery following chemotherapy or to mobilize stem cells (G-CSF) in the peripheral blood for collection pretransplant. To understand the true physiological role of GM-CSF, *in vivo* gene inactivation experiments have been performed in which the gene coding for GM-CSF has been disrupted. Surprisingly for a cytokine with such multilineage activities, no differences in the number of steady-state circulating granulocytes or macrophages were found; this has been explained by redundancy in the system and compensation by other hematological cytokines that act on myeloid cells, namely, G-CSF, macrophage colony-stimulating factor (M-CSF), and IL-3. However, these mice do display an inability to metabolize lung surfactant by lung-specific macrophages, resulting in an alveolar proteinosis-like syndrome. This syndrome can be corrected by administering GM-CSF to the lung or by bone marrow transplantation and is secondary to an inability of circulating monocytes to undergo further differentiation into alveolar macrophages in these mice. Humans deficient in GM-CSF via acquired antibodies or bone marrow genetic mutations in myeloid stem cells resulting in a nonfunctioning GM-CSF receptor also develop pulmonary alveolar proteinosis.

A role for GM-CSF *in vivo*, however, begins to be revealed under conditions of stress in which knockout mice are challenged under conditions that mimic disease situations. For example, GM-CSF −/− mice cannot engage a normal immune response against bacterial and fungal pathogens including *Listeria monocytogenes* and are predisposed to lung infection. Interestingly, GM-CSF −/− mice are refractory to experimentally induced arthritis and toxic shock syndrome (despite levels of TNFα being normal) and are protected against the development of a multiple sclerosis-like disease in mice. Thus, the physiological role of GM-CSF under steady-state conditions appears to be mainly the regulation of lung surfactant metabolism via alveolar macrophage differentiation with essentially no effect on leukocyte cell numbers. However, in response to infection, trauma, and inflammation, GM-CSF is a potent stimulator of both the hematopoietic system and the innate immune system with beneficial outcomes in certain cases but also with the potential to exacerbate chronic inflammation, leukemic cell load, and autoimmune responses.

III. SITES OF PRODUCTION AND GENE REGULATION

Given its diverse and potentially harmful effects, it is not surprising that the production of GM-CSF in various cells throughout the body is under strict control. Copious amounts of GM-CSF are produced by activated T cells as part of either a type 1 or a type 2 helper T-cell response. Upon activation, T cells increase transcription of the GM-CSF gene via the effect of pro-inflammatory transcription factors such as nuclear factor κB (/Rel, activator protein-1, and NFAT. However, naive unstimulated T cells actively repress the GM-CSF gene. In this way, inflammatory responses can be directed in a localized and controlled fashion.

In addition to T cells, constitutive transcription of the GM-CSF gene at low levels has been detected in large variety of cells including monocytes, endothelial cells, fibroblasts, natural killer cells, mast cells, mesothelial cells, epithelial cells, and some tumor cells. In these cells, production of actual GM-CSF protein is regulated primarily by stabilization of the RNA message by an AU-rich element in the 3′-untranslated region. In the resting state, virtually no GM-CSF protein is secreted because of degradation of GM-CSF mRNA soon after it is transcribed. However, in response to inflammatory cytokines such as IL-1 or TNFα or the stimulation of Toll receptors, GM-CSF production can be dramatically and rapidly increased by inhibiting the GM-CSF mRNA degradation pathway. Removal of basal state inhibition of GM-CSF mRNA results in a lethal myeloproliferative disorder.

The GM-CSF gene may be co-regulated with other cytokines and pro-inflammatory genes on the same chromosome by formation of distinct chromatin domains of coiled DNA that are opened or repressed according to incoming nuclear signals. The human GM-CSF gene is localized to chromosome 5q21–q32 adjacent to the IL-3 gene and there is evidence that co-regulation of these genes occurs in some activated T cells.

IV. RECEPTOR AND SIGNALING

The biological effects of GM-CSF are mediated via binding to specific receptors expressed on the surface of target cells. The GM-CSF receptor is a heterodimer consisting of two distinct subunits or polypeptide chains named α and β_c (β_c). The α-subunit is the major binding component specifically binding GM-CSF with low affinity (2–5 nM). The β_c-subunit acts as an affinity converter, allowing the binding of GM-CSF to its heterodimeric receptor with high affinity (100 pM), a property that makes the binding of GM-CSF to its receptor essentially irreversible and ensures a biological outcome. Both subunits are necessary for receptor signal transduction with β_c undergoing phosphorylation and being the major subunit associating with downstream signaling molecules. An important property of β_c is that, unlike the α chain, it is not unique to the GM-CSF receptor but is shared with the IL-3 and IL-5 receptors. This predicts that in cells that co-express these receptors, the respective ligands will exert the same functions. Indeed, this is illustrated best on eosinophils, which show the same qualitative and quantitative biological responses to GM-CSF, IL-3, or IL-5.

The GM-CSF receptor has been detected by means of radiolabeled GM-CSF or antibodies to its receptor chains on the surface of many cells, in the hematopoietic as well as outside the hematopoietic system. These include neutrophils, eosinophils, basophils, monocytes, macrophages, undifferentiated bone marrow cells, dendritic cells, B cells, certain T lymphocytes, uterine cells, and astrocytes. In every case, both subunits of the GM-CSF receptor are present, and to date, there has been no unequivocal example of one subunit being expressed in the absence of the other, suggesting a coordinate control of gene expression and emphasizing the functional requirement for the heterodimer. Myeloid leukemias such as AML, CMML, CML, and JCMML and solid tumors such as prostate cancer, breast cancer, melanoma, and small-cell lung carcinoma can also express the GM-CSF receptor but the contribution that this expression makes to the malignant state remains unexplored.

The binding of GM-CSF to its receptor causes receptor dimerization and the formation of a high-order complex; however, the exact stoichiometry of this complex remains unknown (Fig. 1). Receptor dimerization is accompanied by phosphorylation of the receptor on β_c and of several intracellular proteins. The phosphorylation on the receptor β_c occurs on tyrosine as well as on serine and threonine residues and has the purpose of creating docking sites onto which signaling molecules can be recruited. Although β_c lacks intrinsic kinase activity, GM-CSF has been shown to induce tyrosine phosphorylation of β_c as well as of a diverse group of cytoplasmic proteins including (1) kinases, such as phosphatidylinositol 3-kinase and protein kinase B or AKT; (2) adapter proteins, such as growth factor receptor-binding protein 2, insulin receptor substrate-2, Cbl,

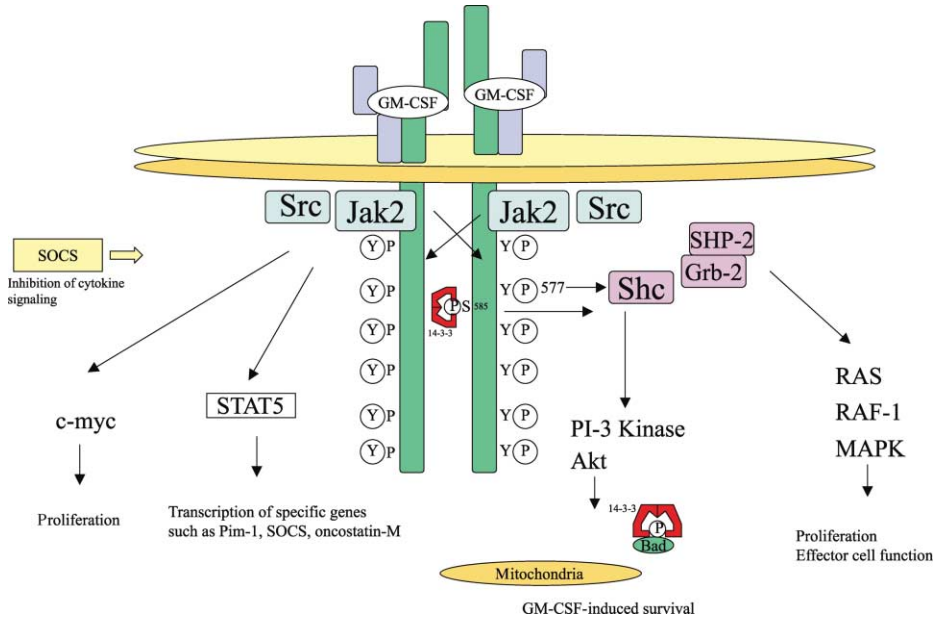

FIGURE 1 Activated GM-CSF receptor signaling complex showing trans-phosphorylation of adjacent Jak2 tyrosine kinase molecules (crossed arrows) subsequent to receptor dimerization. α, GM-CSF receptor α-subunit; β, common β-subunit; GM, GM-CSF ligand. Src kinase is also involved in tyrosine phosphorylation of β_C tyrosine residues and other adapter proteins. Some adapter proteins such as Shc, 14-3-3, and Grb2 are shown in close association with the cytoplasmic portion of β_C. Various downstream signaling pathways are shown with arrows indicating their putative means of activation and the biological outcomes.

and Src homology and collagen protein; (3) guanine exchange factors, such as Vav; (4) phosphatases, such as SH2-domain-containing protein tyrosine phosphatase-2 and SH2-containing inositol phosphatase, and (5) transcription factors, such as signal transducers and activators of transcription (STAT5). This tyrosine phosphorylation is mediated by the receptor-associated tyrosine kinase Janus kinase 2 (JAK2) and Src-family kinases. GM-CSF receptor signaling is initiated by trans-phosphorylation of the JAK2 kinase, which is associated with the proximal intracellular portion of β_c. The phosphorylation of β_c on tyrosine residues by JAK2 in turn promotes the docking of SH2 domain-containing signaling molecules and the amplification of receptor signaling. Different tyrosine residues on β_c couple the receptor to diverse signaling pathways. Although there is redundancy in terms of promoting the binding of STAT5 molecules (they can bind to any one of the six phosphorylated tyrosines in β_c), phosphorylation of Tyr-577 results in the specific recruitment of Shc, an adapter molecule involved in the activation of the ras pathway.

Phosphorylation of β_c on certain serine residues also has been recently noted and shown to be important for GM-CSF receptor signaling. Phosphorylation of Ser-585 located immediately downstream from the Shc-binding site enables association of the 14-3-3 adapter protein and is required in signaling the cell survival response. Protein kinase A can phosphorylate Ser-585; however, it is not known how GM-CSF activates protein kinase A or indeed other potential serine/threonine kinases. Figure 1 summarizes the major known signaling pathways stimulated by GM-CSF.

V. STRUCTURE

Human GM-CSF is a secreted glycoprotein containing 127 amino acids and two intramolecular disulfide bonds. The molecule is rich in N- and O-linked carbohydrates; however, unglycosylated GM-CSF (produced in bacteria) exhibits high-affinity binding, is fully functional, and in fact is approximately 10% more potent. The structure, as determined by X-ray crystallography, shows as its most important feature a four α-helix bundle with a double overhand topology. This fold is common to other cytokines such as growth hormone, IL-2, IL-4, and IL-5. This is particularly striking given the low degree of sequence similarity with these cytokines and suggests a common ancestral origin.

The human GM-CSF receptor α-subunit and β_c-subunit both contain conserved extracellular domains termed cytokine receptor modules (CRMs). Each CRM consists of two repeats of a fibronectin type III-like domain that contains four cysteines with conserved spacing and a WSXWS (where X is any amino acid, W is tryptophan, and S is serine) motif. Mutagenesis of the WSXWS motif has been shown to disrupt receptor activation and is important for correct folding of the extracellular domain of cytokine receptors. The B–C and F–G loops (where A to G are labels for the seven strands in each beta sheet of the CRM) in the domain containing the WSXWS motif are important for cytokine binding, with Tyr-421 in the F–G loop of β_c being crucial for the high-affinity binding and signaling of GM-CSF as well as IL-3 and IL-5.

The exact manner in which GM-CSF interacts with its two receptor subunits is not known as the structure of the GM-CSF receptor complex has not yet been solved. Nevertheless, mutagenesis of GM-CSF and of its two subunits indicates binding through two different faces. One face of GM-CSF would be composed largely by its fourth α-helix binding to the receptor α chain through several weak molecular interactions that involve the surface residues Asp-112 and Glu-108. The second face of GM-CSF would comprise the first α-helix of GM-CSF and in particular Glu-21, which protrudes about halfway through the helix. This residue is essential for GM-CSF interacting with the receptor β_c-subunit and hence is crucial for GM-CSF high-affinity binding and biological activity.

These structure–function studies of GM-CSF and its receptor have facilitated the development of GM-CSF antagonists. The antagonist E21R was developed by substituting the key Glu-21 residue with amino acids of opposite charge, namely, Arg or Lys. These point mutation analogues of GM-CSF fully occupy the receptor α chain but they do not signal because they cannot engage β_c; hence, they behave as competitive antagonists of GM-CSF. E21R is currently undergoing phase II clinical trials for the treatment of certain leukemias. The antagonist BION-1 is an antibody directed to the cytokine-binding region of β_c. As expected, this antibody and its fragments antagonize the high-affinity binding and biological activities of GM-CSF as well as those of IL-3 and IL-5 but not of other cytokines. An antagonist with this specificity is postulated to be useful in pathological conditions in which all these three cytokines are involved. Since eosinophils respond to any of these three cytokines, antagonists such as BION-1 may be useful in diseases in which the eosinophil plays a major pathological role such as in asthma.

VI. CLINICAL USES AND ROLE IN HUMAN DISEASE

The myeloid-stimulating properties of GM-CSF are currently utilized in the treatment of cancer in many centers. Myelosuppression following cytotoxic chemotherapy for the treatment of both hematological and solid cancers is an almost invariable side effect that, if severe, can result in life-threatening infections. Clinically described as febrile neutropenia, such infections usually occur between 6 and 14 days after exposure to chemotherapy when neutrophil counts (half-life 6–8 h) are at their lowest. Both G-CSF and GM-CSF have proven efficacious in hastening the time of neutrophil recovery, reducing the number of infections, and shortening hospital stays. Conventionally, GM-CSF is administered subcutaneously (250 $\mu g/m^2$ per day) 24–72 h after chemotherapy until neutrophil counts recover ($>10{,}000/\mu l$) but mild side effects such as flushing, flu-like symptoms, and myalgias have limited the use of GM-CSF compared with G-CSF.

Another common clinical use of GM-CSF is in peripheral blood stem cell transplantation. Hematopoietic stem cells normally circulate in the peripheral blood but at very low concentrations. Following the administration of certain hematopoietic growth factors such as GM-CSF or G-CSF, the concentration of hematopoietic progenitor cells in blood, as measured by colony-forming units or the expression of CD34 antigen, increases markedly. This has made it possible to harvest adequate numbers of stem cells from the peripheral blood for transplantation into a patient who has received myeloablative chemotherapy. Compared with autologous bone marrow, use of peripheral blood stem cells results in more rapid hematopoietic recovery, particularly with respect to platelet numbers. There are no major differences in the stem cell subsets mobilized with GM-CSF compared with G-CSF or engraftment outcomes but combination therapy appears to dramatically increase the progenitor cell number harvested.

The clinical indications for use of GM-CSF have expanded considerably since it first became available in the early 1990s as a stimulator of myelopoiesis for the treatment of cancer. Research in recent years has uncovered many other diverse biological effects, in addition to hematopoiesis, including responses to infection, inflammation, atherosclerosis, allergy, and pulmonary disease. Such immune-modulating

and -enhancing properties of GM-CSF have sparked diverse clinical trials and approvals for its use in the treatment of human infections, vaccination strategies, and immunosuppression.

An example of the successful use of GM-CSF in stimulating the immune system has been in the treatment of fungal infections in severely immunocompromised patients. Substantial evidence that GM-CSF enhances the ability of neutrophils and macrophages to phagocytose and destroy bacteria and fungi has been obtained from *in vitro* and *in vivo* studies. Some of these effects are attributed to increased neutrophil survival, up-regulation of class II molecules to augment antigen presentation, and increased expression of mannose- and Toll-like receptors on both neutrophils and macrophages. Disseminated fungal infections in bone marrow transplant recipients or patients with acute myeloid leukemia are notoriously difficult to treat with standard antifungal drugs and result in mortality rates approaching 50%. Treatment with GM-CSF resulted in significantly reduced mortality from fungal infection (20 to $\approx$75%) in a phase III trial of 99 elderly patients undergoing chemotherapy for acute myeloid leukemia. Similarly, the pro-inflammatory properties of GM-CSF have been used in the treatment of chronic wounds that do not heal with conventional methods by subcutaneous injection of recombinant GM-CSF around the wound site.

Other emerging applications of GM-CSF utilize its immunomodulatory ability to up-regulate antigen presentation mainly by increasing the number and signal strength of the dendritic cell response. Vaccine strategies that result in the activation of the immune system specifically against proteins expressed by cancer cells have the potential to be effective, low-side-effect anti-cancer therapy. Success in treating metastatic cancer in mice and renal cell, melanoma, and prostate carcinoma in humans has been obtained by the insertion of the GM-CSF gene into cancer cells that are then used to immunize patients. These genetically modified tumor cells produce GM-CSF in the local environment of the tumor cells, specifically activating the patient's T cells and natural killer cells to destroy cancer cells.

Given its many pro-inflammatory properties, it is not surprising that GM-CSF has been detected at sites of acute and chronic inflammation in both infectious and autoimmune disease. Examples of the latter include rheumatoid arthritis, psoriasis, allergy, and graft-versus-host disease. Presumably, the role of GM-CSF at these sites is to recruit and stimulate mainly neutrophils and macrophages as well as to potentiate any autogeneic or allogeneic antigen presentation to T cells. Even atherosclerosis, which is now considered an inflammatory disease, involves GM-CSF secretion in localized tissues by endothelial cells, and macrophages can be stimulated to engulf lipids for atherosclerotic plaque formation in response to GM-CSF. Paradoxically, GM-CSF has also been shown to increase collateral blood flow formation in patients with coronary (atherosclerotic) artery disease.

Glossary

alveolar proteinosis A rare human respiratory disorder characterized by the accumulation of periodic acid-Schiff-positive lipoproteinaceous material (derived from pulmonary surfactant) in the distal airspaces.

cytokine Secreted regulatory peptide or protein that controls certain functions in cells and includes growth factors, interleukins, lymphokines, and colony-stimulating factors.

dimerization The association of two identical molecules (monomers) to form a higher order complex.

granulocyte Any one of the three myeloid cell lineages that contain cytoplasmic granules, namely, neutrophils, eosinophils, and basophils.

granulocyte colony-stimulating factor A hematopoietic cytokine responsible for the regulation of neutrophil production.

innate immune system Ancient immune recognition system of host cells bearing germ-line-encoded pattern recognition receptors that directly recognize foreign antigens or pathogens and comprising natural killer cells, monocytes/macrophages, neutrophils, basophils, eosinophils, and dendritic cell precursors.

JAK Janus tyrosine kinase involved in hematopoietic cytokine receptor signal transduction.

macrophage colony-stimulating factor A hematopoietic cytokine responsible for regulation of monocyte/macrophage production and osteoclast function.

SH2 domain (Src homology-2) A structural domain present in many signal transduction protein molecules that can bind phosphorylated tyrosine residues in the context of a particular recognition sequence.

stem cell transplantation The transfer of stem cells, classically hematopoietic stem cells, from either another organism or the same organism to a recipient animal to reconstitute an entire multilineage cellular system.

Growth Hormone (GH)

PETER E. LOBIE* AND DAVID J. WAXMAN†

*National University of Singapore • †Boston University

Growth hormone (GH) is a member of a class of evolutionarily related hormones that includes prolactin, various placental lactogens, and proliferin. At the cellular level, GH action is mediated by a cell surface receptor, the GH receptor, which initiates multiple intracellular signaling pathways leading to alterations in cell biochemistry and physiology, in many cases by means of changes in gene expression. These cellular responses to GH translate into diverse physiological effects in different organ systems, including stimulation of long bone growth. This article provides a brief overview of the biology, function, and mechanism of action of GH.

I. INTRODUCTION

Many hormones, nutritional factors, and related cell regulators contribute to the regulation of mammalian growth and development; however, only growth hormone (GH) stimulates longitudinal bone growth in a specific and dose-dependent manner. Furthermore, only GH, when secreted at excessive concentrations prior to puberty, is able to induce excessive longitudinal bone growth. In 1909, Harvey Cushing described the relationship between pituitary hyperactivity and gigantism and between pituitary insufficiency and dwarfism. It was subsequently demonstrated that bovine anterior pituitary gland extracts are able to induce supranormal growth in intact rats and that hypophysectomy results in cessation of growth. GH was first isolated in 1944, and purified GH was demonstrated to restore growth in hypophysectomized rats.

II. GENE STRUCTURE AND EXPRESSION AND HORMONE SECRETION

The human GH (hGH) gene is located within a gene cluster composed of five structurally and functionally related genes. Two hGH genes [hGH-N (normal) and hGH-V (variant)] and three placental lactogen (PL) genes constitute this gene cluster, which is located on the long arm of human chromosome 17 (Fig. 1).The GH–PL gene cluster is thought to have evolved from a single ancestral gene by a process involving gene duplications, insertion of gene regulatory elements, and at least one gene conversion event. The five genes in the cluster possess >92% nucleotide sequence identity in their coding and flanking regions. The molecular architecture of each gene is also identical; four small introns split the transcriptional units at identical positions and perfect codon co-linearity exists for the open reading frames of all five genes (Fig. 1, bottom).

Messenger RNAs for two isoforms of hGH-N (designated 22 and 20 kDa hGH) are generated in the somatotrope of the anterior pituitary by differential splicing of the primary transcript. The 22 kDa hGH-N is the predominant form, constituting 90% of pituitary gland GH mRNA. The 20 kDa GH form is identical to the 22 kDa form, except for deletion of amino acid residues 32–46 from exon 2 by an alternate splicing reaction. The hGH-V gene is transcribed and expressed in the placenta, where the protein product is secreted during pregnancy as a 22 kDa isoform.

Comparison of the nucleotide and amino acid sequences of GH from multiple species indicates that the sequence identity between GH and PL in humans (87%) is greater than in other species (65–73% sequence identity between GH and PL genes in porcine, bovine, ovine, equine, and murine). Despite this similarity, hPL has >1% of the growth-promoting potential of hGH. Homology between GH and prolactin family members is substantially lower (~27% sequence identity). Primate GHs, but not GH from other species, can bind to the human GH receptor. Under certain conditions, hGH will also bind and activate the prolactin receptor (e.g., in the rat).

GH is synthesized as a prohormone with a signal peptide at the amino-terminus that is removed during secretion from the cell. The mature 22 kDa hGH-N is a single chain, nonglycosylated 191-amino-acid polypeptide and is the most abundant isoform of hGH in plasma (~76% of total). The half-life of hGH in the human is ~25 min.

The three-dimensional structure of mammalian GH indicates the presence of four α-helices, each 21–30 amino acids in length. The helices are

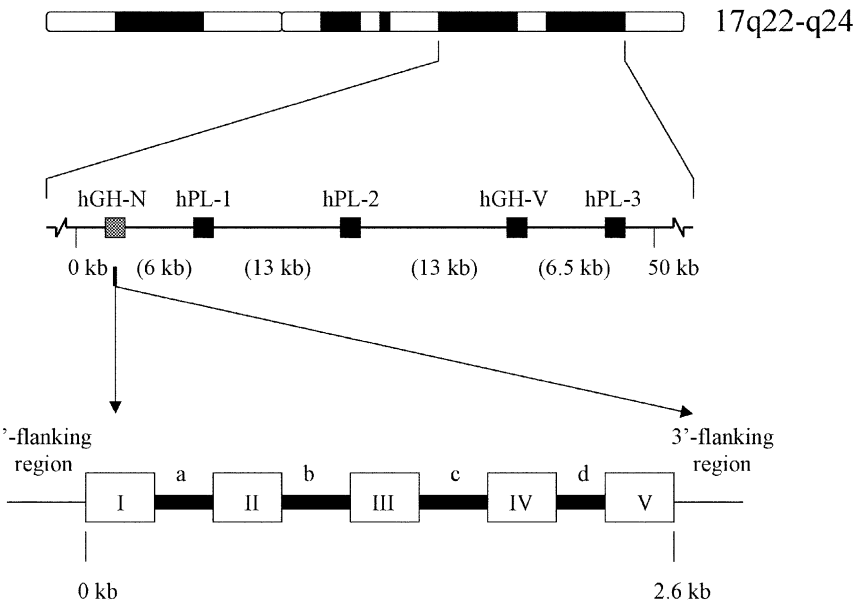

FIGURE 1 The hGH–hPL gene cluster. The five genes shown comprise approximately 8 kb of structural sequences spread over 50 kb of DNA at chromosomal position 17q22–q24. Shown at the bottom are the five exons (I–V) and four introns (a–d) that characterize hGH-N, as well as the other four genes in the cluster.

arranged in a left-handed bundle orientation with an unusual up-up-down-down topology. Long connective loop structures link the two sets of parallel helices, and a shorter loop region connects helix 2 and helix 3. hGH contains disulfide bridges, at Cys-35–Cys-165 and Cys-182–Cys-189. These Cys residues are key components of the loop structures. The central core of the GH molecule is composed of ~20 hydrophobic amino acids. Smaller hydrophobic clusters of amino acids stabilize the four-helix bundle.

The 5′-proximal 0.5 kb promoter sequence of the hGH-N gene contains DNA regulatory elements responsible for the tissue-specific pattern of hGH-N transcription and gene expression. The proximal promoter of the hGH-N gene contains a typical TATA-box, as well as two binding sites for the pituitary transcription factor Pit-1. These sequences, together with more remote sequences as far as 15 kb upstream of the hGH-N transcription initiation site, are required for efficient expression of the hGH-N gene. The proximal hGH-N gene promoter also contains *cis*-acting elements that modulate transcription in response to hormonal signals.

Transcription of the hGH-N gene is stimulated by the hypothalamic GH-releasing hormone, GHRH. GHRH produced in the arcuate nucleus of the hypothalamus binds to and activates a specific GHRH receptor on the surface of the pituitary somatotrope. The GHRH receptor is a G-protein-coupled receptor whose activation by GHRH is linked to an increase in intracellular cyclic AMP (cAMP). The elevated cAMP in turn activates protein kinase A, leading to an increase in the concentration of Pit-1 in the somatotrope. Pit-1 is a member of the POU homeodomain family of transcription factors and binds to two Pit-1-binding sites in the proximal promoter of the hGH-N gene. Thus, GHRH-stimulated hGH-N gene transcription is Pit-1-dependent.

GH is stored in secretory granules of the somatotrope until a secretory signal leading to an increase in intracellular Ca^{2+} or cAMP stimulates the secretion of GH. GH release from pituitary somatotrope cells occurs in a highly pulsatile fashion and is subject to neuroendocrine control. GH secretion is controlled by the opposing action of GHRH and the GH secretagogue GHrelin, both of which stimulate GH secretion, and somatostatin, which inhibits GH release and helps establish the timing and amplitude of the secretory pulse. Somatostatin, derived from the anterior periventricular nucleus in the hypothalamus, can override the stimulatory effects of GHRH. Somatostatin inhibits GH release from the somatotrope by binding to a G_i-protein-coupled cell surface receptor, leading to a decrease in intracellular cAMP levels. GHrelin is a 28-amino-acid polypeptide with a unique *n*-octanoly-serine modification; it is produced in the gastric mucosa and the hypothalamus. GHrelin binds to and activates the GH secretagogue receptor (GHSR) as do various synthetic GH secretagogues. GHSR is a seven-transmembrane G-protein-coupled receptor. Alternative splicing of the GHrelin gene (Gln14-GHrelin) yields a second ligand for GHSR that also promotes GH release. Increased somatrope Ca^{2+} levels, induced by GHrelin, act in a synergistic manner with the increased production of cAMP in response to GHRH to stimulate pituitary secretion of GH. GH secretion can also be regulated by leptin through its effects on hypothalamic GHRH and somatostatin activity. Leptin is thought to be a major adipose tissue-derived signal responsible for the influence of nutritional status on GH secretion (e.g., increased amplitude of GH secretion in the fasted state).

Gonadal steroids play an important role in modulating pituitary GH secretory patterns, with estrogen acting at the level of the hypothalamus to induce more frequent pulses of GH secretion. This results in the occurrence of sex-dependent plasma GH profiles in several species, including humans. Sex differences in plasma GH profiles are most striking in rodents and lead to marked sex differences in GH-induced intracellular signaling and gene expression patterns in the liver. GH secretion in humans declines with age in both sexes, leading to an increase in body fat and a decrease in muscle mass associated with a decrease in GH-stimulated insulin-like growth factor-I (IGF-I) production.

GH is also expressed in various cell types and tissues outside of the pituitary gland, albeit at a much lower level. These include the central nervous system, the mammary gland, gonads from both sexes, and cells of the hematopoietic and immune systems. In some cells, GH expression is responsive to GHRH, and in others, notably lymphocytes, it is independent of Pit-1. GH therefore possesses autocrine/paracrine effects that are distinct from its endocrine effects.

III. GH RECEPTOR AND GH-BINDING PROTEIN

The human GH receptor is encoded by a single-copy gene located in the proximal short arm of chromosome 5 in the region p13.1–p12 and spans ~87 kb (Fig. 2). The hGH receptor gene is characterized by at

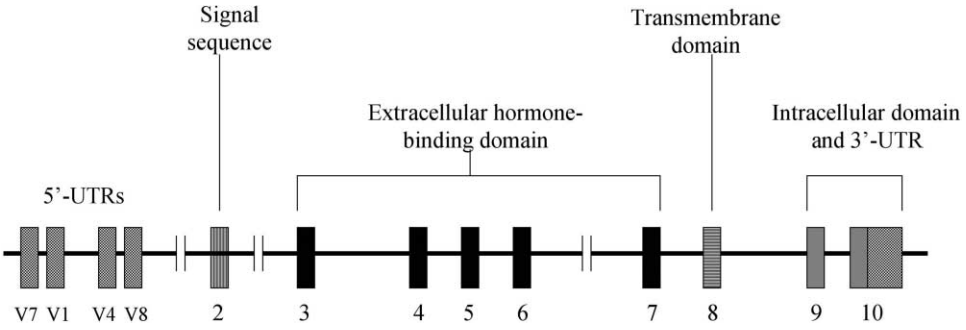

FIGURE 2 Genomic structure of the hGH receptor gene.

least eight distinct, alternative 5′-untranslated region (5′-UTR) variants of exon 1. In liver, GH receptor exon 1 variant 1 (V1) is the most highly expressed form. The untranslated exon 1 is followed by nine protein-coding exons. Exon 2 encodes the last 11 bp of the 5′-UTR, an 18-amino-acid signal peptide, and the first 5 amino acids of GH receptor's extracellular domain. Exons 3–7 encode the majority of the receptor's extracellular domain. Exon 8 encodes the final 3 amino acids in the extracellular domain, a 24-amino-acid transmembrane domain, and the first 4 amino acids of the receptor's intracellular domain. Exons 9 and 10 encode the remaining 346 amino acids of the intracellular domain. Exon 10 also codes for a 2 kb 3′-UTR.

The GH receptor is an ~620-amino-acid single-pass transmembrane protein. The GH receptor contains two extracellular domains (amino acids 1–123 and 128–238) linked by a 4-residue spacer. Each extracellular domain contains seven β strands arranged to form a sandwich of two antiparallel β sheets. The GH receptor also contains three disulfide bonds, bridging Cys-38–Cys-48, Cys-83–Cys-94, and Cys-108–Cys-122. The overall extracellular domain is stabilized by these disulfides, in combination with hydrogen bonding between Arg-43 and Glu-169 and a salt bridge between Arg-39 and Asp-123. The molecular mass of the GH receptor predicted from its amino acid sequence is 70 kDa. However, the actual mass of GH receptor is 100–130 kDa, with the difference in size due to postranslational modifications such as glycosylation and ubiquitination. The GH receptor contains five N-linked glycosylation sites, each adding approximately 10 kDa in mass to the receptor. The GH receptor possesses 19 potential ubiquitination sites and can be polyubiquitinated on multiple lysine residues. Ubiquitination of the receptor is increased by ligand binding and may play a role in GH receptor internalization.

Human GH-binding protein (GHBP) is a proteolytic fragment of the GH receptor that circulates as a plasma-binding protein. It is generated by a metalloprotease-catalyzed cleavage of the plasma membrane-bound receptor form. Up to 60% of plasma GH is bound to GHBP, with the fraction bound decreasing at higher plasma GH concentrations. GHBP acts to increase the half-life of circulating GH by decreasing its rate of clearance and degradation. In rats, mice, and monkeys, GHBP is generated from the GH receptor at the RNA level, by alternative splicing of the GH receptor precursor RNA. Several short but membrane-anchored isoforms of GH receptor have also been described in humans.

GH receptor expression is highest in the liver, a major target organ of GH action. However, GH receptor expression has been observed in many organ systems, including the gastrointestinal tract, male and female reproductive systems, musculoskeletal system, cardiorespiratory system, hematopoietic and immune systems, central nervous system, the integument, renal and urinary systems, and endocrine system. Within each system, the GH receptor is expressed on both differentiated and undifferentiated cell types. The GH receptor is also expressed on cells derived from the ectoderm, mesoderm, and endoderm of the developing fetus.

The heterogeneity in the 5′-UTR exon 1 sequences of the GH receptor gene transcripts noted above indicates complex transcriptional control of the GH receptor locus. Indeed, the level of GH receptor mRNA can be regulated by both nutritional and hormonal factors, including GH itself. Experimental data derived from the GH receptor V1-like transcript of different mammalian species has revealed both positive- and negative-acting 5′-regulatory elements driving transcription. A proximal TATA-box is conserved across species, as is a positive-acting C/EBP and glucocorticoid-response element complex site and a negative-acting CCAAT

site further upstream. The CCAAT site has been demonstrated to bind the transcription factors MSY-1 and NF-Y. Additional regulatory elements may exist further upstream.

IV. PHYSIOLOGIC AND METABOLIC EFFECTS

GH exhibits diverse and pleiotropic effects on cell proliferation, differentiation, morphology, and metabolism. Some of these effects are a response to the direct action of GH in its target tissues, and other effects are indirect and are mediated by growth factors induced by GH, e.g., insulin-like growth factor (IGF-I), whose expression in liver and other tissues is strongly stimulated by GH. Both the direct and the indirect cellular effects of GH are subsequently translated into physiological effects in individual target organ systems.

A major mechanism by which GH affects cellular and, consequently, physiologic function is by regulating the rate of transcription of specific RNA species. Some of these GH-regulated RNAs code for tropic factors, such as IGF-I, which act in an intermediary role to execute cellular actions of GH. IGF-I is produced in many tissues and acts in an endocrine/paracrine manner through either the IGF-I receptor or the insulin receptor. GH also regulates other tropic factors, including hepatocyte growth factor in liver, epidermal growth factor in kidney, basic fibroblast growth factor in chondrocytes, interleukin-6 (IL-6) in osteoblasts, bone morphogenetic proteins 2 and 4 in fibroblasts, IL-1α, IL-1β, and thymulin in thymus, and preadipocyte factor-1 in adipocytes and islet beta cells.

The predominant phenotypic effect of GH is to promote longitudinal bone growth in the postnatal and pubertal growth periods. This is achieved by coordinated stimulation of both chondrocyte and osteoblast proliferation and effects on differentiated cell function. GH also exerts anabolic effects resulting in positive nitrogen balance and muscular hypertrophy consequent to increased protein synthesis.

GH exerts profound effects on body composition through a combination of anabolic, lipolytic, and anti-natriuretic actions. GH enhancement of the lipolytic activity of adipose tissue in combination with a reduction of triglyceride accumulation via inhibition of lipoprotein lipase activity appears to be the major mechanism by which GH acts to stimulate a reduction of total fat mass.

GH is important for cardiac function. hGH has been demonstrated to increase myocardial mass and improve myocardial energy metabolism and hemodynamics.

GH alters the size and morphology of the central nervous system during development and affects differentiated cell function with consequent modulation of cognitive function. Cognitive effects of GH include the enhancement of both long-term memory and delayed extinction responses, improved performance on operant discrimination learning, stimulation of maternal behavior, and an increase in rapid eye movement sleep with a concomitant decrease in slow-wave sleep.

GH increases the renal glomerular filtration rate and also increases renal absorption of sodium, phosphate, and water. GH also increases the activity of 25-hydroxy-1-α-hydroxylase (thereby increasing calcitriol production), as well as renin and erythropoietin synthesis.

GH is required for sexual differentiation and pubertal maturation and it participates in gonadal steroidogenesis, gametogenesis, and ovulation. GH is also required for fetal nutrition and growth during pregnancy and for mammary development and lactation.

GH stimulates hypertrophy throughout the gastrointestinal tract especially by stimulation of the epithelial component. GH also stimulates increased water and mineral transport and stimulates the absorption of specific vitamins such as vitamin B12. Studies in rodents show that GH regulates the expression of a large number of liver metabolic genes and other genes in a sexually dimorphic manner. This sexual dimorphism can be directly attributed to the differential stimulation of gene expression by the male versus female pattern of pituitary GH secretion.

GH has several immunomodulatory functions including the proliferation of B cells and T cells, stimulation of cytokine and immunoglobulin production, and regulation of the activity of neutrophils, macrophages, and natural killer cells.

Postnatal body weight and composition differ between males and females due to sexual dimorphism of the somatotropic axis and its impact on GH secretory patterns, as noted above. Such sex differences predominantly originate at the hypothalamic–pituitary level but are also due to altered responsiveness of target tissues to somatotropic-axis hormones.

V. CLINICAL SYNDROMES

The absence or decrease of pituitary GH production is referred to as isolated GH deficiency (IGHD)

(1 in 500 human births). A small proportion (5–30%) of known clinical cases are hereditary. Four IGHD types can be differentiated according to their pattern of inheritance, severity, and response of the affected individuals to recombinant hGH treatment. Among them, type 1A is an autosomal recessive disorder in which endogenous GH is absent. The loss of GH production is due mainly to homozygous deletion of the hGH-N gene. IGHD type 1A subjects often exhibit short stature and hypoglycemia at birth and by 6 months of age display readily obvious signs of dwarfism.

Acromegaly, a condition due to excessive secretion of GH, is associated with an increased morbidity and mortality. This is largely due to cardiovascular, cerebrovascular, respiratory, and metabolic diseases.

Laron syndrome is a recessively inherited disease characterized by GH resistance. Multiple primary defects that cause the disease include deletion, nonsense, frameshift, missense, and splice site mutations, most often in the extracellular domain of the GH receptor. Mutations in the receptor's intracellular domain, as well as postreceptor signaling defects leading to a typical Laron phenotype, are also known. These mutations result in truncation, abnormal processing, loss of ligand binding, lack of receptor dimerization, and interference with signal transduction of the GH receptor. Humans with Laron syndrome exhibit short stature, trunkal obesity, and low serum IGF-I, but elevated serum hGH concentration and low serum GHBP. Deletion of the GH receptor gene in mice produces a phenotype similar to Laron dwarfism.

VI. SIGNAL TRANSDUCTION

The GH receptor was the first identified member of the cytokine receptor superfamily. Other members of the superfamily include prolactin, erythropoietin, granulocyte colony-stimulating factor, granulocyte/macrophage colony-stimulating factor, ciliary neurotropic factor, thrombopoietin, leptin, interleukins 2–7, IL-9, IL-11, and IL-12 ('class 1' family members). The superfamily also includes receptor subunits that interact with more than one cytokine receptor. Such receptor subunits include gp130 [shared by leukemia inhibitory factor (LIF), oncostatin M, IL-6, IL-11, and IL-12], the β-subunit of the LIF receptor, the γ-chain of the IL-2 receptor (shared by IL-2, IL-4, IL-7, IL-9, and IL-15) and the IL-3 receptor common β chain.

Common features and characteristics of the class 1 cytokine receptor superfamily members include the following (see Fig. 3): (1) possession of a single transmembrane domain; (2) limited amino acid homology (14–44% sequence identity) in a region spanning ~210 amino acids in the extracellular domain (corresponding to two fibronectin III domains); (3) conserved pairs of cysteine residues in the extracellular domain and a conserved tryptophan residue adjacent to the second cysteine in the N-terminal fibronectin domain; (4) a WSXWS (Trp-Ser-X-Trp-Ser)-like motif in the C-terminal fibronectin domain (YXXFS in the mammalian GH receptor); (5) the absence of a canonical tyrosine kinase consensus sequence; (6) two short proline-rich sequences in the intracellular domain; and (7) multiple intracellular domain tyrosine residues, several of which become phosphorylated upon activation of the receptor by ligand binding. In addition, members of the cytokine receptor superfamily utilize similar mechanisms of signal transduction, which is directed by the receptor's C-terminal cytoplasmic tail. Two conserved regions within

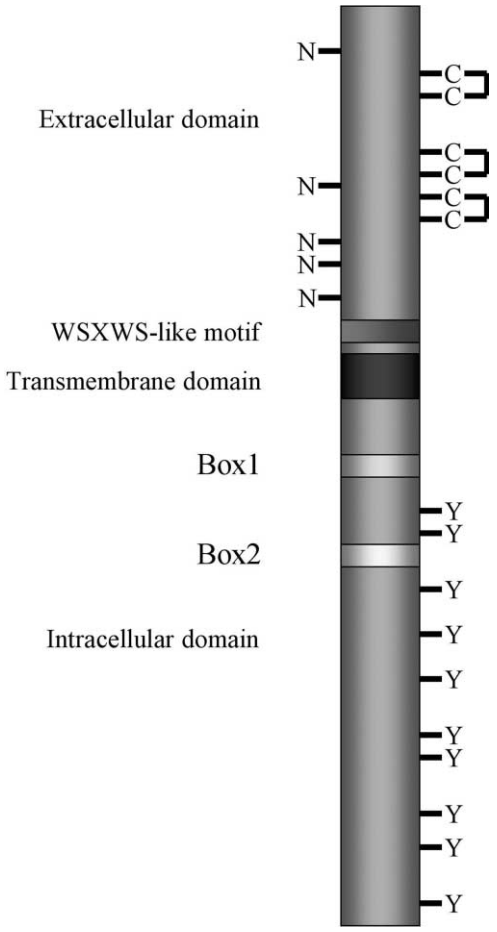

FIGURE 3 Schematic structure of the hGH receptor.

the cytoplasmic tail of the GH receptor and other cytokine receptor family members are designated Box 1 and Box 2. Box 1 is an important site of association of Janus kinase 2 (JAK2) with the GH receptor. Box 1 is located within 20 residues of the transmembrane domain and displays an alΨPXalPXP or ΨXXXalPXP consensus sequence, where al is any aliphatic residue, Ψ is any hydrophobic residue, and P is proline. In mammalian GH receptors, the Box 1 sequence is ILPPVPVP. Box 2 is less well defined and comprises approximately 15 amino acids situated 30 residues C-terminal to Box 1. It consists of a cluster of hydrophobic and acidic residues ending with 1 or 2 basic residues.

GH activates the GH receptor by a sequential receptor dimerization reaction. This dimerization initiates the signal that generates GH's multiple downstream signaling events and biological responses. Each GH molecule contains two receptor-binding sites, a high-affinity binding site, designated site 1, and a lower affinity site, site 2. GH initially binds to one molecule of the GH receptor, via GH site 1. The resultant GH site 1–GH receptor complex then binds to a second receptor molecule via GH site 2. Essentially the same ligand-binding site is used by each GH receptor molecule in forming the GH–$(\text{GH receptor})_2$ complex. In the final, active trimeric complex, one GH molecule bridges two receptor molecules, i.e., (GH receptor)–GH–(GH receptor). GH derivatives with mutations at site 2 form inactive, monomeric GH site 1–GH receptor complexes and provide a basis for the development of effective GH receptor antagonists.

The GH receptor lacks intrinsic tyrosine kinase activity, as do all other members of the cytokine receptor superfamily. The GH receptor therefore recruits the nonreceptor Janus family tyrosine kinase JAK2 to initiate signal transduction in response to GH binding. Unique structural features of JAK2 include the absence of SH2 or SH3 domains and the presence of seven conserved JH regions (JH1–JH7), of which JH1 comprises the functional tyrosine kinase catalytic domain and JH2 is a catalytically inactive pseudo-kinase domain. The pseudo-kinase domain of JAK2 interacts with the kinase domain to negatively regulate JAK2's tyrosine kinase activity. This interaction is required to maintain JAK2 in the inactive state in the absence of a hormonal stimulus.

Upon GH receptor dimerization, the JAK2 protein molecule associated with the box 1 region of each GH receptor chain is spatially positioned and/or conformationally modified to enable the pair of JAKs to carry out a trans-phosphorylation reaction. This reaction results in the phosphorylation of JAK2 on two C-terminal tyrosine residues of each JAK molecule, leading to the activation of JAK2's tyrosine kinase activity. The activated JAK2 then phosphorylates the intracellular domain of the GH receptor on multiple cytoplasmic domain tyrosine residues. The tyrosine phosphorylated GH receptor–JAK2 complex in turn provides docking sites for a variety of signaling molecules that contain Src-homology 2 (SH2) or other phosphotyrosine-binding motifs.

Four major signaling cascades are subsequently initiated by the JAK2-activated GH receptor (Fig. 4). (1) GH-stimulated tyrosine phosphorylation of STAT proteins (signal transducers and activators of transcription) that dock to the GH receptor–JAK2 complex leads to a direct stimulation of target gene transcription (see below); (2) GH activation of the Ras–Raf–MEK pathway results in the activation of mitogen-activated protein kinase (MAP kinase), a dual-specificity kinase whose activity is linked to intranuclear phosphorylation, c-fos transcription, and cell proliferation. GH-induced MAP kinase activation thus links multiple GH-activated signaling pathways; (3) GH activation of phosphatidylinositol 3-kinase (PI 3-kinase), at least in part by tyrosine phosphorylation of insulin receptor substrates (IRS-1 and IRS-2), is thought to contribute to the metabolic and proliferative activities of GH; and (4) GH activation of protein kinase C may impact on the metabolic, differentiative, and proliferative actions of GH. Significant cross talk between these and other GH signaling pathways may also occur.

GH can activate four of the seven known mammalian STAT forms, STATs 1, 3, 5a, and 5b. Each STAT protein resides in the cytoplasm in an inactive form until it is converted by tyrosine phosphorylation to an active dimeric DNA-binding form, which translocates into the nucleus where it activates certain GH target genes. STAT5b appears to be the most important STAT in mediating GH's effects on pubertal growth in male mice. STAT5b is also a key regulator of the sex-dependent transcriptional effects of GH in the liver. Consistent with this role, the pulsatile pattern of plasma GH stimulation that characterizes adult male rodents induces a repeated, pulsatile translocation of liver STAT5b from the cytoplasm to the nucleus. This enables the activated STAT5b to bind to STAT5 DNA-response elements found upstream of male-expressed liver GH target genes. STAT1 and STAT3 may play a role in GH's induction of c-fos, an early GH-induced transcriptional response. STAT5a plays a major role in the effects of prolactin on mammary gland differentiation

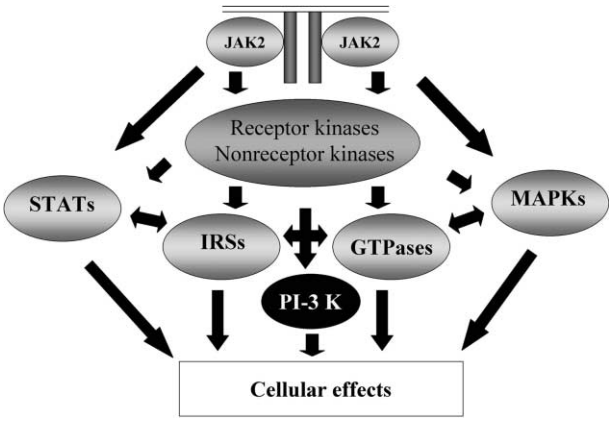

FIGURE 4 GH signal transduction. Shown is a simplified diagram of the major intracellular pathways of GH signal transduction. GH binding to its cell surface receptor induces dimerization of the receptor with subsequent association and activation of the tyrosine kinase JAK2 in association with the recently described protein signaling protein SH2b-β (not shown). JAK2 then induces the subsequent activation of several major groups of signaling molecules. These include (1) STAT family members, including STATs 1, 3, 5a, and 5b, which constitute a major mechanism for transcriptional regulation by GH; (2) small Ras-like GTPases and their downstream target members of the MAP kinase family, including p44/42 MAP kinase, p38 MAP kinase, and JNK/SAPK and their respective downstream signaling pathways; (3) members of the IRS group, including IRS-1, IRS-2, and IRS-3, which serve as docking proteins for further activation of signaling molecules including phosphatidylinositol 3-kinase; and (4) protein kinase C. For further details, see text. GH can also activate other receptor (EGF receptor) and nonreceptor (c-Src, c-Fyn, and FAK) kinases not shown in the figure.

but may also contribute to GH responses in other tissues.

Modulation and attenuation of GH signaling is thought to occur by multiple mechanisms. Two major mechanisms involve (1) the action of specific phosphotyrosine phosphatases, which dephosphorylate and thereby deactivate several key tyrosine phosphorylated GH signaling molecules. These include GH receptor itself, the tyrosine kinase JAK2, and the GH-activated STATs, which are recycled from the nucleus back to the cytoplasm in their inactive, monomeric forms upon dephosphorylation; and (2) the STAT-dependent activation of several immediate-early response genes belonging to the SOCS/CIS (suppressor of cytokine signaling) family. The induced SOCS and CIS proteins feedback inhibit the overall signaling pathway by binding to the tyrosine phosphorylated GH receptor–JAK2 complex via the SOCS protein's SH2 domain. This recruitment of a SOCS/CIS protein blocks further receptor signaling by one of several mechanisms: inhibition of JAK2 activity; competition between SOCS and STAT for GH receptor–phosphotyrosine-binding sites; and stimulation of GH receptor degradation by a proteasome-dependent mechanism. The precise relationship of this latter signal termination mechanism to the established pathways of GH receptor ubiquitination and internalization remains to be clarified.

VII. SUMMARY

GH is the major hormonal regulator of postnatal somatic growth. It is produced predominantly by the pituitary gland as a 191-amino-acid single-polypeptide chain. The cellular actions of GH are initiated by binding to its specific plasma membrane bound receptor in a 1:2 stoichiometry. Signal transduction by GH is predominantly mediated by Janus kinase 2, which tyrosine phosphorylates a variety of intracellular substrates, including the GH receptor and itself. GH also regulates the development and function of the different organ systems, often by stimulation of intermediary tropic factors, such as the insulin-like growth factor IGF-I. The major phenotypic effect of GH is promotion of longitudinal bone growth.

Glossary

growth hormone-binding protein A soluble, circulating form of the growth hormone receptor that is composed of the receptor's extracellular ligand-binding domain and can be formed in different species by proteolytic cleavage of the membrane-bound form or by alternative splicing of the growth hormone receptor primary transcript.

growth hormone secretagogue A synthetic or naturally occurring peptide that interacts with the growth hormone secretagogue receptor to stimulate secretion of pituitary growth hormone.

Janus kinase 2 A nonreceptor tyrosine kinase that associates with the growth hormone receptor and is activated by growth hormone, leading to the initiation of multiple pathways of intracellular signal transduction.

signal transducers and activators of transcription A family of latent cytoplasmic transcription factors whose members contain an SH2 domain, are activated by phosphorylation at a single carboxy-terminal region tyrosine residue in response to cytokine or growth

factor receptor stimulation, and when activated, dimerize and translocate to the nucleus where they induce transcription of specific target genes.

somatotrope A secretory cell type in the anterior hypophysis that is the major site for synthesis and secretion of growth hormone.

Growth Hormone-Releasing Hormone (GHRH) and the GHRH Receptor

SHANE R. CUNHA AND KELLY E. MAYO
Northwestern University

Growth hormone-releasing hormone (GHRH) is the preeminent neuroendocrine factor positively regulating growth hormone (GH) synthesis and secretion. Together with the negative regulator somatostatin, it forms a regulatory network that maintains an appropriate pulsatile pattern of GH release in the adult vertebrate organism. As such, GHRH is itself subject to regulation by a wide variety of neurotransmitters, hormones, and metabolic cues, leading to an appropriate integration of sensory information and a corresponding activation of the GH axis. GHRH exerts its actions through a specific G-protein-coupled receptor expressed on the somatotroph cells of the anterior pituitary. The predominant signaling pathway downstream of the GHRH receptor, leading to increased GH synthesis and secretion, is a cyclic AMP-mediated pathway. In addition, recent studies suggest that activation of other signaling pathways, such as the mitogen-activated protein kinase cascade, play an important role in mediating the early developmental effects of GHRH on somatotroph cell proliferation and differentiation. Consistent with the key role that GHRH and its receptor play in the regulation of GH secretion, the hormone and receptor have been implicated in several diseases or disorders affecting growth in

human. Future study of the receptor and its ligand-binding properties, leading to the design of more effective agonists and antagonists, therefore holds substantial therapeutic promise. Finally, the finding that GHRH and its receptor are expressed in numerous tissues in a regulated fashion suggests additional roles of the hormone that are not well understood and represent a significant challenge for the future.

I. INTRODUCTION

A variety of organs must work together to ensure the proper development and homeostasis of an organism. The endocrine system facilitates communication between these organ systems through the actions of secreted steroid and peptide hormones. Key to the functions of this system is the hypothalamus, which integrates sensory information and regulates hormone secretion from the pituitary gland, producing an appropriate endocrine response. With respect to the growth hormone (GH) axis, the hypothalamus regulates GH secretion from somatotroph cells of the anterior pituitary through the opposing actions of two hormones: growth hormone-releasing hormone (GHRH) and somatostatin (SRIF). GHRH stimulates GH synthesis and secretion, and SRIF suppresses GH secretion (see Fig. 1). GH has important systemic, anabolic functions, many of which are mediated by insulin-like growth factors (IGFs). Many tissues including the liver secrete IGF-I following GH stimulation. Some IGF-mediated functions include stimulation of amino acid uptake by muscles for protein synthesis, activation of cartilage formation and calcification in bones, and inhibition of glucose uptake in adipose tissue, thereby reducing fat deposition.

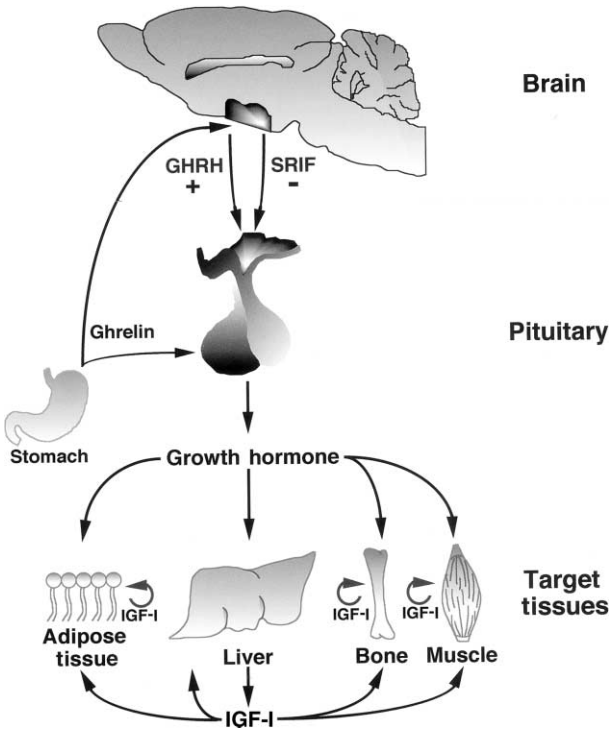

FIGURE 1 Overview of the growth hormone axis. GHRH and somatostatin (SRIF) are the predominant stimulatory and inhibitory factors released from the hypothalamus to modulate GH synthesis and secretion in the pituitary. Ghrelin is a stimulatory factor released from the stomach. GH acts directly on the liver, fat, bones, and muscle. Additionally, some of the effects of GH are mediated by insulin-like growth factor I (IGF-I), which is secreted from the liver and other tissues. GH and IGF-I modulate proliferation, differentiation, and metabolism in the target tissues.

II. GHRH

A. Characterization

GHRH was initially isolated from human pancreatic tumors that caused acromegaly, an endocrine disorder resulting from excessive GH secretion in the adult. Three isoforms were identified: GHRH(1–37)-OH, (1–40)-OH, and (1–44)-NH_2. All three isoforms stimulate GH secretion, but the shorter isoforms are less potent and probably arise from differential processing of the GHRH precursor protein or proteolytic degradation of the full-length GHRH product. The first 29 amino acids of GHRH are remarkably conserved across species and contain the necessary amino acids to confer biological activity. The amino-terminus forms an α-helical structure that is important for receptor binding. This domain has served as the template for subsequent generations of GHRH receptor agonists and antagonists. The carboxyl-terminus increases peptide stability, and amidation of the carboxyl-terminus of GHRH(1–44) further enhances this stability. Unlike human GHRH and GHRH from domestic animals, the mouse and rat GHRH peptides have 42 and 43 amino acids, respectively, and are not C-terminally amidated. Human GHRH is inactivated in serum by cleavage of the first 2 amino acids by dipeptidylaminopeptidase, producing a more stable metabolite, GHRH(3–44)-NH_2, which is 1000-fold less effective at eliciting GH secretion. Subsequent to its isolation from pancreatic tumors, GHRH was isolated from the human and rat hypothalamus. The neurons in the arcuate nucleus of the hypothalamus synthesize GHRH and secrete it into the median eminence,

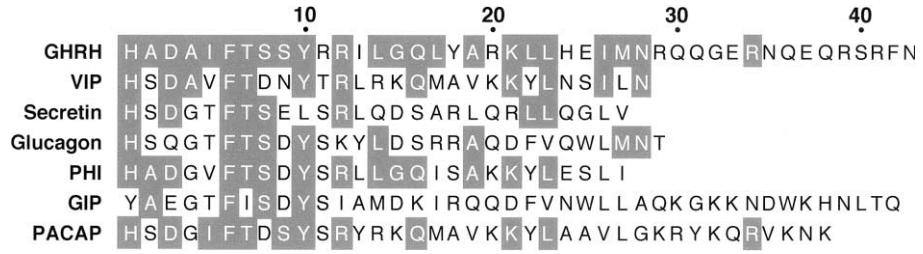

FIGURE 2 Amino acid sequence identity between GHRH and other brain–gut peptides in the rat. Conserved residues are shaded. VIP, vasoactive intestinal peptide; PHI, peptide hormone isoleucine; GIP, gastric inhibitory peptide; PACAP, pituitary adenylate cyclase-activating polypeptide.

where it is released into the portal system, which terminates on the pituitary gland. GHRH or GHRH-like peptides have been characterized in mammals, birds, amphibians, and fish. Based on amino acid sequence homology, GHRH belongs to the family of brain–gut peptides that includes secretin, pituitary adenylate cyclase-activating polypeptide (PACAP), glucagon, glucagon-like peptide-1, vasoactive intestinal peptide (VIP), gastric inhibitory peptide (GIP), and peptide hormone isoleucine/peptide hormone methionine (see Fig. 2).

B. Biosynthesis and Tissue Expression

In mammals, GHRH is proteolytically processed from a precursor protein that consists of a secretatory signal sequence, the mature GHRH peptide, and a C-terminal peptide that is distantly related to GHRH (see Fig. 3). This related peptide is reported to stimulate expression of stem cell factor, which may be involved in reproduction and is necessary for hematopoiesis. The precursor proteins for mouse and rat GHRH are 103 and 104 amino acids long, respectively. In the human, there are two precursor proteins of 107 and 108 amino acids, with the latter isoform containing an additional serine in the carboxyl-terminus as a result of alternative RNA splicing. In nonmammalian vertebrates, a single precursor protein encodes GHRH and the related peptide PACAP.

The gene for GHRH is found on chromosome 20 in human and on chromosome 2 in mouse. In human, rat, and mouse, the gene has four exons encoding the precursor protein, with an alternative first exon encoding unique 5′-untranslated sequences for hypothalamic, placental, or testicular tissue (see Fig. 3). The unique first exon allows for tissue-specific regulation, whereas the remaining four exons, utilized in all tissues, encode the same full-length GHRH precursor protein. Within the gene, the unique testis-specific exon is located upstream of the placental and hypothalamic exons. Alternative splicing of the GHRH gene in the testes results in three transcripts, two of which also include the unique placental exon.

In addition to its expression in the hypothalamus, placenta, and testis, GHRH mRNA has been detected in lymphocytes, pancreas, gastrointestinal tract, and ovary. In the ovary, GHRH modulates the actions of follicle-stimulating hormone on granulosa cells and may promote follicular maturation. Testicular GHRH may act as an intragonadal regulatory factor by modulating gonadotropin-induced steroidogenesis, and placental GHRH probably acts to regulate secretion of fetal growth hormone and maternal placental lactogen. In lymphocytes, GHRH might

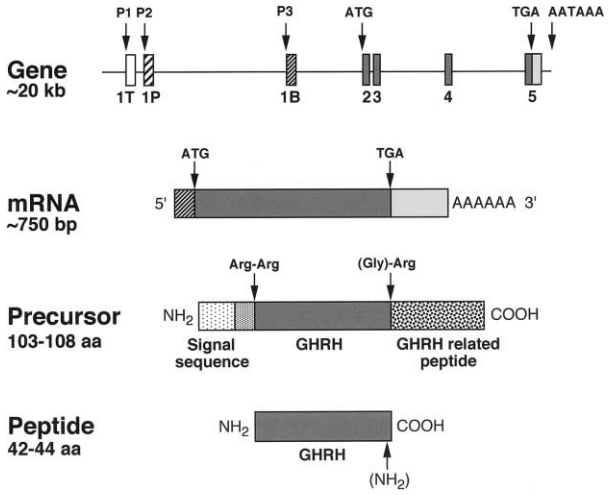

FIGURE 3 Summary of GHRH biosynthesis in mammals. The structure of the GHRH gene, mRNA, precursor protein, and mature peptide are schematically presented. P1, P2, and P3 represent distinct promoters upstream of the first exons used in testis (1T), placenta (1P), or brain (1B) mRNAs. Exons 2–5 are conserved. Arg-Arg and (Gly)-Arg, sites of proteolytic processing; (NH_2), amidation of carboxyl-terminus in GHRH, which occurs in all species except in rodents.

function to modulate immunity, whereas in the pancreas and gastrointestinal tract, GHRH may be involved in hormone secretion.

III. REGULATION OF GHRH

A. Neuroendocrine Regulation of GHRH Secretion

Regulation of GHRH secretion by a variety of neurotransmitters produces a pulsatile secretion pattern. In humans, GHRH pulses are secreted throughout the day with a large bolus of GHRH released at the onset of sleep. Exercise, nutrition, and stress can alter this secretion pattern. This pulsatility in GHRH secretion is partly the result of inhibitory actions by SRIF on GHRH neurons. SRIF receptors are expressed on GHRH neurons and receptor activation inhibits GHRH secretion. Similar to GHRH, SRIF is released in a pulsatile manner and SRIF neurons express GHRH receptors, by which GHRH stimulates SRIF release. Based on findings from rodent studies, a model of alternating patterns of SRIF and GHRH secretion has been proposed. In this model, peaks in SRIF secretion correspond to troughs in GHRH secretion and vice versa. These alternating secretion patterns for GHRH and SRIF could account for the pulsatility in GH secretion.

Additional neurotransmitters regulate GHRH secretion by stimulating GHRH release and/or inhibiting SRIF release (see Fig. 4). Three neurotransmitters that stimulate GHRH secretion by acting directly on GHRH neurons are γ-aminobutyric acid, epinephrine, and norepinephrine. In contrast, galanin inhibits SRIF release and stimulates GHRH release. Interestingly, GHRH neurons co-secrete galanin with GHRH, and galanin receptors are expressed on SRIF neurons, suggesting that galanin may provide an additional mechanism through which GHRH neurons can regulate SRIF release. Opiates increase GHRH secretion by inhibiting SRIF release. The effects of dopamine and serotonin on GHRH secretion vary depending on the species studied. In rodents, dopamine increases SRIF release and inhibits GHRH release. Mice that have elevated levels of dopamine as a result of genetic disruption of the dopamine transporter also exhibit dwarf phenotypes with reduced GHRH mRNA content. In contrast to rodents, humans demonstrate reduced levels of SRIF following dopamine treatment. The effect of serotonin on GHRH secretion is also species-specific. Serotonin stimulates the release of GHRH in rats but inhibits it in sheep.

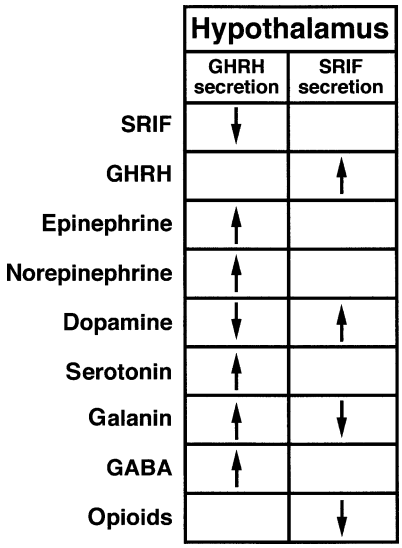

FIGURE 4 Neuroendocrine regulation of GHRH and SRIF secretion in rodents. Arrows indicate changes in GHRH and/or SRIF secretion in response to a variety of hormones or neurotransmitters.

B. Hormonal Feedback Regulation

Hormones of the GH axis, including GH and IGF-I, act on the hypothalamus and pituitary to attenuate the GH response to GHRH (see Fig. 5). GH inhibits GHRH synthesis and secretion in the hypothalamus. In transgenic mice overexpressing human GH, GHRH mRNA synthesis is decreased. In contrast, GHRH mRNA synthesis is increased in the absence of GH following hypophysectomy. These inhibitory effects of GH on GHRH synthesis and secretion in the hypothalamus may be mediated by SRIF input, which is released from SRIF neurons following GH stimulation. In the pituitary, GH acts on somatotroph cells to inhibit GH synthesis, thereby establishing a negative regulatory loop. Similarly to GH, IGF-I reduces GHRH mRNA content in the hypothalamus. IGF-I also inhibits GH synthesis and GHRH-induced GH secretion from the pituitary.

C. Metabolic Cues

Nutritional status and metabolism affect GHRH synthesis and secretion through the actions of thyroid hormones, leptin, ghrelin, and glucocorticoids (see Fig. 5). Thyroid hormones decrease GHRH synthesis and secretion. The ability of thyroid hormones to stimulate GH synthesis may mediate this effect. In hypothyroidism, the reduction in GH synthesis would result in a compensatory increase in GHRH synthesis and secretion. In contrast, GHRH synthesis

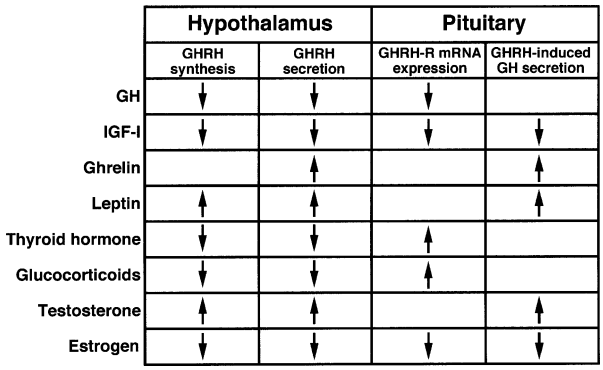

FIGURE 5 Hormonal regulation of the GH axis in rodents. Arrows indicate changes in hypothalamic synthesis and secretion of GHRH and pituitary responsiveness to GHRH in response to a variety of peptide and steroid hormones.

and secretion would be reduced in hyperthyroidism as a result of the elevated GH levels.

Leptin is a hormone released from white adipose tissue that signals satiety to the hypothalamus. In addition to down-regulating mRNA for Neuropeptide Y, a potent stimulator of food intake, leptin increases GHRH synthesis and decreases SRIF synthesis in the hypothalamus. Leptin also enhances GHRH secretion from the hypothalamus and GHRH-induced GH release from somatotroph cells of the pituitary. By increasing GHRH synthesis and GH secretion, leptin may reduce glucose uptake by adipose tissue through the actions of GH and, thereby, inhibit fat deposition.

Ghrelin is a hormone that is released from the stomach and that stimulates food intake, adipogenesis, and GH release from the pituitary. GH secretion is partly stimulated by GHRH released from the hypothalamus following ghrelin stimulation. In addition, ghrelin acts directly on somatotroph cells of the anterior pituitary to stimulate GH secretion. Interestingly, somatotroph cells release GH synergistically following GHRH and ghrelin stimulation.

Glucocorticoids are important regulators of the GH axis. They have a suppressive effect on growth, but they have variable effects on individual hormones in the GH pathway. Glucocorticoids reduce GHRH synthesis and content in the arcuate nucleus of the hypothalamus, suggesting that glucocorticoids negatively regulate hypothalamic expression and content of GHRH.

D. Sex Steroids

Regulation of GHRH by sex steroids may be responsible for the distinct sexual dimorphism in GH secretion. Males exhibit GH secretion profiles characterized by low levels of basal GH release punctuated with regular large-amplitude pulses. In contrast, females have high levels of basal GH secretion with irregular small-amplitude pulses. Studies in rodents have shown that the unique male pattern of GH secretion is the result of neonatal imprinting by androgens. Sex steroids influence mRNA expression, hypothalamic content, and secretion of both GHRH and SRIF (see Fig. 5). Males demonstrate higher levels of mRNA synthesis and content of GHRH and SRIF than females.

Correspondingly, there is a greater release of GHRH from the hypothalamus of males than females. Testosterone treatment increases GHRH synthesis and secretion in the hypothalamus. Furthermore, neonatal testosterone treatment increases the population of hypothalamic GHRH neurons. GHRH synthesis is reduced following castration, an effect that is reversed with testosterone replacement. Contrary to the effects of testosterone treatment, estrogen treatment reduces the hypothalamic content of GHRH in male and female rats. Following ovariectomy, female rats demonstrate elevated levels of GHRH mRNA expression, an effect that is reversed with estrogen treatment.

IV. GHRH RECEPTOR

A. Characterization

Two different approaches were used to isolate the GHRH receptor: (1) polymerase chain reaction amplification of pituitary cDNAs using degenerate oligonucleotides designed using the sequences of the receptors for secretin, parathyroid hormone, and calcitonin and (2) low-stringency cDNA library hybridization using probes for these receptors. The receptor has now been isolated from human, rat, mouse, pig, sheep, goat, cow, and goldfish. It is a G-protein-coupled receptor (GPCR) that binds a stimulatory heterotrimeric G-protein and activates adenylyl cyclase to increase production of the cellular second messenger cyclic AMP (cAMP). Based on amino acid sequence identity, the GHRH receptor belongs to the B-III family of GPCRs, which includes the receptors for brain–gut peptides. Some of these receptors are closely related to the GHRH receptor, but other receptors are more distantly related, including the receptors for calcitonin, corticotropin-releasing factor, and parathyroid hormone (see Fig. 6). The hallmark characteristics of the B-III family

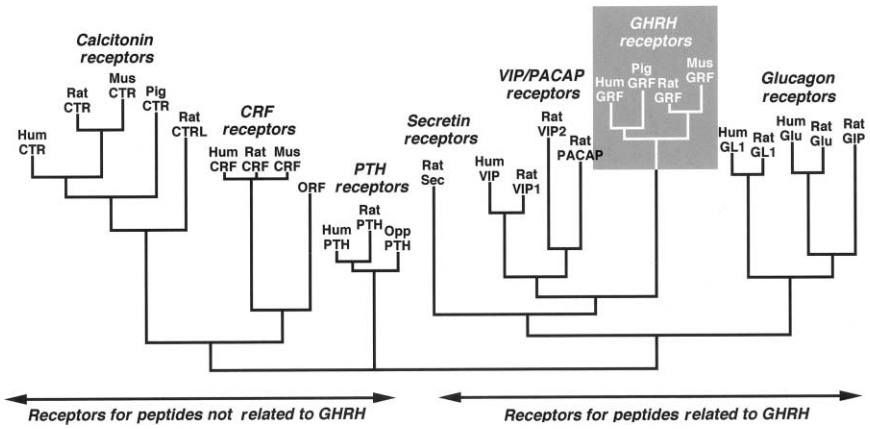

FIGURE 6 Phylogenetic tree of the B-III family of GPCR receptors that includes the GHRH receptor. Relatedness of the GHRH receptor to the receptors for secretin, VIP, PACAP, glucagon, parathyroid hormone (PTH), corticotropin-releasing factor (CRF), and calcitonin is illustrated. This figure was adapted from the GPCR database (http://swift.embl-heidelberg.de/7tm). ORF, open reading frame.

include complex gene structures and six conserved cysteine residues in the extracellular amino-terminus.

Although the GHRH receptor has a high degree of amino acid sequence identity among species, the length of the receptor is quite variable. In human, rat, mouse, and cow, the GHRH receptor is 423 amino acids long. The pig receptor is 451 amino acids long and the sheep and goat receptors are 407 amino acids long. Interestingly, the last 16 amino acids in the human GHRH receptor, missing in sheep and goat, is reported to inhibit receptor signaling by attenuating cAMP production.

B. Gene Structure and Tissue Expression

The gene for the GHRH receptor is located on mouse chromosome 6 and human chromosome 7p14–15. In the rat, the genomic structure of the GHRH receptor consists of 14 exons spanning 15 kb with exons ranging in size from 42 to 456 bp, interrupted by introns ranging in size from 111 bp to more than 2 kb. A longer isoform of rat GHRH receptor is generated by alternative splicing of exon 11 so that 41 amino acids are inserted into the third intracellular loop (see Fig. 7). The short and the long receptor isoforms bind GHRH with similar affinity, but only the short isoform stimulates cAMP production. The long receptor isoform has yet to be associated with a cellular second-messenger pathway, but other receptors in the brain–gut peptide family have alternative isoforms that signal through different second-messenger pathways. For example, two isoforms of the PACAP receptor act distinctly through $G_{\alpha s}$ or $G_{\alpha q}$ to increase cAMP production or to stimulate phospholipase C hydrolysis, respectively. Additional GHRH receptor isoforms have been identified in mouse, pig, and human. The functional significance of these additional isoforms has yet to be clarified within the context of normal physiology. Interestingly, an alternative GHRH receptor isoform, found in human pituitary adenomas, is truncated in the third intracellular loop. It is reported that this receptor isoform is unable to stimulate cAMP production but inhibits cAMP production by the full-length GHRH receptor, suggesting that this alternative isoform may act as a dominant negative protein.

Using sensitive reverse transcriptase-polymerase chain reaction techniques, GHRH receptor mRNA has been detected in the pituitary, gonads, placenta, kidney, hypothalamus, and other brain regions. Of these regions, GHRH receptor (GHRH-R) mRNA is expressed predominantly in the anterior pituitary. This is likely to be due to the dependence of GHRH-R gene transcription on the pituitary-specific transcription factor Pit-1. Pit-1 is a POU domain-containing transcription factor that regulates GH transcription and terminal differentiation of somatotroph, lactotroph, and thyrotroph cells. Consistent with this finding, expression of GH and the GHRH receptor on day 18 during rat embryonic development follows Pit-1 expression on day 13.5. Potential binding sites for Pit-1 have been identified in the promoter regions of both the rat and the human GHRH receptor genes. These sites confer Pit-1-dependent expression of the GHRH receptor promoter in pituitary cell lines that express endogenous Pit-1 or in heterologous cell lines transfected with Pit-1.

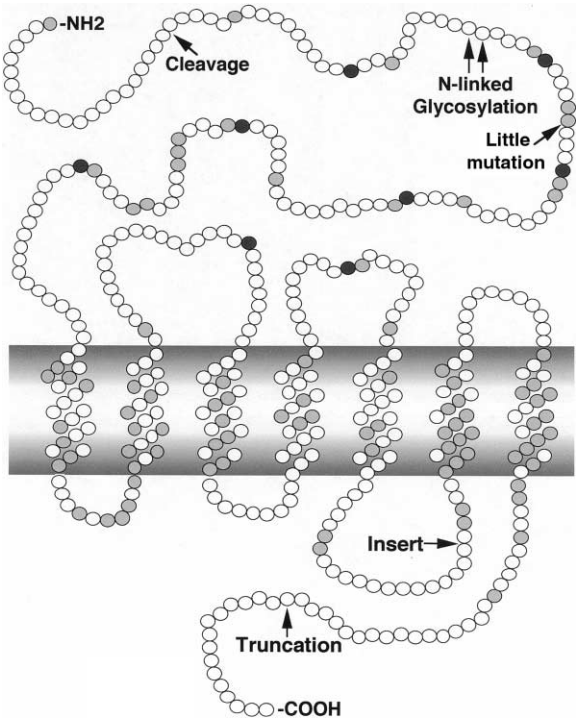

FIGURE 7 Schematic representation of the rat GHRH receptor. The seven membrane-spanning domains are shown crossing the lipid bilayer. The gray circles represent conserved amino acids found in the related receptors for secretin, VIP, GIP, glucagon, PACAP, parathyroid hormone, and calcitonin. The black circles represent the conserved cysteine residues; those in extracellular loops 1 and 2 are found in most GPCRs, whereas those in the N-terminal domain are unique to the GPCRs in the B-III family. The arrowheads indicate the putative signal-peptide cleavage site, the consensus sites for N-linked glycosylation, the conserved aspartic acid residue at position 60, which is mutated in the *little* mouse, the insertion site for the long receptor isoform, and the truncation of the last 16 amino acids in the sheep and goat receptors.

C. Receptor Domains That Interact with GHRH

Hormone binding by the GHRH receptor and related family B-III GPCRs has been investigated through the analysis of mutant and chimeric receptors. Although discrete ligand-binding domains have not been identified, these studies suggest that determinants in both the amino-terminal extracellular domain of the receptor and the three extracellular loops contribute to specific and high-affinity hormone binding. Receptor truncations reveal that although the amino-terminal extracellular domain does not appear to be sufficient for GHRH binding, it is necessary. The importance of the amino-terminus of the receptor for GHRH binding is further supported by studies of the *little* mouse. The *little* mouse exhibits a dwarf phenotype and GH deficiency as a result of a naturally occurring missense mutation that converts amino acid 60 in the amino-terminus of the GHRH receptor from an aspartic acid to a glycine residue (see Fig. 7). This missense mutation disrupts GHRH binding and receptor signaling. A direct interaction between GHRH and the amino-terminus of the GHRH receptor has been demonstrated in mammalian cells using protein cross-linking approaches and in yeast cells using the two-hybrid protein interaction system.

V. GHRH RECEPTOR SIGNALING

A. Protein Kinase A Activation of GH Secretion and Synthesis

GHRH acts through protein kinase A (PKA) to catalyze membrane depolarization and calcium influx, which is required for GH release (see Fig. 8). Specifically, nonselective cation currents and voltage-gated calcium currents are increased by PKA to induce membrane depolarization and to facilitate GH secretion, respectively. Although GHRH stimulates Ca^{2+} influx in pituitary cells, it has no effect on the release of calcium from intracellular stores. Consistent with this finding, some studies have reported that the GHRH receptor does not activate the phospholipase C second-messenger pathway, which mediates protein kinase C activation and intracellular calcium mobilization. In contrast, a recent study of the pig anterior pituitary found two subpopulations of somatotroph cells, distinguishable by the ability of GHRH to activate either adenylyl cyclase or phospholipase C.

As addressed earlier, GH gene expression requires the transcription factor Pit-1 (see Fig. 8). Signaling through cAMP increases Pit-1 transcription and expression. This effect is mediated by the cAMP-responsive element-binding protein (CREB), which binds two cAMP-responsive elements in the Pit-1 promoter. Another mechanism through which cAMP may regulate Pit-1 function includes direct interaction between the CREB-binding protein (CBP) and Pit-1. Activation of Pit-1 by cAMP depends on the amino-terminal domain of CBP. Interestingly, PKA phosphorylation may regulate the interaction between CBP and Pit-1.

B. Somatotroph Cell Proliferation and the Mitogen-Activated Protein Kinase Pathway

In addition to stimulating GH synthesis and secretion, GHRH induces somatotroph cell proliferation. The initial observation that GHRH stimulates

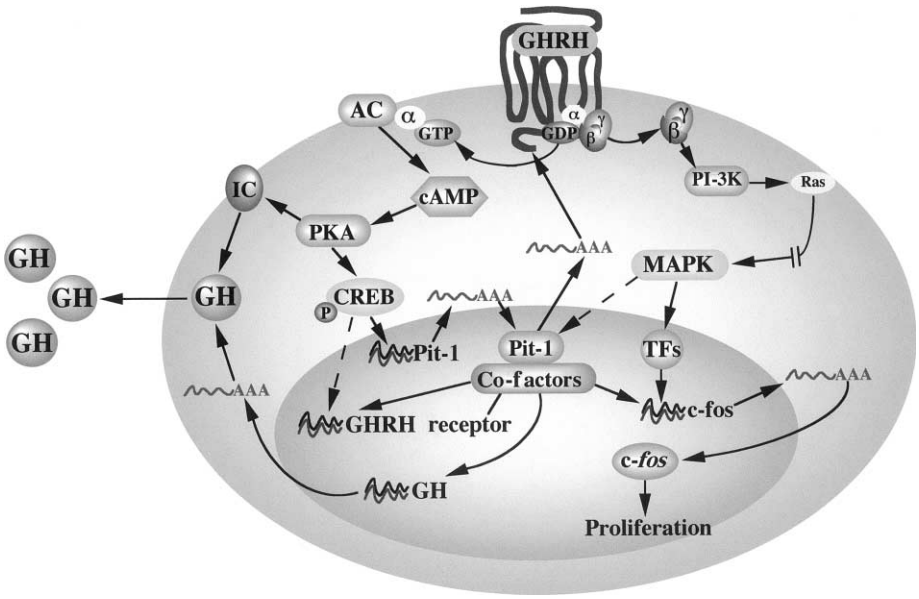

FIGURE 8 The GHRH signaling pathway in the pituitary somatotroph cell. Binding of GHRH to its receptor causes the dissociation of the G-protein into the β γ-subunits and the GTP-bound α-subunit. The α-subunit activates adenylyl cyclase to increase the production of cAMP, which in turn releases the catalytic subunits of protein kinase A (PKA) from its regulatory subunits. PKA acts on ion channels (IC) to facilitate GH release. Additionally, PKA phosphorylates and thus activates cAMP-response element-binding protein (CREB). Activated CREB increases transcription of the pituitary-specific transcription factor Pit-1. CREB may also increase transcription of the GHRH receptor gene. Pit-1 interacts with co-factors to increase the transcription of the GH and GHRH receptor genes. In addition to stimulating GH synthesis and secretion, GHRH activates the mitogen-activated protein kinase (MAPK) pathway that may underlie the ability of GHRH to stimulate somatotroph cell proliferation. MAPK activation by GHRH may occur in part through the actions of the β γ-subunits, phosphoinositol 3-kinase (PI-3K), and Ras. Transcription factors (TFs) activated by MAPK increase transcription of a variety of genes involved in cell proliferation, including c-*fos*. Transcription of c-*fos* may also be stimulated by Pit-1.

somatotroph cell proliferation was described in human case studies that reported somatotroph cell hyperplasia resulting from ectopic secretion of GHRH from endocrine tumors. Further validation of this observation comes from a variety of genetic studies in mice. Overexpression of human GHRH in a transgenic mouse model results in excessive proliferation of somatotroph cells. In contrast, the number of somatotroph cells is significantly reduced in the anterior pituitary of the *little* mouse, which has disrupted GHRH receptor signaling, as previously discussed. Genetic models have also addressed somatotroph cell proliferation in the context of disrupting intermediaries in the GHRH signaling pathway. For example, constitutive activation of the α-subunit of the stimulatory heterotrimeric G-protein following selective targeting of a cholera toxin transgene results in hyperproliferation of somatotroph cells. In contrast, there is a hypoproliferation of somatotroph cells in the anterior pituitary of transgenic mice in which a dominant negative CREB protein was targeted to somatotroph cells. GHRH induces expression of c-*fos*, a transcription factor associated with proliferation, and somatotroph cell proliferation in cultured pituitary cells.

Detailed studies in both pituitary and nonpituitary cell lines have shown that GHRH receptor activation stimulates the mitogen-activated protein kinase (MAPK) pathway. It has been reported that this activation is partly mediated through the actions of the β γ-subunits of the heterotrimeric G-protein, phosphatidylinositol 3-kinase, and $p21^{ras}$ (see Fig. 8). Pituitary cells proliferate following activation of the MAPK pathway by GHRH, an effect that is blocked by co-treatment of the cells with MAPK inhibitors or SRIF.

The transcription factor Pit-1 is also required for somatotroph cell proliferation. Mutations in Pit-1 that disrupt its ability to bind DNA result in hypoplastic anterior pituitaries lacking somatotroph, lactotroph, and thyrotroph cell types. This finding from Snell and Jackson dwarf mice suggests that

Pit-1 is important in the expansion of pituitary cell types that normally express Pit-1. As previously addressed, Pit-1 expression can be regulated by CREB. Inhibition of somatotroph cell proliferation by the dominant negative CREB transgene mentioned above may therefore be the result of reduced Pit-1 expression. Consistent with this notion, inhibition of Pit-1 expression by antisense oligonucleotides significantly reduces proliferation in pituitary cell lines. Pit-1 may regulate somatotroph cell proliferation in part by binding the serum-response element in the c-*fos* promoter and activating transcription.

VI. REGULATION OF THE GHRH RECEPTOR

A. Hormonal Feedback Regulation by the GH Axis

GH and IGF-I inhibit GHRH receptor mRNA expression (see Fig. 5). When GH signaling is disrupted, as demonstrated in two rodent models with GH receptor deficiencies, there is an increase in GHRH receptor mRNA expression. These findings suggest that GH negatively regulates GHRH receptor mRNA expression. When pituitary cells are treated with IGF-I, GHRH binding and GHRH-stimulated GH secretion are significantly reduced, indicating that IGF-I also negatively regulates the GHRH receptor.

GHRH-binding activity in the pituitary is significantly reduced following prolonged exposure to GHRH. This reduction in binding activity may arise from receptor desensitization and internalization. Receptor desensitization, or the process of attenuating the ability of GPCRs to activate heterotrimeric G-proteins, is often followed by receptor internalization. Currently, no studies with the cloned receptor have addressed GHRH receptor desensitization and internalization, but studies on the related receptors for secretin and glucagon have described receptor inactivation by these processes.

Whether homologous down-regulation of GHRH receptor mRNA expression occurs following prolonged ligand exposure is controversial. Whereas one study concluded that GHRH up-regulates receptor mRNA expression, another study found that GHRH down-regulates receptor expression. In yet another study, the inhibitory actions of GHRH on receptor expression were made evident only when SRIF was immunoneutralized, suggesting that homologous down-regulation of the GHRH receptor is obscured by the inhibitory effects of SRIF on receptor expression. Interestingly, GHRH has been localized to secretatory granules of somatotroph cells, suggesting a possible autocrine role for GHRH in perpetuating GH secretion and expediting receptor down-regulation.

B. Metabolic Cues

Nutritional status and metabolism affect the expression of the GHRH receptor through the actions of thyroid hormones and glucocorticoids (see Fig. 5). Pituitary cells treated with thyroid hormones demonstrate an increase in GHRH receptor mRNA expression. Correspondingly, the loss of thyroid hormones after thyroidectomy significantly reduces GHRH receptor mRNA expression, but normal levels can be restored with thyroid hormone replacement. Similar to thyroid hormones, glucocorticoids positively regulate GHRH receptor mRNA expression. The loss of endogenous glucocorticoids after adrenalectomy reduces the number of GHRH-binding sites, and these sites are restored by glucocorticoid replacement. Interestingly, glucocorticoids and thyroid hormones act synergistically to up-regulate GHRH receptor mRNA expression. Glucocorticoids are also important differentiating factors for somatotroph cells. Glucocorticoid treatment of rat fetuses advances expression of GH and GHRH receptor mRNAs, both hallmark transcripts of the somatotroph cell phenotype. In contrast, inhibition of glucocorticoid synthesis delays expression of GH and GHRH receptor mRNAs in the developing rat fetus.

C. Sex Steroids

Sex steroids can influence pituitary responsiveness to GHRH (see Fig. 5). Specifically, estrogen inhibits GHRH-induced GH release and GHRH receptor expression in the pituitary. Consistent with this finding, the promoter regions of both the rat and the human GHRH receptors contain estrogen-response elements. In some studies, a sexual dimorphism in GHRH-R expression has been reported, with males expressing elevated levels of the mRNA compared to females.

VII. GHRH AND THE GHRH RECEPTOR IN DISEASE

As mentioned earlier, acromegaly is an endocrine disorder resulting from adult-onset excessive GH secretion. Symptoms include broadening of the brow

and chin, exaggerated growth of hands and feet, hypertrophy of soft tissue, headaches, fatigue, visual abnormalities, and sleep apnea. Most cases of acromegaly are the result of GH-secreting pituitary adenomas. Many of these pituitary adenomas arise from a mutation in the $G_{\alpha s}$ protein (*gsp*) so that the stimulatory α-subunit is constitutively activated and chronically stimulates adenylyl cyclase to produce cAMP in somatotroph cells. Other cases of acromegaly are the result of excessive GHRH secretion from hypothalamic gangliocytomas or ectopic GHRH-secreting tumors. Hypothalamic gangliocytomas secrete GHRH into the hypophyseal portal vessels and promote somatotroph cell proliferation and adenoma formation. Ectopic GHRH-secreting tumors have been found in pancreatic, pulmonary, and intestinal tissues. Few of these tumors secrete the full-length GHRH(1–44)-NH_2 product, but rather secrete the truncated products GHRH(1–37)-OH and (1–40)-OH. Excision of ectopic GHRH-secreting tumors often leads to full regression of acromegalic symptoms. Conditions of GHRH excess can also be created in a transgenic mouse model in which human GHRH is overexpressed. In this model, mRNA for the transgene is expressed in all tissues, but only tissues that normally express GHRH such as the pituitary, pancreas, and brain produce the mature GHRH(1–44)-NH_2 and (1–40)-OH forms. The remaining tissues produce the inactive GHRH metabolite, GHRH(3–44)-OH. The phenotype of this transgenic mouse model includes gigantism, somatotroph hyperplasia, and pituitary adenoma formation in the older mice. In contrast, pituitary adenoma formation is not found in cases of acromegaly resulting from ectopic GHRH-secreting tumors.

Isolated GH deficiency (IGHD) is an endocrine disorder with symptoms that include dwarfism and low levels of circulating GH, IGF-I and IGF-II. An excellent animal model of IGHD is the *little* mouse. In addition to the above-mentioned symptoms, the *little* mouse exhibits a hypoplastic anterior pituitary that is deficient in somatotroph cells. As discussed in a previous section, this is the result of an autosomal recessive mutation that converts an aspartic acid residue at position 60 in the amino-terminus of the GHRH receptor to a glycine residue. This mutation renders the GHRH receptor incapable of binding GHRH and activating downstream signaling pathways. Introduction of a GH transgene in the *little* mouse produces normal or excessive growth. Although not responsive to GHRH treatment, somatotroph cells cultured from *little* mice secrete GH in response to cAMP analogues, suggesting that the *little* mouse has an intact cAMP signaling pathway capable of eliciting GH secretion. More recently, human studies have reported cases of IGHD arising from mutations in the GHRH receptor. Three kindreds from India, Sri Lanka, and Pakistan have an identical point mutation in the GHRH receptor, which truncates the receptor before the first transmembrane domain. A kindred in Brazil has a donor splice mutation in the receptor that also produces a truncated receptor. All of these patients have short stature, anterior pituitary hypoplasia, and undetectable serum GH concentrations. These patients are unresponsive to GHRH treatment, but they show an increase in growth following GH therapy. These studies have described IGHD in the context of inactivating mutations of the GHRH receptor. Currently, mutations that render the GHRH receptor constitutively active have not been reported, although several studies have looked for such mutations in human GH-secreting tumors.

GHRH has been implicated in promoting tumor proliferation. GHRH acts in an endocrine manner to stimulate tumor proliferation by elevating the circulating levels of GH and subsequently IGF-I, and it may also act in an autocrine manner by directly stimulating tumor tissue. A variety of tumor cell lines locally produce GHRH and express GHRH-binding sites. GHRH treatment of these cell lines usually results in an increase in cAMP production and proliferation. Additionally, some cell lines increase the synthesis and secretion of IGF-I and/or IGF-II, which may then act in an autocrine regulatory manner. Interestingly, GHRH receptor antagonists are effective inhibitors of proliferation in most of these tumor cell lines, including those from ovarian, mammary, prostatic, and pancreatic cancers. These findings suggest that GHRH antagonists may provide a novel approach to the treatment of endocrine cancers.

Glossary

alternative splicing Rearranging the same pre-mRNA in multiple ways to yield multiple different mRNAs that produce distinct proteins.

autocrine Mechanism of regulation in which a released hormone acts on its cell of origin.

dominant negative protein A defective protein that interferes with the function of the normal protein in the same cell.

hypophysectomy Surgical removal of the pituitary gland.

somatotroph cells One of the six distinct hormone-producing cell types present in the anterior pituitary. These cells synthesize and secrete growth hormone.

synergism The action of two or more hormones to achieve a response that each hormone is incapable of achieving individually.

Growth Regulation: Clinical Aspects of GHRH

A. V. B. Castro and S. Melmed

Cedars Sinai Medical Center, Los Angeles

Linear growth results from the interaction of genetic and environmental factors. The key hormone involved in the growth process during these phases is insulin-like growth factor, controlled directly or indirectly by peripheral and central influences. Growth hormone is the principal insulin-like growth factor regulator during the postnatal period.

I. INTRODUCTION: GROWTH AND GH REGULATION

Appropriate growth hormone (GH) pulsatile secretory patterns are essential for physiologic GH effects and occur as a result of the interplay between growth hormone-releasing hormone (GHRH) and somatotropin release-inhibiting factor (SRIF; somatostatin) on pituitary somatotrophs, as well as additional peripheral and central regulators. Physiologic and clinical roles of GHRH and its receptor on growth have been elucidated in sporadic and transgenic models in which they may be overexpressed

or mutated. Synthetic GHRH has been used for diagnostic and therapeutic purposes in growth disorders.

The GH pulsatile pattern is important for exerting an effect on target tissues, and the mechanisms involved in GH pulse generation are complex. GH pulses depend on interactions between hypothalamic GHRH and SRIF and the on-modulatory role of ghrelin, an endogenous GH secretagogue. Neurotransmitters, including NO, neuropeptides, hormones (hypothalamic, pituitary, or peripheral), cytokines, and metabolic signals, influence GHRH and SRIF. In addition, long, short, and ultrashort insulin-like growth factor-I (IGF-I) feedback loops also regulate GH secretion. GH pulses (10 to 20 pulses/24 h) occur concomitantly with GHRH pulses and are assumed to be 180° out of phase with hypothalamic secretory SRIF pulses. Intermittent SRIF withdrawal and/or the release of GH cosecretagogues drive GH pulse timing, and the pulse amplitude is generated primarily by GHRH. GH secretion maintains a nocturnal rhythm in which the bulk (70%) of daily GH secretion occurs during the slow-wave of sleep stages 2 and 3.

GH pulse amplitudes vary throughout life; they are high in the fetus and at birth, decline gradually during infancy, increase significantly at puberty, return to prepubertal levels during early adulthood, and decline progressively beyond middle age. Mechanisms involved in GH pulse variability involve variations in somatotroph sensitivity to GHRH or somatostatin, which is modified by other hormones, including GH secretagogues, sex steroids, and neurotransmitters. In the elderly, the GH secretory capability of the somatotroph is preserved given appropriate external stimuli, such as administration of GHRH, somatostatin inhibitors, or GH secretagogues (GHSs). These hypothalamic influences determine age-related GH secretion patterns.

Sexual dimorphism also characterizes GH secretion patterns. Men and premenopausal women have similar GH pulse frequencies, but premenopausal women exhibit higher baseline GH levels and GH pulse amplitudes. Women are also less prone to the negative impact of GH secretion modifiers, such as age, obesity, and physical fitness. These sexual differences in GH secretion pattern also influence hepatocyte GH signaling. GH signaling is mediated by signal transducer and activator of transcription proteins (Stat3 and Stat5) and is terminated by expression of the suppressor of cytokine signaling (SOCS) protein. A male pulsatile GH pattern elicits increased intracellular Stat levels and an intermittent increase in SOCS levels, which leads to transient hepatocyte unresponsiveness to GH. The more steady female GH secretion pattern elicits more prolonged GH unresponsiveness due to continuous induction of intrahepatic SOCS levels. Other influences that increase GH secretory patterns are exercise, stress, and hypoglycemia (Fig. 1). Conversely, hyperglycemia suppresses GH secretion, as do obesity and hypothyroidism.

II. GROWTH HORMONE-RELEASING HORMONE

GHRH is encoded by a 10-kb gene that contains five exons. Exon 3 segregates the 1–31 sequence responsible for the functional domain of the molecule. GHRH is produced predominantly by neurons localized in hypothalamic arcuate and ventromedial nuclei and is also modestly expressed in normal leukocytes and normal (pituitary, gonadal, adrenal, placental, gut, pancreatic) or tumoral (pituitary, breast, endometrial, and gastrointestinal) tissues.

A. Structure

The size of the active isoform varies from 42 to 44 amino acids among species, differing mainly in the extension and composition of the carboxy-terminal (COOH) region. Conversely, the amino terminus (NH_2), specifically the highly conserved (1–29) residues, plays a key role for the full GH-evoking activity of the peptide, as also does the GHRH tertiary structure (Fig. 2).

Human GHRH is derived from cleavage of a precursor molecule, preproGHRH (containing 107–108 amino acids), yielding a proGHRH molecule that is cleaved by endoproteases into human (h) hGHRH (1–40)-NH_2, hGHRH(1–44)-OH, and a carboxyl-terminal peptide designated GHRH-related peptide (GHRH-RP). After release into the circulation, GHRH is rapidly (within minutes) metabolized to inactive peptide by circulating dipeptidylpeptidase IV. The three sequenced GHRH isoforms, GHRH(1–44)-NH_2, GHRH(1–40)-OH, and GHRH(1–37)-OH, differ in their C-terminal extension.

B. Function

GHRH signaling through the GHRH receptor directly controls somatotroph proliferation and function. The potent GHRH proliferative effect on somatotrophs is corroborated by the observation of pituitary enlargement within days after GHRH

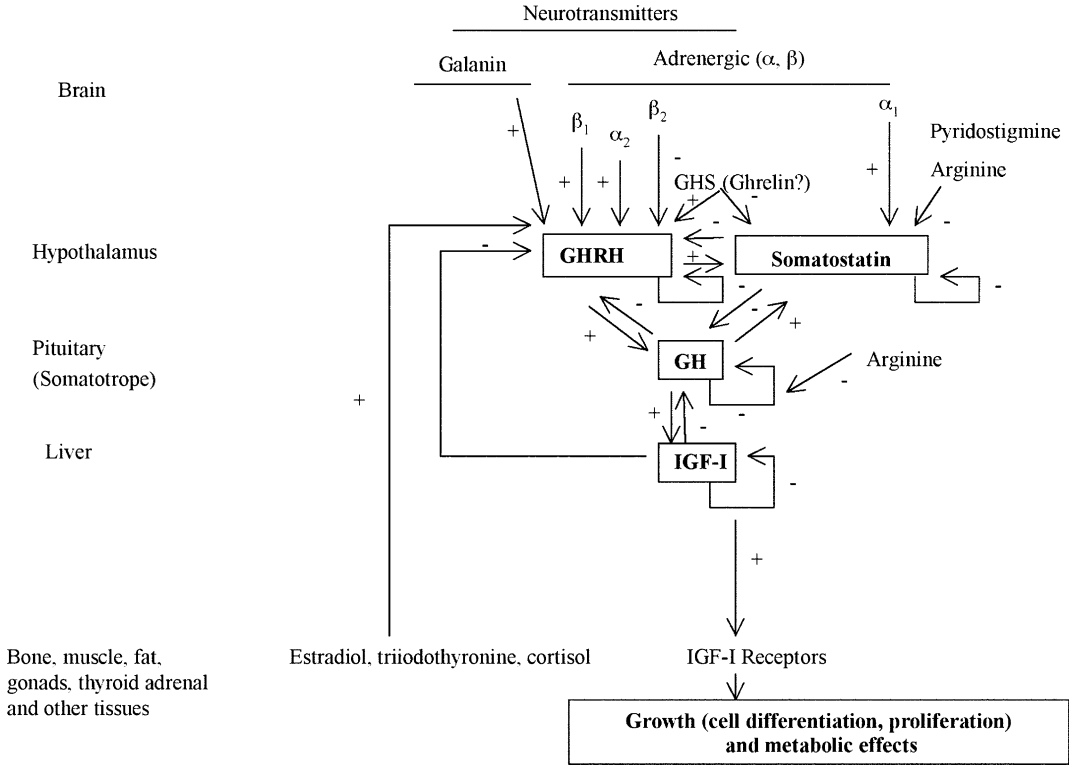

FIGURE 1 Central and peripheral influences on the growth hormone axis, showing the systemic involvement in growth control. Positive (+) and negative (−) neuroendocrine feedbacks contribute to the ultimate secretion of the main components of the growth axis (boxed). Also shown are the arginine and pyridostigmine sites of action. Adapted from Cunha *et al.* (2000) and Giustina and Veldhuis (1998).

administration to normal rats. Furthermore, the direct effect of GHRH in pituitary proliferation is reinforced by the observation of somatotroph hyperplasia and adenomatous transformation in GHRH transgenic mice lacking the GH receptor (MT-hGHRH/GH-R − /−). A paracrine/autocrine role of GHRH is also suggested by a direct correlation between neoplastic progression of somatotroph adenomas and pituitary GHRH content. GHRH also controls GHRH-R, GHS-R, and ghrelin gene expressions, and placental GHRH may play a role in fetal growth.

C. Regulation

Glucocorticoids (acutely administrated), sex steroids, triiodothyronine, and GH-releasing peptide may amplify GHRH-stimulated GH secretion. *In vivo*, glucocorticoid administration decreases hypothalamic GHRH expression. GHRH expression is also down-regulated by GHRH, somatostatin, and GH/IGF-I.

III. GHRH RECEPTOR

The GHRH-R belongs to the G-protein-coupled secretin subfamily B; it is mainly expressed in the pituitary, but also in the placenta, gonads, kidney, and hypothalamus.

A. Structure

The human GHRH-R gene, mapped to the short arm of chromosome 7p14, comprises more than 10 exons spanning 15 kb of DNA. The cDNA encodes a 47-kDa, 423-amino-acid protein containing seven putative transmembrane domains, characteristic of secretin family receptors. The N-terminal extracellular domain plays an important role in GHRH binding. Single mutations or deletions at position 60 of this domain, for example, render the receptor nonfunctional. Other domains are also important for ligand selectivity and binding. Two variants of GHRH-R mRNA have been described in a human bronchial tumor; the truncated nonfunctional isoform was related to the less aggressive behavior of neuroendocrine tumors.

B. Signaling

At the somatotroph, GHRH binding to its receptor activates the G (G_α) stimulatory protein, which sequentially stimulates adenylyl cyclase and cellular cyclic adenosine monophosphate (cAMP). Cyclic AMP binds to cAMP response element binding (CREB) protein, mediating expression of Pit-1 and GH gene transcription. Activation of the mitogen-activated protein kinase (MAPK) pathway by GHRH-R-stimulated βγ subunits accounts for the proliferative actions of GHRH. Other pathways involved in GHRH signaling include inositol phosphate, calcium influx and intracellular mobilization, and calmodulin (Fig. 2).

C. Function

At early stages of pituitary development, several homeodomain transcription factors are active. Among them, factors named prophet of pituitary transcriptional factor-1 (Prop-1) and POU1F1 are critical for specialization of cell lineages, including thyrotrophs, gonadotrophs, somatotrophs, and mammosomatotrophs. Full differentiation of these cells is achieved by the permissive effect of other transcriptional and nontranscriptional factors. Somatotrophs, for example, require the presence of GHRH-R for their proliferation. GHRH stimulates expression of POU1F1, which plays an important role in GHRH-R expression.

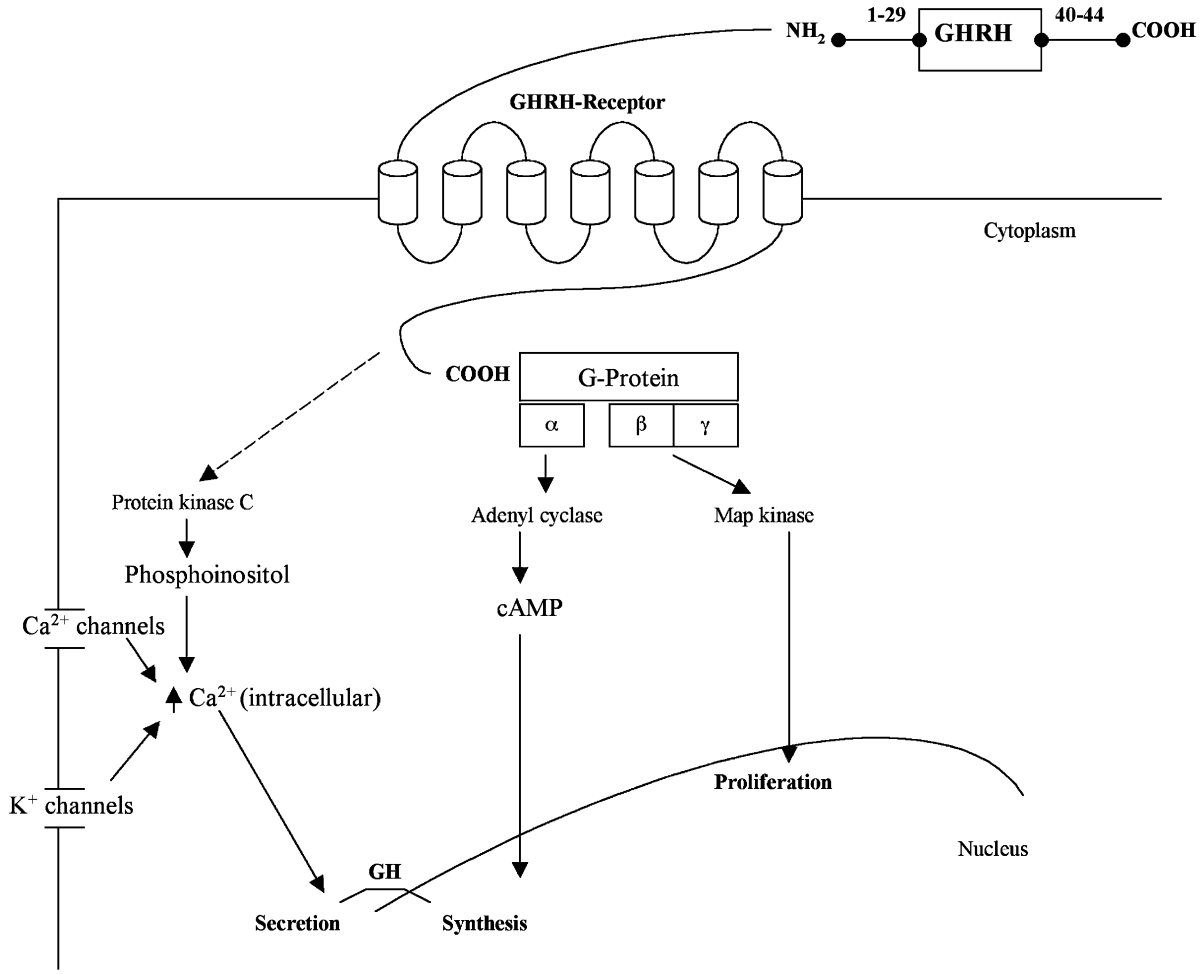

FIGURE 2 Growth hormone-releasing hormone (GHRH) receptor and GHRH signaling in the somatotroph, illustrating the seven-transmembrane domain of the GHRH receptor; its amino-terminal (NH_2) domain, which binds to GHRH (at Asp-60), and the carboxyl-terminal (COOH) domain (linked to G-protein). Binding of GHRH to its receptor elicits activation of the α and βγ G-protein subunits, which activate the cAMP and mitogen-activated protein (MAP) kinase cascades, leading to GH synthesis and somatotroph proliferation, respectively. GHRH also activates protein kinase C and opens ion channels, resulting in an increase in intracellular calcium (Ca^{2+}) and GH secretion.

D. Age-Related GHRH and GHRH-R

Human fetal GHRH neurons appear between 18 and 29 weeks of gestation. In the mouse and rat, GHRH neurons and the GHRH-R develop on embryonic days 16.5 and 18, respectively, reaching adult levels by postnatal day 30. GHRH gene expression and content reach a nadir at 12 days, increase at puberty onset, and subsequently decline in the aging rat. GHRH-R mRNA is highly expressed in neonatal rats and is decreased in aged rats (18 months), which may contribute to the diminished GH response to GHRH observed with aging; the same decrease is also seen in elderly human subjects. However, GHRH sensitivity can be restored by treatment with GHRH.

E. Regulation

In both rats and humans, GHRH-R expression is positively regulated by transcription factors, glucocorticoids, thyroid hormones, and GHRH; GHRH-R expression is down-regulated, however, by estrogen, which may explain the sexual dimorphism observed in GHRH regulation and GH secretion. POU1F1 is also a key determinant of somatotroph differentiation. Hypothalamic GHRH and GHRH-R mRNA levels are higher in male than in female rats, as are the responses of GH to GHRH in *ex vivo* and *in vitro* models. Testosterone enhances GHRH activity in rats, whereas estrogen down-regulates GHRH-R mRNA expression.

IV. DISORDERS OF GROWTH REGULATION

Genetic, nutritional, physical, and psychological conditions interact to determine final physical stature. Growth retardation or overgrowth may occur due to disorders at all hormonal levels of the somatotropic axis, as well as to defective pituitary development because of mutations in pituitary transcriptional factors. Some of these disorders have been described in spontaneous and/or animal transgenic models.

V. GHRH AND GHRH RECEPTOR: CLINICAL ASPECTS

A. Excessive GHRH Secretion

Overexpression of the mouse metallothionein promoter-driven human GHRH (MT-hGHRH) results in increased growth rate, increased body mass, and increased pituitary, liver, kidney, spleen, testis, and vesical weights (Table 1). Massive pituitary enlargement as a result of somatotroph hyperplasia occurs as early as 8 months; adenomatous transformation is observed by 10–12 months in addition to lactotroph and somatomammotroph hyperplasia. Immunoreactive GH, prolactin, $G_{\alpha s}$, and, less frequently, thyroid-stimulating hormone β (TSHβ) are observed in pituitary adenomas in the hyperplastic pituitary of the transgenic mice.

GH secretion and consequently IGF-I levels are markedly increased, with decreased GHRH mRNA levels and increased somatostatin receptor subtype 2 and subtype 5 mRNA expression. Pituitary GHRH-R and GHS mRNA levels are unchanged in relation to wild-type mice. Other alterations that have been described in these mice include increased abdominal fat, hyperinsulinemia, hyperleptinemia, and elevation of prolactin, corticosterone, and galanin.

B. Human GHRH-Secreting Tumors

Gigantism or acromegaly secondary to eutopic (hypothalamic hamartomas, gliomas, and astrocytomas) or ectopic (pancreatic, lung, thymus, and gastrointestinal neoplasias) GHRH secretion occurs

TABLE 1 Genetic and Transgenic Animal Models of Growth Retardation or Overgrowth Related to GHRH

Model	Defect	Phenotype
Little (*lit*) mouse	GHRH receptor missense mutation (autosomal recessive)	Moderate to severe dwarfism, low levels of GH/IGF-I, GHRH-specific absence of response of somatotroph cells, anterior pituitary hypoplasia
Zucker rat	GHRH decrease (unknown mechanism)	Growth retardation, obesity, hyperinsulinemia, and hyperlipidemia; decreased sensitivity to GHRH *in vitro* decreased GHRH and GHRH mRNA levels
Methallothionein human GHRH transgenic mouse (hGHRH)	Overexpression of GHRH gene	Excessive linear growth; extremely high levels of GH/IGF-I, prolactin, and cortiscosterone; organomeglay, dramatic somatotroph hyperplasia (eventually adenoma)

rarely and is frequently associated with multiple endocrine neoplasia. The clinical presentation is related to GH/IGF-I and GHRH excess as well as to syndromes related to primary tumor mass localization and function. Patients also present with pituitary hyperplasia and/or adenomatous transformation, as observed in genetically altered mice (Table 2). Somatotroph adenomas overexpressing intratumoral GHRH also show more aggressive tumor behavior.

C. Decreased GHRH

Obese Zucker rats exhibit growth retardation, pituitary hypoplasia, and decreased pituitary GH content and secretion. Some investigators have suggested a hypothalamic abnormality based on the decreased hypothalamic GHRH and GHRH mRNA levels and the unchanged somatostatin levels or secretion present in this model.

D. Decreased GHRH-R

The *little* mouse harbors an inherited autosomal missense GHRH-R mutation that results in inability of the receptor to bind to its ligand. Consequently, a 70% reduction in somatotroph number occurs and these animals exhibit moderate to severe growth retardation, decreased pituitary GH and GH mRNA, extremely low GH plasma levels, and absence of GH responses to GHRH. *In vitro* studies demonstrate that lack of somatotroph GH response is restricted to GHRH in these mice. GHRH postreceptor events are intact, as demonstrated by somatotroph GH response to cholera toxin, to forskolin (a direct stimulator of the α-subunit of G_s), and to dibutyryl cAMP.

In humans, the disturbance of isolated GH deficiency corresponding to that observed in the *lit/lit* mouse has been described in kindreds from India, Pakistan, Sri Lanka, and Brazil. In familial dwarfism with an autosomal recessive pattern of inheritance, both nonsense and missense mutations lead to disruption of GHRH-R function. These patients have proportional dwarfism, delayed bone age and puberty, pituitary hypoplasia, and impaired GH response to GHRH. GH pulsatility is preserved in these patients, but pulse amplitudes are low, corroborating the amplifier role for GHRH in generation of GH pulses. The response to the GH secretagogues is also decreased either because of somatotroph hypoplasia or because of the key role of the intact GHRH response in the integral somatotroph response to GHSs. The *lit/lit* mouse and patients with GHRH-R mutations are usually fertile, suggesting that GHRH does not play a key role in gonadal function, although GHRH and GHRH-R are expressed in testis and ovary.

TABLE 2 Clinical Features of GHRH Receptor Abnormalities and GHRH-Secreting Neoplasias in Humans

GHRH-R-related dwarfism
Autosomal recessive, nonsense or missense mutation
Proportional dwarfism
Delayed bone age and puberty
Pituitary hypoplasia
GHRH excess related
Somatotrope hyperplasia and/or adenomatous transformation
Excessive GH secretion
Excessive IGF-I levels
Skeletal and other tissue overgrowth; arthropathy; compressive neuropathy; cardiovascular disease (systemic arterial hypertension, atherosclerosis, myocardial hypertrophy, or cardiomegaly); metabolic disorders (diabetes mellitus or hypercalcemia); respiratory dysfunction (sleep apnea)
Tumor-related (type, localization, cosecreted substances)
Benign (carcinoids): facial flushing, diarrhea, peptic ulcers, renal lithiasis, hypoglycemia
Malignant: cachexia

VI. GHRH AS A DIAGNOSTIC TOOL

A. GH Deficiency

GHRH has been used diagnostically and therapeutically in GH deficiency. Differential diagnosis of short stature may be complex, and GH deficiency is only one cause. The first goal is to determine which child is to be investigated (Table 3). Once criteria have been met for investigation, and systemic diseases (diabetes, chronic renal failure, and hypothyroidism) have been excluded or controlled, the next step is to investigate pathologies intrinsic to the somatotropic axis. Pitfalls related to the accuracy of functional diagnostic tools commonly lead to false positive or negative results; care must be taken to assess sensitivity, reproducibility, and arbitrary cutoff levels of hormone measurements, as well as age- and sex-related variations in the patients. Standard tests (insulin-induced hypoglycemia; glucagon, arginine, and clonidine) act through hypothalamic signals to elicit pituitary GH. Thus, an altered GH response

TABLE 3 Short Stature: Clinical Criteria for Investigation[a]

Severe short stature—height ≥ 3 SD below mean for chronological age
Moderate short stature—height between 2 and 3 SD below mean for chronological age and growth
Deceleration (height velocity below 25%)
Growth deceleration
Predisposing condition to growth hormone deficiency (hypothalamic injury, irradiation, etc.) and growth deceleration
Neonatal signs of pituitary deficiencies (hypoglycemia, microphallus, midline craniofacial defects)

[a]Adapted from Rosenfield and Cutler (2001).

does not necessarily distinguish hypothalamic or pituitary disturbance, which potentially might have therapeutic implications.

GHRH is a powerful GH secretagogue in children and adults and may distinguish a hypothalamic or pituitary etiology for GH deficiency. Normal GH responses confirm pituitary integrity. An abnormal GH response to GHRH strongly points to pituitary abnormalities in the etiology of GH deficiency. Some studies have shown that most patients with severe GH deficiency and without demonstrable anatomical hypothalamic–pituitary alterations are in fact GHRH deficient. However, an intact hypothalamic–pituitary connection is required for the GHRH test to be useful.

Currently, the synthetic analogue GHRH(1–29)-NH_2 is commercially available in the United States and Europe for diagnostic and therapeutic purposes in GH deficiency. This compound is equipotent to the natural analogues GHRH(1–40)-OH and GHRH(1–44)-OH in evoking GH secretion.

B. GHRH Testing

GH response to GHRH is dose related; a maximally stimulating dose ~1.0 μg/kg, detectable in 5 min, peaks between 15 and 45 min and returns to baseline after 90–120 min. After an overnight fast, intravenous GHRH(1–29)-NH_2 (1.0 μg/kg) is administered as a bolus and blood is sampled 15 min before and each 15 min thereafter for 60 min. The test may provoke mild and transient side effects such as warmth, face flushing, local inflammation, nausea, vomiting, and chest tightness. GHRH administered continuously or as repeated intravenous boluses provokes GH release and maintains GH pulsatility, although a tendency to subsequent decreased pulsatile frequency has been observed.

1. GH Response to GHRH

There is poor reproducibility and some inter- and within-subject variability when identifying GH status using the GHRH test alone, which limits its diagnostic value.

2. Factors That Interfere with GH Responses to GHRH

a. Age. GH response to GHRH varies throughout life, partially due to variation of somatostatinergic and/or cosecretagogue tones and sensitivity to these molecules. In the immediate postnatal period, there is GH hyperresponsiveness to GHRH. In the prepubertal period, during different stages of puberty and in young adults, the GH response to GHRH remains constant. After the third and fourth decades in men and during menopause in women, GH responsiveness decreases. Increased somatostatin tone is the most likely mechanism for this age-related decline in GH response.

b. Sex. Although both sexes exhibit similar responses, slightly higher GH levels are achieved in women. Menstrual cycle and sex steroid priming do not alter GH responses, suggesting that the related steroids act mainly at the hypothalamic level.

c. Obesity. Obesity, particularly abdominal obesity, suppresses the GH response to GHRH. This negative influence on GH responsiveness may be partially overcome by a combination of GHRH with arginine or GHSs. Blood sugar, free fatty acids, and GH also decrease GH responses to GHRH.

3. Indication

Currently, the main role for GHRH testing is to select children who are candidates for GHRH treatment.

4. GHRH Test Combinations

Combination of GHRH with somatostatinergic inhibitors (such as arginine) and GHSs (such as GHRP-6) may overcome some limitations of GHRH testing.

a. Arginine. Simultaneous intravenous infusion of arginine (0.5 g/kg; administered over a 30-min period) and GHRH is performed and blood is sampled before and at 30-min intervals for 120–180 min. In normal children and adolescents, the ranges in GH response evoked by the combination of arginine/GHRH (22.4–108 μg/liter) are similar and are not influenced by pubertal stage, gender, body mass index, and IGF-I levels. In adults, combined

GHRH/arginine usually overcomes the declining GH response to GHRH with aging, and does not vary with gender. The combination of GHRH and arginine has been proposed as the best alternative to the insulin tolerance test (ITT) in the diagnosis of GH deficiency, due to reproducible efficacy and safety. The combination of GHRH and arginine usually leads to GH peaks greater than the threshold for GH deficiency in adults (3 μg/liter). The proposed diagnostic cutoff for GH deficiency and GH insufficiency in adults was 9 (first percentile) and 16.5 μg/liter (third percentile), respectively.

b. GHS–GHRP-6 (hexarelin). GHRP-6 is synergistic with GHRH in evoking GH secretion. Combined intravenous administration of a bolus of hexarelin (1 μg/kg; blood sampled before and at 15-min intervals for 30–120 min), simultaneously with, before, or after GHRH administration, is safe, well tolerated, and potently evokes GH secretion; this protocol has also been proposed to replace the ITT. Another advantage of this combination is that although anatomic disruption of the hypothalamic–pituitary unit invalidates the GHRH test alone, this may be reversed by addition of a GHS. The proposed threshold of normality has been 15 μg/liter; however, diagnostic cutoff values $\geq$20 μg/liter for normality and $\leq$10 μg/liter for GH deficiency have yielded 100% sensitivity and specificity.

C. Excessive Growth

One of the few indications for the measurement of GHRH levels is to distinguish between central and peripheral (elevated ectopic GHRH syndromes) causes of gigantism/acromegaly.

VII. GHRH: THERAPEUTIC ROLE

The mainstay therapy for GH deficiency, related to both pituitary or hypothalamic causes, and GH insufficiency (GHI) syndrome in childhood has been GH. GHRH treatment is potentially a therapeutic choice for patients who are GHRH deficient (so-called idiopathic GH deficiency) but who have intact somatotroph responses to GH secretagogues. Moreover, GHRH treatment preserves the pulsatile pattern of GH secretion as well as endogenous GH and IGF-I feedbacks. GH is administered daily as subcutaneous or intramuscular injections (25–50 μg/kg/day; usually 30 μg/kg/day for children and a starting dose of 200 μg/day, for adults).

A. Indication

The United States Food and Drug Administration (FDA) has approved GHRH(1–29)-NH_2 for use in GH-deficient children according to the criteria and dosage delineated in Table 4.

B. Response to GHRH Therapy

Either GHRH(1–29) or GHRH(1–44)-NH_2 may be administrated and yield similar dose–response patterns. Studies are still inconclusive regarding effects on final growth stature, although improvement in growth velocity has been observed. Similar to what is observed with GH treatment, children who have a higher height standard deviation and slower growth rates for their chronologic age respond well to GHRH treatment. In contrast, GH response levels in GHRH testing have not proved to be a good predictor of response to GHRH treatment in these children.

Administration of GHRH, either in pulses or once or twice daily, to GH-insufficient children promotes linear growth. Continuous nocturnal GHRH administration augments nocturnal GH release, which suggests that production of a long-lasting GHRH release product can be useful. A combination of GHRH and GHRP elicits a more pronounced growth velocity response than does the use of either compound alone.

1. Adverse Effects

Local injection site inflammation, urticaria, headache, flushing, dizziness, dysphagia, and hyperactivity have been reported. Hypothyroidism (5%) and the need to increase thyroid hormone doses have been observed in children. This effect is also described with GH treatment, perhaps due to an enhanced somatostatinergic tone induced by GH, which subsequently suppresses TSH secretion. Formation of GHRH antibodies has frequently been described, but does not have a negative effect on growth or GH responses to GHRH.

TABLE 4 Current Criteria and Dosage for GHRH Treatment in Growth-Retarded Children[a]

Growth hormone-deficient children with an intact hypothalamic–pituitary axis
Adequate growth hormone response ($>$2 μg/liter) to GHRH
Prepubertal children (bone age $<$7.5 years for girls and $<$8 years for boys)
Dosage: 30 μg/kg/day, once a day, subcutaneously, at bedtime

[a]Adapted from Rosenfield and Cutler (2001).

Glossary

acromegaly Clinical syndrome characterized by overgrowth of extremities and organs and by metabolic disturbances secondary to growth hormone excess, usually due to a growth hormone-secreting pituitary adenoma.

ghrelin Polypeptide growth hormone secretagogue predominantly produced by the stomach; exerts a direct or indirect stimulatory effect on growth hormone secretion by somatotrophs.

growth hormone Polypeptide produced and secreted by the pituitary gland; responsible for inducing growth.

growth hormone-releasing hormone Peptide predominantly produced by the hypothalamus; responsible for inducing growth hormone synthesis and secretion.

growth hormone secretagogues Peptide and nonpeptide compounds produced exogenously (e.g., hexarelin) or endogenously (e.g., ghrelin); stimulate growth hormone secretion directly or synergistically with growth hormone-releasing hormone.

insulin-like growth factor Peptide produced mainly by the liver in response to growth hormone stimulation.

POU-homeodomain-1 Transcription factor-1, previously known as pituitary transcription factor-1; responsible for development of pituitary cell lines (somatotroph, lactotrophs, and thyrotrophs).

somatotroph Pituitary cell responsible for growth hormone production and secretion.

somatotropin release-inhibiting factor Somatostatin; peptide ubiquitously produced in the central nervous system and other tissues. In the pituitary, it exerts an inhibitory effect on growth hormone secretion by somatotrophs.

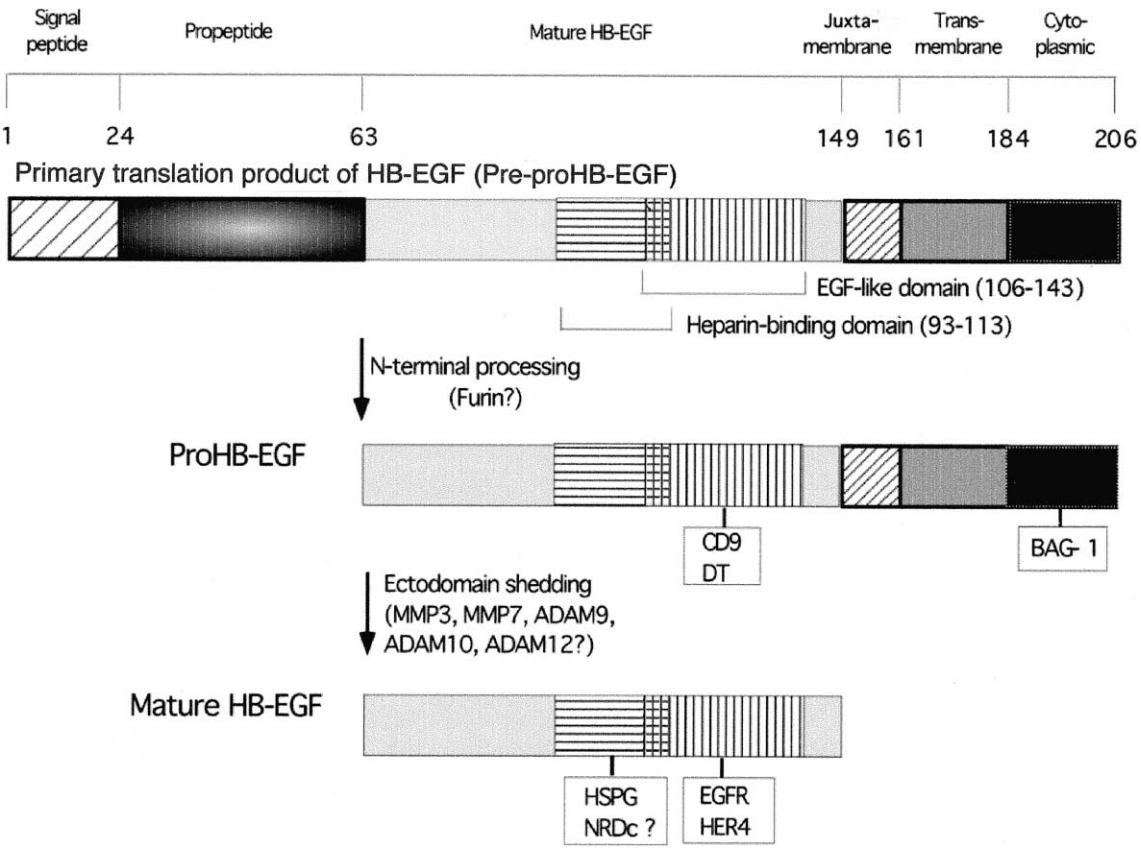

FIGURE 1 HB-EGF domains and binding to various receptors. (Top) The open reading frame of 206 amino acids. The numbers correspond to the amino acids that delineate the various HB-EGF domains. (Middle) PreproHB-EGF is cleaved to proHB-EGF. Binding sites for CD9, diphtheria toxin (DT), and BAG-1 are depicted. (Bottom) Mature HB-EGF is generated by ectodomain shedding induced by a variety of enzymes. HB-EGF receptors are depicted.

contributes to the strong binding of HB-EGF to heparin and HSPG.

B. Gene Structure and Its Regulation

The HB-EGF gene locus has been mapped to chromosome 5 in humans and to chromosome 18 in mice. Cytogenetic localization of human HB-EGF is at 5q23, which is consistent with the finding that diphtheria toxin sensitivity is localized to 5q23. The human gene encoding HB-EGF contains six exons and five introns spanning 14 kb of DNA. So far, only one splice variant of human HB-EGF cDNA has been reported. It encodes a short form of HB-EGF containing the signal peptide, the propeptide, the heparin-binding domain, the first two disulfide loops of the EGF domain, and an additional nine C-terminal amino acids. The biological activity, if any, of this short form of HB-EGF has not been determined.

The gene expression of HB-EGF is highly regulated and a number of regulatory factors have been described. Positive regulators for HB-EGF gene expression include inflammatory cytokines (e.g., tumor necrosis factor-α and interleukin-1), growth factors (e.g., EGF family members, basic fibroblast growth factor, and platelet-derived growth factor), agonists of G-protein-coupled receptors (GPCRs) (e.g., angiotensin II, thrombin, and platelet-activating factor), and atherogenic lipids (e.g., oxidized low-density lipoproteins and lysophosphatidylcholine). Physical stresses, such as sheer stress, stretch, and hyperosmolarity, also up-regulate HB-EGF gene expression. HB-EGF mRNA induction is typically rapid and transient and is not inhibited by blocking protein synthesis, characteristic of immediate-early genes. The HB-EGF promoter has been described

and transcription factors such as MyoD and PDX-1 have been shown to be involved in HB-EGF gene regulation.

III. TRANSMEMBRANE HB-EGF

Transmembrane HB-EGF has a number of activities that are summarized in Fig. 2. The details are presented below.

A. Juxtacrine Activity

The mode of cell-to-cell signaling that is mediated by interaction of a transmembrane growth factor with its receptor on a neighboring cell has been termed "juxtacrine." Juxtacrine growth factor/receptor interactions were first demonstrated for the membrane-anchored forms of TGF-α and tumor necrosis factor α (TNFα). The juxtacrine activity of proHB-EGF was demonstrated using a coculture system of cells expressing proHB-EGF and cells expressing EGFR. Mouse L cells transfected with proHB-EGF stimulated DNA synthesis in 32D cells expressing EGFR. In some cases, however, juxtacrine interactions have induced growth inhibition. ProHB-EGF has also been demonstrated to be a survival factor for renal epithelial and hepatoma cells. Those cells transfected with proHB-EGF show significant resistance to apoptosis induced by H_2O_2, etoposide, or serum starvation. This survival effect appears to be unique for proHB-EGF in that mature HB-EGF does not promote cell survival readily.

B. Diphtheria Toxin Receptor

A unique property of transmembrane HB-EGF is that it is the specific receptor for DT. Expression cloning using a Vero cell cDNA library that was intended to identify DT receptor (DTR) revealed the DTR to be identical to proHB-EGF. Human and monkey proHB-EGFs are functional DTRs whereas mouse and rat proHB-EGFs are not. DT interacts with the EGF-like domain of human proHB-EGF, in which three amino acid residues, Phe-115, Leu-127, and Glu-141, seem to be critical for DT binding. Some of these amino acids are altered in mouse/rat proHB-EGF. The steps in the cytotoxic action of DT are internalization of the DT/proHB-EGF complex, translocation of the A fragment of DT from acidified vesicles to the cytosol, and subsequent inhibition of protein synthesis by ADP-ribosylation of elongation factor 2.

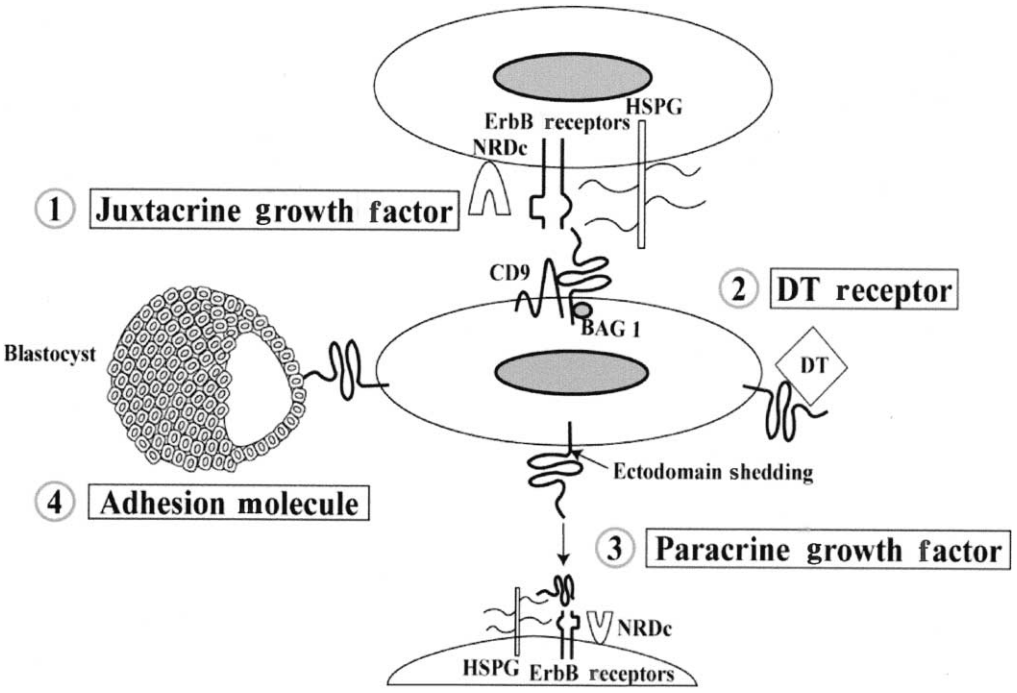

FIGURE 2 Biological properties of HB-EGF. ProHB-EGF is depicted as a juxtacrine growth factor (1), as the receptor for diphtheria toxin (DT) (2), as a target for ectodomain shedding that generates mature paracrine HB-EGF (3), and as an adhesion molecule for the trophoectodermal cells of the blastocyst (4).

Although the internalization rate for the DT is much slower than is typical of classical endocytic receptors, successful toxin effects occur because a single internalized enzymatically active toxin molecule is sufficient to inhibit protein synthesis in the cell. The cytoplasmic domain of proHB-EGF is not required for the internalization step.

C. ProHB-EGF Complexes

Several membrane proteins form complexes with proHB-EGF. CD9/DRAP27 was first identified as the antigen for a monoclonal antibody that inhibited the binding of DT to Vero cells. The antigen was identified as the monkey homologue of human CD9. CD9 is a tetramembrane-spanning protein that physically interacts with the proHB-EGF ectodomain and up-regulates the number of functional DT receptors and enhances sensitivity to DT. CD9 does not affect the expression level of proHB-EGF or the binding affinity of DT. CD9 also potentiates the juxtacrine activities of proHB-EGF. Anti-CD9 antibody does not inhibit the mitogenic activity of mature HB-EGF, but suppresses the juxtacrine activity of proHB-EGF in mouse L cells expressing both CD9 and proHB-EGF, suggesting complex formation. CD9 also interacts with the transmembrane forms of amphiregulin and TGF-α and modulates their bioactivities. On the other hand, other tetramembrane-spanning molecules, CD63, CD81 and CD82, associate with proHB-EGF, but do not affect proHB-EGF activity. Integrin $\alpha_3\beta_1$ forms a complex with proHB-EGF at cell–cell contact sites in epithelial cells. A yeast two-hybrid screen identified BAG-1 as a protein that binds to the cytoplasmic domain of proHB-EGF. BAG-1 has been demonstrated to bind to Bcl-2 and several other signaling molecules and is capable of suppressing apoptosis. Expression of BAG-1 along with proHB-EGF suppresses etoposide-induced apoptosis and increases mature HB-EGF secretion induced by etoposide.

IV. MATURE HB-EGF

Mature HB-EGF is a potent stimulator of cell proliferation and migration. Target cells include epithelial cells, fibroblasts, and SMCs, but not ECs. Target cell specificity may correlate with the expression of HB-EGF receptors. Mature HB-EGF is not only a paracrine factor but also an autocrine factor for some cell types, including keratinocytes, urothelial cells, and prostate stromal cells. Autocrine activity has been demonstrated by the inhibition of cell growth *in vitro* by HB-EGF blocking antibody and CRM197.

Mature HB-EGF binds strongly to heparin–sepharose and is eluted with approximately 1 *M* sodium chloride. Site-directed mutagenesis and synthetic peptide studies indicate that the interaction of mature HB-EGF with heparin is primarily mediated by a stretch of amino acids extending from Lys-93 to Lys-113 of the protein, within which there are three separate basic amino acid stretches. The heparin-binding domain is mostly N-terminal to the EGF-like domain, but one of the three basic amino acid stretches is between the first and the second cysteine of the EGF-like domain.

HB-EGF binding to cell surface HSPG enhances its binding to EGFR and HB-EGF bioactivity in some cell types. Chinese hamster ovary cells mutant in HSPG production and transfected with EGFR do not bind significant levels of HB-EGF unless heparin is present in the medium. Treatment of bovine aortic SMCs with heparitinase or chlorate, an inhibitor of HSPG sulfation, significantly inhibits HB-EGF-stimulated cell migration. A similar inhibition occurs when SMCs are treated with a synthetic peptide corresponding to the heparin-binding domain of HB-EGF. Cell surface HSPG enhances DT sensitivity and DT binding to proHB-EGF/DTR.

V. ECTODOMAIN SHEDDING OF HB-EGF

A. Protease-Mediated Shedding

Ectodomain shedding of proHB-EGF is induced by various stimuli, including phorbol esters, calcium ionophore, and lysophosphatidic acid (LPA). Multiple signaling cascades, such as the mitogen-activated protein kinase (MAPK) and protein kinase C (PKC) pathways, appear to regulate HB-EGF shedding. Metalloproteinases have been implicated as sheddases of proHB-EGF because various metalloproteinase inhibitors efficiently inhibit the ectodomain shedding of HB-EGF. Matrix metalloproteinase 3 (MMP3), MMP7, a disintegrin and metalloproteinase 9 (ADAM9), ADAM10, ADAM12, and ADAM17 have been implicated as responsible proteases. The specific proteases involved in the shedding process of HB-EGF depend on cell type and biological environment. For example, MMP7 appears to be involved in the shedding process in epithelial cells, especially on the apical surface of cells. On the other hand, ADAM12 seems to be responsible for HB-EGF shedding in cardiomyocytes.

Pro148Val149 and Glu151Asn152 have been suggested as the shedding sites of proHB-EGF. Highly specific HB-EGF shedding inhibitors have been found by a screening of hydroxamic acid-based compounds. They inhibit cutaneous wound healing and cardiac hypertrophy in mice, and submandibular gland development in organ culture.

B. G-Protein-Coupled Receptor Ligand-Induced EGF Receptor Transactivation

The transactivation of EGFR by G-protein-coupled receptors (GPCRs) is critical for the mitogenic activity of ligands such as LPA, endothelin, and thrombin. This transactivation is dramatically attenuated by specific HB-EGF inhibitors such as CRM197 and anti-HB-EGF neutralizing antibody. Metalloproteinase inhibitors specific for inhibiting HB-EGF shedding also inhibit EGFR transactivation by GPCRs, indicating that HB-EGF shedding is associated with EGFR transactivation induced by GPCR ligands (Fig. 3). EGFR transactivations induced, for example, by insulin-like growth factor-I and *Helicobacter pylori* also appear to be dependent on HB-EGF shedding.

VI. HB-EGF RECEPTOR

EGFR (HER1) was originally identified as the receptor for HB-EGF. HB-EGF binds to EGFR and induces tyrosine phosphorylation of the receptor. HB-EGF also binds to cells with HER4 receptors and induces chemotaxis but not proliferation in those cells, whereas HB-EGF induces both chemotaxis and proliferation via EGFR. HB-EGF-induced chemotaxis of HER4-expressing cells is inhibited by wortmannin, indicating that phosphoinositol 3-kinase (PI3K) activity is involved in the HER4-mediated chemotaxis. More recently, NRDc has been identified as a highly specific 140-kDa non-tyrosine kinase receptor for HB-EGF, unlike EGFR, which also binds EGF, TGF-α, amphiregulin, betacellulin, and epiregulin. NRDc was initially identified as a metalloendopeptidase with an inverted consensus zinc binding site (HXXEH), thereby placing it in the inverzincin/M16 family of metalloendopeptidases. NRDc expression enhances HB-EGF-induced cell migration via EGFR. Although NRDc is a metalloendopeptidase, the enzyme does not cleave HB-EGF and its enzymatic activity is not required for HB-EGF binding or enhancement of cell motility.

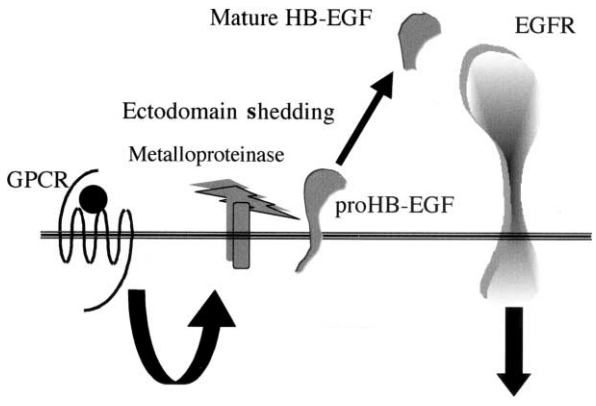

FIGURE 3 Model of transactivation of epidermal growth factor receptor (EGFR) by G-protein-coupled receptor (GPCR) agonists. Agonist binding and activation of the GPCR results in an intracellular signal that induces the extracellular activity of a transmembrane metalloproteinase. Activated metalloproteinase induces the ectodomain shedding of proHB-EGF, resulting in the release of mature HB-EGF. Mature HB-EGF binds to the ectodomain of EGFR and induces an intracellular signal.

VII. PHYSIOLOGICAL ACTIVITIES OF HB-EGF

HB-EGF has been implicated in a number of physiological and pathophysiological processes.

A. HB-EGF in Tumors

HB-EGF expression is enhanced in hepatocellular, pancreatic, gastric, and breast cancer tumors, when compared to normal tissue. Up-regulation of HB-EGF is also detected in a model rat of spontaneous hepatocarcinogenesis. Anti-HB-EGF blocking antibody diminishes the growth of some tumor cells, e.g., glioblastoma and multiple myeloma, suggesting an autocrine loop. Furthermore, transfection of HB-EGF into normal rat kidney cells or chicken embryo fibroblasts induces oncogenic transformation and anchorage-independent growth, indicating an important role of HB-EGF in tumorigenesis. HB-EGF is a direct transcriptional target of oncogenic Raf kinases and the tumor suppressor p53. Inhibiting HB-EGF function with anti-HB-EGF neutralizing antibody inhibits Raf-induced Jun N-terminal kinase (JNK) activation and p53-induced MAPK activation, respectively.

B. Wound Healing

Successful wound healing involves a number of processes, including inflammation, cell proliferation,

cell migration, vascular permeability, and angiogenesis, as well as matrix deposition and tissue remodeling. In cutaneous wound healing, keratinocytes play a central role, not only as a key structural cell type in the repair of skin but also as the source of a number of growth factors, among which the EGF family are prominent. Keratinocyte proliferation and migration are in part mediated in an autocrine manner by EGFR–ligand interactions. Wound stimuli induce keratinocyte shedding of EGFR ligands *in vitro*, particularly HB-EGF. The released mature HB-EGF stimulates transient activation of EGFR, which is essential for keratinocyte migration. HB-EGF, like EGF and TGF-α, is a potent stimulator of keratinocyte proliferation. Metalloproteinase inhibitors such as OSU8-1 and KB-R7785, which are relatively specific for proHB-EGF, block HB-EGF shedding and abrogate the wound-induced activation of EGFR, causing suppression of keratinocyte migration *in vitro*. The application of OSU8-1 to wound sites in mice greatly retards reepithelialization as the result of a failure in keratinocyte migration. This effect can be overcome by including recombinant soluble HB-EGF along with OSU8-1. Based on these findings, the shedding of HB-EGF represents a critical event in keratinocyte migration leading to wound healing.

C. SMC Hyperplasia/Cardiac Hypertrophy

The process of atherogenesis in the arterial wall is characterized by the formation of fibrous lesions and the proliferation of neointimal smooth muscle cells. HB-EGF is a potent chemoattractant and mitogen for vascular SMCs. In human atherosclerotic plaques, marked production of HB-EGF mRNA and protein is detected in SMCs and macrophages in the plaques. Balloon catheter injury of rat carotid arteries induces migration and proliferation of SMCs, with subsequent neointimal formation concomitant with production of HB-EGF mRNA and protein in SMCs. Other stimulants such as osmotic pressure, tension, and other growth factors and cytokines also up-regulate HB-EGF production in SMCs.

Cardiac hypertrophy is a primary and common adaptive response of the heart to a variety of cardiovascular diseases. Prolonged cardiac hypertrophy eventually culminates in chronic heart failure or sudden cardiac death. A variety of endogenous vasoactive reagents that act via GPCRs, such as phenylephrine, norepinephrine, angiotensin II, and endothelin-1, are associated with cardiac hypertrophy. Ectodomain shedding of HB-EGF by metalloproteinases is a key event in GPCR agonist-induced cell signaling via EGFR transactivation. When cardiomyocytes are stimulated by GPCR agonists, shedding of HB-EGF via metalloproteinase ADAM12 activation and subsequent transactivation of EGFR result in cardiac hypertrophy. An inhibitor of HB-EGF shedding, KB-R7785, blocked this GPCR-mediated signaling. In mice with cardiac hypertrophy, KB-R7785 inhibited the shedding of HB-EGF and attenuated hypertrophic changes. These data suggest that shedding of HB-EGF by ADAM12 plays an important role in cardiac hypertrophy, and that inhibition of HB-EGF shedding could be a potent therapeutic strategy for cardiac hypertrophy.

D. HB-EGF in Blastocyst Implantation

Uterine luminal epithelial cells express HB-EGF mRNA at the site of blastocyst implantation 6–7 h before attachment. Immunohistochemical analysis shows that proHB-EGF is expressed in a spatial and temporal manner similar to that of HB-EGF mRNA. Cells expressing proHB-EGF, but not cells expressing mature HB-EGF, adhere to day 4 mouse blastocysts, suggesting that proHB-EGF is an adhesion factor for blastocysts. Blastocysts isolated from egfr −/− mice still interact with blastocysts, indicating that the attachment is mediated by HB-EGF receptors other than EGFR, possibly erbB-4/HER4, NRDc, or HSPG. Mature HB-EGF promotes blastocyst development and hatching in mice, rats, and humans. Local application of HB-EGF-coated beads to the uterine lumen mimics many of the same discrete local responses elicited by the blastocyst, including increased localized vascular permeability, decidualization, and expression of bone morphogenetic protein-2 (BMP-2) at the sites of the beads. Other EGF family ligands, including EGF, TGF-α, and epiregulin, have no such effects. Together, these results suggest an important role for HB-EGF in blastocyst adhesion and blastocyst development.

VIII. SUMMARY

HB-EGF is found in two forms, the precursor proHB-EGF and its cleaved product, mature HB-EGF. ProHB-EGF plays a vital role in a number of processes such as juxtacrine activation, diphtheria toxin binding, and blastocyst implantation. Mature HB-EGF is a potent chemotactic and mitogenic factor. The transition of proHB-EGF to mature HB-EGF is tightly regulated by specific metalloproteinases.

This shedding process plays a central role in GPCR-mediated EGFR transactivation. Antagonizing these metalloproteinases can inhibit transactivation of the EGFR and may be of therapeutic value, for example, in cardiac hypertrophy. Future investigation with transgenic mice (for example, HB-EGF-deficient mice, mice expressing only mature HB-EGF, and mice expressing only a noncleavable mutant of HB-EGF) will yield clues that clarify the biological roles of HB-EGF.

Glossary

HB-EGF ectodomain shedding Irreversible posttranslational modification that converts membrane-anchored HB-EGF into its soluble mature form.

heparin binding Ability of a protein to bind tightly to heparin or heparan sulfate proteoglycan.

juxtacrine Mode of cell-to-cell signaling mediated by interaction of a transmembrane growth factor on one cell with its receptor on another cell.

Heptahelical Receptor Superfamily

KARIN A. EIDNE

Western Australian Institute for Medical Research, The University of Western Australia

G-protein-coupled receptors constitute extraordinarily large and diverse gene families in fungi, plants, and animals and form the central component of one of the primary mechanisms used by eukaryotic cells to receive and interpret a signal and then respond to it.

I. INTRODUCTION

G-protein-coupled receptors (GPCRs) account for approximately 1% of the human genome. Mutations in GPCR genes can result in altered function and have been associated with a number of hereditary or somatic disorders ranging from infertility to cancer. Members of the superfamily of GPCRs mediate the cellular responses to an enormous range of physiological processes such as the perception of light, taste, smell, and pain, synaptic neurotransmission, and chemotaxis. GPCRs also mediate the effects of numerous therapeutic agents such as the analgesic effects of opiates, the hormonal control of many physiological processes, the stimulation and regulation of mitotic events, and even the entry of viruses into cells.

GPCRs are functionally linked to G-proteins, the means by which they broadcast an external ligand message to the internal compartment of the cell and subsequently activate a cascade of second-messenger events to convert the extracellular signal into an intracellular response. Members of this receptor family have conserved protein sequences consisting of a single polypeptide chain that snakes back and forth across the lipid bilayer seven times, hence the term seven-transmembrane domain or 'heptahelical' receptors.

II. CLASSIFICATION OF HEPTAHELICAL RECEPTORS

When the first gene encoding a GPCR, the β2-adrenergic receptor, was cloned in the 1980s, it was revealed that receptors involved in hormonal signaling shared their characteristic heptahelical structure with that of the visual receptor, rhodopsin. However, there is little conservation of amino acid sequence across the entire superfamily and this variability is thought to accommodate the diverse range of ligands that bind to these molecules. Only approximately 25% of sequence homology is shared within each family, occurring mainly within the transmembrane regions with very little homology beyond the predicted transmembrane core domain. GPCRs have been identified in all species thus far examined and represent the most evolutionarily ancient of signaling devices (more than 800 million years old), as they are also present in the earliest metazoa and protozoa. The recent sequencing of the *Caenorhabditis elegans* genome has revealed that GPCRs constitute the most abundant family of genes in this organism, with more than 1000 GPCRs encoded by 5% of the genome. In addition to the seven transmembrane domains, characteristic structural features are the extracellular N-terminal domain and loops and the intracellular C-terminal tail domain and loops. Key sequence motifs can be found within phylogenetically related subclasses of receptors and these have been useful for the classification of receptors into six families (Families A to F; Table 1). In addition to each of these classes, many GPCRs exist as subtypes of a particular receptor. These subtypes allow for further discrimination of cellular responses based on tissue distribution or expression levels and in some cases provide for negative feedback regulation or inhibition. The majority of GPCRs are grouped into Families A, B, and C (Fig. 1, Table 2).

A. Family A

Family A constitutes the largest family that has key residues conserved, such as the DRY (Asp-Arg-Tyr)

TABLE I Classification of Hepthelical GPCR Families

Family	Classified GPCR
A	Rhodopsin-like
B	Secretin-like
C	Metabotropic glutamate/pheromone
D	Fungal pheromone
E	Class E cAMP receptors (*Dictyostelium*)
F	Frizzled/Smoothened family
Family	Classified putative GPCR
	Ocular albinism proteins
	Drosophila odorant receptors
	Plant Mlo receptors
	Nematode chemoreceptors
Family	Unclassified putative GPCR
	Orphans

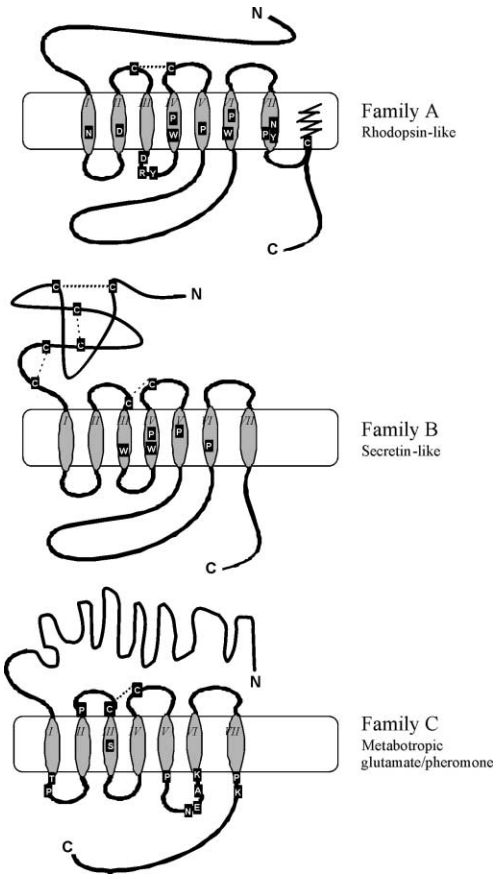

FIGURE 1 Major heptahelical receptor subfamilies. Of the receptors that have been classified into the main family groups, the majority have characteristic features and key residues. Members of Family A, the largest family, have an Asp-Arg-Tyr (DRY) motif in transmembrane 3 (TM3), an Asn-Pro-Tyr (NPY) motif in TM7, conserved Pro residues in TMs 4, 5, 6, and 7, Trp residues in TMs 4 and 6, an extracellular disulfide bridge, and a palmitoylation group in the C-terminal tail. Family B is characterized by a distinctively large extracellular N-terminus that contains several Cys residues thought to form a network of disulfide bridges. Pro residues in TMs 4, 5, and 6 and Trp residues in TMs 3 and 4 (different than those found in Family A) are conserved. Family C members have a very long N-terminus (approximately 600 amino acids), which is thought to contain the ligand-binding domain. In contrast to Families A and B, the third intracellular loop is extremely short and highly conserved. A putative extracellular disulfide bridge is shown.

motif in the third transmembrane domain (TM3) (Fig. 2). Among this family of receptors are the amine receptors (e.g., adenosine, adrenergic, dopamine, histamine, muscarinic, and serotonin receptors), the peptide receptors (e.g., angiotensin, bradykinin, chemokines, endothelin, and opioid receptors), and the hormone receptors (e.g., follicle-stimulating hormone, luteinizing hormone, and thyrotropin-stimulating hormone receptors). The sensory receptors, including rhodopsin (detects photons in the rod photoreceptor cell) and the olfactory receptors (detects smells), also belong to this family. Olfactory receptors make up the majority of this family, although to date it has approximately 200 nonolfactory members that have been functionally characterized.

B. Family B

This family has none of the distinctive motifs apparent in Family A (i.e., the DRY motif is missing and different prolines are conserved). Common to all

TABLE 2 Three Major GPCR Subfamilies

Family A	Family B	Family C
Adenosine	Calcitonin	Calcium-sensing
Adrenergic	CGRP	Metabotropic GABA
Angiotensin	CRF	Metabotropic glutamate
Bombesin	Gastrin	Taste
Bradykinin	GHRH	Vomeronasal
Cannabinoid	Glucagon	
Chemokine	Glucagon-like	
Dopamine	Latrotoxin	
Eicosanoid	PACAP	
Endothelin	PTH	
FSH	PTHrP	
Galanin	Secretin	
GnRH	VIP	
Histamine		
LH		
Melatonin		
Muscarinic		
Neuropeptide Y		
Neurotensin		
Olfactory		
Opioid		
Oxytocin		
Protease-activated		
Rhodopsin		
Somatostatin		
Serotonin		
TRH		
TSH		
Vasopressin		

Note. CGRP, calcitonin gene-related peptide; CRF, cortiotropin-releasing factor; FSH, follicle-stimulating hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; PTH, parathyroid hormone; PTHrP, parathyroid hormone-related peptide; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone; VIP, vasoactive intestinal peptide.

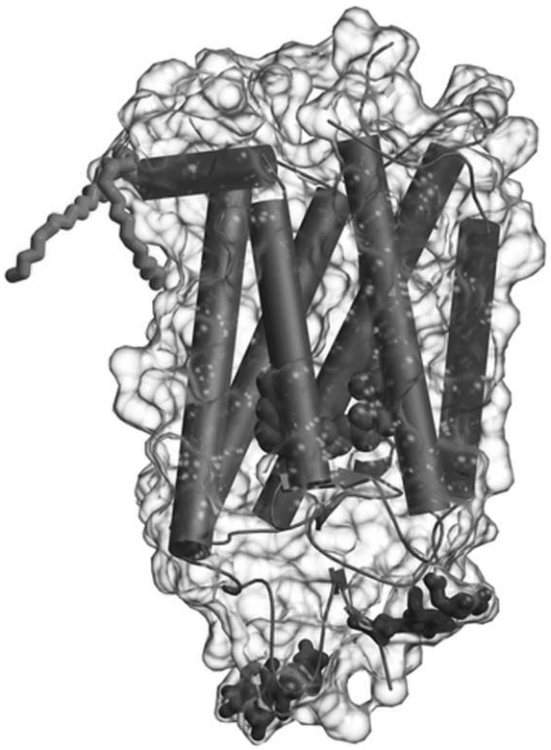

FIGURE 2 Three-dimensional structure of bovine rhodopsin. Helical portions of the protein, including the seven transmembrane helices with the 11-*cis*-retinal (RET) chromophore bound, are shown as rods, and the transparent envelope around the protein represents the molecular surface. The ball-and-stick groups at the bottom of the figure denote carbohydrate groups attached to the protein and two palmitoyl groups covalently attached to the protein are shown at the top left. Figure drawn by Craig Behnke. Modified with permission from Teller, D. C., Okada, T., Behnke, C. A., Palczewski, K., Stenkamp, R. E., (2001). Advances in determination of a high-resolution three-dimensional structure of rhodopsin, a model of G-protein coupled receptors (GPCRs). *Biochemistry* **40**, 7761–7772. Copyright 2001 American Chemical Society.

Family B receptors is a network of disulfide bridges connecting the first and second extracellular loops (ECLs), consequently forming a large extracellular amino-terminus consisting of a number of cysteine residues. This family comprises approximately 25 members that include calcitonin, gastrin, glucagon, vasoactive intestinal peptide, growth hormone-releasing hormone, parathyroid hormone, and secretin receptors. Most of the members of this family have receptors that couple to the guanosine triphosphate (GTP)-binding protein, G_s, and signal via adenylyl cyclase.

C. Family C

Receptors belonging to this family are distinguishable by a remarkably long amino-terminus (500–600 amino acids). As in Families A and B, in Family C, disulfide-forming cysteines in ECL1 and ECL2 are present and it is believed that the amino-terminus of Family C receptors contains the ligand-binding site. A relatively small number of receptors belong to this family, which consists of the metabotropic glutamate and γ-aminobutyric acid (GABA) receptors, the calcium receptors, the vomeronasal mammalian pheromone receptors, and the recently identified putative taste receptors.

D. Family D

This family encompasses the yeast pheromone receptors, STE2 receptors and STE3 receptors.

E. Family E

Family E is a minor but unique family that is composed of four different cyclic AMP-linked receptors from *Dictyostelium discoideum*.

F. Family F

Frizzled (FZD) and smoothened (SMO) are integral membrane proteins with characteristic G-protein-coupled receptor features of seven membrane-spanning domains and extracellular N-terminal and hydrophilic C-terminal domains. FZD and SMO are segment polarity genes required for the transmission of polarity information during tissue morphogenesis. Secreted Wnt glycoproteins, important in developmental control, are ligands for FZD receptors, whereas the smoothened receptor mediates hedgehog signaling. FZD receptors are mostly coupled to the β-catenin canonical signaling pathway, which results in activation of disheveled proteins, inhibition of glycogen synthase kinase-3, nuclear accumulation of β-catenin, and activation of Wnt target genes.

G. Classified Atypical GPCRs

Additionally, there are atypical (or putative) GPCR families: These include ocular albinism proteins, *Drosophila* odorant receptors, plant Mlo receptors, nematode chemoreceptors, and vomeronasal receptors (V1R and V3R). All the different GPCR families share the same seven-membrane-spanning domain topology; however, the evolutionary relationships

among the different families are uncertain since there is no significant degree of sequence similarity among them. It is likely that these families evolved independently and convergently adopted the G-protein signal transduction pathway.

H. Orphan GPCRs

A number of structurally similar yet novel receptors for which the endogenous ligands are not yet known have also been isolated. These receptors, known as "orphan" GPCRs, show homology to known GPCRs at levels that are too low to classify them into any known receptor subfamily with any degree of confidence. It is possible that these receptors represent novel subfamilies of GPCRs with functions and physiology that are distinct from those of identified GPCRs. Orphan GPCRs represent a valuable resource for novel drug targets and more than 200 orphans have been identified following the completion of the Human Genome Project. The challenge lies in being able to characterize these novel genes and to understand their physiological and pathophysiological roles. Identification of the activating ligand of a receptor with unknown function has proven to be extremely difficult and time-consuming. The overall strategy for characterizing orphan GPCRs involves a "reverse pharmacology" approach in which many ligands are used to screen for the functional activation of a particular orphan GPCR. But despite a great deal of effort by many groups working in this area, the ligands for only a very few orphan GPCRs have been identified.

III. HEPTAHELICAL STRUCTURE

The characteristic membrane-spanning heptahelical regions of GPCRs are generally composed of 20–27 amino acids, whereas the other segments can vary in size: N-terminal segments are 7–595 amino acids, C-terminal segments are 12–359 amino acids, and extracellular and intracellular loops are 5–230 amino acids. Only recently has the structure of the first GPCR, rhodopsin, been solved, and to date, this is the only GPCR that has yielded a crystal structure. To obtain crystals, bovine rhodopsin was purified from rod outer segment membranes and the crystal structure was determined to 2.8 Å resolution. A diagram of the rhodopsin molecule with its bound 11-*cis*-retinal chromophore intact is shown in Fig. 2 and confirms the presence of an anti-clockwise bundle of seven transmembrane α-helices that are connected by extracellular and intradiscal loops of varying size. The helices are irregular, differing in length, and tilting at various angles with respect to the membrane surface. Although the rhodopsin structure can be useful as a template for other GPCRs, it is not ideal. Although rhodopsin shares similarities with other GPCRs, it also possesses many specialized features, such as visual pigments.

Ligands can bind to the TM, extracellular loops, and amino-terminus. Evidence suggests that smaller ligands bind primarily to the TM core and larger peptides can bind to the amino-terminus, extracellular loops, and TMs. Binding of the ligand is thought to induce a change in the position of the seven TMs, leading to a conformational change in the receptor. This results in increased coupling of the receptor to heterotrimeric G-proteins and consequently G-protein activation; however, this theory is still under intense investigation.

An intriguing question is why are there seven TMs? Possible reasons for this might be that the receptor must be of sufficient size in order to provide the versatility required for the ligand specificities, regulatory mechanisms, and G-protein contact sites as well as other signaling molecules. Perhaps five TMs would not be large enough to form a stable TM core with sufficient flexibility, but nine TMs would be too many. Also, an uneven number of TMs allows the terminal segments to be positioned at opposite membrane surfaces, thus permitting glycosylation and ligand binding at the N-terminal segment and phosphorylation and palmitoylation at the C-terminal segment (important for desensitization and internalization).

IV. SIGNAL TRANSDUCTION PATHWAYS OF GPCRS

A. G-Proteins

The generally accepted dogma for the action of a GPCR is that upon activation by ligand, the receptor binds to and activates a G-protein. G-proteins belong to a superfamily of highly conserved GTPases that play a role in many aspects of cell regulation. They are heterotrimeric, consisting of three different subunits: α, β, and γ. The α-subunit has a site for binding GDP or GTP and a catalytic center for hydrolyzing GTP to GDP. G-protein subunits have lipid anchors that permit lateral diffusion, protein–lipid interactions, and protein–protein interactions. The α-subunit is usually modified by a fatty acyl lipid

TABLE 3 Classes of G-Protein α-Subunits

G-protein	Types	Function	Receptor
G_s	$G_{\alpha s}$, $G_{\alpha olf}$	Activates cAMP pathway	ACTH, adenosine A2, β-adrenergic, CCK, dopamine D1, FSH, histamine H2, LH, MSH, olfactory, PGE1, PGE2, PGE12, TSH, taste
G_i	$G_{\alpha i1}$, $G_{\alpha i2}$, $G_{\alpha i3}$, $G_{\alpha o1}$, $G_{\alpha o2}$, $G_{\alpha t}$, $G_{\alpha gus}$, $G_{\alpha z}$	Inhibits cAMP pathway and regulates ion channel function through release of $G_{\beta\gamma}$	Adenosine A1, adrenergic A2, dopamine D2, $GABA_B$, histamine H3, muscarinic M2, opioid (μ, κ, δ), prostaglandin, 5HT-1a
G_q	$G_{\alpha q}$, $G_{\alpha 11}$, $G_{\alpha 14}$, $G_{\alpha 16}$	Activates inositol phosphate pathway	Adrenergic, bradykinin, CCK, histamine H1, GnRH, muscarinic M1, PAF, thromboxane, TRH, substance K, substance P, vasopressin V1, VIP, 5H2C
G_{12}	$G_{\alpha 12}$, $G_{\alpha 13}$	Activates Rho-GEF, which modulates the cytoskeleton	Angiotensin AT1, lysophosphatidic acid, muscarinic, thrombin

Note. ACTH, adrenocorticotropic hormone; CCK, cholecystokinin; FSH, follicle-stimulating hormone; LH, luteinizing hormone; MSH, melanocyte-stimulating hormone; PAF, platelet activating factor, PGE1, 2, and 12, prostaglandin E1, 2, and 12; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone, VIP, vasoactive intestinal peptide; 5HT-1a, 5-hydroxytryptamine 1A; 5H2C, 5 hydroxytryptamine 2C.

anchor (myristoyl or palmitoyl), and the γ-subunit has an isoprenoid lipid anchor (farnesyl).

There are four main classes of G-proteins that are categorized according to their α-subunit (Table 3). The $G_{s\alpha}$ and $G_{i\alpha}$ subunits both interact with adenylyl cyclase isoforms. Their actions, however, are opposite: G_s stimulates and G_i inhibits the synthesis of cyclic AMP from ATP. Members of the $G_{i\alpha}$ family are also defined by their ability to activate K^+ channels. The actions of these two α-subunits may be differentiated in the laboratory by the bacterial toxins cholera toxin and pertussis toxin (Table 4). The $G_{q\alpha}$ family members are not substrates for cholera or pertussis toxin but stimulate the β class of phospholipase C (PLC-β) enzymes. Members of the fourth class of G-proteins are also insensitive to cholera and pertussis toxins and include $G_{12\alpha}$ and $G_{13\alpha}$, which have been implicated in the regulation of small GTP-binding proteins.

B. G-Protein GTPase Cycle

Heterotrimeric G-proteins differentially control the kinetics and amplitude of signal transduction via a regulated G-protein/GTP cycle of binding and hydrolysis (Fig. 3A). In the "inactive" or "basal" state, the G-protein α-subunit is bound to the βγ-subunit (forming the heterotrimer) with GDP bound to the guanine nucleotide-binding site of the G_α subunit. Upon activation of the receptor by its ligand, the subunits dissociate, GDP is released from the Gα subunit, and GTP binds to and activates G_α. Thus, the activated receptor acts as a guanine nucleotide exchange factor. Both G_α (with GTP bound) and the $G_{\beta\gamma}$ subunits regulate effector molecules until GTP is hydrolyzed, and the heterotrimer reassociates, returning the system back to the beginning of the cycle. The rate at which G_α is able to hydrolyze receptor-bound GTP determines the duration of the active state. GTPase-activating proteins (GAPs) accelerate the rate of GTP hydrolysis. Examples of these include regulators of G-protein signaling (RGS) (see below), G_α-interacting proteins, and phospholipase C-β.

C. Regulators of G-Protein Signaling

RGS proteins function to regulate the hydrolysis of GTP to GDP, thereby promoting conversion of the G_α

TABLE 4 Bacterial Endotoxins and Their Effect on Signal Transduction[a]

Bacterium	Toxin	Cellular target/residue
Bordetella pertussis	Pertussis	$G_{i\alpha}$/Cys
Vibrio cholerae	Cholera	$G_{s\alpha}$/Arg

[a]Pertussis toxin and cholera toxin have ADP-ribosyltransferase activity and their intracellular substrates are $G_{i\alpha}$ and $G_{s\alpha}$ subunits, respectively. Pertussis toxin targets a Cys residue of G_i, which then becomes ADP-ribosylated, thus locking it in the inactive state. Cholera toxin targets an Arg residue of G_s, which then becomes ADP-ribosylated; GTPase activity is abolished, and G_s is "locked" in the active monomeric state.

subunit from an active to an inactive state (Fig. 3B). These proteins provide another mechanism for shutting off G-protein signaling; however, this process differs from that of arrestins and G-protein receptor kinases (GRKs) by acting at the level of the G-protein instead of the receptor. RGS proteins constitute a family of 20 proteins. They were first discovered when discrepancies were noted between the rate at which certain physiological responses were terminated (approximately milliseconds) and the rate at which isolated G_α subunits hydrolyzed GTP (approximately seconds) in systems such as photoreception. The duration of GPCR signaling is subject to the rate of G_α GTP hydrolysis, and signal deactivation of the GTP-bound G-protein can occur only by means of the intrinsic guanosine triphosphatase activity of the G_α subunit. Clues to this timing inconsistency came from the discovery that certain effectors can also act as GAPs by enhancing the rate of GTP hydrolysis by G_α subunits (Fig. 3B).

In addition to their role as effectors for G-proteins, RGS proteins can also act as positive regulators of G_s-coupled receptors, or by increasing the concentration of free $G_{\beta\gamma}$ subunits. Specific RGS proteins inhibit different G_α subfamilies. For example, RGS4 is thought to inhibit signaling from some $G_{q\alpha}$-coupled receptors. GRKs also contain RGS domains, which can provide an explanation for the direct effect that GRK2 has on $G_{q\alpha}$ activity.

D. Receptor–G-Protein Interactions

GPCRs interact with an ever-increasing number of G-proteins (Table 3), giving rise to the question of how a GPCR dictates the recruitment of a particular G-protein. Numerous studies using either synthetic peptides or minigenes encoding GPCR cytoplasmic domains, receptor chimeras, and site-directed mutagenesis have provided strong evidence that the important receptor contact sites for G-proteins are located in the third intracellular loop of a variety of GPCRs. Specificity for a particular G-protein may be due to different contact sites within the same domain or multiple domains within the receptor.

Receptor–G-protein interactions do not use only the G_α subunit, as $G_{\beta\gamma}$-binding sites have also been identified in some GPCRs. With regard to $G_{\beta\gamma}$, current evidence suggests that these tightly associated subunits can also regulate effector molecules including adenylate cyclase, PLC-β, and phospholipase A2, regulate the activation of mitogenic-activated protein kinase (MAPK) pathways, and, in a more recently proposed role, function as a docking protein to provide an interface for an array of signaling pathways.

E. GPCR Signaling

GPCRs translate an extracellular signal into an intracellular response, regulating events such as proliferation, apoptosis, secretion, and differentiation. This signal transduction event involves a complex network of interwoven signaling cascades in which the signal becomes amplified and directed in a specific manner. The propagation and amplification of the primary signal involve a wide array of enzymes with very specialized functions. Many of these signaling enzymes propagate the signal by posttranslationally modifying other cellular proteins involved in the signaling cascade. Enzymes such as protein phosphatases and kinases play an important role with respect to the phosphorylation state of cellular proteins. Altering the phosphorylation state of proteins determines whether or not a signal is transduced.

Following ligand binding by GPCRs, the receptor undergoes a conformational change that is thought to involve helical rearrangements within the structure of the receptor. The activation signal is then transmitted via the cognate G-protein located on the cytoplasmic surface of the membrane, to the interior of the cell. Activation of the receptor causes initiation of a number of downstream effectors, such as second-messenger-generating adenylyl cyclases, phospholipases, and ion channels. There is also a concomitant increase in GTPase activity of the G_α subunit.

Classical examples of GPCR signaling are shown in Fig. 4. Binding of GPCRs to $G_{s\alpha}$ activates adenylyl cyclase to produce cAMP, which acts as a second messenger to activate protein kinase A (PKA). PKA is a serine/threonine kinase that is able to phosphorylate a plethora of substrates leading to a cellular response. $G_{i\alpha}$ has an inhibitory effect on adenylyl cyclase activity and regulates ion channel function through release of the βγ-subunits. Binding of GPCRs to the $G_{q\alpha}$ family of proteins activates the plasma membrane-associated PLC-β, causing hydrolysis of phosphatidylinositol 4,5-biphosphate to diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP_3). IP_3 activates IP_3 receptors located on intracellular calcium stores, causing a rise in intracellular Ca^{2+}. DAG can also activate calcium channels. Both DAG and Ca^{2+} activate protein kinase C (PKC), which in turn can initiate signaling of the MAPK cascade pathways. MAP kinases

play a central role in mitogenic signaling and growth-promoting pathways. They complete the signal transduction pathway by translocating themselves into the nucleus and initiating the transcription process. This process ultimately regulates the expression of genes essential for cellular processes such as proliferation and development.

V. ATTENUATION OF GPCR SIGNALING

GPCRs provide a rapid response to a variety of ligands and are often rapidly attenuated in their signaling despite the continued presence of the stimuli. Failure to terminate GPCR signaling resulting in prolonged stimuli can have dramatic consequences for the cell. The balance between receptor signaling, desensitization, and resensitization is very important in maintaining cell function and GPCR responsiveness. From a clinical perspective, receptors undergoing rapid desensitization can limit the therapeutic effects of many receptor agonists. GPCR systems have a number of mechanisms for attenuating the agonist-stimulated signal. These include ligand removal, receptor desensitization, internalization, and down-regulation. Following internalization, receptors are either degraded via the lysosomal pathway or recycled back to the cell surface, contributing to the process of resensitization. The cell's ability to either maintain responsiveness or shut off response to repeated signals represents a coordinated balance between the molecular mechanisms governing receptor signaling, desensitization, internalization, and recycling.

A. Removal of Ligand

Certain receptors utilize a mechanism whereby the signaling molecule is removed from the extracellular fluid. Neurotransmitters such as acetylcholine have a specific degrading enzyme (acetylcholinesterase) that effectively can accomplish ligand removal. Inhibition of acetylcholinesterase results in prolonged signaling at the neuromuscular junction and can have detrimental effects in humans such as leading to uncontrollable spasms. On the other hand, acetylcholinesterase inhibitors can be used as a form of therapy for patients with Alzheimer's disease. These patients have fewer cholinergic neurons and inhibitors of acetylcholinesterase can compensate for the loss in cholinergic stimuli. Transporters for ligands such as dopamine, serotonin, and GABA are able to remove these neurotransmitters from the synapse, thus terminating signaling. This is in contrast to the degrading enzyme, as reuptake conserves neurotransmitter so that it can then be recycled back to the receptor. Drugs such as cocaine act by inhibiting reuptake of dopamine or adrenaline, thus preventing termination of signaling.

B. Desensitization

Desensitization refers to the phenomenon in which the prolonged stimulation of a response induced by a receptor begins to wane. Desensitization consists of three processes: receptor phosphorylation, which occurs in seconds to minutes; internalization, which occurs in minutes to hours; and down-regulation, which continues for hours to days. There are two types of desensitization: homologous desensitization, which is defined as the agonist-induced reduction in cellular response that occurs when the receptor is stimulated only by this particular agonist, and heterologous desensitization, which is defined as the reduction in response of a particular receptor following activation of other receptors in the cell by their respective agonists. These processes are reversible following removal of the agonist, after which a process known as resensitization occurs and GPCRs gradually regain their ability to respond to ligands.

C. Receptor Phosphorylation

Following exposure to ligand, receptors undergo rapid phosphorylation events and this modification

FIGURE 3 (A) G-protein GTPase cycle. In the basal state (I), the G-protein is a heterotrimer with GDP bound tightly to the G_α subunit. Agonist-bound receptor (II) acts with the G-protein and catalyzes the release of bound GDP, allowing GTP to bind (III). This exchange results in the dissociation of the G_α from the $G_{\beta\gamma}$ subunit, which in turns interacts with an effector protein to produce an intracellular signal (IV). Effector regulation by G-proteins is transient and terminated by an intrinsic GTPase activity of G_α, resulting in the hydrolysis of bound GTP to GDP and a return to the basal state where the G_α has high affinity for $G_{\beta\gamma}$, thus reassociating to form the heterotrimer. (B) Regulators of G-protein signaling (RGS proteins). Following agonist-induced stimulation, RGS proteins accelerate the rate of GTP hydrolysis as a mechanism of reducing receptor signaling. (I) Agonist binding to receptors enhances guanine nucleotide exchange (GEF) activity, resulting in the association of GTP with the G_α subunit. (II) RGS proteins act as GTPase-activating proteins (GAPs) for heterotrimeric G-proteins by accelerating the rate of GTP hydrolysis by G_α, leading to reassociation of G_α with $\beta\gamma$-subunits.

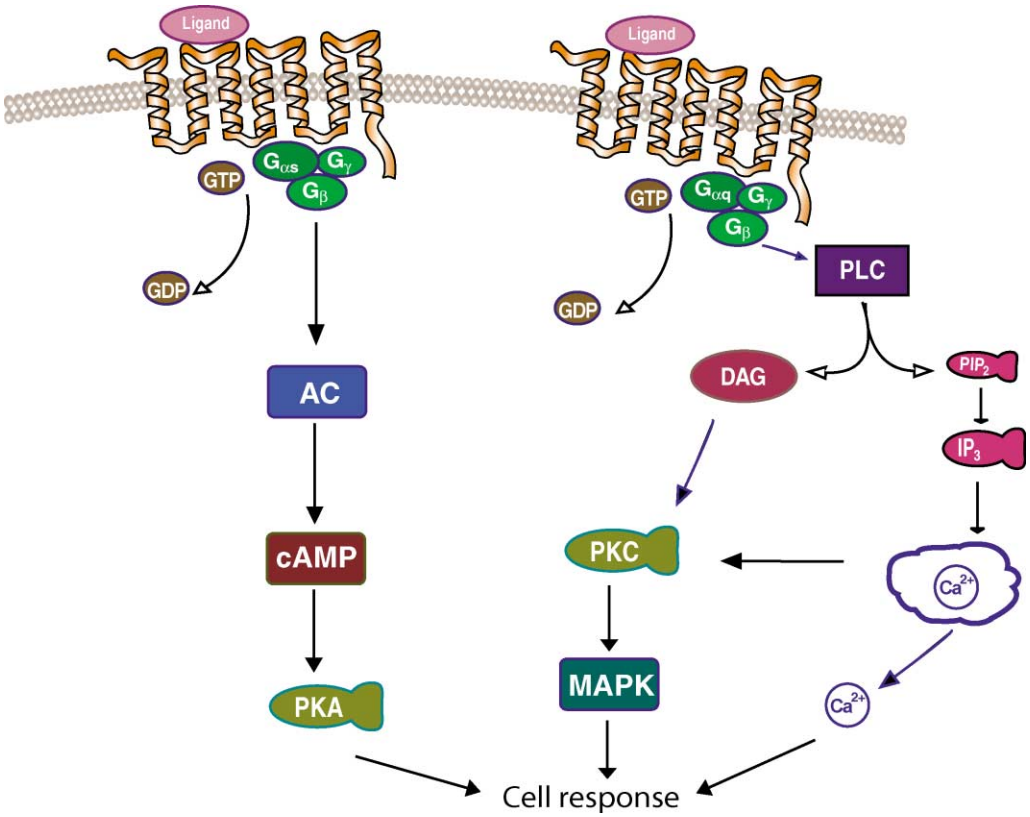

FIGURE 4 G-protein receptor signal transduction pathways. Simplified signaling pathways highlighting cyclic nucleotide and phospholipase cascades triggered by ligand-activated GPCRs. Ligand binding to a G_s-coupled GPCR results in the activation of adenylate cyclase (AC), causing an accumulation of cyclic AMP (cAMP). Cyclic AMP binds to protein kinase A (PKA), which then phosphorylates targets in the cytoplasm and nucleus, resulting in a cellular response. Ligand binding to G_q/G_{11}-linked GPCR results in activation of phospholipase C (PLC), which cleaves phosphatidylinositol 4,5-bisphosphonate (PIP_2) into 1,2-diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). The IP_3 interacts with a calcium channel in the endoplasmic reticulum, raising intracellular Ca^{2+} levels. The increase in Ca^{2+} levels activates protein kinase C (PKC), which then initiates signaling via the mitogen-activated protein kinase (MAPK) cascade pathways, resulting in a downstream cellular response.

is thought to be responsible for G-protein uncoupling. Phosphorylation consensus sites are found in the intracellular domain of the GPCR, particularly within the third intracellular loop and the C-terminal tail. Different kinases have been implicated in GPCR phosphorylation and these include the second-messenger kinases (PKA, PKC), the family of GRKs (GRK1–GRK7), and casein kinases (1a and II). Of these, the GRKs have received the most attention for their roles in GPCR desensitization and internalization. There are currently seven members of the GRK family, all of which share significant sequence homology, but differ in their tissue distribution and regulatory properties. GRK1 is confined to the retina and pineal gland; GRK4 is localized to the testis and GRK7 to the retina. GRK2, GRK3, GRK5, and GRK6 are ubiquitously expressed. Distinct consensus sites for GRK phosphorylation are largely unknown although Ser and Thr residues that are GRK substrate sites have been characterized for some GPCRs. Interestingly, cross-talk between PKC and GRKs exists (e.g., PKC can phosphorylate GRK2, which enhances its kinase activity).

D. Model of GPCR Internalization

The molecular mechanisms surrounding internalization of numerous GPCRs have been studied, and the following model, which implicates key players regulating this event, has been proposed (Fig. 5). Briefly, the first step in this process is the binding of agonist to receptor. This then triggers GPCR

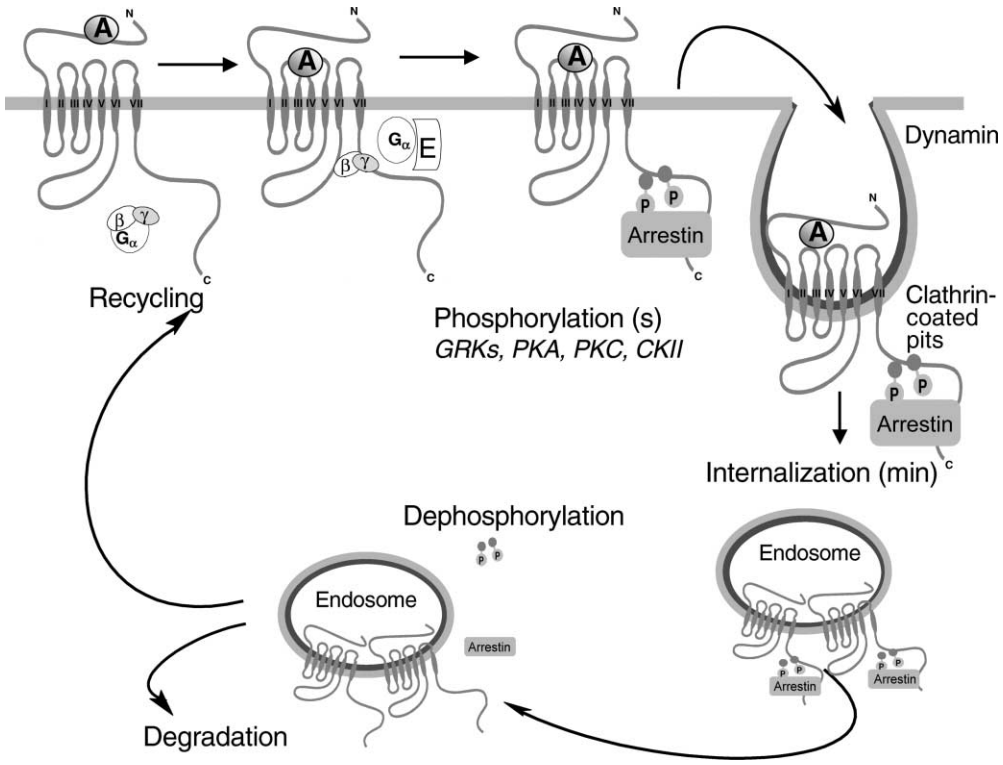

FIGURE 5 Heptahelical receptor trafficking. Agonist occupancy of the receptors leads to activation of G-proteins, resulting in the dissociation of α- and βγ-subunits. G-protein receptor kinases are recruited to the receptor by the free βγ-subunits and phosphorylation of intracellular domains of the receptor then occurs. Agonist-induced receptor phosphorylation occurs within seconds, causing the receptor to become desensitized to further stimuli. Subsequently, β-arrestins facilitate recruitment of the receptors to clathrin-coated pits and they undergo internalization into the interior of the cell. Dynamin plays a role in pinching off vesicles from the cell membrane. Following dephosphorylation, receptors either are recycled back to the cell surface ready for reactivation by ligand or enter the lysosomal pathway and undergo degradation.

phosphorylation by phosphorylating enzymes (i.e., GRKs), which then results in the creation of high-affinity binding sites for the β-arrestins. β-Arrestins then bind to the receptor, forming a complex with the adapter protein, activator protein-2 (AP-2) as well as the heavy chain of clathrin. AP-2 is thought to be responsible for targeting the receptor–β-arrestin complex to clathrin-coated pits. Thereafter, the vesicles containing the receptors begin to bud from membranes, a step that requires the GTPase activity of dynamin. β-Arrestin interacts with another protein, c-Src, a tyrosine kinase that regulates the phosphorylation state of dynamin. Vesicles are then targeted to the endocytic compartment of the cell via the endosomes. The fate of the receptor is dependent on whether it is retained within the endosomes before being recycled back to the cell surface or whether it is destined for the lysosomal pathway to be degraded. Specific molecular determinants that determine receptor fate are contained within the GPCR intracellular domain and clusters of serine residues in the carboxy tail have been implicated in this regard.

E. Arrestins

Binding of arrestins to agonist-activated GPCRs results in the deactivation of the signaling pathway. Arrestins are cytoplasmic adapter proteins that rapidly translocate to the cell surface to bind to GPCRs upon their phosphorylation. The binding of arrestins to phosphorylated receptors has been implicated in G-protein uncoupling, desensitization, and internalization. To date, the arrestin gene family consists of at least four members: the visual arrestins (rod and cone) and β-arrestins 1 and 2. β-Arrestin 2 is also referred to as arrestin-3, although an additional two arrestin isoforms, D- and E-arrestins, may also exist. D- and E-arrestins are partial clones that are

expressed in a broad range of tissues and have not yet been properly characterized. Visual arrestins are found mainly in the retina and less so in the pineal gland, cerebellum, and primary blood leukocytes. Cone arrestins are found mostly in cone photoreceptors but are also localized to the pineal gland and pituitary. β-Arrestins 1 and 2 are ubiquitously expressed. The phenomenon of cytosolic arrestins being recruited to the cell surface where they colocalize with receptors has been demonstrated using confocal microscopy with β-arrestins fused to green fluorescent protein.

VI. RECEPTOR–PROTEIN INTERACTIONS

GPCRs appear to be capable of interacting with a bewildering array of adapter/scaffolding proteins, some of which play a role in pulling proteins together. Some of these protein–protein interactions are thought to lead to other signaling pathways for GPCRs, beyond the classical G-protein-dependent pathways, represented in Fig. 4. In addition to facilitating GPCR–effector interactions, these proteins can play a role in determining the specificity of the activation of downstream signaling cascades as well as ensuring that these signaling complexes are directed to the appropriate compartments within the cell.

Thus far, a number of novel binding partners for GPCRs that can activate nonclassical G-protein-mediated signaling have been discovered. Of particular note is the large family of PDZ-domain-containing proteins (named after the first three proteins in which they were discovered, i.e., the postsynaptic density protein PSD-95, the *Drosophila* tumor suppressor protein discs-large, and the tight junction protein ZO-1) that interact with the C-terminal domains of GPCRs (e.g., β_2-adrenergic receptor, rhodopsin, dopamine D2 receptor, and somatostatin receptor 2). In the case of the β_2-adrenergic receptor, the interaction of the PDZ protein NHERF allows receptor regulation of a Na^+/H^+ exchange, whereas for the rhodopsin receptor, InaD acts as a multisignaling scaffold that can interact with downstream effectors such as PLC, PKC, and ion channels. Since many more GPCR/PDZ interactions are being reported, this has led to the suggestion that signaling via these proteins may be a common feature among GPCRs. Other non-G-proteins involved in GPCR signaling bind to proline-rich domains in the receptor, e.g., the interaction between Homer 1 and metabotropic glutamate receptor, which facilitates the interaction with IP_3 receptors, which in turn regulate intracellular calcium release. In addition, dopamine D4 receptors interact via their SH3 domain with the adapter proteins Grb2 and Nck, providing a mechanism for GPCR activation of tyrosine kinase signaling cascades.

Transactivation of growth factor receptors by GPCRs represents another non-G-protein-mediated mechanism for GPCR activation of the signaling pathways (MAPK pathways) for receptor tyrosine kinase. GPCRs are known to transactivate the growth factor receptors, such as epidermal growth factor receptor, by a currently unknown mechanism. Recent studies have shown that the β_2-adrenergic receptor and insulin-like growth factor receptor exist as complexes, suggesting that these two receptors may physically interact or dimerize to achieve this transactivation.

There are several examples of adapter/scaffolding proteins that link GPCRs to effectors within the classical G-protein-linked pathways. For instance, the A-kinase anchoring proteins link GPCRs with $G_{\alpha 12}$ and PKA. In some cases, the mechanism of linking proteins together in this manner may facilitate the rapid signaling necessary for certain functions such as fly vision.

Another receptor–protein interaction that has been shown to occur is one between spinophilin and the third intracellular loop of the dopamine D2 receptor. Spinophilin, also known as neurabin-2, contains several protein-binding domains including a PDZ domain and an F-actin-binding domain. It is also known to bind the third intracellular loop of the α2-adrenoceptor, suggesting that this protein might serve to localize or coordinate signaling for a range of GPCRs, although the precise functional role of this interaction is not fully understood.

Certain GPCRs such as the calcitonin receptor-like receptor (CRLR) have been shown to form associations with receptor activity-modifying proteins (RAMPs). This association was shown to be important both for targeting the receptor to the cell surface and for altering its pharmacological properties. RAMP1 converted CRLR into a receptor with properties resembling calcitonin-gene-related-peptide receptor, and RAMP2-associated receptors displayed properties similar to that of an adrenomedullin receptor. It is not yet clear whether RAMPs form associations with other GPCRs and if they do, what roles they may play in GPCR function.

VII. GPCR OLIGOMERIZATION

The recent literature suggests that GPCRs might exist as oligomers, undergoing homo- and/or hetero-oligomerization. For Class A receptors, hydrophobic interactions between transmembrane domains are thought to be important in receptor–protein interactions. In addition, there is evidence that extracellular cysteine residues might be involved in covalently cross-linking receptors, and another possibility is that the intracellular carboxy tails might provide a mechanism for holding the receptor dimers together.

A. Approaches for Demonstrating Receptor Oligomerization

Early biochemical evidence was mainly provided by co-immunoprecipitation studies that demonstrated both homo- and hetero-oligomerization of GPCRs. However, more definitive evidence of oligomers forming a functional unit resulted from studies using 'split receptors.' Upon co-expression of each 'half' of the receptor, full receptor function could be restored even when the halves of two different receptors were co-expressed as chimeras, suggesting the existence of heterodimers. Similarly, transcomplementation experiments also provide evidence for the existence of a functionally active receptor complex. Here, individual receptors are inactivated by mutations in distinct receptor domains and have restored function upon co-expression of each mutant receptor. Resonance energy transfer techniques such as fluorescence resonance energy transfer and bioluminescence resonance energy transfer have been useful for detecting oligomerization in live cells for a number of GPCRs, such as the β2-adrenergic receptor, thyrotropin-releasing hormone receptor, gonadotropin-releasing hormone receptor, and somatostatin and opioid receptor subtypes.

B. Functional Significance of GPCR Oligomerization

In some cases, the occurrence of homo- versus hetero-oligomerization has been proposed to play an important role in determining the functional characteristics of receptors, thus generating the possibility of pharmacological diversity. The importance of hetero-oligomer formation between GPCRs is highlighted by an example provided by the $GABA_B$-R1 receptor, which forms a heterodimer with the $GABA_B$-R2 receptor. The R1 receptor is incapable of forming a functional receptor by itself as it becomes trapped in the *trans*-Golgi network and is unable to traffic to the cell surface. Only when it forms a hetero-oligomer with the $GABA_B$-R2 receptor can it be delivered to the cell surface. Interestingly, the $GABA_B$-R2 receptor expressed as a homo-oligomer can form a functional receptor; however, there have been reports that the homo-oligomer receptor displays different signaling properties than the hetero-oligomer.

Localization of GPCRs to their site of action within a cell is critical for the correct functioning of these receptors. This involves both the targeting of the receptor to its proper location in the membrane and the retention of the receptor after it reaches its destination. Receptor oligomerization may occur either at biosynthesis or after the receptors have reached the cell surface, the latter opening the possibility for ligand-induced effects. The majority of GPCRs studied thus far appear to undergo oligomerization constitutively, although for some receptors, the ligand may also have a role in regulating oligomerization.

The fact that this process has been reported for such a variety of receptors across different subclasses suggests that dimer and/or oligomer formation is a universal process among this superfamily of receptors. If so, the current level of understanding is just at the initial stage of deciphering how and why this occurs for different receptor systems.

VIII. GPCR MUTATIONS AND DRUG TARGETS

Many agonists and antagonists of GPCRs are used for therapeutic purposes, as GPCRs are the target for more than half of all known medicines. For instance, the dopamine agonist L-DOPA is the agent of choice in the treatment of Parkinson's disease, and a dopamine antagonist is used to treat schizophrenia as well as Huntington's disease in its early stages. Agonists and antagonists of adrenoceptors are used for the treatment of hypertension and other cardiovascular disorders as well as anxiety and asthma. Muscarinic agonists are used in the treatment of glaucoma and tachycardia, serotonin antagonists are effective tools to treat migraine, and histamine H1 antagonists are used against allergic and anaphylactic reactions, hay fever, itching, and motion sickness.

Mutations in GPCRs can result in altered function and have been associated with a number of hereditary or somatic disorders ranging from infertility to cancer. Examples of these disease-causing mutations include retinitis pigmentosa, nephrogenic diabetes

insipidus, and asthma. Defects of some GPCRs result in a gain-of-function phenotype, the consequences of which is constitutive bioactivity. This is in contrast to loss-of-function phenotypes that result in deficient bioactivity. Table 5 gives a brief summary of some receptors and their associated disease states, effects, and treatments.

The process of heterodimerization occurring between GPCRs has also been implicated in certain disease states and an example is a recent observation that heterodimers formed between the AT_1 receptor for the vasopressor angiotensin II and the B_2 receptor for the vasodepressor bradykinin are involved in preeclampsia. As hetero-oligomer formation can result in altered pharmacology, it provides a novel target for drug discovery. Therefore, by using combined treatments that selectively target the hetero-oligomer, it could be envisaged that some of the unwanted side effects encountered with some GPCR agonists could be overcome.

TABLE 5 Disorders and Treatments Related to GPCR Dysfunction

Receptors	Related diseases, effects, and treatments
Adrenoreceptors	Asthma, hypertension, anxiety
Angiotensin II/bradykinin B2	Preeclampsia
Bradykinin	Inflammation, pain, shock
Calcitonin	Paget's bone disease
CCK	Anxiety
Dopamine	Parkinson's disease, schizophrenia, Huntington's disease
FSH	Infertility
$GABA_B$	Analgesics
GnRH	Prostate cancer, precocious puberty
Histamine 1	Hay fever, itching, motion sickness
Metabotropic	Tinitus
Muscarinic	Glaucoma, tachycardia
Opioid	Pain
Opsins	Color blindness
Oxytocin	Induces labor and promotes lactation
PAF	Inflammation, asthma
PTH	Chondrodysplasia
Rhodopsin	Retinitis pigmentosa
Serotonin	Depression, migraine, postoperative vomiting
Somastostatin	Tumors, glucagonoma
TSH	Hyperthyroid
Vasopressin	Nephrogenic diabetes insipidus

Note. CCK, cholecystokinin; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; PAF, platelet activating factor; PTH, parathyroid hormone; TSH, thyroid-stimulating hormone.

IX. SUMMARY

GPCRs are elegantly engineered switches designed to turn on (and off) an enormous range of physiological responses. These include sensory perception (pain, taste, smell, and light), hormonal control of most physiological functions, synaptic neurotransmission, regulation of chemotaxis, stimulation of mitosis, and entry of viruses into cells. In addition to responding to such a range of natural ligands and stimuli, GPCRs form the targets for more than half of all prescription drugs currently on the market. However, despite their pivotal role in all these functions, how the heptahelical receptors actually operate as ligand-activated control systems is still not fully understood. Although the structure of rhodopsin has been solved, inherent difficulties have been experienced in obtaining the crystal structure of any other GPCR, GPCR–ligand, or GPCR–G-protein complex. GPCRs have been found to form either homo-oligomers or hetero-oligomers with a structurally different GPCR. Additionally, GPCRs are able to interact with a range of "partner proteins" such as β-arrestins and RAMPs. This ability to form interactions with adapter proteins and scaffolding proteins has resulted in a paradigm shift away from the more classical linear signaling pathways, instead focusing on more complex signaling networks in which common components orchestrate the responses of multiple interlinking pathways. The identification of the natural ligands for the many orphan GPCRs is still awaited and it is anticipated that this information will greatly aid in the intervention and treatment of a variety of diseases that involve the GPCR family.

Glossary

arrestins Proteins that arrest receptor function by uncoupling the receptor from its cognate G-proteins to target the receptor to the intracellular compartment of the cell by means of endocytosis. The arrestin family consists of visual arrestins (rod and cone arrestins), which have limited tissue distribution, and β-arrestin 1 and β-arrestin 2, which have a more widespread distribution.

desensitization Loss of functional response; can be short-term (seconds or minutes) or long-term (hours).

down-regulation Loss of total receptor number (not just on the cell surface) due to agonist-induced endocytosis and subsequent degradation.

endocytosis Movement of receptor–ligand from the plasma membrane to an internal compartment.

G-protein-coupled receptors A pharmacologically important protein superfamily with more than 400 genes identified to date. Pathways involving these receptors

are the targets of hundreds of drugs, including antihistamines, neuroleptics, antidepressants, and antihypertensives.

G-proteins Guanine nucleotide-binding proteins are heterotrimeric and composed of α-, β-, and γ-subunits. A number of these subunits have been identified (to date, 20 α-, 5 β-, and 12 γ-subunits) and make up at least four general classes of G-proteins: G_s, G_i, $G_{q/11}$, and G_{12}. G-proteins are responsible for transducing signals from G-protein-coupled receptors to effectors, including adenylyl cyclase and phospholipases.

heptahelical receptors (G-protein-coupled receptors) Relates to the characteristic structure in which stretches of hydrophobic amino acids span the cell's membrane seven times.

internalization Also termed sequestration; the loss of surface receptor number determined by a combination of the effects of endocytosis and recycling. A commonly used route for G-protein-coupled receptor internalization is via clathrin-coated pits.

receptor A protein molecule that binds very specifically to its cognate hormone to generate a receptor–hormone complex. This complex activates a cellular signal transduction pathway, resulting in the appearance of a biological response.

receptor–ligand binding The binding of a ligand to a receptor can be described mathematically by a dissociation constant (K_d), whose unit is concentration. This equilibrium constant provides information on the amount of ligand needed to elicit a biological effect. The lower the magnitude of K_d, the greater the affinity between ligand and receptor.

receptor recycling Movement of a receptor from an internal compartment to the cell surface.

RGS proteins (regulators of G-protein signaling proteins) Effectors that act as guanosine triphosphatase-activating proteins, enhancing the rate of GTP hydrolysis by G_α subunits.

Heterodimerization of Glucocorticoid and Mineralocorticoid Receptors

GERALD LITWACK

Thomas Jefferson University, Philadelphia

Glucocorticoid receptors (GRs) and mineralocorticoid receptors (MRs) are proteins with ligand-binding sites for glucocorticoids, such as cortisol, and for aldosterone, respectively. If both GRs and MRs are present in the same cell and the ligands for both receptors are also present, heterodimerization as well as homodimerization of the receptor molecules may take place. The relative amounts of the homodimers GR–GR and MR–MR and of the heterodimer GR–MR that are present will depend on the number of molecules of each receptor type as well as the amounts of the ligands in the cell. The heterodimer produces effects that differ from those produced by the homodimeric species.

I. INTRODUCTION

Glucocorticoids, such as cortisol, are generated in the adrenal cortex (most cortisol comes from the middle layer of cells called the zona fasciculata) in response to a stress signal. This stress signal emanates from the brain through the hippocampus, the anterior pituitary, and finally the adrenal cortex, with specific hormones being released from the hippocampus and pituitary, each signaling the next organ in the sequence and ultimately causing cortisol to be synthesized and secreted into the bloodstream. Elevated levels of cortisol in the bloodstream, in turn, feed back negatively on the brain, the hippocampus, and the anterior pituitary to shut off the original signals. This is accomplished by the binding of cortisol to intracellular (cytoplasmic) glucocorticoid receptors (GRs) whose actions lead to a reduction of the forward-feeding hormone that culminated in the release of cortisol. Thus, the system is poised to receive another set of signals when a new stress arises. However, stress resulting in the secretion of cortisol from the adrenal cortex is not the only mechanism whereby this hormone is released. The adrenal cortex is also under the control of cells in the brain that release serotonin, and the release of serotonin occurs by an endogenous mechanism that may be independent of the stress mechanism. However, once serotonin is released, the same mechanism that is seen during stress is activated except that the secretion of serotonin is elevated in the early morning, declines for the rest of the day, and rises again in the early morning of the next day; thus, this cycle can be viewed as a biorhythmic mechanism. Superimposed on the serotonin mechanism are stress events that can take place at any time during the day.

On the other hand, aldosterone, the ligand for the mineralocorticoid receptor (MR), is released from the outer layer of the adrenal cortex (zona glomerulosa) essentially only as the result of a stress stimulus. Although both of these receptors are located in the cellular cytoplasm before the ligand enters the cell, their actions take place in the cellular nucleus after the cognate ligand binds to its receptor. First, the receptor complex in the cytoplasm is "activated" or "transformed" and carried into the nucleus by a complex mechanism. Here, the receptor binds to a hormone-responsive element on the promoter of specific genes, causing RNA to be synthesized from the specific gene, and the RNA is transported into the cytoplasm where it is translated into proteins. These may be catalytic proteins (enzymes) that alter the cellular metabolism and account for the cellular response to the hormone. Overall, the summation of all the cellular responses (that may be different from different target cells) lead to the systemic (bodily) response. Glucocorticoids affect a large number of genes in different cells. This is exemplified by inhibition of inducible cyclooxygenase II, an inflammation-causing enzyme by virtue of its catalytic role in the synthesis of certain prostaglandins. Inhibition of the enzyme activity by reduction of its synthesis produces an anti-inflammatory response. Over a prolonged period of stress, the production of antibodies may be reduced, making it more difficult to fight off infections, and there may be a breakdown of proteins, causing muscle wasting after surgical stress, for example.

Mineralocorticoids, such as aldosterone, affect a smaller set of genes; they function primarily to increase the uptake of sodium ions in the kidney, distal colon, and elsewhere by stimulating the components of the sodium conductance channel in the apical cells lining lumens. Mineralocorticoids also increase the levels of sodium–potassium ATPase on the basolateral cell membrane (blood side), where both effects increase the uptake and transport of sodium ions across the cell and result in the accumulation of sodium ions in the bloodstream. If the uptake of sodium ions into the blood is sufficient, the effect on the posterior pituitary, which senses the increased sodium ion concentration, is such that water is reabsorbed by the kidney tubule, increasing the partial pressure in the blood vessels. Recently,

several genes have been discovered to be under the control of aldosterone, and the studies on such genes are ongoing.

In some cell types, for example, cells found in the kidney and the distal colon, both GRs and MRs are produced by the same cell. Also, both cortisol and aldosterone can be taken up by these cells. Cortisol will usually be available at least through the serotonergic mechanism in the absence of stress, and both aldosterone and more cortisol will be released during a stress response. Thus, in a stress situation, both ligands will be available to the target cells and presumably both receptors could be activated and generate transcriptional responses (new RNA molecules) in the nucleus. When solely cortisol is taken up by the cell, its effects would be manifested. The liganded cortisol (glucocorticoid) receptor will homodimerize (two receptor molecules bound to cortisol form a complex by binding head to head) and in that form can bind to the hormone-response element on DNA and generate effects associated with glucocorticoid actions, some of which are mentioned above. If the concentration of cortisol is high enough, both GRs and MRs could be activated to generate homodimers and heterodimers, although little is known about the *in vivo* situation. However, after a stress event, aldosterone will also become available and will bind preferentially to the MR in that same cell, and the two liganded receptors can interact by a process called heterodimerization. In this case, the actions of both receptors are expected to be different at the level of DNA so that the individual responses to cortisol and to aldosterone are different when heterodimers are formed compared to only homodimers.

II. GLUCOCORTICOID AND MINERALOCORTICOID RECEPTORS

Glucocorticoid and mineralocorticoid receptors are unique among members of the steroid receptor gene family because they are located exclusively in the cytoplasm of the target cell in the absence of the hormonal ligand (cortisol for the GR and aldosterone for the MR), whereas the other well-known receptors in this family are located exclusively in the nucleus or partitioned between the nucleus and the cytoplasm. Each receptor structure can be divided into domains, from the N-terminus to the C-terminus: the N-terminal domain, the DNA-binding domain, containing a "hinge" domain, and the steroid-binding domain at the C-terminal end. There are great similarities in the DNA-binding and steroid-binding domains, such that both receptors can bind to the same DNA sequence (hormone-responsive element) and the steroid-binding domains can bind many of the same compounds. Importantly, both receptors bind cortisol with approximately equal affinity so that expression of the receptor type in a given cell and the availability of cortisol and/or aldosterone to the cell become important to the biological effects. The N-terminus of each receptor is quite different, however, so that in this region there is only approximately 15% similarity between the two receptors. It may be that differences in receptor functions are reflected in the different sequences in the N-termini. Additionally, there are two classes of nuclear receptors: those that are associated with heat-shock proteins (Class I) and those that are not (Class II). Both the GR and the MR are Class I molecules, as are the progesterone receptor, the androgen receptor, and the estrogen receptor. On the other hand, Class II includes those receptors in this supergene family that appear to be completely compartmentalized in the nucleus in the absence of ligand; these receptors include the thyroid hormone receptor, the retinoic acid receptor, the vitamin D receptor, and peroxisome proliferator-activated receptor. Thus, the association of the GR and MR in the cytoplasm with heat-shock proteins and other proteins constitutes a "repressed" state until the specific steroidal ligand becomes available to the cell, after which cytoplasmic activation (or transformation) occurs to develop the active form, which probably dimerizes in the cytoplasm and which is able to translocate to the nucleus. Once in the nucleus, either receptor will bind to DNA (in dimerized form) and will associate with co-activator molecules and the specific gene promoter to trigger the transcriptional process. Pure nuclear forms of receptors in this gene family (Class II receptors) will be expected to reside in the nucleus in the absence of ligand and associate with co-repressors, and in the presence of ligand they would dissociate from the co-repressor proteins and associate with co-activators to enable the transcriptional process. GR and MR would not be expected to associate with co-repressors in the nucleus since their association with heat-shock proteins in the cytoplasm would constitute the repressed state.

III. HETERODIMERIZATION AND EFFECTS

Either GR or MR can be associated with specific gene promoters in the homodimerized state. Thus,

two molecules of the GR would be associated in head-to-head fashion, allowing the DNA-binding domains of each to participate in binding the major groove in DNA. The DNA-binding domain consists of two zinc-fingers in each molecule; the upstream (toward the N-terminus) zinc-finger of each binds in the major groove of DNA at the hormone-responsive element, which is the same sequence for both glucocorticoid and mineralocorticoid receptors (AGAACAnnnTGTTCT). The second, more downstream zinc-fingers of each receptor, in addition to recognizing the spatial distance between the half-sites, interact, stabilizing the dimeric complex. In the case where both the GR and the MR are present in the same cell and ligands for both receptors are present, heterodimerization may take place between each type of receptor in addition to homodimerization. The relative amounts of GR–GR, MR–MR, and GR–MR (the heterodimer) should be a consequence of the number of molecules of each receptor type as well as the amounts and types of the ligands. Interestingly, the presence of the heterodimer produces effects that are different from those produced by the homodimeric species. Thus, in hemopoietic cell systems, there may be down-regulation of the effects of either the GR or the MR. In other systems, the heterodimer results in greater activity than the homodimer or generates different outcomes altogether.

In this new area of research, there are a few specific examples to explain the effects of GR–MR heterodimers compared to GR–GR or MR–MR homodimers. It is of significance to clinical therapeutics when a receptor heterodimer targets genes differently than the homodimer. Thus, it has been shown recently in rats that a single dose of dexamethasone (specific for the GR) will generate apoptotic loss of cells that contain both GR and MR in the dentate gyrus of the hippocampus. High doses of corticosterone (equivalent to cortisol in the human), which will bind to both GR and MR, did not lead to apoptotic cell death. Furthermore, in rats pretreated with corticosterone before dexamethasone was administered, there was no cell death, suggesting that corticosterone, which activated both the GR and the MR to form heterodimers, regulates genes mediating cell survival differently from the effect of dexamethasone, which activates the GR–GR alone. Thus, clinicians may want to consider using a glucocorticoid such as prednisolone for an anti-inflammatory effect that activates GR–MR rather than a drug such as dexamethasone that activates GR–GR alone.

Another observation concerns repression of the 5-HT1A receptor promoter. This is a neuronal serotonin receptor whose repression by glucocorticoids may lead to clinical depression. Using different cells in culture, it was determined that transcriptional inhibition of the 5-HT1A receptor was greater in the presence of GR–MR heterodimers than with either GR–GR or MR–MR alone. This work suggested that GR and MR form a novel head-to-tail heterodimeric complex with a negative GRE (glucocorticoid-response element). The negative GRE contains two half-sites separated by 6 bases compared to the normal palindrome in which the two half-sites are separated by 3 bases. Apparently, the head-to-tail MR–GR accommodates binding to the negative GRE with the 6-base spacing. In the negative GRE, elimination of 3 bp between the two half-sites reverts the GRE to a positive element.

Finally, interesting studies have been carried out on the formation of GR–MR heterodimers in solution in the absence of DNA. In the formation of the GR–GR homodimer, the hinge region is sufficient to promote this dimerization in solution; peptides that mimic this region have been synthesized, and these peptides can associate with the GR to form a dimer. In the case of formation of the MR–GR heterodimer in solution, some grouping in the MR structure binds to the ligand-binding domain (in the C-terminal region) of the GR. It appears likely that the dimerization process occurs in the cytoplasm and that the dimer is transported into the nucleus in this or in a more complex form. There may be factors involved in the formation of GR–MR heterodimers in cells that are, as yet, unidentified. Figure 1 presents a concept of the dimerization of GR–GR, MR–MR, and GR–MR and how these receptor forms could interact with gene targets in the cell.

Glossary

glucocorticoid receptor A protein with a ligand-binding site for glucocorticoids, the major one of which in the human is cortisol. In the human, this receptor is located in all tissues except hepatobiliary cells and pars intermedia-like cells in the pituitary.

mineralocorticoid receptor A protein with a ligand-binding site for specific ligands, in this case, those related to aldosterone, which is the primary ligand in the human. The receptor is not ubiquitously distributed throughout the body, like the glucocorticoid receptor, but is found mainly in epithelial cells that line lumens (tubes).

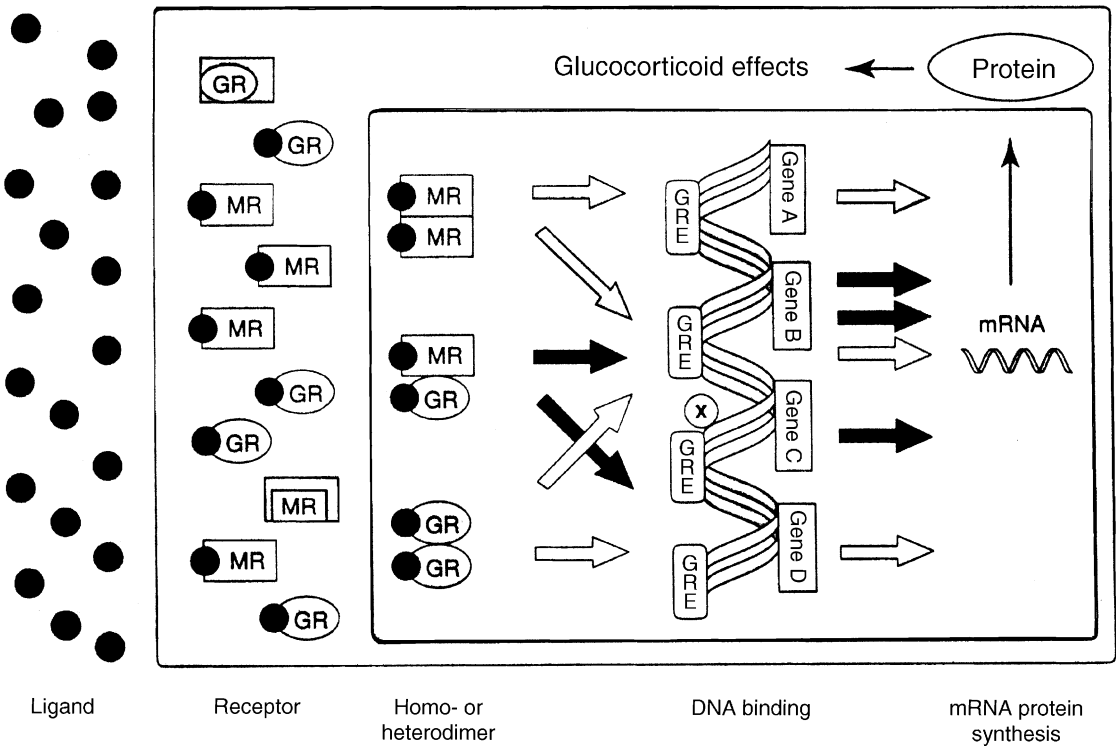

FIGURE 1 Model of corticosteroid-activated gene expression. Steroids enter the target cell by passive diffusion, where they bind to the cognate receptor (MR). This binding leads to a conformational change in the receptor and its dissociation from the inhibitory hetero-oligomeric structure. After intranuclear translocation, the MR and GR homodimers or the corticosteroid heterodimer is formed, depending on the relative concentrations of both receptors. The different corticosteroid receptor dimers bind to GREs in the flanking regions of target genes with particular DNA-binding kinetics. The binding of the dimer to the GRE leads to mRNA production and protein synthesis. The unique transcriptional activities and DNA-binding kinetics of the corticosteroid receptor are indicated by black and white arrows. The use of different genes in this illustration indicates that different corticosteroid dimers may regulate an overlapping set of genes and activate the expression of dimer-specific candidate genes. The regulation of certain genes by a specific corticosteroid receptor dimer may predominantly depend on dimer-specific protein–protein interactions with other transcription factors that are repressed in this model by a DNA-binding factor X. FIGURE 1 Hormone receptor complexes act as guanine nucleotide exchange factors (GEFs) to catalyze the activation of the trimeric G-protein with formation of α–GTP plus βγ, both of which modulate effector functions. Spontaneous decay of α–GTP to α–GDP can be modulated by GTPase-activating proteins (GAPs), such as RGSs and some effectors, and by activators of G-protein signaling (AGSs) that tilt the balance between effects resulting from α–GTP and those resulting from βγ.

GTP to GDP—and reassociation of the separated members in preparation for reactivation by a new round of GDP/GTP exchange promoted by the activating hormone receptor (HR) complex (bottom panel of Fig. 1). As shown in Fig. 1, the basic cycle is affected by regulators of G-protein signaling, the RGSs, which increase the rate at which α–GTP deactivates, and the AGS2- and AGS3-type modulators, which sequester either α–GDP or $G_{\beta\gamma}$ and thereby bias signaling through α–GTP versus signaling through $G_{\beta\gamma}$ (see below).

II. *Ras*, THE PROTOTYPIC REGULATORY GTPase

As the name indicates, regulatory GTPases are proteins that bind and hydrolyze GTP. Their regulatory power lies in the fact that their conformation differs when occupied by GTP or GDP. They are also referred to as molecular switches. Due to their intrinsic GTPase activity, they carry a built-in inactivating timer that prevents the GTP state from being long-lived. The crystal structure of the 180 aa regulatory GTPase *ras*, in its GTP- and GDP-liganded forms, shows two principal regions that differ in the GTP state compared to the GDP state, referred to as Switch I and Switch II. Switch I, amino acids 32 through 40, is a large loop connecting α-helix 1 (α1) to β-strand 2 (β2). Mutations in this region interfere with activation of several of the downstream effectors of *ras*. Switch II, amino acids 60 through 75, changes conformation even more drastically than Switch I, to the extent that upon binding of GTP, aa 66 through 74 rearrange into a well-ordered α-helix (α2). Switches I and II are required for activation of a downstream effector(s) by *ras*-GTP, the activated form of *ras*. *Ras*-GDP appears to be neutral. Mutations of Gln-61 (at the start of Switch II after β3) and of Gly-12 (at the base of α1) reduce the intrinsic GTPase activity of *ras*, prolonging the lifespan of the activated GTP state. As is the case for most, if not all, regulatory GTPases, the *ras* GTPase is under the regulation of two types of proteins, a guanine nucleotide exchange factor (GEF), responsible for promoting the transition of *ras*-GDP to *Ras*-GTP, and several GTPase-activating proteins (GAPs), which, as their name indicates, shorten the lifespan of *ras*-GTP by increasing the catalytic efficacy of its intrinsic GTPase. Sos (*son of sevenless*) and *ras*-GAP1 are the prototypes of *ras*-GEF and *ras*-GAP, respectively. Mutation of Ser-17 to Asn-17, roughly in the middle of α2, interferes with the nucleotide exchange reaction and locks *ras*-GDP in an inactive conformation in which it may still bind to proteins regulated by *ras*-GTP but without affecting their activity. By reason of occupying the site to which *ras*-GTP should bind to activate effectors, Asn-17 *ras* interferes with signaling by wild-type *ras*-GTP and is

referred to as a dominant negative form of *ras*. Figure 2 depicts *ras* in its GTP and GDP conformations and highlights the locations of Gly-12 (G12), Ser-17 (S17), Gln-61 (Q61), Switch I, and Switch II. The upper left panel of Fig. 2 presents this basic GTPase cycle in schematic form with GEF and GAP regulating the lifetimes of the GTP and GDP states. The upper right panel of Fig. 2 is a schematic two-dimensional representation of the main three-dimensional features of this regulatory GTPase.

III. HETEROTRIMERIC G-PROTEINS

Trimeric G-proteins are responsible for transducing the effects of the seven-transmembrane superfamiliy of receptors and are regulatory GTPases, which, though more complex than *ras*, nevertheless preserve the basic features of the *ras*-type regulatory GTPases. G-proteins activated by seven-transmembrane receptors are αβγ trimers, of which the α-subunit is the GTPase-bearing subunit. The β- and γ-subunits form a dimer that exists either free or in association with α–GDP. G_β and G_γ have never been found isolated as individual proteins.

A. Subunit Structure

α-Subunits were crystallized in the laboratories of Paul Siegler at Yale University and of Steven Sprang at the University of Texas at Dallas, in collaboration with Heidi Hamm then at the University of Illinois (Chicago) and Alfred Gilman at the University of Texas at Dallas. From a structural viewpoint, α-subunits of heterotrimeric G-proteins are made up of a *ras*-like GTPase domain and a helical domain with six α-helices (αA through αF) inserted in the center of what would be *ras*'s Switch I (Figs. 3 and 4). In its GDP-liganded form, G_αs have a disorganized Switch II region and exhibit high affinity for $G_{\beta\gamma}$. G_α–GDPs are therefore found associated with $G_{\beta\gamma}$s as heterotrimers. $G_{\beta\gamma}$ locks GDP into its binding

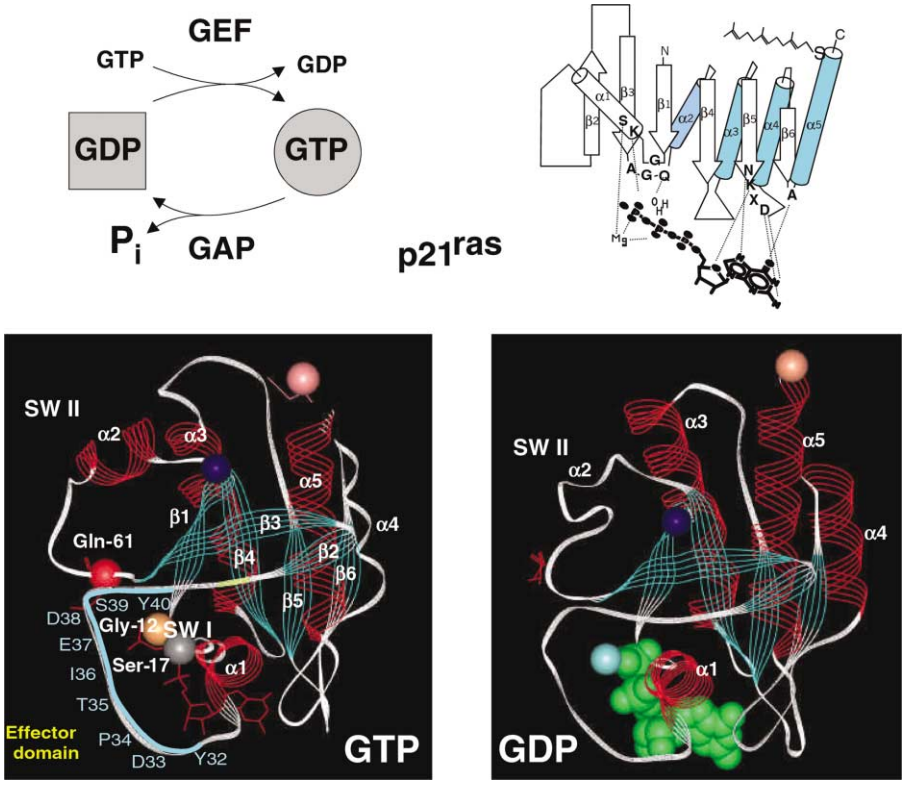

FIGURE 2 Model of the crystal structure of *ras* in its GTP and GDP states (PDB Accession Nos. 521P and 1Q21), highlighting secondary structures (α-helices and β-strands) as well as Switch 1 (effector domain) and Switch 2 regions. Top left illustrates the basic GTPase regulatory cycle and its two principal modulators: GEFs, responsible for activation, and GAPs, responsible for deactivation of the regulatory GTPases. The top right diagram is a two-dimensional representation of the three-dimensional features of the basic GTPase fold found in all regulatory GTPases.

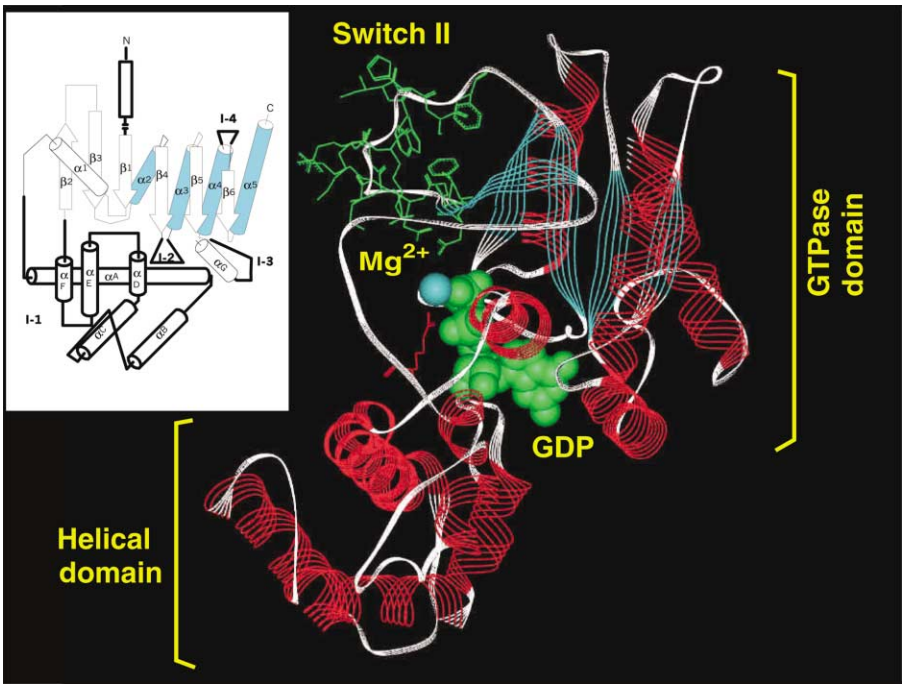

FIGURE 3 Crystal structure of an α-subunit of a heterotrimeric G-protein in its GDP state (PDB Accession No. 1TAG). Its GTPase domain is oriented in the same way as *ras* in Fig. 2. Atoms of amino acid side chains of Switch II are displayed as sticks; space-filling CPK atoms were used to represent GDP. Mg is represented by a ball. (Inset) Two-dimensional diagram of the three-dimensional features of heterotrimeric G-protein (α-subunit). Additions to the *ras* structure are shown as boldface lines. GTPase and helical domains are highlighted.

site on G_α, causing its dissociation rate to drop by a factor of 10. At the same time, $G_{\beta\gamma}$ also shields the Switch II region from interacting with possible effectors (Fig. 4). Consequently, activation of a heterotrimeric G-protein requires two events: (1) the exchange of GTP for GDP and (2) the dissociation of $G_{\beta\gamma}$ from G_α. Subunit dissociation has not been measured in intact cells in an unequivocal way but it is readily seen *in vitro*. Dissociation exposes the regulating surface of G_α–GTP and allows for effector regulation with direct involvement of Switch II. The converse also applies. That is, $G_{\beta\gamma}$ is a signaling molecule able to regulate effector functions and its association with G_α–GDP results in occlusion of its ($G_{\beta\gamma}$'s) signaling surface.

The structure of $G_{\beta\gamma}$ deserves separate comment (Figs. 4 and 5). G_β is a seven-bladed propeller, each blade of which is made up of four anti-parallel β-strands running from the center to the periphery. The innermost β-strand runs parallel to the axis of rotation of the propeller. The next two strands change pitch to approach the orientation of the outermost strand, which runs along the periphery of the propeller and is co-planar with the circle described by the rotating propeller. Blade VII is made up of three β-strands contributed by the very C-terminus of G_β and a fourth (outermost) "zipping" β-strand recruited from the sequence immediately preceding those that create blade I. Preceding the zipping β-strand is an extended N-terminus with a long α-helix that interacts with G_γ by forming a coiled coil. $G_{\beta\gamma}$ dimers have thus far been crystallized only in association with G_α subunits or with a retinal regulatory protein, phosducin, but not in isolation. Conformational changes in G_β that occur upon dissociating from G_α, if they occur, have not been observed as yet.

B. Lipid Modifications

G_α and $G_{\beta\gamma}$ subunits engaged in signal transduction are membrane bound by virtue of lipid modifications. $G_{\beta\gamma}$ dimers are anchored to membranes through a C-15 or C-20 polyisoprene attached to the Cys of a C-terminal CAAX motif. Posttranslational processing not only attaches the polyisoprene but also removes the last three amino acids and methylates the new C-terminus. Prenylation is not necessary for association of G_γ with G_β, but is required for association

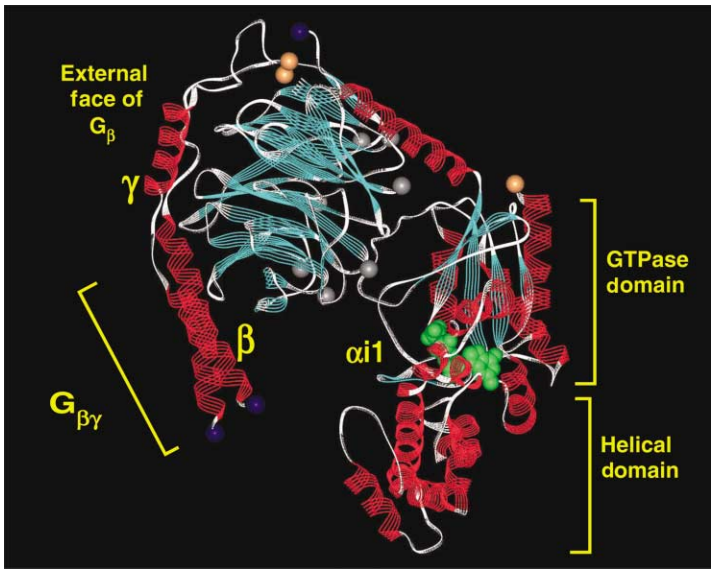

FIGURE 4 Model of G_{i1} heterotrimer with bound GDP deduced from crystal X-ray diffraction studies (PDB Accession No. 1GG2). Note that the internal face of G_β shields the G_α subunit's Switch II from being accessible to effectors. N-terminal α-carbons, C-terminal α-carbons, and α-carbons of conserved aspartic acids are shown.

of $G_{\beta\gamma}$ to G_α–GDP and for regulation of effector, e.g., adenylyl cyclase. Furthermore, prenylation contributes to the association of the G_γ dimer to membranes. Most G_α subunits engaged in signal transduction are palmitoylated near their N-terminus. Palmitoylation facilitates their anchoring to the plasma membrane. G_α subunits of the G_i/G_o family are also myristoylated at N-terminal glycines (Gly-2 of the primary transcript). G_α myristoylation increases affinity for $G_{\beta\gamma}$ dimers. Removal of myristic acid by Gly-2 to Ala-2 mutation renders $G_i\alpha$ subunits inactive as inhibitors of adenylyl cyclase. Some but not all nonpalmitoylated G_α subunits fail to localize to membranes and are found in the cytosol. Lipid modification of G_α and G_γ subunits is therefore essential for their normal biological activity.

C. Molecular Diversity of G-Proteins

Each of the subunits that make up a heterotrimeric G-protein is encoded by a family of structurally homologous genes. There are 16 G_α (one with two splice variants), 5 G_β, and 11 G_γ genes, leading to the theoretical possibility of close to 1000 distinct heterotrimers. G_α subunits are the longest of the three subunits, ranging from 350 to 390 amino acids. Their sequence similarities vary from almost identical when $G_{i1\alpha}$ is compared to $G_{i3\alpha}$ (86% identical) to only 40% identical when $G_{s\alpha}$ is compared to $G_{16\alpha}$. Amino acid sequence alignments show G_βs to be a structurally very closely related family, with β1–4 all being 350 aa long and differing by no more than 17% in their amino acid sequences. $G_{\beta5}$, with 395 aa, exhibits the same degree of similarity, differing primarily by a 45 aa N-terminal extension. G_γs are the shortest (68–75 aa) and are the most diverse, differing in amino acid sequence between 40 and 65%. GGL (G_γ-like) domains of RGS 6, 7, 9, and 11 (for RGS proteins, see below) constitute an additional group of G_γ subunits that interact with $G_{\beta5}$'s atypical N-terminal extension.

The actual number of G-protein isoforms in any given cell is much lower than 1000, for two reasons: (1) there is no cell known to express all G-protein subunit genes and (2) there are structural limitations that do not allow all βγ dimers to form; e.g., whereas β1 interacts with γ1, γ2 and γ3, β3 does not interact with γ1 or γ2 but instead partners with γ4. Vice versa, γ1 partners with β1 but not with either β2 or β3, and γ2 partners with β1 and β2 but fails to do so with β3. The complete spectrum of permissible interactions among the 5 β- and 11 γ-subunits still needs to be worked out. One G_β, $G_{\beta5}$, interacts preferentially with the GGL domain of γ-subunits 6, 7, 9, and 11. It is quite possible that even for biochemically permissible interactions, there may be βγ dimers that never form because they are not co-expressed in the same cell.

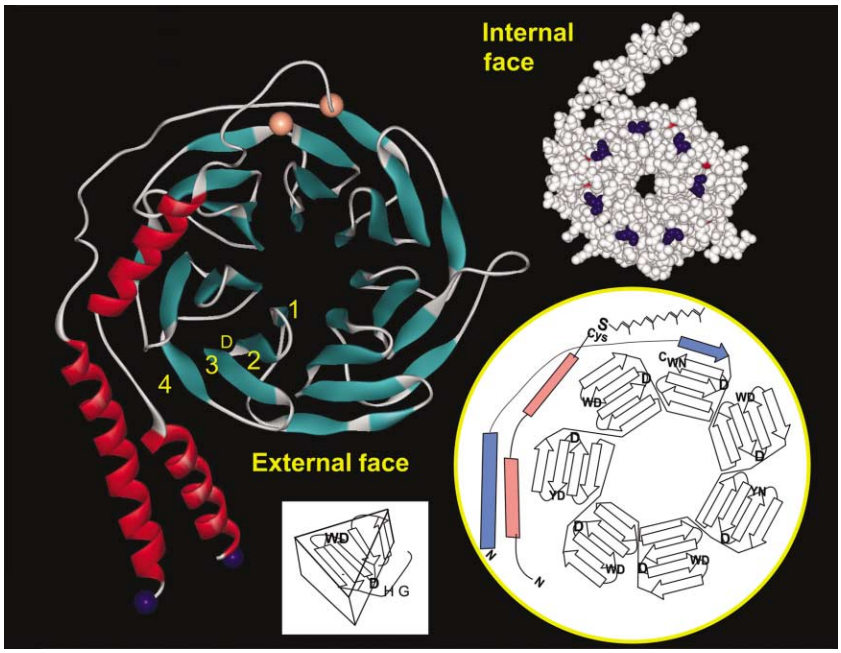

FIGURE 5 View of a seven-bladed G_β propeller from the "external" side determined by its orientation when complexed with α–GDP. (Top right) CPK representation of the same propeller viewed from the side facing α–GDP in its trimeric form. Conserved aspartic acids (D) are present in each propeller blade. (Bottom right) Two-dimensional diagram of the three-dimensional features of a G_β propeller highlighting the "zipping," outermost β-strand of blade VI and location of conserved D residues shown in the space-filling representation of the model. Note the γ coiled-coil interaction of the γ-subunit with the N-terminus of the G_β subunit.

G-proteins are named after their α-subunit. This nomenclature originated from the fact that for first two G-proteins discovered, G_s and transducin (G_t), the major (then sole) signaling function resided in their α-subunits. $G_{\alpha s}$ subunits activate adenylyl cyclases (ACs), and $G_{\alpha t}$ subunits activate visual phosphodiesterase (PDE, a tetramer of one α, one β, and two inhibitory γ subunits). Activation of visual PDE results from the association of αt–GTPs with the PDEγs, thereby suppressing their inhibitory effects on PDEαβ. A phylogenetic tree of G-protein α-subunits (Fig. 6) clusters their sequences into four subfamilies: G_s, G_q, $G_{12/13}$, and the pertussis toxin (PTX)-sensitive G_α subunit subfamily. The latter includes three α-subunits that play roles in light and taste perception, plus the α-subunits of the G_i/G_o family. PTX-sensitive α-subunits not only show higher sequence similarity to one another than to the remaining α-subunits, but as their name indicates, they are substrates for the ADP-ribosyltransferase activity of the S1 subunit of pertussis toxin. The ADP-ribosylated amino acid is a Cys at position −4 from their C-termini. PTX uncouples this group of G-proteins from activation by receptors by virtue of creating of a steric hindrance to the G-protein–receptor interaction. Included in this structural group is the α-subunit of G_z (αz), which lacks a Cys at −4 from the C-terminus and is PTX-insensitive. It is functionally a G_i, its closest structural homologue.

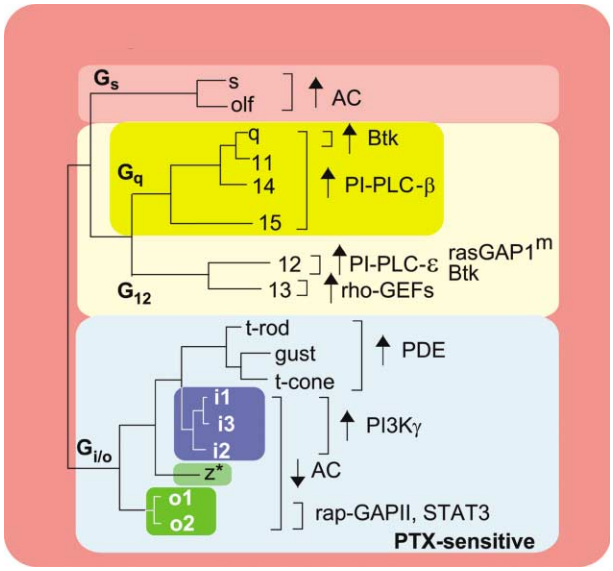

FIGURE 6 Phylogenetic analysis of G-protein α-subunits reveals structural subdivisions that have functional correlates.

As illustrated in Fig. 6 and in more detail in Fig. 7, α-subunits modulate the activity of a large and diverse group of enzymes, including ACs, phospholipase C-βs (PLC-βs), phosphatidylinositol 3-OH kinases (PI3Ks), type 6 visual and type 3 gustatory PDEs, and a Rho-GEF for regulation of cytoskeletal remodeling.

Both G_{α} subunits and $G_{\beta\gamma}$ dimers modulate, positively or negatively, an extraordinarily diverse set of cellular functions. In some instances, the effects of $G_{\beta\gamma}$ dimers are in concert with those of α-subunits; in other instances, regulation of the effector by $G_{\beta\gamma}$ is unrelated to regulation by a G_{α}. It is not clear at this time whether effectors distinguish between $G_{\beta\gamma}$ isoforms. As illustrated in Fig. 8, the gamut of $G_{\beta\gamma}$ effectors is as complex and as diverse as that of the α-subunits. Among the regulated functions worth mentioning are inhibition of type 1 AC, but co-stimulation with $G_{s\alpha}$ of type 2 and type 4 ACs; stimulation of type 3 PLC-β independent of co-existing stimulation by the $G_{q/11}$ group of α-subunits; co-stimulation with $G_{\alpha i2}$ (possibly also $G_{\alpha i1}$ and $G_{\alpha i3}$) of PI3Kγ; and co-stimulation of PI3Kβ with tyrosine-phosphorylated p85, the regulatory subunit of PI3K. *In vitro* reconstitution experiments in which PI3Kβ was incubated with $G_{\beta\gamma}$ and a tyrosine-phosphorylated peptide corresponding to the tyrosine-phosphorylated sequence of p85 showed that stimulation by each was 3- to 5-fold but became 100-fold when the tyrosine-phosphorylated peptide and the $G_{\beta\gamma}$ were added together. This type of cross-dependence on dual inputs is highlighted in Figs. 7 and 8. $G_{\beta\gamma}$ also modulates, sometimes positively and other times negatively, a variety of ion channels and thereby provides a nexus between regulation of second-messenger formation by enzymes and regulation of cell excitability by voltage, which it can augment (activation of potassium channels) or dampen (inhibition of presynaptic Ca^{2+} channels) (Fig. 8).

In conclusion, signal transduction by G-proteins is the result of structurally similar receptors activating structurally very similar G-proteins, which then regulate positively or negatively the activity of a diverse gamut of structurally unrelated cellular functions that affect intracellular levels of cAMP, inositol 1,4,5-triphosphate, Ca^{2+}, diacylglycerol (DAG), and phosphatidylinositol 3 phosphates, as well as ion channel activity, formation of lamellipodia and filopodia, and the attendant cytoskeletal changes. Moreover, since second messengers such as cAMP,

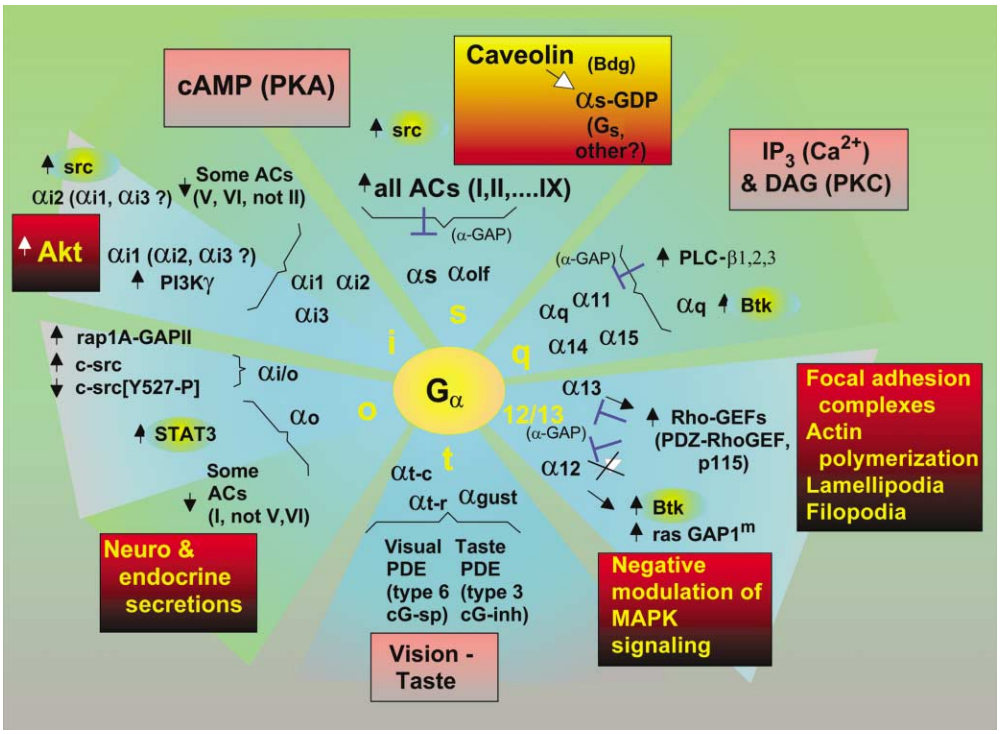

FIGURE 7 Effectors of activated α-subunits. The figure shows the different signaling systems affected by α-subunits at the periphery, with increasing detail toward the center. ⊣, inhibition.

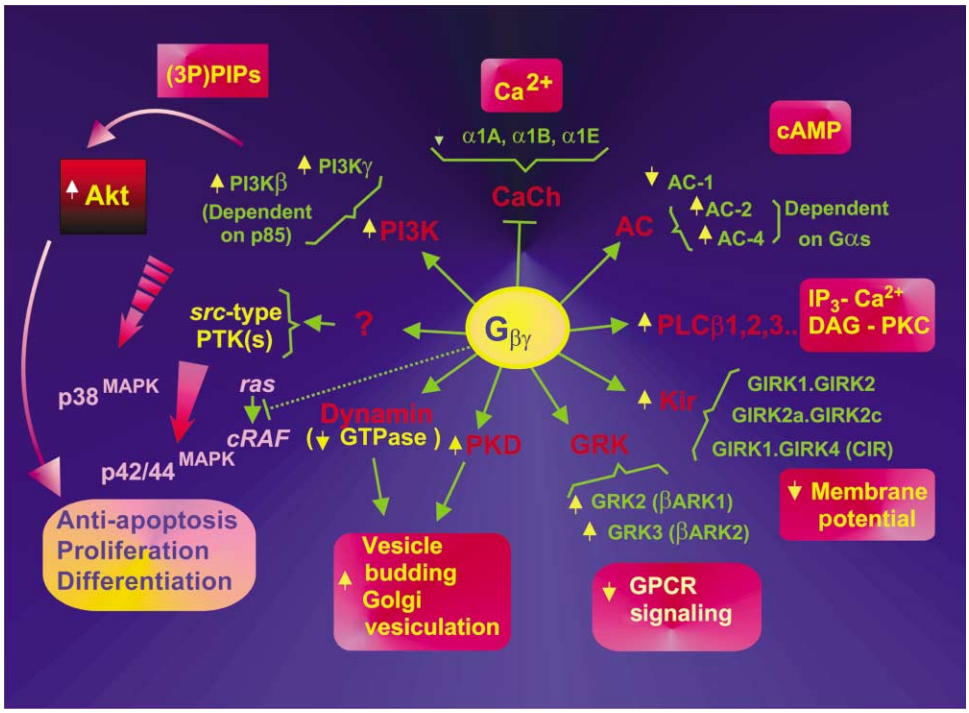

FIGURE 8 Effectors of βγ dimers. The different intracellular signaling systems affected by $G_{\beta\gamma}$ dimers at the periphery are shown, with increasing detail toward the center. →, stimulation; —|, inhibition; ····|, stimulation or inhibition.

DAG, and Ca^{2+} affect protein kinases, it is unlikely that there is a cellular function that in one way or another is not under the controlling or modulatory influence that emanates from activation of heterotrimeric G-proteins. Indeed, as indicated in Figs. 7 and 8, cellular responses included are the PI3K–PDK–Akt–nuclear factor κB anti-apoptotic response of cells to extracellular signals and the effects of $G_{\beta\gamma}$ on dynamin, Golgi vesiculation, and vesicle budding.

IV. MECHANISM OF G-PROTEIN ACTIVATION BY RECEPTORS AND MODULATION OF ACTIVITY

Receptors acting through heterotrimeric G-proteins are referred to as G-protein-coupled receptors (GPCRs). They play the role of GEFs in the regulatory GTPase cycle. Ligand binding to GPCRs, all of which belong to the rhodopsin superfamily of seven-transmembrane receptors, has as its final effect the GDP/GTP exchange with attendant subunit dissociation into G_{α}–GTP plus $G_{\beta\gamma}$ (Fig. 1). The final effect of a hormone acting through a GPCR on any given cell depends on the type of G-protein activated by the receptor and the repertoire of effectors, i.e., regulatable enzymes, ion channels, and other affected molecules in the target cell.

A. Mechanism of Activation of a G-Protein by a Receptor

At the molecular level, activation of a G-protein by a rhodopsin-like receptor is still poorly understood. This is because of lack of knowledge of which amino acids of the receptor make contact with which amino acids of the G-protein. In contrast, the regions of each molecule important for productive interaction are well known, as are some of the changes in the kinetic and molecular states that occur when a receptor under the influence of an activating ligand, i.e., agonist, interacts with and activates a G-protein. Thus, binding of an agonist to a GPCR in the absence of guanine nucleotide (GTP or GDP), as can be done *in vitro* with purified membranes, has two consequences: (1) a shift of the equilibrium between two states of the receptor, from being mostly in state I (inactive), characterized by having low affinity for agonist as well as for the G-protein(s), to being mostly in state II (active), characterized by having higher affinity for the activating ligand; and (2) the stable association of the agonist–receptor complex with

the G-protein. The latter causes the G-protein to reduce its affinity for GDP. Bound GDP, or prebound [^{3}H]GDP, will thus dissociate under these conditions. Mg^{2+} ion must be present if the receptor is to cause GDP dissociation. Addition at this point of GTP or a GTP analogue, such as GTPγS or GMP-P(NH)P, leads to its binding in place of GDP and to the activation of the G-protein as seen by stimulation of the activity of an effector, such as adenylyl cyclase or visual phosphodiesterase. For most of the cases in which this has been studied, a high concentration of Mg^{2+} ion, ca. 50 m*M*, mimics the action of the agonist-activated receptor. With a purified G-protein, incubation with Mg^{2+} ion and GTPγS or GMP-P(NH)P leads not only to accumulation of G_α-bound guanine nucleotide, but also to subunit dissociation, i.e., formation of G_α–GTPγS plus free $G_{\beta\gamma}$, Dissociation is evident in several ways, the easiest to determine being a shift in sedimentation velocity from that corresponding to a protein with a M_r of approximately 100,000 ($G_{\alpha\beta\gamma}$) to that of two co-sedimenting proteins of M_r ca. 50,000 (G_α–GTPγS + $G_{\beta\gamma}$). M_rs of α-subunits are in the range 40,000–50,000 and those of $G_{\beta\gamma}$ complexes are also approximately 50,000.

In intact membranes, where activation of a G-protein of the αβγ type by agonist occupancy of a receptor can be measured in terms of stimulation of the activity of an effector, e.g., adenylyl cyclase, phospholipase C, visual phosphodiesterase, or an inwardly rectifying potassium channel, the net effect of receptor activity is thus facilitation of the activation of the G-proteins by Mg^{2+} ion. This comes about as a consequence of a receptor-induced shift in the apparent K_m for Mg^{2+} ion from high millimolar to low micromolar concentrations. In other words, a receptor appears to act by reducing the concentration of Mg^{2+} required for activation of the G-protein by GTP from being above physiologic to being below physiologic concentrations. Free cytosolic Mg^{2+} is on the order of 0.5 m*M*. The effect of glucagon (receptor) shifting the concentration of Mg^{2+} ion required for activation of liver G_s (the stimulatory regulatory component of adenylyl cyclase) by GTPγS, is illustrated in Fig. 9.

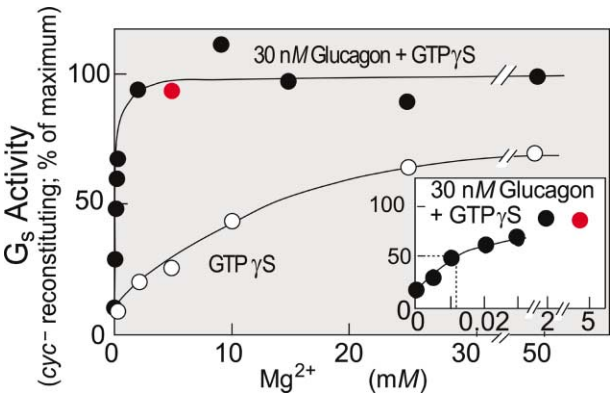

FIGURE 9 GPCRs reduce the concentration of Mg^{2+} ion required for G-protein activation by GTP. The results of a three-step reaction are shown. In the first step (not shown), the adenylyl cyclase enzyme of liver membranes was inactivated by treatment with *N*-ethyl maleimide, leaving an intact receptor–G-protein system in its natural membrane environment. The second step tested for the effect of varying Mg^{2+} ion on GDP/GTPγS exchange in the absence and in the presence of the hormone glucagon. In the third step, the $G_{s\alpha}$–GTPγS complexes formed were extracted and quantified in a standard reconstitution assay. The figure shows the effect of the glucagon-activated receptor on the Mg^{2+} required for G-protein activation. Note that (1) hormone was not necessary for G_s activation as long as a high enough (supraphysiologic) concentration of Mg^{2+} was present during incubation with GTPγS and (2) in the presence of the hormone, the Mg^{2+} concentration that was required to activate G_s was ca. 1000-fold lower than in its absence. (Inset) Same as main panel but with an expanded Mg^{2+} concentration scale. Adapted from Iyengar and Birnbaumer (1987).

B. Structural Determinants

At the molecular level, mutational analysis has shown that amino acids in the third intracellular loop of GPCRs are involved in the ability of a GPCR to activate a G-protein. Swapping intracellular loops between receptors that bind preferentially to different G-proteins, such as switching the loops of the M1 and M2 muscarinic receptors or switching those of the β- and α1-adrenergic receptors, also points to the third intracellular loop as being responsible for defining G-protein specificity. Furthermore, most of the receptor mutations that are of the gain-of-function type are in the distal (C-terminal) end of the third intracellular loop. It is not known, however, why some mutations are activating and others inactivating. Moreover, it is also not known whether these amino acids actually contact the G-protein and, if so, which G-protein subunit they contact.

Mutational analysis and sequence swapping experiments with G-protein α-subunits indicate that receptors interact with the very C-terminus of the G-protein α-subunit. Indeed, swapping as few as 3 of the last 10 amino acids between two α-subunits can lead to a switch in the type of receptor that activates the G-protein. The C-terminus is not the only region of interaction of an α-subunit with a receptor. Multiple

sites have been identified by mutational analysis, including the α3β5 and α4β6 loops of the GTPase domain (Figs. 2 and 10). The α-subunit C-terminus and the α3β5 and α4β6 loops are part of the same face of the molecule presumed to be immediately juxtamembranous. Receptors do not interact with only the α-subunit of a trimeric G-protein. Free G_α subunits are not recognized by receptors; they are recognized only in the context of the heterotrimer. In agreement with this conclusion, injection of subunit-specific antisense oligonucleotides or subunit-specific antibodies leads to the loss of receptor-mediated effector regulation, including not only the suppression of G_α but also G_β or G_γ subunits, all in a gene-specific manner. It has been shown that in pituitary cells the M4 muscarinic receptor activates a G_o protein of subunit composition αo1β3γ4, whereas the somatostatin receptor activates a G_o of subunit composition αo2β1γ3. It follows that receptors "proofread" the subunit subtypes that make up the particular trimer that they contact.

Figure 5 shows that only one of the two faces of the G_β propeller is exposed to the milieu; the other faces the α-subunit's Switch II region. The exposed face and the sides of the propeller are therefore available for interaction with the receptor. In turn, since the receptor interacts with G_β and G_γ, it can reasonably be expected that receptors may affect the $G_{\beta\gamma}$ interaction with G_α. One model based on these considerations, as well as on the results shown in Fig. 9, is that whereas the interaction of the receptor with the C-terminus of G_α is essential for selection of the type of $G_{\alpha\beta\gamma}$ that will be activated through the GDP/GTP exchange reaction, the "activating" effect of the receptor may in fact be mediated by $G_{\beta\gamma}$. In this sense, the $G_{\beta\gamma}$ dimers would have a receptor-dependent GEF activity. Thus, although $G_{\beta\gamma}$ alone prevents GDP dissociation by acting as a

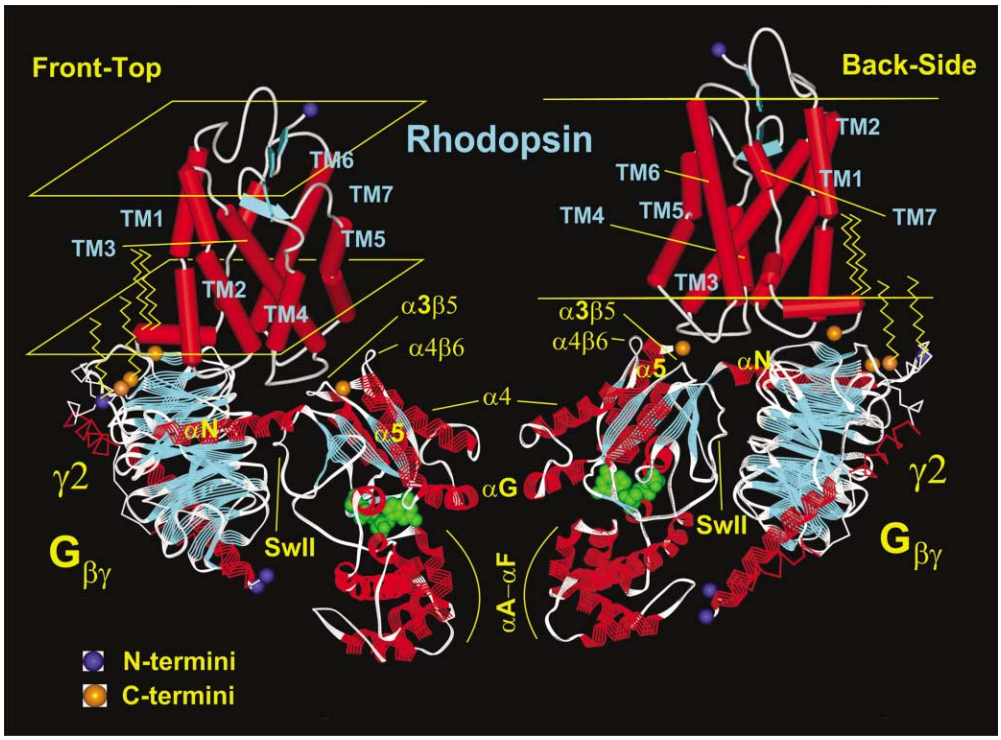

FIGURE 10 Model of orientation of a G_α subunit with respect to both the inner plane of the plasma membrane and a membrane-embedded GPCR. Based on the crystal structures of bovine rhodopsin (PDB Accession No. 1F88) and the GDP-occupied G_{i1} trimer (PDB Accession No. 1GG2). The molecules are shown in a near-docking situation with the receptor in its "inactive" conformation and the G-protein with GDP bound to it. Two views are shown and the main structural features are annotated. Vertical zigzag lines denote the α-subunit N-terminal myristoylation and/or palmitoylation and the γ-subunit C-terminal polyisoprenylation. Positions of lipids are approximate because the modified N- and C-terminal amino acids were not resolved in the crystal structure of G_{i1}. Double zigzag approximately 13 amino acids after the TM7 of rhodopsin denotes double palmitoylation of the C-terminus at that position. Single or double palmitoylation of GPCR C-termini is a common but not universal feature of GPCRs.

guanine nucleotide dissociation inhibitor (GDI), the $G_{\beta\gamma}$–receptor complex has GEF activity, facilitating binding of GTP to its site on G_α. Artificial "bending" of the N-terminus, mimicking what $G_{\beta\gamma}$ might do if it were acting as a GEF, does indeed lead to an apparently constitutively active G-protein. It has been speculated that $G_{\beta\gamma}$ may be the site of action of the Mg^{2+} ion. If so, the role of the receptor would be simply to promote binding of the Mg^{2+} ion to $G_{\beta\gamma}$. The Mg^{2+} ion would then be responsible for changing the activity of $G_{\beta\gamma}$ from a GDI to a GEF.

Regardless of the final outcome regarding the events responsible for G-protein activation by a receptor at the submolecular level, the overall reaction for a receptor activating a G-protein is facilitation of the action of the Mg^{2+} ion to promote GDP/GTP exchange, followed by dissociation of the trimer into G_α–GTP plus $G_{\beta\gamma}$.

C. RGSs or Regulators of G-Protein Signaling

As there are receptors that by virtue of their GEF activity promote activation of the heterotrimeric G-proteins, there are also GAPs that accelerate the GTPase activity of activated, GTP-liganded G_α subunits. Two types of G_α GAPs have been identified. One type consists of the RGSs. RGSs accelerate GTPase activity by 100-fold or more and exhibit G_α subunit selectivity. Sixteen RGSs are known and many of them are multidomain, multifunction proteins and thus not only affect the G_α subunits but also aid in the organization of multicomponent "signaling complexes." The second type of GAP includes some of the effectors regulated by the α-subunits. GAP activities of effectors increase the k_{cat} of the G_α–GTP complexes by only 10- to 20-fold. In both instances, increased GTP hydrolysis ensures not only prompt deactivation of the signaling protein but also a faster approach to equilibrium, therefore increasing the rate at which responses to an extracellular stimulus can be obtained. Indeed, for RGS proteins, faster on/off rates of the regulated function may be a primary raison d'être. In contrast, when effectors act as GAPs, the primary purpose may be to ensure that they are indeed affected by the activated G_α–GTP complex. The intrinsic GTPase activity of G_α subunits is very low, on the order of 4–8 per second, giving them a rather long half-life, ensuring that they "find" their effector(s) while still in their GTP state. Once the effector has been found and the receptor message is delivered, the recipient of the message "kills" the messenger through activation of its deactivating mechanism. Thus, continued stimulation of effector, if this is desirable, requires the continued presence of receptor, agonist and constant reactivation of the G-protein.

Figure 11 illustrates the effect of GAPs on accelerating the rate at which equilibrium is established in a simple on/off reaction, such as binding of a hormone (H) to its receptor (R). The three panels show (1) the basic rate at which a bimolecular reaction reaches equilibrium; (2) the effect of increasing the k_{off} rate on the rate at which equilibrium is reached, expressed as HR formed in absolute concentrations; and (3) the fact that although the number of complexes at equilibrium decreases with increasing values of k_{off}, the rate at which equilibrium is reached increases with increasing values of k_{off}. It follows that, given the low intrinsic GTPase activity of G_α subunits, the need for a rapid response can be satisfied only by both the existence of a GAP and a very high concentration of reactants so that the amplitude of the read-out signal (regulated effector) is large enough upon activation of only a small fraction of the GTPase. This is in fact the case with the activation of transducin (heterotrimeric G-protein) by rhodopsin. The GTPase of transducin is stimulated by RGS9, a GGL RGS. This ensures that the physiological rapid turn-off occurs within a tenth of a second as opposed to having a half-life of 10 s ($t_{1/2} = \ln 2/k_{off} = 10$ s, where k_{off} corresponds to the published intrinsic GTPase activity of G_α subunits of 4/min). However, to ensure that sufficient active transducin will be formed, Mother Nature endowed the visual system with the highest known concentrations of receptor (rhodopsin: 40% of disc membrane protein) and regulated G-protein (transducin: 10% of disc protein).

D. Other Forms of G-Protein Modulation: Activators of G-Protein Signaling—The GoLoco Domain

As described above, the free G_α–GTP and the $G_{\beta\gamma}$ released on G-protein activation are both active regulators of effector systems. RGSs and effectors acting as GAPs shorten the lifetime of the active G_α with formation of G_α–GDP. Due to the high affinity of G_α–GDP for $G_{\beta\gamma}$, a GAP activity accelerates the deactivation of not only G_α-regulated effectors, but also the $G_{\beta\gamma}$-regulated effectors from which $G_{\beta\gamma}$ is sequestered by G_α–GDP. Activators of G-protein signaling (AGSs) were discovered in a search for molecules that potentiate the effect of α-factor in baker's yeast. α-Factor acts by activating an αβγ

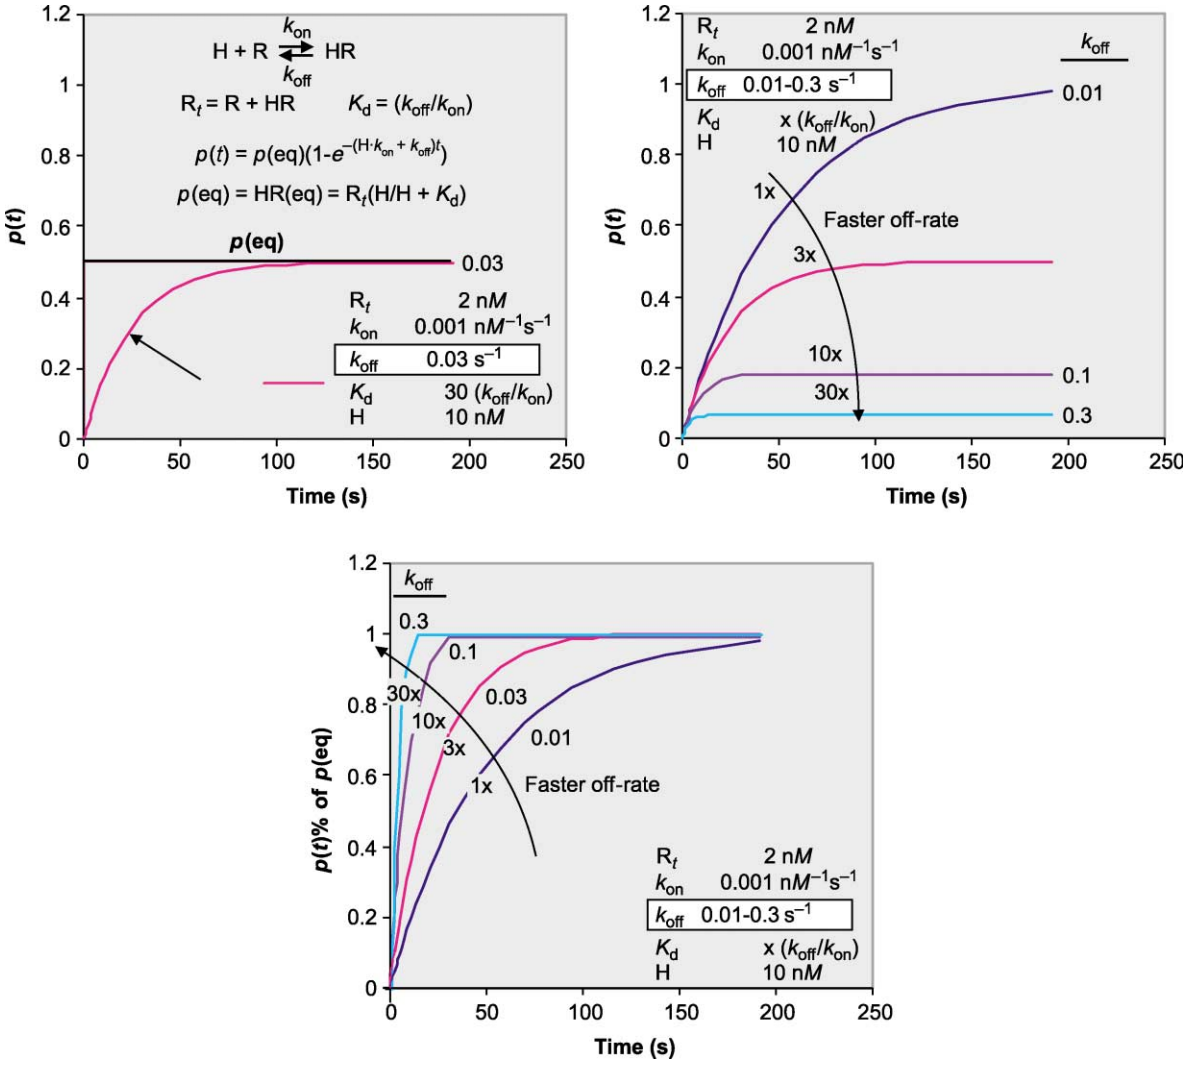

FIGURE 11 Approach to equilibrium of a reversible bimolecular reaction, $H + R \underset{k_{off}}{\overset{k_{on}}{\Longleftrightarrow}} HR$, HR = 0 at t_o. The panels illustrate the effect of increasing the k_{off} rate, equivalent to the effect of introducing a GTPase-activating RGS into a regulatory GTPase cycle. R_t, total receptor concentration.

heterotrimeric G-protein and initiating a $G_{\beta\gamma}$-mediated cascade of reactions that leads to growth arrest and preparation for mating to the opposite mating type. One of the AGSs, AGS3, was found to potentiate $G_{\beta\gamma}$ signaling by binding preferentially to G_α–GDP and to do so via a domain found in unrelated proteins and referred to as GoLoco. In mammalian systems, GoLoco domains act as they do in yeast: they bind preferentially to the GDP-liganded G_α subunit of the G_i/G_o type, thus prolonging $G_{\beta\gamma}$ signaling. In addition to AGS3, proteins with a GoLoco domain include several RGSs and Rap–GAPII. This hints at a role that transcends its direct function of binding the GDP forms of G_i/G_o and involves participation in the integration of multi-component signaling pathways.

Even though they were identified in the same type of bioassay, AGS1, AGS2, and AGS3 differ in their mode of action. AGS1 (also Rasdex1) is a ras-related protein that appears to act as a GEF, whereas AGS2 interacts with $G_{\beta\gamma}$ and AGS3 binds to α–GDP.

Why a $G_{\beta\gamma}$-interacting protein (AGS2) would enhance the effectiveness of either a $G_{\beta\gamma}$ or a G_α–GTP remains to be determined. Another $G_{\beta\gamma}$-interacting protein, phosducin, serves to attenuate the action of transducin in the retina. The existence of $G_{\beta\gamma}$- and G_α-interacting proteins (RGSs, GoLoco proteins, phosducin, and non-GoLoco AGSs) points

to the fact that fine-tuning of the basic regulatory G-protein cycle is required for proper cell homeostasis. These fine-tuning mechanisms are therefore responsible for the ultimate ability of a cell to live a productive life that is in concert with the needs of the whole organism.

Glossary

ANF (atrial natriuretic factor) A peptide produced by the heart that causes the kidney to excrete sodium.

cGMP (3′,5′-guanosine monophosphate) A cyclic nucleotide that promotes the intracellular reactions that generate a visual signal in the brain.

EGF (epidermal growth factor) A small mitogenic protein involved in regulating normal cell growth, oncogenesis, and wound healing.

NGF (nerve growth factor) A neurotrophic factor that promotes a wide range of responses in its target cells. These include neuronal differentiation, maintenance of survival, and regulation of metabolic activity.

PDGF (platelet-derived growth factor) A dimeric protein that acts as a mitogen for almost all mesenchymally derived cells.

TGF-β (transforming growth factor-β) A cytokine capable of regulating cell growth, extracellular matrix protein synthesis, and immune cell functions.

HGF (Hepatocyte Growth Factor)/MET System

S. GIORDANO, S. CORSO, P. CONROTTO, A. PETRELLI, AND P. M. COMOGLIO

University of Torino School of Medicine, Italy

Hepatocyte growth factor belongs to the scatter factor protein family; these proteins act through tyrosine kinase receptors of the Met family to control a genetic program that regulates cell detachment, repulsion, protection from apoptosis, invasiveness of extracellular matrices, and proliferation. This genetic program equates to a pleiomorphic response that is defined as "invasive growth."

I. INTRODUCTION

Under physiological conditions, the process of "invasive growth" leads to morphogenic cell movements through the matrix and to ordered building of epithelial tubules. Dysfunctions in this program cause enhanced proliferation, uncontrolled migration into surrounding tissues, and failure to differentiate, events that promote tumor growth and invasiveness. Hepatocyte growth factor, a member of the scatter

factor family, involved in promotion of invasive growth, acts through the *Met* tyrosine kinase receptor. During the past few years, a deeper knowledge of the mechanisms through which these receptors exert their physiological activities has enhanced the understanding of how alterations of the tyrosine kinases or of their signal transduction pathways are responsible for cancer onset and progression toward metastasis.

II. HGF AND THE FAMILY OF SCATTER FACTORS

Hepatocyte growth factor is the prototype of the scatter factor family, so far encompassing two members: hepatocyte growth factor/scatter factor 1 (HGF) and macrophage-stimulating protein/scatter factor 2 (MSP) (Fig. 1). HGF, a heterodimer composed of a 62-kDa α-chain disulfide linked to a 32/34-kDa β-chain, is produced mainly by cells of mesenchymal origin. The α-subunit is characterized by the presence of an N-terminal "hairpin" loop, which is involved in low-affinity binding, and by four repeated domains, named "kringles," which are homologous to those found in plasminogen. The high-affinity receptor for HGF is the transmembrane tyrosine kinase encoded by the *Met* protooncogene. Low-affinity receptors for HGF are heparan sulfate proteoglycans, membrane-bound molecules that allow accumulation of HGF in the extracellular matrix, in the proximity of target cells. The binding sites for both high-affinity and low-affinity receptors, located in the kringles, are known to act as protein–protein interaction motifs. The HGF β-chain is highly homologous to serine protease of the blood-clotting cascade (40% homologous to plasminogen), but it lacks enzymatic activity due to the replacement of critical amino acids in the catalytic site.

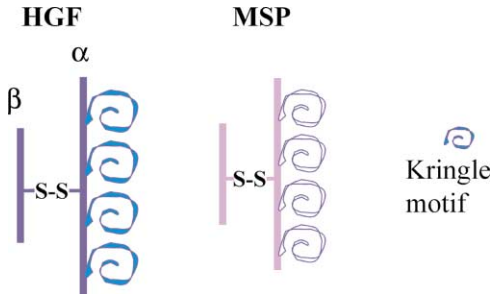

FIGURE 1 Schematic representation of the two known members of the scatter factor family, hepatocyte growth factor (HGF) and macrophage-stimulating protein (MSP). Scatter factors are disulfide-linked (–S–S–) α/β heterodimers. The α-subunit contains four kringles, which are highly conserved protein–protein interaction motifs. The β-subunits (sharing a 50% homology) are similar to serine proteases, although mutations abrogate the catalytic activity. Scatter factors are synthesized as single-chain precursors (pro-HGF and pro-MSP) and are then cleaved in the extracellular environment by specific proteases.

The heterodimeric HGF originates from a 728-amino-acid (pro-HGF) biologically inactive single-chain precursor that is secreted and bound by proteoglycans. In the extracellular environment, pro-HGF is converted in its bioactive form by a single proteolytic cleavage between Arg-494 and Val-495. This cleavage is performed in vitro by several proteases, including tissue-type and urokinase-type plasminogen activators (uPAs), coagulation factor XII, and one homologous serine protease (XII-like factor). Interestingly, uPA, which is capable of extracellular matrix degradation, is a powerful pro-HGF convertase and is also transcriptionally induced by HGF.

The second member of the scatter factor family, macrophage-stimulating protein, so named because it enables peritoneal macrophages to respond to chemoattractants, is highly homologous to HGF and displays similar biological activities (Fig. 1). It is a heterodimer composed of a 53-kDa α-chain containing four kringle motifs that are disulfide linked to a 25-kDa β-chain; the β-chain domain that is homologous to serine protease is devoid of enzymatic activity. In mammalians, the high-affinity MSP receptor is the tyrosine kinase encoded by the *Ron* protooncogene. It has been shown that the avian tyrosine kinase Sea can bind MSP; it has not been formally proved yet that Sea is the avian homologue of mammalian Ron. MSP is secreted as an inactive single-chain precursor that is converted into the fully active dimeric form via proteolytic cleavage by members of the coagulation cascade, including kallikrein.

III. SCATTER FACTOR RECEPTORS

The products of the protooncogenes *Met* (the HGF receptor; Met) and *Ron* (the MSP receptor; Ron) form a distinct family of protein tyrosine kinase receptors sharing a highly homologous structure. The protooncogene *Sea*, once listed as a third member of the family, is likely to be the avian counterpart of *Ron*. The prototype of this family, encoded by the *Met* gene, is the HGF receptor, a dimeric molecule composed of a 50-kDa α-chain disulfide linked to a 145-kDa β-chain in an α/β complex of 190 kDa. The α-chain is exposed at the cell surface and the β-chain

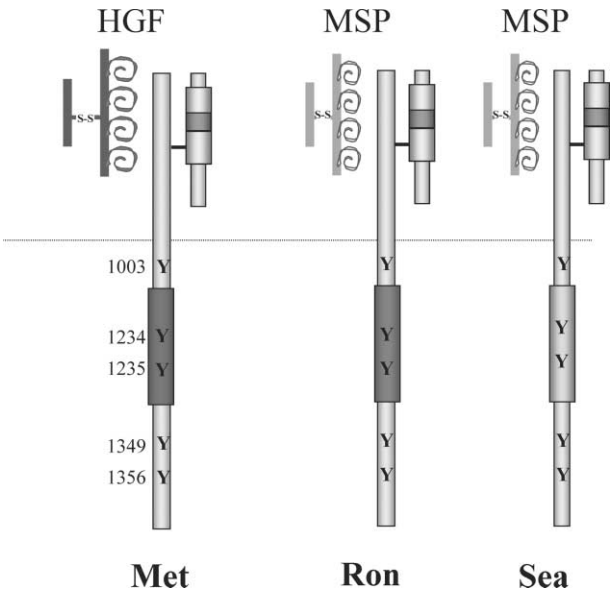

FIGURE 2 The tyrosine kinase family of scatter factor receptors. The two mammalian members, Met (HGF receptor) and Ron (MSP receptor), share a 63% overall percentage homology. Met and Ron are disulfide-linked heterodimeric proteins formed by an extracellular α-chain and by a β-chain that spans the membrane. The extracellular domains of Met and Ron contain the sema domain [common to the signaling molecules (semaphorins) and to their receptors (plexins)]. The intracellular β-chain contains the two autocatalytic tyrosines in the tyrosine kinase domain (dark gray shaded segment in the cytoplasmic domain), a juxtamembrane tyrosine that is responsible for the negative regulation of the enzyme, and two tyrosines in the C-terminal tail, forming a multifunctional docking site that recruits the full spectrum of signal transducers. The *Sea* gene, found only in avians, is likely to encode the avian counterpart of Ron, which also binds to MSP.

spans the plasma membrane (Fig. 2). The HGF receptor, synthesized as a large precursor (pr170) that includes both the α-chain and the β-chain, undergoes cotranslational glycosylation and is further cleaved by proteases of the furin family to form the mature subunits. Both the α-subunit and the β-subunit are necessary for biological activity. The intracellular portion of the receptor can be divided into three functional domains: a juxtamembrane domain, a tyrosine kinase catalytic domain, and a C-terminal tail.

The juxtamembrane domain negatively regulates Met-mediated activity. Two residues are responsible for the inhibitory effects of the juxtamembrane region: Ser-975 and Tyr-1003. The negative effect of Ser-975 depends on its phosphorylation, which results from activation of protein kinase C and of a Ca^{2+}/calmodulin-dependent kinase. The negative effect exerted by Tyr-1003 is less understood and may involve phosphorylation-dependent recruitment to the receptor of a cytosolic tyrosine phosphatase. Moreover, very recently it has been shown that Tyr-1003 plays a critical role in receptor down-regulation. Once phosphorylated, in fact, this tyrosine interacts with Cbl, an ubiquitin ligase that drives Met ubiquitination and, by recruiting a complex formed by CIN85 and endophilins, activates ligand-dependent Met down-regulation.

The tyrosine kinase catalytic domain contains the major phosphorylation site, represented by tyrosine residues 1234 and 1235, which are essential for full activation of the enzyme. On phosphorylation of these residues, the enzymatic activity of the Met kinase is strongly up-regulated in an autocatalytic fashion. Substitution of one of the tyrosine residues with a negatively charged residue results in increased receptor activity, probably due to a conformational change that mimics the one usually observed on phosphorylation of the normal residue.

The C-terminal domain of the Met receptor is crucial for its biological activity; the tail comprises a short sequence containing two tyrosines that are phosphorylated on HGF binding and are responsible for mediating high-affinity interactions with multiple SH2-containing cytoplasmic effectors (Fig. 3). Unlike the docking sites identified in other tyrosine kinase receptors, the Met sequence $Y^{1349}VHVNATY^{1356}VNV$ is able to interact with Grb2, p85/phosphatidylinositol 3-kinase (PI3K), phospholipase

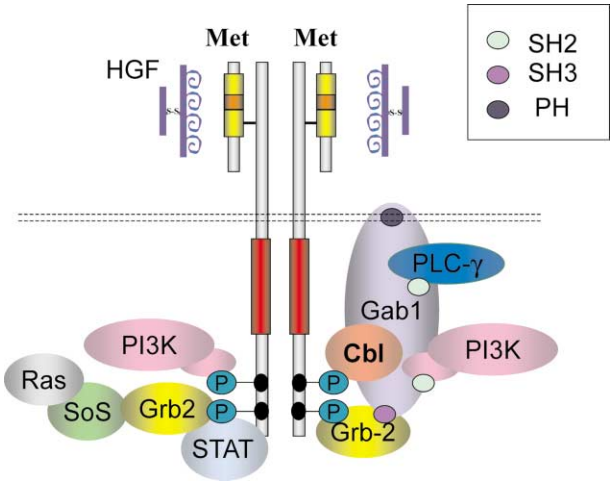

FIGURE 3 Met signaling machinery. On binding to HGF, Met undergoes dimerization, becomes active, and phosphorylates the two tyrosines in the C-terminal tail of the receptor. These tyrosines then recruit SH2-containing intracellular transducers (e.g., Gab1, Grb2, Stat, PI3K, and Cbl).

C-γ (PLC-γ), Stat3, Shc, and Gab1 and is therefore referred to as the HGF receptor "multifunctional docking site." The multifunctional docking site is essential for Met-mediated biological responses. Substitution of both tyrosines with phenylalanine does not affect the receptor kinase activity but completely abolishes proliferation, motility, invasion, and tubulogenesis. Recent genetic evidence has confirmed the crucial role of the multifunctional docking site for Met signaling *in vivo*.

The components of the signal transduction machinery implicated in individual Met-mediated biological responses have been partially elucidated. Coupling of the receptor to the Ras-mitogen-activated protein kinase (MAPK) pathway is both essential and sufficient for proliferation. Conversely, activation of PI3K as well as the Ras/Rac/Rho pathways is required to induce motility. Notably, concomitant activation of Ras-MAPK and PI3K is both necessary and sufficient for the HGF receptor-induced invasion. The morphogenetic response, which is specifically induced by Met and cannot be elicited by other receptor tyrosine kinases, involves Gab1 and Stat3.

IV. SCATTER FACTOR RECEPTORS INDUCE INVASIVE GROWTH

Invasive growth is a complex cellular response to a program specifically evoked by scatter factors. Because these ligands and their receptors are widely expressed throughout the body, invasive growth takes place physiologically in almost every tissue. This can be observed during epithelial morphogenesis as formation of tubular structures (such as gland ducts) or in endothelial cells in the process of angiogenesis. Scatter factors stimulate cells to form ramified tubules, sprouting like branches from a tree. By arranging themselves into tridimensional structures, epithelial and endothelial cells develop to their terminal differentiation and become polarized. In the bone marrow, scatter factors stimulate early erythroid cells to dissociate from their stem colonies and to enter the blood circulation. During bone remodeling, invasive growth is observed when osteoclasts migrate into the mineralized matrix and recruit the osteoblasts that will form osteogenic centers. In the embryo, myoblast precursors migrate from myotomes to their peripheral destination following a gradient of scatter factors. A particular form of invasive growth, more recently discovered, takes place in neural tissues, wherein scatter factors stimulate the process of axon guidance when neurites sprout and give origin to ramifications that will reach distant targets.

The accomplishment of the process of invasive growth implies different steps. The first, which is observed *in vitro* within a few hours after stimulation, is cell–cell dissociation. In early studies, this phenomenon was originally described in epithelial cells as "cell scattering." Loss of intercellular contacts allows cells to migrate through the surrounding tissues and across the basement membrane. Active migration requires cytoskeletal reshaping, digestion of the matrix by secreted proteases, and remodeling of cell–matrix contacts. In this process, scatter factors enable cells to survive "anoikis," which usually occurs when cell adhesion is impaired. Cell proliferation and acquisition of polarity are the final steps of this process. Deregulated execution of this process can sustain the invasive behavior of tumor cells.

V. DEVELOPMENTAL ROLE OF SCATTER FACTORS

A. Control of Cell Migration in Early Embryogenesis

During gastrulation, HGF and its receptor are expressed in the endoderm and in the mesoderm. Subsequently, the expression of HGF is limited to the mesenchymal cells, whereas that of the receptor is induced in the surrounding ectoderm. At this stage, approximately embryonic day 13 (E13), HGF contributes to the development of several epithelial organs (e.g., lungs, liver, and gut) and induces migration of myogenic precursor cells. HGF, in fact, is expressed in limb mesenchyme and can thus provide the signal for migration, which is received by c-Met expressing myogenic precursors. In c-Met homozygous mutant (−/−) mouse embryos, the limb bud and diaphragm are not colonized by myogenic precursor cells and, as a consequence, skeletal muscles of the limb and diaphragm do not develop. It is also interesting to note that during this process HGF must dissociate the epithelium lining the lateral plate of dermomyotomes to allow the migration of the myogenic precursors. Moreover, transgenic mice overexpressing HGF exhibit ectopic skeletal muscles and melanocytes in the central nervous system, suggesting that HGF has scatter activity *in vivo* and that tight regulation of HGF expression is critical for the correct development. Collectively, these observations are consistent with a role of c-Met and HGF as key regulator molecules in the migration of myogenic cells.

B. Mesenchymal–Epithelial Interactions

Several observations indicate that c-Met and HGF play an important role in the process of epithelial morphogenesis. One of the best examples is given by the formation of kidney tubules from metanephric tissue and ureteric buds. Metanephric mesenchymal cells secrete HGF whereas epithelial cells of the ureteric bud express the receptor. When the latter contact the metanephros, they form branching tubules; in turn, some of the metanephric cells start to express the receptor for HGF and—stimulated by the autocrine loop—undergo a process known as "mesodermic–epithelial transition." They acquire epithelial features, form cell–cell junctions, polarize, and eventually form tubules. It is interesting to note that, although all of the mesenchymal cells of the renal cortex express HGF, the receptor is found only in those cells that give origin to the renal tubules and not in the cells forming the glomeruli. In the adult, only mesangial cells, which probably represent a poorly differentiated compartment for regeneration, co-express HGF and its receptor.

The mammary gland is a good example of an organ that undergoes major morphological changes after birth and in which branching development takes place during pregnancy and lactation. This program of differentiation relies on sequential stimulation of the epithelium by HGF and neuregulin, which are secreted by the mesenchyme in different developmental stages. HGF is expressed at puberty and promotes branching of the ductal tree, whereas neuregulin is responsible for alveolar budding and the production of milk proteins during pregnancy and lactation.

C. Signal Transduction Studies in Met Knockout and Knock-in Mice

Genetic analysis in the mouse has elucidated the developmental functions of scatter factors and their receptors. Mutant embryos lacking Met or HGF die *in utero* due to hyponutrition, caused by a reduction of the labyrinth layer of the placental trophoblast, which is normally responsible for controlling the invasion of maternal tissues to expand the placenta. Moreover, these embryos display impaired development of the liver and lack skeletal muscles deriving from long-range migrating precursors.

To analyze the requirement of *Met*-activated signal transduction pathways in development and function of different tissues and organs, a Met receptor impaired in its signal transduction properties was used to construct knock-in mice. Loss of the Met multifunctional docking site ($met^{D/D}$ construct) resulted in embryonic lethality and produced a phenotype coincident with that observed in Met null mutants. In contrast, embryos with a Met docking site modified only to prevent Grb2 binding were viable. In these animals, muscles deriving from migratory precursors were heavily affected, indicating a requirement for Grb2-mediated signaling for survival and proliferation of myoblasts en route to their final destination.

These engineered mice have been also very useful in elucidating the role played by *Met* in the development of the nervous system. It is known that both Met and HGF are expressed in the developing nervous system and that HGF promotes neural induction, stimulates Schwann cell proliferation, and promotes axon outgrowth from P19 embryonal carcinoma cells. Moreover, HGF is a limb mesenchyme-derived chemoattractant for motor axons. Analysis of Met signaling mutants showed that mice carrying the inactivating $met^{D/D}$ alleles have intercostal nerves that are much reduced in length and elaborate fewer terminal branches. Interestingly, Met signaling via Grb2 is not required for sensory neuron development but is critical for survival of sympathetic neuroblasts.

VI. SCATTER FACTOR RECEPTOR RELATIVES: PLEXINS AND SEMAPHORINS

The search for receptors homologous to Met and Ron has led to identification of the *plexin* gene family, comprising at least nine different genes in humans. These genes are grouped into four subfamilies (*plexins A* to *D*) and encode transmembrane proteins that have extracellular segments containing regions of homology with scatter factor receptors. The cytoplasmic domain of plexins is highly conserved within the family, but, surprisingly, it does not contain any known functional domain. However, this domain includes a number of tyrosine residues that can be phosphorylated and a long α-helix motif, common to protein–protein interaction modules.

Plexins are the receptors for semaphorins, a large family of related proteins, encompassing at least 20 members, that are either secreted or membrane bound. A distinctive feature of these molecules is the presence of the sema domain, a protein–protein interaction domain that mediates receptor-binding specificity. The observation that this domain is present also in plexins and in scatter factor receptors

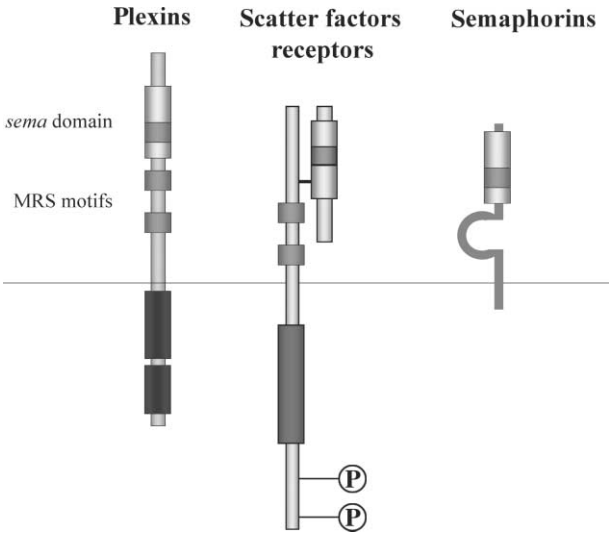

FIGURE 4 The scatter factor, semaphorin, and plexin superfamily. Scatter factor receptors are part of a larger family of molecules, characterized by the presence of the sema domain and of the Met-related sequence (MRS) in the extracellular domain. Semaphorins are signaling molecules that regulate neuronal axon guidance and plexins are their receptors. Plexins are single-pass transmembrane molecules that have a peculiar intracellular domain, conserved among the different plexins, endowed with still unknown functions. The overall homology between scatter factor receptors and plexins is confined to their extracellular domains.

(Fig. 4) raises the possibility that it can mediate homophilic interactions, establishing a interplay with plexins and scatter factor receptors. This view is consistent with the partial overlapping of the biological functions of scatter factors and semaphorins. In fact, semaphorins were first identified as repelling cues for axon guidance during the development of nervous system. More recently it has been discovered that plexins can mediate repelling signals in almost all tissues. Repulsion results in dissociation of packed cells, a process very reminiscent of scatter. Interestingly, semaphorins are overexpressed in invasive and metastasizing tumors, in which they can sustain motility, invasion, and cell survival.

VII. ALTERATION OF THE INVASIVE GROWTH PATHWAY: THE MALIGNANT PHENOTYPE

Scatter factor receptors are associated with, and in some cases directly responsible for, a wide variety of human cancers. The most convincing evidence of the involvement of Met in human cancer arose from analysis of patients affected by hereditary papillary renal carcinoma (HPRC), a form of inherited cancer, characterized by the presence of multiple, bilateral tumors. These patients bear germ-line missense mutations of Met that are also found in somatic cells of patients affected by sporadic renal carcinomas or childhood hepatocellular carcinoma. Some mutations are homologous to those found in the oncogenes *Ret* or *Kit*, which are responsible for inherited multiple endocrine neoplasia (type 2) or for hematological disorders, respectively. *In vitro* studies show that these mutated forms of Met display an increased tyrosine kinase activity, are transforming, and confer to cells in nude mice the ability to form tumors and to overcome apoptosis. Unexpectedly, it has been demonstrated that tumorigenesis is strictly dependent on stimulation by the ligand and that it is abolished in the presence of HGF specific inhibitors. Conceivably, the onset of HPRC depends both on the presence of inherited Met mutations and on the availability of HGF.

Mutated forms of Met have also been shown to play a role in the metastatic process in human tumors. It has been reported that somatic mutations of Met are selected during the metastatic spread of head and neck squamous carcinoma. One of these point mutations results in substitution of Tyr-1235, critical for the autocatalytic activation of the kinase, with an aspartate, conferring a permanent negative charge that mimics the presence of a phosphate group and is responsible of constitutive kinase activation.

Met overexpression in the absence of missense mutations is the most common alteration found in human tumors and is often associated with metastatic tendency and poor prognosis. In the case of colorectal carcinoma, amplification of the Met gene, associated with protein overexpression, confers a selective advantage for acquiring metastatic potential to the liver. In some instances, tumorigenesis is associated with ectopic expression of Met. Although absent in adult skeletal muscle, Met is expressed in a significant proportion of human sarcomas. Because these cells express HGF, aberrant Met expression results in the formation of an autocrine loop, which confers invasive properties.

Glossary

gene knock-in Technique in which the coding sequences of one gene are replaced with those of another.

gene knockout Technique for selectively inactivating a gene in the germ-line of an animal by replacing the gene with a mutant allele.

mesenchyme Embryonic tissue from which are formed the connective tissues, blood, and lymphatic vessels.

Src homology 2 (SH2) domains Protein segments able to recognize and bind to phosphorylated tyrosines. They are present in several intracellular proteins acting as signal transducers.

tyrosine kinases Enzymes able to transfer the terminal γ-phosphate groups from ATP to tyrosines that reside in intracellular substrates.

ubiquitin Small protein that becomes covalently linked to lysine residues in other intracellular proteins. This reaction is catalyzed by ubiquitin ligases. Ubiquitinylated proteins are usually degraded in the proteasome.

Humoral Hypercalcemia of Malignancy

ARTHUR E. BROADUS AND LAUREN H. GOLDEN
Yale University

Parathyroid hormone-related protein is a factor that structurally and functionally resembles parathyroid hormone. When produced by normal tissues, parathyroid hormone-related protein plays an important role in physiological development. When secreted into the circulation by malignancies, parathyroid hormone-related protein is the principal factor responsible for the development of humoral hypercalcemia of malignancy.

I. INTRODUCTION

Parathyroid hormone-related protein (PTHrP) was identified in 1987, as investigators strove to unravel the underlying pathophysiologic mechanisms of malignancy-associated hypercalcemia. Hypercalcemia is a common, life-threatening metabolic complication of malignancy, affecting 10–20% of patients with advanced cancers of varying etiologies. Patients present with classic signs and symptoms, including polyuria, polydipsia, nausea and vomiting, constipation, and impairment of mental status. Volume contraction and dehydration often occur as a direct result of hypercalcemia-induced diuresis, and often precipitate renal compromise. Malignancy-associated hypercalcemia progresses and decompensates rapidly, compared to the more gradual onset of hypercalcemia associated with primary hyperparathyroidism. As a result, malignancy-associated hypercalcemia is commonly associated with dramatic symptoms and carries a very poor prognosis for survival.

Two distinct mechanisms have been implicated in the pathogenesis of malignancy-associated hypercalcemia: local osteolytic hypercalcemia (LOH) and humoral hypercalcemia of malignancy (HHM). Osteoclastic bone resorption is the final common pathway leading to hypercalcemia in both LOH and HHM.

II. MECHANISMS OF MALIGNANCY-ASSOCIATED HYPERCALCEMIA

Local osteolytic hypercalcemia involves hypercalcemia induced as a consequence of direct tumor involvement of the skeleton. Malignant cells metastatic to bone produce bone-resorbing cytokines, including tumor necrosis factor β (TNFβ), tumor necrosis factor α (TNFα), interleukin-6, interleukin-1, and transforming growth factor-α (TFG-α). Local production of these cytokines in the bone microenvironment results in cytokine-induced activation of osteoclasts and, ultimately, bone resorption. LOH occurs most commonly in the setting of breast cancer, multiple myeloma, and other hematologic malignancies such as leukemia and lymphoma (Table 1). Overall, LOH accounts for approximately 20% of clinical cases of malignancy-associated hypercalcemia.

In contrast to local osteolytic hypercalcemia, humoral hypercalcemia of malignancy is mediated by tumor-induced production of humoral factors that are secreted into the general circulation in the presence or absence of skeletal metastases. Historically, the identification of HHM hinged on recognition by clinicians that not all patients with malignancy-associated hypercalcemia suffered extensive skeletal involvement. Thus, local lysis of bone with a resultant release of calcium could not be implicated as the sole pathogenic factor underlying the metabolic derangement. In addition, these patients displayed an associated hypophosphatemia, which could not otherwise be explained.

In 1941, Dr. Fuller Albright described one such patient, a man with a renal carcinoma and a single skeletal metastasis. The clinical association of hypercalcemia and hypophosphatemia, a paucity of bony metastases, as well as the reversal of the metabolic derangement upon resection of the primary tumor, prompted Albright to hypothesize that the tumor was secreting a "humoral" calcemic phosphaturic factor. He speculated that the proposed factor resembled

TABLE 1 Tumors Commonly Associated with Hypercalcemia

Local osteolytic hypercalcemia	Humoral hypercalcemia of malignancy
Multiple myeloma	Squamous cell
Breast cancer	Lung
Lymphoma	Esophagus
	Cervix
	Head and neck
	Genitourinary tract
	Renal
	Bladder
	Ovary
	Breast cancer
	HTLV-1 lymphoma

parathyroid hormone in its actions, capable of inducing bone resorption and of modulating calcium homeostasis.

III. PARATHYROID HORMONE-RELATED PROTEIN

In 1987, the principal tumor-derived factor responsible for HHM was isolated, purified, and identified. The gene for this new factor was localized to the short arm of chromosome 12 and its intron–exon organization was found to resemble that of the PTH gene located on the short arm of chromosome 11. Three gene products of varying lengths and molecular weights were identified, the results of alternative splicing. The total lengths of the three protein products are 139, 141, and 173 amino acids, respectively. Comparison of the amino acid sequence of the new peptide with that of parathyroid hormone revealed striking homology at positions 1–13 of the amino-terminal end, with the first eight amino acids being identical to those of native PTH, and with divergence of the sequences thereafter. It was thus given the name parathyroid hormone-related protein. Posttranslational processing of PTHrP produces N-terminal [PTHrP(1–36)], midregion, and C-terminal peptides in a cell-specific fashion.

It is the amino-terminal portion of the PTH molecule that binds to the PTH receptor. Activation of the classical PTH receptor by PTHrP(1–36) was soon confirmed, a consequence of the above-mentioned amino-terminal homology. In addition to partial sequence homology and an ability to activate the PTH receptor, PTHrP exhibits many physiological actions similar to those of native parathyroid hormone, namely, an ability to stimulate bone resorption, renal tubular calcium reabsorption, and renal phosphate wasting.

IV. FEATURES OF HUMORAL HYPERCALCEMIA OF MALIGNANCY

Humoral hypercalcemia of malignancy accounts for approximately 80% of cases of malignancy-associated hypercalcemia. Tumors that are often associated with HHM include those of squamous cell origin (lung, esophagus, cervix, and head/neck) and those of genitourinary tract origin (renal, bladder, and ovary), as well as tumors of the breast. HHM is also associated with adult T-cell leukemia/lymphoma, an uncommon malignancy resulting from chronic infection with human T-cell leukemia virus type 1 (HTLV-1). The presence of hypercalcemia in these clinical settings reflects the capacity of particular malignant cells to elaborate quantities of PTHrP sufficient to elevate levels in systemic circulation and induce bone resorption. It is important to note that some malignancies possess the capacity to induce hypercalcemia through both LOH and HHM. For example, it has been demonstrated that the majority of breast cancer skeletal metastases elaborate PTHrP, whereas the majority of nonskeletal metastases do not.

From a biochemical standpoint, HHM shares many features with primary hyperparathyroidism, namely, hypercalcemia, hypophosphatemia, and hypercalciuria. Close examination of the physiologic actions of the two hormones, however, reveals features of HHM that are, in some ways, unlike those of PTH excess (primary hyperparathyroidism), resulting in distinct metabolic profiles. (Table 2).

At the level of bone, the two hormones exert distinct actions. Although both PTH and PTHrP stimulate intense bone resorption, PTH stimulates coupled bone turnover, an increase in bone resorption that is accompanied by an increase in bone formation. In contrast, HHM stimulates uncoupled bone turnover. That is, in HHM there is a marked increase in bone resorption, accompanied by suppression of bone formation. Bone biopsies from patients with HHM reveal increased numbers of osteoclasts, mediators of bone resorption, few or no osteoblasts, and a paucity of osteoid, a premineralized bony substrate that reflects new bone formation (Fig. 1).

In addition, the action of PTHrP at the level of the kidney differs from that of PTH. Nephrogenous

TABLE 2 Biochemical and Metabolic Features of Primary Hyperparathyroidism and Humoral Hypercalcemia of Malignancy

Feature	Primary hyperparathyroidism	Humoral hypercalcemia of malignancy
Serum calcium	↑	↑
Serum phosphorus	↓	↓
$1,25(OH)_2D_3$	↑	↓
PTH	↑	↓
PTHrP	↓	↑
Urinary calcium excretion	↑	↑↑
Nephrogenous cAMP	↑	↑
Bone resorption	↑	↑↑
Bone formation	↑	↓

FIGURE 1 Photomicrograph of a bone biopsy specimen from a patient with humoral hypercalcemia of malignancy. Note the increased numbers of osteoclasts, the absence of osteoblasts, and the paucity of osteoid.

(kidney-derived) cyclic adenosine monophosphate (cAMP) has been established as a sensitive and specific index of parathyroid hormone bioactivity. As mentioned above, PTHrP interacts directly with the PTH receptor in the kidney, and its activity is reflected by the generation of nephrogenous cAMP. Like PTH, PTHrP stimulates renal tubular calcium reabsorption, although to a lesser degree than native PTH. Thus, urinary calcium excretion, increased in both primary hyperparathyroidism and HHM, tends to be elevated to a greater extent in HHM. Like PTH, PTHrP also stimulates renal phosphate excretion, resulting in hypophosphatemia.

The renal actions of PTH and PTHrP appear to differ with regard to the production of $1,25(OH)_2D_3$, the activated form of vitamin D. Infusions of both PTH and PTHrP have been shown to induce increases in plasma levels of $1,25(OH)_2D_3$. However, levels of $1,25(OH)_2D_3$ are inappropriately normal or frankly low in patients with HHM, whereas they are elevated in patients with primary hyperparathyroidism. The mechanisms responsible for this suppression of $1,25(OH)_2D_3$ in HHM remain to be elaborated. Because activated vitamin D contributes to absorption of calcium by the gut, absorption of dietary calcium is not a significant contributor to the hypercalcemia associated with HHM.

V. MANAGEMENT

The hypercalcemia of HHM induces a diuresis that results in dehydration and often precipitates renal compromise. Management of HHM involves three targeted steps: (1) correction of the dehydration, (2) enhancement of calciuresis (renal calcium excretion), and (3) inhibition of further osteoclastic bone resorption.

Rehydration restores intravascular volume and optimizes glomerular filtration rate. Initial frontline therapy in the management of symptomatic hypercalcemia involves aggressive volume repletion with isotonic saline. The rate of intravascular fluid administration is dictated by the severity of the hypercalcemic symptoms and the degree of hemodynamic compromise. Re-expansion of intravascular volume with a sodium load not only corrects the dehydration associated with hypercalcemia, but also increases renal blood flow, enhancing filtration and calciuresis. A modest decline in serum calcium levels occurs as a result. Once intravascular volume has been effectively repleted, the addition of a loop diuretic (i.e., furosemide) to the treatment regimen may further enhance calciuresis by inhibiting both calcium and sodium reabsorption in the ascending loop of Henle.

The mainstay of the pharmacologic treatment of hypercalcemia of malignancy is a class of antiresorptive agents known as bisphosphonates. Bisphosphonates disrupt osteoclastic bone resorption via direct inhibition of osteoclast activity. They also inhibit osteoclastogenesis and promote increased osteoclast apoptosis. Thus, in the setting of HHM, bisphosphonates block the key end-organ effect of PTHrP, blunting the osteoclastic resorptive response and the resultant release of calcium into the systemic circulation.

Bisphosphonates have a core phosphorus–carbon–phosphorus structure. They are rapidly deposited into bone, where they bind to hydroxyapatite crystals. Once deposited into bone, their skeletal half-life is long, on the order of years. Although a variety of bisphosphonates have been used successfully in the treatment of HHM, intravenous pamidronate disodium, a second-generation bisphosphonate, is presently used as firstline treatment. Improvements in serum calcium are not immediate and the duration of response is variable.

More recently, a third-generation bisphosphonate, zoledronic acid, has been shown to have increased antiresorptive potency. Zoledronic acid is administered over a shorter infusion time and demonstrates increased efficacy and prolonged response times compared to pamidronate.

Glossary

cytokines Small, secreted proteins or glycoproteins that function as chemical messengers and regulate growth, differentiation, and activation of cells; may exert influence on the cell of origin, on contiguous cells, or on cells in a distant location, i.e., they may exert autocrine, paracrine, or endocrine effects.

osteoblasts Bone-lining cells that synthesize bone matrix; responsible for bone formation.

osteoclasts Bone-lining cells responsible for bone resorption.

Hypoglycemia in Diabetes

SALIMA MITHANI AND ELIZABETH R. SEAQUIST
University of Minnesota

Blood glucose levels are maintained within a narrow range by a careful balance between insulin and the hormones that counteract its effects. Hypoglycemia occurs when serum glucose concentrations fall below the normal range. To prevent hypoglycemia, a complex and redundant system of neuroendocrine responses is activated, but these responses are altered in patients with diabetes. Acute hypoglycemia and its accompanying neurogenic and neuroglycopenic symptoms have a profound impact on the lives of patients with diabetes and can cause significant physical and psychosocial morbidity and mortality in these patients.

I. INTRODUCTION

The brain requires glucose as its metabolic fuel. In normal subjects, serum glucose concentrations are maintained within a narrow range by a system of coordinated neuroendocrine mechanisms. Whenever hypoglycemia occurs, counterregulatory hormonal responses are activated to ensure an adequate supply of glucose to the brain. However, maintaining euglycemia in persons with diabetes can present a therapeutic challenge. Hyperglycemia often requires treatment with insulin or oral hypoglycemic drugs but many patients develop defective counterregulatory mechanisms and ultimately suffer from hypoglycemia.

The incidence of hypoglycemia in patients with diabetes is probably much greater than appreciated. Severe hypoglycemia is usually defined as an episode of low blood sugar that requires the assistance of another for recovery. In the Diabetes Control and Complications Trial in which more than 700 patients were provided intensive insulin therapy, the frequency of severe neuroglycopenia was 0.62 episodes/patient/year. The frequency of hypoglycemia in people with type 2 diabetes treated with insulin is approximately 2% per year, but when patients with type 2 diabetes and pancreatic beta-cell failure are compared to subjects with type 1 diabetes with a similar duration of insulin treatment, the frequency of severe hypoglycemia is similar.

Acute hypoglycemia causes significant physical and psychosocial morbidity and mortality in patients with diabetes. As many as 4% of deaths of patients with type 1 diabetes have been attributed to hypoglycemia. These deaths may occur because of hypoglycemia-induced cardiac arrhythmias and myocardial ischemia. Acute neuroglycopenia can also lead to coma, convulsions, cerebral ischemia, and transient hemiplegia. The cognitive impairment that can result from hypoglycemia may result in accidents and physical injury. Acute and chronic changes in mood can also occur in diabetic patients with hypoglycemia. Some investigators have found that frequent hypoglycemia increases the risk of developing depression in patients with type 1 diabetes.

Restoration of euglycemia is an essential therapeutic goal in patients with diabetes because good glycemic control has been shown to reduce the risk of microvascular disease in patients with both type 1 and type 2 diabetes. Unfortunately, patients who follow an intensive therapeutic plan are at increased risk for severe hypoglycemia. Indeed, hypoglycemia is the limiting factor in the treatment of diabetes. This article reviews what is known about neuroendocrine responses to hypoglycemia and how these responses are changed in patients with diabetes.

II. GLUCOSE HOMEOSTASIS

The maintenance of normal plasma glucose concentrations requires a precise balance between insulin and the hormones that oppose insulin's actions. Insulin acts to reduce plasma glucose concentrations by enhancing glucose disposal into muscle and fat and by inhibiting endogenous glucose production from the liver and kidney. The most important hormone to oppose insulin's action under normal homeostatic conditions is glucagon. This hormone serves to increase endogenous glucose production. Insulin and glucagon are both produced in the islets of Langerhans in the pancreas. Each islet consists of a few hundred cells. The insulin-producing beta cells constitute approximately 60% of islet mass and form the core of the structure. These cells are surrounded by the glucagon-producing alpha cells, which constitute approximately 25% of islet mass. After a meal or whenever plasma glucose concentrations begin to rise, insulin is released from the beta cell into the blood that perfuses the islet. Insulin first reaches the alpha cell, where it inhibits glucagon secretion, and then enters the general circulation. As plasma glucose concentrations fall, insulin secretion is reduced and the inhibitory effects on glucagon secretion are removed. Glucagon can then be released into the circulation to maintain glucose homeostasis.

The brain is one organ that is particularly dependent on the maintenance of normal glucose homeostasis. The energy requirements for the brain are very high, approximately 1.0 mg/kg/min or 100 g/day in an adult. Glucose oxidation normally provides more than 90% of the energy needed for brain function and although some glucose is stored in the brain as glycogen, the vast majority of glucose used for cerebral metabolism originates in the blood and passes into the brain across the blood–brain barrier. Under euglycemic conditions, glucose transport is essentially saturated because serum glucose concentration remains well above the 1 to 3 mM concentration that is equal to the K_m defined for this process.

III. GLUCOSE COUNTERREGULATION

Because of the importance of providing a continuous source of fuel to the brain, the body has developed an elaborate system of compensatory responses to maintain glucose delivery to the brain when blood glucose levels begin to fall. The first step in these compensatory responses is the inhibition of insulin secretion, which serves to reduce insulin-mediated glucose uptake into tissues and to relieve the inhibitory effects of insulin on endogenous glucose production. If serum glucose continues to fall to below 60–65 mg/dl (3.3–3.6 mM), glucagon, epinephrine, norepinephrine, cortisol, and growth hormone are all released into the circulation. These counterregulatory hormones serve to oppose the action of insulin and cause the elevation of serum glucose concentrations. The coordination of glucose counterregulation relies on the interaction of organs that sense a reduction in plasma glucose concentrations and initiate a defense against hypoglycemia, organs that respond to signals from glucose-sensing organs by secreting hormones and neurotransmitters that are important in modulating plasma glucose concentrations, and organs that respond to these hormonal and neural signals by releasing glucose into the blood.

A. Glucose-Sensing Organs

The brain is of key importance in sensing hypoglycemia. The ventromedial hypothalamus, amygdala, and brainstem are particularly important is sensing a reduction in plasma glucose. The liver and the portal vein also have sensors that convey a drop in plasma glucose to the central nervous system, although these sensors are probably of lesser importance than the glucose-sensing regions in the brain. In addition, hypoglycemia is sensed in the pancreatic beta cell, where it leads to a reduction in insulin secretion. Finally, a drop in plasma glucose elicits a glucagon secretory response from the pancreatic alpha cell, although whether the alpha cell independently senses this reduction in glucose or whether it is responding to neural input is not completely understood.

B. Counterregulatory Hormones and Neurotransmitters

Once hypoglycemia is detected, the glucose sensors initiate hormonal and neural responses to restore euglycemia. These responses are elicited at different levels of glycemia (see Fig. 1) and provide a redundant system through which to maintain euglycemia. In normal circumstances, the first response to a drop in plasma glucose is the inhibition of insulin release at a plasma glucose concentration of approximately 80 mg/dl (4.7 mM). When plasma glucose falls to 65 mg/dl (3.6 mM), glucagon is released from the pancreatic alpha cell, epinephrine is secreted from the adrenal medulla, and growth hormone is released from the pituitary. Cortisol is secreted from the adrenal cortex when plasma glucose falls below 60 mg/dl (3.3 mM). The sympathetic nervous system also responds to a reduction in plasma glucose and increases norepinephrine release from sympathetic postganglionic neurons when plasma glucose falls below 60 mg/dl (3.3 mM). All of these counterregulatory agents increase plasma glucose by increasing endogenous glucose production and reducing glucose utilization by muscle and fat.

The relative importance of these counterregulatory agents was studied extensively by Cryer and associates in a series of experiments in which glucose recovery following insulin administration was examined in subjects with selected deficiencies in the counterregulatory hormones. In these experiments, secretion of glucagon and growth hormone was suppressed by the infusion of somatostatin, the effects of epinephrine and norepinephrine were blocked by α- or β-adrenergic blockade, or epinephrine secretion was absent as a result of bilateral adrenalectomy. The results of these investigations are depicted in Fig. 2. They demonstrate that subjects with isolated deficiencies in epinephrine, norepinephrine, or growth hormone recover from hypoglycemia as well as controls do but that subjects with isolated glucagon deficiency recover from hypoglycemia more slowly than unmanipulated controls.

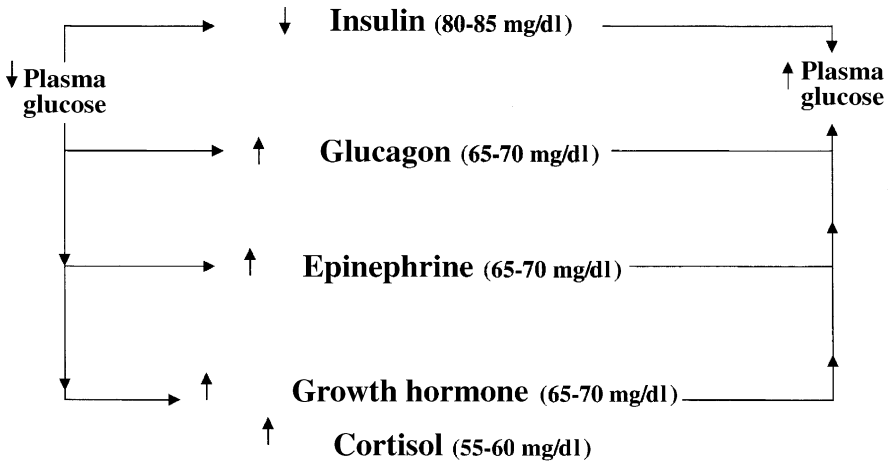

FIGURE 1 Hormonal responses to hypoglycemia. As plasma glucose concentrations fall, insulin secretion is reduced and the release of the counterregulatory hormones glucagon, epinephrine, growth hormone, and cortisol is stimulated to maintain glucose homeostasis.

However, when glucagon secretion was suppressed in adrenally insufficient subjects or in subjects with α- or β-adrenergic blockade, glucose recovery was completely prevented. These observations demonstrated that glucagon secretion is of primary importance in glucose recovery following insulin administration but that catecholamine secretion is also necessary for normal counterregulation to occur.

C. Organs Responding to Hypoglycemia-Induced Counterregulation

Many organs respond to the counterregulatory signals elicited by hypoglycemia. The liver and the kidney respond by increasing gluconeogenesis and glycogenolysis. Muscle responds to the proteolytic signals of glucagon and cortisol, thereby providing amino acid substrates for gluconeogenesis. Adipose tissue releases free fatty acids in response to increases in glucagon and catecholamines. Catabolism of these free fatty acids creates energy that can be used to support hepatic glucose production.

IV. SYMPTOMATIC RESPONSES TO HYPOGLYCEMIA

Experiments in which normal subjects were given insulin and their blood sugar levels were allowed to fall in a controlled fashion have defined the symptoms that accompany the counterregulatory response to hypoglycemia. Although glucagon release is not associated with any distinct symptomatology, the release of catecholamines and activation of the autonomic nervous system cause specific neurogenic symptoms in healthy subjects subjected to experimental hypoglycemia. As listed in Table 1, adrenergic symptoms include rapid heart rate, shakiness, tremulousness, and anxiety. These symptoms result from the release of epinephrine from the adrenal medulla and release of norepinephrine at the sympathetic postganglionic nerves. Cholinergic symptoms, which occur as a result of acetylcholine release from the sympathetic postganglionic nerves, include sweating, hunger, and tingling. Neurogenic symptoms begin to appear when blood glucose drops to 50–55 mg/dl (2.8–3.1 mM). When blood glucose is allowed to drop to a lower level, symptoms of neuroglycopenia occur (see Table 1). These symptoms include dizziness, headache, blunted mental activity, loss of fine motor skills, confusion, abnormal behavior, seizures, and loss of consciousness. Because the neurogenic symptoms are elicited at a higher blood glucose level than the neuroglycopenic complaints and because they are not associated with impaired judgment or mental capacity, they usually prompt the patient to eat something to increase their blood sugar. If the neurogenic symptoms are not treated before neuroglycopenia occurs, the patient becomes unable to help himself and must rely on the assistance of another to overcome the episode of hypoglycemia.

TABLE 1 Symptoms of Hypoglycemia

Type of symptoms	Symptoms
Adrenergic symptoms	Rapid heart rate
	Shakiness
	Tremulousness
	Anxiety
Cholinergic symptoms	Sweating
	Hunger
	Tingling
Neuroglycopenic symptoms	Dizziness
	Headache
	Blunted mental activity
	Loss of fine motor skills
	Confusion
	Abnormal behavior
	Seizures
	Loss of consciousness

V. HYPOGLYCEMIA IN DIABETES

In healthy human beings, severe hypoglycemia is prevented by the counterregulatory mechanisms discussed above. However, patients with diabetes who are treated with insulin and/or drugs that enhance endogenous insulin secretion may lack some of the normal counterregulatory responses that prevent hypoglycemia in healthy individuals (Fig. 3). Perhaps most importantly, patients receiving such treatments are unable to reduce the amount of circulating insulin when their blood sugar drops to below 80–85 mg/dl (4.4–4.7 mM). In addition, patients with type 1 diabetes lose their ability to secrete glucagon in response to hypoglycemia after 5 or more years of disease. As a result of the loss of hypoglycemia-induced glucagon secretion, patients with long-standing type 1 diabetes must rely on their hypoglycemia-induced catecholamine responses to detect a fall in their blood glucose and to attempt to restore euglycemia. However, many patients with diabetes and recurrent hypoglycemia may not experience hypoglycemia-induced catecholamine secretion and neurogenic symptoms until blood glucose has fallen below the level that causes neuroglycopenia and consequently develop the syndrome of hypoglycemia unawareness.

It is still uncertain which mechanisms are responsible for the pathogenesis of hypoglycemia unawareness. Some investigators have suggested that elevations in serum cortisol levels during and in response to hypoglycemia may somehow alter neuronal function so that the brain does not perceive additional reductions in glycemia. Other scientists

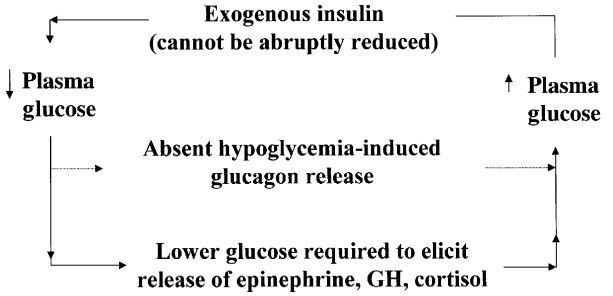

FIGURE 3 Hormonal responses to hypoglycemia in long-standing type 1 diabetes. Recovery from hypoglycemia is hampered in patients with long-standing type 1 diabetes by the inability to reduce blood insulin concentrations and an altered counterregulatory response.

have made observations that suggest that recurrent hypoglycemia may up-regulate brain glucose transport across the blood–brain barrier. If this does occur, the brain may maintain normal rates of glucose delivery and become unaware of the reduction in glucose experienced by the rest of the body during hypoglycemia until plasma glucose levels drop so low that glucose transport becomes the factor limiting brain metabolism. Regardless of the mechanism, which will eventually be defined, recurrent episodes of hypoglycemia within a sufficient short period of time appear to be of key importance. Many laboratories have demonstrated that recurrent hypoglycemia raises the glucose threshold (that is, lowers the plasma glucose concentration) at which counterregulatory hormone responses to hypoglycemia are elicited. Even brief episodes of hypoglycemia on the order of minutes have been shown to alter the counterregulatory response to an episode of hypoglycemia that occurs days later. Interestingly, the threshold at which cognitive dysfunction occurs is not altered as much by recurrent hypoglycemia as is the hormonal response, so patients can manifest symptoms of neuroglycopenia before they develop the adrenergic symptoms that should prompt the immediate ingestion of carbohydrate. Consequently, patients with hypoglycemia unawareness often become dependent on the assistance of others to overcome episodes of severe hypoglycemia.

Patients who are at particular risk for hypoglycemia can be identified by certain clinical characteristics, such as intensive insulin management, previous episodes of hypoglycemia, and a low hemoglobin A1c. However, none of these characteristics are very sensitive or specific in predicting which patients are at greatest risk for severe hypoglycemia. Although educating patients about the importance of carefully adjusting insulin doses for changes in meals and exercise is certainly of benefit in helping some patients avoid low glucose values, many episodes of hypoglycemia occur without any clearly defined departure from the usual management plan. If patients experience enough recurrent hypoglycemia to develop the hypoglycemia unawareness syndrome, relaxing the intensity of the insulin management and strictly avoiding any episodes of low glucose values will restore hypoglycemia-induced catecholamine secretion after a few weeks. Such patients also regain their neurogenic symptoms of hypoglycemia and thereby restore their ability to recognize and treat low blood glucose values before the development of neuroglycopenia.

Patients with type 2 diabetes appear to be at lower risk than patients with type 1 diabetes for the development of hypoglycemia. Such patients, at least those in the early stages of the disease who maintain adequate beta-cell function, retain the capacity to reduce their own endogenous insulin secretion when blood glucose levels fall. Consequently, they may be able to abort an episode before it begins, just as healthy subjects are able to do in response to mild hypoglycemia. Hypoglycemia-induced glucagon secretion also remains active in patients with long-standing type 2 diabetes so they may be able to restore euglycemia through this mechanism before neurogenic symptoms develop. Finally, patients with type 2 diabetes often are not managed as intensively as patients with type 1 diabetes and their average blood sugar levels may never even approach a normal level of glycemia. As patients and their health care team begin to appreciate the importance of controlling glycemia in type 2 diabetes, the risk of hypoglycemia in these patients may rise.

VI. CONCLUSION

Serum glucose values are maintained within in a narrow range by a careful balance between insulin and the hormones that oppose insulin's actions. To prevent hypoglycemia, the body has developed a complex and redundant system of responses that include a reduction in insulin secretion, an increase in the secretion of glucagon, epinephrine, growth hormone, and cortisol, and activation of the sympathetic nervous system. These responses are altered in patients with diabetes. The inability to protect

oneself from hypoglycemia has a profound impact on the lives of patients with diabetes. Not only do hypoglycemia and its attendant symptoms interfere with daily activities, severe hypoglycemia can cause death from arrhythmias and accidents. Fear of hypoglycemia has been called the primary factor limiting the intensity with which diabetes management can be applied. The fear is more than trivial. Multiple studies have now demonstrated that the risk of developing the microvascular complications of diabetes, and probably the macrovasular complications of diabetes as well, can be reduced by achieving near normoglycemia. Therefore, fear of hypoglycemia prevents patients from working to normalize their blood sugar levels and places them at risk for developing all of the long-term complications of the disease.

Glossary

counterregulatory responses Hormonal and neural responses to hypoglycemia that serve to restore blood glucose levels to the normal range.

epinephrine A catecholamine hormone released from the adrenal medulla in response to hypoglycemia.

glucagon A hormone secreted by the pancreatic alpha cell in response to hypoglycemia.

hypoglycemia A decrease in blood glucose concentration to below the normal level, which can generally be considered 65 mg/dl (3.6 mM).

hypoglycemia unawareness syndrome Occurs in some insulin-treated patients with diabetes who experience frequent bouts of hypoglycemia. Such patients are unable to mount a counterregulatory response to hypoglycemia or develop symptoms of hypoglycemia until blood glucose falls below the level at which neuroglycopenia occurs (generally below 40 mg/dl or 2.2 mM).

insulin A hormone secreted by the pancreatic beta cell in response to an increase in plasma glucose. It is used as a therapy for diabetes and can cause hypoglycemia.

neurogenic symptoms Occur as a result of hypoglycemia-induced epinephrine secretion and activation of the sympathetic nervous system and include rapid heart rate, tremulousness, and sweating.

neuroglycopenic symptoms Occur as a result of inadequate glucose delivery to the brain and include dizziness, confusion, seizures, and loss of consciousness.

target cells, replacing tissue lost at menstruation (in human; only a few other species menstruate). This corresponds to the proliferative phase of the endometrial cycle. Estrogen also triggers the expression of progesterone receptors in the endometrium. Luteinizing hormone rises to a peak, and approximately 36 h later ovulation occurs. In the luteal (postovulatory) phase of the ovarian cycle, both progesterone and estrogen are produced by steroidogenic cells comprising the corpus luteum. Progesterone, rising to a maximum in the midluteal phase, binds to receptors, producing changes in endometrium that prepare it to accept an implanting blastocyst. This part of the endometrial cycle is known as the secretory phase.

In humans, up to this point, the endocrine patterns of conception and nonconception cycles are similar, though circulating luteal phase estrogen and progesterone levels are somewhat higher in implantation than nonimplantation cycles. However, the next stages are quite distinct. If no pregnancy has occurred, progesterone begins to decline and the corpus luteum collapses, leading to menstruation, in which over three-quarters of the endometrium is shed. Alternatively, if an embryo is present, the trophectodermal cells and their immediate progeny (trophoblast) produce the polypeptide hormone chorionic gonadotropin, and this binds to receptors in the corpus luteum, rescuing it and ensuring a continuing rise in progesterone and the survival of the endometrium. In other species, survival of the corpus luteum is achieved by means of different signaling pathways.

The endometrial cycle is less well understood, at least as regards the key requirements for implantation. Rat and mouse endometria permit implantation for only approximately 24 h at day 4–5 of pregnancy, a period known as the implantation window. It is clear that this is maternally controlled, because unimplanted blastocysts recovered by flushing and transferred to receptive mothers give normal pregnancies. The precise hormonal requirements for implantation have been defined by replacing embryos in ovariectomized animals under various regimes of exogenous steroid. The required sequence is estrogen (E) followed by progesterone (P) and then estrogen plus progesterone. The E/P-primed uterus supports the survival of blastocysts in its cavity for a considerable time as long as daily progesterone is administered (this is known as delayed implantation), and a single dose of E during P stimulation is an absolute requirement for their implantation. This corresponds to the nidatory estrogen pulse in natural cycles. The postreceptive uterus is hostile to unimplanted embryos, which degenerate.

In human, assisted reproduction programs have generated much deductive data on implantation rates and optimal timing. It appears that the endometrium is receptive for approximately 4 days, from 7 to 11 days after the luteinizing hormone peak. This may well end when corpus luteum rescue is no longer feasible; that is, it is probably not controlled from the uterus. Thus, the risk of early pregnancy loss increases with later implantation from 13% on day 9 after ovulation to 82% on day 12 or later. It remains unclear whether luteal-phase estrogen production is required for implantation in human. In artificial cycles in women with premature ovarian failure, precise replication of the natural pattern of steroid is not required; for example, the follicular phase can be extended, and constant daily doses of estrogen and progesterone are often used. Furthermore, estrogen followed by progesterone alone is sufficient to support pregnancy, suggesting that the nidatory estrogen required in rodents may not be an absolute requirement for human implantation. However, the human embryo expresses the enzyme aromatase and may therefore be capable of producing its own estrogen, which could act locally on maternal cells at the implantation site. Rather low rates of pregnancy are achieved in women after embryo replacement, however (rarely over 50% and more usually 25% even in younger women). The reasons are discussed below.

Histological changes in the endometrium indicate the tissue's response to ovarian hormones, with the production in glands of glycogen and glycoproteins destined for secretion evident as early as 3 days after the luteinizing hormone (LH) peak. Secretion reaches a maximum 7 days after the LH peak, and bulbous apical plasma membrane swellings known variously as pinopodes or uterodomes appear at the surface of endometrial epithelial cells, surviving for approximately 2 days, dependent on expression of the homeobox gene Hoxa-10. At about this time, the stroma begins to become edematous. However, endometria from as many as 30% of normally fertile women show histological features that vary from the normal midluteal-phase phenotype. Provided that embryo quality is high (see below), some variation in the differentiation state of the endometrium is compatible with implantation. Numerous molecular changes that correlate with the receptive phase have been reported, but there is little evidence in either human or other animal species to throw light on the molecular interactions that attach the implanting

embryo to the endometrium. Indeed, this is one of the important unsolved problems of contemporary biology.

III. THE IMPLANTING EMBRYO

The development of assisted reproductive technology (ART) has led to the widespread practice of oocyte recovery, *in vitro* fertilization (IVF), embryo culture, single-cell preimplantation diagnosis, and embryo transfer. As a result, it has become evident that embryo quality is a major determinant of pregnancy outcome.

For reasons that are not understood, humans produce a high proportion of karyotypically abnormal embryos. Thus, it is estimated that 32% of oocytes, 8% of sperm, and 37% of embryos are aneuploid. By the first trimester of pregnancy, 8–10% of surviving embryos are aneuploid, and by term, the figure is only 0.6%. These figures indicate that a substantial proportion of aneuploid embryos fail to implant, fail to rescue the corpus luteum, or at least fail to progress beyond the earliest stages of development. Some specific chromosomal abnormalities—the monosomies and trisomy 1 are examples—have never been observed in postimplantation stages. Other abnormal karyotypes form blastocysts and implant but do not survive beyond the first trimester. Still others, such as trisomy 21, can survive to term, though even this relatively common abnormality shows approximately 80% prenatal selection. Women who suffer recurrent miscarriage produce higher numbers of aneuploid embryos than normal controls, pointing to ovarian function as a major element in reproductive failure.

Other embryonic attributes are also of major significance in pregnancy outcome. A high proportion of embryos fertilized *in vitro* suffer arrested development. Embryos that do reach the blastocyst stage are variable in terms of the total number of cells, their allocation to inner cell mass and trophectoderm, and the rates of apoptosis in these two compartments. Light microscopic techniques are not available to distinguish cell number and viability in living embryos. Though a low rate of apoptosis appears to be a common feature, it is clear that high levels cannot be compatible with normal development.

There is great interest in the issue of how cell number and partitioning are controlled in the developing embryo. Culture techniques have improved with increased understanding of the metabolic changes that occur during early development, from the relative quiescence of the cleavage stages to the metabolically active blastocyst with its high rate of glucose uptake. Replacement of embryos at the blastocyst stage has become a more widespread approach as it also allows preimplantation genetic studies to be carried out after removal of one or two cells at the cleavage stages. A two-stage culture protocol has been adopted with richer nutrient provision for later stages of development. If culture is carried out continuously in lower-nutrient medium, some embryos do develop to blastocysts, but implantation rates are reduced. Just as with the karyotype, the metabolic characteristics of morphologically normal blastocysts vary greatly, providing yet another strong indication that the ability of an embryo to develop to this stage does not guarantee successful pregnancy.

These issues are not the exclusive preserve of IVF practitioners wishing to improve pregnancy rates. Defining the influence of the maternal reproductive tract environment on the embryo's preimplantation development is just as important for pregnancies conceived without laboratory assistance. Studies of women who were pregnant during the Dutch famine of 1945 have shown that inadequate food intake in early pregnancy leads to small offspring. When female mice are exposed to a low-protein diet before mating and during the first few days of pregnancy, they produce small blastocysts (that is, with fewer cells). Even if the mothers are transferred to a normal diet for the remainder of pregnancy, these small embryos give rise to undergrown pups. Small size at birth, in addition to being associated with elevated childhood morbidity and mortality, increases the risk of high blood pressure, heart disease, and diabetes in adult life.

Superovulation cycles, frequently used in both ART and laboratory animals, produce lower pregnancy rates in both human and mouse in the context of much higher estrogen and progesterone. Though this has been taken as evidence of endometrial compromise (for example, histological abnormalities have been reported), blastocysts from superovulated mice are developmentally delayed and produce fewer and smaller pups after transfer to normally cycling foster mothers. High levels of estrogen also compromise the development of human embryos.

IV. THE ENDOMETRIUM AT IMPLANTATION

The classical model of estrogen acting on endometrial cells to stimulate progesterone receptor expression,

with progesterone then inducing differentiation and preparation for implantation, is an oversimplification, because receptor expression varies in a complex fashion in different cell types and tissue compartments in the uterus. The basal endometrium differs from the superficial or functional layer, and this is particularly significant in humans because it is the former from which postmenstrual regeneration occurs. These differences arise at least in part because of site-specific paracrine interactions between the epithelium and the stroma in regulating endometrial function, as established most elegantly in studies of mice lacking estrogen receptors. Epithelial proliferation in response to estrogen does not occur in estrogen receptor-α (ER-α)-negative stroma recombined with wild-type epithelium, but occurs normally if the receptor is present in the stroma and not in the epithelium. However, the control of expression of epithelial secretory substances such as mouse lactoferrin relies on the presence of the receptor in both the stromal and the epithelial compartments. The same principles apply to human endometrium; for example, in the secretory phase, progesterone stimulates progesterone receptor (PR)-bearing stromal cells to produce transforming growth factor-β (TGF-β), and this in turn suppresses the production of matrix metalloproteinase 7 (MMP7) by the epithelium in a progesterone-independent step. At the end of the cycle, progesterone levels fall and MMP7 contributes to extracellular matrix (ECM) remodeling during menstruation.

Endometrium in both mouse and human expresses the estrogen receptor variant ER-β, though at lower levels than ER-α. Ablation of ER-β in mice compromises reproductive function, and current evidence suggests that it may act to modulate ER-α. Similarly, both progesterone receptor variants A and B, which arise by alternative splicing, are expressed and function as distinct transcription factors. PRB appears to have a role in epithelial proliferation.

Endometrial cells also express the androgen receptor (AR) and luteinizing hormone receptor (LHR). The AR can be expressed in stromal as well as epithelial cells but its functions in endometrial physiology have not been defined. Human chorionic gonadotropin (hCG) is a ligand for LHR, raising the possibility of a paracrine interaction with the embryo. Mice genetically altered to lack the LHR develop a very small uterus. When steroid replacement is undertaken, the uterus grows back to a normal size and histological features are fairly normal, though fewer glands are present. Embryos replaced into these mice, however, produce no pregnancies. At present, the explanation for this infertility is not clear. In human, there is evidence to suggest that hCG treatment in the luteal phase advances endometrial differentiation.

Glands are a feature of the endometrium in most species and are responsible for secreting substances that act either on the endometrium itself or on the embryo. This is discussed further below.

Angiogenesis occurs in endometrium during postmenstrual regeneration, and then the differentiation of spiral arteries occurs in the late secretory phase or during decidualization. These arteries are further modified during pregnancy to become wide, passive channels for the uninterrupted supply of large amounts of maternal blood to the placenta.

V. THE EMBRYO–ENDOMETRIAL DIALOGUE

Growth factors secreted in response to estrogen and progesterone from both oviductal and endometrial epithelia contribute to the milieu of the developing embryo. Numerous factors, including insulin, leukemia inhibitory factor (LIF), and heparin-binding epidermal growth factor (HB-EGF) have been shown to increase either the rate of embryo development to blastocyst stage or the size of the blastocyst during culture *in vitro*. The complexity of biological fluids and the large range of factors that have been detected make it difficult to establish the contribution made by individual components *in vivo*, and detailed discussion lies beyond the scope of this article. However, studies in genetically modified mice are proving effective in overcoming this problem. Granulocyte/macrophage colony-stimulating factor (GM-CSF) is produced by the uterine epithelium. Secretion is stimulated by estradiol, but more strongly by TGF-β_1, which is abundant in seminal plasma, suggesting a role for male tract secretions in the preparation of the female tract for pregnancy. The embryo expresses a GM-CSF receptor, indicating the potential for a preimplantation interaction with maternal secretions. Indeed, mice genetically altered to lack GM-CSF produce blastocysts with fewer cells in the ICM, and these give rise to small pups. The most extreme phenotype is associated with the absence of GM-CSF from both the maternal and the embryonic genotypes, indicating that partial rescue is possible from either direction. The defect can be rescued by culturing null preimplantation embryos in medium supplemented with GM-CSF before replacement. Human embryos

also contain GM-CSF receptors, indicating the possibility of a similar mechanism.

Delayed implantation is a phenomenon observed in a wide variety of animal species in which the embryo develops as far as the blastocyst stage, but then enters metabolic quiescence, sometimes for periods of several months. This is useful in seasonally breeding species; for example, in American black bears, ovulation occurs in June, with the blastocyst remaining in the uterine cavity until early December. Thus, quiescence is induced in the blastocyst for approximately 5 months. The dormant blastocyst is released by a process known as activation, so that implantation is timed to allow the offspring to maximize their growth before the arrival of the next winter season. There is little clear evidence that delayed implantation occurs in human, though sporadic reports of follicular phase implantation have prompted speculation to this effect.

Studies of delayed implantation in mouse are important for the light they have thrown on the subtle maternal–embryonic dialogue of early pregnancy (see Table 1). In the presence of progesterone, dormant blastocysts remain closely apposed to the uterine epithelium but do not attach. Estrogen treatment produces a receptive state in the uterus and also activates the embryo. However, the latter occurs by an indirect mechanism. Estradiol induces uterine receptivity, whereas the embryo is activated by a catecholestrogen, 4-hydroxyestradiol-17β, produced locally in the endometrium as a metabolite of estradiol.

Calcitonin is an endometrial gland cell secretory product expressed in response to progesterone just prior to implantation, and it is important for pregnancy outcome in rodents, as indicated by a reduction in implantation rates if maternal expression in rats is blocked using antisense oligonucleotide. Calcitonin acts on the preimplantation embryo by binding a G-protein-coupled receptor, triggering an increase in intracellular calcium, activation of adenyl cyclase, and expression of the fibronectin receptor, integrin α5β1. Binding to fibronectin in the maternal stroma is likely to be important in trophoblast invasion in the postimplantation phase.

The epidermal growth factor family is involved in the embryo–endometrial dialogue. This includes six related ligands that interact with four erbB receptor tyrosine kinases. The ligands amphiregulin, epiregulin, β-cellulin, neuregulin, and HB-EGF are all induced in the endometrial mouse lumenal epithelium in the preimplantation phases of pregnancy. HB-EGF appears in epithelial cells immediately adjacent to the implanting embryo just 6–7 h before the embryo attaches. In delayed implantation, HB-EGF appears only after the nidatory estrogen stimulus is given. HB-EGF has been suggested to play two different roles; in addition to accelerating embryo development, it has a membrane-bound variant that can mediate intercellular attachment by binding to erb-B4 and heparan sulfate proteoglycan, both of which are present on the blastocyst.

VI. ATTACHMENT AND INVASION MECHANISMS

Before an embryo can attach to the uterine surface, it must hatch from the zona pellucida. This is an outer glycoprotein capsule that is present from the time the oocyte is ovulated. Two serine proteases, ISP1 and ISP2 (implantation serine proteases 1 and 2), have been implicated in hatching. ISP1 is produced by the embryo, whereas ISP2 is produced by uterine glands. These enzymes may also be required for local proteolysis of maternal tissue as part of the process of invasion.

The maternal surface is specifically nonreceptive except during the window phase. Like other epithelial surfaces, it contains an apical glycocalyx

TABLE 1 Molecular Pathways Identified in Mouse Implantation

Stage of implantation	Molecular signals
Embryo development or activation (see text)	Catecholestrogen, calcitonin, EGF family ligands? LIF, GM-CSF
Barrier withdrawal	Loss of Muc1 (and Muc4 in rats)
Apposition	Cell surface glycans? HB-EGF?
Attachment	Unknown
Decidual stimulus	LIF, prostaglandin (PG12), EP3, EP4, PPARδ, Hoxa-10, Hoxa-11, Hmx3, IL11R
Epithelial apoptosis	Fas?
Early trophoblast invasion	β1 integrins, maternal ECM, MMPs

(thick glycoprotein coat) that allows the diffusion of small molecules but inhibits cell adhesion. In this way, it acts as a component of the innate immune system, protecting the upper female tract from infectious agents. The cell surface mucin MUC1 is a component of the uterine glycocalyx. In mice and rats, Muc1 is down-regulated precisely at the time of implantation under the control of maternal steroids. There is evidence that another mucin, Muc4, is also down-regulated in rodents. In contrast, humans express high levels of MUC1 throughout the receptive phase. Experimental studies of human implantation in which embryos hatch and attach to endometrial epithelial cells in monolayer culture have shown that MUC1 disappears from a small area of cells that surround the attached embryo (Fig. 1). Maternal cells farther away continue to express the glycoprotein, thus presumably maintaining their barrier property and minimizing the access of pathogens to the underlying tissue and vasculature. The mechanism by which MUC1 disappears has not been established, but the phenomenon indicates that there is a highly localized dialogue that occurs between embryonic and maternal cells.

Apposition of the embryo to the epithelium and intercellular attachment between the trophectoderm and the uterine epithelial cells then occur. Though several adhesion molecules have been identified at these two surfaces, and it is likely that a cascade of adhesion events is required, the molecular details have not been worked out. In species including farm animals, the embryo attaches to the uterine epithelial surface and remains in the uterine cavity. In contrast, mouse and human have interstitial implantation, in which the embryo crosses the epithelium, and the placenta, once developed, makes direct contact with maternal blood (hemochorial). In mice, attachment to the maternal epithelial surface is followed by apoptosis of the epithelial cells, thus allowing the trophoblast direct access to the underlying basement membrane and stroma. In human, it is thought that intrusive penetration of the epithelium is followed by its displacement, but there is also evidence for apoptosis triggered by interaction between the Fas ligand on the trophectoderm and Fas on the uterine lumenal epithelium.

Binding to the extracellular matrix in the maternal stroma is important at the next stage; the trophoblast expresses integrins, cell surface adhesion molecules that act as receptors for ECM ligands. Mouse embryos genetically modified to lack integrin β1, a polypeptide subunit that dimerizes with a family of α chains to produce a wide repertoire of ECM

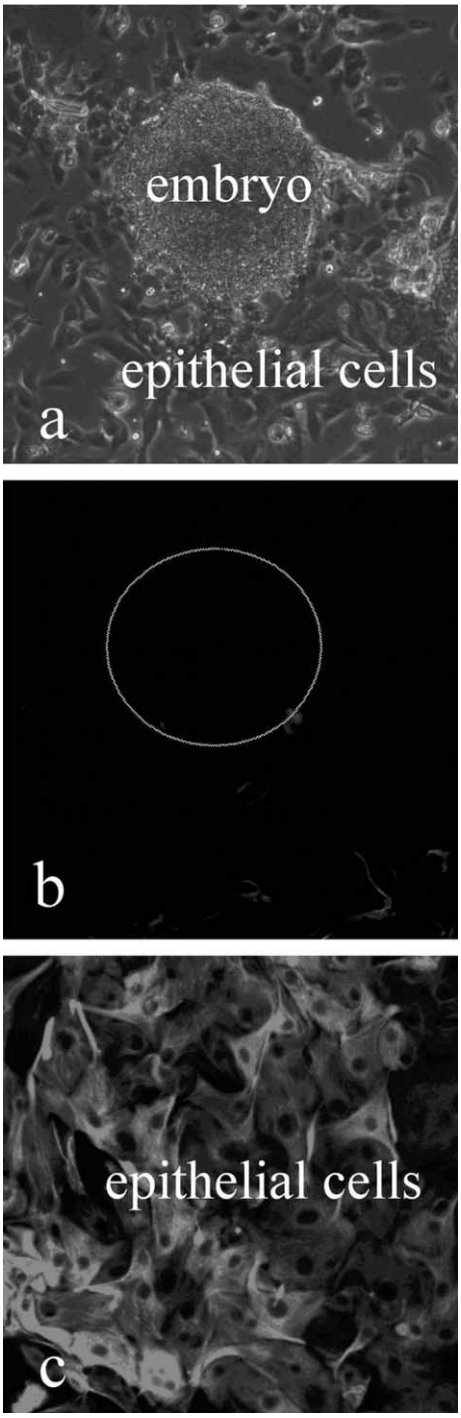

FIGURE 1 (a) Human embryo attached to a cultured endometrial epithelial monolayer with (b) MUC1 imunolocalization in the same field. (c) MUC1 localization in the same culture but distal to the site of embryo attachment. Clearance of MUC1 from epithelial cells in the vicinity of the embryo is evident. receptors, fail to complete implantation, probably because they lack the ability to bind the maternal ECM. Local tissue remodeling is also necessary, and a balance between matrix metalloproteinase activity and its inhibition is established. If disturbed by experimental elevation of TIMP activity at the implantation site, morphological abnormalities of placentation result, though the effects on pregnancy outcome have not been tracked.

VII. DECIDUALIZATION: THE POSTIMPLANTATION ENDOMETRIUM

Decidualization is a change that occurs in the endometrial stroma of pregnancy in which the resident fibroblasts enlarge, extend processes to contact neighboring cells, acquire an increased cytoplasmic-to-nuclear ratio, and produce a distinctive range of secretions. Glandular epithelial cells become hypotrophic. The extracellular matrix undergoes remodeling, with the loss of bundles of fibrillar collagen and (in human) the appearance of capsular basement membrane around the decidualizing stromal cells. The proportion of immune cells increases; after decidualization, as many as 35% of the cells present are derived from bone marrow, and these comprise predominantly macrophages and an unusual type of large granulated lymphocyte with some natural killer cell-like features. There are also a few T cells and mast cells. Steroid hormones govern the abundance and phenotype of immune cells by regulating local cytokine and chemokine synthesis. Tolerance is required in the maternal immune system to paternal antigen in the embryo, but it must continue to provide resistance to pathogens. Several mechanisms operate in parallel to achieve these aims, but their description lies outside the scope of this article.

By and large, stromal decidualization occurs only in species that undergo interstitial implantation, and the timing and extent of the changes are species-dependent too. In human, decidual changes are evident in the late secretory phase of nonpregnant cycles, and under chronic contraceptive progesterone stimulation, the endometrium becomes fully decidualized. Thus, decidualization can occur independently of embryonic signals. Embryos implant into an undecidualized stroma, with decidualization occurring during the following few days. In contrast, in the mouse and rat, attachment of the embryo to the anti-mesometrial uterine lumenal epithelium initiates a signaling process in steroidally sensitized endometrium that triggers decidualization. Similar changes (known as deciduomata) can be elicited in hormonally sensitized mice, by a mechanical insult to the uterine lumen or by instillation of an irritant such as oil. During days 5–8 of pregnancy, decidual changes spread from the subepithelial anti-mesometrial stroma into deeper anti-mesometrial regions and then spread laterally, eventually including the mesometrial stroma. The anti-mesometrial and mesometrial decidual cells have distinct secretory repertoires.

It is likely that the early decidual changes create a maternal environment in which paracrine support is provided for the conceptus by local secretory activity, before a hemochorial placenta is established with the capacity to extract nutrients directly from maternal blood. Several maternal decidual secretory components—prolactin (PRL) and TGF-β are examples—are found in amniotic fluid. Much remains to be done to define the precise function of decidua in relation to the developing conceptus. However, genetic manipulation of mice has given useful insights into the signaling pathways through which decidualization is mediated, as well as providing clear evidence that decidual differentiation in early pregnancy is a critical requirement for successful outcome (Table 1).

Cox-2 is one of two cyclooxygenases that catalyze the rate-limiting step in prostaglandin production. The uterine stroma does not decidualize in mice lacking Cox-2, and implantation fails. This phenotype appears to result from lack of prostacyclin, the effects of which are mediated by activation of the nuclear hormone receptor peroxisome proliferator-activated receptor-δ (PPAR-δ).

Hoxa-10 and Hoxa-11 are adjacent homeobox genes that are expressed in the developing genitourinary tract and induced by progesterone in the adult uterus during early pregnancy. Defective implantation and decidualization occur in the absence of either maternal Hoxa-10 or Hoxa-11. Hoxa-10 expression is required for the development of epithelial pinopodes, suggesting an early role in the implantation cascade. Hoxa-11 expression is normally regulated by progesterone in Hoxa-10 null mice. Steroid-dependent stromal cell proliferation is reduced in Hoxa-10 knockouts, with a lower level of cyclin D3 in stroma 1 day after the initiation of decidualization. Cox-2 induction in stroma is significantly reduced in Hoxa-10 null mice; however, decidualization cannot be restored by prostaglandin treatment, probably because two prostaglandin receptors, EP3 and EP4, are aberrantly expressed and inappropriately regulated by progesterone in the stroma. This suggests that

Hoxa-10 mediates steroidal regulation of EP3 and EP4. However, expression of several other progesterone-regulated gene products is identical in wild-type and Hoxa-10 mutant mice.

Ablation of expression from another homeobox gene, Hmx3, results in the failure of decidualization and infertility, despite normal ovulation and fertilization. The major site of expression of Hmx3 is in myometrium, where localization is largely anti-mesometrial on day 4.5 of pregnancy, immediately before the onset of decidualization in the overlying anti-mesometrial stroma. These data raise interesting speculation about the possibility of cross talk between the myometrium and the endometrium in regulating differentiation.

Uterine cells in LIF null mice do not decidualize, either in pregnancy or in response to artificial stimuli applied in pseudo-pregnancy, and the females are infertile. Thus, wild-type embryos transferred to LIF null females fail to implant, and LIF null blastocysts transferred to wild-type females progress to term and produce $-/-$ adults. LIF up-regulation in glandular epithelium is abolished in Hmx3 and Hoxa-11 knockout mice, indicating that LIF is downstream of these two gene products. Expression of LIF, in contrast, is unaffected in Hoxa-10 nulls. The LIF and prostaglandin pathways converge in the initiation of decidual changes in stromal cells.

IL-11 is important at a slightly later point in mouse decidualization. Inactivation of the gene encoding the unique α chain of the interleukin-11 (IL-11) receptor produces a phenotype in which the extent of decidualization is much reduced. At day 4.5 postcoitus, IL-11 is expressed in the primary decidual zone (the anti-mesometrial stromal region beneath the site of attachment) and the IL-11Rα is in the surrounding deeper stroma that later becomes secondary decidua. Both in pregnancy and in deciduoma, the null endometrium differentiates to form primary decidua but rather little secondary decidua, implicating IL-11 in the signaling pathway that amplifies and regulates the spatiotemporal expression of the decidual phenotype. As a result, hemorrhage occurs into the uterine lumen at day 6 and embryos are necrotic by day 9. However, the secondary trophoblast giant cell population expands to occupy the area that normally contains the mesometrial decidua. Trophoblast overgrowth in the absence of secondary decidua provides support for the hypothesis that the decidua plays some role in the restriction of trophoblast invasion.

Human endometrium contains Hoxa-10 transcript, IL-11, LIF, PRL, and prostaglandins but it is important in comparing the two species to bear in mind that although both require progesterone priming for decidualization, in the mouse it is initiated by a signal transmitted from the blastocyst to the uterine epithelium and then into the superficial anti-mesometrial stroma, whereas in human, decidualization occurs throughout the endometrium even in the absence of a conceptus. Thus, mechanisms for spatial and temporal regulation may be species-specific.

VIII. CONCLUSION

Is the improvement of implantation rates a suitable goal for medical research?

Miscarriage imposes a less severe biological burden than the evasion of natural selection by a fraction of abnormal embryos. High rates of early pregnancy failure in human reflect the high rate of embryo abnormality in our species and the fact that the optimal time period in which to select a healthy conceptus is the preimplantation and early postimplantation phases.

The quality of the preimplantation embryo is critical for optimal fetal development and the health of offspring. In mice, blastocysts that have larger numbers of cells go on to produce larger pups. Epidemiological evidence shows that low birth weight is a risk factor for high blood pressure (in rats and humans) and heart disease and diabetes (in humans). Facilitating the implantation of poor-quality embryos would be counterproductive if sustained good health into old age is an agreed aim. On the other hand, with high-quality embryos, pregnancy is possible in both infertile and postmenopausal women. This is not to argue that the uterus is a passive vehicle; instead, it is an active participant in a two-way molecular dialogue with the embryo, and this process itself contributes to embryo selection. Both uterine receptivity and embryo quality are influenced by locally produced growth factors and cytokines, and these in turn depend on cyclic alterations in steroid hormone production by the ovary. Improved endometrial receptivity can become a reasonable therapeutic objective when defective receptivity can be unequivocally specified as the cause of infertility.

Glossary

blastocyst Stage of embryo development at which implantation occurs.

decidua Endometrium of pregnancy.

endometrium Mucosal lining of the uterus.
estrogen One of the two major ovarian steroid hormones upon which implantation depends.
implantation Establishment of a stable tissue interface between the maternal endometrium and the embryo.
implantation window A restricted period of time during which the endometrium permits implantation of a competent blastocyst.
progesterone One of the two major ovarian steroid hormones upon which implantation depends.

Inhibin Receptor Signaling

DANIEL J. BERNARD

Center for Biomedical Research, Population Council and Rockefeller University, New York

Inhibins are dimeric endocrine hormones produced by the gonads that suppress follicle-stimulating hormone (FSH) production and release by the anterior pituitary gland. Activins are closely related proteins that stimulate pituitary FSH. Whereas the activins are known to bind a serine/threonine kinase receptor complex and to signal through intracellular proteins in the Smad family of transcription factors, the mechanisms of inhibin action are less well understood. Recent data indicate that the inhibins can bind with high affinity to activin receptors in the presence of a co-receptor protein, betaglycan. Thus, inhibins appear to act, at least in part, by blocking activin binding and thereby disrupting downstream signal transduction events.

I. INTRODUCTION

Inhibins are endocrine hormones produced in the gonads that regulate the synthesis and secretion of pituitary follicle-stimulating hormone. Two forms of inhibin, inhibin A and B, are produced and secreted by granulosa cells of ovarian follicles in female mammals. Inhibin B is also produced by testicular Sertoli cells and is the major circulating form of inhibin in adult males.

Although some data indicate that inhibins are synthesized within the adrenal gland, castration

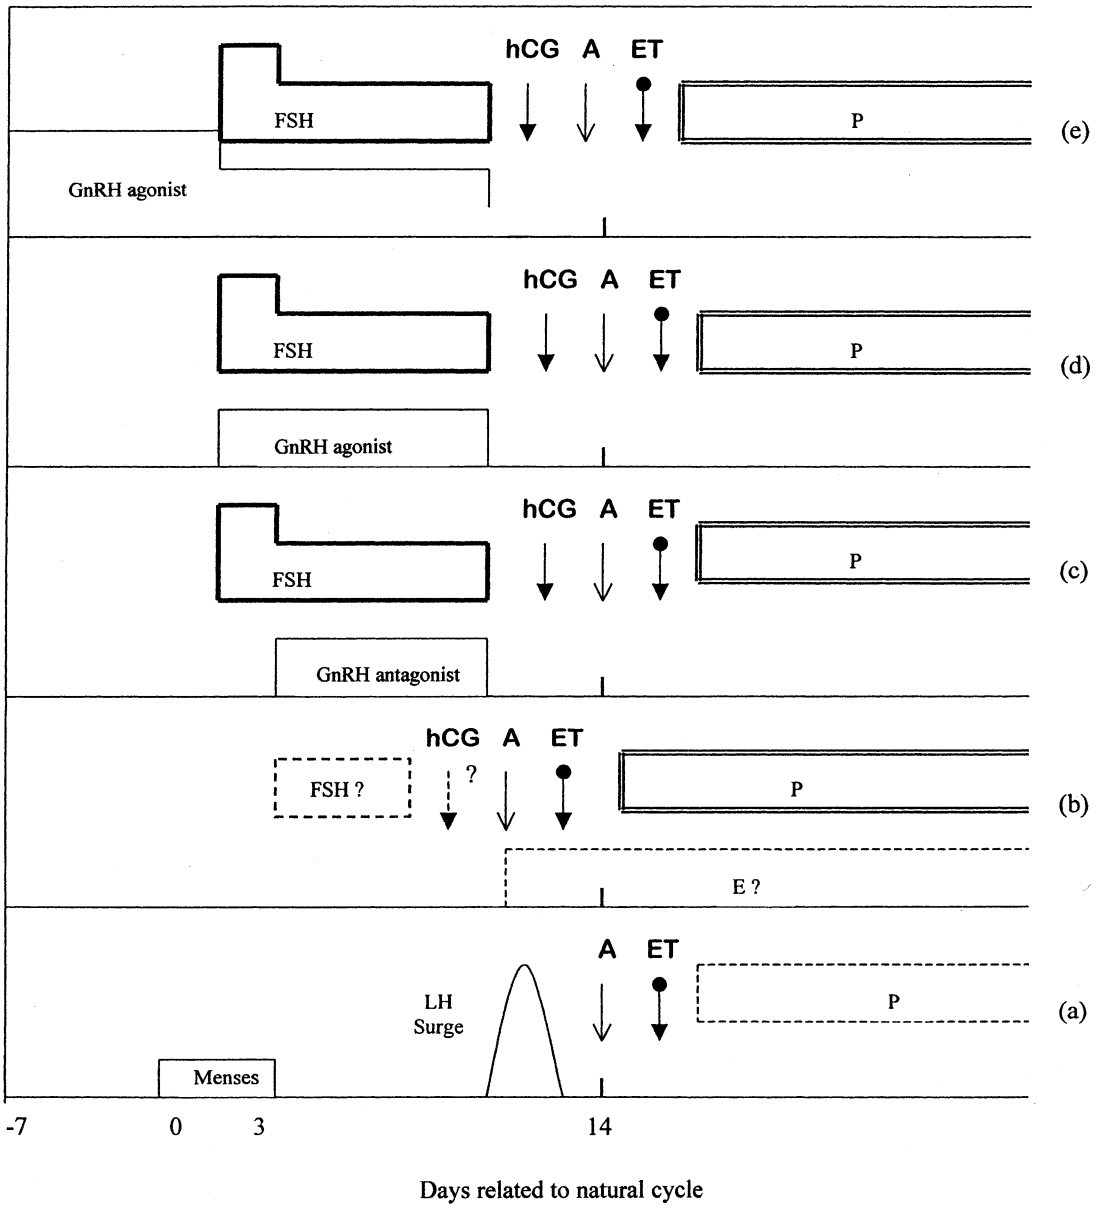

FIGURE 1 Five protocols for recovering oocytes for IVF and embryo transfer (ET): (a) the natural cycle requires the spontaneous LH surge to be detected before the single dominant follicle is aspirated (A); (b) *in vitro* maturation of oocytes (IVM) is based on a natural cycle, but may include mild gonadotropin stimulation and supplementation with estrogen (E) and progesterone (P); (c) GnRH antagonists and GnRH agonists using either the short protocol (d) or the long protocol (e) provide control over endogenous gonadotropins while exogenous FSH and hCG/LH are being administered.

mediators, such as insulin-like growth factor-I. Serum concentrations of FSH control the number of follicles surviving and are regulated by feedback from follicular estrogen and inhibin. FSH also promotes estrogen production by stimulating aromatase activity in granulosa cells, with androgen substrates being produced in the follicular theca under the influence LH ("two-cell theory"). Since follicle rupture occurs approximately 28 h after a natural LH surge or 36 h after administration of a luteinizing agent [LH or human chorionic gonadotropin (hCG)], oocyte collection must be timely; otherwise the oocyte and its cumulus cell envelope may be lost.

III. CONTROLLED OVARIAN STIMULATION

The use of drugs to induce multiple follicle development for IVF was pioneered in several centers, notably at Monash University in Australia and the Jones Institute in Virginia. Initially, clomiphene citrate was used to raise endogenous FSH levels by alleviating hypothalamic feedback suppression. This selective estrogen receptor modulator was replaced by injections of human menopausal gonadotropin, a semipurified urinary preparation containing approximately equal proportions of FSH and LH. When the additional follicles have grown to full size, they undergo preovulatory maturation in response to LH/hCG. In young ovaries, a crop of 8–10 follicles is normally generated, although patients with low follicular reserves respond as well to gonadotropins. Women with polycystic ovaries produce exaggerated responses, requiring careful monitoring and protocols with mild or no stimulation (Fig. 1b). Hormonal stimulation has undergone a technical evolution from the introduction of impure urinary FSH preparations to highly purified preparations to recombinant gonadotropins, and a meta-analysis confirmed the overall advantages of purified FSH.

IV. HYPOTHALAMIC DOWN-REGULATION

One of the drawbacks of superstimulation is that raised serum estradiol secretion can trigger a premature surge of pituitary LH and preovulatory follicular changes. As a consequence, treatment cycles may have to be cancelled, fewer oocytes are recovered, and pregnancy rates are lower. This problem has been overcome by suppressing the pituitary gland using long-acting gonadotropic hormone-releasing hormone analogues (GnRHa), and three types of protocol have now emerged (Figs. 1c–1e). The first GnRHa compounds that became available clinically were superactive agonists, which produce a "flare" release of LH and FSH before down-regulating the GnRH receptor and causing hypogonadotropism. In the long protocol, therapy is initiated in the luteal phase of the preceding cycle, and this has become the standard treatment (Fig. 1e). In the short protocol, treatment begins on day 2 or 3 of the cycle, around the time when FSH injections begin (Fig. 1d). Recently introduced GnRH antagonists lack serious allergic side effects and produce immediate inhibition of LH and FSH release. Treatment with antagonists can be shorter and avoid triggering hot flashes and, because the pituitary gland is less profoundly suppressed, less FSH may need to be administered. GnRH antagonists may eventually replace agonists in this role, although pregnancy rates have not improved.

V. COMPLICATIONS OF OVULATION INDUCTION

The hypothalamic–pituitary–ovarian axis has evolved feedback control mechanisms to prevent polyovulation and multiple pregnancy, which is risky for both mother and child. Administration of exogenous FSH bypasses these safeguards and carries the serious additional risk of ovarian hyperstimulation in which increased vascular permeability associated with multiple corpora lutea and excessive vascular endothelial growth factor causes an accumulation of ascitic fluid within the peritoneal cavity and, later, in the pleural cavity. Since this accumulation occurs at the expense of the intravascular space, there is a tendency toward hypercoagulability, thrombosis, oliguria, decreased organ perfusion, and alterations in electrolytes that can cause fatal cardiac arrhythmias. Another adverse side effect of ovulation induction and ovarian enlargement is the risk of ovarian torsion, possibly requiring surgical intervention and even the need to remove a gangrenous ovary.

VI. OOCYTE AND EMBRYO QUALITY

The oocyte is often the prime biological factor limiting IVF success. Oocytes and embryos have remarkably high incidences of chromosome abnormalities, including aneuploidy, polyploidy, mosaicism, and chaotic karyotypes. What is more, the frequency of aneuploidy rises with maternal age. The etiologies of these defects are not well understood, and it is doubtful whether changes in hormonal stimulation or embryo culture conditions will radically improve cellular defects originating during gametogenesis. Identifying euploid embryos with high implantation potential is a priority for the aim of single embryo transfer to be realized and for multiple pregnancy to be avoided. Preimplantation genetic diagnosis using fluorescence *in situ* hybridization for screening embryos after blastomere biopsy is becoming more widely used (Fig. 2). Another strategy is to prolong culture so that vigorous embryos with higher survival and implantation rates are self-selected.

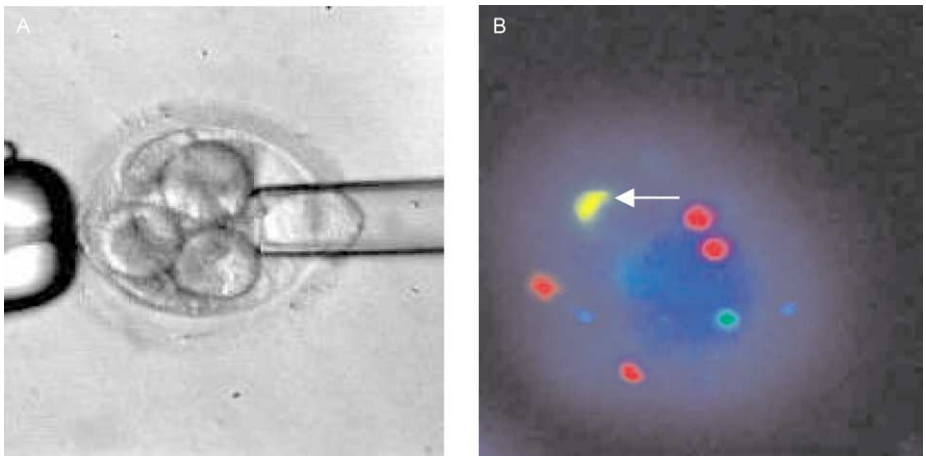

FIGURE 2 (A) A seven-cell human embryo, laser hatched using the Zona Laser Treatment System (Hamilton Thorne Research, Beverly, MA), demonstrating a biopsy of a nucleated blastomere. (B) Fluorescence photomicrograph of a nucleus from human blastomere (counterstained with DAPI). The nucleus has been evaluated by fluorescence *in situ* hybridization using alpha-satellite DNA-specific probes for chromosomes 13/21, 18, X, and Y (arrow).

VII. THE FUTURE

Assisted reproductive technology has expanded enormously in the past two decades and the year 2002 is reckoned to mark the birth of the millionth baby conceived by IVF. But pregnancy success rates have risen gradually, and the procedure remains costly and complex and carries some risks. Research is addressing all of these issues. After the recent introduction of recombinant FSH and LH, it is likely that long-acting gonadotropins will emerge from advances in molecular engineering. These agents will not require being administered as frequently and may, in turn, be succeeded by orally active molecules, which could completely eliminate the need for injections.

These innovations are unlikely to radically improve the control over multifollicular development and avoid ovarian hyperstimulation syndrome. However, women with polycystic ovaries, and perhaps others, could benefit from a procedure that is routinely used in animal breeding—*in vitro* maturation (IVM) of oocytes. Oocytes recovered early in the cycle at the germinal vesicle stage undergo spontaneous maturation and can be fertilized *in vitro*. IVM is being tested in clinical trials and has resulted in the birth of several dozen healthy babies. There is no standard protocol, and both unstimulated and hormonally primed cycles have been tested (Fig. 1b). Before the advent of clinical IVF and controlled hormonal stimulation, infertility pioneers envisaged that IVM might be necessary to generate oocytes for IVF, and this procedure could well play a larger role in the future if pregnancy rates are satisfactory.

Advances in cell biology are more likely than in endocrinology to underpin improvements in the quality of embryos so that fewer will need to be transferred and the multiple pregnancy rate can fall. Cytogenetic screens and biomarkers of embryo viability will become more important in the future, but it is less certain whether it will be possible, or safe, to rescue poor-quality oocytes or engineer them from somatic cells. The answers will emerge from ongoing studies of cytoplasmic transfer from donor eggs and induction of haploidy in somatic cell nuclei. Reproductive aging has become a key issue for many women who are deferring child-bearing until the less fertile years of life. Technology may enable them to elect to cryopreserve their immature oocytes as an insurance against infertility or premature menopause. Whatever happens, it is certain that the revolutionary conquest of infertility is continuing and will further increase individual freedom to control fertility.

Glossary

dominant follicle The ovulable follicle emerging during the menstrual cycle as a result of stimulation by follicle-stimulating hormone.

follicle stimulating hormone A pituitary polypeptide hormone that acts on granulosa cells to promote follicle survival and estrogen production.

gonadotropic hormone Polypeptide hormones that stimulate gonadal function.

gonadotropin-releasing hormone analogue A synthetic peptide molecule that binds to the gonadotropin hormone-releasing hormone receptor and possesses either antagonist or agonist activity.

intracytoplasmic sperm injection Fertilization of an oocyte by direct injection of a sperm into its cytoplasm.

luteinizing hormone A pituitary polypeptide hormone that promotes ovarian steroidogenesis and triggers ovulation.

oocyte retrieval A procedure for recovering oocytes by follicular aspiration using a needle guided by transvaginal ultrasound.

ovarian hyperstimulation syndrome A potentially life-threatening condition that is triggered by superovulation treatment of women with polycystic ovaries.

polycystic ovary An ovary containing numerous antral follicles, which is associated with a clinical profile varying from regular ovulatory cycles to anovulation with virilization (polycystic ovarian syndrome).

Iodine: Symporter and Oxidation, Thyroid Hormone Biosynthesis

KRISTA M.D. LA PERLE AND SISSY M. JHIANG
The Ohio State University

The thyroid hormones T3 and T4 are assembled in the thyroid follicular lumen through iodination of tyrosine residues within thyroglobulin by thyroid peroxidase and hydrogen peroxide. Iodide, an essential component of thyroid hormone, is delivered to the follicular lumen through the sequential actions of the sodium/iodide symporter at the thyrocyte–blood interface and the apical transporter pendrin. Numerous factors, either stimulators such as thyroid-stimulating hormone or inhibitors such as follicular thyroglobulin, regulate hormone biosynthesis and release. Defects occurring in any of these key molecules significantly

removes all detectable forms of inhibins. Thus, the gonads appear to be the primary source of circulating inhibins, at least under normal physiologic conditions.

In women, inhibins A and B are differentially regulated throughout the menstrual cycle (Fig. 1). During the luteal to follicular phase transition, follicle-stimulating hormone (FSH) secretion increases. This FSH signal is critical for recruitment of ovarian follicles that may ovulate during a subsequent cycle. Developing follicles produce inhibin B and estradiol, which feed back to the gonadotrope cells of the anterior pituitary to suppress FSH release. Whereas inhibin B levels are elevated during the follicular phase, inhibin A levels are low and increase just prior to the midcycle surges of FSH and luteinizing hormone (LH). Both inhibin A and B levels increase in association with the primary gonadotropin surges. Thereafter, inhibin B levels decline, but inhibin A levels remain elevated throughout much of the luteal phase. Increased secretion of inhibin A and progesterone suppresses FSH secretion during this stage of the cycle. In the absence of pregnancy, the corpus luteum degenerates, and inhibin A and progesterone levels decline. Circulating FSH levels begin to increase in the absence of these potent negative feedback signals and the cycle repeats as a new follicular phase commences.

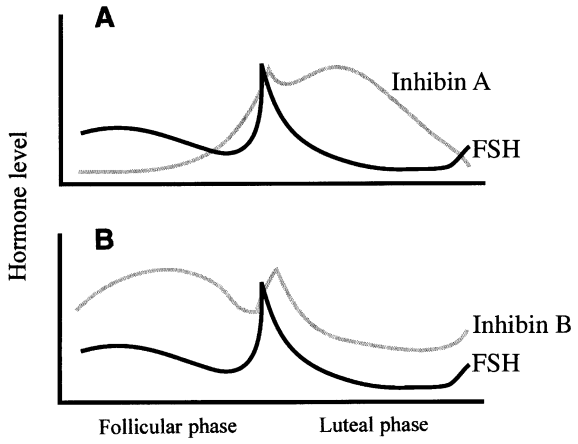

FIGURE 1 Schematic representation of circulating inhibin A (A), inhibin B (B), and FSH levels across the human menstrual cycle. FSH levels are shown in both plots as a solid black line. Inhibin levels are in gray. Inhibin A is elevated during the luteal phase and, along with progesterone, suppresses FSH secretion during this stage of the cycle. Inhibin B levels are produced by developing ovarian follicles in response to FSH stimulation and are elevated during the follicular phase. The secondary "surge" of FSH observed during this stage of the cycle is suppressed by inhibin B and estradiol.

Similar to the situation in women, female rats exhibit differential patterns of inhibin A and B secretion throughout their reproductive cycles. During the first 2 days of the 4-day estrous cycle (metestrus and diestrus), inhibin B levels are elevated and FSH levels are low. Inhibin B levels begin to decline the following day on proestrus, prior to primary gonadotropin surges (which occur on the afternoon of proestrus). Inhibin A levels are low on metestrus and increase gradually until their peak on the afternoon of proestrus. Both inhibin A and inhibin B are low on the morning of estrus, allowing a secondary surge of FSH to occur. This selective increase in FSH is necessary for recruitment of ovarian follicles that may subsequently ovulate and is analogous to the follicular-phase FSH rise observed in humans.

In adult men, inhibin B appears to be the most potent endocrine regulator of FSH secretion. Indeed, FSH and inhibin B levels are negatively correlated and FSH stimulates inhibin B production. Sertoli cells are thought to be the main source of circulating inhibin B, and germ cells are clearly involved in inhibin B regulation. Sperm count and inhibin B levels are positively correlated and men with spermatogenic defects show diminished inhibin B secretion in response to elevated FSH.

II. STRUCTURE OF THE INHIBINS

Inhibins are members of the transforming growth factor-β (TGF-β) superfamily of growth and differentiation factors. They are produced through the dimeric assembly of an α-subunit (inhibin α) with one of two β-subunits (inhibin β_A or inhibin β_B) (Fig. 2). Dimers of α-β_A and α-β_B form inhibin A and inhibin B, respectively. Inhibin α is produced as a preprohormone (Fig. 2). In humans, the carboxy-terminal 134 amino acids of the 366-amino-acid precursor constitute the "mature" α-subunit (αC). There are three potential N-linked glycosylation sites within the α-subunit, one in the pro region (N146) and two in the mature domain (N268 and N302), and biologically active inhibins appear to be mono- or diglycosylated. The α-subunit can be secreted in multiple forms both alone and in association with β-subunits. In fact, free α-subunit isoforms (e.g., pro-αC and pro-αN-αC) appear to be secreted in excess of inhibin dimers but are biologically inactive. Biologically active forms of inhibin are composed of the mature region of inhibin α disulfide linked to the mature region of one of the two β-subunits (see below and Fig. 2).

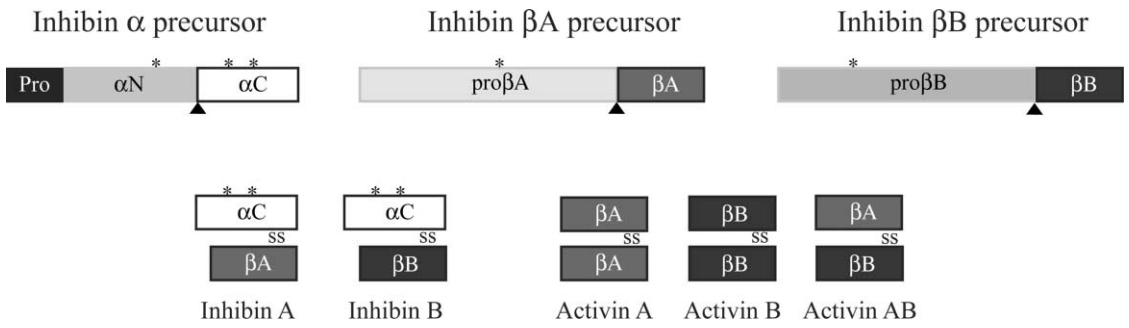

FIGURE 2 Structure of inhibins and activins. Inhibins and activins are dimeric proteins produced through the assembly of subunit proteins. Inhibin A and inhibin B are produced through the disulfide bonding of the mature region of the inhibin α-subunit (αC) with the mature regions of the inhibin βA- and inhibin βB-subunits, respectively. The inhibin β-subunits are produced as prohormones. The mature regions are cleaved from the carboxy-termini of the precursor proteins (shown at the top). Activins A, B, and AB are produced through dimerization of the mature regions of the β-subunits. The pro regions of the precursors appear to be critical for dimerization but must be cleaved for biological activity of the hormones. Arrowheads indicate where the mature domains are cleaved from the pro regions. Asterisks indicate putative N-linked glycosylation sites. Disulfide bonds are indicated by "ss." Note that other (intermediate) dimeric forms of the inhibins and activins, which include the pro and/or αN domains, are also produced but are not pictured here.

The β-subunits share high sequence similarity with one another but are transcribed from different genes. Both β-subunit proteins are produced as prohormones and are proteolytically cleaved to produce the mature β-subunits (Fig. 2). As described for the α-subunit, the C-terminal domains of the β-subunits (115 or 116 amino acids) represent the mature parts of the proteins and cleavage of the pro region is necessary for biological activity. Both β-subunits can be glycosylated in the pro regions, but not in the mature regions, of the proteins.

The mature β-subunits possess the nine conserved cysteines characteristic of ligands within the TGF-β superfamily. Eight of the cysteines form four intrachain disulfide bonds and the ninth cysteine is involved in dimerization, forming an interchain disulfide bond. The mature α-subunit contains seven cysteines, six of which likely form three intrachain disulfide bonds, with the seventh involved in dimerization. The crystal structures of the activins and inhibins have not yet been solved, but based on structures of other superfamily ligands as well as mutagenesis analyses, cysteine 95 of α, cysteine 80 of β_A, and cysteine 79 of β_B are implicated in interchain disulfide bonding.

The β-subunits can also homo- and heterodimerize to form activin A, activin B, and activin AB (Fig. 2). Activins were first identified during the purification of inhibins and were shown to stimulate pituitary FSH secretion. Thus, despite sharing β-subunits, activins and inhibins have opposing actions, at least at the level of the pituitary gonadotrope. Activins were subsequently shown to have diverse biological functions both during development and in adulthood. Although inhibins appear to function outside of the reproductive axis, their best understood role continues to be that of FSH regulation.

Two additional β-subunits, β_C and β_E, have been described in mammals. These subunits can homodimerize to form activin C and activin E and can heterodimerize with each other and the β_A- and β_B-subunits to form various activin isoforms. However, there is no evidence that either β_C or β_E can dimerize with the inhibin α-subunit. Moreover, these subunits are most highly expressed in liver and do not appear to play any role in mammalian reproduction.

III. ACTIVIN SIGNALING MECHANISMS

Since the molecular characterization of the inhibins in 1985 and of the activins the following year, much more has been learned about the mechanisms of activin, than of inhibin, signal transduction (Fig. 3). The relative disparity in knowledge stems mainly from the 10-year gap between the identification of the first activin receptor and the identification of the first inhibin receptor (see below). In 1991, the first activin type II receptor (now referred to as ActRIIA) was cloned from a mouse corticotropic cell line. The receptor was shown to be a membrane-bound serine/threonine kinase and its identification facilitated the rapid characterization of similar receptors for other

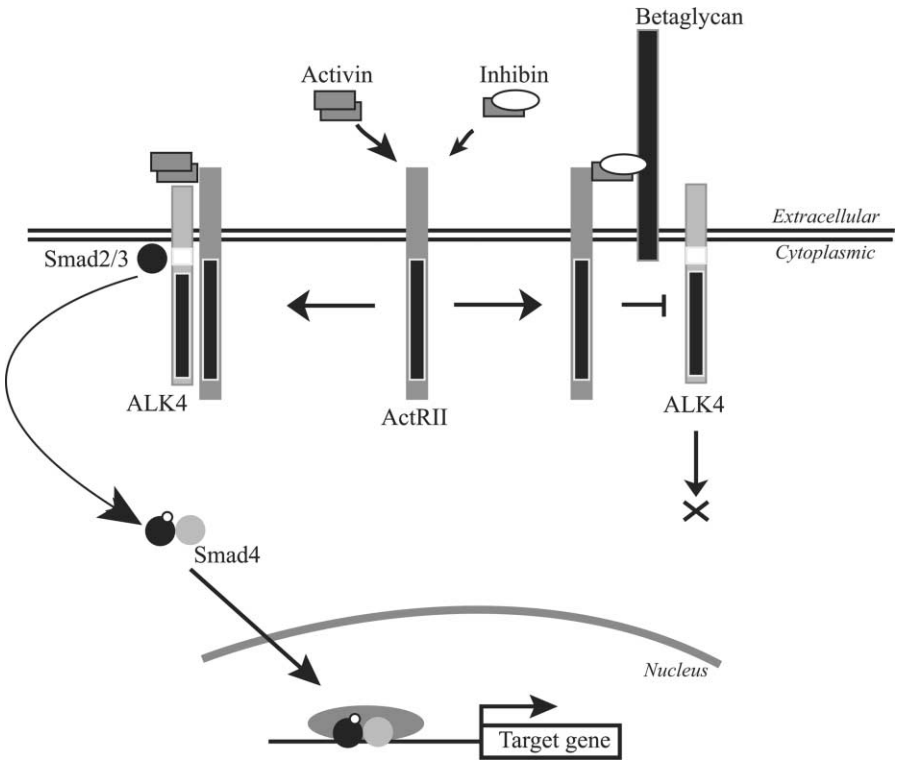

FIGURE 3 Mechanisms of activin signaling and inhibin antagonism. Activins bind one of two activin type II receptors (shown generically as ActRII in the figure). Upon activin binding (left part of the figure), the activin type IB receptor (ALK4) is recruited into the complex and phosphorylated by the serine/threonine kinase domain of ActRII. ALK4, also a serine/threonine kinase, then phosphorylates the intracellular signaling molecules, Smad2 or Smad3. Phosphorylated Smad2/3 dissociates from ALK4 and associates with the co-Smad4 in the cytoplasm. The activated Smad complex then translocates to the nucleus where it interacts with co-factor proteins to stimulate or repress target gene transcription. Inhibins also bind ActRII but do so with lower affinity than the activins. In the presence of the co-receptor betaglycan, inhibins bind ActRII with high affinity. ALK4 is not recruited into the complex and downstream Smad-dependent signaling does not occur. This provides a powerful mechanism for inhibins to antagonize the actions of the activins. The black rectangles in ActRII and ALK4 denote the approximate locations of the kinase domains. The white box in ALK4 indicates the glycine-/serine-rich region in which ALK4 is phosphorylated (and activated) by ActRII. The white circle on Smad2/3 indicates that the protein has been phosphorylated.

ligands within the TGF-β superfamily, although not for the inhibins.

There are two types of ligand-binding activin type II receptors, ActRIIA and ActRIIB, which are produced by different genes. At least five splice variants of ActRIIB and two of ActRIIA have been described. These receptors bind activin A with high affinity (~100–400 pM). Upon ligand binding, the activin type IB receptor (also known as activin receptor-like kinase 4, ALK4) is recruited into the complex and is phosphorylated in a glycine-/serine-rich region of its intracellular domain by the constitutively active kinase domain of the type II receptor. This phosphorylation activates the catalytic domain of ALK4, which also has serine/threonine specificity. ALK4 then phosphorylates serine residues at the carboxy-termini of two members of the Smad family of transcription factors, Smad2 or Smad3, which are anchored in the vicinity of the type I receptor by membrane-associated proteins (not pictured in Fig. 3).

Phosphorylation of the Smads causes a conformational change that precludes their association with both ALK4 and the anchoring proteins, and they are "released" within the cytoplasm. Phosphorylated Smad2 or Smad3 then associates with the partner or co-Smad, Smad4. The Smad complex translocates to the nucleus to affect target gene transcription. The carboxy-terminal domain (also known as the Mad homology 2 or MH2 domain) of Smad2 and Smad3 has transactivation function and associates with the transcriptional co-activator proteins CREB binding

protein and p300. The N-terminal MH1 domains of Smad3 and Smad4, but not Smad2, can bind DNA, although they do so with low affinity and low specificity. Instead, Smads interact with DNA-binding transcription factors that recruit the activated Smad complex to distinct promoter elements within target genes. Although many of the details of the "generic" activin signaling pathway have been characterized, the specific mechanisms through which activins stimulate FSH have not yet been described.

Other members of the TGF-β superfamily, including TGF-β_{1-3}, Müllerian inhibiting substance, and bone morphogenetic proteins, use a similar dual-receptor and Smad signaling system to convey signals to target cells. To date, there is no evidence to suggest that inhibins signal in this way, and attempts to identify receptor serine/threonine kinases that specifically bind inhibins have been unsuccessful. As a result, one current model of inhibin signaling posits that inhibins do not generate intracellular signals but rather generate their effects by blocking the actions of activins through competition for binding to the activin type II receptors (see below and Fig. 3). In the case of FSH synthesis and release, activin B produced locally within gonadotropes appears to stimulate FSH production through an autocrine or paracrine loop. Inhibins from the gonads may therefore act by blocking the intrinsic stimulatory effect of activin B.

IV. INHIBIN ANTAGONISM OF ACTIVIN SIGNALING

One way that inhibins may exert their biologic effects is by competing with activins for binding to the activin type II receptors. Inhibins can bind both ActRIIA and ActRIIB. This binding appears to occur through the β-subunits of the inhibins. At least in the case of mouse ActRIIA, activin A and inhibin A have been shown to bind to the same hydrophobic amino acids of the receptor (phenylalanine 42, tryptophan 60, and phenylalanine 83). Unlike the case for activins, when inhibins bind the type II receptor, ALK4 is not recruited to the complex nor is it phosphorylated. As a result, when inhibins are bound to the type II receptors, activin signaling can be blocked.

This model, although appealing in its parsimony, does not account for all inhibin actions, however. In particular, inhibin appears to have 10-fold lower affinity for activin type II receptors than does activin A, suggesting that inhibins must be in molar excess of activins to exert their antagonistic effects. Yet, inhibins are known to antagonize activin actions in some contexts where the two ligands are present at equimolar levels. In addition, in other situations, inhibins are unable to antagonize activin actions, even when present in large molar excess quantities. Finally, several cell types, including ovine pituitary cells and testicular Leydig cells, express proteins that bind inhibins but not activins. Collectively, these data indicate that either inhibin receptors independent of activin type II receptors exist or co-receptor proteins are expressed that increase the affinity of the inhibins for activin type II receptors.

To date, there is no evidence that inhibins bind unique signal-transducing receptors. In 2000, however, betaglycan (also known as the TGF-β type III receptor) was shown to bind inhibin A, but not activin A, with high affinity. This membrane-tethered protein lacks any known intracellular kinase domains and therefore cannot generate intracellular signals. This protein is indispensable, however, for some forms of TGF-β signaling. There are three forms of TGF-β in mammals. Unlike TGF-β_1 and TGF-β_3, TGF-β_2 does not bind the TGF-β type II receptor, TβRII, with high affinity. However, in the presence of betaglycan, TGF-β_2 binds TβRII with an affinity similar to that of the other TGF-β ligands. Remarkably, in the presence of betaglycan, inhibin A binds ActRIIA with an affinity comparable to that of activin A, and the ternary complex between inhibin A, betaglycan, and ActRIIA appears to be resistant to disruption by activin A. Therefore, betaglycan provides a mechanism for high-affinity ActRIIA binding and, as a consequence, activin A antagonism. Whether this model of antagonism applies to inhibin B or to ActRIIB has not yet been reported.

Inhibin A binds to a juxtamembrane domain of betaglycan that shares high sequence conservation with the highly excreted protein uromodulin (the U-domain). This large domain is conserved in other proteins, including the sperm receptors ZP2 and ZP3. Betaglycan is expressed in a variety of tissues and cell types, including some not known to be inhibin responsive. Importantly, however, it is expressed in the anterior pituitary gland and specifically within FSH-producing gonadotropes. Thus, betaglycan is expressed in a manner consistent with its putative role in inhibin's *in vivo* regulation of FSH; however, such a role has not yet been confirmed experimentally.

V. ALTERNATE MECHANISMS OF INHIBIN ACTION

It is not yet known whether inhibins act exclusively via betaglycan and activin type II receptors to exert all of their cellular effects. It is possible that (1) inhibins

bind other co-receptors that increase binding affinity to activin type II receptors or (2) inhibins bind novel receptors that transduce intracellular signals. Thus far, there are no reports in the literature that support the latter possibility. However, inhibin-binding proteins that are distinct from the activin type II receptors and betaglycan have been observed in pituitary, adrenal, testicular, and bone cells. Neither the identities of these proteins nor their mechanisms of action have yet been described.

At the same time that betaglycan was demonstrated to be an inhibin co-receptor, a second candidate inhibin receptor was also described. Inhibin-binding protein or p120 (InhBP/p120) was identified as an inhibin A-binding moiety by affinity chromatography from bovine pituitary membrane extracts. InhBP/p120 was further shown to be expressed highly in the pituitary gland in a variety of species, including rat, mouse, and rhesus monkey. Messenger RNA levels for InhBP/p120 in the pituitary fluctuate throughout the rat estrous cycle, so that levels are highest when circulating FSH levels are lowest and vice versa. Moreover, InhBP/p120 was shown to interact with ALK4 *in vitro* and to antagonize activin A signal transduction in the presence of inhibin B. Nonetheless, more recent analyses have failed to confirm that InhBP/p120 binds inhibin A or inhibin B directly. It is therefore unclear what role, if any, InhBP/p120 plays in inhibin biology *in vivo*.

VI. EXTRAPITUITARY ROLES OF THE INHIBINS

Although the inhibins are best understood in terms of their pituitary FSH regulation, they also play roles in the other parts of the body. In the ovary, inhibin A can stimulate follicle growth and can increase LH-stimulated androgen production by theca cells. Early reports indicated that inhibin A potentiated LH-stimulated testosterone production by testicular Leydig cells, but these results have not been observed consistently. In humans, inhibins are produced and secreted by the placenta throughout much of pregnancy, although the biological functions of placental inhibins have not been thoroughly described. Outside of the reproductive axis, inhibin A binds bone marrow cells *in vivo*, and *in vitro* it appears to inhibit both osteoblastogenesis and osteoclastogenesis. Adrenocortical cells can also produce inhibins, but the function of adrenal inhibins has not been elucidated.

Inhibins have been implicated as tumor suppressors, particularly in the mouse gonads and adrenal gland. Genetically modified mice that lack the ability to produce the inhibin α-subunit (and therefore inhibin A and inhibin B) developed sex cord stromal tumors. If these mice were castrated before the onset of gonadal tumorigenesis, they developed adrenocortical tumors with nearly 100% penetrance. A role for inhibins as tumor suppressors in human ovarian and adrenal cancers is less clear. Moreover, the effect of inhibin deficiency on tumor growth in mice may be indirect. Mice deficient in both inhibins and the gonadotropins (FSH and LH) fail to develop gonadal or adrenal tumors. These data suggest that dysregulated gonadotropin production (FSH production in particular) rather than inhibin deficiency per se may lead to tumor development in mice.

VII. SUMMARY

The gonadal inhibins suppress pituitary FSH synthesis and secretion. Inhibins A and B are released in discordant fashion and suppress FSH during the luteal and follicular phases of the human menstrual cycle, respectively. Inhibin B alone is produced by testicular Sertoli cells and is arguably the most potent gonadal regulator of FSH in men. Activins are structurally related to inhibins but have opposing actions. That is, activins stimulate pituitary FSH. Although the mechanisms by which activins affect FSH have not been thoroughly characterized, they appear to exert their effects through dual-receptor serine/threonine kinases and Smad proteins. Inhibins, on the other hand, do not generate intracellular signals. Rather, they appear to act by abrogating activin signaling. Inhibins bind the activin type II receptors with high affinity in the presence of the co-receptor, betaglycan. This prevents activins from binding to their receptors and generating intracellular signals.

Glossary

betaglycan The TGF-β type III receptor that increases the affinity of inhibin A for the activin type II receptor.

dimeric protein A protein formed by the joining of two similar or identical proteins (or subunits).

follicular phase The approximately 2-week-long stage of the human menstrual cycle, prior to the luteinizing hormone surge, during which ovarian follicles develop prior to subsequent ovulation.

luteal phase The approximately 2-week-long stage of the human menstrual cycle, after ovulation has occurred,

during which the corpus luteum produces progesterone and inhibin A.

receptor serine/threonine kinase A cell surface protein that can catalyze the phosphorylation of serine or threonine residues in target proteins.

Smads Intracellular proteins that convey signals from activated receptors in the TGF-β superfamily to the nucleus.

TGF-β superfamily A group of more than 30 structurally related dimeric proteins involved in diverse processes, including cell growth, differentiation, homeostasis, and hormone secretion.

Inhibins

DAVID J. PHILLIPS AND DAVID M. DE KRETSER
Monash University, Melbourne, Australia

The inhibins belong to the transforming growth factor-β superfamily of growth and differentiation factors. They are somewhat unusual for this family in that they have a relatively restricted tissue distribution and function. Inhibins are recognized as the specific negative feedback signals for follicle-stimulating hormone. However, other functions, such as the roles they play in the adrenal gland and as a tumor suppressor gene, have emerged recently. In this article, the basic structure and function of the two forms of inhibin will be outlined, in addition to their effects on target cells and the clinical relevance of these actions.

I. DISCOVERY

The concept of inhibin (from the Latin "*inhibeo*," to restrain) first originated in the 1930s, when

D. Roy McCullagh postulated the existence of a nonsteroidal factor produced by the testis that would suppress the function of the pituitary and adrenal glands. A key point was that, unlike androgens, the yet-to-be-isolated inhibin would not affect the function of the secondary sex glands, such as the prostate and seminal vesicles. Fifty-three years after the publication of McCullagh's hypothesis, inhibin was isolated, but surprisingly, from the follicular fluid of ovarian follicles. The inhibin entity was found to be a protein made up of two subunits, one of approximately 18 kDa, termed the α-subunit, and a smaller 14 kDa subunit, termed the β-subunit, joined by disulfide bonds. Moreover, two forms of the β-subunit were detected by sequencing, and these were given the nomenclature β_A and β_B. Because inhibin was made up of an α component and a β component, the $\alpha-\beta_A$ dimer became known as inhibin A and the $\alpha-\beta_B$ dimer as inhibin B. The two forms of inhibin are clearly separate entities and have different patterns of expression and function.

II. INHIBIN GENES AND PROTEIN ASSEMBLY

Inhibins arise from three gene products: the α subunit is on human chromosome 2q35, the β_A subunit gene is on 7p14.1, and the β_B gene is on 2q14.2. As in other related proteins, the subunits are first synthesized by cells as larger precursor forms. These are subsequently cleaved by enzymes into the mature subunits, but dimers can form from precursor subunits as well as from the cleaved, mature forms (Fig. 1). It is important to be able to recognize the precursor and intermediate forms because they are known to be present in significant quantities in body fluids and tissues, and some tumors secrete these variants in preference to mature inhibin dimers. It is also a key point that the β-subunits can form dimers with each other independently of the α-subunit. In this case, the dimers are known as activins; their actions counteract that of inhibin and affect a wider range of physiological processes. The balance between the amounts of α- and β-subunits will determine how much inhibin versus activin is formed; more α-subunit favors the formation of inhibin.

III. BINDING PROTEINS, RECEPTORS, AND SIGNALING

The mechanism by which cells respond to inhibin has been the subject of extensive yet frustrating research. Many groups have sought an inhibin "receptor," but

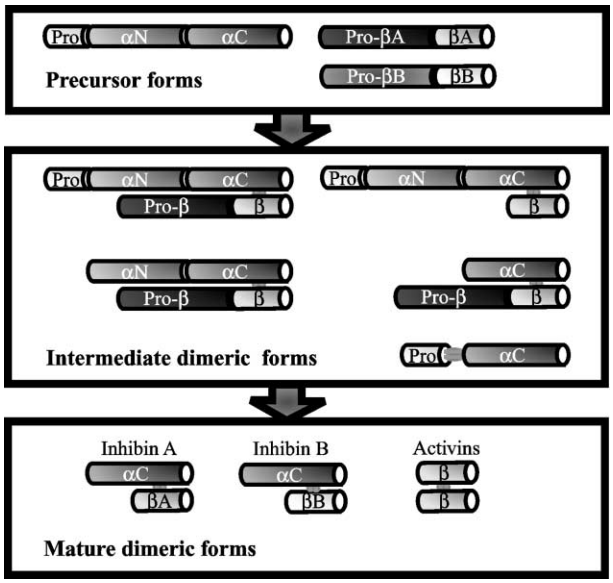

FIGURE 1 Schematic representation of inhibin-containing proteins. Note that several of the precursor and intermediate forms, such as the free α-subunit, are secreted and may be found in serum and other biological fluids. For simplicity, the intermediate forms are depicted as containing a generic β-subunit, which may be either the β_A or the β_B forms. The disulfide bonds linking subunits are depicted as two parallel lines.

to date, a true receptor has not been identified. What can be said about inhibin and how it acts? It is known that inhibin often has the property of blocking the actions of its sister protein, activin. This is partly due to the ability of inhibin to bind to activin receptors but the inability, once bound, to initiate intracellular signaling pathways. More recent research has identified two proteins, betaglycan and inhibin-binding protein, that enhance the ability of inhibin to couple with activin receptors and make the receptors unstable. Further research is needed to determine whether these mechanisms fully account for the actions of inhibin or whether additional elements remain to be elucidated.

IV. TISSUE DISTRIBUTION

Low levels of inhibin are made by many tissues in the body, but those that express significant amounts of inhibin are the ovary, placenta, testis, prostate gland, pituitary gland, brain, and adrenal gland. Of these, the testis and ovary are responsible for the majority of inhibin present in the circulation, as blood levels of inhibin plummet to almost undetectable levels when the ovaries or testes are removed. The adrenal gland is a minor source of inhibin in the blood.

V. PHYSIOLOGY OF INHIBIN

A. In the Female

Specific assays for the inhibin A and B forms have highlighted the different intraovarian sources of these hormones, although both forms fulfill the role of feedback hormones, suppress follicle-stimulating hormone (FSH) secretion from the pituitary gonadotrope cells, and have a negative correlation with FSH in the circulation. During the menstrual cycle, inhibin A in the bloodstream is low during the follicular phase, begins to rise at the midcycle luteinizing hormone (LH) peak, and then remains high during the luteal phase. The ovulatory follicle and its transformation into the corpus luteum are responsible for this profile. In contrast, inhibin B is highest during the follicular phase and immediately after the LH peak but then drops to low levels during the luteal phase. In this case, inhibin B is a product of the cohort of recruited follicles that are maturing in size and function during the follicular phase. In women approaching menopause, the reduction in the function of follicles being recruited is reflected in a decline in blood levels of inhibin B compared with younger women. Inhibin A levels remain similar to those in younger women and then decline late in the menopausal transition, when increasingly the largest follicle does not proceed to ovulation and menstrual cycles eventually cease.

A potential function has been suggested for inhibin in the maturation of the oocyte around the time of ovulation. However, studies have reported both stimulatory and inhibitory effects on the breakdown of cumulus–oocyte complexes and blastocyst development. It is currently unclear whether the conflicting reports relate to species differences in response, the type of inhibin preparation used, or other experimental conditions.

The placenta is an important source of inhibin during pregnancy. The majority of inhibin arising from the placenta itself, the corpus luteum, the trophoblast, and the developing fetus is inhibin A; inhibin B is almost undetectable throughout most of pregnancy. Inhibin A levels are detectable by approximately week 4 of pregnancy and reach an initial peak in the first trimester before decreasing again in the second trimester. In the third trimester, inhibin A increases steadily to reach at term the highest concentrations of pregnancy. Although the physiology behind the release of inhibin in pregnancy is still not clearly understood, inhibin A levels have been assessed as a marker of abnormal pregnancy or fetus, as is discussed in a later section of this article.

B. In the Male

Use of the specific inhibin assays has highlighted that in the male the relevant form is inhibin B and that inhibin A is undetectable. Inhibin B is negatively correlated with FSH levels in adult men and is largely the product of Sertoli cells in the testis. The testicular Leydig cell may also make small amounts of inhibin B, but this is not an important contribution to the circulating pool.

Inhibin B levels are detectable in the cord blood of male newborns, rise to levels that are higher than the adult range by 6 months of age, and then decline to low levels at 3–6 years. The initial peak in inhibin is positively correlated with FSH and most likely reflects the increase in Sertoli cell numbers and function that occurs during this period. During puberty, inhibin B levels increase again to adult levels and become negatively correlated with FSH levels. Furthermore, inhibin B in the adult reflects the spermatogenic status of the individual, so that inhibin B is inversely related to FSH concentrations but is directly correlated with sperm counts. In this way, inhibin B fulfills the original hypothesis of McCullagh by signaling to the pituitary gland the status of sperm production by the testis.

The fluid component of the ejaculate, seminal plasma, has high concentrations of inhibin B derived from the testis, since vasectomized men have undetectable levels in seminal plasma. Although inhibin B in seminal plasma generally correlates with sperm production, there are some men with normal sperm counts who have low to undetectable inhibin B levels in this fluid.

The prostate gland is another organ with the capacity to produce inhibin but that may fulfill a paracrine role and not contribute to levels in the circulation or in seminal plasma. The α- and β-subunits are made by epithelial cells in the normal prostate tissue and also in the glands of men with benign prostatic hyperplasia. However, in the development of prostate cancer, the epithelial cells appear to lose the ability to synthesize the α-subunit, resulting in a shift from production of both inhibins and activin in the normal gland to the exclusive production of activin. These clinical findings, in addition to results from mice with a congenital absence ("gene knockout") of the inhibin α-subunit, which also develop tumors, have led to the concept that the α-subunit may be a tumor suppressor gene.

C. In the Adrenal Gland

The adrenal gland has been known as an inhibin-producing organ for a number of years, but the role of inhibin in this gland is not well understood. The α-subunit is localized to the inner zones of the cortex, whereas the β-subunits are found in all regions of the adrenal gland. Mice in which the α-subunit has been knocked out first develop gonadal tumors, but if the gonads are removed, adrenal tumors develop. This again is consistent with the concept that inhibin may function as a tumor suppressor gene.

VI. CLINICAL AND/OR COMMERCIAL APPLICATIONS

Potential applications of inhibin in clinical medicine center around its use in two broad areas: as a tool in diagnosing reproductive abnormalities and in defining various types of tumors. In terms of the former, the most widely adopted application has been the use of inhibin A as a marker for the detection in the second trimester of Down's syndrome pregnancies. Inclusion of inhibin A as a screen of maternal serum along with α-fetoprotein and human chorionic gonadotropin (hCG) enables approximately 75% of Down's syndrome pregnancies to be detected, compared with approximately 53% when only α-fetoprotein and hCG are used. Other situations in which inhibins may have utility include early pregnancy. Low inhibin B and high FSH levels have been shown to indicate a poor ovarian response in assisted reproductive technology procedures. However, this index has not been widely adopted in clinical practice because of the difficulty in setting threshold limits for inhibin B that are reliable predictors of a poor outcome. Inhibin A provides an excellent index of corpus luteum function (and number) and has also been assessed as a marker for miscarriages. Although it is able to identify very early miscarriages from nonviable pregnancies, it is not a useful marker for predicting a subsequent miscarriage in pregnancies that proceed beyond approximately 6 weeks.

The most remarkable predictive index for inhibin is in granulosa cell tumors of the ovary. Total α-inhibin levels (not discriminating between the A and the B forms) are used to detect 100% of these tumors; these cancers, however, are very rare and constitute only 5–10% of ovarian tumors. In terms of the more common epithelial ovarian cancers, α-inhibin levels are elevated in approximately 80% of mucinous tumors but in only 5–35% of serous tumors. The assessment of inhibin in defining these subtypes of ovarian cancers is ongoing and may lead to useful tests to detect malignancy.

In the adult male, inhibin B is a useful indicator of Sertoli cell function and germ cell complement, but it is not absolutely predictive. Currently, it does not offer additional diagnostic discrimination beyond the traditional assessment of semen analysis, testicular histology, and FSH levels in the blood. One application may be in the detection of nonpalpable testes in disorders such as cryptorchidism or ambiguous genitalia.

Previous sections have also touched on the use of inhibin as a marker of certain types of cancers. The role of inhibin as a tumor suppressor is suggested from mouse models where gonadal and adrenal tumors develop in mice in which the inhibin α gene has been knocked out. The ovarian tumors in these mice derive from the sex cord stroma, making it difficult to reconcile this origin with the large quantities of α-subunit secreted by human sex cord stromal tumors (which include granulosa cell tumors). As discussed, however, total α-inhibin has been evaluated as a serum marker for a number of human ovarian cancers, with particular use in detecting these granulosa cell tumors.

Histological assessment of tissue sections using α-subunit-specific antibodies has also been informative for some cancers. Loss of α-subunit expression has been recorded in prostate cancers compared with normal prostate tissue, and indeed prostate cancer cell lines do not express the α-subunit either. The use of α-subunit staining on tissue sections has been particularly useful in differentiating between adrenal gland corticocarcinomas (negative for α-inhibin) and renal cell carcinoma (positive for α-inhibin), both of which may be detected as abdominal masses and for which fine-needle biopsies are often taken to help diagnose, based on pathology, the two conditions.

VII. SUMMARY

Significant leaps in the biology of the inhibins have been made in the 15 years since they were isolated. The concept that inhibins provide a mechanism through which the gonad communicates with the pituitary gland is indubitable, but additional functions in the establishment and maintenance of pregnancy, in the adrenal gland, and in tumor biology have emerged. The development of highly specific immunoassays for the two forms of inhibin has been a vital component in this process. A key area yet to be clarified is exactly how inhibin affects cells: through blocking activin signaling, through its own receptor

pathways, or through a combination of the two. Finally, although some of the clinical applications for inhibin have emerged in the arena of reproductive physiology and some cancers, clearly continuing assessment of inhibin is needed in other conditions, for instance, in other significant malignancies such as breast cancer.

Glossary

endocrine Describes the action of a factor that is produced by one tissue and circulates through the bloodstream to reach another target organ on which it has an effect. This is the classical definition of all hormones.

negative feedback The inhibition of the action or function of a factor, cell, or organ by another factor or hormone. This type of system is often described as a feedback loop because of its autoregulatory nature.

paracrine Describes the action of a factor produced by a cell or groups of cells that acts on neighboring cells of the same type or different types within the same tissue or organ.

pituitary gonadotrope cells The cells in the anterior pituitary gland responsible for producing follicle-stimulating hormone and luteinizing hormone, which regulate the function of the gonad. The gonadotropes are one of the primary sites of action for inhibin.

Inhibins, Activins, and Follistatins

DAVID M. DE KRETSER, DAVID J. PHILLIPS, AND KATE L. LOVELAND

Monash University, Melbourne, Australia

This article discusses the physiology of three groups of proteins, the inhibins, activins, and follistatins, specifically regarding their role in fine-tuning the cross-talk between the gonad and the pituitary gland to regulate male reproductive function. In addition, aspects relating to functions within the testis itself and in the male accessory organs will be covered. Not covered herein are some other aspects of inhibin, activin, and follistatin physiology that relate to additional important roles for these proteins in other tissue systems, including the female reproductive tract.

I. INHIBIN, ACTIVIN, AND FOLLISTATIN

Inhibin, activin, and follistatin were originally isolated for their property of modifying the release of follicle-stimulating hormone (FSH) from the pituitary gland. Although purified as separate entities, these proteins are intertwined in terms of their biochemistry and mode of action. Inhibin consists of two subunits (α and β) and, as its name implies, inhibits the production of FSH. Activin, on the other hand, is formed from two β-subunits and stimulates FSH production. It is now

believed that inhibin exerts its effect by antagonizing (i.e., blocking) the ability of activin to bind to its cell surface receptors and transduce an intracellular signal. Recent findings have also unveiled the potential for a distinct inhibin-specific mode of action. Follistatin, like inhibin, is a negative regulator of FSH but mediates its effects through physically binding to and preventing activin access to its receptor. It acts as a "sink" for activin, in contrast to an antagonistic receptor occupant, such as inhibin.

Although the above simplistic definitions introduce these three proteins, in fact, each of them consists of a larger set of variants arising from different subunit structures. Four mammalian inhibin/activin β-subunit genes have been isolated, although currently only two of these, βA and βB, are regarded as relevant to male reproductive physiology. The combination of these β-subunits with an α-subunit yields two forms of inhibin, inhibin A and inhibin B. In male mammals, inhibin A is undetectable in serum and tissues and inhibin B is the active form. An exception appears to be the sheep, in which only inhibin A is detectable, although both β-subunits are synthesized by the testis. For activin, combinations of β-subunits give rise to activin A (a homodimer of βA subunits), activin AB (a dimer of βA/βB), and activin B. Follistatin is present in two major forms that vary in both size and function, and more recently, another protein with structural similarity to follistatin and that shows some follistatin-like properties, follistatin-related protein, has also been isolated. In subsequent sections, where relevant to explaining biological processes, the specific forms of activin or follistatin are mentioned, otherwise the generalized effects of these proteins are meant.

II. THE PITUITARY–TESTICULAR AXIS: ENDOCRINE EFFECTS

Control of male reproductive processes is mediated predominantly by interactions among the hypothalamus, pituitary gland, and testis. The hypothalamus produces gonadotropin-releasing hormone (GnRH), which drives the pituitary production of gonadotropin hormones, luteinizing hormone (LH), and FSH. The hypothalamus is responsive to negative feedback signals from the testis in the form of steroids, with testosterone being the primary component. The pituitary gland is also responsive to testicular factors, with testosterone affecting gonadotropin output. Inhibin, activin, and follistatin were proposed to be nonsteroidal feedback factors produced by the testis and that acted at the pituitary gland to specifically regulate FSH (their effects on LH are negligible). The case for inhibin is well established. In some species, such as monkeys, inhibin is the principal testicular hormone responsible for FSH regulation, whereas in other species, such as the sheep, both inhibin and testosterone are involved. Unlike inhibin, in normal circumstances activin and follistatin produced in the testis do not play a significant role in the pituitary feedback system. As discussed in subsequent sections, however, they fulfill important roles as paracrine regulators within the pituitary, testis, and male accessory glands.

III. PARACRINE EFFECTS WITHIN THE PITUITARY

Inhibin, activin, and follistatin are all synthesized in the pituitary gland. The α- and βB-subunits are specifically produced by gonadotrope cells, the cell type that produces LH and FSH. Minor amounts of the βA-subunit are synthesized by other cell types in the pituitary, and follistatin is produced in most pituitary cells, including gonadotropes. Activin B produced by the gonadotropes drives stimulatory signals for increased FSH production by gonadotrope cells, tempered by the inhibitory influences of inhibin and follistatin. Inhibin can originate from testicular sources via the feedback mechanism discussed above or from locally produced sources (the gonadotrope); for follistatin, pituitary cells are the predominant source. Additional inputs from the hypothalamus and testis are also important in this local network. The nature of GnRH pulses released from the hypothalamus and testosterone levels from the testis influence the pituitary expression levels of inhibin, activin, and follistatin genes.

IV. PARACRINE AND AUTOCRINE EFFECTS WITHIN THE TESTIS

Functional interactions of these factors within the testis have been difficult to dissect because of the apparent importance of both paracrine and autocrine effects on the dynamic assortment of somatic and germ cell populations. It is clear that the major production of the inhibin α-subunit within the testis is within Sertoli cells, though Leydig cells may also make inhibin. The Sertoli cells produce the large amounts of circulating inhibin protein that control FSH secretion, and the level of Sertoli cell secretion of inhibin B is used as an indicator of testicular function

in adults. Men with severe impairment of spermatogenesis have dramatically reduced serum inhibin B levels, including those men with Sertoli cell-only syndrome. Surprisingly, boys with Sertoli cell-only syndrome have normal inhibin B levels for their age, but they have undetectable levels of inhibin in adulthood.

At least two distinct receptor-like proteins for inhibin have been identified on Leydig cells and Sertoli cells, betaglycan and p120, and it has been suggested that each of them detects a specific inhibin isoform. These findings hint at a paracrine or an autocrine effect of inhibin that remains to be elucidated.

In contrast to the inhibin α-subunit, the activin β-subunit is made in several somatic and germ cell types, including Sertoli cells, Leydig cells, peritubular myoid cells, macrophages, gonocytes, and spermatocytes, so each of these cell types can produce the various types of activin. Specific activin receptor subunits have been detected on all somatic and germ cell types in the adult testis. Deletion of the mouse gene encoding one of the activin receptors, which is normally found on Sertoli cells, spermatogonia, and spermatocytes, results in animals with smaller testes and reduced fertility, due to the presence of lower than normal numbers of Sertoli cells and germ cells. This observation of reduced Sertoli cell numbers suggests that activin, directly or through its action on FSH, affects Sertoli cell proliferation in the juvenile animal, a result that is supported by *in vitro* culture experiments with testis fragments from developing animals. Although a similar phenotype occurs in mice that fail to synthesize FSH, it is apparent that breeding these mice to produce a "double-knockout" phenotype causes a further reduction in sperm production without a significant additional change in testis size. Therefore, the two factors function both together and independently to regulate testis development, and again, this observation is supported by *in vitro* experimental data.

Follistatin production has been observed in Sertoli cells and spermatogonia of the adult, and local accumulation of extracellular protein is evident in the interstitial regions of the immature and adult testis. This accumulation of follistatin protein in the extracellular matrix surrounding seminiferous tubules and Leydig cells suggests that it plays a role in regulating activin bioactivity by modulating activin access to its receptor on Leydig, Sertoli, and spermatogonial cells.

As described above, variation in activin isoform bioactivity has important functional implications for germ cell maturation. The production of activin β_A by gonocytes is limited to a discrete window of germ cell development, with its mRNA synthesized in the fetal testis and the β_A protein stored in the germ cells until they mature into spermatogonia after birth. There appears to be a switch at this stage of germ cell development, so that spermatogonia make follistatin in both juvenile and adult animals. However, as they enter meiosis, germ cells once again synthesize activin, but now producing activin β_B. Activin A is regarded as the more potent form and appears therefore to be required for the initial stages of spermatogenesis. In other experiments, overexpression of activin or follistatin in spermatocytes causes spermatogenic failure, further indicating that local control of activin bioactivity is important for normal testicular function.

Regulation by activin of both somatic and germ cell proliferation has been demonstrated in cell culture experiments, and its impact appears to change as the testis matures. At birth, Sertoli cells multiply in response to FSH alone, but thereafter both FSH and activin are required. In contrast to the effect on Sertoli cells, activin appears to inhibit division of germ cells when FSH is present. By puberty, when the Sertoli cells stop dividing and begin to differentiate, neither of these agents alone or in combination can provoke further division. These results highlight the dynamic situation that exists in the developing testis at the onset of spermatogenesis. Although there is less information concerning the local role of activin in the adult testis, it is clear that spermatogenesis can proceed to completion in mice that produce reduced levels of functional activin.

V. EFFECTS WITHIN OTHER ORGANS OF THE MALE TRACT

Development of external genitalia involves the regulation of the actions of activin and related family members. Activin β_A is made in the fetal genitalia during development, and replacement of this subunit by activin β_B in transgenic mice leads to genital enlargement in adulthood.

In the adult, production of inhibin α- and activin β-subunits occurs within the epididymis, though whether their role is local or hormonal is not clear. Early in development, local interactions between activin and follistatin are implicated in prostate growth, affecting development of the characteristic branches that form the backbone of the secretory epithelium. In the adult prostate, the synthesis of these factors appears to be required for homeostasis,

as the loss of inhibin α expression has been associated with the development of high-grade cancer pathologies. Secretion of high levels of follistatin by the prostate gland or seminal vesicles into seminal fluid may modulate the downstream effects of activin derived from the testis or the epididymis.

VI. SUMMARY

The concept that male reproductive function is regulated not only by steroid hormones but also by protein factors was first proposed approximately 70 years ago. It is only recently with the development of highly specific assays for the various forms of inhibins, activins, and follistatins, new molecular tools, and transgenic animal models that our understanding has moved beyond this initial concept. It is clear the inhibin B is a major regulator of male reproductive function and is of use in the clinical diagnosis of male infertility. Important roles for activin and follistatin as paracrine and autocrine factors within the pituitary, testis, and accessory male glands are suggested from transgenic mouse models and sophisticated *in vitro* studies. Their precise function within these tissues is becoming apparent with the development of tools that can dissect how these molecules direct the complex interactions among various cell types in the normal process of spermatogenesis and in pathological states.

Glossary

autocrine Describes the action of a factor produced by a cell that has an action on that cell itself.

endocrine Describes the action of a factor that is produced by one tissue and circulates through the bloodstream to reach another target organ on which it has an effect. This is the classical definition of all hormones.

germ cells Cells that can grow to form the reproductive cells (sperm or eggs). In the testis, these are the gonocytes, spermatocytes, spermatids, and spermatozoa.

paracrine Describes the action of a factor produced by a cell or groups of cells that acts on neighboring cells of the same type or different types within the same tissue or organ.

somatic cells All cells of the body except the germ cells. In the testis, the somatic cells include the Sertoli cells, peritubular myoid cells, Leydig cells, and macrophages.

Inositol Phosphate Signaling

JAMES W. PUTNEY, JR.

National Institute of Environmental Health Sciences, National Institutes of Health, North Carolina

In many cell types, hormone activation of surface membrane receptors is associated with a rise in cytoplasmic calcium ($[Ca^{2+}]_i$). This rise in $[Ca^{2+}]_i$ is the initial trigger for a cascade of short-term responses, such as secretion or muscle contraction, and long-term responses, such as cell differentiation, cell division, and even cell death. In most cell types, there are two sources of signaling Ca^{2+}. Ca^{2+} is initially released into the cytoplasm from intracellular organelles and also enters the cytoplasm across the plasma membrane. Thus, at least for the intracellular release of Ca^{2+}, a signaling messenger is required. There may be several different kinds of Ca^{2+}-mobilizing messengers in different cell types. The first of these to be discovered was D-*myo*-inositol 1,4,5-trisphosphate [(1,4,5)IP_3]. (1,4,5)IP_3 is formed when receptor stimulation is coupled to the activation

of a polyphosphoinositide-specific phospholipase C enzyme that degrades a plasma membrane phospholipid, phosphatidylinositol 4,5-bisphosphate. The products of this reaction are diacylglycerol and the head group of the lipid, (1,4,5)IP_3. Diacylglycerol functions in signaling pathways by activating a specific protein kinase (protein kinase C), and (1,4,5)IP_3 signals the release of intracellular Ca^{2+}.

I. METABOLISM OF INOSITOL PHOSPHATES

Virtually all cellular signals are terminated either by transport mechanisms or by metabolic degradation. Following phospholipase C activation and formation of (1,4,5)IP_3, the molecule is rapidly degraded by a 5-phosphatase producing the inactive product inositol 1,4-bisphosphate. This is in turn sequentially dephosphorylated back to inositol, which is used in resynthesis of phosphatidylinositol, the precursor of phosphatidylinositol 4,5-bisphosphate.

The degradative pathway for (1,4,5)IP_3 metabolism is only one aspect of the complex network of inositol phosphate metabolism in cells. (1,4,5)IP_3 is also rapidly phosphorylated at the three position by a 3-kinase producing inositol 1,3,4,5-tetrakisphosphate [(1,3,4,5)IP_4]. There is evidence, albeit controversial, that (1,3,4,5)IP_4 may function as a signal in its own right (discussed below); nonetheless, it is clear that this molecule is the starting point of a complex synthetic pathway generating a variety of inositol phosphates whose functions are not yet completely understood.

The major synthetic and degradative pathways for inositol phosphates in mammalian cells are summarized in Fig. 1. In lower organisms, inositol phosphates can be synthesized by direct phosphorylation of inositol, but the available evidence in mammalian systems suggests that (1,4,5)IP_3 is the precursor for all of the major inositol phosphates. A key step in the synthetic pathway is the phosphorylation of inositol 1,3,4,6-tetrakisphosphate to inositol pentakisphosphate [(1,3,4,5,6)IP_5 or simply IP_5]. This step apparently proceeds at near saturation even under resting, unstimulated conditions. Thus, phospholipase C activation will increase the levels of inositol phosphates at this step and at subsequent steps but does not directly increase the synthesis of higher inositol phosphates. In general, the inositol phosphates with five or more phosphates turn over very slowly, and their functions are not yet fully understood. A breakdown product of IP_5, (3,4,5,6)IP_4, increases when phospholipase C is activated, probably because lower inositol phosphates inhibit its degradation. This inositol tetrakisphosphate may have signaling roles, especially in controlling chloride channels in some cell types.

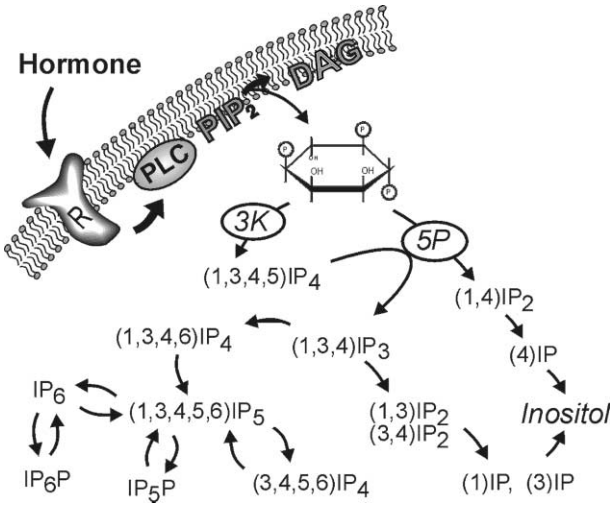

FIGURE 1 Pathways of inositol phosphate metabolism. Agonist activation of a surface receptor (R) activates, usually through a G-protein, a polyphosphoinositide-specific phospholipase C (PLC), which catalyzes the breakdown of phosphatidylinositol 4,5-bisphosphate (PIP_2) into the Ca^{2+}-signaling messenger, (1,4,5)IP_3 (whose structure is shown), and the protein kinase C activator, diacylglycerol (DAG). (1,4,5)IP_3 is metabolized by two enzymes, a 5-phosphatase (5P) and a 3-kinase (3K), initiating complex degradative and synthetic pathways of inositol phosphate metabolism.

The higher inositol phosphates, IP_5 and phytic acid (IP_6), can be phosphorylated on existing phosphate residues, resulting in pyrophosphates. There is considerable evidence that these pyrophosphates turn over more rapidly than their precursors and that their levels are regulated by other signaling pathways. Although it is likely that these interesting molecules have important cellular roles, as yet, their precise functions are not known.

II. ACTIONS OF INOSITOL PHOSPHATES

Two of the inositol phosphates, (1,4,5)IP_3 and (1,3,4,5)IP_4, have been shown, or suggested to play roles in cellular calcium signaling. Of the two, the role of (1,4,5)IP_3 as a Ca^{2+}-mobilizing messenger is well established. The role of (1,3,4,5)IP_4 is less certain, and will be discussed only briefly.

As discussed briefly above, (1,4,5)IP_3 was the first Ca^{2+}-mobilizing second messenger to be discovered. When receptors coupled to phospholipase C are activated, (1,4,5)IP_3 is formed at the plasma membrane and diffuses to the endoplasmic reticulum

where it activates (1,4,5)IP_3 receptors. These receptors are ion channels, and their activation leads to the discharge of stored Ca^{2+} into the cytoplasm. The endoplasmic reticulum is capable of accumulating and storing significant amounts of Ca^{2+} because of the presence of SERCA (sarcoplasmic–endoplasmic reticulum calcium ATPase) Ca^{2+} pumps, and because the endoplasmic reticulum contains a number of low-affinity, high-capacity Ca^{2+}-binding proteins, such as calreticulin and calsequestrin. Some subcellular fractionation studies have shown that the site of Ca^{2+} storage has somewhat different properties from classical endoplasmic reticulum, and the term 'calciosome' has been proposed for the critical Ca^{2+}-storing organelle involved in receptor-dependent Ca^{2+} signaling. At present, it is not clear whether the calciosome is an organelle clearly distinct from endoplasmic reticulum or a specialized component of the endoplasmic reticulum. It is clear, however, that Ca^{2+} is released from stores that utilize SERCA pumps for Ca^{2+} accumulation, because drugs that poison SERCA pumps in most instances release the same store of Ca^{2+} that is released by (1,4,5)IP_3. It is also clear that Ca^{2+} is not released from mitochondria, as was once thought. Rather, there exists an intimate association between mitochondria and Ca^{2+} release sites [i.e., (1,4,5)IP_3 receptors] in the endoplasmic reticulum to facilitate the conveyance of $[Ca^{2+}]_i$ signals to the mitochondrial matrix where they serve to regulate Ca^{2+}-sensitive metabolic pathways.

In many cell types, activation of the (1,4,5)IP_3 pathway results in complex temporal and spatial behavior of Ca^{2+} signals, resulting in the appearance of repetitive $[Ca^{2+}]_i$ spikes; spatially these spikes are often represented as propagated $[Ca^{2+}]_i$ waves (Fig. 2). The significance of this discontinuous behavior is not known for certain, but a favored view is that it provides better signal-to-noise ratio by utilizing a digital or frequency-encoded signal. The cellular and molecular mechanism underlying these oscillatory signaling patterns may result from properties of (1,4,5)IP_3 receptors, which are susceptible to complex regulation by Ca^{2+}. Low concentrations of Ca^{2+} activate (1,4,5)IP_3 receptors, and higher concentrations inhibit them. In addition, the time course of the development of inhibition appears to be slower than for the activation. These kinetic parameters may contribute to the all-or-none behavior often seen in the generation of intracellular Ca^{2+} spikes. In addition, the concentration of Ca^{2+} in the lumen of the endoplasmic reticulum also regulates the (1,4,5)IP_3 receptor in a positive fashion; thus, filled

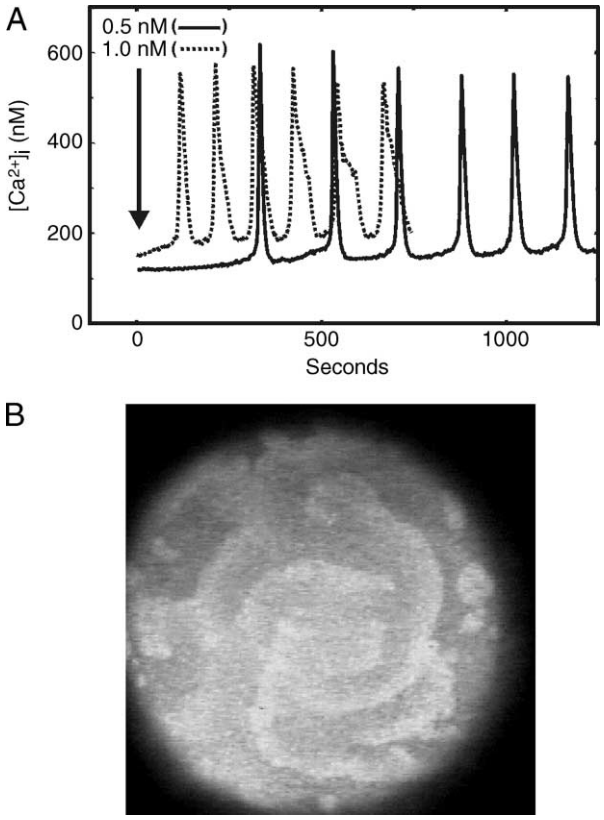

FIGURE 2 Calcium waves and oscillations. (A) A single rat hepatocyte treated with vasopressin exhibits low-frequency baseline spikes of $[Ca^{2+}]_i$. The latency to the first spike and the frequency of spiking are related to the concentration of hormone. (B) A *Xenopus* oocyte was microinjected with ~1 μM IP_3. The discontinuous fluorescence depicts the characteristic calcium waves and spirals seen in this preparation.

stores are more sensitive to (1,4,5)IP_3 than are empty ones. This may contribute to the triggering of each new $[Ca^{2+}]_i$ spike as intracellular stores become recharged.

An alternative mechanism for the production of regenerative $[Ca^{2+}]_i$ signals involves cyclical activation and inactivation of the enzyme generating (1,4,5)IP_3, resulting in oscillations in (1,4,5)IP_3 levels. Calcium is an activator of phospholipase C, which could produce the necessary regenerative force, and the diacylglycerol that is formed can inhibit the enzyme through activation of protein kinase C. It is difficult to demonstrate such a mechanism directly because, unlike the case for Ca^{2+}, there are no fluorescent indicators that can track (1,4,5)IP_3 levels at the single-cell level in real time. Nonetheless, there is strong evidence for such a regulatory mechanism in some instances. It is possible that in some situations,

$[Ca^{2+}]_i$ oscillates in response to fluctuating (1,4,5)IP_3 levels, and in other situations, $[Ca^{2+}]_i$ oscillates at constant (1,4,5)IP_3 levels due to cyclical Ca^{2+} regulation of the (1,4,5)IP_3 receptor activity.

Activation of cells through the phospholipase C pathway almost inevitably results in an increased flux of Ca^{2+} across the plasma membrane. There are a few instances in which this regulated flux of Ca^{2+} occurs through (1,4,5)IP_3 receptors present in the plasma membrane. However, in the majority of instances, the activation of Ca^{2+} entry is a more indirect process. The fall in Ca^{2+} in the lumen of the endoplasmic reticulum in some manner signals to plasma membrane channels, leading to their activation. The process is known as capacitative calcium entry, or store-operated calcium entry. The electrophysiological current associated with capacitative calcium entry is very small and difficult to detect, but it has been characterized in some cell types. In hematopoietic cells, and perhaps some others, the current is highly calcium selective, distinguishing calcium from ions of similar size and charge such as barium and strontium. This highly selective current has been designated I_{crac} for calcium release-activated calcium current. Other cell types may have channels with differing ionic selectivity, including some with store-operated nonselective cation channels. This suggests molecular diversity among store-operated channels in different cell types.

The obvious role of (1,4,5)IP_3 in capacitative calcium entry is to deplete calcium from the endoplasmic reticulum, which in turn initiates the signaling to the plasma membrane. However, (1,4,5)IP_3 may also play a more direct role in the signaling mechanism for capacitative calcium entry. Currently, there are two general theories regarding the mechanism of signaling capacitative calcium entry. One idea holds that the depleted endoplasmic reticulum releases an unknown signal that diffuses to the plasma membrane and activates channels. The alternative idea, termed conformational coupling, suggests that (1,4,5)IP_3 receptors in the endoplasmic reticulum interact directly with plasma membrane channels. In some systems, maintenance of store-operated channels in an active state has been shown to require (1,4,5)IP_3 as well as the (1,4,5)IP_3 receptor; in other systems, capacitative calcium entry proceeds normally in the complete absence of (1,4,5)IP_3 receptors. At present, the issue of the mechanism for signaling capacitative calcium entry is far from resolved. It is possible that more than one signaling mechanism exists, depending on the cell type.

III. INOSITOL PHOSPHATE RECEPTORS

The biological actions of inositol phosphates depend upon their interaction with specific receptor sites in cells. There is little information about inositol phosphate receptors, other than the receptor for (1,4,5)IP_3. This is because, as discussed above, the evidence for biological actions of other inositol phosphates is sketchy at best. For the case of (3,4,5,6)IP_4, which seems to regulate chloride channels, direct interaction with the channels or an accessory protein has not yet been demonstrated. It is likely that such an interaction will be found in the not too distant future. For (1,3,4,5)IP_4, the phosphorylation product of (1,4,5)IP_3, a specific binding protein was isolated and appears to be a Ras-GAP; that is, a protein that activates the GTPase activity associated with the small G-protein, Ras. The significance of this protein to Ca^{2+} signaling is unknown. One problem with understanding the function of an (1,3,4,5)IP_4 receptor is that the biological role of (1,3,4,5)IP_4 is not well established. A second problem is that the putative (1,3,4,5) IP_4 receptor also binds and is activated by the 3-phosphorylated lipid, phosphatidylinositol 3,4,5-trisphosphate, and some believe that this may be the physiological ligand for the receptor.

Much more is known about the structure and function of (1,4,5)IP_3 receptors. The best characterized function of (1,4,5)IP_3 receptors is as a Ca^{2+} release channel in response to the formation of (1,4,5)IP_3. However, as discussed above, they may also function to link endoplasmic reticulum to plasma membrane Ca^{2+} channels, supplying a signal for capacitative calcium entry. There is also evidence from a number of studies that (1,4,5)IP_3 receptors play a role in programmed cell death, or apoptosis. It is not known whether this is due to the ion channel function of the molecule or to some other role of the receptor molecules. To date, there are three known genes for (1,4,5)IP_3 receptors designated type I, type II, and type III, each sharing considerable sequence homology. The different forms are similar in both sequence and behavior, although there are some functional differences, especially with regard to regulation by Ca^{2+}. Although many cell types express all three types of receptors, there are some cell types that express two subtypes or only one subtype. The predicted molecular weight of the receptors is $\sim$300 kDa. In native membranes, a functional receptor is a tetramer of four receptor molecules; these may be of the same or distinct subtypes. Although it is clear that *in situ* (1,4,5)IP_3 receptors

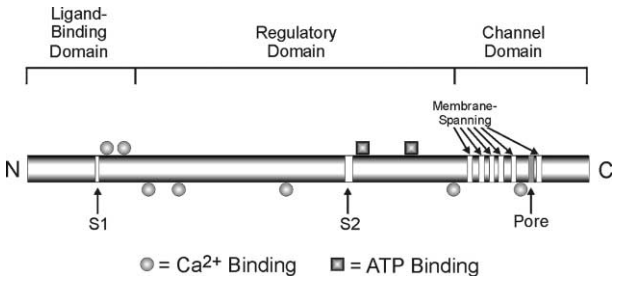

FIGURE 3 Structure of the type I (1,4,5)IP_3 receptor. The (1,4,5)IP_3 receptor is composed of ligand-binding, regulatory, and channel domains. The positions of two of the three known splice sites, the membrane-spanning regions, and the putative channel pore region are shown. Also shown are the positions of putative ATP- and Ca^{2+}-binding sites.

associate with other proteins, purified recombinant proteins form (1,4,5)IP_3-regulated ion channels, indicating that the basic receptor and channel functions are contained within the receptor molecule.

As expected, all three types appear to be localized in the endoplasmic reticulum, as well as in the nuclear envelope, an extension of the endoplasmic reticulum. In the endoplasmic reticulum, they function to release Ca^{2+} to the cytoplasm following activation of the phospholipase C pathway. There is also evidence for phosphoinositide metabolism and specialized release of Ca^{2+} in the nucleus, where Ca^{2+} signaling may play a specific role in gene regulation. In many cells, biochemical evidence suggests the presence of a minor fraction of (1,4,5)IP_3 receptors in the plasma membrane. However, there are few data on the functional significance of these receptors, as the major route of Ca^{2+} entry during signaling appears to be the capacitative calcium entry pathway.

Structural analysis of (1,4,5)IP_3 receptors by deletions of specific sequences has revealed three major domains of the (1,4,5)IP_3 receptor (Fig. 3): an N-terminal (1,4,5)IP_3-binding domain, a long regulatory or coupling domain, and a somewhat shorter C-terminal hydrophobic, channel domain. The type I form has three splice sites (two are shown in Fig. 3), giving rise to a large number of splice variants. The N-terminal region contains the IP_3-binding region, the S1 splice site, and two Ca^{2+}-binding sites. The regulatory domain contains additional Ca^{2+} sites; presumably, some or all of these sites are responsible for the complex regulation of (1,4,5)IP_3 receptor function by cytoplasmic Ca^{2+}. The regulatory domain is so named because in this region, regulatory molecules such as calmodulin and FK-binding protein have been shown to interact. In addition, sites for regulatory phosphorylation by cyclic nucleotide-dependent protein kinases are found within this region. The regulatory domain of the type I receptor also contains two positive regulatory binding sites for ATP.

The C-terminal domain contains six hydrophobic sequences that would be predicted to be membrane spanning from hydropathy plots. Accordingly, the C-terminus is predicted to be cytoplasmic. Between the fifth and the sixth membrane-spanning sequences is a hairpin loop that may constitute the ion channel pore. There is also a Ca^{2+}-binding site within this region; however, its affinity for Ca^{2+} appears to be too high for it to be regulated within the range of [Ca^{2+}] expected within the endoplasmic reticulum. Deletion of the C-terminal domain results in a soluble protein that does not form tetramers; thus, the C-terminus is thought to contain sequences important for both localization and appropriate oligomerization.

IV. CONCLUSIONS

A variety of hormones and neurotransmitters regulate cell function by activation of a polyphosphoinositide-specific phospholipase C, resulting in the liberation of the signal, (1,4,5)IP_3. (1,4,5)IP_3 in turns binds to specific (1,4,5)IP_3 receptors in the endoplasmic reticulum that function as ion channels, causing the release of stored Ca^{2+} to the cytoplasm (see Fig. 4).

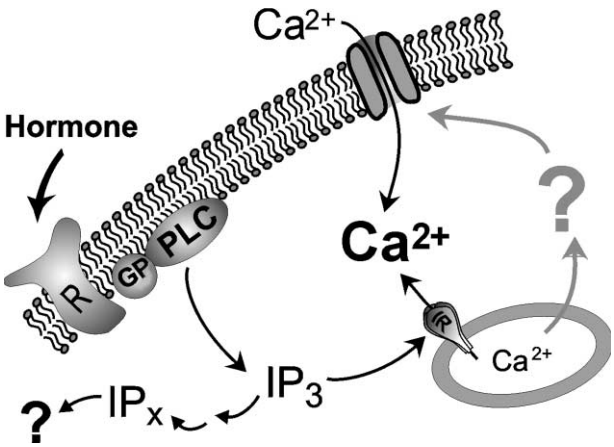

FIGURE 4 Schematic depiction of inositol phosphates and calcium signaling. Agonist activation of a surface receptor (R) leads to activation of a polyphosphoinositide-specific phospholipase C (PLC), usually through the intermediate action of a heterotrimeric G-protein (Gp). (1,4,5)IP_3 is formed and activates a (1,4,5)IP_3 receptor channel (IR), causing a rapid release of Ca^{2+}. This release in turn signals positively to a capacitative calcium entry channel in the plasma membrane. (1,4,5)IP_3 also serves as precursor for a number of inositol polyphosphates, some of which may function in other aspects of Ca^{2+} signaling.

$(1,4,5)IP_3$ also serves as the precursor of a number of higher inositol phosphates and pyrophosphates, some of which may also have functions in various signaling pathways. Coordinated with the intracellular release of Ca^{2+} by $(1,4,5)IP_3$ is an accelerated entry of Ca^{2+} into the cell across the plasma membrane. The signal for this plasma membrane entry is not well understood. It involves a process known as capacitative calcium entry, whereby the signal is somehow initiated by the depletion of the endoplasmic reticulum stores by $(1,4,5)IP_3$. In some instances, $(1,4,5)IP_3$-mediated Ca^{2+} signaling results in the generation of repetitive spikes of intracellular Ca^{2+}, sometimes referred to as Ca^{2+} oscillations. The varied and complex patterns of Ca^{2+} signaling initiated by $(1,4,5)IP_3$ control multiple cellular functions, from immediate to long-term responses.

Glossary

calciosome A theoretical organelle, or subcellular fraction, that is specifically involved in storing and releasing Ca^{2+} during Ca^{2+} signaling.

calcium influx factor A hypothetical factor released from the endoplasmic reticulum following Ca^{2+} depletion, which diffuses to the plasma membrane and activates Ca^{2+} channels.

calcium oscillations Cycles of regenerative, all-or-none rises in cytoplasmic Ca^{2+} superimposed on a stable baseline. Also called calcium spikes. Calcium feedback properties of the $(1,4,5)IP_3$ receptor may underlie these oscillations, at least in some cell types.

capacitative calcium entry A process by which the depletion of intracellular endoplasmic reticulum Ca^{2+} stores, either artificially or by the signal $(1,4,5)IP_3$, initiates a signaling process to open channels in the plasma membrane.

conformational coupling A theory for signaling capacitative calcium entry whereby depletion of intracellular Ca^{2+} stores causes a conformational change in $(1,4,5)IP_3$ receptors, which in turn interact with plasma membrane Ca^{2+} channels, resulting in their activation.

inositol phosphates A series of phosphorylated derivatives of the hexitol, D-*myo*-inositol. In mammalian cells, inositol phosphates are derived from inositol 1,4,5-trisphosphate, formed by cleavage of phosphatidylinositol 4,5-bisphosphate by phospholipase C.

inositol 1,4,5-trisphosphate [$(1,4,5)IP_3$] An inositol phosphate that is one of the initial products of phospholipase C cleavage of phosphatidylinositol 4,5-bisphosphate. $(1,4,5)IP_3$ is an important signaling molecule that acts by binding to a specific receptor on the endoplasmic reticulum, triggering release of Ca^{2+} to the cytoplasm. It is also the precursor for higher inositol phosphates, some of which may have roles in various signal transduction pathways.

$(1,4,5)IP_3$ receptor A high-molecular-weight protein, located primarily in the endoplasmic reticulum, that forms a tetrameric channel. The channel opens in response to binding of $(1,4,5)IP_3$, resulting in the release of Ca^{2+} to the cytoplasm.

phospholipase C An enzyme that cleaves phospholipids at the glycerol–head group diester bond, yielding a phosphorylated head group and diacylglycerol. Some phospholipases C are specific for certain phospholipids, for example, for polyphosphoinositides, which yield the signaling inositol phosphates.

sarcoplasmic-endoplasmic reticulum calcium ATPase pump (SERCA pump) The predominant active Ca^{2+} transport molecule responsible for concentrating Ca^{2+} in the sarcoplasmic and endoplasmic reticulum.

as do vertebrates. Also, neurosecretions from the brain regulate the function of the various endocrine organs just as the hypothalamus of the brain releases the cascade of endocrine gland functions in vertebrates.

II. INSECT BODY PLAN AND DEGREES OF METAMORPHOSIS

An overview of a general insect body plan and the types of metamorphosis will provide a framework for the description of the anatomy of the endocrine system in insects and the functions that they regulate. The head is a fusion of the first 6 segments of the embryo. It bears the eyes, antennae, and mouth parts that include the labrum and labium (above and below the mouth), mandibles, and maxillae, variously modified in different orders of insects. The thorax is composed of 3 segments, prothorax, mesothorax, and metathorax; each bears a pair of legs, whereas wings are on the last 2 segments. The abdomen, which usually bears no locomotory appendages except in larval forms, typically consists of 11 segments. The terminal segments bear the reproductive structures.

The internal anatomy reflects the segmentation pattern (Fig. 1). The brain of three fused segments (proto-, deuto-, and tritocerebrum) is connected by circumesophageal connectives to the ventral subesophageal ganglion, also composed of three fused segments. Paired connective nerves join this ganglion to those of the ventral nerve cord. A ganglion serves each thoracic and abdominal segment. In addition to the brain and ventral ganglia of the CNS, there is a stomatogastric nervous system with connections to the brain and subesophageal ganglion. It consists of several ganglia and nerve tracts along the digestive tract.

The major organ for movement of blood in insects is a long dorsal tube, called the dorsal vessel or heart. Blood moves into segmental openings of the heart and as a general rule is pumped anteriorly. The function of gas transport is carried out by a system of trachea rather than by respiratory pigments. The trachea are air-filled tubes lined with cuticle that lead to all of the tissues of the body from external openings, called spiracles. The major organ of intermediary metabolism and storage is voluminous fat body tissue. The Malpighian tubules and the gut, primarily the anterior and posterior parts of the hindgut, are the major organs regulating water and ion balance.

The degree of metamorphosis in insects varies from little to extreme. The Ametabola (little or no metamorphosis) are ancient wingless insects of which there are only a few species. They change little during the life cycle except for size as they grow and shed their exoskeleton (molt). As wingless adults, they reproduce and continue to grow and molt. The Hemimetabola (incomplete metamorphosis) have

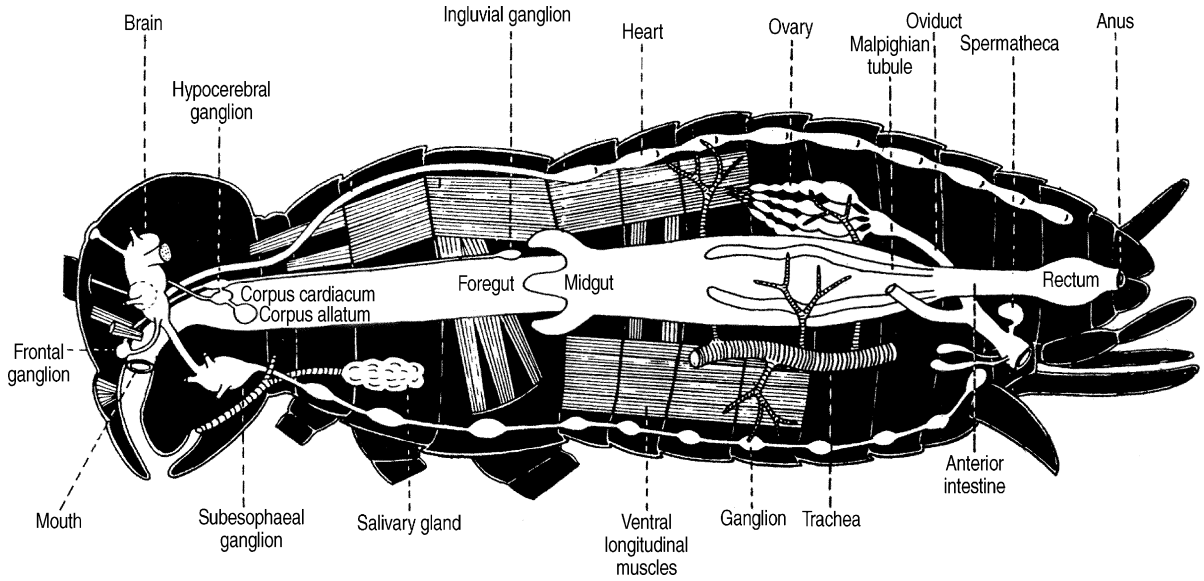

FIGURE 1 Major internal organs of a generalized insect. The frontal, hypocerebral, and ingluvial ganglia contain the cell bodies of the stomatogastric nervous system. The anterior intestine and rectum are hindgut structures. Modified from Du Porte, E. M. (1959). "Manual of Insect Morphology," p. 152. Reinhold, New York, with permission.

larval (also called nymphal) stages that resemble the adults in form. The larvae are wingless but have external wing pads on thoracic segments that become larger at each larval molt. The adult has wings, is reproductive, and no longer grows and molts. The Holometabola, which constitute the majority of insect species, have larval forms that are specialized for feeding. They show reduced appendages, possess internal imaginal discs (clusters of embryonic cells that will form appendages and external reproductive structures of the adult), and do not resemble the adult in form or life style. After the larva stops feeding, it molts to another form, the nonfeeding pupa. During this stage, the imaginal discs differentiate and larval tissues are degraded or rearranged into the adult form. The winged adults, now specialized for dispersal and reproduction, no longer grow and molt.

III. ANATOMY OF INSECT ENDOCRINE SYSTEM: ORGANS AND PRODUCTS

A. Prothoracic Glands

The prothoracic glands produce ecdysteroids, steroid hormones with multiple functions, the most notable of which is to promote the growth that precedes a molt. Consequently, ecdysteroids are often referred to as molting hormones and the endocrine organs that produce them are ecdysial glands. Ecdysteroid is the general term for the several forms found in insects and other invertebrates (Fig. 2). 20-Hydroxyecdysone is the effective form in most insects; in some insects, however, the active form is the homologue, 24-methyl-20-hydroxyecdysone, known as makisterone A (e.g., the Heteroptera, bugs).

Prothoracic glands are paired glands derived from lateral ectoderm in the head region. Their final position and form vary among different orders of insects. Generally, they become located ventrally in the prothorax associated with a tracheal branch. Most often the form is ribbon-shaped (Fig. 3A), but in Lepidoptera and Hymenoptera (e.g., moths and bees), they are diffuse strings of cells (Fig. 3B). These extended shapes make them difficult or impossible to remove with certainty. In the higher Diptera (e.g., flies), the lateral parts of the ring gland that encircles the heart consist of cells that produce ecdysteroid (Fig. 3C).

The prothoracic glands are composed of endocrine epithelial cells of one type enclosed in an extracellular sheath of fibrous material. Volume and organellar composition of the cells change with their cycles of hormone synthesis. The most conspicuous

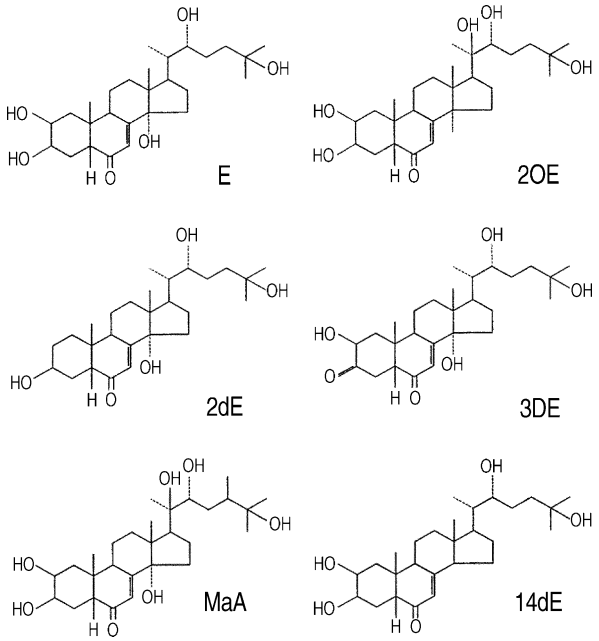

FIGURE 2 Structural formulas of some major ecdysteroids of insects. E, ecdysone; 20E, 20-hydroxyecdysone; 2dE, 2-deoxyecdysone; 3DE, 3-dehydroecdysone; MaA, makisterone A (24Me20E); 14dE, 14-deoxyecdysone. Reprinted from Gäde *et al.* (1997). *Physiol. Rev.*, p. 997, with permission.

features of the cells that are actively secreting hormone are the processes on the cell surface (Fig. 4), lobulated nuclei, abundant rough endoplasmic reticulum, followed by an abundant smooth endoplasmic reticulum, and large mitochondria characteristic of the steroid-producing cells of vertebrates. The cells do not store hormone but secrete it as it is produced.

Nerve fibers, some of which contain peptidergic secretory vesicles, enter the glands and there is some evidence of stimulation and inhibition of hormone synthesis by this route. However, the principal tropic hormone is a neurohormone, prothoracicotropic hormone (PTTH), produced by neurosecretory cells in the brain and released into the hemolymph from the retrocerebral complex, organs behind the brain, the corpora cardiaca and the corpora allata (see Fig. 6A and Section IV, B1a). Evidence for neuropeptide inhibition of ecdysteroid synthesis has been confirmed recently by the identification of two different inhibitory peptides. In blowflies, a factor that inhibits ecdysteroid synthesis by the prothoracic gland was isolated from both the larval nervous system and the adult ovaries. This is a hexapeptide that also inhibits trypsin-like enzymes in the digestive tract (see Section III, D1). An entirely different

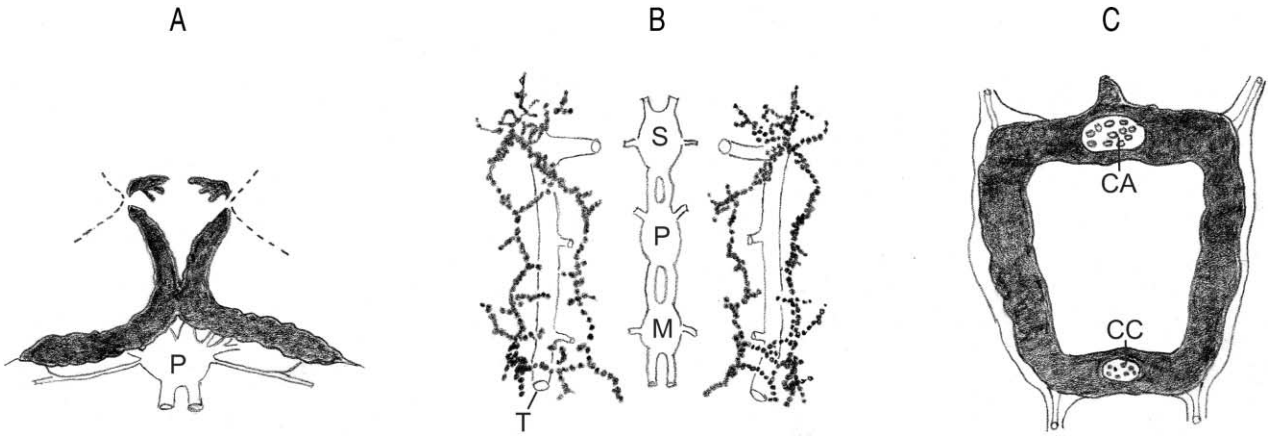

FIGURE 3 Representative forms of prothoracic glands (black structures). (A) solid ribbon-type from a cockroach, (B) diffuse-type from a moth, (C) ring gland from a fly surrounds the heart. peptide, identified in *Manduca sexta*, similar to vertebrate galanins also acts as a prothoracicostatic neurohormone. It was first discovered as an inhibitor of muscle contraction. In locusts, this peptide appears to be released from the retrocerebral complex.

As with other endocrine glands, many factors interact to modulate the activity of the prothoracic glands, including juvenile hormone and feedback from ecdysteroid. In adult insects that no longer molt, the prothoracic glands degenerate. This is a programmed cell death that may take one to several days or weeks depending on the insect. The cells involute asynchronously. In the process, many lysosomes and autophagic vacuoles containing cellular organelles

are present, and in late stages of degeneration, nuclei become dense and cells fragment within the sheath. In the adult insects, ecdysteroids are again produced by other organs (see Section III, D and F).

B. Corpora Allata

The corpora allata (CA) produce juvenile hormone (JH), a lipophilic sesquiterpenoid that, like the ecdysteroids, has multiple functions but, as the name of the hormone implies, it plays a major role in morphogenesis. Its presence maintains the immature form and its absence allows adult development to proceed. In most insects, juvenile hormone also regulates reproductive functions. In the 1930s, V. B. Wigglesworth was the first to experimentally demonstrate these functions in the blood-sucking bug *Rhodnius prolixus*, which requires a blood meal to grow and to produce eggs. In most insects, JH is required for the synthesis of vitellogenin (yolk protein) by the fat body and its uptake by oocytes as well as for accessory gland secretions. As with ecdysteroids, there is a family of juvenile hormones, although one juvenile hormone, JH III, is produced in most species (Fig. 5).

The CA are paired glands that arise from lateral ventral ectoderm in the head near the origin of mandibles and maxillae. The small cellular masses migrate dorsally and centrally and come to rest just behind the brain in various positions, some more ventral than others, depending on the insect order. In the more highly evolved orders, the glands are more dorsal and rest on top of the esophagus under the dorsal vessel (Fig. 6A). In some insects, the pair fuse into a single medial gland (Fig. 6B). In the ring gland of the higher Diptera, the fused CA are on the dorsal side of the ring (Fig. 3C).

The CA are innervated by nerves from the brain and subesophageal ganglion in most insects. The nerve fibers from the brain come from cell bodies in clusters of neurosecretory cells in the medial and lateral parts of the protocerebrum and in the tritocerebrum. These axons exit the brain in nerves called corpora cardiacal nerves (NCC) because they pass through and, in some cases, branch in the paired neurohemal release organs called the corpora cardiaca (CC). The NCC I originates in the contralateral medial protocerebrum, NCC II originates in the ipsilateral lateral protocerebrum, and NCC III originates in the tritocerebrum (Fig. 6A). There are also branches of these nerves that enter the stomatogastric nervous system. Together, this assemblage of

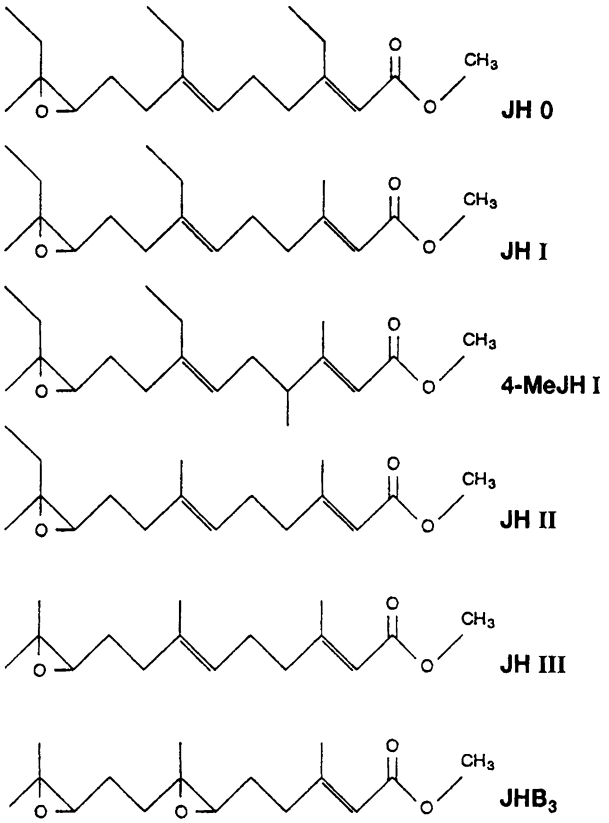

FIGURE 5 Members of the juvenile hormone family. JH 0, I, II, and III, juvenile hormones 0–III; 4-MeJHI, 4-methyl JH I; JHB_3, JH III bisepoxide. Reprinted from Gäde *et al.* (1997). *Physiol. Rev.*, p. 986, with permission.

nerves and the CC and CA are known as the retrocerebral complex (Fig. 6A).

The CA are generally oval in shape and are a single cell type surrounded by an extracellular sheath. Although the description of cell structure varies in different orders of insects, it is clear that cycles of hormone production are accompanied by changes in the morphology of the cells. As with ecdysteroids, the JH is released as it is produced. Increased hormone synthesis is correlated with an increase in plasma membrane projections from the cell surfaces, increase in mitochondrial number and size, and elaboration of much smooth endoplasmic reticulum, characteristics also seen in prothoracic glands. Though not true in all cycles of synthesis of JH, generally the cytoplasmic volume of cells increases as hormone production increases. Involution of the cytoplasmic organelles accompanies low levels of synthesis and cell numbers may decrease. Unlike prothoracic glands, the corpora allata persist in the adult and their hormone assumes new functions such as stimulation of vitellogenin

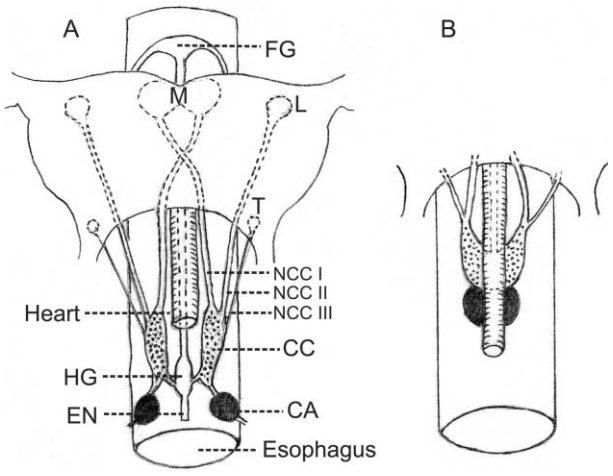

FIGURE 6 Diagram of two forms of corpora allata (black structures). (A) Paired glands in relationship to the corpora cardiaca (CC), the nerves entering the corpora cardiaca (NCC I, II, and III), and the location in the brain of the soma that give rise to these nerves: medial neurosecretory cells (M), lateral neurosecretory cells (L) in the protocerebrum, and tritocerebral cells (T). FG, frontal ganglion; HG, hypocerebral ganglion; EN, esophageal nerve. (B) Single corpus allatum (fused pair) positioned centrally under the heart. Modified from Cassier, P. (1998). synthesis by the fat body and incorporation of this protein into maturing oocytes.

The regulation of hormone production by the CA is undoubtedly multifaceted. A principal pathway occurs through the neurosecretory cell innervation of the glands. Axons in NCC I, II, and probably III enter and arborize in the CA. Their neurosecretory products are released and act at close range (paracrine neurosecretion). In a few insects, the identity and effect of some of these secretions are known. Both allatotropin and allatostatin peptides have been identified for the tobacco hornworm *M. sexta* and related species of insects. A family of allatostatic peptides has been identified that inhibit JH synthesis quickly and reversibly by the CA of crickets and cockroaches following application to the glands in an *in vitro* radiochemical assay. Another family of peptides related to the prothoracicostatic peptide of *M. sexta* was found to inhibit JH synthesis by cricket CA. These peptides act quickly and reversibly *in vitro*. An as yet unidentified neuropeptide inactivates JH synthesis more slowly and for longer periods of time in some species. These peptides may represent only some of several other regulators of CA activity that have yet to be isolated and identified. It is known that JH production by cockroach CA responds indirectly to concentrations of both JH and ecdysteroids in the hemolymph.

C. Epitracheal Glands

A series of three-celled glands occur attached to the ventral surface of a tracheal branch near the spiracles (Fig. 7). Their function in the larvae of the moth *M. sexta* was discovered in 1996 by Dutsan Zitnan and colleagues, who observed that the one large opalescent cell (termed the Inka cell) of these glands released its contents prior to onset of the behavior associated with shedding of the exoskeleton (ecdysis behavior). Three peptide products of the cell have been identified: preecdysis-triggering hormone (PETH, an 11-amino-acid amidated peptide), ecdysis-triggering hormone (ETH, a 26-amino-acid amidated peptide), and a larger nonamidated ETH-associated peptide. PETH and ETH are part of an intricate cascade of humoral and neurohumoral interactions that lead to successful ecdysis. Eclosion hormone, produced in the brain (released into the blood as well as in the ventral nerve cord), and crustacean cardioactive peptide in cells of the ventral ganglia are part of this cascade. Changing concentrations of ecdysteroid in the blood also condition the production and release of the components of the cascade. Such a cascade is likely to be common to ecdysis in all insects. The gene for both ETH and PETH has been cloned in *D. melanogaster* as well as in *M. sexta*.

D. Gonads

1. Ovary

The endocrine function of the insect ovary was not realized until 1974–1975, when D. A. Slaeger and colleagues showed that the ovary was the source of ecdysteroid in mosquito blood, and H. H. Hagedorn and colleagues demonstrated that this ecdysteroid stimulated production of vitellogenin, the precursor of yolk protein, by the fat body. It is known that ovaries of many kinds of insects produce ecdysteroids and that the ovarian ecdysteroids govern processes other than vitellogenin synthesis, e.g., in *Rhodnius*, the ovarian ecdysteroid elicits the release of a brain myotropic factor required for ovulation. In some insects, it has been shown that the source of the ecdysteroid is the follicle cells surrounding the oocytes. In insects in which ecdysteroids are not required for vitellogenin synthesis, the ecdysteroid is transferred from follicle cells to the egg, usually at the

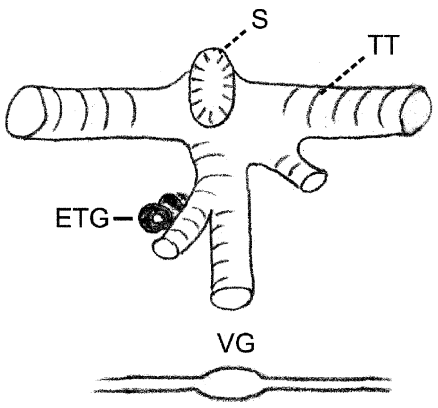

FIGURE 7 Three cells (Inka cell is the largest) of the epitracheal gland (ETG) on the ventral surface of a tracheal branch above the ventral ganglia near each spiracle (S). VG, ventral ganglion; TT, tracheal trunk. Based on Kingan *et al.* (1997). *J. Exp. Biol.* **200**, 3245–3256 and Truman (1996) *Science* **271**, 40–41.

close of vitellogenesis, and is stored in inactive form for activation at appropriate stages of embryogenesis. Thus, indirectly, the ovary is acting as an endocrine source for embryonic development.

In addition to production of a steroid hormone, the ovary has been demonstrated to produce peptide hormones that play a role in reproductive cycles. In mosquitoes and flies, an ovarian peptide inhibits trypsin synthesis by the gut, thus preventing the digestion of protein required for vitellogenin synthesis. This peptide is called trypsin-modulating oostatic factor (TMOF). The amino acid sequence of TMOF in flies differs from that in mosquitoes, but both affect trypsin synthesis by the gut. The fly TMOF is also an inhibitor of ecdysteroid production by larval and pupal prothoracic glands of flies. Yet another peptide from the fly ovary inhibits JH synthesis by the CA. No doubt other endocrine factors produced by the ovary have yet to be discovered.

As is true of other endocrine glands, the nervous system plays a crucial role in regulating the endocrine activity of the ovary. In mosquitoes, an identified brain neurosecretion of the insulin family known as egg development neurosecretory hormone stimulates the ovary to produce ecdysteroid. Thus, it acts as an ovarian ecdysiotropin. There is evidence that such brain–ovarian axes occur in other insects, although the peptides differ (e.g., ovary-maturing parsin of locusts). In crickets, a brain peptide (of the XWX_6W_9 amide family) that also inhibits JH synthesis inhibits *in vitro* production of ecdysteroid by the cricket ovary.

2. Testis

Endocrine function has also been shown for the testis. The sheath of the larval and pupal testes in *Heliothis* and *Lymantria virescens dispar* (moths) produces ecdysteroid. This in turn promotes production of other growth factors that stimulate growth of the male genital tract. The hormonal activity of the testis is initiated by a peptide produced by the brain. This testis ecdysiotropin is a 21-amino-acid peptide and it differs from the ovarian and prothoracic gland ecdysiotropins. However, the production of ecdysteroid by testes appears also to be influenced by the circulating ecdysteroid concentration. Thus, as in the ovary, there is a web of interactions regulating the hormonal activity of the testis.

E. Digestive Tract

In vertebrates, a large and important component of the endocrine system is the sum of the cells distributed individually or in groups along the epithelial lining of the stomach and intestine. Many of these gastrointestinal hormones are also found in the central and peripheral nervous system. A parallel localization of nervous system–gut hormones occurs in insects. The endocrine gut cells of insects are similar in structure to vertebrate gut cells and are found in the midgut, the portion of the alimentary canal that also functions in digestion and absorption (Fig. 8). The midgut lies between the foregut and the hindgut. Unlike the latter two parts, the midgut cells do not produce an apical cuticle. Rather, there is usually a delicate detached membrane that protects the epithelial lining, which is

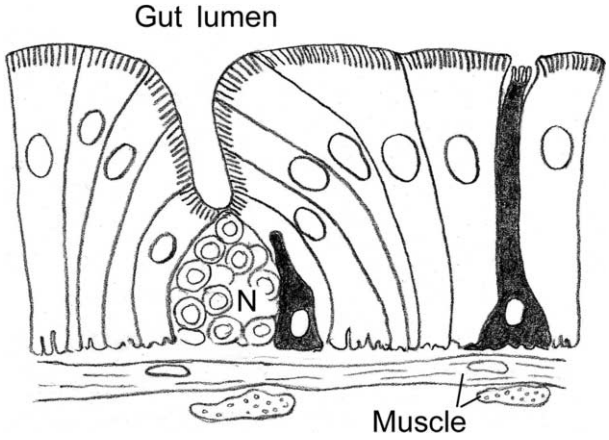

FIGURE 8 Diagram of a portion of a cross section of midgut. Endocrine cells are black. One lies near a nidus (N), a cluster of regenerative cells; the other lies between the columnar epithelial cells of the midgut.

typically composed of columnar or cuboidal cells with microvilli at their apical surfaces. At the base of these digestive cells are clumps of regenerative cells (nidi) that give rise to new exocrine cells as well as the endocrine cells that become individually dispersed in the epithelial lining (Fig. 8). The extracellular material at the base of the epithelial cells (basal lamina) is continuous with that of the muscle layers surrounding the midgut, a latticework of inner circular and outer longitudinal muscles. The endocrine cells vary in size and shape but usually they are small compared to the exocrine cells. All endocrine cells contact the basal lamina of the epithelium and extend long thin 'necks' toward the lumen of the gut. Some extend all the way to the surface and have microvillar projections at their apical surfaces; some extend only part way to the inner surface (Fig. 8). The endocrine cells may be distributed throughout the midgut but are often found to be more numerous in the posterior part of the midgut.

At the electron microscope level of resolution, these cells exhibit structures consistent with endocrine function. They contain electron-dense membrane-bound vesicles that on occasion have been seen in the process of releasing their contents at the basal surface of the cell. That these vesicles contain humoral factors was confirmed by their immunoreactivity with antibodies against several different neurohormones that also occur in the nervous system. Several of these neurohormones are known to be modulators of muscle function, for example, the tetrapeptide phenylalanine–methionine–arginine–phenyalanine amide (FMRF amide) and other members of this family occur in midgut endocrine cells and in the nerves to the gut in representatives of most insect orders. This peptide is also found in the CNS. Many vertebrate gut hormones have been demonstrated in insect gut by immunocytochemistry, which indicates at least some structural similarity between gut hormones of insects and those of vertebrates. Little is known about how these hormones function in the insects. However, changes in hormone content of the endocrine cells in insects subjected to different conditions of feeding and starvation suggest that they play some role in nutritional state. Experimental studies on gut tissue in short-term culture indicate that some of the hormones may stimulate digestive enzyme secretion and some may act on the muscles surrounding the midgut. The innervation of the midgut muscle layer is far less extensive than that of hind- and foregut. Much remains to be learned about the function of these gut endocrine cells.

F. Oenocytes and Blood Cells

Oenocytes are large cells that arise in the abdominal epidermis and remain there in some insects but in others they become associated with the fat body or remain in isolated groups. The oenocytes are associated primarily with cuticle formation but they have also been shown to produce ecdysteroids in several insect species. Little is known about the importance of this endocrine function of oenocytes.

A class of granular blood cells in the cockroach, *Diploptera punctata*, was found to synthesize allatostatin, the neuropeptide that inhibits JH synthesis and muscle contraction. The physiological role of the peptide occurring in these cells has not been investigated. There are very likely other neuropeptides that remain to be described in granular blood cells.

IV. NEUROSECRETORY SYSTEM

A. Discovery of Neurohormones and Their Abundance

The hormones produced by the nervous system far outnumber those produced by endocrine glands proper and these neurosecretions are involved in the regulation of all aspects of insect biology. The first experimental evidence for a humoral function of the nervous system in any animal was shown in insects. In 1917, Stefan Kopeć demonstrated that the brain of a European silk moth larva was necessary for metamorphosis and that the influence was not through nerves but through the blood. In the 1940s and 1950s, special neurosecretory cells of the nervous system were visualized with specific stains in both vertebrates and invertebrates, including insects, by Ernst and Berta Scharrer. Through the use of several neurosecretory stains, the distribution of different types of neurosecretory cells in the CNS and in specialized release sites were described in many different insects. It was also recognized that in some instances these cells and their release sites could be recognized in living insects because the intracellular granules containing the secretory material scatter light to produce a blue opalescence, known as the Tyndall effect. It was not until 1975, when methods became available for purification of small amounts of material, that the chemical structure of the first insect neuropeptide, the pentapeptide proctolin, was described. Since then, hundreds of neuropeptides have been identified. Antibodies to these identified neurosecretory substances have provided for

localization of the nerve cell bodies (soma) producing specific neuropeptides and the projections of their processes. The morphology of neurosecretory cells may be very complex in their ramifications in both the CNS and the periphery.

Some of the neurosecretory cells release their product into the blood from organized release sites that form conspicuous organs, whereas others release their product from varicosities in the axons that project to various organs from which they could be released into the blood or could act locally (paracrine release). Other neurosecretory cells possess axons projecting only within the CNS, suggesting that their secretions act on other nerve cells. Many of the individual neuropeptides have been shown to occur in numerous cells in different parts of the nervous system and release their products in these different ways. Also, the same neuropeptide may occur in cells other than nerve cells (e.g., endocrine cells of the gut and blood cells). Such diverse localization suggests multiple functions for a single type of neuropeptide and indeed this has been shown for many of them. It is also now known that a single cell may produce more than one neuropeptide.

B. Anatomy of the Neurosecretory System

1. Central Nervous System

a. Brain–Retrocerebral Complex. The brain is a major source of neurohormones. Neurosecretory cells of the brain send axons posteriorly to adjacent paired organs, the CC and the CA. The CC are the major release sites for brain neuropeptides but the CA also serve this function in some species. Together, this part of the neurosecretory system is known as the brain–retrocerebral complex (Fig. 6A). The CC–CA usually lie under the heart and dorsal or lateral to the esophagus. Branches of the axons from the neurosecretory cells of the brain also extend from the CC onto the heart, which also acts as a neurohemal release site. Nerves from the CC also extend into the hypocerebral ganglion and onto the esophagus (part of the stomatogastric nervous system; see Section IV, B2).

In the first segment of the brain, the protocerebrum, there are two conspicuous bilateral groups of neurosecretory cells: a large medial group located at the junction of the two cerebral lobes and a smaller lateral group. Dendrites of these cells have extensive branches within the brain. The third brain segment, the tritocerebrum, also has conspicuous neurosecretory cells. These groups send axons to the corpora cardiaca in nerves called corpus cardiacum nerves NCC I, II, and III, as was described for the innervation of the corpora allata (Section III, B).

The corpora cardiaca are release sites not only for cerebral neurosecretory cells but also for neurosecretions from intrinsic cells (i.e., cell bodies within the CC). The intrinsic cells arise during embryonic development from the esophageal epithelium. In some orders of insects, the intrinsic cells and axon terminals of cerebral cells are intermixed, whereas in others, these compartments are separate lobes, called secretory and storage lobes, respectively. A major product of intrinsic cells is adipokinetic or hyperglycemic hormone, which promotes the release of lipid or carbohydrate, respectively, from the fat body. The storage lobes release many different neurohormones.

The corpora allata have neurosecretory axons in their surrounding sheath and also axons that branch between CA cells. These axons originate in both medial and lateral neurosecretory cells of the brain. The neurosecretory material is released from both the surface nerves and those within the CA. Some of this neurosecretory material has been identified and shown to stimulate JH synthesis (allatotropin) or inhibit JH synthesis (allatostatins). In cockroaches, allatostatin circulating in the hemolymph can inhibit JH production but paracrine release from nerve terminals within the CA is more effective. Surprisingly, in the tobacco hornworm, prothoracicotropic hormone is released from axons that enter the CA, but whether this peptide also affects JH production has not been demonstrated. In this insect, a small form of prothoracicotropic hormone (known as bombyxin in species in which it does not stimulate ecdysteroid production by the prothoracic glands) is released from the nerves surrounding the CA.

b. Ventral Nerve Cord and Perivisceral Organs. The ventral nerve cord consists of the subesophageal ganglion in the head, connected to the brain by circumesophageal connectives, and a chain of ganglia in the thoracic and abdominal segments interconnected by paired nerves. Some of the many neurosecretory cells of the subesophageal ganglion release secretions in the retrocerebral complex and others release secretions in more peripheral locations in the head. The release sites for the neurosecretions of the thoracic and abdominal ganglia are in the well-known perivisceral organs (also called perisympathetic organs), which have been described for many insect species. The most conspicuous perivisceral organs occur on the transverse branches of the medial nerves (Fig. 9). Generally, these are dense oval structures consisting of axon terminals of neurosecretory cells of the ventral ganglia. Smaller and less

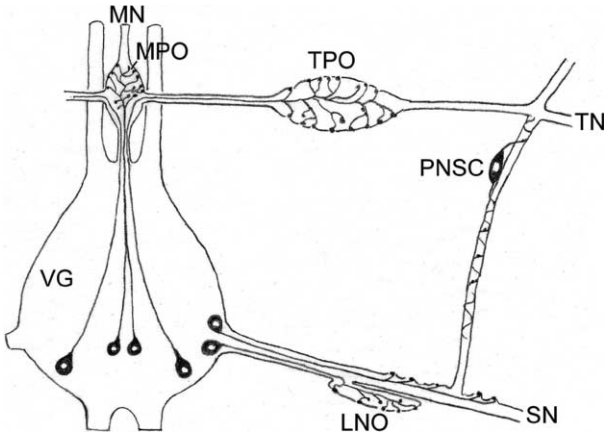

FIGURE 9 Perisympathetic organs and other neurohemal release sites. Neurosecretory cells (black) in a ventral ganglion (VG) send axons in the medial nerve (MN) to neurohemal release sites in the medial perisympathetic organ (MPO) and to the transverse perisympathetic organ (TPO) along the transverse nerve (TN). Lateral neurohemal organs (LNO) and swellings on the nerve sheath are release sites for neurosecretory cells projecting axons into somatic nerves (SN). Peripheral neurosecretory cells (PNSC) and their release sites are on the surface of nerves. Modified from Schooneveld, H. (1998). Neurosecretion. *In* "Microscopic Anatomy of Invertebrates" (F.W. Harrison and M. Locke, eds.), Vol. 11B, Fig. 18, p. 481. This material is used by permission of John Wiley & Sons, Inc.

conspicuous neurohemal organs occur on the medial nerve proper and on somatic nerves leaving the ganglia (Fig. 9). The transverse nerves continue beyond the perivisceral neurohemal organs with branches to the spiracles and to the nerves that extend along the dorsal heart.

c. Diffuse Release Sites. Immunostaining with antibodies against specific neurosecretions has revealed that the perivisceral organs are not the exclusive release areas of the neurosecretory cells of the ventral ganglia. Axons from some of these cells emerge from the peripheral nerves and form networks in the sheath surrounding the nerve. The blebbed or varicose morphology of these networks suggests that they release their product into the hemolymph and thus may constitute a large, diffuse neurohemal area (Fig. 9). In the larvae and pupae of the tobacco hornworm, axons of brain cells that produce eclosion hormone (one of a cascade of hormones involved in molting) travel to the last ganglion of the abdomen and release their hormone into the hemolymph from the surface of the nerve to the hindgut.

d. Targeted Release. Many neuropeptides produced by neurosecretory cells of the ventral ganglia that have been demonstrated to circulate in the hemolymph may also function in a paracrine manner; that is, they affect the target organ at close range. For example, nerves carrying myomodulatory peptides innervate the muscles of the gut and probably act locally. As already mentioned, paracrine release of allatostatins is the most effective in inhibition of the production of juvenile hormone.

2. Stomatogastric Nervous System

In addition to the CNS, there are a series of small ganglia of soma and their interconnecting nerves that are associated with the anterior alimentary canal. Some of the system is illustrated in Figs. 1 and 6A. The frontal ganglion is connected to the tritocerebrum of the brain and in turn to the hypocerebral ganglion near the corpora cardiaca and corpora allata. The esophageal nerve extends between the hypocerebral ganglion and the ingluvial ganglion at the posterior end of the esophagus. Thus, these nerves serve largely the foregut, though some extend over the midgut. This stomatogastric system is interconnected with the CNS. Many different neurosecretory substances have been demonstrated by immunostaining in the nerve cells of this system, and the varicosities of their axon branches on musculature of the anterior gut indicate that neurosecretory material is released from these sites.

3. Peripheral Neurosecretory Cells

Neurosecretory cells (cell bodies and axons) that lie outside of the CNS are distributed in numerous places in the insect body. They are found on the foregut, on specific nerves where they may penetrate into the nerve and send axons toward the CNS or form an extensive network on the surface of the nerve (Figs. 9 and 10).These individual cells may also constitute a significant area for the release of neurohormones.

4. Identified Neurohormones and Their Functions

As mentioned in Section IV (Neurosecretory System), many neurohormones affect more than one type of target tissue and their effects on these targets differ. For example, in cockroaches, allatostatins that inhibit JH synthesis by the CA also inhibit gut muscle contraction, and their occurrence in interneurons suggests that they also act as neuromodulators. A second example of a multifunctional neurohormone is the insect kinin family of diuretic hormones that were originally described as stimulators of muscle contraction and later shown to have diuretic activity. In addition, myomodulators may stimulate one type of muscle and inhibit a different type.

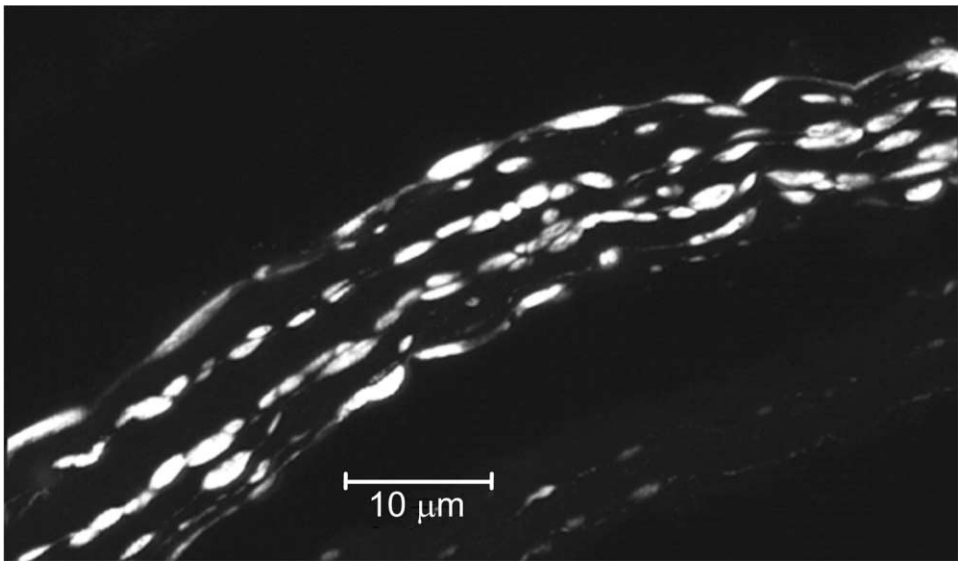

FIGURE 10 Axons with neurohemal release sites (blebs) of peripheral neurosecretory cells on a somatic abdominal nerve of an unfed larval *Rhodnius prolixus*. The immunofluorescence indicates the presence of leucokinin. Micrograph courtesy of Victoria TeBrugge; antibody against leucokinin I, a myokinin, from D. R. Nassel.

Another generality about neurohormones and their functions is the variability of cross-species effectiveness of a neuropeptide family. Some have conserved sequence structures (at least in part, presumably that part required for biological activity) and maintain the same function in distantly related orders of insects. For example, adipokinetic/hypertrehalosemic hormones, members of the red pigment-concentrating hormone family of crustaceans, have been isolated from more than 30 species from a wide variety of insect orders and found to have a reasonably well-conserved peptide sequence and to play similar roles in mobilization of energy reserves. On the other hand, a neuropeptide family such as the cockroach allatostatins are known to act on CA only in cockroaches and crickets and not in more distantly related insects such as flies, bees, and moths, although these insects produce related peptides that act as inhibitors of muscle contraction, a function also found in crickets and cockroaches.

Reference to the names and functions of several neuropeptides has been made in the description of the anatomy of the neurosecretory system. Table 1 presents some of the major neurosecretory hormones and a presumed principal function, but many of these hormones have multiple functions.

V. INTEGRATION OF ENDOCRINE FUNCTIONS

The nervous and endocrine systems are functionally integrated in insects as they are in vertebrates. The foregoing description of neurohormones that regulate endocrine glands and neurohormones that directly affect the physiology of other organs indicates clearly that the CNS controls the release of neurohormones and hormones and thus the neurohormonal and endocrine regulation of development, physiology, and behavior of insects. Sensory information that the brain receives from both the external and the internal environments is then integrated to influence this neuroendocrine regulation. For example, environmental conditions, such as temperature and day length, and internal conditions, such as body weight, nutritional state, and juvenile hormone titer, may determine the timing of prothoracicotropic hormone production by the brain that stimulates the production of ecdysteroid required for the next molt.

The tissues themselves also modulate the effect of the hormones through the regulation of receptor abundance, because the response of tissues depends on the presence of receptors for these messengers. Receptor presence and abundance are time- and stage-dependent so that tissues are responsive only when receptors are present. For example, prothoracic glands may be sensitive to PTTH only at specific times, presumably because the receptors are present during sensitive periods and not during the insensitive periods. In addition, different tissues can respond differently to the same hormone and thus multiple functions can be regulated by a single hormone. For example, a single neuropeptide (diuretic hormone) increases urine output by the Malpighian tubules

TABLE 1 Representative Neurohormones and Their Functions

Type	Hormone	Source	Target	Action
Metabolism	Adipokinetic hormone	Intrinsic CC cells	Fat body	Lipid mobilization
	Hypertrehalosemic hormone	Intrinsic CC cells	Fat body	Carbohydrate mobilization
Ion and water balance	Diuretic hormones			
	(a) Corticotropin-releasing hormone-like family	CNS	Malpighian tubules	Urine production (ion transport; H_2O movement into gut)
	(b) Kinins	CNS	Malpighian tubules	Urine production (ion transport; H_2O movement into gut)
	Anti-diuretic hormones			
	(a) Neuroparsin	Intrinsic CC cells	Hindgut	Resorption of solutes and water
	(b) Ion transport protein	Brain	Hindgut, anterior part	Resorption of solutes and water
Metamorphosis and reproduction	Prothoracicotropic hormone	Brain	Prothoracic glands	Stimulation of ecdysteroid synthesis
	Prothoracicostatic hormone	Brain	Prothoracic glands	Inhibition of ecdysteroid synthesis
	Allatotropins	Brain	Corpora allata	Stimulation of JH synthesis
	Allatostatins	Brain	Corpora allata	Inhibition of JH synthesis
	Eclosion hormone	Brain	Inka cells	Stimulation of ecdysis-triggering hormone
			Ventral nerve cord	Initiation of motor pattern of ecdysis
	Bursicon	Thoracic ganglia	Epidermal cells	Secretion of cuticle tanning agents
	Pheromone biosynthesis-activating neuropeptide	Subesophageal and ventral ganglia	Pheromone-secreting gland	Production of sex phermone
	Egg development neurosecretory hormone	Brain	Ovary	Stimulation of ecdysteroid synthesis
	Ovary-maturing parsin	Brain	Ovary	Stimulation of egg growth
	Cricket allatostatin/ecdysiosuppressin	Brain	Ovary	Inhibition of ecdysteroid synthesis
	Testis ecdysiotropin	Brain	Testis	Stimulation of ecdysteroid synthesis
	Diapause hormone	Subesophageal ganglion	Oocytes	Diapause in embryos
Myomodulatory	Proctolin	Ventral nerve cord	Visceral and body muscles	Stimulation
	Corazonin	Brain, CC	Heart muscle	Stimulation
	Cardioactive peptide	Ventral nerve cord	Heart muscle	Stimulation
	Kinins			
	Myokinins; sulfakinins; pyrokinins; tachykinins; periviscerokinins	CNS	Visceral muscle	Stimulation
	Myosuppressin and other FLRF amides	CNS	Visceral muscle	Inhibition

Note. CC, corpora cardiaca; CNS, central nervous system; FLRF, phenylalanine–leucine–arginine–phenylalanine; JH, juvenile hormone.

and decreases the output in the hindgut (i.e., acts as an anti-diuretic hormone). Neurohormones can also act synergistically with other neurohormones. For example, a locust diuretic hormone and kinin act to promote more urine formation when administered together than when administered separately (synergism).

A single neuropeptide may be found in neurosecretory cells that are widely dispersed in the CNS, in peripheral nerve cells, and in endocrine cells of the midgut. Such a peptide may be produced at different times in development or as a consequence of different physiological states. These spatial and temporal differences in occurrence of neuropeptides, as well as their limited local action, could provide for local regulation of many different physiological, developmental, and behavioral functions by a single neuropeptide.

Glossary

ecdysteroid A major insect hormone family (a group of related steroids produced by the prothoracic gland primarily) necessary for molting (ecdysis) and growth between stages. In some insects, ecdysteroids regulate reproductive functions and are produced by gonads.

hemolymph The fluid that moves in the open circulatory system of insects (i.e., a heart that is open to the body cavity or hemocoel). Also referred to as blood.

juvenile hormone A major insect hormone family (a group of similar sesquiterpenoids produced by corpora allata) necessary for maintaining immature characteristics in development and, in most insects, necessary for reproductive functions.

larva An immature stage of the life cycle. Nymph is also a larval stage, usually referring to immature stages of insects with incomplete metamorphosis.

metamorphosis Changes in form from the immature to the sexually mature stage of the life cycle. The change varies in degree with evolutionary lineage of the orders from primitive to more highly evolved: very little change (ametabolous); some change (incomplete or hemimetabolous); extreme change (complete or holometabolous).

molting The process of shedding the exoskeleton between developmental stages. This process is also called ecdysis or eclosion.

neurohemal organs Sites of neuronal terminals specialized for release of neurohormones into the hemolymph (circulating body fluid).

neurosecretions Peptides, produced by cells of the nervous system, that regulate numerous functions. Some act locally, diffusing to target organs through local extracellular space (paracrine), and others circulate in the body fluid to act at distant target organs (neuroendocrine or humoral).

Insect Gut as an Endocrine Organ

MARK R. BROWN
University of Georgia

The endocrine system of insects has both glandular and "diffuse" components that secrete diverse chemical messengers into the open circulatory system. The major endocrine glands of insects include the corpora allata, prothoracic glands, gonads, and epitracheal glands (Inka cells). The "diffuse" endocrine component exists as tens to thousands of solitary endocrine cells distributed throughout the midgut, the primary organ for digestion, detoxification, and absorption of food in insects. These cells have essentially the same structure as gut endocrine cells in vertebrates, and in both groups of animals, the gut endocrine system is a primary source of numerous peptide hormones and biogenic amines also found in the nervous system. Past studies of the midgut endocrine

system in insects focused on cell structure and distribution. More recently, specific peptide hormones originating from this system have been identified, and their roles in the regulation of satiety, digestion, and nutrient absorption and metabolism are being explored.

I. THE INSECT GUT

In insects, the alimentary tract consists of a foregut, midgut, and hindgut, and in all life stages, it forms a contiguous sensory and functional interface between the insect and its food. In a generalized insect, the mouth and esophagus empty into the foregut, which differentiates from the embryonic ectoderm, and is covered by a thin protective cuticle on the luminal side. In this gut region, food passes over chemosensory elements en route to the midgut and may be diverted into one or more storage organs. The midgut is formed from anterior and posterior invaginations of embryonic endoderm and, when developed, begins in the thorax at the cardia, where the foregut and midgut join, and ends at the junction of the Malpighian tubules and hindgut. In the immature stages of some insects, the anterior midgut is differentiated into several pouches or gastric ceca. In those insects undergoing metamorphosis in the pupal stage, the larval gut is re-formed into a very different adult gut. The hindgut of ectodermal origin also has an inner cuticular layer and functions to resorb water and other nutrients and to excrete undigested food. Blind-ended Malpighian tubules extend from the junction of the midgut and hindgut into the body cavity. Tubule cells move waste products with water from the hemolymph to the lumen and into the hindgut for excretion. The musculature of the foregut and anterior midgut is innervated by the stomatogastric nervous system, a chain of ganglia connected to the brain and other glands, and the posterior midgut and hindgut by axons from the last two abdominal ganglia of the central nervous system.

The midgut is a tubular monolayer of polarized epithelial cells that is differentiated into several regions. Columnar cells are the largest and most numerous cell type and extend from the outer basal lamina bathed by the open circulatory system to the lumen where food resides. These cells secrete digestive and detoxifying enzymes and facilitate transport of nutrients and ions into the hemolymph. Small endocrine cells and regenerative cells are scattered among these cells. In addition, "goblet" cells specializing in ion transport are present in the midgut of some insect orders. A peritrophic matrix lines the interior of the midgut and is secreted either by the whole epithelium or by specialized cells in the cardia. Air tube cells, circular and longitudinal muscles, and nerve axons intermingle outside the basal lamina of the epithelium.

II. DISTRIBUTION AND MORPHOLOGY OF MIDGUT ENDOCRINE CELLS

Electron microscopy studies in the early 1970s led to the discovery and first brief descriptions of "clear cells" in the midgut of the silkworm and other insects. Their ultrastructural organization is the same as that of gut endocrine cells in mammals, also first described as clear cells. Only a few studies have described in detail the ultrastructure and distribution of midgut endocrine cells in specific insects, and most reports on midgut ultrastructure simply note the presence of such cells.

In general, endocrine cells are dispersed as solitary cells throughout the midgut, including the cardia and hindgut junction. The cells are positioned basally in the epithelium and are much smaller than the surrounding columnar cells (Fig. 1A). Most endocrine cells have a cone or flask shape due to an apical extension to the midgut lumen that is capped with microvilli and often are termed "open cells" (Fig. 1B). Occasionally, basal extensions are observed on these cells. Other endocrine cells lack an apical extension, as confirmed by serial-section microscopy, and are known as "closed" cells. Notably, both cell types vary in the electron density of the cytoplasm and are seen as clear or dark cells in electron micrographs; the significance of this cytoplasmic condition is not known.

The frequent pairing of endocrine cells and regenerative cells in insect midguts has been noted. Regenerative cells are thought to be stem cells and, depending on the insect group, either form nests or are scattered in the epithelium. These cells typically have a dark cytoplasm and lack secretory granules and apical extensions. In cockroaches, nests of regenerative cells were the first and only ones in the adult male midgut labeled with [^{3}H]thymidine by 7 days postinjection, but by 14 to 21 days, both columnar cells and endocrine cells were labeled. These observations suggest that endocrine cells differentiate from regenerative cells and may even release factors that affect the division and differentiation of regenerative cells into other cell types.

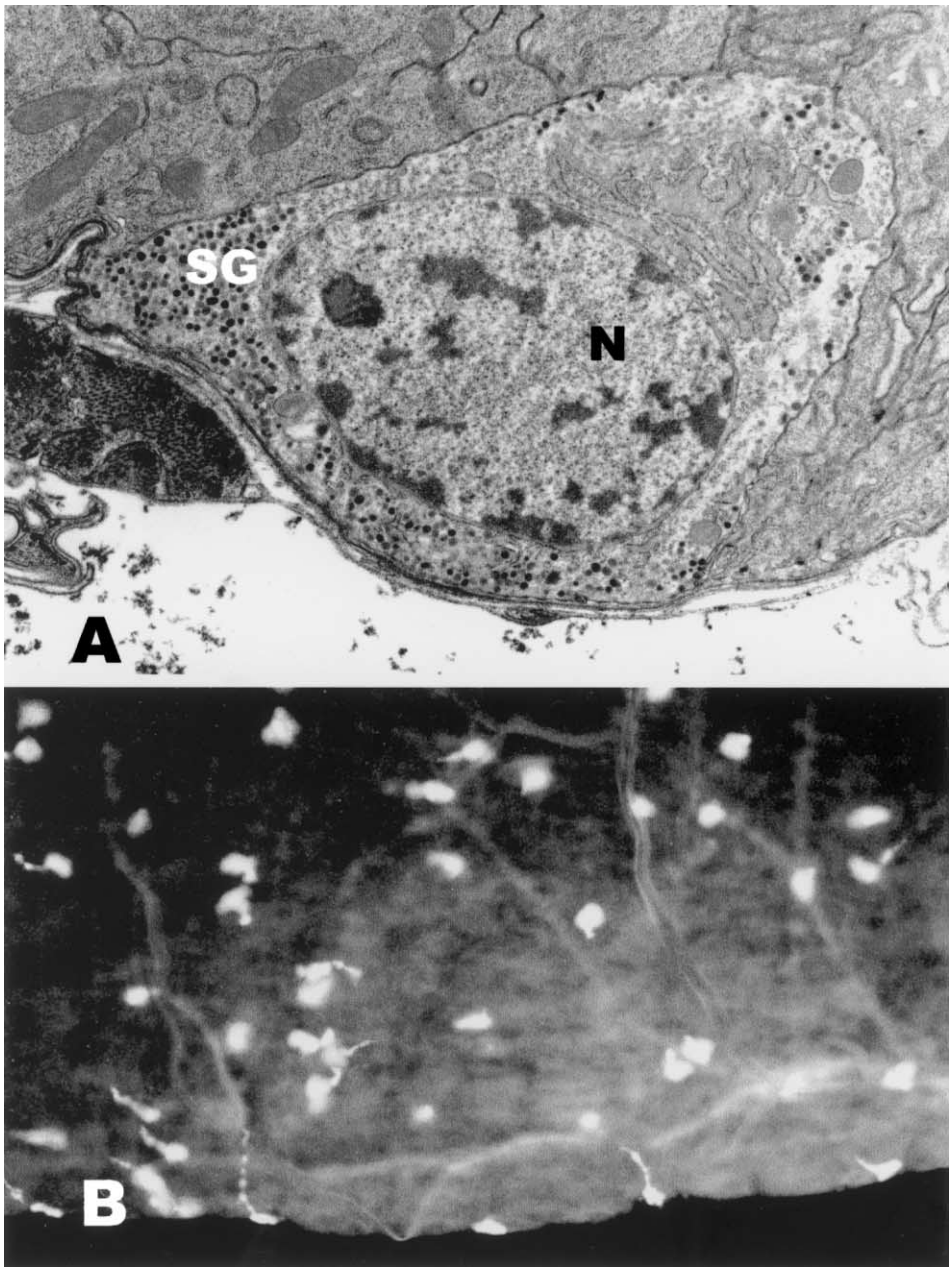

FIGURE 1 (A) Electron micrograph of an endocrine cell positioned basally in the midgut of a female mosquito. N, nucleus; SG, secretory granules. (B) Numerous endocrine cells immunostained with an antiserum to *Drosophila* neuropeptide F and located in the posterior region of a female mosquito midgut. Note stained apical extensions of the endocrine cells on the rim of the midgut.

A. Formation and Release of Secretory Granules

The most definitive characteristics of midgut endocrine cells are the presence of membrane bounded secretory granules in the basolateral cytoplasm and the absence of a basal membrane labyrinth. In contrast, surrounding digestive cells have only a few such granules and extensive enfolding of the basal membrane. Among the endocrine cells described for insects, secretory granules range in size from 60 to 800 nm and in number from a few to hundreds in a cell (Fig. 1A). In addition, different types of granules have been observed in the endocrine cells

of a particular species, but each cell contains only one type. These granule characteristics have been used to classify endocrine cells in the midgut of a few insects, and the different cell types were confined to specific midgut regions.

The ultrastructure of midgut endocrine cells is similar to other cells known to secrete peptide hormones. Peptide precursors or prohormones are transcribed from mRNA into the rough endoplasmic reticulum, after which the precursors move to the Golgi complexes for enzymatic processing and packaging in secretory granules. As demonstrated for midgut endocrine cells, these granules contain peptides, and their contents are released into the extracellular space for diffusion to neighboring cells and into the hemolymph for transport to other target tissues.

B. Lamellar Bodies

Lamellar bodies (up to 1 μm in diameter) often are present in the apical and lateral regions of midgut endocrine cells. In female mosquitoes, these organelles contain a few secretory granules and lack acid phosphatase, which is present in the degradative organelles (lysosomes) of adjacent digestive cells. Comparable lamellar bodies have been reported for neurosecretory cells in other invertebrate and vertebrate animals and are thought to play a role in the recycling of secretory granules during periods of active secretion.

III. IDENTIFIED CHEMICAL MESSENGERS

Comparative endocrinology has elucidated two trends in peptide hormone signaling common to insects and vertebrate animals. First, the structure and function of peptide hormones, their processing and degrading enzymes, and their receptors are conserved to a surprising degree. Second, cells that secrete these messengers are found primarily in the nervous system and gut. In both animal groups, discoveries supporting these trends largely were made with immunoassays that detect putative peptide hormones based on their antigenically similar amino acid sequences. Immunocytochemistry stains midgut cells that secrete the peptide of interest (Fig. 1B); thus, the distribution and number of cells and effects of food ingestion or starvation can be determined. Radioimmunoassays or enzyme-linked immunoassays allow for the identification and quantification of related peptides in tissue extracts and are used to monitor the purification of peptides.

Immunocytochemistry most often is used to identify putative peptide hormones secreted by midgut endocrine cells in diverse insects and can be a first step toward the structural and functional characterization of native peptides. Most studies have focused on vertebrate-like peptide hormones because their antisera are readily available. The list of vertebrate peptides found in midgut endocrine cells includes pancreatic polypeptide (PP), enkephalin, endorphin, gastrin, cholecystokinin, corticotropin-releasing factor/urotensin, insulin, and tachykinins. Surprisingly, only one report has shown that the biogenic amine, serotonin, exists in the midgut endocrine system of an insect. Endocrine cells, as well, contain insect-specific peptides, such as allatostatin (an inhibitor of juvenile hormone synthesis by cockroach corpora allata), and different peptides having Arg-Phe-amide (RFa) at the carboxyl-terminus, e.g., myosuppressin. Many studies found that peptide RFa- and PP-like immunostaining is colocalized in the same midgut endocrine cells and the stomatogastric nervous system. These results may be due in part to the fact that RFa and the Arg-Tyr-amide on the PP of higher vertebrates are highly antigenic epitopes and common to many other peptides found in invertebrate and vertebrate animals. Thus, antisera generated to a particular peptide with either of these carboxyl-termini likely recognize unrelated peptides with only this epitope in common. More revealing is the localization of peptide mRNA in midgut cells by *in situ* hybridization. This has been accomplished for neuropeptide F, the invertebrate orthologue of PP, in the midgut of *Drosophila* larvae and for myosuppressin and allatostatin in cockroach midgut.

Although the biological activity of midgut extracts was first reported in the late 1940s and later in the 1960s, there is to date only one report of a midgut peptide that was purified based solely on its bioactivity. The myotropic peptide was isolated from an extract of midguts of tobacco hornworm larvae, and its sequence of five amino acids has little similarity to vertebrate and invertebrate peptides. Allatostatins, myosuppressin, and tachykinins were first isolated from the insect nervous system and later from midgut extracts as immunoreactive peptides that have identical sequences. As synthetic peptides, allatostatins and myosuppressin inhibit muscle contractions of guts and other tissues from a variety of insects, and both peptides stimulate invertase and amylase activity in the lumen of cockroach midguts. Release of tachykinins from midguts has been demonstrated, and these peptides stimulate muscle contractions on many insect tissues.

In all higher vertebrate animals, insulin is produced only in a specialized gut region, and there are several reports on the extraction and purification of insulin-like factors from midguts of insects. Both the immunoreactivity and the bioactivity of these factors have been demonstrated, but to date, insulin peptides have been isolated only from the brains of silk moths and locusts, and they are similarly expressed in *Drosophila*.

At this time, a listing of insect peptide hormones found only in the midgut or nervous system or common to both organs would be highly speculative because it would be derived largely from immunocytochemical studies, which often examine one tissue but not the other of a particular insect and use loosely specific antisera. In the near future, exploration of the genomic and expressed sequence databases for *Drosophila* and other insects likely will produce a reasonably complete list of genes encoding peptide messengers. Only when the tissue and developmental expression of these genes is known will their function as midgut hormones, neuropeptides, or both be defined.

IV. FUNCTION

Although the regulatory dimensions of the midgut endocrine system have yet to be revealed, a review of the studies to date shows it to be a ubiquitous source of diverse peptide hormones in insects. Identification of additional midgut peptide hormones will be relatively easy in comparison to defining their regulatory roles. Future studies will need to encompass screening for activity in diverse bioassays, receptor identification and tissue localization, and effects of peptide or receptor gene "knockouts" and "overexpression" to identify functions for midgut peptides. Most importantly, these peptides cannot be considered hormones until their release into the hemolymph is shown to occur prior to or accompany the regulated physiological process.

Conceptually, the diffuse distribution of endocrine cells in the midgut likely is an important factor in the system's ability to regulate digestive, absorptive, and metabolic processes in insects. Food in the midgut lumen is "outside" the insect body; thus, endocrine cells with extensions to the lumen would act as "sensory/effector" cells to monitor the quality and quantity of food throughout the midgut. Food molecules or the absence of food would be detected by receptors on the microvilli or by uptake into the cells. Intracellular mediation of these external signals would in turn block or stimulate peptide secretion by endocrine cells. The released peptide hormones may have paracrine effects on neighboring digestive cells that would respond to a titered signal by releasing enzymes in the amount required to digest the food present. Then, as the food was depleted by digestion and absorption, other endocrine cells would signal the muscles to move the food around or out of the midgut. Other gut-specific processes may be regulated, as indicated by the clustering of endocrine cells in the junction of the midgut, hindgut, and Malpighian tubules of locusts that are thought to sense and alter fluid content and flow in the lumen of these tissues relative to hemolymph. Midgut peptide hormones likely have endocrine effects on the fat body, the primary organ of nutrient metabolism and storage, and other tissues by signaling food quality and quantity or its absence. In addition, interactions between the nervous system and midgut endocrine system may coordinate digestive and excretory processes with feeding behavior.

Glossary

endocrine cells Small cells scattered basally in the midgut epithelium that secrete peptide hormones.

immunocytochemistry A microscopy technique that identifies cells containing peptides or proteins recognized by specific antibodies, which are labeled.

***in situ* hybridization** A microscopy technique that identifies cells containing messenger RNA for specific peptides or proteins by hybridization to labeled complementary nucleotide probes.

midgut The organ for digestion and absorption of food in insects that also has important roles in water balance, nutrient metabolism, and detoxification.

radioimmunoassay A solution-based assay for the competition and separation of unlabeled and radioactive isotope-labeled molecules bound to specific antibodies that allows for the identification and quantification of the molecules in tissue extracts and chromatography fractions.

Insulin Actions

RALPH A. DEFRONZO AND LAWRENCE J. MANDARINO
University of Texas Health Science Center, San Antonio

Type 2 diabetes mellitus is characterized by moderate to severe insulin resistance and impaired beta cell function. When the accelerated rate of insulin secretion no longer can compensate for the severity of insulin resistance, overt diabetes ensues. In type 2 diabetic individuals, there is an increase in hepatic glucose production that correlates closely with the elevation in fasting plasma glucose concentration. Muscle and adipose tissue are resistant to insulin and contribute to postprandial hyperglycemia. Impaired insulin signaling (reduced insulin receptor and IRS-1 tyrosinephosphorylation and diminished PI-3 kinase activity and PI-3 kinase activity with IRS-1), decreased glucose transport and phosphorylation, and diminished glycogen synthase all contribute to be insulin resistance in insulin target tissues.

I. INSULIN RESISTANCE AND TYPE 2 DIABETES

Both longitudinal and cross-sectional studies have documented conclusively that hyperinsulinemia precedes the development of type 2 diabetes in most ethnic populations with a high incidence of type 2 diabetes. Studies employing the euglycemic insulin clamp, minimal model, and insulin suppression techniques have provided direct quantitative evidence that the progression from normal to impaired glucose tolerance is associated with the development of severe insulin resistance, whereas plasma insulin concentrations, both in the fasting state and in response to a glucose load, are increased (see above discussion on insulin secretion).

Himsworth and Kerr, using a combined oral glucose and intravenous insulin tolerance test, were the first to demonstrate that tissue sensitivity to insulin was diminished in diabetic patients. In 1975, Reaven and colleagues, using the insulin suppression test, found that the ability of insulin to promote tissue glucose uptake in type 2 diabetes was severely reduced. A defect in insulin action in type 2 diabetes also has been demonstrated with limb infusion of insulin using the forearm and leg catheterization techniques, as well as with radioisotope turnover studies, the modified intravenous glucose tolerance test, and the minimal model technique.

DeFronzo *et al.*, using the more physiologic euglycemic insulin clamp technique, have provided the most conclusive documentation that insulin resistance is a characteristic feature of lean type 2 diabetic individuals. Because diabetic patients with severe fasting hyperglycemia ($>180-200$ mg/dl, 10.0–11.1 mmol/liter) are known to be insulinopenic, and insulin deficiency is associated with the emergence of a number of intracellular defects in insulin action, only diabetics with mild to modest elevations in the fasting plasma glucose concentration (mean $= 150 \pm 8$ mg/dl, 8.3 ± 0.4 mmol/liter) were included in these studies in order to focus on the early stages of the evolution of type 2 diabetes in normal-weight subjects. Insulin-mediated whole-body glucose disposal was reduced by $\sim 40-50\%$ in type 2 diabetic subjects, conclusively demonstrating the presence of moderate to severe insulin resistance. Three additional points are noteworthy: (1) in lean type 2 diabetics with more severe fasting hyperglycemia (198 ± 10 mg/dl), the severity of insulin resistance is only slightly (10–20%) greater than that in diabetic patients with mild fasting hyperglycemia; (2) the defect in insulin action is observed at all

plasma insulin concentrations, spanning the physiological and pharmacological range (3) in diabetic patients with overt fasting hyperglycemia, even maximally stimulating plasma insulin concentrations are not capable of eliciting a normal glucose metabolic response under euglycemic conditions. With a few exceptions, the great majority of investigators have demonstrated that lean type 2 diabetic subjects are resistant to the action of insulin. The ability of glucose, i.e., hyperglycemia, to stimulate its own uptake also is impaired in type 2 diabetics.

II. SITES OF INSULIN ACTIONS AND RESISTANCE

The maintenance of whole-body glucose homeostasis is dependent on a normal insulin secretory response by the pancreatic beta cells and normal tissue sensitivity to the independent effects of hyperinsulinemia and hyperglycemia (i.e., the mass-action effect of glucose) to augment glucose uptake. In turn, the combined effects of insulin and hyperglycemia to promote glucose disposal are dependent on three tightly coupled mechanisms (Table I): (1) suppression of endogenous (primarily hepatic) glucose production; (2) stimulation of glucose uptake by the splanchnic (hepatic plus gastrointestinal) tissues; and (3) stimulation of glucose uptake by peripheral tissues, primarily muscle. Muscle glucose uptake is regulated by flux through two major metabolic pathways: glycolysis (~90% of which represents glucose oxidation) and glycogen synthesis.

A. Hepatic Glucose Production

In the overnight fasted state, the liver of healthy subjects produces glucose at the rate of ~1.8–2.0 mg·kg^{-1}·min^{-1}. This glucose flux is essential to meet the needs of the brain and other neural tissues, which utilize glucose at a constant rate of ~1–1.2 mg·kg^{-1}·min^{-1}. Brain glucose uptake accounts for ~50–60% of glucose disposal during the postabsorptive state and this uptake is insulin independent. Therefore, brain glucose uptake occurs at the same rate during absorptive and postabsorptive periods and is not altered in type 2 diabetes. Following glucose ingestion, insulin is secreted into the portal vein and carried to the liver, where it suppresses hepatic glucose output. If the liver does not perceive this insulin signal and continues to produce glucose, there will be two inputs of glucose into the body, one from the liver and another from the gastrointestinal tract, and marked hyperglycemia will ensue.

In type 2 diabetic subjects with mild to moderate fasting hyperglycemia (140–200 mg/dl, 7.8–11.1 mmol/liter), basal hepatic glucose production (HGP) is increased by ~0.5 mg/kg·min (Fig. 1). Consequently, during the overnight sleeping hours (2200 h to 0800 h), the liver of an 80 kg diabetic individual with modest fasting hyperglycemia adds an additional 30 g of glucose to the systemic circulation. The increase in basal HGP is closely correlated with the severity of fasting hyperglycemia (Fig. 1). Thus, in type 2 diabetics with overt fasting hyperglycemia (>140 mg/dl, 7.8 mmol/liter), an excessive rate of hepatic glucose output is the major abnormality

TABLE I Factors Responsible for the Maintenance of Normal Glucose Tolerance in Healthy Subjects

Insulin secretion
Tissue glucose uptake
Peripheral (primarily muscle)
Splanchnic (liver plus gut)
Suppression of HGP
Decreased FFA
Decreased glucagon
Route of glucose adminstration

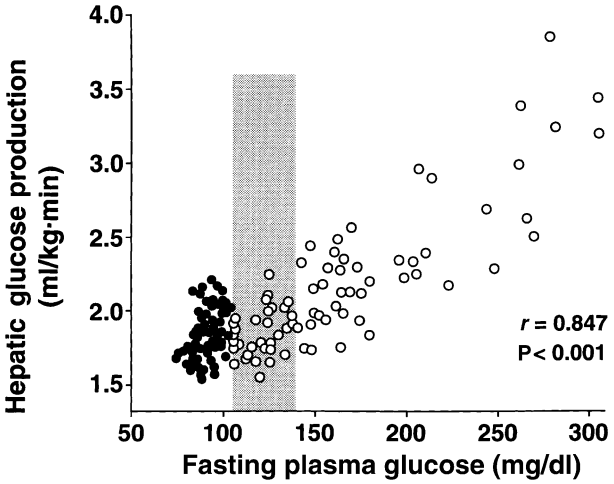

FIGURE 1 Summary of HGP in 77 normal-weight type 2 diabetic subjects (○) with fasting plasma glucose concentrations ranging from 105 to >300 mg/dl; 72 control subjects matched for age and weight are shown by solid circles. In the 33 diabetic subjects with fasting plasma glucose levels <140 mg/dl (shaded area), the mean rate of HGP was identical to that of control subjects. In diabetic subjects with fasting plasma glucose concentrations >140 mg/dl, there was a progressive rise in HGP that correlated closely ($r = 0.847$, $P < 0.001$) with the fasting plasma glucose concentration. Reprinted from DeFronzo *et al.* (1989), *Metabolism* **38**, 387–395, with permission.

responsible for the elevated fasting plasma glucose concentration. The close relationship between fasting plasma glucose concentration and HGP has been demonstrated in numerous studies.

In the postabsorptive state, the fasting plasma insulin concentration in type 2 diabetics is two- to fourfold greater than in nondiabetic subjects. Because hyperinsulinemia is a potent inhibitor of HGP, hepatic resistance to the action of insulin must be present in the postabsorptive state to explain the excessive output of glucose by the liver. Hyperglycemia per se also exerts a powerful suppressive action on HGP. Therefore, the liver also must be glucose resistant with respect to the inhibitory effect of hyperglycemia to suppress hepatic glucose output, and this has been well documented.

Using the euglycemic insulin clamp technique in combination with tritiated glucose, the dose–response relationship between hepatic glucose production and the plasma glucose concentration has been defined. The following points should be emphasized: (1) the dose–response curve relating inhibition of HGP to the plasma insulin concentration is quite steep, with an effective dose for half-maximal insulin concentration (ED_{50}) of ~30–40 μU/ml; (2) in type 2 diabetic individuals the dose–response curve is shifted to the right, indicating the presence of hepatic resistance to the inhibitory effect of insulin on hepatic glucose production. However, at plasma insulin concentrations within the high physiologic range (~100 μU/ml), the hepatic insulin resistance can be largely overcome and a near normal suppression of HGP can be achieved; and (3) the severity of the hepatic insulin resistance is related to the severity of the diabetic state. In type 2 diabetic individuals with mild fasting hyperglycemia, an increment in plasma insulin concentration of 100 μU/ml causes a complete suppression of HPG. However, in diabetic subjects with more severe fasting hyperglycemia, the ability of the same plasma insulin concentration to suppress HGP is impaired. These results suggest that there is an acquired component of hepatic insulin resistance and that this defect becomes progressively worse as the diabetic state decompensates over time.

The glucose released by the liver can be derived from either glycogenolysis or gluconeogenesis. Studies employing the hepatic vein catheter technique have shown that the uptake of gluconeogenic precursors, especially lactate, is increased in type 2 diabetic subjects. Consistent with this observation, radioisotope turnover studies, using lactate, alanine, and glycerol, have shown that ~90% of the increase in HGP above baseline can be accounted for by accelerated gluconeogenesis. More recent studies employing ^{13}C magnetic resonance imaging (MRI) and D_2O have confirmed the important contribution of accelerated gluconeogenesis to the increase in HGP. An increased rate of glutamine conversion to glucose also has been shown to contribute to the elevated rate of gluconeogenesis in type 2 diabetic subjects. The mechanisms responsible for the increase in hepatic gluconeogenesis include hyperglucagonemia, increased circulating levels of gluconeogenic precursors (lactate, alanine, glycerol), increased FFA oxidation, enhanced sensitivity to glucagon, and decreased sensitivity to insulin. Although the majority of evidence indicates that increased gluconeogenesis is the major cause of the increase in HGP in type 2 diabetic subjects, it is likely that accelerated glycogenolysis also contributes.

Because of the inaccessibility of the liver in human, it has been difficult to assess the role of key enzymes involved in the regulation of gluconeogenesis [pyruvate carboxylase, phosphoenolpyruvate carboxykinase (PEPCK)], glycogenolysis (glycogen phosphorylase), and net hepatic glucose output [glucose-6-phosphatase (G-6-Pase)]. However, considerable evidence from animal models of type 2 diabetes and some evidence in humans have implicated increased activity of PEPCK and G-6-Pase in the accelerated rate of hepatic glucose production.

The kidney also has been shown to produce glucose and estimates of the renal contribution to total endogenous glucose production have varied from 5 to 20%. These varying estimates of the contribution of renal gluconeogenesis to total glucose production are largely related to the methodology employed to measure glucose production by the kidney. One unconfirmed study suggests that the rate of renal gluconeogenesis is increased in type 2 diabetics with fasting hyperglycemia. Arguing against this possibility are studies employing the hepatic vein catheter technique that have shown that the entire increase in total-body endogenous glucose production (measured with [3-^{3}H]glucose) in type 2 diabetics can be accounted for by increased hepatic glucose output (measured by the hepatic vein catheter technique).

B. Peripheral (Muscle) Glucose Uptake

Muscle is the major site of glucose disposal in human. Under euglycemic hyperinsulinemic conditions, approximately 80% of total-body glucose uptake occurs in skeletal muscle. Studies employing

the euglycemic insulin clamp in combination with femoral artery/vein catheterization have examined the effect of insulin on leg glucose uptake in type 2 diabetic and control subjects. Since bone is metabolically inert and adipose tissue takes up less than 5% of an infused glucose load, muscle represents the major tissue responsible for leg glucose uptake.

In response to a physiologic increase in plasma insulin concentration (~80–100 μU/ml), leg (muscle) glucose uptake increases linearly, reaching a plateau value of 10 mg/kg leg weight per minute. In contrast, in lean type 2 diabetic subjects, the onset of insulin action is delayed for ~40 min and the ability of the hormone to stimulate leg glucose uptake is markedly blunted, even though the study is carried out for an additional 60 min in the type 2 diabetic group to allow insulin to more fully express its biological effects. During the last hour of the insulin clamp study, the rate of total body glucose uptake was reduced by 50% in the diabetic group. These results provide conclusive evidence that the primary site of insulin resistance during euglycemic insulin clamp studies performed in type 2 diabetic subjects is muscle tissue. Using the forearm and leg catheterization techniques, a number of investigators have demonstrated a decreased rate of insulin-mediated glucose uptake by peripheral tissues. The use of positron emission tomography (PET) scanning to quantitate leg glucose uptake in type 2 diabetic subjects has provided additional support for the presence of severe muscle resistance to insulin in diabetic subjects.

C. Splanchnic (Hepatic) Glucose Uptake

In humans, it is difficult to catheterize the portal vein, and glucose disposal by the liver has not been examined directly. Using the hepatic vein catheterization technique in combination with the euglycemic insulin clamp, the contribution of the splanchnic (liver plus gastrointestinal) tissues to overall glucose homeostasis has been examined in lean type 2 diabetic subjects with mild to moderate fasting hyperglycemia. In the postabsorptive state, there is a net release of glucose from the splanchnic area (i.e., negative balance) in both control and type 2 diabetic subjects, reflecting glucose production by the liver. In response to insulin, splanchnic glucose output is promptly suppressed (reflecting the inhibition of HGP) and, by 20 min, the net glucose balance across the splanchnic region declines to zero (i.e., there was no net uptake or release). After 2 h of sustained hyperinsulinemia, there is a small net uptake of glucose (~0.5 $mg \cdot kg^{-1} \cdot min^{-1}$) by the splanchnic area (i.e., positive balance). This uptake is virtually identical to the rate of splanchnic glucose uptake observed in the basal state, indicating that the splanchnic tissues, like the brain, are insensitive to insulin at least with respect to the stimulation of glucose uptake. There was no difference between diabetic and control subjects in the amount of glucose taken up by the splanchnic tissues at any time during the insulin clamp study.

The results of these studies illustrate another important point: namely, that under conditions of euglycemic hyperinsulinemia, very little of the infused glucose is taken up by the splanchnic (and therefore hepatic) tissues. During the insulin clamp, the rate of whole-body glucose uptake averaged 7 $mg \cdot kg^{-1} \cdot min^{-1}$, and of this, only 0.5 $mg \cdot kg^{-1} \cdot min^{-1}$, or 7%, was disposed of by the splanchnic region. Because the difference in insulin-mediated total-body glucose uptake between the type 2 diabetic and control groups during the euglycemic insulin clamp study was 2.5 $mg \cdot kg^{-1} \cdot min^{-1}$, from a purely quantitative standpoint it is obvious that a defect in splanchnic (hepatic) glucose removal never could account for the magnitude of impairment in total-body glucose uptake following intravenous glucose/insulin administration. However, after glucose ingestion, the oral route of administration and the resultant hyperglycemia combine to enhance splanchnic (hepatic) glucose uptake and, under these conditions, diminished hepatic glucose uptake has been shown to contribute to the impairment in glucose tolerance in type 2 diabetes (see discussion below).

D. Summary: Whole-Body Glucose Utilization

Insulin-mediated whole-body glucose utilization during the euglycemic insulin clamp is summarized in Fig. 2. The total height of each bar represents the amount of glucose taken up by all tissues in the body during the insulin clamp in control and type 2 diabetic subjects. Net splanchnic glucose uptake, quantitated by the hepatic venous catheterization technique, is similar in both groups and averaged 0.5 $mg \cdot kg^{-1} \cdot min^{-1}$. Adipose tissue glucose uptake accounts for less than 5% of total glucose disposal. Brain glucose uptake, estimated to be 1.0–1.2 $mg \cdot kg^{-1} \cdot min^{-1}$ in the postabsorptive state, is unaffected by hyperinsulinemia. Muscle glucose uptake (extrapolated from leg catheterization data) in control subjects accounts for ~75–80% of the total glucose uptake. In type 2 diabetic subjects, the largest part of the impairment in insulin-mediated glucose uptake is accounted for by a defect in muscle

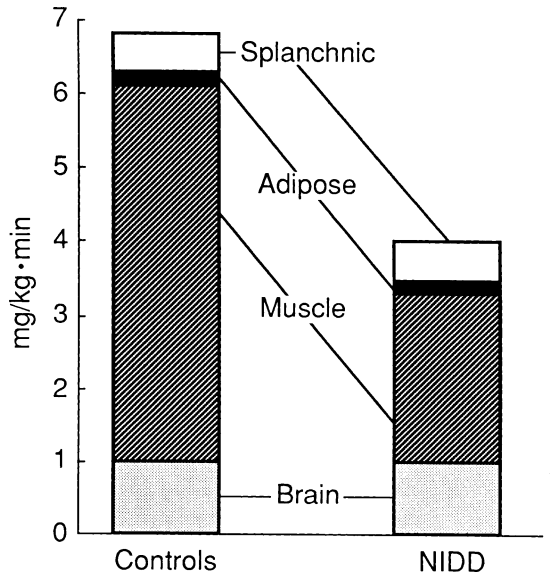

FIGURE 2 Summary of glucose metabolism during euglycemic insulin (100 μU/ml) clamp studies performed in normal-weight type 2 diabetic and control subjects; see text for a more detailed discussion. Reprinted from DeFronzo (1997), with permission.

glucose disposal. Even if adipose tissue of type 2 diabetic subjects took up absolutely no glucose, it could, at best, explain only a small fraction of the defect in whole-body glucose metabolism.

E. Glucose Disposal During OGTT

In everyday life, the gastrointestinal tract represents the normal route of glucose entry into the body. However, the assessment of tissue glucose disposal following glucose ingestion presents a challenge because of the difficulties in quantitating the rate of glucose absorption, suppression of hepatic glucose production, and organ (liver and muscle) glucose uptake. Moreover, because the plasma glucose and insulin concentrations are changing simultaneously, it is difficult to draw conclusions about insulin secretion or insulin sensitivity.

To address these issues, Ferrannini, DeFronzo, and colleagues administered oral glucose to healthy control subjects in combination with hepatic vein catheterization to examine splanchnic glucose metabolism. The oral glucose load and endogenous glucose pool were labeled with [1-^{14}C]glucose and [3-^{3}H]glucose, respectively, to quantitate total-body glucose disposal (from tritiated glucose turnover) and endogenous HGP (difference between the total rate of glucose appearance, as measured with tritiated glucose, and the rate of oral glucose appearance, as measured with [1-^{14}C]glucose).

During the 3.5 h after glucose (68 g) ingestion: (1) 19 g, or 28%, of the oral load was taken up by splanchnic tissues; (2) 48 g, or 72%, was disposed of by peripheral (nonsplanchnic) tissues; (3) of the 48 g taken up by peripheral tissues, the brain (an insulin-independent tissue) accounted for ~15 g (~1 mg·kg^{-1}·min^{-1}), or 22%, of the total glucose load; and (4) basal HGP declined by 53%. Similar percentages for splanchnic glucose uptake (24–29%) and suppression of HGP (50–60%) in normal subjects have been reported by other investigators. The contribution of skeletal muscle to the disposal of an oral glucose load has been reported to vary from a low of 26% to a high of 56%, with a mean of 45%. These results emphasize several important differences between oral and intravenous glucose administration. After glucose ingestion: (1) HGP is less completely suppressed, most likely due to activation of local sympathetic nerves that innervate the liver; (2) peripheral tissue (primarily muscle) glucose uptake is quantitatively less important; and (3) splanchnic glucose uptake is quantitatively much more important.

In type 2 diabetic individuals, the disposition of an oral glucose load is significantly altered. The disturbance in glucose metabolism is accounted for by two factors: (1) decreased tissue glucose uptake and (2) impaired suppression of HGP. Splanchnic glucose uptake is similar in diabetic and control groups. Inappropriate suppression of HGP accounted for approximately one-third of the defect in total-body glucose homeostasis, whereas reduced peripheral (muscle) glucose uptake accounted for the remaining two-thirds. Since hyperglycemia per se enhances splanchnic (hepatic) glucose uptake (SGU) in proportion to the increase in plasma glucose concentration, the splanchnic glucose clearance (SGU divided by plasma glucose concentration) is markedly reduced in all type 2 diabetic subjects following glucose ingestion. Using a combined insulin clamp/OGTT technique, an impairment in glucose uptake by the splanchnic tissues in type 2 diabetics has been demonstrated directly.

When viewed in absolute terms, most studies have demonstrated that the total amount of glucose taken up by all tissues of the body over the 4 h period following the ingestion of an oral glucose load is normal or slightly decreased. However, this occurs at the expense of postprandial hyperglycemia. Thus, the efficiency of glucose disposal, i.e., the glucose

clearance (tissue glucose uptake divided by plasma glucose concentration), is severely reduced. It should be emphasized that it is not the absolute glucose disposal rate but rather the increment in glucose disposal above baseline that determines the rise in plasma glucose concentration above the fasting value. Every published study has demonstrated that the incremental response in whole-body glucose uptake is moderately to severely reduced in type 2 diabetic individuals. Similar results have been reported for forearm muscle glucose uptake, pointing out the important contribution of diminished muscle glucose disposal to impaired oral glucose tolerance in type 2 diabetes.

In summary, results of the OGTT indicate that both impaired suppression of HGP and decreased tissue (muscle) glucose uptake contribute approximately equally to the glucose intolerance of type 2 diabetes. The efficiency of the splanchnic (hepatic) tissues to take up glucose (as reflected by the splanchnic glucose clearance) also is impaired in type 2 diabetic individuals.

F. Summary of Insulin Resistance in Type 2 Diabetes

Insulin resistance involving both muscle and liver is a characteristic feature of glucose intolerance in type 2 diabetic individuals. In the basal state, the liver represents a major site of insulin resistance, and this is reflected by an overproduction of glucose despite the presence of both fasting hyperinsulinemia and hyperglycemia. This accelerated rate of hepatic glucose output is the primary determinant of the elevated fasting plasma glucose concentration in type 2 diabetic individuals. Although tissue (muscle) glucose uptake in the postabsorptive state is increased when viewed in absolute terms, the efficiency with which glucose is taken up (i.e., the glucose clearance) is diminished. After glucose infusion or ingestion (i.e., in the insulin-stimulated state), both decreased muscle glucose uptake and impaired suppression of HGP contribute to insulin resistance. Following glucose ingestion, the defects in insulin-mediated glucose uptake by muscle and the suppression of HGP by insulin contribute approximately equally to the disturbance in whole-body glucose homeostasis in type 2 diabetes. However, under euglycemic hyperinsulinemic conditions, HPG is largely suppressed and impaired muscle glucose uptake is primarily responsible for the insulin resistance.

III. CELLULAR MECHANISMS OF INSULIN

The stimulation of glucose metabolism by insulin requires that the hormone must first bind to specific receptors that are present on the cell surface of all insulin target tissues. After insulin has bound to and activated its receptor, "second messengers" are generated and these second messengers initiate a series of events involving a cascade of phosphorylation–dephosphorylation reactions that eventually result in the stimulation of intracellular glucose metabolism. The initial step in glucose metabolism involves activation of the glucose transport system, leading to an influx of glucose into insulin target tissues, primarily muscle. The free glucose, which has entered the cell, subsequently is metabolized by a series of enzymatic steps that are under the control of insulin. Of these, the most important are glucose phosphorylation (catalyzed by hexokinase), glycogen synthesis (controlled by glycogen synthase), and glycolysis and glucose oxidation (regulated by PFK and PDH, respectively).

A. Insulin Receptor/Insulin Receptor Tyrosine Kinase

The insulin receptor is a glycoprotein consisting of two α-subunits and two β-subunits linked by disulfide bonds (Fig. 3). The α-subunit of the insulin receptor is entirely extracellular and contains the insulin-binding domain. The β-subunit has an extracellular domain, a transmembrane domain, and an intracellular domain that expresses insulin-stimulated kinase activity directed toward its own tyrosine residues. Insulin

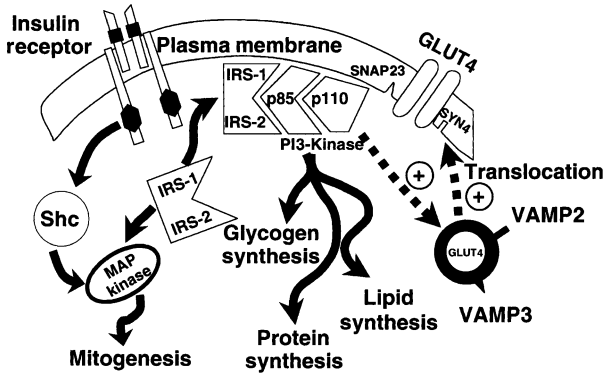

FIGURE 3 Schematic representation of the insulin receptor and the cascade of intracellular signaling molecules that have been implicated in insulin action; see text for a more detailed discussion. SNAP, soluble N-ethylmaleimide sensitive fusion protein attachment protein; VAMP, vesicle-associated membrane protein.

receptor phosphorylation of the β-subunit, with subsequent activation of insulin receptor tyrosine kinase, represents the first step in the action of insulin on glucose metabolism. Mutagenesis experiments have shown that insulin receptors devoid of tyrosine kinase activity are completely ineffective at mediating insulin stimulation of cellular metabolism. Similarly, mutagenesis of any of the three major phosphorylation sites (at residues 1158, 1163, and 1162) impairs insulin receptor kinase activity, resulting in a decrease in the acute metabolic and growth-promoting effects of insulin.

B. Insulin Receptor Signal Transduction

Following activation, insulin receptor tyrosine kinase phosphorylates specific intracellular proteins, of which at least nine have been identified. Four of these belong to the family of insulin-receptor substrate proteins: IRS-1, IRS-2, IRS-3, and IRS-4 (the others include Shc, Cbl, Gab-1, $p60^{dok}$, and APS). In muscle, IRS-1 serves as the major docking protein that interacts with the insulin receptor tyrosine kinase and undergoes tyrosine phosphorylation in regions containing amino acid sequence motifs (YXXM or YMXM) that, when phosphorylated, serve as recognition sites for proteins containing *src*-homology 2 (SH2) domains (where Y denotes a tyrosine, M denotes a methionine, and X denotes any amino acid). Mutation of these specific tyrosines severely impairs the ability of insulin to stimulate glycogen and DNA synthesis, establishing the important role of IRS-1 in insulin signal transduction. In liver, IRS-2 serves as the primary docking protein that undergoes tyrosine phosphorylation and mediates the effect of insulin on hepatic glucose production, gluconeogenesis, and glycogen formation. In adipocytes, Cbl represents another substrate that is phosphorylated following its interaction with the insulin receptor tyrosine kinase and that is required for stimulation of GLUT4 translocation. Phosphorylation of Cbl occurs when the CAP/Cbl complex associates with flotillin in caveolae, or lipid rafts, containing insulin receptors.

In muscle, the phosphorylated tyrosine residues on IRS-1 mediate an association between the two SH2 domains of the 85 kDa regulatory subunit of PI3-kinase, leading to activation of the enzyme (Fig. 3). PI3-kinase is a heterodimeric enzyme composed of an 85 kDa regulatory subunit and a 110 kDa catalytic subunit. The latter catalyzes the 3′ phosphorylation of phosphatidylinositol (PI), PI 4-phosphate, and PI 4,5-diphosphate, resulting in the stimulation of glucose transport. Activation of PI3-kinase by phosphorylated IRS-1 also leads to activation of glycogen synthase, via a process that involves activation of PKB/Akt and subsequent inhibition of kinases such as glycogen synthase kinase-3 (GSK-3) and activation of protein phosphatase 1 (PP1). Inhibitors of PI3-kinase impair glucose transport by interfering with the translocation of GLUT4 transporters from their intracellular location and block the activation of glycogen synthase and HKII expression. The action of insulin to increase protein synthesis and inhibit protein degradation also is mediated by PI3-kinase and involves the activation of mTOR. mTOR controls translation machinery by phosphorylation and activation of p70 ribosomal S6-kinase ($p70^{rsk}$) and phosphorylation of initiation factors. Insulin also promotes hepatic triglyceride synthesis by increasing the transcription factor steroid regulatory element-binding protein-1c and this lipogenic effect of insulin also appears to be mediated via the PI3-kinase pathway.

Other proteins with SH2 domains, including the adapter protein growth factor receptor-binding protein 2 (Grb2) and *Shc*, also interact with IRS-1 and become phosphorylated following exposure to insulin. Grb2 and *Shc* serve to link IRS-1/IRS-2 to the mitogen-activated protein (MAP) kinase signaling pathway (Fig. 3), which plays an important role in the generation of transcription factors. Following the interaction between IRS-1/IRS-2 and Grb2 and *Shc*, Ras is activated, leading to the stepwise activation of Raf, MAP kinase kinase (MEK), and extracellular signal-related kinase (ERK). Activated ERK than translocates into the nucleus of the cell, where it catalyzes the phosphorylation of transcription factors that promote cell growth, proliferation, and differentiation. Blockade of the MAP kinase pathway prevents the stimulation of cell growth by insulin but has no effect on the metabolic actions of the hormone.

Under anabolic conditions, insulin stimulates glycogen synthesis by simultaneously activating glycogen synthase and inhibiting glycogen phosphorylase. The effect of insulin is mediated via the PI3-kinase pathway, which inactivates kinases such as glycogen synthase kinase-3 and activates phosphatases, particularly PP1. It is believed that PP1 is the primary regulator of glycogen metabolism. In skeletal muscle, PP1 associates with a specific glycogen-binding regulatory subunit, causing dephosphorylation (activation) of glycogen synthase. PP1 also phosphorylates (inactivates) glycogen phosphorylase. The precise steps that link insulin receptor tyrosine kinase/PI3-kinase activation to stimulation of PP1

have yet to be defined. Some evidence suggests that p90 ribosomal S6-kinase may be involved in the activation of glycogen synthase. Akt also has been shown to phosphorylate and thus inactivate GSK-3. This decreases glycogen synthase phosphorylation, leading to activation of the enzyme. A number of studies have convincingly demonstrated that inhibitors of PI3-kinase inhibit glycogen synthase activity and abolish glycogen synthesis. From a physiological standpoint, it makes sense that activation of glucose transport and glycogen synthase should be linked to the same signaling mechanism in order to provide a coordinated stimulation of intracellular glucose metabolism.

C. Insulin Signal Transduction Defects in Type 2 Diabetes

1. Insulin Receptor Number and Affinity

Both receptor and postreceptor defects have been shown to contribute to insulin resistance in type 2 diabetic individuals. Some but not all studies have demonstrated a modest 20–30% reduction in insulin binding to monocytes and adipocytes from type 2 diabetic patients. This reduction is due to a decreased number of insulin receptors without a change in insulin receptor affinity. In addition to the decreased number of cell-surface receptors, a variety of defects in insulin receptor internalization and processing have been described. However, some caution should be employed in interpreting these studies. Muscle and liver, not adipocytes, represent the major tissues responsible for the regulation of glucose homeostasis *in vivo* and insulin binding to solubilized receptors obtained from skeletal muscle biopsies and liver has been shown to be normal in obese and lean diabetic individuals when expressed per milligram of protein. Moreover, a decrease in insulin receptor number cannot be demonstrated in over half of type 2 diabetic subjects, and it has been difficult to demonstrate a correlation between reduced insulin binding and the severity of insulin resistance. The insulin receptor gene has been sequenced in a large number of type 2 diabetic patients from diverse ethnic populations using denaturing-gradient gel electrophoresis or single-stranded conformational polymorphism analysis, and, with very rare exceptions, physiologically significant mutations in the insulin receptor gene have not been observed. This excludes a structural gene abnormality in the insulin receptor as a cause of common type 2 diabetes mellitus.

2. Insulin Receptor Tyrosine Kinase Activity

Insulin receptor tyrosine kinase activity has been examined in a variety of cell types (skeletal muscle, adipocytes, hepatocytes, and erythrocytes) from normal-weight and obese diabetic subjects. Most but not all investigators have found reduced tyrosine kinase activity that cannot be explained by alterations in insulin receptor number or insulin receptor binding. However, near normalization of the fasting plasma glucose concentration (by weight loss) has been reported to correct the defect in insulin receptor tyrosine kinase activity. This observation suggests that the defect in tyrosine kinase is acquired and results from some combination of hyperglycemia, defective intracellular glucose metabolism, hyperinsulinemia, and insulin resistance—all of which improved after weight loss. A glucose-induced reduction in insulin receptor tyrosine kinase activity has been demonstrated in rat fibroblast culture *in vitro*. Insulin receptor tyrosine kinase activity assays are performed *in vitro*, and the results of these assays could provide misleading information with regard to insulin receptor function *in vivo*. To circumvent this problem, investigators have employed the euglycemic hyperinsulinemic clamp in combination with muscle biopsies and anti-phosphotyrosine immunoblot analysis. Such an analysis yields a "snapshot" of the insulin-stimulated tyrosine phosphorylation state of the receptor *in vivo*. The results of these studies have demonstrated a substantial decrease in insulin receptor tyrosine phosphorylation in both obese nondiabetic and type 2 diabetic subjects. When insulin-stimulated insulin receptor tyrosine phosphorylation was examined in normal glucose-tolerant or impaired glucose-tolerant individuals at high risk of developing type 2 diabetes, a normal increase in tyrosine phosphorylation of the insulin receptor was observed. These observations are consistent with the concept that impaired insulin receptor tyrosine kinase activity in type 2 diabetic patients is acquired secondarily to hyperglycemia or some other metabolic disturbance.

3. Insulin Signaling (IRS-1 and PI3-Kinase) Defects

A physiologic increase in the plasma insulin concentration stimulates tyrosine phosphorylation of the insulin receptor and IRS-1 in lean healthy subjects to 150–200% of basal values. In obese nondiabetic subjects, the ability of insulin to activate these two early insulin receptor signaling events in muscle is reduced, whereas in type 2 diabetics insulin has no significant stimulatory effect on either insulin

receptor or IRS-1 tyrosine phosphorylation. The association of p85 protein and PI3-kinase activity with IRS-1 also is greatly reduced in obese nondiabetic and type 2 diabetic subjects compared to lean healthy subjects. Insulin also failed to increase the association of the p85 subunit of PI3-kinase with IRS-2 in muscle, indicating that type 2 diabetes is characterized by a combined defect in IRS-1 and IRS-2 function. The decrease in insulin stimulation of the association of the p85 regulatory subunit of PI3-kinase with IRS-1 is closely correlated with the impairment in muscle glycogen synthase activity and *in vivo* insulin-stimulated glucose disposal. Defective regulation of PI3-kinase gene expression by insulin also has been demonstrated in skeletal muscle and adipose tissue of type 2 diabetic subjects. In animal models of diabetes, an 80% decrease in IRS-1 phosphorylation and a greater than 90% reduction in insulin-stimulated PI3-kinase activity have been reported.

In the insulin-resistant, normal glucose-tolerant offspring of two type 2 diabetic parents, IRS-1 tyrosine phosphorylation and the association of p85 protein/PI3-kinase activity with IRS-1 are markedly decreased despite normal tyrosine phosphorylation of the insulin receptor; these insulin signaling defects are correlated closely with the severity of insulin resistance, measured with the euglycemic insulin clamp technique. In summary, a defect in the association of PI3-kinase with IRS-1 and in its subsequent activation appears to be a characteristic abnormality in type 2 diabetics, is closely correlated with *in vivo* muscle insulin resistance, and is unrelated to a disturbance in insulin receptor tyrosine phosphorylation. Several groups have reported that a common mutation in the IRS-1 gene (Gly972Arg) is associated with type 2 diabetes, insulin resistance, and obesity, but the physiologic significance of this mutation remains to be established.

The profound insulin resistance of the PI3-kinase signaling pathway contrasts markedly with the ability of insulin to stimulate MAP kinase pathway activity in insulin-resistant type 2 diabetic and obese nondiabetic individuals. Hyperinsulinemia increases MEK1 activity and ERK1/2 phosphorylation and activity to the same extent in lean healthy controls as in insulin-resistant obese nondiabetic and type 2 diabetic patients. This finding of selective insulin resistance is similar to that recently observed in the vasculature of Zucker fatty rats. Two possible reasons for this difference are alternate insulin signaling pathways and differential signal amplification. With regard to the former, the MAP kinase pathway can be activated through Grb2/Sos interaction with IRS-1/IRS-2 or with Shc. Because IRS-1 tyrosine phosphorylation is dramatically reduced in diabetics, it is possible that insulin activation of the MAP kinase pathway *in vivo* primarily occurs through Shc activation. There is evidence from *in vitro* studies to support this concept. Like ERK and MEK activity, insulin increased Shc phosphorylation to the same extent in lean and obese nondiabetic and type 2 diabetic subjects. These results indicate that, in type 2 diabetes, insulin induces sufficient activation of the insulin receptor tyrosine kinase to increase Shc phosphorylation normally. It also is possible that differential signal amplification in the PI3-kinase and MAP kinase pathways can explain their differing susceptibilities to the effects of insulin resistance.

Maintenance of insulin stimulation of the MAP kinase pathway in the presence of insulin resistance in the PI3-kinase pathway may be important in the development of insulin resistance. ERKs can phosphorylate IRS-1 on serine residues, and serine phosphorylation of IRS-1 and the insulin receptor itself has been implicated in desensitization insulin receptor signaling. Continued ERK activity, when IRS-1 function already is impaired, could lead to a worsening of insulin resistance. Thus, diabetic and obese subjects have inappropriately high MAP kinase activity. One also could postulate that insulin resistance in the metabolic (PI3-kinase) pathway, with its compensatory increase in beta-cell function and hyperinsulinemia, leads to excessive stimulation of the MAP kinase pathway in vascular tissue. This would result in the proliferation of vascular smooth muscle cells, increased collagen formation, and increased production of growth factors and inflammatory cytokines, possibly explaining the accelerated rate of atherosclerosis in type 2 diabetic individuals.

D. Glucose Transport

Activation of the insulin signal transduction system in insulin target tissues leads to the stimulation of glucose transport. The effect of insulin is brought about by the translocation of a large intracellular pool of glucose transporters (associated with low-density microsomes) to the plasma membrane. There are five major, different facilitative glucose transporters with distinctive tissue distributions (Table II). GLUT4, the insulin regulatable transporter, is found in insulin-sensitive tissues (muscle and adipocytes), has a K_m of ~ 5 mmol/liter, which is close to that of the plasma glucose concentration, and is associated with HKII. In adipocytes and muscle, its

TABLE II Classification of Glucose Transport and HK Activity According to Their Tissue Distribution and Functional Regulation

Organ	Glucose transporter	Hexokinase	Classification
Brain	GLUT1	HKI	Glucose dependent
Erythrocyte	GLUT1	HKI	Glucose dependent
Adipocyte	GLUT4	HKII	Insulin dependent
Muscle	GLUT4	HKII	Insulin dependent
Liver	GLUT2	HKIVL	Glucose sensor
GK beta-cell	GLUT2	HKIVB (glucokinase)	Glucose sensor
Gut	GLUT3 symporter	—	Sodium dependent
Kidney	GLUT3 symporter	—	Sodium dependent

Reprinted from DeFronzo (1997), with permission.

concentration in the plasma membrane increases markedly after exposure to insulin, and this increase is associated with a reciprocal decline in the intracellular GLUT4 pool. GLUT1 represents the predominant glucose transporter in the insulin-independent tissues (brain and erythrocytes), but also is found in muscle and adipocytes. It is located primarily in the plasma membrane, where its concentration changes little after the addition of insulin. It has a low K_m ($\sim$1 mmol/liter) and is well suited to its function, which is to mediate basal glucose uptake. It is found in association with HKI. GLUT2 predominates in the liver and pancreatic beta cells, where it is found in association with a specific hexokinase, HKIV. In the beta cell, HKIV is referred to as glucokinase. GLUT2 has a high K_m ($\sim$15–20 mmol/liter) and, as a consequence, the glucose concentration in cells expressing this transporter rises in direct proportion to the increase in plasma glucose concentration. This characteristic allows these cells to respond as glucose sensors. In summary, each tissue has a specific glucose transporter and associated hexokinase, which allow it uniquely to carry out its specialized function to maintain whole-body glucose economy.

Glucose transport activity in type 2 diabetic patients uniformly has been found to be decreased in adipocytes and muscle. In adipocytes from type 2 diabetic humans and rodent models of diabetes, there is a severe reduction in GLUT4 mRNA and protein, and the ability of insulin to elicit a normal translocation response and to activate the GLUT4 transporter after its insertion into the cell membrane is impaired. In contrast, muscle tissue obtained from lean and obese type 2 diabetic subjects exhibits normal or increased levels of GLUT4 mRNA expression and normal levels of GLUT4 protein. Moreover, acute (2–4 h) physiological hyperinsulinemia does not increase the number of GLUT4 transporters in muscle in either healthy or type 2 diabetic subjects. Several studies have demonstrated an increase in muscle GLUT4 mRNA levels in response to insulin in control subjects, but not in diabetics, suggesting insulin resistance at the level of gene transcription. However, the physiological significance of the blunted increase in muscle GLUT4 mRNA levels in type 2 diabetic subjects is unclear, since both basal and insulin-stimulated GLUT4 protein levels are normal. Large populations of type 2 diabetics have been screened for mutations in the GLUT4 gene. Such mutations are very uncommon and, when detected, have been of questionable physiologic significance.

The results summarized above indicate that the gene (GLUT4) encoding the major insulin-responsive glucose transporter and its transcriptional/translational regulation are not impaired in type 2 diabetes. However, in contrast to the normal expression of GLUT4 protein and mRNA in muscle of type 2 diabetic subjects, every study that has examined adipose tissue has reported reduced basal and insulin-stimulated GLUT4 mRNA levels, decreased GLUT4 transporter numbers in all subcellular fractions, diminished GLUT4 translocation, and impaired intrinsic activity of GLUT4. These observations demonstrate that GLUT4 expression in humans is subject to tissue-specific regulation. Although insulin does not increase GLUT4 expression in muscle, it stimulates the translocation of GLUT4 transporters from their intracellular location to the cell membrane. In type 2 diabetic humans, the ability of insulin to stimulate GLUT4 translocation in muscle is impaired. Using a novel triple-tracer technique, the *in vivo* dose–response curve for the action of insulin on glucose transport in forearm skeletal muscle has been examined in nondiabetic and type 2 diabetic subjects. Insulin-stimulated inward muscle glucose transport was severely impaired in type 2 diabetic subjects who were studied under euglycemic conditions. The defect

in glucose transport cannot be overcome by repeating the insulin clamp at each subject's normal fasting glucose (hyperglycemia) level. Since the number of GLUT4 transporters in the muscle of diabetic subjects is normal, impaired GLUT4 translocation and decreased intrinsic activity of the glucose transporter must be responsible for the defect in muscle glucose transport. Impaired *in vivo* muscle glucose transport in type 2 diabetics also has been demonstrated using MRI and PET.

E. Glucose Phosphorylation

Glucose phosphorylation and glucose transport are tightly coupled phenomena. Isoenzymes of hexokinase (HKI–HKIV) catalyze the first committed intracellular step of glucose metabolism, the conversion of glucose to G-6-P (Table II). HKI, HKII, and HKIII are single-chain peptides that have a number of properties in common, including a very high affinity for glucose and product inhibition by G-6-P. HKIV, also called glucokinase, has a lower affinity for glucose and is not inhibited by G-6-P. Glucokinase (HKIVB) is believed to be the glucose sensor in the beta cell, whereas HKIVL plays an important role in the regulation of hepatic glucose metabolism.

In both rat and human skeletal muscle, HKII transcription is regulated by insulin. HKI also is present in human skeletal muscle, but it is not regulated by insulin. In response to physiological euglycemic hyperinsulinemia, HKII cytosolic activity, protein content, and mRNA levels increase by 50–200% in healthy nondiabetic subjects and this is associated with the translocation of hexokinase II from the cytosol to the mitochondria. In contrast, insulin has no effect on HKI activity, protein content, or mRNA levels.

In forearm muscle, insulin-stimulated glucose transport (measured with the triple-tracer technique) has been shown to be markedly impaired in lean type 2 diabetics. However, since the rate of intracellular glucose phosphorylation was impaired to an even greater extent, insulin caused an increase in the intracellular free glucose concentration. By performing the insulin clamp at each diabetic's normal level of fasting hyperglycemia, normal rates of whole-body glucose disposal and a normal rate of glucose influx into muscle were elicited. However, the rate of intracellular glucose phosphorylation increased only modestly; consequently, there was a dramatic rise in the free glucose concentration within the intracellular space that is accessible to glucose. These observations indicate that in type 2 diabetic individuals, although both glucose transport and glucose phosphorylation are severely resistant to the action of insulin, impaired glucose phosphorylation (HKII) appears to be the rate-limiting step for insulin action. A similar pattern of impaired muscle glucose phosphorylation and transport is present in the insulin-resistant, normal glucose-tolerant offspring of two diabetic parents. These results are consistent with dose–response studies using PET to evaluate glucose phosphorylation and transport in skeletal muscle of type 2 diabetics. They also are consistent with ^{31}P nuclear magnetic resonance (NMR) studies that demonstrate that, during hyperinsulinemia, muscle G-6-P concentrations decline in type 2 diabetic versus control subjects. However, subsequent studies using ^{31}P NMR in combination with [1-^{14}C]glucose suggest that the defect in insulin-stimulated muscle glucose transport exceeds the defect in glucose phosphorylation and is responsible for the decline in muscle G-6-P concentration. Because of methodologic differences, the results of the triple-tracer and MRI studies cannot be reconciled at present. Nonetheless, observations from these studies are consistent in demonstrating that the defects in glucose phosphorylation and glucose transport in muscle are established early in the natural history of type 2 diabetes and cannot be explained by glucose toxicity. Clear evidence that HKII activity is crucial for glucose uptake derives from studies in transgenic mice who overexpress HKII. In this model, HKII overexpression increased both insulin- and exercise-stimulated muscle glucose uptake.

In healthy nondiabetic subjects, physiologic hyperinsulinemia for as little as 2–4 h increases muscle HKII activity, gene transcription, and translation. In lean type 2 diabetics, insulin-stimulated HKII activity and mRNA levels are markedly reduced compared to controls. Decreased basal muscle HKII activity and mRNA levels and impaired insulin-stimulated HKII activity in type 2 diabetic subjects have been reported by other investigators. A decrease in insulin-stimulated muscle HKII activity also has been described in subjects with IGT. Because of its central role in insulin-mediated muscle glucose metabolism, several groups have looked for point mutations in the HKII gene in individuals with type 2 diabetes. Although several nucleotide substitutions have been found, none have been located close to the glucose- and ATP-binding sites and none have been associated with insulin resistance. Thus, an abnormality in the HKII gene is unlikely to explain the inherited insulin resistance in common variety type 2 diabetes mellitus.

F. Glycogen Synthesis

After glucose is phosphorylated by hexokinase II, it can either be converted to glycogen or enter the glycolytic pathway. Of the glucose that enters the glycolytic pathway, ~90% is oxidized. At low physiologic plasma insulin concentrations, glycogen synthesis and glucose oxidation are of approximately equal quantitative importance. With increasing plasma insulin concentrations, glycogen synthesis predominates. If the rate of glucose oxidation (determined by indirect calorimetry) is subtracted from the rate of whole-body insulin-mediated glucose disposal (determined from the insulin clamp), the difference represents nonoxidative glucose disposal (or glucose storage), which reflects primarily glycogen synthesis. Glucose conversion to lipid accounts for <5% of total-body glucose disposal and less than 5–10% of the glucose taken up by muscle is released as lactate. Reduced insulin-stimulated glycogen synthesis is a characteristic finding in all insulin-resistant states, including obesity, diabetes, and the combination of obesity plus diabetes. Impaired glycogen synthesis also represents the major cause of insulin resistance in obese subjects with normal or only slightly impaired glucose tolerance. Thus, the inability of insulin to promote glycogen synthesis is a characteristic and early defect in the development of insulin resistance in both obesity and type 2 diabetes. The emergence of overt diabetes with fasting hyperglycemia is associated with a major reduction in insulin-mediated nonoxidative glucose disposal (glycogen synthesis) in all ethnic groups. Impaired glycogen synthesis also has been demonstrated in the normal glucose-tolerant offspring of two diabetic parents, in the first-degree relatives of type 2 diabetic individuals, and in the normoglycemic twin of a monozygotic twin pair in which the other twin has type 2 diabetes.

Using NMR imaging spectroscopy, a decrease in insulin-stimulated incorporation of [^{1}H, ^{13}C]glucose into muscle glycogen of type 2 diabetic subjects has been demonstrated directly. In type 2 diabetics, there was a marked lag in the onset of insulin-stimulated glycogen synthesis that was similar to the delay in insulin-mediated leg muscle glucose uptake. The rate of glycogen synthesis in type 2 diabetic subjects was decreased by ~50%, paralleling the decrease in total glucose uptake by leg muscle, and impaired muscle glycogen synthesis accounted for essentially all of the defect in whole-body glucose disposal.

In summary, an abundance of convincing evidence demonstrates that impaired glycogen synthesis is the major metabolic defect in normal glucose-tolerant obese subjects, in individuals with IGT, and in patients with overt diabetes. Moreover, numerous studies have documented that the earliest detectable metabolic abnormality responsible for the insulin resistance in normal glucose-tolerant individuals who are destined to develop type 2 diabetes is impaired glycogen synthesis.

Glycogen synthase is the key insulin-regulated enzyme that controls the rate of muscle glycogen synthesis. Insulin enhances glycogen synthase activity by stimulating a cascade of phosphorylation–dephosphorylation reactions (see above discussion of insulin receptor signal transduction), which ultimately lead to the activation of PP1 (also called glycogen synthase phosphatase). The regulatory subunit (G) of PP1 has two serine phosphorylation sites, site 1 and site 2. Phosphorylation of site 2 by cAMP-dependent kinase inactivates PP1, whereas phosphorylation of site 1 by insulin activates PP1, leading to the stimulation of glycogen synthase. Phosphorylation of site 1 of PP1 by insulin in muscle is catalyzed by insulin-stimulated protein kinase 1 (ISPK-1), which is part of a family of serine/threonine protein kinases termed ribosomal S6-kinases. Because of their central role in muscle glycogen formation, considerable attention has focused on the three enzymes, glycogen synthase, PP1, and ISPK-1, involved in the pathogenesis of insulin resistance in individuals with type 2 diabetes.

Glycogen synthase exists in an active (dephosphorylated) and an inactive (phosphorylated) form. Under fasting conditions, total glycogen synthase activity in type 2 diabetic subjects is reduced and the ability of insulin to activate glycogen synthase is severely impaired. An impaired ability of insulin to activate glycogen synthase also has been demonstrated in the normal glucose-tolerant relatives of type 2 diabetic individuals. Insulin-mediated activation of glycogen synthase and insulin-stimulated glycogen synthase gene expression have been shown to be impaired in cultured myocytes and fibroblasts from type 2 diabetic subjects. Studies in insulin-resistant nondiabetic and diabetic Pima Indians have documented that the ability of insulin to activate muscle PP1 (glycogen synthase phosphatase) is severely reduced. PP1 dephosphorylates glycogen synthase, leading to its activation. Therefore, a defect in PP1 appears to play an important role in muscle insulin resistance.

The effect of insulin on glycogen synthase gene transcription and translation *in vivo* has been studied extensively. Most studies have shown that insulin

does not increase glycogen synthase mRNA or protein expression in human muscle studied *in vivo*. However, glycogen synthase mRNA expression is decreased in muscle of type 2 diabetic patients, explaining in part the decreased glycogen synthase activity in this disease. However, the major abnormality in glycogen synthase regulation in type 2 diabetes and other insulin-resistant conditions is its lack of dephosphorylation and activation by insulin as a result of insulin receptor signaling abnormalities (see previous discussion). The glycogen synthase gene has been the subject of extensive investigations. An association between glycogen synthase gene markers and type 2 diabetes has been demonstrated in Japanese, French, Finnish, and Pima Indian populations. However, DNA sequencing has revealed either no mutations or rare nucleotide substitutions that cannot explain the defect in insulin-stimulated glycogen synthase. Nonetheless, the association between the glycogen synthase gene and type 2 diabetes mellitus suggests that another gene close to the glycogen synthase gene may be involved in the development of type 2 diabetes. The genes encoding the catalytic subunits of PP1 and ISPK-1 have been examined in insulin-resistant Pima Indians and Danes with type 2 diabetes. Several silent nucleotide substitutions were found in the PP1 and ISPK-1 genes in the Danish population; the mRNA levels of both genes were normal in skeletal muscle. No structural gene abnormalities in the catalytic subunit of PP1 were detected in Pima Indians. Thus, neither abnormalities in the PP1 and ISPK-1 genes nor abnormalities in their translation can explain the impaired enzymatic activities of glycogen synthase and PP1 that have been observed *in vivo*. Similarly, there is no evidence that an alteration in glycogen phosphorylase plays any role in the abnormality in glycogen formation in type 2 diabetes.

In summary, glycogen synthase activity is severely impaired in patients with type 2 diabetes mellitus and in insulin-resistant normal glucose-tolerant individuals who are predisposed to develop type 2 diabetes. However, the defect cannot be explained by an abnormality in the genes encoding glycogen synthase or its promoter or by other key genes—PP1 or ISPK-1—involved in the regulation of glycogen synthase activity.

G. Glycolysis/Glucose Oxidation

Glucose oxidation accounts for ~90% of total glycolytic flux and anaerobic glycolysis accounts for the other 10%. Two enzymes, PFK and PDH, play pivotal roles in the regulation of glycolysis and glucose oxidation, respectively. The glycolytic/glucose oxidative pathway has been shown to be impaired in many individuals with type 2 diabetes. Although one study suggested that the activity of PFK is modestly reduced in muscle biopsies from type 2 diabetic subjects, the majority of evidence indicates that the activity of PFK is normal. Insulin has no effect on muscle PFK activity, mRNA levels, or protein content in either nondiabetic or diabetic individuals. PDH is a key insulin-regulated enzyme whose activity in muscle is acutely stimulated by a physiological increment in the plasma insulin concentration. Three previous studies have examined PDH activity in type 2 diabetic patients. Insulin-stimulated PDH activity is decreased in isolated subcutaneous human adipocytes from patients with type 2 diabetes mellitus and in skeletal muscle from type 2 diabetic subjects undergoing euglycemic hyperinsulinemic clamps. However, when type 2 diabetic patients had muscle biopsies during hyperglycemic hyperinsulinemic clamps, activation of PDH by insulin was normal, in concert with normalized rates of muscle glucose uptake. These results suggest that insulin stimulation of PDH activity is influenced by glycolytic flux.

Both obesity and type 2 diabetes mellitus are associated with accelerated FFA turnover and oxidation, which would be expected, according to the Randle cycle, to inhibit PDH activity and consequently glucose oxidation. Thus, any observed defect in glucose oxidation or PDH activity could be acquired secondarily to increased FFA oxidation and feedback inhibition of PDH by elevated intracellular levels of acetyl CoA and reduced availability of NAD. Consistent with this observation, the rates of basal and insulin-stimulated glucose oxidation have been shown to be normal in the normal glucose-tolerant offspring of two diabetic parents and in the first-degree relatives of type 2 diabetic subjects, whereas it is decreased in overtly diabetic subjects. Studies examining PHD activity in muscle tissue from lean diabetic subjects with mild fasting hyperglycemia are needed before the role of this enzyme in the development of insulin resistance in type 2 diabetes can be established or excluded.

In summary, postbinding defects in insulin action primarily are responsible for the insulin resistance in type 2 diabetes. Diminished insulin binding, when present, occurs in individuals with IGT or very mild diabetes and results secondarily from down-regulation of the insulin receptor by chronic sustained hyperinsulinemia. In type 2 diabetic patients with

overt fasting hyperglycemia, postbinding defects are responsible for the insulin resistance. A number of postbinding defects have been documented, including diminished insulin receptor tyrosine kinase activity, insulin signal transduction abnormalities, decreased glucose transport, reduced glucose phosphorylation, and impaired glycogen synthase activity. The glycolytic/glucose oxidative pathway appears to be largely intact and, when defects are observed, they appear to be acquired secondarily to enhanced FFA/lipid oxidation. From a quantitative standpoint, impaired glycogen synthesis represents the major pathway responsible for insulin resistance in type 2 diabetes, and family studies suggest that a defect in the glycogen synthetic pathway represents the earliest detectable abnormality in type 2 diabetes. Recent studies link the impairment in glycogen synthase activation to a defect in the ability of insulin to phosphorylate IRS-1, causing a reduced association of the p85 subunit of PI3-kinase with IRS-1 and decreased activation of PI3-kinase.

Glossary

endogenous glucose production Synthesis of glucose by the internal organs of the body. Approximately 85% of endogenous glucose production is derived from the liver and 15% is derived from the kidneys. Of the total endogenous glucose production, approximately half is derived from glycogenolysis and the other half from gluconeogenesis.

glucose transport and phosphorylation Transport of free glucose from the interstitial compartment into the cell via the GLUT4 transporter and its subsequent phosphorylation by hexokinase within the cell.

impaired insulin secretion Inability of the pancreatic beta cells to secrete sufficient amounts of insulin to maintain normal glucose tolerance.

insulin resistance Impaired ability of insulin to exert its normal effects on insulin target tissues, including muscle, liver, and adipocytes.

insulin signal transduction The intracellular events [tyrosine phosphorylation of the insulin receptor and insulin receptor substrate-1 (IRS-1), association of the p85 regulatory subunit of phosphatidylinositol 3-kinase (PI3-kinase) with IRS-1, and activation of PI3-kinase] whereby insulin binding to its receptor stimulates, glucose transport.

splanchnic glucose uptake The amount of glucose taken up by the splanchnic tissues (liver plus gastrointestinal tissues) during the postabsorptive state and/or following glucose ingestion. The great majority (~80–90%) of splanchnic glucose uptake occurs in the liver.

type 2 diabetes mellitus This form of diabetes is characterized by insulin resistance and, at least initially, by a relative lack of insulin secretion. With time, there is a progressive decline in beta-cell function and absolute insulin deficiency ensues.

Insulin Gene Regulation

MICHAEL S. GERMAN
University of California, San Francisco

Although insulin production is limited almost exclusively to the beta cells in adult mammals, most mammalian cells can produce insulin if insulin gene transcription is activated. The mechanisms that control insulin gene transcription therefore restrict insulin production to the beta cells. In addition, beta cells modulate insulin gene transcription in response to medium-term (days to weeks) changes in nutrient status and insulin production requirements. Insight into the regulation of the insulin gene provides a view of how beta cell function is directed at the genetic level.

I. INTRODUCTION

Insulin plays a central role in energy metabolism in vertebrates. In response to rising blood glucose levels after meals, the beta cells in the islets of Langerhans in the pancreas synthesize insulin and secrete it into the bloodstream. Circulating insulin binds to specific receptors found on the surface of most cells; insulin-receptor binding alerts the cells to the presence of excess nutrients and stimulates nutrient uptake and metabolism, storage of energy, and growth. Equally important, a decrease in insulin production and secretion in response to fasting results in the release of stored energy and in the synthesis of glucose by the liver and kidney. Impairment of insulin production or function leads to hyperglycemia and metabolic derangement characteristic of diabetes mellitus.

Beta cell insulin production, directed at the genetic level, is under the control of a multicomponent activation complex that forms on the insulin gene promoter. The almost exclusive production of insulin by pancreatic beta cells, despite the presence of the insulin gene in most mammalian cells, is a starting point for analysis of the underlying transcription activation mechanisms.

II. INSULIN GENE STRUCTURE

The human insulin gene (*INS*) resides on the short arm of chromosome 11, immediately between the genes encoding tyrosine hydroxylase and insulin-like growth factor-II (IGF-II) (see Fig. 1). The gene consists of three exons totaling 446 base pairs that form the mature preproinsulin mRNA. The first intron, IVS1, lies within the 5′ untranslated sequence; IVS2 splits the sequence that codes for the C-peptide (see Fig. 2). The mature preproinsulin mRNA encodes the preproinsulin peptide, which includes a 20-amino-acid prepeptide that is proteolytically removed prior to the packaging of proinsulin in granules.

Adjacent to the sequences encoding the preproinsulin mRNA, 362 bp upstream of the transcription start site, lies a highly polymorphic sequence consisting of a variable number of simple tandem repeats of a G-rich 14 bp sequence [the *INS* gene variable number of tandem repeats (*INS* VNTR)]. Although there is wide variation in the human population, most individual *INS* VNTRs fall into three classes distinguished by having approximately 20, 40, or 80 repeats. The inheritance of longer VNTRs appears to provide some reduction in the risk of developing type 1 diabetes. Although the explanation for this protection is uncertain, it may be related to the demonstrated ability of the VNTRs to affect transcription rates from the adjacent *INS* gene.

The structure of the insulin gene has been remarkably well conserved in vertebrates, and this conservation generally extends to the IGF genes and the insulin/IGF genes found in invertebrates. Rats and mice have two copies of the insulin gene, apparently due to reverse transcription and reintegration of an incompletely processed RNA transcript of the original insulin gene (*insulin2*). The duplicate gene (*insulin1*) lacks IVS2 but retains IVS1 and most of the structural features of the ancestral gene. All of the other known insulin genes and the human gene have retained the same exon/intron structure, although the exact lengths and the internal sequences of both introns have not been conserved. Only primate genes contain the VNTR.

III. INSULIN GENE PROMOTER

Transcription of the insulin gene depends on untranscribed sequences immediately upstream (5′ flanking sequences) of the transcription start site: the insulin promoter (see Fig. 3). The insulin promoter is defined as all of the 5′ flanking DNA necessary for appropriate initiation and regulation of transcription. The exact 5′ end of the promoter is ill defined, but sequences as far as several kilobases upstream of the start site may contribute. Although the overall sequence of the insulin promoter is not well conserved, the position and sequences of the functional sequence elements have been well conserved in mammals.

Although it normally functions as an integral component of the insulin gene, and may interact with other sequences around the gene such as IVS1, the insulin promoter can function as an independent unit. When isolated from the remainder of the gene and linked to a reporter gene such as firefly luciferase, the promoter can direct expression of the heterologous gene. The isolated promoter can direct expression of a reporter gene specifically to beta cells in both *in vitro* cell lines and *in vivo* transgenic animals. In addition, Studies with such chimeric reporter constructs have permitted the careful mapping of functionally important sequences within the promoter and have provided much of our present understanding of how the insulin gene is regulated at a molecular level.

Deletion and mutation analyses of the human and rat promoters both in cell lines and in transgenic mice have defined a series of functionally critical sequence elements along the proximal promoter, as outlined in Fig. 3. In essence, these sequences form a code that acts as recognition sites for nuclear DNA-binding proteins, the transcription factors. Transcription factors found in the beta cell nucleus bind to these

FIGURE 1 The human insulin (*INS*) gene and surrounding loci on chromosome 11. *TH*, Tyrosine hydroxylase gene; *IGF2*, insulin-like growth factor II gene.

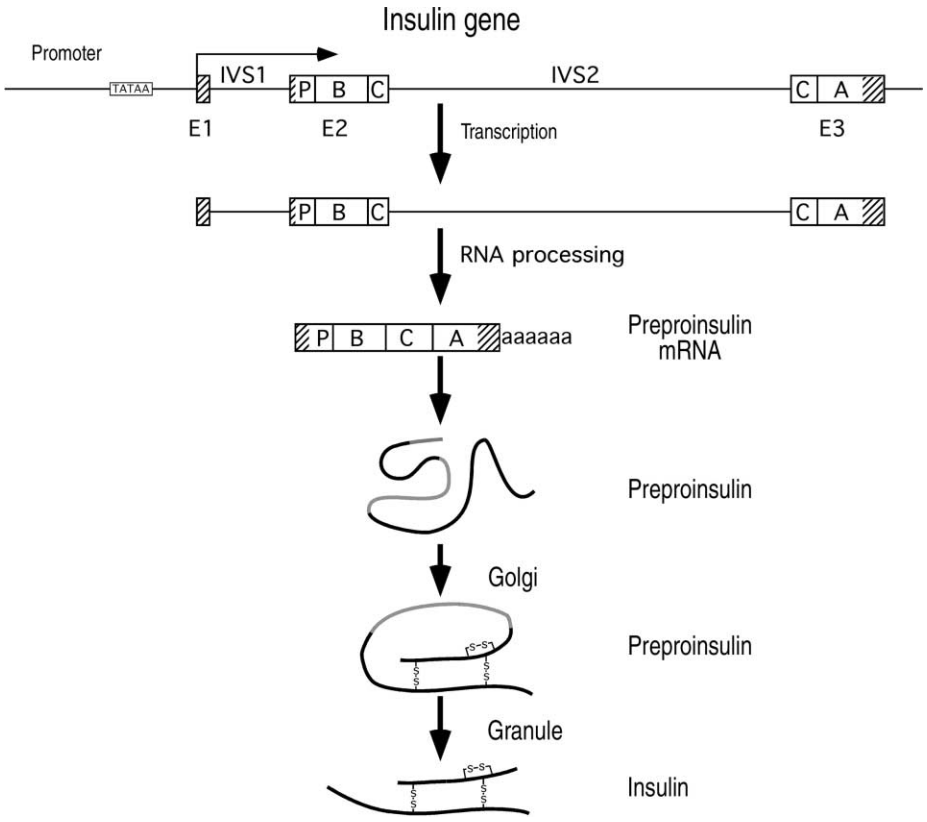

FIGURE 2 Production of insulin from gene to mature peptide. The pathway by which insulin is produced in the beta cell starts with insulin gene transcription and progresses through the processing of proinsulin to mature insulin, the form that is secreted from the beta cell.

sites and form a unique DNA-protein complex that activates transcription. Other cell types with different sets of nuclear proteins cannot form the unique beta cell complex and therefore cannot activate transcription.

IV. TRANSCRIPTION FACTORS

A. Basic Helix–Loop–Helix Factors

As shown in Fig. 3, the proximal insulin promoter contains multiple sequence elements, but much of

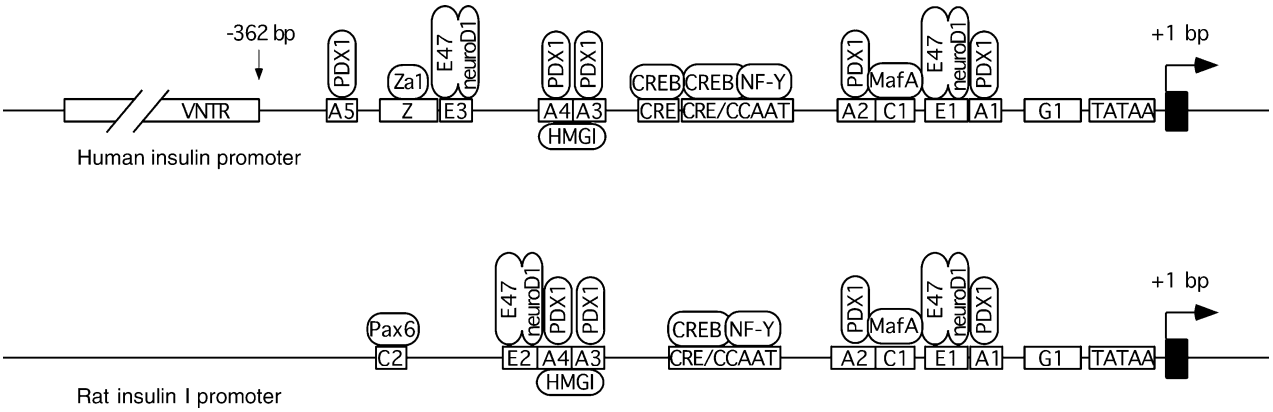

FIGURE 3 The human insulin and rat insulin I gene promoters with known sequence elements and binding factors. The boxes represent functionally important sequence elements. Some of the key transcription factors that bind to these sites are shown above or below the promoter.

the activity of the promoter depends on juxtaposed E and A sequences and their cognate binding proteins. The E elements contain the core sequence CANNTG and act as binding sites for basic helix–loop–helix (bHLH) proteins, transcription factors containing a stretch of basic amino acids adjacent to a helix–loop–helix motif. The bHLH proteins bind to DNA as dimers, using the HLH domain for dimerization and the basic domain for DNA binding.

The predominant E-element-binding complex in beta cells consists of a heterodimer formed by a ubiquitous bHLH protein and a cell-type-specific bHLH protein. The role of the ubiquitous partner is filled by one of three proteins, HEB, E12, or E47. The predominant cell-type-specific partner that dimerizes with these ubiquitous bHLH proteins in beta cells is neuroD1 (also called Beta2). NeuroD1 belongs to a large family of neural bHLH proteins and is expressed in neurons and gut endocrine cells as well as all islet cells. Mice homozygous for a targeted disruption in the *neuroD1* gene have a marked defect in insulin production. In addition, absence of neuroD1 also causes a reduction in the number of beta cells due to accelerated apoptosis, demonstrating a role for neuroD1 in beta cell maintenance as well as in insulin gene transcription.

B. Homeodomain Factors

By itself, ectopic expression of neuroD1 in non-beta cells is sufficient to activate the insulin promoter modestly, but it cannot fully activate the promoter in the absence of an appropriate A-element-binding protein. The A elements contain a consensus TAAT core sequence and function as binding sites for homeodomain transcription factors. The para-hox homeodomain protein PDX1 (also called IPF1, STF1 and IDX1) binds to all of the A sites in the insulin promoter and is expressed in antral stomach, duodenum, and pancreas. Early in development, all or most of the pancreatic cells express PDX1, but with maturation, high-level expression of IPF1 becomes largely limited to the beta cells, delta cells, and duodenum, with lower level expression in some duct cells and acinar cells. Like neuroD1, PDX1 by itself can only weakly activate the insulin promoter in non-beta cells, but in some non-insulin-producing islet cell lines, forced expression of PDX1 can activate the endogenous insulin gene.

Mice homozygous for a targeted disruption of the *pdx1* gene fail to develop a pancreas and die shortly after birth, demonstrating that PDX1 is required for development of the entire pancreas. Mice heterozygous for a targeted disruption of the *pdx1* gene develop normally but have an impaired ability to clear glucose after a glucose challenge. Furthermore, targeted inactivation of the *pdx1* gene selectively in beta cells causes beta cell loss and dysfunction, impaired insulin production, and diabetes, providing additional evidence that PDX1 is specifically required for normal beta cell function. Human genetic studies have demonstrated that PDX1 plays a similar role in humans. Human patients lacking a normal copy of the *IPF1* gene (the human homologue of the mouse *pdx1* gene) also fail to develop a pancreas, and heterozygous mutation of the *IPF1* gene is associated with the development of diabetes in young adults.

Beta cells express multiple homeodomain proteins in addition to PDX1, including Pax6, a member of the paired homeodomain protein family. In addition to the homeodomain, Pax6 shares a second DNA-binding domain, the paired domain, with other paired homeodomain proteins. Pax6 is present in all islet cells as well as some gut endocrine cells and regions of the nervous system. Pax6 binds to the C2 element in the rodent insulin genes and can activate insulin gene transcription. Mice homozygous for a null mutation of the *pax6* gene have severe defects in neural development and both a general defect in islet cell formation and reduced insulin mRNA levels in their remaining beta cells. The role of Pax6 in human insulin gene transcription is uncertain, because the C2 site is not completely conserved in the human insulin promoter.

C. MafA

Function of the human and rat insulin II promoters depends on the proximal C1 element as well as the E and A elements. MafA, a transcription factor originally identified in the chick eye, has recently been purified from beta cell nuclei and shown to bind to the C1 element. Although the function of MafA in beta cells is unknown, it likely plays an important role in controlling insulin gene expression along with the bHLH and homeodomain proteins that bind to the E and A elements.

V. TRANSCRIPTION ACTIVATION COMPLEX

The insulin promoter is more than the sum of its independent parts. Each cis-acting element with its cognate binding factors is not an independent unit but functions instead by interacting with the other elements along the promoter to activate transcription synergistically. The result is a promoter that can

function properly only in the presence of a minimal set of transcription factors. In the nuclei of beta cells, the insulin promoter forms a large DNA–protein complex, the function of which is dependent on all its parts. This model explains the exquisite cell-type specificity of the pancreatic promoters, because deletion or substitution of any of these factors in non-beta cells will drastically reduce promoter activity.

The physical interactions that produce this complex can be observed as functional cooperativity among factors in assays of promoter activity. For example, although neither neuroD1 nor PDX1 can activate the insulin promoter more than modestly, the two factors together dramatically activate the promoter. This synergistic activation can be further enhanced by including other proteins that contribute to the complex (see Fig. 4). Other members of the complex include the small DNA-binding high-mobility group (HMG) nuclear proteins such as HMGI(Y), which bind to the minor groove of the DNA and limit its flexibility, thus stabilizing interactions among the complex components. The DNA-binding proteins can then cooperatively recruit non-DNA-binding co-activator proteins such as P300, which link the activation complex to the basal transcriptional machinery binding at the TATAA box and activate RNA polymerase II.

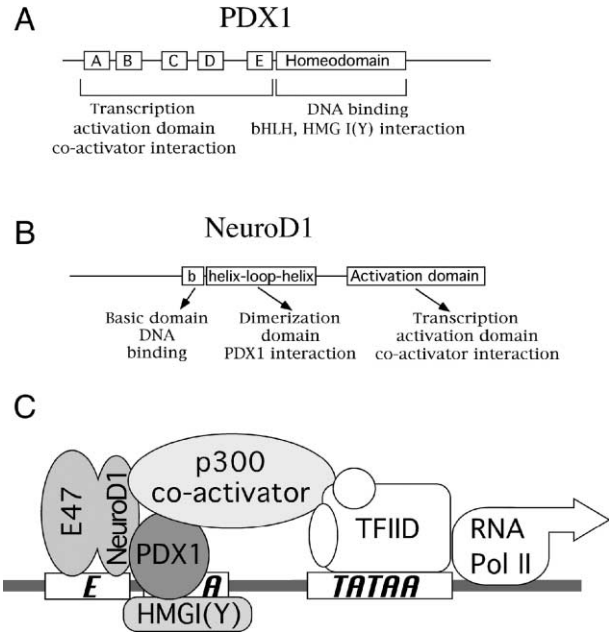

FIGURE 4 The insulin promoter transcription activation complex. (A) The functional domains of the PDX1 protein; the regions labeled A–E represent conserved domains within the activation domain. Domains that interact with other components of the complex are indicated. (B) The functional domains of the neuroD1/Beta2 protein are outlined with the domains that interact with other components of the complex indicated. (C) Interactions among PDX1, the bHLH proteins, HMGI(Y), and p300 result in transcriptional activation of the insulin promoter.

The very complexity of these interactions ensures that they cannot be completely replicated in other cell types. In addition, the dependence of the transcription complex on multiple interacting factors provides multiple opportunities for regulation, because regulation of any one factor can affect its interactions with the other components of the complex and thereby alter the overall activity of the promoter and the rate of insulin gene transcription.

VI. METABOLIC REGULATION

Using the circulating glucose concentration as a gauge of nutritional status, beta cells promptly respond to the feeding state of the organism by rapidly altering the rate of insulin secretion and synthesis. Beta cells sense changes in glucose concentration indirectly through the end products of glucose catabolism. Rapid changes in insulin secretion rates, even in response to modest changes in glucose concentration, hold serum glucose concentrations in a narrow range in healthy mammals. Insulin mRNA levels, however, change much more slowly and contribute very little to meal-to-meal variations in circulating insulin levels. Insulin mRNA in beta cells has an exceptionally long half-life, in the range of several days. The large pool of stable insulin mRNA buffers any rapid changes in insulin gene transcription and prevents rapid swings in mRNA levels on any scale less than many hours.

On the other hand, insulin mRNA levels do vary in response to long-term changes in food intake and probably play an important role in the beta cell response to prolonged fasting, to seasonal changes in diet, or to insulin resistance such as seen in obesity. Over a period of many hours to several days, glucose stimulates a rise in insulin mRNA levels in beta cells due to the combined effects of increased insulin gene transcription, increased insulin preRNA splicing, and decreased insulin mRNA degradation. The effect of glucose on transcription rate in the beta cell is selective for the insulin gene and is due, at least in part, to regulation of the insulin promoter.

Detailed knowledge of the insulin promoter has allowed mapping of sequence elements responsible for glucose activation, and has revealed multiple pathways for glucose regulation of insulin gene transcription. Several regions of the promoter have been found

to respond to glucose, including the E/A element combinations, the C1/E1 region, and the human insulin promoter Z element. Further fine mapping has implicated the E and A elements, the C1 element, and the Za1 site. The multiplicity of metabolic regulatory elements demonstrates that, like cell-type-specific transcription, glucose regulation results from the combined interactions of multiple promoter elements and their cognate binding proteins.

Binding of the beta cell bHLH heterodimers to the E elements increases in response to glucose over several days, apparently due, at least in part, to phosphorylation of both dimer partners. Furthermore, overexpression of dominant negative bHLH dimers dampens the glucose response by the insulin promoter. These data suggest a model in which glucose catabolism by the beta cell results in the activation of the E47/neuroD1 dimer. This dimer then binds the E elements and synergizes with PDX1 binding at the A elements to activate insulin gene transcription (see Fig. 5).

Glucose also stimulates an acute increase in PDX1 binding to the A elements. In response to the rise in glucose concentration, PDX1 is phosphorylated through a pathway that involves phosphatidylinositol 3-kinase (PI3K) and possibly the stress-activated protein kinase 2 (SAPK2). Phosphorylation of PDX1 has several effects on its function, possibly due to phosphorylation at multiple sites. First, it increases its affinity for the insulin promoter A sites. Second, phosphorylation stimulates a shift in the cellular distribution of PDX1 to the nucleus. Finally, glucose-stimulated phosphorylation also increases the activation potential of the PDX1 activation domain, presumably by increasing its affinity for co-activator proteins. Together, these glucose-stimulated modifications significantly enhance PDX1-dependent transcription in the beta cell nucleus and increase synergy with the activated bHLH complex binding to the E element (see Fig. 5).

In addition to the activation of the bHLH heterodimer and PDX1, binding of the protein complex that was recently identified as MafA to the C1 element next to the E1 element also increases in response to glucose, and this increase in binding is dependent on phosphorylation. Although the pathway by which MafA is activated remains to be elucidated, it seems likely that activated MafA will synergize with other components of the insulin promoter activation complex, thereby magnifying the overall response to glucose. All of these effects would then combine to give the overall increase in insulin gene transcription observed in response to glucose.

Similar to its effect on insulin secretion, glucose stimulates insulin gene transcription indirectly through the end products of its catabolism. Both the end product (ATP) and the intermediates of glycolysis are required for this response. The rate-limiting step for glycolysis in beta cells is phosphorylation of glucose to glucose 6-phosphate by glucokinase, the high-K_m hexokinase found in hepatocytes and beta cells. As a result, any alteration in the levels or activity of hexokinase in beta cells directly affects insulin gene transcription rates.

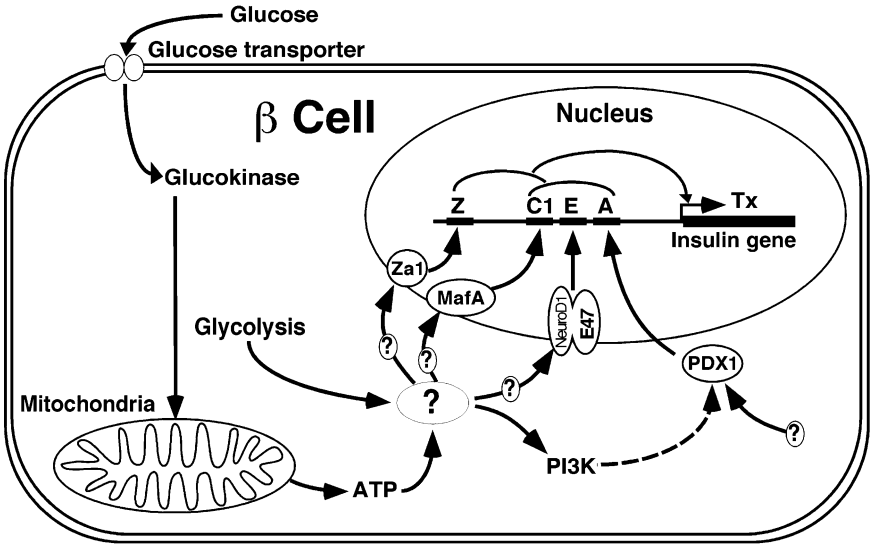

FIGURE 5 Pathways for glucose regulation of insulin gene expression. Question marks indicate unknown steps in the pathway or the probable intersection with other pathways. Dashed lines indicate a multistep pathway.

VII. SUMMARY

Insulin gene transcription in the beta cell depends on the activity of a multicomponent transcription activation complex that forms on the insulin gene promoter. The very complexity of this activation complex ensures its specificity because other cells lack the correct set of factors to build a functional complex. Glucose affects the formation of this complex by altering the availability of the components and their interactions. As a result, the insulin gene transcription factors play a central role in insulin production and therefore in metabolic homeostasis.

Glossary

basic helix–loop–helix proteins Family of transcription factors; bind to DNA as dimers. DNA binding depends on a stretch of basic amino acids adjacent to the dimerization domain formed by a helix–loop–helix structure.

co-activator Non-DNA-binding component of the transcription activation complex; links the transcription factors binding to upstream promoter elements to the basal transcription machinery and promotes transcription of the gene.

homeodomain proteins Family of transcription factors; contain a DNA-binding domain with a helix–turn–helix motif originally described in homeotic genes in *Drosophila*.

MafA Transcription factor of the Maf family originally described in chick eye development; contains a basic leucine-zipper-type DNA-binding domain and binds to and activates through the insulin promoter C1 element.

neuroD1 A bHLH protein present in neurons and islet cells; heterodimerizes with ubiquitous bHLH proteins, binds to the E elements in the insulin promoter, and stimulates insulin gene transcription.

Pax6 Paired-homeodomain transcription factor; contains both paired domain and homeodomain DNA-binding motifs; present in all islet cells and binds to the C2 site in the insulin promoter and stimulates insulin gene transcription.

PDX1 A para-hox class homeodomain transcription factor; present in duodenum and pancreas, with high-level expression in mature beta cells; binds to the A elements in the insulin promoter and stimulates insulin gene transcription.

promoter Untranscribed DNA sequences upstream of the transcription start site; regulates transcription of the linked gene; includes all sequences involved in directing the transcription initiation site and controlling the rate of transcription initiation.

transcription factor Nuclear protein that forms part of the transcription activation complex binding to a gene promoter; is involved in regulating transcription from that gene.

peptide sequence. The conversion of proinsulin to active, mature insulin occurs mostly in the secretory granule of the beta cell by limited proteolysis and is catalyzed by the endopeptidases PC-2 and PC-3 and the exopeptidase carboxypeptidase-H. A defect in proinsulin processing and insulin production leads to hyperproinsulinemia, which is a characteristic feature of type 2 diabetes.

I. INTRODUCTION

Normal glucose homeostasis is the result of the coordinated regulation of insulin production and utilization. Insulin is produced and stored in the pancreatic beta cell and released only in response to an appropriate stimulus. Stimulated insulin secretion is accompanied by a parallel increase in proinsulin biosynthesis, primarily at the translational level, in order to replenish the beta-cell insulin stores. Insulin was the first polypeptidic hormone found to be synthesized as a larger precursor, proinsulin. Thereafter, it was established that most polypeptide hormones, neuropeptides, and many other secretory proteins are also synthesized as larger, inactive precursor molecules. The maturation of these precursors involves limited proteolysis at specific sequences of several basic amino acid residues. Correct proinsulin to insulin conversion is essential for coping with an increase in circulatory glucose levels, since proinsulin biological activity is $<5\%$ that of insulin. Proinsulin processing occurs in the insulin secretory granule of the beta cell by the action of two endopeptidases, PC-2 and PC-3, and the exopeptidase, carboxypeptidase-H. A defect in the normal processing of proinsulin and production of insulin results in hyperproinsulinemia, which is a characteristic feature of type 2 diabetes. Hyperproinsulinemia can be the result of (1) mutation of key residues of the proinsulin molecule; (2) a defect in the production or action of the proinsulin processing enzymes; or (3) an increased secretory demand of the beta cell, which may result in defective sorting of proinsulin and/or the proinsulin processing enzymes to the beta-cell compartment where processing normally occurs.

II. STRUCTURE OF THE PROINSULIN MOLECULE

The proinsulin molecule is a 12 kDa single-chain polypeptide that comprises the B-chain (30 amino acids) and the A-chain (21 amino acids) of insulin joined by the connecting peptide, C-peptide (Fig. 1).

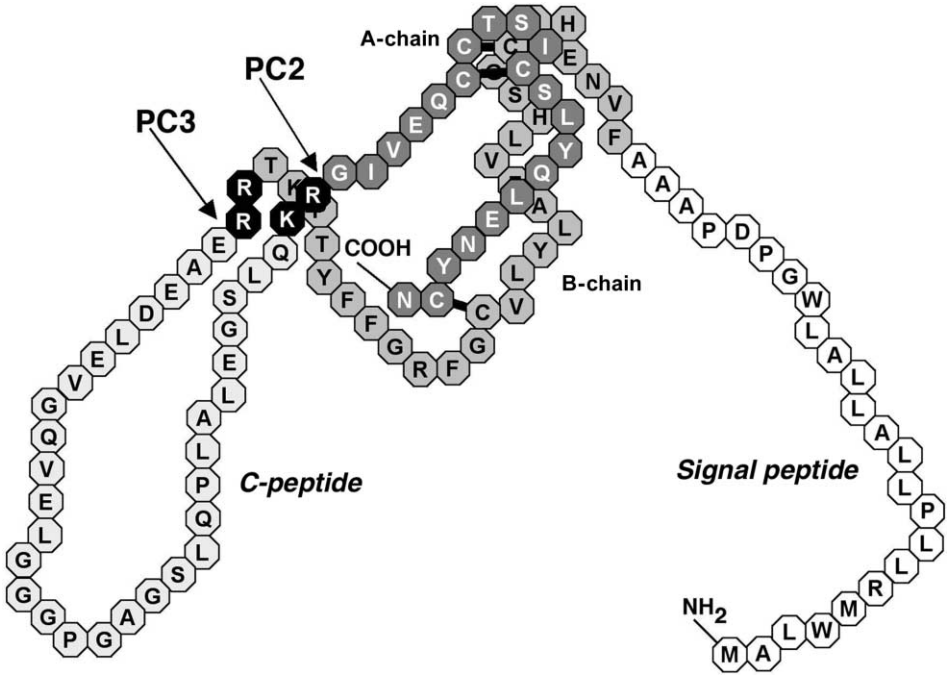

FIGURE 1 The primary structure of preproinsulin indicating the N-terminal signal peptide, followed by the insulin B-chain, the connecting-peptide (C-peptide), and then the C-terminal insulin A-chain. The two dibasic proteolytic conversion sites and the endoproteases that cleave at these are also indicated (PC-3 at Arg31Arg32 and PC-2 at Lys64Arg65).

It contains two disulfide bonds between chains A and B and one A-chain intrachain disulfide bridge. Proinsulin to insulin conversion occurs by cleavage at the B-chain/C-peptide and C-peptide/A-chain junctions and release of the C-peptide. The insulin molecule consists of the two independent chains A and B bound by the disulfide bridges. The proinsulin primary amino acid sequence, mainly that of chains A and B, is highly conserved in higher vertebrates. The sequence of the C-peptide shows greater variation and its length also varies: It contains between 26 and 38 residues in higher vertebrates. The position of the disulfide bonds, as well as the dibasic amino acid residues at the proinsulin to insulin conversion site, is also highly conserved among species.

Insulin is initially synthesized as a preproinsulin precursor, a single polypeptide chain consisting of the sequence of proinsulin flanked at the N-terminus by the signal peptide (24 amino acids). Signal sequences are commonly found in the precursors of secretory, plasma membrane, lysosomal, endoplasmic reticulum (ER), and Golgi proteins. The function of the signal peptide is to direct the protein synthesized in the ribosomal/mRNA complex from the cytoplasm into the lumen of the rough endoplasmic reticulum (RER). Removal of the preproinsulin signal sequence to generate proinsulin occurs rapidly, 1–2 min after synthesis initiation, even before translation is completed. In the RER, the proinsulin molecule folds and the disulfide bridges are formed to give the molecule its secondary structure (Fig. 1). The secondary structure of the proinsulin molecule mostly resembles that of insulin except for the presence of the C-peptide, which shows very little secondary structure. The A-chain of insulin contains two α-helices linked by a certain length of extended polypeptide. The B-chain includes a central α-helix between two stretches of extended polypeptides. In addition, the predicted secondary structure of proinsulin molecule reveals the presence of β-turns enclosing the two processing sites and Ω-loops (sequences of no ordered structure) flanking the β-turn at the C-peptide/A-chain junction. These structures seem to be required for proinsulin to insulin conversion. Moreover, the secondary structure of proinsulin indicates close proximity of the two dibasic processing sites to each other, which also contributes to the efficient proteolytic conversion to insulin.

Mature insulin is stored in the secretory granule of the beta cell in a hexameric crystalline structure. A major characteristic of a pancreatic beta cell, when viewed by electron microscopy, is that it is full of insulin secretory granules (Fig. 2). The electron-dense

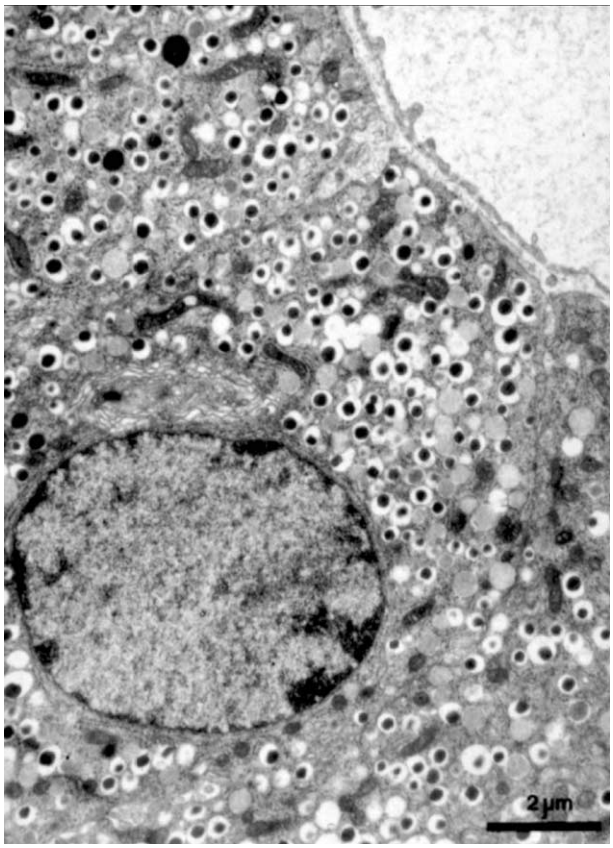

FIGURE 2 Electron micrograph of a pancreatic beta cell indicating the abundance of insulin secretory granules with electron-dense hexameric insulin crystalline cores.

core of the granule is actually a large hexameric-shaped insulin crystal containing an estimated 250,000 insulin molecules. This high concentration of insulin in the secretory granule, along with the favorable acidic environment and the presence of Zn^{2+} ions, facilitates the hexameric aggregation of insulin molecules. The hexameric structure consists of three insulin dimers bound by interaction with two Zn^{2+} atoms at His10 of the insulin B-chain. This arrangement dictates that Zn^{2+} be localized to the center of the insulin hexamer. The insulin moiety within the proinsulin molecule is also able to form three-dimensional structures similar to that of insulin hexamers. In this instance, the C-peptide is located on the outer surface of the hexamer, making the dibasic processing sites easily accessible to the endopeptidases and hence highly efficient at proinsulin to insulin processing. This is reflected in the fact that the proinsulin content in the beta-cell secretory granule is less than 2% that of insulin.

III. PROINSULIN BIOSYNTHESIS

A. Translation, Translocation, and Transport through the Secretory Pathway

The first step in the mechanism of proinsulin biosynthesis is the translation of preproinsulin mRNA into preproinsulin polypeptide. The intracellular localization of preproinsulin mRNA translation in the beta cell is on the ribosomes of the RER. Initially, ribosomes are attached to free preproinsulin mRNA in a beta-cell cytosolic storage pool by the process of translation initiation normally applied to most mammalian mRNAs under the control of eukaryotic initiation factors (eIFs). Preproinsulin mRNA translation to polypeptide begins in the cytosol with synthesis of the signal peptide of the preproinsulin molecule. This emerging signal sequence binds the signal recognition particle (SRP), a cytosolic ribonucleoprotein complex. Then, by binding of SRP to the SRP receptor, an integral ER membrane protein, the preproinsulin mRNA/ribosomal complex is localized to the RER. More than one ribosome can scan along a single preproinsulin mRNA to form polyribosomal complexes, the consequence of which is that many preproinsulin polypeptide copies can be produced from a single preproinsulin mRNA template. As the SRP binds to its SRP receptor, the nascent signal peptide of the newly forming preproinsulin dissociates from SRP and is transferred to another RER integral membrane protein called the signal sequence receptor (SSR). The SSR is thought to be part of a "translocation pore" that facilitates transport of the newly forming preproinsulin polypeptide across the RER membrane into the RER lumen. As the elongation phase of preproinsulin mRNA translation continues, increasing the length of the preproinsulin polypeptide, the signal peptide is cleaved by another RER membrane-associated protein, the signal peptidase. Cleavage of the signal peptide from newly forming preproinsulin polypeptide by signal peptidase probably occurs co-translationally before preproinsulin mRNA translation is complete. Preproinsulin polypeptide elongation is halted at the UAG stop codon on preproinsulin mRNA and is mediated by a GTP-binding protein called releasing factor (RF). RF promotes the release of the newly formed (pre)proinsulin polypeptide from the preproinsulin mRNA/ribosomal complex concomitant with GTP hydrolysis and allows recycling of ribosomes for another round of preproinsulin mRNA translation initiation/elongation. The C-terminal portion of the newly formed (pre)proinsulin polypeptide then completes translocation across the RER, resulting in a soluble nascent proinsulin molecule in the RER lumen.

The proinsulin molecule then undergoes appropriate folding so that the intrachain disulfide bond of the insulin A-chain and two A-/B-chain interchain disulfide bridges within the proinsulin molecule can be correctly aligned. This process is likely catalyzed by the molecular chaperonin, BiP, and a disulfide isomerase activity, both of which are found in the RER lumen of beta cells. Newly synthesized proinsulin is then transported from the RER in small transport vesicles to the *cis*-Golgi apparatus. It then passes from stack to stack of the Golgi apparatus in small COP-coated vesicles, eventually arriving at the *trans*-Golgi network (TGN). The newly synthesized proinsulin then aggregates (mostly likely in Zn^{2+}-containing dimer/hexameric form) in clathrin-coated regions of the TGN, which are the sites of insulin secretory granule biogenesis. So-called immature, partially clathrin-coated, insulin secretory granules then bud off the TGN. It is in this intracellular compartment that the majority of proinsulin to insulin conversion takes place as granule maturation occurs.

The process of insulin secretory granule maturation includes a progressive intragranular acidification from approximately pH 6.9 to pH 5.0 via activation of the ATP-dependent H^+-pump present in the granule membrane. This provides the appropriate environment (pH 5.0–5.5) for optimal proinsulin conversion and formation of the insulin crystal around the isoelectric point of insulin (pK_i 5.3) to occur. The patches of clathrin coat on the immature insulin secretory granule membrane are also removed during the maturation process. Once a mature granule is formed, it is retained in a "storage compartment" in the beta cell for several days and undergoes exocytosis in order to secrete insulin only upon the introduction of an appropriate stimulus. This is characteristic of (pro)insulin being specifically targeted to the beta cell's regulated secretory pathway. Although the mechanism of sorting of proinsulin to secretory granules at the level of TGN is not, for the moment, particularly well understood, it is nonetheless a highly efficient process with $>99\%$ of newly synthesized proinsulin targeted to insulin secretory granules.

B. Effectors and Inhibitors of Proinsulin Biosynthesis

Proinsulin biosynthesis can be regulated by nutrients and certain hormones, but, among these, glucose is

the most physiologically relevant. Long-term glucose exposure to beta cells (>6 h) modestly up-regulates preproinsulin gene transcription by approximately 2-fold. In addition, preproinsulin mRNA stability is increased. However, the predominant control mechanism of glucose-induced proinsulin biosynthesis (especially in normal circumstances of glucose stimulation, <2 h) is at the translational level (see below). The stimulation of proinsulin biosynthesis by glucose is rapid. Upon an increase from a basal 3 mM glucose to a stimulatory 10 mM glucose, there is a lag period of about 20 min followed by a marked rise in the rate of proinsulin biosynthesis translation that reaches a maximum by 60 min, 20- to 30-fold above the rate at basal glucose, without any change in preproinsulin mRNA levels. The threshold concentration of glucose required to stimulate proinsulin biosynthesis translation is between 2 and 4 mM glucose, which is lower than the glucose threshold of 4–6 mM required to stimulate insulin secretion. Glucose metabolism is required to generate stimulus-coupling signals for proinsulin biosynthesis translation. Currently, it is thought that such a secondary metabolic signal for glucose-induced proinsulin biosynthesis emanates from anaplerosis of the tricarboxylic acid cycle where succinate/succinyl-CoA is the most promising candidate.

In general, most nutrients that increase insulin secretion also control proinsulin biosynthesis in parallel. This ensures that intracellular stores of insulin in the beta cell are maintained at optimal levels. However, there is one notable exception for parallel nutrient-induced control of proinsulin biosynthesis/insulin secretion. Fatty acids are marked potentiators of glucose-induced insulin secretion; however, if anything, fatty acids inhibit glucose-induced proinsulin biosynthesis. As such, there is a failure to replenish beta-cell insulin content at the biosynthetic level when insulin secretion is stimulated by fatty acids that can lead to decreased insulin secretory capacity after prolonged exposure to fatty acids and consequently is a contributing factor to beta-cell dysfunction in the pathogenesis of type 2 diabetes.

It should be noted that the stimulus-coupling signaling mechanism for glucose-induced control of proinsulin biosynthesis translation is distinct from that for insulin secretion. ATP is required for general protein synthesis in the beta cell, but is not a specific coupling signal as for glucose-induced insulin secretion. Indeed, the K_{ATP} channel plays a key role in stimulus-coupling mechanism for glucose-induced insulin secretion, but is not involved in the control of proinsulin synthesis. Neither the agonists of the K_{ATP} channel (e.g., sulfonylureas) that stimulate insulin secretion nor the antagonists (e.g., diazoxide) that inhibit insulin secretion affect glucose-induced proinsulin biosynthesis. Moreover, increased cytosolic $[Ca^{2+}]_i$ is a prerequisite for the mechanism of glucose-induced insulin secretion, but glucose-induced translational control of proinsulin biosynthesis is Ca^{2+}-independent. Finally, while certain hormones can either stimulate (e.g., GLP-1) or inhibit (e.g., epinephrine) both glucose-induced insulin secretion and proinsulin biosynthesis in parallel, other hormones (e.g., somatostatin) can markedly inhibit glucose-induced insulin secretion without affecting proinsulin biosynthesis.

C. Translational Control for Proinsulin Biosynthesis

In general, glucose modestly increases general protein synthesis in the beta cell 1.5- to 2-fold. This seems to occur in response to phosphorylation regulation of certain eIFs, in particular, eIF2α, eIF-2B, and eIF-4E-BP. However, the effect of glucose on proinsulin synthesis translation, as well as the synthesis of a small subset of all beta-cell proteins most of which are components of the insulin secretory granule, is much greater (reaching >10-fold stimulation). This indicates a more specific effect of glucose on the translational control of preproinsulin mRNA translation. It is known that glucose increases the rate of "free cytoplasmic" preproinsulin mRNA translocation to ribosome and polyribosome complexes, indicating control at the initiation phase of translational mechanism where 40S and 60S ribosomal subunits are attached to mRNA. Glucose then promotes translocation of preproinsulin mRNA–ribosomal complexes to the RER membrane, most likely via increasing the association of the SRP initiation complex with the SRP receptor. However, this happens to all proteins in the beta cell that possess a signal peptide on entering the secretory pathway and does not account for the specific nature of glucose-induced preproinsulin biosynthesis. This likely occurs via translational control *cis*-elements in the untranslated regions (UTRs) of preproinsulin mRNA itself. Indeed, in the 5′-UTR there is a "stem-loop" secondary structure (not necessarily primary sequence), which is highly conserved across mammalian preproinsulin mRNAs. Moreover, in the 3′-UTR of preproinsulin mRNA, just downstream of the polyadenylation signal is a highly conserved primary sequence containing a UUGAA core. Recent studies

have shown that the 5′-UTR stem-loop element of the preproinsulin mRNA is required for glucose stimulation of proinsulin biosynthesis, since the translation of a preproinsulin mRNA variant that lacks this 5′-UTR does not undergo glucose-induced translational regulation. However, when the 3′-UTR UUGAA element is additionally present, the effect of the 5′-UTR on glucose stimulation of proinsulin biosynthesis is augmented. The effect of the 3′-UTR *cis*-element appears to be a glucose-induced alleviation of a translational block, but this occurs only when the 5′-UTR stem-loop is present. Thus, it appears that there is cooperativity between the preproinsulin mRNA 5′- and 3′-UTRs for the *specific* translational control of proinsulin biosynthesis influenced by extracellular glucose concentrations (Fig. 3). In addition, the preproinsulin mRNA 3′-UTR UUGAA *cis*-element also encodes a signal that preserves preproinsulin mRNA stability specifically in beta cells, which in turn could contribute to longer term up-regulation of proinsulin biosynthesis by glucose. It is currently postulated that certain beta-cell-specific *trans*-acting factors associate with the 5′- and 3′-UTRs of preproinsulin mRNA, which will be key to the specific control of proinsulin biosynthesis by glucose. However, the identity of such *trans*-acting factors is not yet known. Notwithstanding, once such factors are identified, a connection between secondary factors emanating from glucose metabolism and control of proinsulin biosynthesis should be made, which in turn will markedly improve our understanding of the control mechanism behind proinsulin production in the beta cell.

IV. PROINSULIN PROCESSING

A. Proinsulin Processing Enzymes

Proinsulin to insulin conversion is catalyzed by the action of two endopeptidases, PC-2 and PC-3 (also known as PC-1), and the exopeptidase, carboxypeptidase-H (CP-H). The enzymatic process of proinsulin conversion is outlined in Fig. 4. In 1988, two distinct proinsulin processing enzymatic activities were identified in secretory granules of insulinoma cells and named type I and type II activities. These two activities were Ca^{2+}-dependent and had an acidic pH optimum (~pH 5.0). These activities were subsequently cloned in the early 1990s, and the type I and type II proinsulin processing activities were

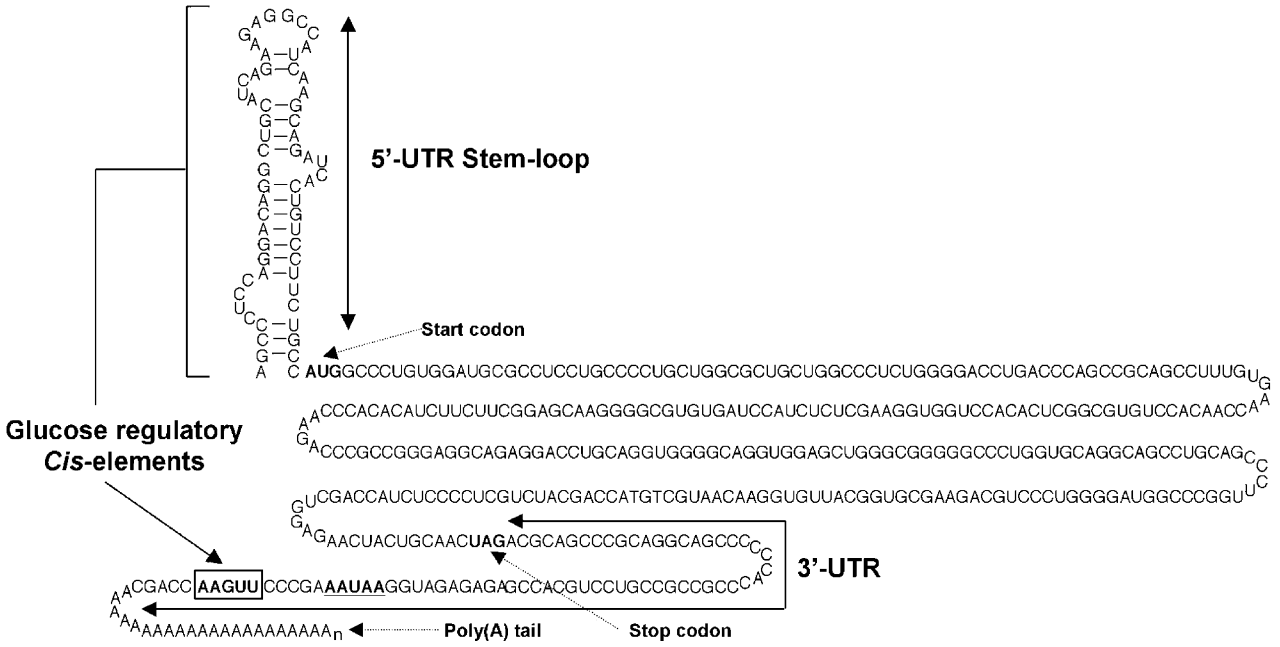

FIGURE 3 Schematic representation of human preproinsulin mRNA. The primary sequence of human preproinsulin mRNA is shown highlighting the glucose-responsive *cis*-elements in the 5′- and 3′-untranslated regions (UTRs). The predicted "stem-loop" secondary structure of the 5′-UTR is shown, followed by the AUG start codon (in boldface type) intervening coding sequence ending with the UAG stop codon (in boldface type), followed by the 3′-UTR and poly(A) tail. Within the 3′-UTR, the polyadenylation signal (boldface and underlined) and glucose regulatory/mRNA stability UUGAA *cis*-element (boxed) are shown.

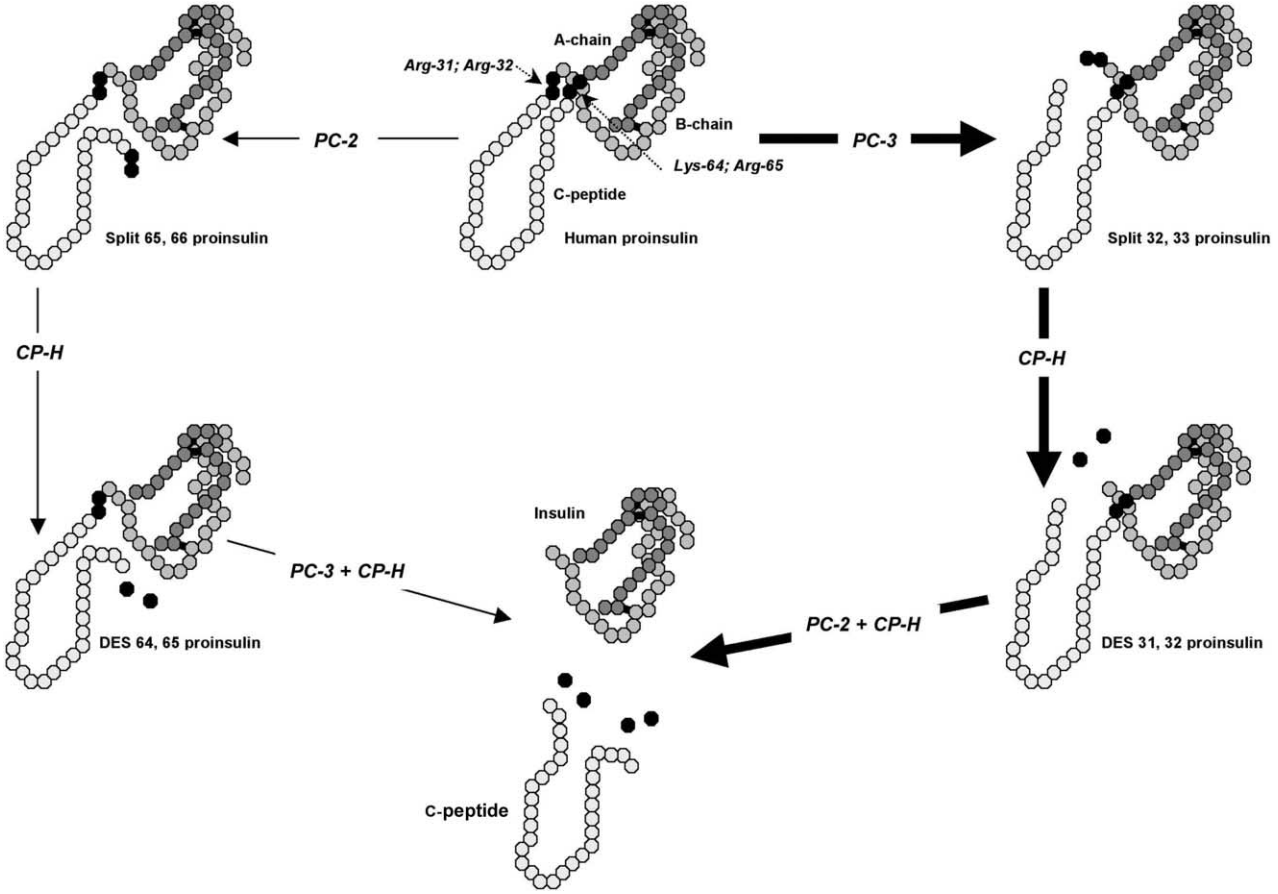

FIGURE 4 Pathways of proinsulin processing. The two potential pathways of proteolytic conversion of proinsulin by PC-2, PC-3, and CP-H to the final products of mature insulin, C-peptide, and free basic amino acids is shown. However, one of these routes is preferred as indicated by the broader arrows between each catalytic step.

identified as the subtilisin-like endopeptidases PC-3 and PC-2, respectively. Mammalian PC-2 and PC-3 are members of the proprotein processing subtilisin family of serine proteases, which also includes yeast Kex2 and the other mammalian endopeptidases furin/PACE, PC-4, PACE-4, PC-5/PC-6, and LPC/PC-7/PC-8. Proprotein-converting endopeptidases are responsible for the posttranslational conversion of most prohormones, neuropeptide precursors, and other protein precursors into their biologically active forms. Members of this endopeptidase family all share a homology with a subtilisin-like catalytic domain where conserved Asp, His, and Ser residues make up the catalytic triad aligned by similar flanking sequences. Proprotein-converting endopeptidases contain a signal peptide targeting them to the cell's secretory pathway, as well as a propeptide that is likely autocatalytically removed upon maturation in a zymogen-like manner.

The tissue distribution of different proprotein-converting endopeptidases varies. Furin, PACE-4, PC-5, and PC-7 are broadly expressed in a wide number of different tissues. In contrast, expression of PC-2 and PC-3 is restricted to neuroendocrine tissues (e.g., pancreatic islets, pituitary, adrenal medulla, and other brain tissues). PC-4 is highly specialized where its expression is limited to testicular spermatogenic cells. Furin, PACE-4, PC-5, and PC-7 are responsible for the conversion of proprotein precursors generally secreted via the constitutive pathway, including proalbumin, certain clotting factors, some growth factors, and plasma membrane receptor proteins. However, PC-2 and PC-3 generally process precursors of hormones and neurotransmitters that are secreted via regulated pathways. Indeed, proPC-2 and proPC-3 are transported to the secretory granules along with their proprotein substrates and undergo maturation beginning in the TGN.

Intriguingly, proPC-2 and proPC-3 are accompanied by individual chaperonin molecules, 7B2 and pro-SAAS, respectively, that specifically inhibit the activity of these endopeptidases. Some believe that 7B2 and proSAAS should even be considered regulatory subunits for proPC-2 and proPC-3, respectively. Proteolytic cleavage of 7B2 by PC-2, and proSAAS by PC-3, in the TGN/immature secretory granule compartment alleviates the inhibition of proPC-2 and proPC-3, promoting their maturation and activation to mature PC-2 and PC-3. This then provides a degree of regulating proPC-2 and proPC-3, helping to restrict their activation to the secretory granule compartment. It appears that the 7B2 and proSAAS chaperonins are very important in controlling PC-2 and PC-3 activity *in vivo*, as illustrated by the 7B2 knockout mouse, which has multiple neuroendocrine disorders including hypoglycemia, hyperproinsulinemia, hypoglucagonemia, and Cushing syndrome. Likewise, there is marked defective prohormone conversion in PC-2 knockout mice and multiple endocrine disorders in a human patient deficient in PC-3, both of which have defective proinsulin conversion resulting in hyperproinsulinemia.

The substrate specificity of all endopeptidases is cleavage of proproteins on the carboxylic side of multibasic amino acid sequences. The cleavage site for proproteins of the constitutive pathway is typically Arg-X-Lys/Arg-Arg, whereas those for the regulated pathway proproteins are more often the dibasic sequences Lys-Arg and Arg-Arg. For human proinsulin, PC-2 preferentially cleaves on the carboxylic side of the dibasic Lys64Arg65 site and PC-3 on the carboxylic side of Arg31Arg32 (Fig. 1). Other prohormones processed by PC-2 and/or PC-3 include proopiomelanocortin in the pituitary anterior and intermediate lobes and proglucagon in the pancreatic α-cell and certain gut cells. These particular precursor molecules can be differentially processed to yield different hormone products in a tissue-specific manner, which depends mostly on the relative expression level of PC-2 and PC-3 in that particular cell type.

Once PC-2 and PC-3 have cleaved proinsulin at the dibasic sites Arg31Arg32 and Lys64Arg65, the newly exposed basic residues are removed by the action of the exopeptidase CP-H (also known as CP-E). CP-H is a carboxypeptidase B-like enzyme that is widely expressed in many endocrine and neural tissues including the pancreatic beta cell. The important role of CP-H *in vivo* has been demonstrated in obese *fat/fat* mice, where a single Ser-202 to Pro mutation abolishes CP-H enzymatic activity. These animals have defective proinsulin processing, resulting in hyperproinsulinemia, and indeed there is little insulin present since most of the "insulin" formed is actually diarginyl-[Arg31, Arg32]-insulin due to the failure of CP-H to trim off the dibasic residues after PC-3 cleavage. Diarginyl-insulin has only approximately 50% of the biological activity of native insulin, so that these animals are mildly insulin deficient. However, this does not explain the obese phenotype of the *fat/fat* mice; this is more likely due to deficient processing of neuronal peptides associated with appetite control.

B. Regulation of Proinsulin Processing

Proinsulin conversion begins in the region of the TGN, but takes place mostly in the immature secretory granule compartment and is ongoing as part of the secretory granule maturation process. As mentioned previously, autocatalytic cleavage of the propeptide on proPC-2 and proPC-3 occurs in this compartment to yield active PC-2 and PC-3. This is accompanied by an alleviation of the inhibition on PC-2 and PC-3 mediated by proteolytic cleavage of the proPC-2 chaperonin, 7B2, and pro-PC-3 chaperonin, proSAAS. However, this complex proteolytic activation process is dictated by generation of the appropriate intraorganellar environment suitable for the optimal activity of PC-2 and PC-3 endopeptidases. PC-2, PC-3, and CP-H require an acidic pH for optimal activity. Intragranular acidification from approximately pH 6.8 in the TGN to pH 5.0–5.5 in the insulin secretory granule occurs as part of the immature insulin secretory granule maturation process. This acidification is a result of activating an ATP-dependent proton pump present on insulin secretory granule membranes. The developing acidic environment in an immature granule ensures that the majority of PC-2, PC-3, and CP-H activation occurs within the secretory granule compartment, confining insulin production and crystallization to the intracellular compartment in which it is stored. In addition, both PC-2 and PC-3 are Ca^{2+}-dependent enzymes requiring >1 mM $[Ca^{2+}]$ for full activity. This is a relatively high Ca^{2+} requirement; however, there is a correspondingly high free $[Ca^{2+}]$ present in the insulin secretory granule. Thus, the Ca^{2+} dependency of PC-2 and PC-3 activity also ensures that insulin conversion is confined to the insulin secretory granule compartment.

As indicated above, glucose can markedly increase proinsulin biosynthesis at the translational level, as much as 20- to 30-fold within 60 min. This obviously places an increased demand on the proinsulin

conversion process in beta cells. However, this is compensated for by a parallel glucose-induced increase in proPC-2 and proPC-3 biosynthesis at the translational level. Intriguingly, both preproPC-2 and preproPC-3 mRNAs have a conserved stem-loop secondary structure in their 5′-UTR that is very similar to that in preproinsulin mRNA, which acts as a glucose-regulatory *cis*-element to stimulate proinsulin biosynthesis translation. However, neither preproPC-2 nor preproPC-3 mRNA contains the 3′-UTR glucose regulatory *cis*-element found in preproinsulin mRNA, which might account for the observation that glucose-induced translational control of PC-2 and PC-3 biosynthesis is not as robust as that of proinsulin and that preproPC-2 or preproPC-3 mRNA is less stable than preproinsulin mRNA in beta cells. Interestingly, CP-H biosynthesis is not regulated by glucose, and preproCP-H mRNA has neither a predicted 5′- or 3′-UTR glucose-regulatory *cis*-element. Nevertheless, the constitutively high concentration of CP-H in the beta cell, which comprises 2–5% of the total insulin secretory granule protein content, seems to be sufficient to cope with the requirement of glucose-stimulated increase of proinsulin processing.

C. Sequential Proinsulin Processing

Proinsulin is coordinately cleaved on the carboxylic side of two sites, Arg31Arg32 and Lys64Arg65 on human proinsulin, to generate the final products of mature insulin, C-peptide, and free basic amino acids (Fig. 4). This can occur by two possible routes. PC-2 may first cleave at Lys64Arg65 to yield a split 65, 66 proinsulin intermediate, followed by CP-H trimming of the newly exposed lysine and arginine residues to yield des 64, 65 proinsulin. PC-3 can then cleave des 64, 65 proinsulin at Arg31Arg32, which together with CP-H trimming of the exposed arginine residues, yields insulin and C-peptide (Fig. 4). Alternatively, PC-3 may first cleave at Arg31Arg32 to yield a split 32, 33 proinsulin intermediate, followed by CP-H trimming of the revealed arginine residues to yield des 31, 32 proinsulin. PC-2 can then cleave des 31, 32 proinsulin at Lys64Arg65, which, together with CP-H trimming of the lysine and arginine residues, yields insulin and C-peptide (Fig. 4). However, although both of these routes can occur in the beta cell *in vivo*, experimental evidence indicates that the latter route (via the des 31, 32 proinsulin intermediate) is predominant. The PC-2 endopeptidase activity has a better affinity for des 31, 32 proinsulin as a substrate than intact proinsulin. In contrast, PC-3 can readily cleave at Arg31Arg32 on intact proinsulin. Nuclear magnetic resonance analysis of proinsulin has indicated an ordered structure around the Lys64Arg65 C-peptide/A-chain junction, termed the CA-knuckle, that seems to affect substrate recognition by PC-2 by acting as a blocking structure to prevent PC-2 access to the cleavage site Lys64Arg65 in intact proinsulin. However, upon PC-3 cleavage of intact proinsulin at Arg31Arg32, to generate des 31, 32 proinsulin (with CP-H trimming), the CA-knuckle structural constraint is alleviated, allowing better access for PC-2 to Lys64Arg65 on its preferred des 31, 32 proinsulin substrate. Thus, the majority of proinsulin conversion is sequential, where PC-3 first cleaves at Arg31Arg32 on proinsulin, followed by PC-2 cleavage at Lys64Arg65 on des 31, 32 proinsulin. This is corroborated by the observation of a marked increase in des 31, 32 proinsulin levels in PC-2 knockout mice. Moreover, there are much higher circulating levels of des 31, 32 proinsulin than of des 64, 65 proinsulin in humans.

V. SUMMARY

Insulin is initially synthesized in the RER of the pancreatic beta cell as a larger precursor molecule, preproinsulin. Preproinsulin is processed to proinsulin in the RER by removal of the signal peptide sequence. Proinsulin conversion to active, mature insulin occurs mostly in the beta-cell secretory granule by limited proteolysis and is catalyzed by the endopeptidases PC-2 and PC-3 and the exopeptidase CP-H. PC-3 and PC-2 process proinsulin in a preferential sequence. PC-3 first cleaves proinsulin at the pair of basic amino acid residues Arg31Arg32, which after trimming of the newly exposed basic residues by CP-H yields des 31, 32 proinsulin. Then, PC-2 processes des 31, 32 proinsulin at the dibasic pair Lys64Arg65, which, after CP-H trimming of the basic residues, yields mature insulin and C-peptide. Proinsulin conversion can be regulated on multiple levels governed by translational control of proPC-2 and proPC-3 in parallel to their proinsulin substrate; by specific chaperonin molecules 7B2 (for proPC-2) and proSAAS (for proPC-3), which guide zymogen-like activation of proPC-2 and proPC-3 maturation; and by the acidic (pH 5.5) and high free [Ca^{2+}] (>1 mM) intragranular environment. This ensures that insulin production is confined to the compartment in which it is stored, a process that under normal conditions in the beta cell is $>99\%$ efficient. However, under abnormal conditions, such as type 2 diabetes where a chronic increased demand for

insulin production is placed on the beta cell by hyperglycemia and peripheral insulin resistance, proinsulin production and processing become dysfunctional and hyperproinsulinemia results. This, in turn, further contributes to the insulin-deficient condition of type 2 diabetes, since proinsulin has $<5\%$ of the activity of mature insulin.

Glossary

endopeptidases The enzymes responsible for the limited proteolysis of proproteins, usually on the carboxylic side of dibasic amino acid sequences, to yield the active mature protein. Proprotein convertase 2 (PC-2) and PC-3 are the endopeptidases that catalyze proinsulin to insulin conversion in the insulin secretory granule compartment of the pancreatic beta cell. Also known as convertases.

exopeptidase An enzyme involved in the mechanism of proprotein processing. It selectively removes the carboxylic basic amino acids exposed after the endopeptidase cleavage. Carboxypeptidase-H (CP-H) trims the newly exposed arginine and lysine residues after the proteolysis of proinsulin by PC-2 and PC-3.

insulin secretory granule The intracellular compartment of the pancreatic islet beta cells where insulin is stored, ready to be released when an appropriate stimulus triggers the beta cell. The insulin secretory granule is formed in the *trans*-Golgi, where proinsulin, the precursor of insulin, is sorted into the clathrin-coated immature insulin secretory granule. Secretory granule maturation comprises clathrin uncoating, granule acidification, and conversion of proinsulin to insulin.

proinsulin The precursor of insulin; it has less than 5% of the biological activity of insulin. Proinsulin is processed to mature, active insulin by limited proteolysis.

Insulin Receptor Signaling

SUZANNE G. LAYCHOCK

State University of New York, Buffalo

Insulin is the principal hormone regulating blood glucose levels and glucose metabolism in mammals; in addition, insulin affects lipid metabolism, protein synthesis, and cell growth. Binding of insulin to the insulin receptor serves as a signal that leads to modification of expression of many enzymes and proteins involved in cellular activity.

I. INTRODUCTION

Insulin has a molecular weight of about 6000 and is composed of two chains (A and B) of amino acids joined together by disulfide linkages (Fig. 1). The secondary structure of the insulin protein situates chain A between the amino- and carboxy-terminal ends of the folded B-chain. Insulin is synthesized from proinsulin, a single-chain precursor that is packaged into secretory granules and released from the pancreatic islet of Langerhans beta cells in response to glucose and other secretagogues. After secretion from the beta cell, insulin is carried in the blood to target tissues. The major insulin target tissues are liver, adipocytes, and muscles. However, insulin has effects on many tissues, including the cardiovascular system and the brain.

At target tissues, the insulin ligand binds to and activates the insulin receptor localized in the plasma membrane. The insulin receptor tyrosine kinase activity autophosphorylates the receptor in response to insulin binding. The phosphorylated receptor then binds to and initiates phosphorylation of intracellular substrates that act as signal transduction elements. There are now more than 100 genes targeted by insulin regulation. Insulin modifies the expression of numerous enzymes and proteins in cells that possess

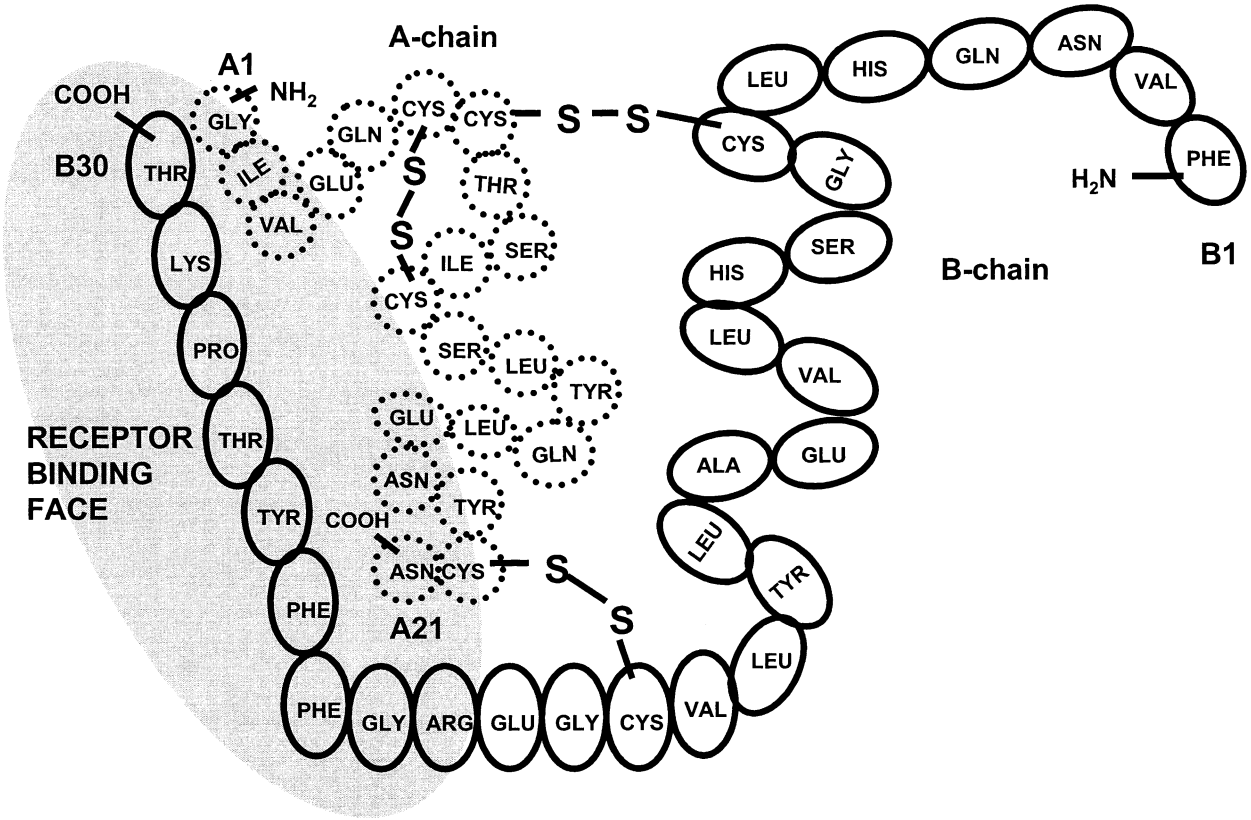

FIGURE 1 Insulin molecule amino acids of the A-chain (dotted-line circles) and the B-chain (solid-line ovals), showing terminal amino acids in each chain (numbers) and disulfide bonds (–S–S–). Amino acids in the approximate receptor-binding face of the molecule (shaded area) will bind to the α-subunits of the insulin receptor.

an insulin receptor, indicating that insulin signals the nucleus to increase the transcription of genes needed to carry out pleiotropic cellular activities.

II. DYNAMICS OF INSULIN RECEPTOR STIMULATION

The action of insulin at its target tissues is to interact at the plasma membrane with a receptor that initiates a series of intracellular responses. The tail of the B-chain and part of the A-chain amino acid sequence constitute the receptor-binding face of the insulin molecule (Fig. 1).

Many of the biochemical responses to insulin receptor stimulation involve protein phosphorylation and dephosphorylation. However, the insulin receptor is an active participant in cellular responses. The ligand-bound insulin receptor autophosphorylates due to an inherent tyrosine kinase activity and migrates within the plane of the plasma membrane of the cell and is internalized (endocytosed) to the cytoplasm, where it can be degraded in lysosomes, or the receptor is recycled back to the plasma membrane from endosomes (Fig. 2). The acidic environment of the endosome leads to insulin dissociation from the receptor and degradation by acidic insulinase (Fig. 2). Insulin-bound receptors in the endosome can phosphorylate substrates spatially distinct from those at the plasma membrane, but once the insulin and receptor are dissociated, phosphorylation events cease and the receptor is dephosphorylated by extralumenal endosomal-associated protein tyrosine phosphatases. The insulin receptor can be recycled to the plasma membrane, and insulin receptor protein synthesis can also contribute to the insulin receptor population (Fig. 2). When circulating insulin levels are

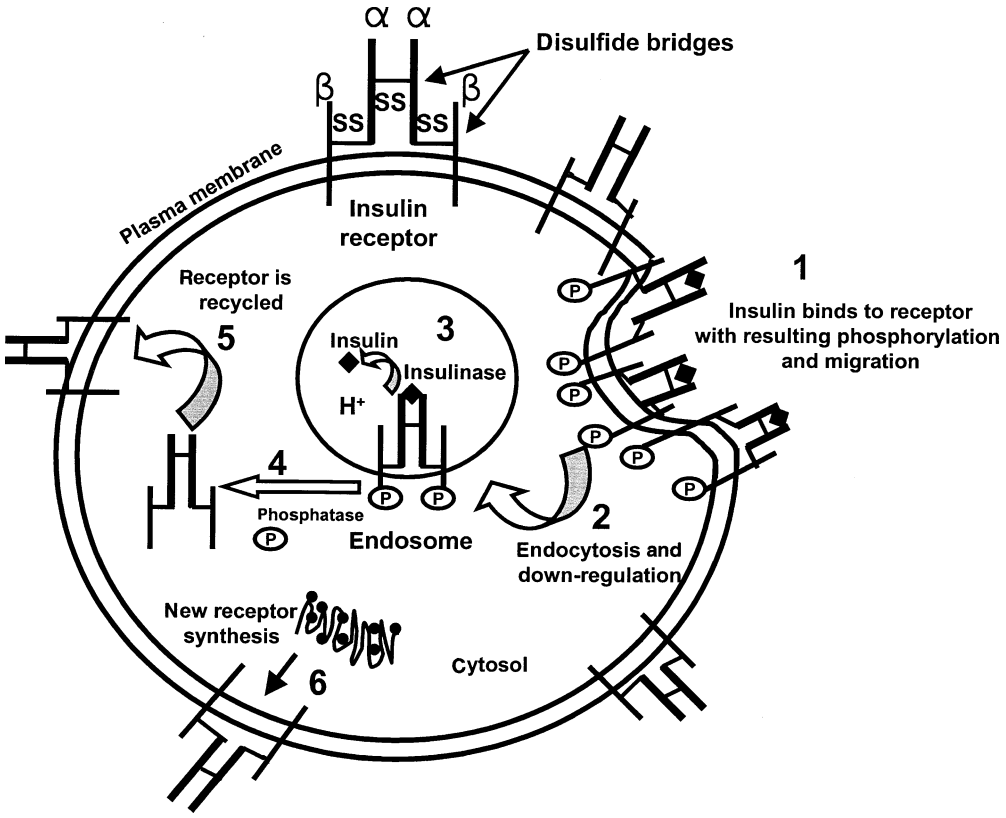

FIGURE 2 Insulin receptor stimulation, endocytosis, and recycling. The insulin receptor heterotetramer is shown with two α-subunits and two β-subunits connected by disulfide bonds (SS). (1) Insulin (◆) binds to insulin receptor α-subunits, initiating insulin receptor autophosphorylation (P) and aggregation within the plane of the plasma membrane. (2) The aggregated insulin receptors undergo endocytosis and (3) within the acidic environment of the endosome the insulin is removed from the receptor by insulinase. (4) Phosphate groups on the β-subunits of the receptor are removed by endosome-associated phosphatase and (5) the receptor is recycled to the plasma membrane, where it can bind to another insulin molecule and begin the cycle again. (6) New insulin receptor molecules are synthesized in the endoplasmic reticulum and added to the plasma membrane population of receptors.

elevated and stimulation of receptors is prolonged, the population of available insulin receptors is down-regulated with degradation of the receptor, and insulin responses can be muted. In non-insulin-dependent (type 2) diabetes mellitus, this down-regulation creates a state of insulin resistance, i.e., the target cells fail to respond adequately to insulin. On restoration of insulin stimulation to normal, insulin receptors will be reinstated at the plasma membrane to mediate insulin stimulatory responses.

III. THE INSULIN RECEPTOR

The insulin receptor is present in virtually all vertebrate tissues, although the levels of receptor in the membrane can vary from a few per cell to several thousand in the major insulin-responsive tissues. The insulin receptor gene on human chromosome 19 encodes a transmembrane glycoprotein composed of an α_2/β_2 heterotetramer with a molecular mass of 300–400 kDa. The two α-subunits (135 kDa) are composed of 719 or 731 amino acids, depending on whether there is alternative splicing of messenger RNA (mRNA) surrounding exon 11 in the gene. A disulfide bond links the two α-subunits. The β-subunits are 95 kDa, comprising 620 amino acids. The α- and β-subunits are derived from a single proreceptor molecule by proteolytic processing and are linked in the mature β/α/α/β heterotetramer by disulfide bonds (Fig. 2). The α-subunits are oriented entirely extracellular to the surface of the plasma membrane and contain the insulin-binding domain at the N-terminus. Between one and two insulin molecules bind per receptor. The β-subunits are transmembrane peptides that contain (1) an extracellular portion containing a cysteine that forms a disulfide bridge with an α-subunit cysteine (Figs. 2 and 3), (2) a transmembrane domain, and (3) an intracellular extension that includes the juxtamembrane domain, ATP-binding site, catalytic tyrosine kinase domain, and C-terminal domain (Fig. 3). The intrinsic β-subunit protein tyrosine kinase activity is inhibited by unoccupied α-subunits.

When the receptor is activated by insulin, there occurs a noncovalent oligomerization, resulting in autophosphorylation of several tyrosine residues in the β-subunit intracellular juxtamembrane region, a regulatory region, and the carboxyl terminus of the β-subunit. The binding of insulin to the α-subunits induces a conformational change that brings the α-subunits into closer proximity and enables ATP to bind the β-subunit intracellular domain. Although

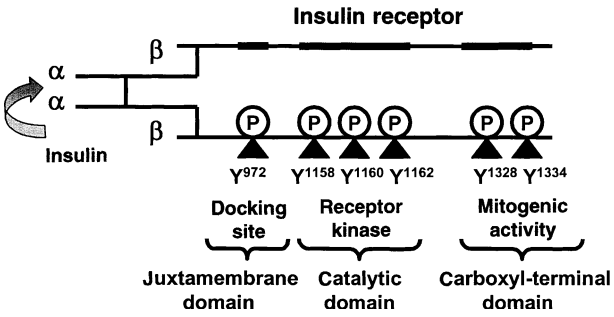

FIGURE 3 The insulin receptor tyrosine phosphorylation sites of regulation. Insulin binds to the receptor and initiates the autophosphorylation of tyrosines within the three major regulatory domains of the receptor. The functionality of the domains is indicated. Numbers refer to the position of tyrosine (Y) in the β-subunit amino acid sequence.

seven tyrosine residues are phosphorylated in the β-subunit, three main clusters of autophosphorylation sites are recognized to play a functional role in insulin action, including Tyr-972 in the juxtamembrane domain (an important "docking site" in the interaction between the receptor and its intracellular substrates); Tyr-1158, Tyr-1160, and Tyr-1162 in the catalytic domain (essential for receptor kinase activity); and Tyr-1328 and Tyr-1334 in the carboxyl-terminal domain (suggested to mediate mitogenic activity of the receptor) (see Fig. 3, in which tyrosine is designated with the one-letter symbol, Y). Progressive phosphorylation of tyrosine residues in the regulatory region results in parallel changes in biological activity. Phosphorylation and activation of the insulin receptor kinase activity have two important functions: to signal the receptor-ligand complex to be endocytosed at regions of clathrin-coated pits in the plasma membrane and to signal the tyrosine phosphorylation of insulin receptor substrate (IRS) proteins and other proteins.

There is also phosphorylation on serine and threonine residues of the insulin receptor under basal and stimulated cell conditions. Stimuli such as insulin, phorbol esters (which stimulate protein kinase C activity), and cyclic AMP (which stimulates protein kinase A) can induce serine and threonine phosphorylation of the insulin receptor. It is possible for serine phosphorylation to decrease insulin-stimulated tyrosine kinase activity. Thus, at least three levels of regulation of the insulin receptor—tyrosine kinase autophosphorylation, serine/threonine phosphorylation, and inhibitory serine phosphorylation—are regulated by extracellular signals and intracellular messengers and other events.

IV. INSULIN RECEPTOR SUBSTRATES

Insulin receptor substrate-1 (IRS-1) was the first docking protein identified within the IRS class of molecules. Five other related proteins within the family have also been identified, including IRS-2, IRS-3, IRS-4, Gab1, and $p62^{dok}$. Each of the IRS proteins share a common architecture: an NH_2-terminal pleckstrin homology and/or a phosphotyrosine-binding (PTB) domain, tyrosine residues that create SH2 (SRC homology 2) protein-binding sites, proline-rich regions for SH3 or WW domain recognition, and serine/threonine-rich regions. Insulin, insulin-like growth factor-I (IGF-I), and certain cytokine receptors can phosphorylate IRSs at specific Y-x-x-M (methionine) motifs that then serve as molecular bonding agents to other signaling molecules capable of transducing a signal to the diverse array of metabolic and biochemical pathways influenced by insulin. The PTB domain provides a coupling site for IRS with the insulin receptor, and binds weakly to the phosphorylated NPXY (asparagine, proline, X, tyrosine) motif in the juxtamembrane region of the insulin receptor. The pleckstrin homology domain may also play a role in IRS protein binding to the insulin receptor.

IRS-1 and IRS-2 are expressed in many tissues, but their levels are regulated independently. IRS-3 is expressed in adipose tissue, liver cells, pancreatic islet beta cells, and fibroblasts, whereas IRS-4 is expressed in kidney, brain, and thymus. Gab1 (Grb2-associated binding protein) is found in many mammalian tissues, and insulin induces tyrosine phosphorylation. In the absence of IRS-4, there is modest growth retardation and insulin resistance, whereas loss of Gab1 activity results in an embryonic-lethal phenotype.

IRS proteins in conjunction with activated insulin receptor become tyrosine phosphorylated and bind to the SH2 domains of various signaling proteins to generate downstream signals (Fig. 4). IRS-1 and IRS-2 associate with phosphatidylinositol 3-kinase (PI3K); the phosphotyrosine phosphatase SHP2; the Src-like kinase fyn; and the adapter proteins Grb2 (growth factor receptor binding protein 2), Nck, and Crk. IRS-1 and IRS-2 have some functional similarities, but also retain unique characteristics. IRS-1

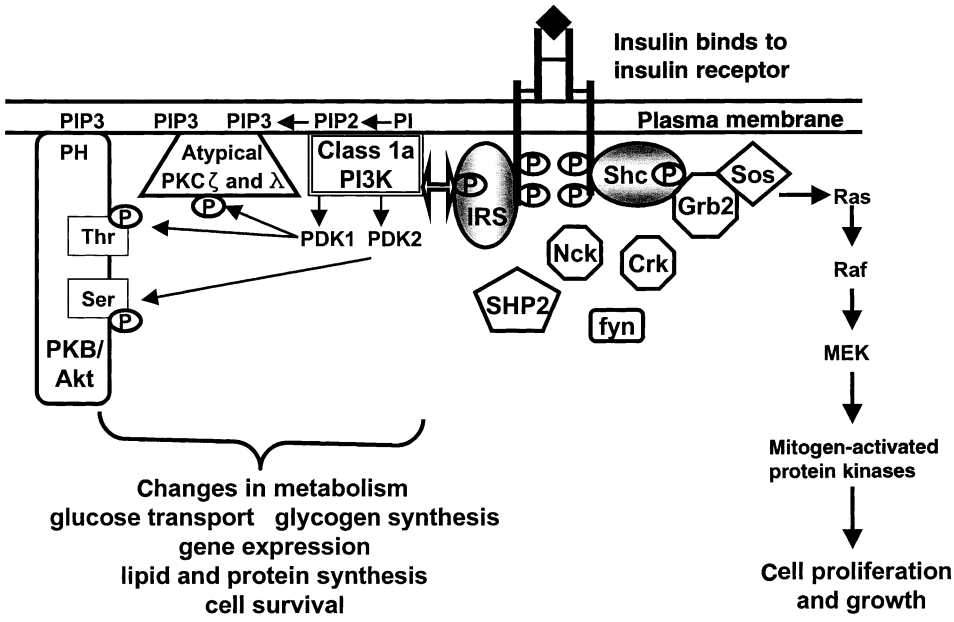

FIGURE 4 Activated insulin receptor signal transduction pathways. Insulin binding to the insulin receptor initiates phosphorylation of the receptor and subsequent binding of insulin receptor substrate (IRS) proteins and Shc protein substrates. Adapter proteins Grb2, Nck, and Crk mediate signal transduction events. SHP2 is an IRS phosphatase. Phosphorylated IRS proteins activate PI3K, increasing phosphatidylinositol 4,5-bisphosphate (PIP_2) and phosphatidylinositol 3,4,5-trisphosphate (PIP_3) levels in the plasma membrane. PI3K also activates phosphoinositide-dependent kinases (PDK1 and PDK2) to phosphorylate protein kinase C (PKC) isoforms and/or PKB/Akt. Receptor-mediated binding and phosphorylation of Shc induces association with an adapter protein that activates Sos and the mitogen-activated protein kinase cascade. Insulin activation of PKC and PKB/Akt initiates cell responses unique from those elicited by the mitogen-activated protein kinase pathway.

and IRS-2 coordinate insulin effects on metabolism, islet beta cell function, reproduction, and growth and development. IRS-3, when tyrosine phosphorylated, binds PI3K. It has yet to be proved that IRS-4 behaves in a similar manner, although it contains several potential tyrosine phosphorylation sites. $p62^{dok}$ is unique in its failure to bind PI3K.

In addition to IRS proteins, products of the *shc* gene are also substrates of the insulin receptor. The protein products of this gene contain SH2 domains and are tyrosine phosphorylated in response to insulin receptor activation. Shc and IRS proteins compete for the same binding site on the insulin receptor. Phosphorylated Shc associates with Grb2 and can activate the Ras (superfamily of small guanosine trisphosphatases)/mitogen-activated protein kinase (MAPK) pathway independently of IRS-1 (Fig. 4). Grb2, an adapter protein containing SH3 domains, allows constitutive association with the guanine nucleotide exchange factor Sos (son-of-sevenless) and is part of the cascade including Ras, Raf, and MEK [the dual-specificity MAPK/extracellularly regulated kinase (ERK)] that leads to activation of MAPK and mitogenic responses characterized by gene transcription initiated by transcription factors such as elk1 and c-fos (Fig. 4). Thus, insulin initiates cell proliferation in certain target tissues.

IRS proteins are important loci of signal divergence in insulin signaling. One path leads to IRS-1 and Grb2 activation of the ERK–MAPK cascade, promoting gene transcription. The alternative path leads to IRS protein activation of PI3K class 1a. PI3K class 1a has been implicated in biological responses to insulin and insulin-like growth factor, including glucose transport, DNA synthesis, changes in glycogen metabolism, and cell survival with antagonism of apoptotic responses. IRS-1 seems to be particularly important for somatic growth, especially embryonic and neonatal growth, as demonstrated in mice. Interestingly, IRS-2 cannot substitute for IRS-1 in mediating somatic growth, suggesting unique roles for these IRS proteins. IRS proteins display signal redundancy as well as diversity in the activation of PI3K. IRS-1 and IRS-3 activate PI3K more strongly than does IRS-2, whereas IRS-4 barely activates PI3K in cell-based assays. In liver, IRS-2 plays a major role in PI3K activation.

IRS-1 exerts its greatest effect on metabolism by mediating insulin signals in muscle and adipose tissue, with lesser effects on liver metabolism, for which IRS-2 dominates. In mice with *irs1* or *irs2* gene disruption, there is marked insulin resistance compared with wild-type mice, which have normal gene function. It appears that the lack of IRS-1 in IRS-$1^{-/-}$ knockout mice leads to loss of insulin responsiveness, mainly due to decreased insulin-stimulated peripheral glucose uptake; the lack of IRS-2 in IRS-$2^{-/-}$ mice results in insulin resistance largely associated with decreased peripheral glucose uptake and unsuppressed hepatic gluconeogenesis. The IRS-$2^{-/-}$ knockout mice also show poor suppression of lipolysis in response to insulin. With regard to carbohydrate and lipid metabolism, IRS-1 seems to play a major role in muscle and adipose tissue, whereas IRS-2 has primary importance in liver and muscle.

A. The Insulin–IRS Pathway and the Pancreatic Beta Cell

The insulin–IRS pathway also plays an important role in the functioning of the insulin-secreting pancreatic beta cells. In mice that lack the IRS-1 gene (IRS-$1^{-/-}$) but that are heterozygous for IRS-$2^{-/+}$, there is no overt diabetes mellitus because an active beta cell compensates for insulin resistance by increasing the amount of insulin secreted. In contrast, homozygous IRS-$1^{-/-}$/IRS-$2^{-/-}$ mice fail to compensate for peripheral insulin resistance, have underdeveloped beta cell mass and hyperglycemia, and die before maturity. There is also evidence that IRS-2 signaling may be important for embryonic development and postnatal growth of pancreatic beta cells. The importance of insulin and the IRS-signaling pathway in normal glucose metabolism is emphasized by the roles these molecules play, not only in general aspects of metabolism but also in beta cell survival and glucose-sensitive insulin secretion.

V. PHOSPHATIDYLINOSITOL 3-KINASE

An initial step in insulin signal transduction is the IRS-induced activation of PI3K. Phosphorylation of IRS proteins creates recognition/docking sites for the two SH2 domains of an adapter protein complexed with cytosolic class 1a PI3Ks (Fig. 5). Such docking promotes the translocation of the cytosolic PI3Ks to the juxtamembrane region, where they phosphorylate their lipid substrate inositol ring (Fig. 5). Phosphatidylinositol (PI) is a phospholipid with a hydrophobic domain consisting of two fatty acid molecules attached by ester bonds to a three-carbon glycerol moiety in the plane of the plasma membrane; a hydrophilic phosphorylated base group

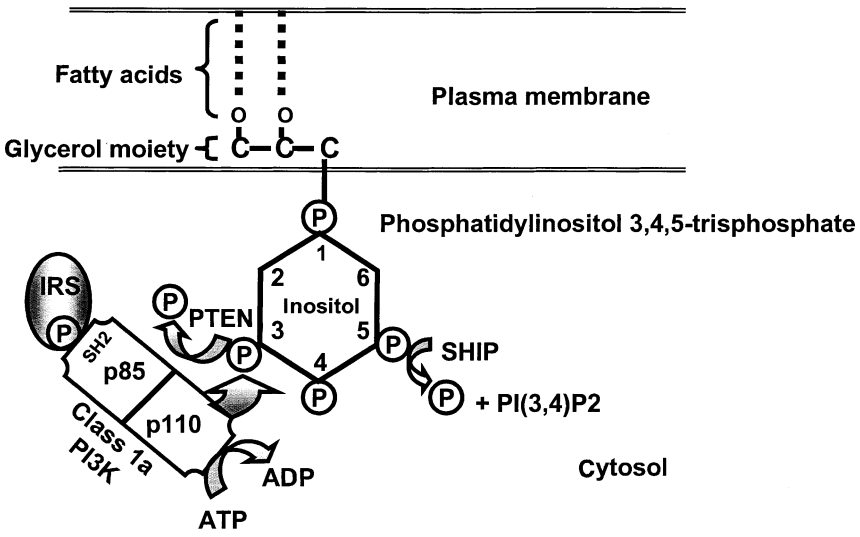

FIGURE 5 Phosphatidylinositol 3,4,5-trisphosphate formation and dephosphorylation. The two fatty acid side chains on C-1 and C-2 of the glycerol backbone of phosphatidylinositol 4,5-bisphosphate [PI(3,4)P2] are situated in the plane of the membrane, whereas the phosphorylated inositol ring base group extends to the cytosol. Phosphatidylinositol 3-kinase (PI3K) class 1a is activated by complex formation with insulin-activated insulin receptor substrate (IRS) protein at the adapter protein p85 subunit. The activation of p85 initiates catalytic activity of the p110 subunit, utilizing ATP and transferring a phosphate (P) group to the 3′ position of the inositol ring, to form phosphatidylinositol 3,4,5-trisphosphate. SHIP and PTEN are phosphatases, removing P and converting phosphatidylinositol 3,4,5-trisphosphate to phosphatidylinositol 4,5-bisphosphate and/or phosphatidylinositol 4-phosphate.

(inositol phosphate) extends from the glycerol moiety into the juxtamembrane region of the cytosol (Fig. 5). PI3K catalyzes the phosphorylation of phosphoinositides at the 3′ position of the inositol ring or proteins at serine residues. The predominant class 1a PI3K exists as heterodimers, with an adapter 85-kDa subunit associated with a catalytic 110-kDa subunit. However, diversity within the PI3K family is achieved through the expression of multiple regulatory subunits (p85α, p85β, $p55^{PIK}$, p55α/AS53, and p50α) and multiple catalytic subunits (p110α, p110β, or p110δ). Class 1a PI3K exists as several isoforms and splice variants of the adapter and catalytic subunits. The class 1b PI3K is regulated by G-protein-coupled receptors and not by insulin.

Class 1 PI3Ks *in vitro* have been shown to prefer specific substrates: PI, phosphatidylinositol 4-phosphate (PIP), and phosphatidylinositol 4,5-bisphosphate (PIP_2). However, in intact cells PI3Ks seem to prefer PIP_2 as substrate. The most abundant product formed by PI3K activation in response to insulin stimulation is phosphatidylinositol 3,4,5-trisphosphate (PIP_3). Class 2 PI3K can be activated by insulin stimulation, but it cannot utilize PIP_2 as a substrate. Class 3 PI3K seems to use only PI as a substrate. Thus, it is not likely that class 2 or class 3 PI3Ks mediate insulin signaling in large measure. The levels of the phosphatidylinositols are reduced by the actions of specific phosphatases. The lipid phosphatase PTEN (for phosphatase and tensin homologue deleted from chromosome 10) dephosphorylates 3-phosphoinositides specifically at position 3 of the inositol ring and has highest specificity for PIP_3 (Fig. 5). SH2 domain-containg phosphatase 2 (SHIP-2), widely expressed in nonhematopoietic cells, is an inositol 5′-phosphatase that hydrolyzes PIP_3 to PIP_2 (Fig. 5). SHIP-1 is an isoform found in hematopoietic cells. In cells lacking SHIP, there is prolonged activation of PIP_3-dependent pathways.

PI3K activation mediates cellular responses to insulin in a variety of ways. Phospholipid products of PI3K recruit serine kinases to the plasma membrane, including phospholipid (3-phosphatidylinositol)-dependent protein kinases (PDK1 and PDK2) and protein kinase B (PKB)/Akt (a product of the *akt* protooncogene) (Fig. 4). PI3K activates PKB/Akt and atypical protein kinase Cs (PKCs) that are not stimulated by diacylglycerol but are responsive to PIP_3 (PKC ζ and PKC λ) (Fig. 4). PIP3 also activates salt- and glucocorticoid-induced kinases and wortmannin-sensitive and insulin-stimulated serine kinases, among others.

VI. PROTEIN KINASE B/AKT

PKB/Akt is a serine/threonine kinase that contains a pleckstrin homology domain, a catalytic domain, and a putative regulatory fragment at the carboxyl terminus. PKB/Akt activation involves interaction with PIP_3 and/or PIP_2 through binding of the phospholipids at the pleckstrin homology domain (Fig. 4). Three isoforms of PKB/Akt encoded by three separate genes have been identified in mammalian cells. PKB/Aktα is predominantly activated by insulin in muscle, liver, and adipocyte tissue. In adipocytes, it is PKB/Aktβ that is primarily activated, whereas PKB/Aktγ is not activated by insulin in the major target tissues, although there is activation in some cultured cells. The activation of class 1a PI3K is necessary and sufficient for activation of PKB/Akt, and blockade of PI3K activity blocks the stimulation of PKB/Akt. The activation of PKB/Akt by insulin appears to be primarily through phosphorylation on two sites (threonine and serine). The threonine site is associated with the catalytic subunit and the serine phosphorylation site is associated with the regulatory fragment. PDK1 is responsible for phosphorylation at the threonine site in each of the PKB/Akt isoforms, and phosphorylating activity is dependent on the presence of PIP_3 *in vitro*. The enzyme responsible for serine phosphorylation in PKB/Akt has yet to be cloned, but has been named PDK2. The inositol–lipid interaction recruits PKB/Akt to the plasma membrane, where it undergoes a conformational change and opens threonine and serine residues to phosphorylation by PDK1 and PDK2, respectively (Fig. 4). Once phosphorylated and activated, PKB/Akt can phosphorylate specific substrates, including glycogen synthase kinase-3 (GSK-3), which results in inhibition of the enzyme and an increase in glycogen synthesis—a major metabolic mechanism of action of insulin in hepatocytes and other tissues. However, PKB/Akt activation mediates several of insulin's pleiotropic responses, including changes in metabolism, glucose transporter synthesis and mobilization, gene expression, and lipid and protein synthesis (Table 1).

The forkhead (FKH) transcription factor family, including FKHR, FKHRL, and AFX, has important effects on gene transcription and may mediate insulin effects on genes, such as those encoding IGF-I, phosphoenolpyruvate carboxykinase, and glucose 6-phosphatase. FKHR enhances transcription of genes that regulate glucose synthesis and cell division as well as cell death (apoptosis). The phosphorylation of these factors leads to inactivation. Insulin induces the phosphorylation of FKHR by PIP_3-dependent kinases, such as PKB/Akt and others. Due to the fact that FKHR is inhibited by insulin-induced phosphorylation, this limits transcription of genes

TABLE 1 PKB/Akt-Mediated Signal Transduction Events

Target	Response	Event
PKB/Akt target		
Phosphofructokinase-2	Activation	Activates phosphofructokinase-1, increases glycolysis
GLUT4	Translocation	Increases glucose uptake
mTOR	Activation	Activates P70 S6 kinase and protein synthesis, activates eIF-4 initiation complex, increases mRNA translation, increases peptide chain elongation
eIF-2B	Activation	Activates eIF-2, increases mRNA translation, inactivation of GSK-3
IκB kinase	Activation	Promotes IκB dissociation from NF-κB, activates NF-κB-mediated gene transcription
Phosphodiesterase 3B	Activation	Regulates intracellular cyclic AMP levels
Cyclic AMP response element binding protein	Activation	Transcriptional activation
Glycogen synthase kinase-3	Inhibition	Increases glycogen synthesis
Glycogen synthase kinase-3β	Inhibition	Activates AP-1 and other transcription factors, increases transcription
Forkhead factor FKHR	Inhibition	Limits transcription of genes regulating apoptosis, glucose production, and cell division
Gene target		
GLUT1, GLUT3	Increased	Increases glucose uptake
Fatty acid synthase promoter	Increased	Increases fatty acid synthesis
c-fos	Increased	Increases transcription
Phosphoenolpyruvate carboxykinase	Decreased	Decreases gluconeogenesis

that are antagonistic to insulin actions (Table 1). PKB/Akt may also affect other transcription factors, such as nuclear factor-κB (NF-κB); cAMP response element binding protein (CREB), which is phosphorylated by PKB/Akt to induce transcriptional activation; and eukaryotic initiation factor eIF-2B. The effects of PKB/Akt on NF-κB are indirect, initiated by activation of IκB kinase with subsequent degradation of IκB and activation of NF-κB.

In addition to transcription factors, PKB/Akt can have effects on messenger RNA translation by affecting other factors. PKB/Akt can activate the mammalian target of rapamycin (mTOR), which activates 4E-BP, which in turn activates eIF-4E (Table 1). Through the activation of mTOR, PKB/Akt may be able to influence the elongation of translation through p70 ribosomal S6 kinase (p70 S6 kinase) and elongation factor activation. Elongation initiation factor activity and mRNA translation may also be mediated through the inhibition of GSK-3.

Metabolism is affected by PKB/Akt at several levels. PKB/Akt increases expression of the glucose transporters GLUT1 and GLUT3 and the translocation of GLUT4 to the plasma membrane. Moreover, glycogen synthase activation and glycogen synthesis follow the inactivation of GSK-3. In cardiac cells, the rate-limiting step in mammalian glycolysis, phosphofructokinase-1, is activated by PKB/Akt (Table 1). PKB/Akt also affects several other genes involved in metabolic control, such as the fatty acid synthase promoter and the phosphoenolpyruvate carboxykinase gene.

Consistent with effects on metabolism, PKB/Akt has been shown to promote cell survival and block apoptosis. Similar to some growth factors, PKB/Akt maintains the integrity of mitochondria and prevents the release of cytochrome *c*, which initiates the apoptotic cascade. These effects may be integral to the antiapoptotic effects of PKB/Akt. It is also likely that the positive metabolic effects of PKB/Akt activation on glycolysis and protein synthesis contribute to cell survival.

VII. p70 S6 KINASE

Another serine/threonine kinase involved in insulin action is p70 S6 kinase, which requires phosphorylation for activation. Evidence suggests that PI3K, PKB/Akt, and mTOR activation participates in the activation of p70 S6 kinase, because inhibition of PI3K or PKB/Akt blocks its activation. Although there is no direct evidence that p70 S6 kinase is phosphorylated by PKB/Akt, PDK1 phosphorylates one of the threonine residues that activates the enzyme. PI3K-independent mechanisms also regulate p70 S6 kinase, but these entail longer activation times. Because rapamycin can inhibit the activation of p70 S6 kinase, this is evidence that mTOR is in one of the pathways regulating this enzyme.

VIII. ATYPICAL PROTEIN KINASE Cs

Insulin-induced PI3K activation results in activation of protein kinase C ζ and PKC λ. These are atypical PKCs that do not require Ca^{2+} and are not activated by diacylglycerol or phorbol ester. Blockade of PI3K prevents the insulin-stimulated activation of PKC ζ, whereas the phospholipids PIP_3 and PIP_2 directly stimulate PKC ζ *in vitro* to mimic the effects of insulin. Likewise, in mutant cells lacking IRS-1–PI3K binding sites, the ability of insulin to activate PKC ζ is lost. PI3K appears to act through the kinase PDK1 to phosphorylate and activate PKC ζ. However, in the cascade, PKC ζ activation does not lead to PKB/Akt, or to mTOR and p70 S6 kinase activation, suggesting that PKC ζ and PKC λ promote effector pathways separate from those responsive to PKB/Akt. Like PKC ζ, the activation of PKC λ is not dependent on PKB/Akt activation in response to PI3K. In addition, atypical PKC ζ and PKC λ have been implicated in insulin-dependent glucose transport and protein synthesis.

IX. MITOGEN-ACTIVATED PROTEIN KINASE

Another of the signaling pathways for insulin is the mitogen-activated protein kinase series of enzymatic reactions. As a result of insulin stimulation, IRS proteins and Shc bind to the SH2 domains of small adapter proteins (Fig. 4). One such adapter protein, Grb2, links IRS/Shc and Sos. The two SH3 domains on Grb2 associate with proline-rich regions in the guanine nucleotide exchange factor, Sos. Sos stimulates GDP/GTP exchange on Ras. Ras is a key player in recruiting the serine/threonine kinase Raf to the plasma membrane. Once Raf is activated, a cascade of activation begins with the activation of MEK, the dual-specificity MAPK kinase/extracellularly regulated kinase. MEK is activated by phosphorylation at two serine residues, but activates MAPK by phosphorylating both tyrosine and threonine. The p90 ribosomal protein S6 kinase (p90 rsk), phospholipase A_2, and many transcription factors are activated as a result of MAPK-induced phosphorylation. Among the signaling pathways identified for insulin, the MAPK pathway is not very sensitive to insulin

and is not involved in the major metabolic responses to insulin. It has been proposed that activation of GTP-loaded Ras interacts directly with PI3K; however, the functional interaction of these two players in insulin action remains under investigation.

X. INHIBITION OF INSULIN SIGNALING

Mechanisms for termination of insulin receptor signal transduction include promoting serine phosphorylation of IRS proteins or the insulin receptor, and dephosphorylating serine or tyrosine. The IRS-1- and Grb2-activated MAPK pathway participates in the former process. Because phosphorylation and dephosphorylation of distinct proteins play major roles in insulin stimulation of cells, phosphatases may be viewed as negative modulators of insulin action—removing phosphate groups from enzymes dependent on them for activation. The phosphatase family of enzymes comprises more than 100 different genes. SHP2 is an SH2-containing phosphatase (also known as Syp or SH-PTP2) negatively modulating insulin receptor activity. The association of SHP2 SH2 domains with tyrosine-phosphorylated IRS-1 during insulin stimulation promotes phosphotyrosine dephosphorylation, thus attenuating insulin signaling by reducing the association with effector proteins in certain signaling pathways. PTPase 1B is another tyrosine phosphatase that is a potential negative modulator of insulin action as it has been demonstrated to dephosphorylate the insulin receptor *in vitro*. The role of PTPase 1B in insulin action *in vivo* remains to be demonstrated, although mice lacking PTPase 1B exhibit a phenotype with enhanced insulin sensitivity.

Phosphatase activation also plays an important metabolic role in insulin actions. Insulin activates protein phosphatase-1 (PP-1), a serine/threonine phosphatase that is part of the signal transduction cascade regulating glycogen metabolism. Phosphorylation is required for PKB/Akt activity, and dephosphorylation is a potential mechanism for cellular termination of an insulin response. Phosphatase 2A may be an important enzyme in the regulation of PKB/Akt. Phosphatase inhibitors such as vanadate and okadaic acid can augment PKB/Akt activity. Moreover, a specific inhibitor of phosphatase 2A, calyculin A, can prevent dephosphorylation and inactivation of PKB/Akt. The activity of PKB/Akt is also modulated by PTEN and SHIP dephosphorylation of PIP_3.

XI. CELLULAR RESPONSES TO INSULIN

A. Glucose Transport

The major metabolic actions of insulin relate to changes in glucose metabolism. Blood glucose levels are lowered and metabolism is fueled by glucose influx into cells across plasma membranes by GLUT-mediated facilitated diffusion. Glucose transporters are integral membrane-spanning glycoproteins with molecular masses of about 50,000 Da. Insulin–receptor binding initiates the translocation of intracellular vesicles containing glucose transporters (GLUT4 and GLUT1) to the plasma membrane, and glucose transport is proportional to the increase in transporter population in the membrane; insulin also diminishes the rate of dissociation of GLUT back to the cytoplasm (Fig. 6). The mobilization of glucose transporters is reversible on reduction in the insulin stimulus, when the transporters are sequestered back to the intracellular vesicular pool (Fig. 6). GLUTs associate and dissociate from the plasma membrane in the basal state. However, not all GLUTs are insulin responsive; for example, GLUT2 in plasma membranes of pancreatic islet beta cells allows these cells to respond directly to extracellular glucose concentrations.

Two models for GLUT sequestration/mobilization argue either that GLUT-containing vesicles are mobilized in response to insulin receptor stimulation, or that GLUTs are constitutively prevented from cycling to the plasma membrane by some inhibitory factor, and that insulin receptor stimulation removes that inhibition. Certain of the factors supporting the former vesicular sequestration model have been identified. The vesicle containing GLUT4 is proposed to dock onto and fuse with the plasma membrane via a v-SNARE protein (vesicle SNAP receptor) pairing with a target site on the membrane and/or recognizing t-SNAREs (Fig. 6). VAMP-2 is the predominant v-SNARE found in GLUT4 vesicles. Within the plasma membrane of insulin-responsive cells, the main t-SNAREs are syntaxin 4 and SNAP-23. Synip is a syntaxin 4-binding protein that dissociates in response to insulin and allows GLUT4 translocation. Munc18 is another syntaxin 4-binding protein that dissociates after insulin stimulation, thus allowing increased binding of VAMP-2 to syntaxin 4 and constituting docking of the GLUT vesicle to the plasma membrane.

The elements of the insulin receptor signaling cascade that are important for GLUT4 translocation include the tyrosine kinase activity of the receptor

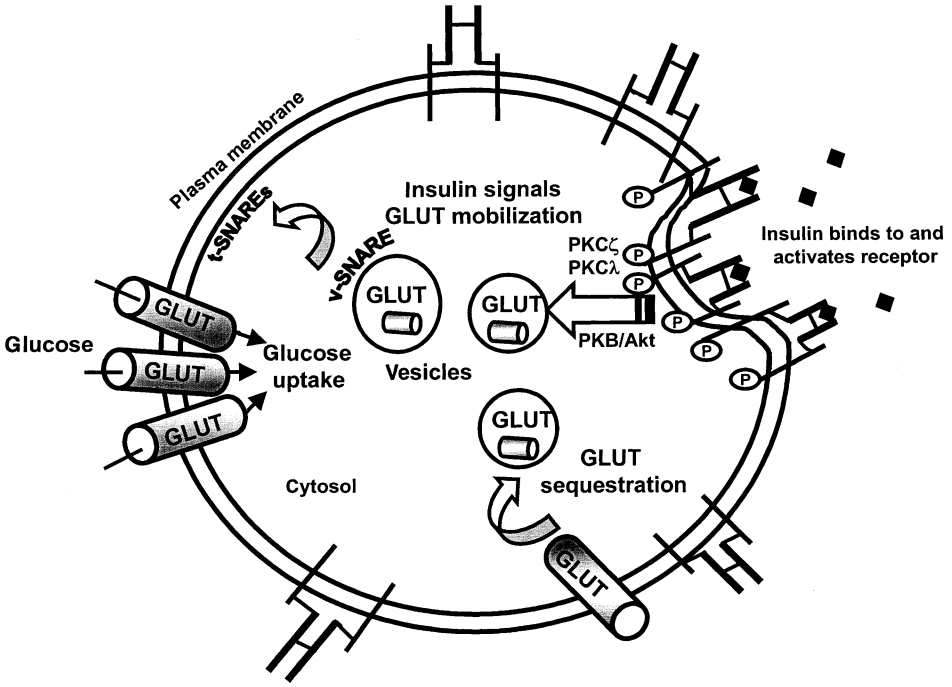

FIGURE 6 The vesicle model of GLUT translocation. Insulin binding activates the insulin receptor and the downstream effector molecules that participate in the mobilization of GLUT-containing vesicles to the plasma membrane. For glucose facilitated diffusion, v-SNARE peptides in the vesicles recognize t-SNARE peptides at the plasma membrane docking sites for GLUT insertion to the plasma membrane. In the absence of insulin receptor binding, GLUTs are sequestered in intracellular vesicles, from which they can be mobilized.

and IRS activation, although IRS-1 may not play an essential role and in fact many mechanisms contributing to GLUT translocation are not known. PI3K has also been implicated in GLUT regulation because PI3K inhibition can inhibit GLUT4 mobilization, whereas overexpression of the PI3K gene increases GLUT4 translocation in adipocytes and increases glucose uptake. However, PI3K does not appear to be a sufficient stimulus for glucose uptake, because stimuli other than insulin that increase PI3K activity do not increase glucose uptake.

PKB/Akt has been implicated in the regulation of glucose transport downstream of PI3K. Active PKB/Akt is associated with GLUT4 translocation to the plasma membrane and increased glucose transport. Moreover, PKB/Aktβ associates with GLUT4-containing vesicles following insulin stimulation of cells. A more specific role for PKB/Akt isoforms in glucose uptake remains to be determined. The atypical PKCs also appear to play a role in regulating glucose uptake. Expression of PKC ζ in cells increases GLUT4 translocation and glucose transport in response to insulin. With the expression of a dominant negative PKC ζ mutant in adipocytes and a muscle cell line there is inhibition of PKC ζ synthesis and partial inhibition of GLUT4 translocation and glucose uptake. Similarly, expression of PKC λ mutants deficient in kinase activity leads to reduced GLUT4 translocation and inhibition of glucose uptake.

Downstream in the insulin response pathway, p70 S6 kinase activation is not required for insulin-stimulated glucose uptake or for GLUT4 translocation. However, p70 S6 kinase mediates long-term effects of insulin on synthesis of GLUT1 transporter in cells. The MAPK pathway also does not seem to play a major role in the rapid stimulation of glucose transport in muscle and fat cells. Ras-microinjected adipocytes do not show increased GLUT4 translocation, nor does Ras inhibition negatively impact insulin-stimulated translocation. Moreover, inhibition of MEK does not inhibit the glucose transporter response to insulin stimulation. In contrast, the long-term effects of insulin on synthesis of GLUT3 in muscle cells appear to be mediated by the MAPK pathway.

B. Glycogen Synthesis

One of the major actions of insulin is to promote glucose uptake into cells with storage of energy in

the form of glycogen, primarily in skeletal muscle and liver cells. Glycogen synthase in skeletal muscle is subject to phosphorylation at multiple sites by many protein kinases. When insulin induces dephosphorylation of glycogen synthase, there is an increase in catalytic activity. Protein phosphatase 1G (PP1G) is a glycogen-bound form of protein phosphatase 1 and is responsible for dephosphorylation of glycogen synthase. Insulin-stimulated phosphorylation of PP1G may contribute to regulation of its activity. Whether p90 rsk2, which phosphorylates PP1G, mediates PP1G activity in intact cells is a subject of debate. Or, in lieu of a phosphatase to remove phosphate groupings, the inhibition of a kinase may regulate glycogen synthase. GSK-3 is phosphorylated in response to insulin, and inactivated. PI3K phosphorylates GSK-3, and the downstream PI3K effectors PKB/Akt, mTOR, and p70 S6 kinase may also play roles in glycogen synthase activation and glycogen storage. The underlying molecular mechanisms regulating glycogen synthase activity continue to undergo investigation.

C. Protein Synthesis

One of the major actions of insulin is on protein synthesis, involving not only changes in transcriptional activation and messenger RNA production, but also increased translational activity of specific proteins in certain tissues. The mRNA cap-binding protein, eukaryotic initiation factor-4E (eIF-4E), recognizes the mRNA cap structure and regulates translation. Insulin activation induces the phosphorylation of serine in eIF-4E, which in turn increases the affinity of eIF-4E for the mRNA cap structure and increases translation. The eIF-4F initiation complex is formed by the association of eIF-4E, and the RNA helicase eIF-4A, and eIF-4G (which forms a bridge between eIF-4E and eIF-4A) (Fig. 7). During insulin stimulation of adipocytes, there is phosphorylation of eIF-4E-binding protein [4E-BP1; also known as the phosphorylated heat- and acid-stable protein (PHAS-1)], which subsequently dissociates from eIF-4E, allowing translation to commence (Fig. 7). Such a regulatory phenomenon has been observed for skeletal muscle, adipocytes, and myoblasts. Insulin activation of PI3K, with subsequent activation of PKB/Akt and the mTOR pathway, mediates insulin-induced phosphorylation of 4E-BPs. It does not appear that the p70 S6 kinase downstream of mTOR, nor the MAPK pathway, participates in this regulatory process.

eIF2 is another important component of the mRNA translational sequence. A requirement for initiation is the role of eIF2 to bind the initiator Met-tRNA to the 40S ribosomal subunit. eIF-2B is a guanine nucleotide exchange factor that promotes release of bound GDP and binding of GTP to eIF2. In addition, PI3K activation appears to play a role in insulin activation of eIF-2B. The mTOR, p70 S6 kinase, and the MAPK pathways do not appear to play a role in eIF-2B activation. Elongation of peptide chains is crucial for protein synthesis, and elongation factors eEF1 and eEF2 are required. Insulin stimulates the elongation rate and increases the phosphorylation of eEF1, in contrast with a reduction in eEF2 phosphorylation. PI3K acting through the mTOR pathway mediates insulin actions on elongation.

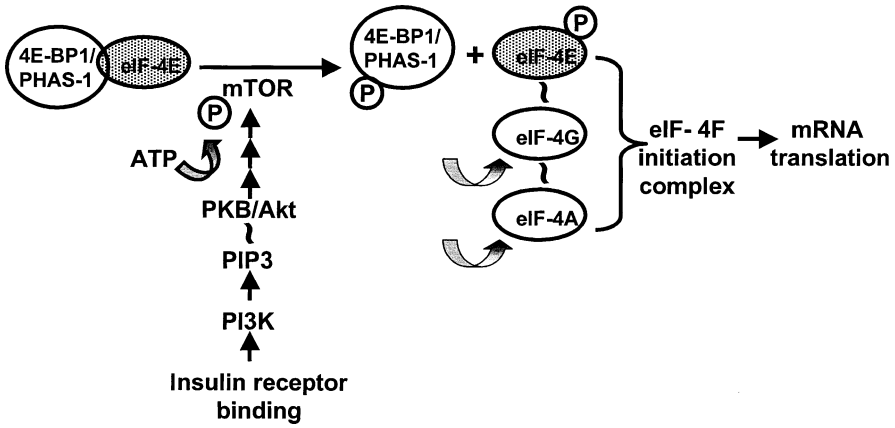

FIGURE 7 Insulin stimulation of mRNA translation. Insulin stimulates PKB/Akt activity, which leads to phosphorylated (P) mTOR; mTOR activation phosphorylates 4E-BP1, which causes dissociation of the inactive 4E-BP1–eIF-4E heterodimer complex. Phosphorylated eIF-4E associates with the bridge factor eIF-4G, which links to eIF-4A to form the eIF-4F initiation complex that mediates increased mRNA translation and protein synthesis.

XII. SUMMARY

Insulin is notable for the variety of cellular responses that it evokes in target cells and tissues. Accounting for the pleiotropic responses, the insulin receptor signal transduction mechanism represents complex regulatory and counterregulatory pathways and events. The primary and secondary structures of the insulin molecule and insulin receptor have been elegantly sequenced and modeled, providing a window with a view as to how these complex molecules interact at the molecular level. Major players in the insulin receptor signaling cascade, including peptide mediators and adapter proteins, enzymes such as PI3K with their elaborate pathways for regulating metabolic, genetic, and protein synthetic responses in target cells, provide a strong base on which to formulate future hypotheses concerning the regulation of insulin-stimulated activities in cells.

Glossary

apoptosis The process of programmed cell death. Numerous genetic and biochemical pathways contribute to apoptosis, and the process is linked to degradation of nuclear DNA.

autophosphorylation Transfer of a phosphate group to an amino acid within a protein (self-phosphorylation). Certain proteins have kinase activity as a part of their molecular structure and have this ability.

catalytic domain Amino acid sequence that contains a specific enzymatic activity associated with a protein.

diabetes mellitus Disease characterized by high blood glucose levels and low insulin levels and/or insufficient insulin receptor activity (insulin resistance).

endocytosis The process of membrane engulfment by a cell. A portion of the plasma membrane "pinches off" into the cytoplasm such that there is formation of an inside-out intracellular vesicle that contains the proteins, etc. that were originally present in the plasma membrane.

pleiotropic Having more than one effect; a single stimulus can often evoke several different cellular responses, often mediated by distinct intracellular messengers or pathways.

protein kinase C A family of serine/threonine protein kinases characterized by their ability to be activated by Ca^{2+} and diacylglycerol (classical PKCs), by diacylglycerol alone (novel PKCs), or not by diacylglycerol or Ca^{2+} but by phospholipids and phosphorylation (atypical PKCs).

receptor Protein that resides in the cell membrane, cytoplasm, or nucleus of cells. A ligand binds and activates the receptor to initiate a cellular biochemical or molecular response unique to each receptor.

substrate Molecule that will be altered by the actions of an enzyme.

transcription The molecular process of copying a gene to form a messenger RNA molecule; regulated by initiation factors and promoter regions in the nuclear chromatin.

translation The processing of information coded in messenger RNA to form amino acid sequences; results in cytoplasmic peptide and protein synthesis.

translocation The process of movement within a cell; usually the movement of a subcellular molecule or organelle from one site to another.

with abnormalities in glucose tolerance, insulin secretion, and lipoprotein profiles.

Obesity contributes to the insulin resistance in PCOS. However, the magnitude of insulin resistance exceeds that which would be predicted on the basis of total or even fat-free body mass. The cause of obesity in PCOS remains elusive. Nonetheless, it has been clearly documented that attenuation of insulin resistance, whether by weight loss or pharmacologically with diazoxide, metformin, or troglitazone, ameliorates many of the metabolic aberrations in women with PCOS.

A. Impaired Glucose Tolerance and Type 2 Diabetes

Obesity is a well-recognized risk factor for the development of type 2 diabetes, but alone is insufficient to cause glucose intolerance. Thus, although it is generally accepted that women with PCOS are predisposed to type 2 diabetes, the development of diabetes cannot be attributed solely to the obesity that typically accompanies PCOS.

Recent data have established that the prevalence of impaired glucose tolerance (IGT) and type 2 diabetes mellitus among women with PCOS is exceptionally high and consistent across populations of varied ethnic and racial backgrounds. The prevalence of IGT is between 30 and 40% and that of type 2 diabetes is between 5 and 10%. These prevalences approximate those in Pima Indians, who have one of the highest rates of diabetes in the world. In addition, there appears to be a nearly 5- to 10-fold increase in the expected conversion rate from IGT to type 2 diabetes in PCOS with evidence for an enhanced rate of development of diabetes evident from long-term follow-up of women with the disorder.

This predisposition to type 2 diabetes in PCOS is related in part to insulin resistance, the magnitude of which is greater in women with PCOS than in carefully matched controls. A distinct and possibly selective form of insulin resistance may account for these findings.

Yet, although a substantial proportion of women with PCOS develop glucose intolerance, the majority do not. It is therefore reasonable to ask whether the defects in insulin action described above are sufficient to account for the high prevalence of diabetes in this population. Specifically, what factors distinguish insulin-resistant women with PCOS who develop glucose intolerance from those who are able to maintain normoglycemia?

Defects in insulin secretion play an important role in the propensity to develop diabetes in PCOS and are most appropriately expressed in relation to the magnitude of ambient insulin resistance. The product of these measures can be quantitated (the so-called "disposition index") and related as a percentile to the hyperbolic relationship for these measures established in normal subjects. In so doing, researchers have found that a subset of PCOS subjects have beta-cell

TABLE 1 Insulin Lowering Therapies in Polycystic Ovary Syndrome

Therapy	Mechanism(s) of action	Examples	Use(s)[a]
Weight loss	Reduction in insulin demand, decreased secretion		
Diazoxide	Decreased pancreatic insulin secretion		
Biguanides	Reduce hepatic glucose production, secondarily lowering insulin levels; ?direct effects on ovarian steroidogenesis	Metformin (Glucophage, Glucophage XR)	1, 2, 3, 4
Thiazolidinediones	Enhance insulin action at target tissue level (adipocyte, muscle); some evidence for direct effects upon ovarian steroidogenesis	Rezulin, Pioglitazone (Actos), Rosiglitazone (Avandia)	1, 2, 3, 4
D-*Chiro*-inositol	Enhanced insulin action by repletion of specific D-*chiro*-inositol-containing inositolphosphoglycan	Not applicable	2, 3, 4

[a](1) Hirsutism and/or acne; (2) oligomenorrhea/amenorrhea; (3) ovulation induction; and (4) insulin-lowering therapy.

secretory dysfunction. In absolute terms, women with PCOS had normal first-phase insulin secretion compared to controls. In contrast, when first-phase insulin secretion was analyzed in relation to the degree of insulin resistance, women with PCOS exhibited a significant impairment in beta-cell function. This reduction was particularly marked in women with PCOS who had a first-degree relative with type 2 diabetes. Beta-cell function in PCOS has been additionally quantitated by examining the insulin secretory response to a graded increase in plasma glucose and by the ability of the beta cell to adjust and respond to induced oscillations in the plasma glucose level. Results from both provocative stimuli were consistent: when expressed in relation to the degree of insulin resistance, insulin secretion was impaired in PCOS subjects with a family history of type 2 diabetes when compared to controls. The inability to secrete insulin in quantities adequate for the degree of insulin resistance appears to have a heritable component in PCOS kindreds.

III. TREATMENT OF HYPERINSULINEMIA IN PCOS

The realization that hyperinsulinemia is a key component in the pathogenesis of PCOS has provided the basis for these recent advances in treatment strategies for women with the disorder. Weight reduction, when it can be achieved, is still an important component in the treatment of PCOS. However, not all women with PCOS are obese, and since the etiology of obesity in PCOS in not known, there is currently no effective way to target this problem in PCOS. Pharmacologic reduction in insulin levels appears to offer another therapeutic modality for PCOS and is one that may ameliorate the sequelae of both hyperinsulinemia and hyperandrogenemia (Table 1). However, additional studies and long-term follow-up of patients so treated are necessary before these agents can be considered first-line treatment for PCOS.

Glossary

insulin resistance The state in which insulin concentrations that are equal to or greater than normal produce less than the expected biologic effect.

oligomenorrhea Menstrual cycle pattern consisting of fewer menstrual periods within a given time, typically fewer than nine menstrual periods in 12 months.

Insulin Secretion

ROBERT A. RITZEL, DARREN J. MICHAEL, AND PETER C. BUTLER

University of Southern California, Los Angeles

Upon stimulation of pancreatic beta cells, insulin is released into the pancreatic vein, which empties into the portal vein, to reach insulin's primary site of action, the liver. In humans, insulin is secreted in high-frequency pulses with a mean period of 4–6 min.

I. OVERALL ROLE OF INSULIN

Insulin is perhaps the most widely studied hormone. The absence of insulin leads to the life-threatening disease diabetes mellitus. Insulin has multiple actions on carbohydrate, fat, and protein metabolism. In the short term, its most important action is to regulate the concentration of glucose in the circulation at a concentration of ~90 mg/dl (~5 mmol/liter) (Fig. 1). Circulating glucose concentrations that are either too low (hypoglycemia) or too high (hyperglycemia) are life-threatening. Therefore, the concentration of glucose in the circulation is the predominant regulator of the insulin secretion rate.

II. ANATOMY OF THE PANCREAS, BETA-CELL MASS, AND ITS REGULATION

Although the existence of an insulin-secreting organ had been anticipated for many years, it was not until the late 19th century that the pancreas was identified by the German physiologist Minkowski as the

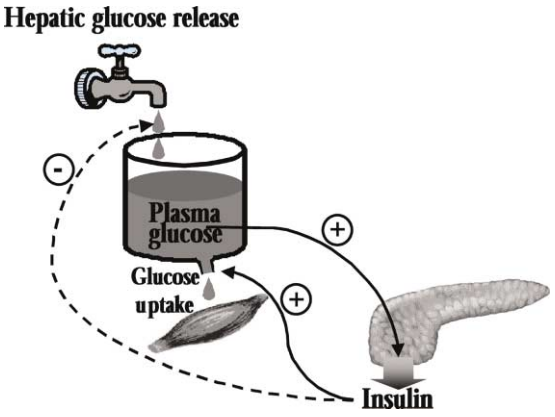

FIGURE 1 After nutrient intake, insulin secretion from the endocrine pancreas is enhanced to maintain physiologic plasma glucose concentrations (normoglycemia). Insulin stimulates glucose uptake into tissues and suppresses hepatic glucose release.

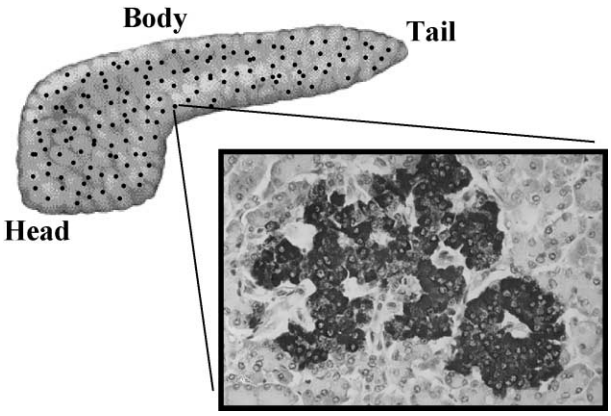

FIGURE 2 Macroscopically, the human pancreas is subdivided into head, body, and tail. The inset shows an islet of Langerhans (immunostained for insulin), which is surrounded by exocrine tissue.

organ from which insulin was secreted. The pancreas is a retroperitoneal organ that consists mostly of exocrine tissue (Fig. 2). This exocrine tissue synthesizes and secretes digestive enzymes for delivery to the small bowel via the exocrine duct in response to food ingestion. The endocrine component of the pancreas is only ~1% of the pancreas by volume and is dispersed throughout the much larger exocrine pancreas in the form of approximately one million clusters of cells called islets of Langerhans, after the German anatomist Paul Langerhans (Fig. 3), who first described them in 1869. Each islet consists of approximately 3000 endocrine cells, the most frequent of which are the insulin-producing beta cells. The beta cells are present in the core of the islet surrounded by a mantle of the other endocrine cells, glucagon-secreting alpha cells, somatostatin-secreting delta cells, and pancreatic polypeptide-secreting PP cells.

Each islet of Langerhans is independently vascularized and innervated. The supplying arteriole penetrates into the core of the islet, from which the capillary network supplies the beta cells first, before reaching the periphery of the islet. In consequence of this specific islet-microanatomy, the insulin concentration in the efferent venule is very high when it reaches the other endocrine cells, such as the glucagon-secreting alpha cells. When the isolated pancreas preparation was perfused via the conventional arterial route versus the reverse venous route, it was confirmed that this local release of insulin into the islet capillary network does have a local regulatory effect on downstream endocrine cells (i.e., alpha cells). Islets of Langerhans also secrete vascular and neurotropic factors, leading to the observation that islets transplanted into the liver regain their independent vascularization and innervation within approximately 1 week and 1 month, respectively.

During embryonic development, new islets bud off from the pancreatic duct. This process continues in adult life. In fact, regulation of beta-cell number (or beta-cell mass) is an important facet of regulation of insulin secretion. Since there is a basal rate of apoptosis of beta cells within islets, there must be replenishment of beta cells or the beta-cell mass would gradually diminish to zero. There are two potential sources for replenishment of beta cells: (1) the formation of new islets, called islet neogenesis, to replace aging and diminishing islets and (2) beta-cell replication within islets.

Beta-cell mass adaptively increases in rodents exposed to either sustained high blood glucose concentrations or insulin resistance resulting from obesity. In rodents, this increase is largely accomplished through the mechanism of increased beta-cell replication and, to a lesser extent, through increased neogenesis. Rodents with an acute decrease in beta-cell mass, induced by a partial pancreatectomy, show an impressive capacity to replace beta-cell mass within a few days by both mechanisms, a marked increase in islet neogenesis and beta-cell replication within the new islets. In humans, neogenesis is also

FIGURE 3 Paul Langerhans (1847–1888). Reprinted from "Diabetes in Medizin- und Kulturgeschichte" (von Engelhardt, ed.), copyright 1989 Springer-Verlag, Berlin, with permission.

present and, as in rodents, it increases in response to obesity by approximately 50%. In contrast, beta-cell replication is almost absent in mature islets in humans. However, human islets cultured *in vitro* and dispersed to a monolayer show some capacity for beta-cell replication. At present, it is unclear whether there are circumstances *in vivo* when beta-cell replication becomes important in mature human islets.

In summary, in humans insulin is secreted by pancreatic beta cells that exist in clusters of ~3000 cells, called islets of Langerhans. Approximately one million of these islets are scattered throughout the pancreas. Islets are created throughout life from stem cells within the exocrine ducts. Regulation of islet turnover (neogenesis and apoptosis) defines the beta-cell mass. In healthy individuals, beta-cell mass adapts to the demand for insulin. The mechanisms involved in the regulation of islet neogenesis and beta-cell apoptosis are currently under active investigation as potential cures for diabetes.

III. INSULIN SYNTHESIS, STORAGE, AND SECRETION AT THE SINGLE BETA-CELL LEVEL

Soon after the source of insulin was established to be the endocrine pancreas, several efforts were made to isolate an insulin extract from the pancreas for the purpose of injection into people with diabetes. This was finally achieved by the team of Banting, Best, Collip, and MacLeod in 1921. Subsequently, insulin was the first protein to be crystallized to establish its structure. In humans, the insulin gene is on chromosome 11. Insulin is synthesized as a 109-amino-acid preproinsulin that is processed to an 86-amino-acid proinsulin. Proinsulin is predominantly trafficked to the secretory pathway via the Golgi apparatus into secretory vesicles (Fig. 4). Within these vesicles, proinsulin is cleaved into insulin and C-peptide. In beta cells, as examined by electron microscopy, insulin appears to be organized in crystals, in so-called dense core granules. As insulin secretory vesicles mature, they become acidified by a proton pump. It is believed that this acidification is responsible for the formation of insulin crystals although proof that these crystals are present *in vivo*, as opposed to being an artifact of electron microscopy, is missing.

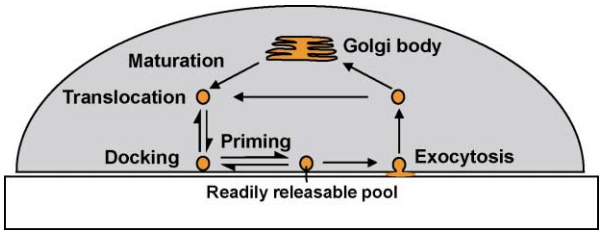

FIGURE 4 The secretory pathway of insulin secretion in the pancreatic beta cell. Vesicles bud off the Golgi apparatus and undergo maturation, translocation, docking, and priming to enter the readily releasable pool. Upon stimulation of the cell, exocytosis occurs and the vesicles may reenter the pathway.

The rate of proinsulin biosynthesis can be regulated, both at the level of gene transcription and at the level of messenger RNA translation. Insulin within aging vesicles is subject to degradation when mature vesicles fuse with lysosomes (crinophagy). Therefore, the size of insulin stores depends on the rates of proinsulin biosynthesis, insulin degradation, and insulin secretion. Oloffson and colleagues established that in mouse beta cells there are ~9000 insulin vesicles, ~650 of which appear to be in close relation to the beta-cell plasma membrane, potentially in the membrane-docked pool (Fig. 5). In other neuroendocrine cells, such as chromaffin cells, the relationship between the docking (and undocking) of secretory vesicles and subsequent secretion has been elucidated in some detail. Similar studies are now under way with pancreatic beta cells.

Secretion of insulin is tightly regulated (Fig. 6). The most important regulator of insulin secretion, glucose, readily gains access to beta cells through glucose transporter proteins in the cell membrane (glucose-2-transporter) and is phosphorylated to glucose-6-phosphate by glucokinase. The K_m of glucokinase in beta cells is ~10 mmol/liter. This ensures that the rate of glucose-6-phosphate production reflects the concentration of glucose to which the beta cell is exposed. Glucose-6-phosphate undergoes glycolysis to pyruvate, which is then oxidized to carbon dioxide and water via the tricarboxylic acid cycle in the mitochondria. The resulting energy generates a proton gradient across the inner mitochondrial membranes through the electron transport chain. This mitochondrial membrane proton gradient is in turn employed to generate ATP from ADP and phosphate. The increment in ATP closes the ATP--sensitive potassium channel in the beta-cell membrane, resulting in depolarization of the cell membrane. Beta-cell depolarization results in an influx of calcium via voltage-gated calcium channels, which triggers the exocytosis of preformed vesicles to stimulate insulin secretion.

In this widely held scheme for glucose-mediated insulin secretion by beta cells, glucokinase can

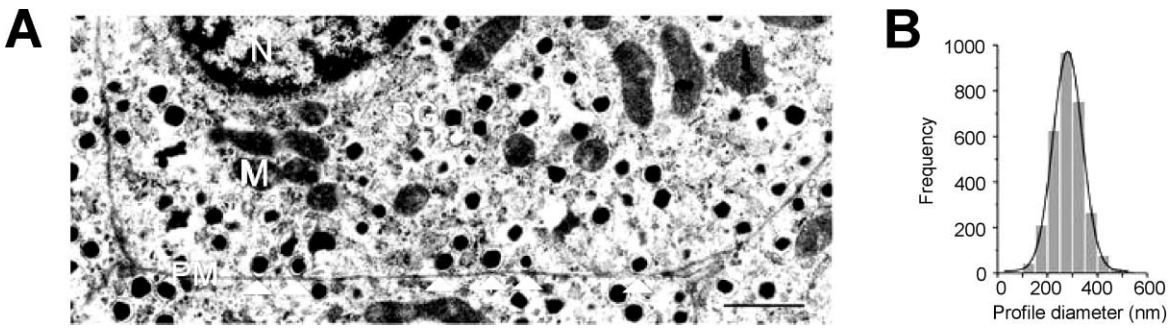

FIGURE 5 (A and B) Ultrastructure of the pancreatic beta cell. (A) Electron micrograph of a beta cell in an intact islet. Physiol.* **444**, 43–51, copyright Springer-Verlag, 2002, with permission.

therefore be considered the signal-sensing component. The increment in cytoplasmic ionized calcium is proportionate to the provision of glucose-6-phosphate and represents the signal effector component for regulated insulin secretion. There are numerous points of potential modulation of the extent of the insulin secretion response to a given increment in glucose within this system. For example, on the sensing side any change in flux of glucose through glucokinase, change in tricarboxylic acid cycling, or change in efficiency in ATP production per oxidized glucose molecule would adjust the signal-to-response ratio. An example of this is the action of uncoupling protein-2 (UCP-2) present in mitochondrial membranes of beta cells. UCP-2 allows the leakage of protons down the proton gradient (generating heat) and so diminishes the signal for insulin secretion at any given glucose concentration. UCP-2 expression increases in response to chronic high glucose and thus attenuates subsequent glucose-mediated insulin secretion. If UCP-2 expression is decreased, insulin secretion increases at any given glucose concentration. On the response arm of this regulatory pathway, alterations in the magnitude of the increment in calcium, such as those mediated through cyclic AMP, can amplify or attenuate the insulin secretory response to a given glucose stimulus. For example, glucagon like-peptide 1 (GLP-1) activates adenylate cyclase to generate cyclic AMP, resulting in an amplified increment in insulin secretion in response to an increment in glucose concentration.

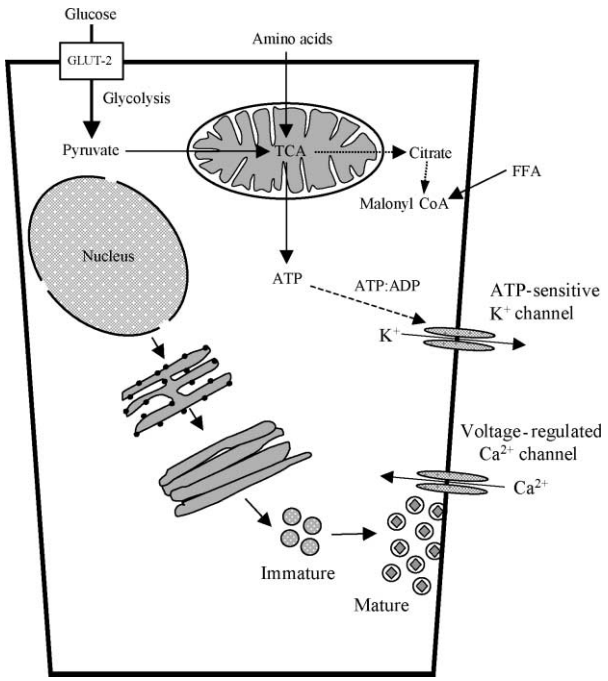

FIGURE 6 Stimulus–secretion coupling in the pancreatic beta cell.

Other potential metabolic sources that lead to energy production and increased ATP concentrations can also enhance insulin secretion through the same final common pathway. For example, high plasma levels of free fatty acids induce their own oxidation within the mitochondria to increase ATP production and insulin secretion, although more prolonged exposure to elevated free fatty acids can lead to decreased insulin secretion. After meal ingestion, insulin inhibits the lipolysis of stored triglycerides and the circulating levels of free fatty acids decrease. However, the free fatty acid concentration inside the beta cells might be increased, because insulin-sensitive lipoprotein lipase enhances the lipolysis of meal-related triglycerides. The enhanced insulin

secretion following meal ingestion is therefore presumably reflective of both the increased circulating levels of glucose and the acute increase in the tissue levels of free fatty acids. In addition to this direct fuel-generated stimulation of insulin secretion, meal ingestion enhances insulin secretion through the mechanism of incretin hormones. The incretin effect describes the phenomenon that glucose ingestion induces a greater insulin response than intravenous glucose administration, either when the same amount of glucose is infused or when the same glucose concentration profile is reproduced. Incretin hormones are released from the gut by oral nutrients and stimulate insulin secretion only at elevated glucose levels. After meal ingestion, the incretin effect contributes to total insulin secretion with 30–60%. Glucose-dependent insulinotropic peptide (GIP) and GLP-1 are examples of incretin hormones.

In summary, the regulation of insulin secretion by individual beta cells is largely dependent on the glucose stimulus but also other circulating sources of energy. They increase the production of ATP, which subsequently depolarizes the beta-cell membrane, leading to the influx of ionized calcium to trigger insulin granule exocytosis. There are numerous additional complexities in the signal transduction pathway superimposed on this scheme that allow both enhanced and attenuated responses to nutrient levels. Although it is convenient to examine the signal transduction pathways for insulin secretion in the simplified scheme of a single beta cell, cell clusters (as in islets) behave quite differently than single beta cells. To examine the regulation of insulin secretion, it is therefore essential to study the intact islet and indeed the whole organism.

IV. PHYSIOLOGY OF INSULIN SECRETION: ISLETS

Many studies of insulin secretion have been performed at the level of isolated islets. One advantage of this approach is that there are fewer confounding effects than might be present *in vivo*. Changes in insulin secretion or other parameters of islet function can be therefore more directly related to the experimental condition or action of a potential compound. For example, use of a compound that stimulates insulin secretion *in vivo* might be expected to decrease glycemia, which would attenuate the effect of the compound. Another important advantage of islet studies is that they allow measurement of insulin secretion in mouse islets, whereas the measurement of insulin secretion in mice *in vivo* has technical limitations due to a low blood volume. This is important given the frequent use of transgenic, knockout, and knock-in experiments in mice to establish the molecular basis of physiology. The use of isolated islets as an experimental model has the disadvantage that they may very well behave differently than islets *in vivo*, due to the loss of islet innervation and vascularization. There are also technical limitations: small changes in temperature, pH, or osmotic pressure, which inadvertently occur in such studies, may have profound effects on islet secretion. Despite these limitations, studies in isolated islets have contributed substantially to the field of islet biology.

V. PHYSIOLOGY OF INSULIN SECRETION *IN VIVO*

Insulin secretion *in vivo* has also been extensively studied. As predictable from the studies of single beta cells described above, the most important regulators of insulin secretion are circulating nutrients, in particular, glucose. In the fasting state, insulin secretion is maintained at levels that provide sufficient insulin to constrain hepatic glucose release at rates that match glucose utilization ($\sim$2 mg/kg/min) and so the plasma glucose concentration is maintained at normal levels of $\sim$90 mg/dl ($\sim$5 mmol/liter). After meal ingestion, glucose concentrations in the circulation rise and stimulate insulin secretion (Fig. 7). Increased delivery of insulin into the circulation causes further suppression of hepatic glucose release (to $\sim$0.5 mg/kg/min) and increased stimulation of glucose uptake by insulin-sensitive tissues such as muscle to restore normoglycemia. Therefore, the simplest model to describe insulin secretion *in vivo* would have two components: a constant basal rate of insulin secretion superimposed on which are meal-related increments. Although this model (concept of basal-bolus insulin therapy) is commonly employed by physicians attempting to replace insulin in patients who secrete insufficient insulin, it is an oversimplification of a very complex dynamic neuroendocrine secretory system.

Even basal insulin secretion in the fasting state can be resolved into several complex secretory patterns. First, there is a circadian rhythm of insulin release with decreased insulin secretion during the night. Second, insulin secretion can also be resolved into an ultradian rhythm with an $\sim$40 min oscillatory period that might reflect the feedback loop between insulin secretion and insulin action through the intermediary of the prevailing plasma glucose concentration.

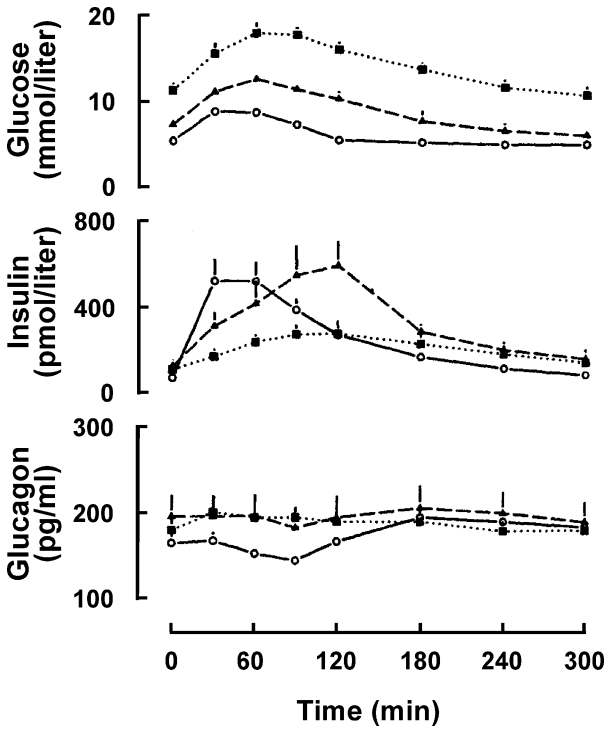

FIGURE 7 Plasma glucose, insulin, and glucagon concentrations after meal ingestion (at 0 min) in nondiabetic (○), glucose-intolerant (▲), and type 2 diabetic (■) subjects. After an initial increase, plasma glucose decreases rapidly in nondiabetic humans, whereas sustained postprandial hyperglycemia occurs in glucose-intolerant and type 2 diabetic subjects. The increase in plasma insulin concentration is delayed and markedly reduced in humans with type 2 diabetes. Reprinted from Butler *et al.*, *Diabetes* 40, 1991, 73–81, with permission. Copyright 1991 American Diabetes Association.

Third, insulin secretion can also be resolved into high-frequency discrete insulin secretory bursts, so-called pulsatile insulin secretion (Fig. 8). These pulses occur approximately once every 4 min and yield an insulin concentration profile in the portal vein that shows dramatic peaks and troughs of as much as 5000 pmol/liter in amplitude. Virtually all insulin is secreted in these discrete 4 min insulin secretory bursts, indicating that regulation of insulin secretion is accomplished through changes in either insulin pulse frequency or pulse mass. In fact, almost all regulation of insulin secretion is accomplished by the modulation of pulse mass (*vide infra*). To understand the mechanisms that result in pulsatile insulin secretion, it is necessary to contemplate both a pacemaker and a pulse coordinator (between islets).

Individual or perfused islets also secrete insulin in ~4 min discrete insulin pulses, indicating that the pacemaker responsible for generation of pulsatile insulin release is present in each islet. Two hypotheses are currently being investigated: one suggests that the pacemaker might arise at the level of the membrane due to intermittent depolarization of the membrane; the other hypothesis is that oscillations in glycolysis drive an oscillatory production of ATP. Perhaps both hypotheses are correct and an intermittent membrane depolarization temporarily decreases ATP concentrations (ATP is consumed, restoring the resting membrane potential). The dip in ATP would be expected to elicit a surge in glycolysis and entrain the natural glycolytic oscillations generated at the level of the reversible interconversion of fructose-1-phosphate and fructose-1,6-diphosphate. Even if the individual islets are potentially independent pacemakers, the question remains how approximately one million islets, scattered throughout the pancreas, are synchronized to secrete insulin in coordinate insulin secretory bursts? The best available evidence suggests that this is mediated through the intrapancreatic neural network. The denervated, isolated-perfused pancreas retains pulsatile insulin secretion, indicating that intrinsic innervation is not required for this process. Islets that are transplanted into the portal

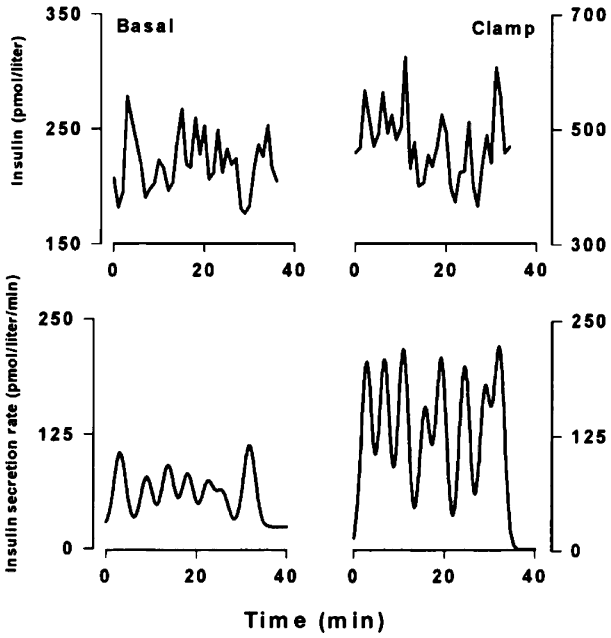

FIGURE 8 Portal vein insulin concentration profiles (top panels) and corresponding deconvolved insulin secretion rates (bottom panels) obtained by 1 min sampling in the basal state (left panels) and during a hyperglycemic clamp (right panels). Reprinted from Song *et al.* (2000), Direct measurement of pulsatile insulin secretion from the portal vein in human subjects. *J. Clin. Endocrinol. Metab.* 85, 4491–4499, with permission. Copyright 2000 The Endocrine Society.

vein secrete insulin in a noncoordinated manner until they become reinnervated and coordinate pulsatile insulin secretion is reestablished. Regulation of insulin secretion is accomplished by modulation of the magnitude of insulin secretory bursts with amplification following meal ingestion, glucose infusion, or GLP-1 infusion and inhibition with somatostatin, a hormone that inhibits insulin secretion.

In numerous studies of insulin secretion *in vivo*, the technique of an acute bolus injection of glucose, arginine, or glucagon (all insulin secretagogues) has been used. Following this approach, insulin is secreted in a biphasic manner with a first phase of insulin secretion over ~15 min generally ascribed to release of insulin from the readily releasable insulin vesicles already docked to the beta-cell membrane. The first-phase insulin release is decreased in the setting of a partial loss of beta-cell mass, as is the magnitude of insulin pulses in response to an increment in glucose. Taken together, these data indicate that the insulin secretory bursts and first-phase insulin release are derived from a physiologically related pool of insulin vesicles.

The second phase of insulin secretion is separated from the first phase by a nadir. It is characterized by a lower amplitude and longer duration and lasts as long as the secretory stimulus is active on the beta cells. The underlying mechanism that leads to the more sustained nature of the second phase is under active investigation. There is evidence from studies at the single-cell level to suggest that vesicle maturation and mobilization from a reserve pool into the membrane-bound readily releasable pool may be the rate-limiting steps determining V_{max} of the second-phase secretion process. The characteristic physiology of insulin secretion with a biphasic response to a step increase in the ambient glucose concentration and a typical pulsatile pattern is preserved in isolated human islets, which are independent of innervation and vascularization. *In vivo*, insulin secretion follows a circadian rhythm (~24 h period), an ultradian rhythm (~40 min period), and a high-frequency rhythm (~4 min period). Insulin secretion is regulated by modulation of the mass of the high-frequency pulses and pulse frequency remains remarkably stable. Correlative studies at the level of the single beta cell should help establish the basis of regulation of the insulin secretion with each pulse.

Glossary

beta cell Pancreatic beta cells form 70–80% of the endocrine cell mass. They contain insulin, which is formed by proteolytic cleavage from a precursor molecule, proinsulin. The resulting by-product, C-peptide (connecting peptide), is secreted together with insulin at a 1:1 molar ratio.

beta-cell mass The total mass of all beta cells in the endocrine pancreas. The beta-cell mass is a functional unit and expands in insulin-resistant states. In humans with type 2 diabetes, the beta-cell mass is reduced.

insulin Hormone synthesized in the beta cells of the islets of Langerhans, which form the endocrine pancreas. The main function of insulin is the regulation of carbohydrate metabolism.

islets of Langerhans Structures that form the endocrine pancreas (~1% of mean pancreatic volume). There are 10^5 to 10^6 islets in the human pancreas. Each islet consists of 2000–3000 cells. Four endocrine cell types can be distinguished in the islets: alpha cells (secrete glucagon), beta cells (secrete insulin), delta cells (secrete somatostatin), and PP cells (secrete pancreatic polypeptide).

secretory granule Beta cells contain ~9000 secretory granules. Upon stimulation, their contents are released by exocytosis. These granules contain insulin crystals made up of zinc–insulin hexamers.

genes produces alternative E peptides, but the physiological significance of the diversity of the prohormones is unclear. The presence of multiple leader exons in mammalian Igf-I genes also results in variation in the signal peptide of the preprohormones, but the physiological consequences of this are also unclear. The organization and splicing of the human and rodent Igf-II genes are also complex, but involve noncoding exons and, therefore, do not affect the structure of the mature Igf-II molecule or its precursor forms.

B. Igf-I and Igf-II Expression

The expression of the Igf-II gene in rodents is widespread prenatally and diminishes drastically after birth, with the choroid plexus and the leptomeninges being the persistent sites of synthesis in adult animals. Murine expression of Igf-I, on the other hand, is low prenatally and significantly increases during puberty, with hepatic production being a major contributor to overall Igf-I levels in the circulation. Igf-I produced by numerous other organs, including kidney, lung, and bone, contributes to endocrine, paracrine, and autocrine effects. The overall picture of Igf expression in rats and mice initially led to the concept that Igf-II functioned as a fetal growth factor and that Igf-I acted as an adult growth factor. This model is not applicable to humans, however, because both Igf-I and Igf-II are produced throughout life by multiple tissues. In fact, circulating levels of Igf-II are consistently several-fold higher than those of Igf-I, which raises the issue of potentially divergent roles for Igf-I and Igf-II in human physiology.

III. THE Igf RECEPTORS

A. The Classical Igf Receptors

The Igf-I and Igf-II ligands interact with an array of cell-surface receptors that may be present singly or in combination on target cells. These are depicted in Fig. 1. It was initially thought that Igf-I primarily activated the type I Igf receptor (Igf-IR), a transmembrane tyrosine kinase that is structurally and functionally related to the insulin receptor (IR). Igf-II, on the other hand, was known to interact with high affinity with the type II Igf receptor (Igf-IIR). Subsequent studies have shown that both Igf-I and Igf-II interact with the Igf-IR, albeit with an $\backsim$ threefold difference in affinity (Igf-I $>$ Igf-II). The cloning of the cDNA encoding the Igf-IIR revealed that it was identical to the previously characterized cation-independent mannose 6-phosphate (M6P) receptor involved in endocytosis and intracellular trafficking of M6P-tagged proteins. Although some early studies proposed an active role for the Igf-IIR in Igf-II signaling based on apparent sequence homology between the cytoplasmic domain of the Igf-IIR and the intracellular loops of G-protein-coupled receptors, subsequent studies ruled out the ability of the short intracellular domain of the Igf-IIR to mediate signal transduction. The function of this molecule in Igf-II action is thought to reflect its ability to serve as a clearance receptor for Igf-II, thereby influencing the extracellular concentration of Igf-II.

B. Igf-IR and Insulin Receptors

Most, if not all, of the effects of Igf-I result from its activation of the Igf-IR. Igf-I does not cross-react with the IR except at pharmacological doses (i.e., the relative affinity of Igf-I for the Igf-IR vs the IR differs by almost two orders of magnitude). Until recently, it was thought that Igf-II, like Igf-I, bound appreciably only to the Igf-IR, as compared to the IR. Studies in knockout mice lacking various components of the Igf and IR systems suggested that Igf-II acted through the IR in early development, prior to detectable Igf-IR gene expression. The molecular basis for this phenomenon was revealed when it was discovered that a splice variant of the IR displayed high affinity for Igf-II. Specifically, the IR transcript is subject to alternative splicing of exon 11, which encodes a 12-amino-acid segment in the C-terminus of the extracellular α-subunit. Previous studies had shown that the version of the IR encoded by the mRNA lacking the exon 11 sequence (IR-A) displayed a twofold higher affinity for insulin than did the IR-B form specified by the exon 11-containing mRNA. More recently, it has been reported that IR-A, in fact, functions as a high-affinity receptor for Igf-II and exhibits predominantly proliferative effects as compared to the principally metabolic effects elicited by insulin stimulation of IR-B. Thus, Igf-I functions primarily by activating the Igf-IR, whereas Igf-II has the capacity to act through either the Igf-IR or through the A form of the IR.

C. Hybrid Receptors and the Insulin Receptor-related Receptor

The scope of Igf signaling is made considerably more complex by the existence of hybrid receptors that

result from the dimerization of Igf-IR and IR hemireceptors, each consisting of a single α and β subunit linked by disulfide bonds. These hybrid receptors are formed by the formation of intra-α-subunit disulfide bonds in the Golgi apparatus of cells expressing both the Igf-IR gene and the IR gene. Although originally considered to represent a small proportion of the total number of Igf-IRs and IRs in a given cell, some recent evidence suggests that the formation of hybrids is actually preferred over the formation of classical Igf-IR and IR heterotetramers. This may conceivably be due to the preferential formation of disulfide bonds between cysteine residues in the Igf-IR and IR α-subunits. Thus, in some circumstances, hybrid receptors may outnumber "pure" Igf-IR or IR molecules at the cell surface.

With respect to ligand binding, Igf-IR/IR hybrid receptors retain high affinity for Igf-I, but exhibit severely reduced affinity for insulin. It is thought that this reflects the ability of Igf-I to bind efficiently to either Igf-IR α-subunit, whereas tight insulin binding requires its interaction with both of the β subunits found in the IR. As a consequence, the existence of a significant number of hybrid receptors may preferentially diminish cellular responsiveness to insulin, but not to Igf-I. This has, in fact, been proposed as a mechanism through which up-regulation of Igf-IR expression could result in insulin resistance in cells expressing the IR. The situation with hybrid receptors has, of course, been further complicated by the existence of and the Igf-II-binding characteristics of IR-A and IR-B. IR-A/IR-B hybrid receptors undoubtedly occur, because most cells express both splice variants. The difficulty in distinguishing these variants experimentally has precluded an examination of the binding characteristics and signaling capabilities of this particular class of hybrid receptors. It has been demonstrated, however, that Igf-IR/IR-A hybrids bind Igf-I, Igf-II, and insulin, whereas Igf-IR/IR-B hybrids bind Igf-I with high affinity, Igf-II with low affinity, and do not bind to insulin. Thus, the relative expression of the Igf-IR and IR genes and the degree of alternative splicing of exon 11 of the IR gene govern the ability of a given cell to respond to Igf-I, Igf-II, and insulin.

The insulin receptor-related receptor (IRR) is the third member of the Igf-IR/IR family; it does not exhibit binding to Igfs or to insulin. Although still considered an orphan receptor, it has been shown to form hybrids with the IR when both entities are overexpressed in NIH3T3 fibroblasts. The formal possibility exists, therefore, that Igf-IR/IRR, IR-A/IRR, or IR-B/IRR hybrids may occur in the restricted set of tissues that express the IRR gene, and that the formation of such hybrids could, like the formation of Igf-IR/IR hybrids, influence cellular Igf and insulin responsiveness. The characterized and potential receptor hybrids that may be involved in Igf signaling are depicted in Fig. 2.

D. Igf-IR and IR Signaling Pathways

The particular pathways involved in Igf signaling are, in large part, represented by those identified to date for the Igf-IR (depicted in Fig. 3). On binding of Igf-I or Igf-II to the extracellular α-subunit (specifically, a binding region composed of three domains corresponding to the N-terminus, the internal cysteine-rich region, and the C-terminus of the α-subunit), a conformational change is induced in the transmembrane β-subunits, resulting in trans-autophosphorylation of the tyrosine kinase domain intrinsic to the cytoplasmic portion of the β-subunit. This process fully activates the receptor tyrosine kinase, with the autophosphorylated additional tyrosine residues in the juxtamembrane and C-terminal domains that flank the tyrosine kinase domain. These residues, particularly Tyr-950 in the juxtamembrane domain, then serve as docking sites for members of the insulin receptor substrate (IRS) and the Shc adapter protein families. Subsequent phosphorylation of these proteins by the receptor tyrosine kinase allows IRS and Shc proteins to engage factors such as Grb2/Sos and the p85 regulatory subunit of phosphatidylinositol 3-kinase (PI3K), leading to activation of the mitogen-activated protein kinase (MAPK) and PI3K cascades that constitute the major signal transduction cascades emanating from the activated Igf-IR. Among the ultimate targets of the MAPK and PI3K cascades are members of the Ets and forkhead transcription factor families, which provides a mechanism for Igf action at the cell-surface to effect the changes in gene expression that underlie the effects of Igf signaling on cellular proliferation, differentiation, and apoptotic sensitivity.

Although Igf action can clearly be controlled by the levels of extracellular ligand and the number (and types) of receptors at the cell-surface, the relative abundance of receptor targets may be an important factor in determining the effects of Igfs in a given target cell. For example, there are four members of the IRS family, IRS-1–IRS-4, each of which has a similar, yet unique, structure. The presence of different combinations of IRS proteins may result in differential responses to Igf-IR activation. In fact,

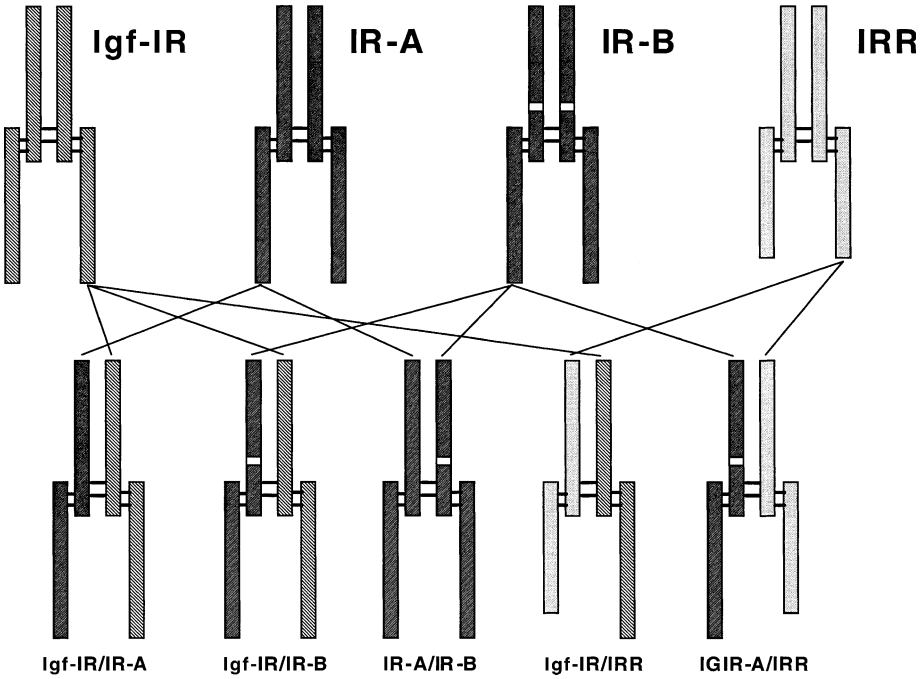

FIGURE 2 Hybrid receptors involved in insulin-like growth factor (Igf) signaling. Shown are hybrids involving the Igf-I receptor (Igf-IR), insulin receptors (IR-A and IR-B), and the insulin receptor-related receptor (IRR) that are involved in Igf signaling. Igf-IR/IRR hybrids have not been demonstrated to date, but their existence is inferred from the ability of the IR and the IRR to form hybrids. IR-B/IRR hybrids are also a formal possibility, but would not be expected to be involved in Igf signaling because they would presumably not bind Igfs or insulin.

recent studies have suggested that IRS-3 and IRS-4 can inhibit processes activated through IRS-1 and IRS-2. The relative levels of Shc and IRS proteins may also be an important factor influencing Igf action, in that they have been shown to compete for binding to Tyr-950 of the activated Igf-IR.

The general characteristics of signaling and the regulatory possibilities for the Igf-IR also apply to the IR (with IR-A and Igf-IR/IR hybrid receptors being relevant here), but there are important differences between the Igf-IR and IR that may have important ramifications for differential actions of Igf-I and Igf-II. In the first place, apart from the conserved tyrosine 950/960 in the Igf-IR and the IR, the position and number of tyrosine residues in the juxtamembrane and C-terminal domains that are subject to autophosphorylation differ between the Igf-IR and IR. In addition, the Igf-IR and the IR have been shown to utilize different heterotrimeric G-proteins as part of their signaling mechanisms, and other proteins have been identified that interact specifically with the C-terminus of the Igf-IR, but not with the IR. A final difference in signaling pathways engaged by the Igf-IR and the IR is the involvement of Stat3 and Stat5 in Igf-IR signaling.

IV. Igf-BINDING PROTEINS

The biological activities of the Igf ligands are modulated by a family of high-affinity Igf-binding proteins (IgfBP-1 through IgfBP-6) that are found in the circulation and in extracellular fluids (either free or cell-surface associated). IgfBP-3 is the predominant IgfBP in serum, and most circulating Igf-I and Igf-II molecules are not found in a free form, but in a ternary complex with IgfBP-3 and a third component, acid-labile subunit (ALS), in a 1:1:1 molar ratio. IgfBP-5 also forms ternary complexes with Igfs and ALS. Although IgfBP-1–IgfBP-4 have generally similar affinities for Igf-I and Igf-II (within twofold), IgfBP-5 and IgfBP-6 bind Igf-II with 10- and 100-fold greater affinity, respectively, compared to Igf-I. The IgfBPs do not bind insulin. The IgfBPs control Igf action by increasing the half-lives of circulating Igfs, by controlling their availability for receptor binding, and, in the case of cell-surface-associated IgfBPs, by potentially influencing their direct interaction with receptors. Each of the IgfBPs is subject to limited and potentially regulated proteolysis by various proteases. Therefore, ligand-receptor interactions in the Igf signaling systems are subject to complex

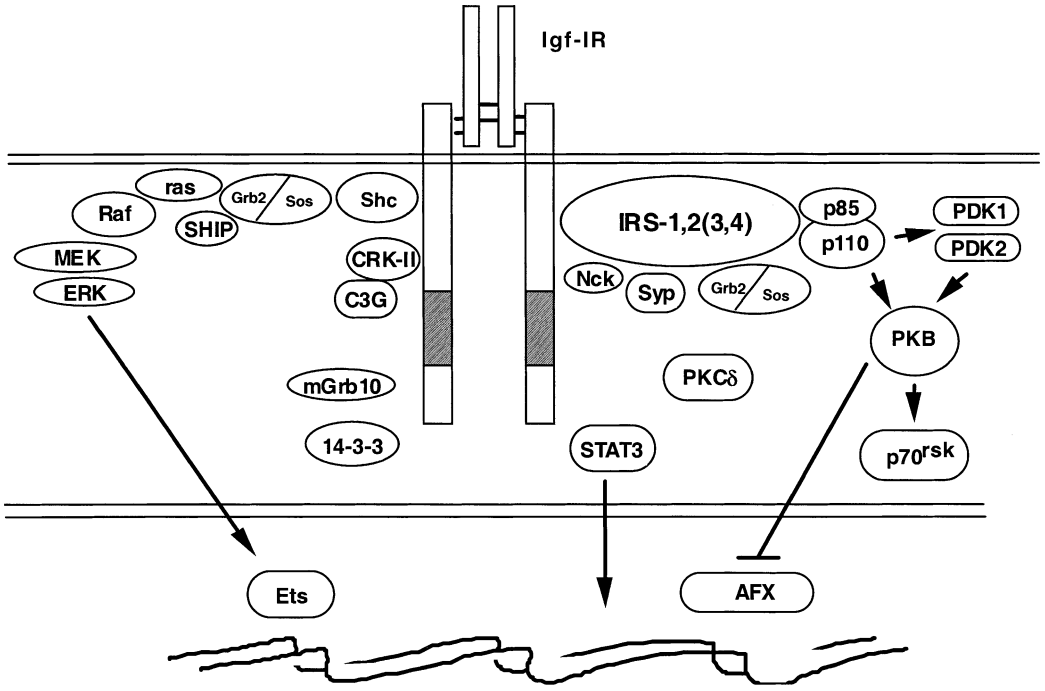

FIGURE 3 Insulin-like growth factor-I receptor (Igf-IR) signaling pathways. The activated Igf-IR initiates signaling through two primary cascades, the mitogen-activated protein kinase and phosphatidylinositol 3-kinase pathways. As shown, insulin receptor substrate (IRS) proteins couple the receptor to the phosphatidylinositol 3-kinase cascade, and Shc couples the receptor to the mitogen-activated protein kinase cascade. In reality, IRS proteins, through their association with Grb2/Sos, also couple to the mitogen-activated protein kinase pathway, whereas Shc, through interaction with the IRS homologue Gab-1, can activate the phosphatidylinositol 3-kinase pathway. Thus, IRS proteins and Shc both integrate Igf activation of these two signaling pathways. A number of other factors, some of which are illustrated, have been shown to interact with, or be in some way involved in, Igf-IR action.

regulation as a result of IgfBP levels, expression profile, degree of cell-surface association, and extent of proteolysis.

A series of studies performed over the past several years has established the concept of Igf-independent actions of some of the IgfBPs. IgfPB-3 and IgfBP-5, in particular, have been shown to exhibit effects on proliferation, migration, and sensitivity to apoptosis that are independent of their effects on Igf signaling per se. Some of these "Igf-independent" effects are still modulated by Igf binding to the responsible IgfBP, so that "Igf receptor-independent action" may be a more accurate term for these novel functions. The cell-surface or intracellular molecules that participate in those effects are poorly characterized, but IgfBP-3 and IgfBP-5 have been identified in the nuclei of cells following exposure to exogenous recombinant protein. This aspect of IgfBP action, when clarified, will add an important dimension to understanding the Igf signaling system in general.

V. PHYSIOLOGICAL AND PATHOPHYSIOLOGICAL ASPECTS OF Igf ACTION

The complex Igf signaling system plays an important role in normal growth and development and in a variety of pathological situations, particularly tumorigenesis. The role of Igf action in prenatal growth was first demonstrated by the severe growth retardation seen in knockout mice in which the Igf-I, Igf-II, or Igf-IR genes had been inactivated by homologous recombination. In humans, severe growth retardation is seen in rare individuals with mutations in, or reduced copy number of, the Igf-I, Igf-IR, or IR genes. The increased expression of Igf-I during puberty is thought to be a major contributor to adult height, because this pattern of Igf-I expression is blunted in populations such as African Pygmies, who exhibit constitutional short stature. Igf action is also important in specific organ development, such as in the nervous system, in which Igf signaling

regulates neuronal proliferation, apoptosis, and survival.

A major aspect of human disease in which Igf signaling plays a critical role is in cancer development and progression. A growing body of epidemiological data suggests that high levels of circulating Igf-I constitute a risk factor for the development of breast, prostate, colon, and lung cancer. Additionally, the expression levels of Igf-IR and IR are predictive of breast cancer outcome. Experimentally, modulation of Igf-IR activity affects the growth of many types of tumor cells. As a result of these findings, intensive research is being conducted on the utility of the Igf system as both a diagnostic marker and a therapeutic target in cancer therapy.

In summary, the Igf signaling system plays a central role in many aspects of mammalian development and exerts a major influence on both normal and abnormal physiology. The complexity of this system, as outlined in this brief review, is a reflection of the importance of Igf signaling and the attendant need for exquisite regulation of its actions.

Glossary

insulin-like growth factor Member of a class of hormones structurally related to insulin, but exhibiting proliferative and differentiative, rather than metabolic, effects.

mitogen-activated protein kinase cascade Signaling pathway involving Ras, Raf-1, MEK, and ERK in a series of tyrosine and serine–threonine phosphorylation events that generally lead to proliferation.

phosphatidylinositol 3-kinase cascade Signaling pathway involving phosphoinositide 3′-kinase, PDK1, PDK2, and PKB/Akt in lipid-mediated serine–threonine phosphorylation events leading to differentiation and control of apoptosis.

receptor tyrosine kinase Member of a class of cell-surface molecules that includes the insulin-like growth factor and insulin receptors, which respond to binding by extracellular ligands by undergoing autophosphorylation and subsequent phosphorylation of downstream targets to initiate specific signaling pathways.

Insulin Processing

CRISTINA ALARCON, BARTON WICKSTEED, AND CHRISTOPHER J. RHODES

Pacific Northwest Research Institute and University of Washington

Most polypeptidic hormones and neurotransmitters, as well as other secretory and cell constituent proteins, are synthesized as larger, inactive precursors. Insulin is first synthesized in the rough endoplasmic reticulum (RER) of the pancreatic beta cell as the precursor molecule preproinsulin. Preproinsulin is processed to proinsulin in the RER by removal of the signal

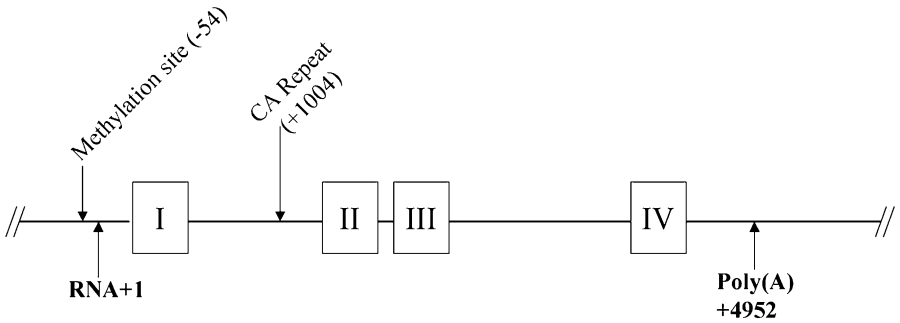

FIGURE 1 Human IFN-γ: genomic structure. Boxes I–IV represent exons.

that interact with the nuclear factor κB (NF-κB) and signal transducers and activators of transcription (STAT) families of transcription factors. Interestingly, the STAT-binding region of the first intron is not conserved in the mouse gene and its role in regulating human IFN-γ gene transcription has not been defined.

The length of the CA repeat in the first intron of the human gene varies between individuals, ranging in size from 11 to 16 repeats. Two of the six alleles are present in 37% of the population. Correlations of the incidence of a particular CA repeat length and gene expression or the occurrence of diseases, such as multiple sclerosis and allograft fibrosis in lung transplant patients, have been reported. However, no functional role in regulating gene expression has been identified for the CA repeat, and the reported associations with disease incidence are thought to be due to linkage with other changes in the gene regulatory regions. Consistent with this hypothesis, a strong correlation between the repeat length, IFN-γ production, and a single-nucleotide polymorphism (SNP) in a NF-κB-binding site in the first intron of the gene has been reported. Other SNPs in the human promoter, introns, and 3′-untranslated region have been identified and although specific nucleotide alterations have been shown to result in changes in protein complexes binding to the DNA, no association of the specific SNPs with specific disease occurrence has been demonstrated. A polymorphism in the promoter of one strain of rat has been found and this polymorphism has been shown to alter DNA binding of a nuclear protein. Although C57/Bl6 mice are considered to be the prototype high IFN-γ producer strain and Balb/C mice are thought of as low IFN-γ producers, no direct nucleotide changes have been reported between these two strains. In contrast, a deletion in the promoter has been detected in SJL/J mice but the effect of this deletion on promoter function was not directly investigated. Although mice that lack the IFN-γ gene have been generated, there have been no reported cases of a human that has lost the IFN-γ gene due to mutation of the structural portion of the gene. In contrast, mutations in the IFN-γ receptor chains have been identified and result in a partial or complete loss of IFN-γ-induced signal transduction.

Early attempts to understand the regulation of IFN-γ expression in T cells mapped several DNase I hypersensitivity sites in the promoter and first intron regions of the IFN-γ gene. One of these DNase I hypersensitive sites falls close to the proximal promoter region that contains a number of putative *cis*-acting elements that may aid in tissue-specific expression of IFN-γ. Abbreviated lists of nuclear factors that interact with these elements include T-bet (T-box expressed in T cells), GATA-3, Ca^{2+}/cAMP-response element-binding protein (CREB)-ATF (activating transcription factor), NF-κB, NFAT (nuclear factor of activated T cells), and YY-1 (Yin–Yang 1). (Fig. 2). T-bet appears to play a major role in $CD4^+$ T helper 1 (Th1) IFN-γ gene expression as T helper 2 (Th2) cells can be induced to express IFN-γ by introduction of the T-bet protein. In addition, T-bet null mice demonstrate significantly decreased IFN-γ gene expression in $CD4^+$ T cells and NK cells. STAT4 is also essential for interleukin-12 (IL-12)-induced IFN-γ expression as demonstrated by the inability of IL-12 to induce IFN-γ in STAT4 null mice. Although the abundance of regulatory sites in the IFN-γ promoter as well the complexities associated with the number of DNA-binding proteins has blocked full understanding of tissue-specific transcriptional control of IFN-γ at this time, it is clear that multiple cell signaling pathways can activate IFN-γ transcription and these pathways appear to work through different regulatory elements within the IFN-γ genomic DNA.

The induction of IFN-γ mRNA expression by extracellular signals involves many different cell

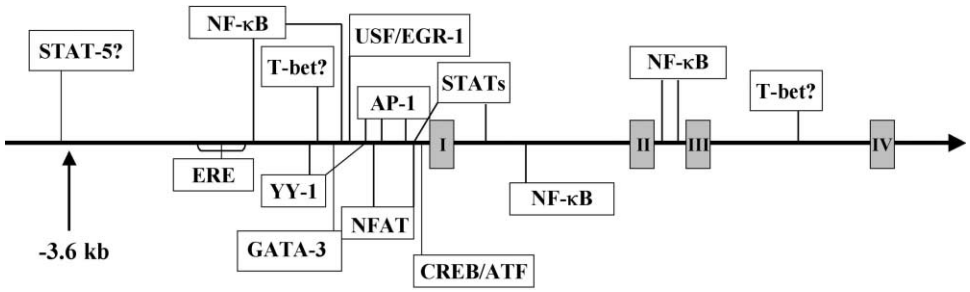

FIGURE 2 Potential regulatory elements in the human IFN-γ gene. EGR-1, early growth response 1; ERE, estrogen-response element; USF, upstream stimulatory factor. Boxes I–IV represent exons.

signaling pathways. Major contributors to IFN-γ gene regulation are the extracellular signal-regulated kinase (ERK) signaling pathway and the p38 mitogen-activated protein (MAP) kinase pathway. These pathways are activated by distinct routes; TCR- and NK-activating receptors involve the ERK pathway and IL-12 and IL-18 signaling involves the p38 MAP kinase pathway. When both pathways are concurrently activated, strong synergy in IFN-γ mRNA and protein expression is observed. In addition to the ERK and MAP kinases, protein kinase C has been demonstrated to be involved in the signal transduction pathways leading to IFN-γ mRNA induction.

Methylation appears to be another important regulator of IFN-γ gene promoter expression. In all species, except chicken, for which the genomic DNA has been sequenced, the proximal promoter contains a highly conserved methylation site at position −54. Methylation of this site correlates with an absence of interferon-γ expression in Th2 cells and adult naive T cells. Likewise, IFN-γ-producing cells such Th1 and $CD4^+$ memory T cells lack methylation at this site. Methylation-mediated control of IFN-γ expression is further supported by the induction of interferon-γ expression in Th2 cells treated with the demethylating agent 5-azacytidine.

Alterations in IFN-γ expression are not strictly due to changes in transcription. Additional regulation of the gene is due to posttranscriptional mechanisms. Stabilization of IFN-γ mRNA has been observed in both T and NK cells. The mechanism responsible for posttranscriptional control of IFN-γ has been studied in NK cells and appears to be mediated by events that result in nuclear retention of the IFN-γ mRNA. Retention of the mRNA is not permanent in that transcription-independent nucleo-cytoplasmic shuttling of the IFN-γ mRNA occurs very rapidly following stimulation of cells by an IFN-γ-inducing agent, such as IL-2.

III. PROTEIN STRUCTURE AND PRODUCING CELLS

The human IFN-γ protein is a 166-amino-acid polypeptide. The first 23 amino acids represent a hydrophobic signal sequence that is removed by proteolysis, resulting in a 17 kDa protein of 143 aa. The murine protein, only 40% homologous to the human protein at the amino acid level, is 15.4 kDa and the mature protein is composed of 134 aa. The active protein is a noncovalent homodimer and is N-glycosylated at two sites. However, glycosylation does not have significant effects on protein activity as nonglycosylated protein produced in bacteria is biologically active. The structure of the molecule is mostly helical (62%) and is composed of six α-helices without any β-sheet structure. The N-terminal and C-terminal regions of the protein are important for receptor interaction and signal transduction based on studies with truncated proteins, peptides, and antibodies directed against these regions. The proteins are also highly species specific as human and mouse proteins signal only through their homologous receptor. Interestingly, a nuclear localization signal (NLS) is present in the molecule and accounts for evidence of an intracellular function and nuclear localization of the protein.

The cell types that account for most of the IFN-γ production *in vivo* are T cells, NK cells, and NKT cells. The primary stimulus for T-cell IFN-γ production is antigen in the context of either MHC class II ($CD4^+$ T cells) or MHC class I antigens ($CD8^+$ T cells). IFN-γ expression has been utilized to define T-cell populations as $CD4^+$ Th1 and $CD8^+$ T cytotoxic 1 (Tc1) cells are considered IFN-γ producers, whereas Th2 and Tc2 cells are defined by their production of IL-4 and lack of production of IFN-γ. In contrast, NKT cells produce both IFN-γ and IL-4. Cytokines, including IL-2, IL-7, IL-12, IL-18, IL-21, tumor necrosis factor, and IFN-α, chemokines,

and triggering through other cell surface receptors, including CD28, can also play an important role in either directly inducing or enhancing IFN-γ expression from T cells. Expression of IFN-γ mRNA in T cells is transient, occurring as quickly as 1 h after induction and peaking at approximately 6–8 h. However, some signals (e.g., CD28 co-stimulation) result in a stabilization of the IFN-γ mRNA. NK cells are the major producers of IFN-γ in the innate arm of the immune system. The major inducing agents are the cytokines IL-2, IL-12, IL-15, and IL-18, and combinations of these cytokines (e.g., IL-2 + IL-12, IL-12 + IL-18) show dramatic synergy in their ability to induce IFN-γ mRNA. In addition to transcriptional activation, IL-2 + IL-12 results in the stabilization of IFN-γ mRNA. In the mouse, cross-linking of the LY49-activating receptors also potently induces IFN-γ expression. Triggering of other cell surface receptors, such as CD16, on IL-2-activated human NK cells further enhances IFN-γ expression. Other cell types, including macrophages and macrophage cell lines, B cells, mast cells, neutrophils, astrocytes, sensory neurons, trophoblasts, and even preimplantation human embryos, have been reported to express IFN-γ. As with T cells, B cells have been subdivided into IFN-γ producers and nonproducers. The major inducer of expression in B cells and macrophages is the combination of IL-12 + IL-18.

IV. RECEPTOR STRUCTURE AND SIGNALING PATHWAYS

The IFN-γ receptor (IFNGR) is a heterodimeric receptor composed of the IFNGR-1 (α chain) and IFNGR-2 (β chain) chains. The IFNGR-1 subunit binds IFN-γ with the highest affinity. It is a 90 kDa glycoprotein that is encoded on human chromosome 6 and mouse chromosome 10. The IFNG-2 chain is a 60 to 67 kDa glycoprotein encoded on human chromosome 21 and mouse chromosome 16. The IFNGR-2 subunit does not actively bind IFN-γ; however, it is necessary for the IFN-γ-specific activation of the intracellular signal transduction pathway.

Both chains of the IFN-γ receptor belong to the class II family of cytokine receptors. This family of receptors lacks intrinsic kinase activity. Thus, signaling through the IFNGR requires both Janus kinase 1 (JAK1) and JAK2 tyrosine protein kinases. JAK1 and JAK2 tyrosine kinases are constitutively associated with IFNG-1 and IFNG-2 subunits, respectively (Fig. 3). Ligand binding initiates receptor oligomerization, with two IFNGR-1 chains binding one IFN-γ homodimer and subsequent recruitment of the two IFNGR-2 chains. The clustering of the receptor complex brings the inactive JAK1 and JAK2 kinases in close proximity with one another. The JAKs become activated by sequential auto- and transphosphorylation events. The activated JAKs phosphorylate a specific C-terminal tyrosine residue (Y440 in humans) in the IFNGR-1 chain. This allows for Src homology 2 (SH2)-mediated docking of two STAT family proteins (STAT1α) to the IFNGR-1 subunits. The receptor-associated JAKs phosphorylate the STAT1α proteins, which homodimerize to form a gamma-activated factor. The STAT1α homodimer translocates to the nucleus, where it interacts with a 9-nucleotide sequence known as a gamma-activated site (GAS) element to mediate IFN-γ-specific activation of gene transcription.

Nuclear translocation of the STAT1α homodimers is due to endocytosis of the IFNGR-1/IFN-γ complex. After ligand-mediated IFNGR oligomerization, JAK1 and JAK2 activation, and STAT1α binding and dimerization, the IFNGR-1 subunit and its bound cargo (JAK1, JAK2, STAT1α dimer, and IFN-γ) dissociate from the IFNGR-2 subunit and undergo receptor-mediated endocytosis. Nuclear translocation of this complex is mediated by a NLS in the C-terminus of the IFN-γ protein. The NLS is retained on the cytoplasmic side of the endocytic vesicle and is recognized by the importin-α homologue Npi-1, which in turn facilitates binding to importin-β to initiate RAN (RAs related nuclear protein) GTPase import of the IFN-γ/IFNGR-1/STAT1α complex into the nucleus. Once in the nucleus, STAT1α dissociates from the ligand/receptor complex. The STAT1α homodimer binds concurrently to the IFN-γ-specific DNA GAS elements and the transcriptional co-activator CREB-binding protein to activate transcription of IFN-γ-specific genes.

Although IFN-γ requires the JAK/STAT pathway to mediate the majority of IFN-γ-dependent cellular events, a published study utilizing STAT1 null mice demonstrates the existence of a STAT1-independent signaling pathway. The alternative signaling pathway regulates *in vitro* proliferation and differentiation of myeloid cells as well as cellular migration. In this system, gene activation requires the presence of the IFNGR and JAK1. Although STAT1 is not required, when present it can influence the IFN-γ alternative signaling pathway. To this end, some genes are equally regulated in the presence or absence of

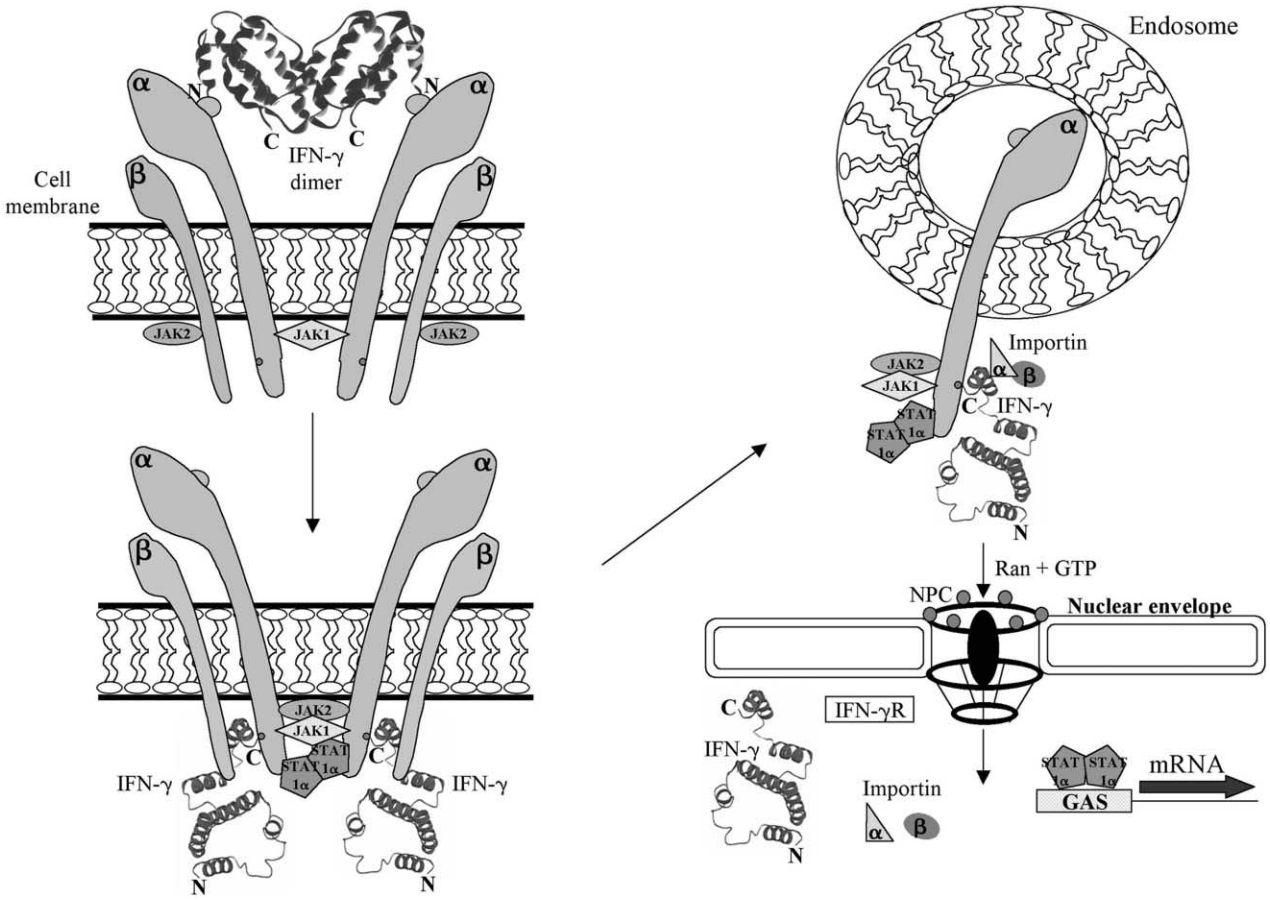

FIGURE 3 IFN-γ signal transduction pathway. Binding of IFN-γ to the IFNGR activates JAK1 and JAK2 and induces binding of a STAT1α dimer to the α chain of the IFNGR. The IFN-γ/IFNGα receptor complex and the receptor-associated STAT1α/JAK1/JAK2 proteins are removed from the cytoplasmic membrane by endosome-mediated endocytosis and relocate to the cytoplasm. In the cytoplasm, the C-terminal portion of IFN-γ associates with the importin α/β complex. Nuclear import of the STAT/IFN-γ/IFNGα receptor complex is mediated by the Ran GTPase transport system. Figure by Mike Sanford based on Subramaniam *et al.* (2001).

STAT1, whereas other genes are regulated only in the absence of STAT1. The molecular mechanism for the STAT1-independent signal transduction pathway is unknown at this time. It is possible that another STAT family member may become activated and substitute for STAT1 to transduce a cellular response; however, further studies are required to support this hypothesis.

V. ACTIVITIES AND FUNCTIONS

IFN-γ is a multipotent protein, acting on many cell types by inducing or inhibiting many cellular functions through direct effects on gene expression. IFN-γ has a clear role in host defense against viruses, including hepatitis B, herpes simplex, lymphocytic choriomeningitis virus, and mousepox, as has been demonstrated by experiments in IFN-γ and IFN-γ receptor null mice as well as studies utilizing IFN-γ neutralizing antibodies. The antiviral properties of IFN-γ are primarily due to the induction of double-stranded activated protein kinase and 2′-5′ oligo-adenylate synthase. Interestingly, poxviruses have evolved mechanisms to defend against the biological activities of IFN-γ by encoding genes that act either as direct IFN-γ receptor decoys or as decoys for the IL-18 receptor. IFN-γ enhances immune function by promoting the growth of Th1 cells while inhibiting Th2 cell growth and enhancing NK cytotoxic activity. Furthermore, IFN-γ promotes switching to immunoglobulin G2a production by B cells and enhances antigen presentation by activating dendritic cells and inducing MHC class I and class II gene expression on the surface of target cells. IFN-γ is

the major activator of macrophages, primarily through the induction of superoxide, nitric oxide production, and NRAMP (natural resistance-associated macrophage protein) gene expression. This function of IFN-γ is critical for host resistance to intracellular pathogens. In addition to these activities, IFN-γ has been shown to inhibit growth and induce apoptosis of many cells, including tumor cells. Indeed, IFN-γ has been found to be critical for enhanced host resistance to the development of chemically induced tumors. Curiously, IFN-γ has been described as both promoting and inhibiting angiogenesis, depending on the experimental system being tested. Part of these effects may be mediated by the direct induction in the tumor targets of the chemokines IP-10 (IFN-γ inducible protein 10) and MIG (monokine induced by IFN-γ). IFN-γ also has numerous negative effects, including suppression of erythropoiesis and hematopoietic progenitor precursor formation. In addition, high-level expression of IFN-γ is associated with the development of autoimmune disease and allograft rejection. The association of IFN-γ expression in autoimmune disease is consistent with findings of higher levels of IFN-γ expression in female mice and the report that estrogen acts as a co-factor for IFN-γ expression, through three estrogen-response elements identified in the IFN-γ promoter.

It should be noted that although studies in mice lacking various components of the IFN-γ signaling pathway have demonstrated increased susceptibility to numerous viral, microbial, and fungal pathogens, humans with defects in the signaling pathway show a predominant susceptibility to *Mycobacterium sp*. and *Salmonella sp*. infection.

VI. SUMMARY

Interferon-γ is a single-copy gene that has pleiotropic effects on many cell types in the body. It functions as a homodimer and mediates its effects through specific cell surface receptors. Gene expression, although generally transient, is induced by a number of soluble mediators (e.g., interleukins) and via cross-linking of cell surface receptors. Importantly, strong synergy of IFN-γ gene expression is observed when multiple activating signals are combined. Although IFN-γ was initially identified as protein produced by the host in response to viral infection, subsequent research has provided strong evidence for its multifunctional role in modulating the host response to infection, inflammation, and cancer.

Glossary

cytokines Soluble proteins that act as humoral regulators at nano- to picomolar concentrations and modulate the functional activities of individual cells and tissues.

cytotoxic T cell A white blood cell (lymphocyte) defined by expression of CD8 ($CD8^+$) on the cell surface; it expresses a specific T-cell receptor and has the ability to specifically recognize and kill target cells.

interferons Secreted proteins that elicit a non-virus-specific antiviral activity.

interleukins Proteins secreted by leukocytes or other cells that are involved in cell–cell communication.

lymphokines Soluble proteins (generally 12–30 kDa) produced by various lymphocyte populations following their stimulation by an antigen or another mode of cell activation.

natural killer cell A white blood cell (leukocyte) that can nonspecifically kill virally and bacterially infected cells and tumor cells.

regulatory elements Regions of genomic DNA that are bound by specific proteins and involved in the regulation of gene expression.

single-nucleotide polymorphism Single-nucleotide differences in the DNA sequence identified when sequences from multiple individuals are compared.

T helper cell A white blood cell (lymphocyte) defined by expression of CD4 ($CD4^+$) on the cell surface and that is capable of expressing a specific T-cell receptor. T helper 1 cells are defined by their ability to express IFN-γ, whereas T helper 2 cells are defined by their lack of expression of IFN-γ and expression of interleukin-4.

Interferons: α, β, ω, and τ

JOSEPH BEKISZ, HANA SCHMEISSER, CAROL PONTZER*, AND KATHRYN C. ZOON†

*Food and Drug Administration • *University of Maryland • †National Cancer Institute*

Interferons (IFNs) constitute a family of species-specific vertebrate proteins that display a number of biological activities. Type I IFNs include IFN-α, IFN-β, IFN-τ, and IFN-ω; they are classified according to their gene sequences. IFN-α and -β have been used as model systems to elucidate receptor interactions and signal transduction. Interferons confer nonspecific resistance to a broad range of viral infections, affect cell proliferation, and modulate immune responses.

I. INTRODUCTION

Interferons (IFNs) were originally discovered in 1957 by Isaac and Lindenmann. They were originally characterized as soluble proteins that induce antiviral activity in chicken cells. These molecules were subsequently identified in many vertebrates including humans. Numerous biological activities have subsequently been attributed to IFNs including anti-tumor, immunomodulatory, antiparasitic, and antiproliferative properties. Type I IFNs include IFN-α, IFN-β, IFN-τ, and IFN-ω. They were originally categorized based on their antigenicity; however, later they were described by their gene sequences.

In addition to viruses, a number of agents including bacteria, mycoplasma, fungal cell wall products, and protozoans induce the synthesis of IFN-α and IFN-β. It has also been shown that exposure of cells to synthetic double-stranded RNA molecules, growth factors such as colony-stimulating factor-1, and cytokines such as interleukin-1 (IL-1), IL-2, and tumor necrosis factor also induce the expression of type I IFNs. Interferon-α production is mediated by interferon regulatory factors (IRFs). These DNA-binding proteins, especially IRF-3 and IRF-7, modulate the transcription of IFN-α (see Fig. 1). Type I interferon proteins are secreted by the cells and then interact with specific cell surface receptors. It has been shown that IFN-α and IFN-β share the same receptor complex, which is composed of two proteins, IFNAR-1 and IFNAR-2. Following their interaction with their cell surface receptors, the signal is transduced to the nucleus by a series of steps that lead to transcription of messenger RNAs and ultimately translation of proteins that result in the many biological properties associated with these molecules.

Interferon-ω (IFN-ω) was first described in 1985 and the IFN-ω genes are believed to have diverged from the IFN-α genes over 100 million years ago. It appears to be as potent as IFN-α with respect to antiviral and antiproliferative activities, and no unusual biological activities have been attributed to it. IFN-ω has been shown to compete for binding to the common type I interferon receptor shared by IFN-α and IFN-β. Interferon-τ (IFN-τ), of which there are at least 12 species, constitutes a new class of type I interferons that is not virus inducible. It is expressed in the outer epithelial layer of the developing placenta

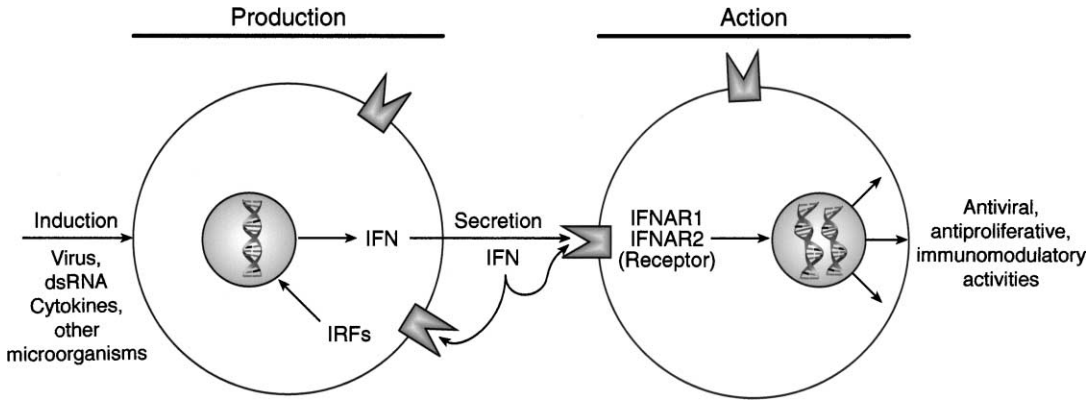

FIGURE 1 Production and action of type I interferons. Interferon production can be induced by a number of agents (viruses, cytokines, etc.). Upon secretion, interferon binds to the type I receptor complex (IFNAR-1/IFNAR-2), resulting in antiviral, antiproliferative, and immunomodulatory effects.

in a number of ruminants and allows for the maintenance of the corpus luteum. It is glycosylated, with an apparent molecular weight of 20,000. Like IFNs-α and-ω, it has two disulfide bonds and, like IFN-ω, it consists of 172 amino acids. Like the other type I interferons, IFN-τ also binds to the type I receptor complex (IFNAR-1/IFNAR-2) (see Table 1).

II. STRUCTURE AND FUNCTION

Distinct cellular genes encode various type I IFNs. In humans, there are at least 18 IFN-α nonallelic genes, 4 of which are pseudogenes found on chromosome 9. These genes encode a minimum of 14 different IFN-α proteins (165–166 amino acids). The IFN-α species are homologous in amino acid sequence structure (75–99%) and display a high level of species specificity in their biological properties. Human IFN-β is present as a single copy in the human genome (chromosome 9) and is expressed as a single protein (166 amino acids). IFN-ω consists of a family of 7 genes (only 1 of which is functional) also found on chromosome 9. Like IFN-α and IFN-ω, IFN-τ constitutes a multigene family. There is approximately 30% amino acid sequence homology between IFN-α and IFN-β. IFN-τ and IFN-ω (with approximately 50 and 75% sequence identity to IFN-α, respectively) contain 172 amino acids each compared to the 166 amino acids that constitute IFN-β and most IFN-αs (IFN-α_2 contains 165 amino acids). These 6 additional amino acids are located at the C-terminal end of the molecule in both IFN-τ and IFN-ω (Table 1).

Twenty-two IFN-α subtypes derived from Sendai virus-induced Namalwa cells have been purified and characterized. Each subtype was found to consist of a single polypeptide chain of 165–166 amino acids with apparent molecular weights under reducing conditions ranging from 17,500 to 27,000 Da. Of the 22 subtypes examined, there are 3 major glycoforms. Removal of the carbohydrate moieties has no appreciable effect on antiviral or antiproliferative activities *in vitro*. However, it is well known that glycosylation can play a major role in the pharmacokinetics of proteins.

TABLE 1 Human Interferons -α, -β, and -ω

	Class		
	α	**β**	**ω**
Number of species	≥22	1	1
Glycosylation	≥3 species	Yes	Yes
Apparent molecular weight (reducing)	17,500–27,000	20,000	25,000
Disulfide bonds	2	1	2
Number of amino acids	165–166	166	172
Chromosome coding for IFN	9	9	9
Chromosome coding for IFN receptor	21	21	21

Type I IFNs are similar to members of the α-helical cytokine family, which have a common four-helix bundle topology, but they differ from the other α-helical cytokines in that they possess a fifth helix. A computer-built, three-dimensional, atomic-level model for human IFN-α has been constructed using the primary amino acid sequence of consensus IFN-α and the α-carbon Cartesian coordinates of murine IFN-β (see Fig. 2). The tertiary structure that is derived consists of five major α-helix segments: helix A (encompassing amino acids 12–24), helix B (amino acids 51–67), helix C (amino acids 80–99), helix D (amino acids 115–132), and helix E (amino acids 141–165). The interconnecting regions are designated loops AB (amino acids 25–50), BC (amino acids 68–79), CD (amino acids 100–114), and DE (amino acids 133–140). IFN-β and IFN-τ also have the same type of structure with five helices (A, B, C, D, and E) and four loops (AB, BC, CD, and DE) although the amino acids that make up those regions are not the same as those cited for IFN-α. X-ray crystallographic structures have been published for three type I IFNs, murine IFN-β, HuIFN-α2b, and HuIFN-β, and the structure of HuIFN-α2a was determined by nuclear magnetic resonance spectroscopy. Experiments using monoclonal antibodies against IFN-α/β as well as site-directed mutagenesis revealed the functional importance of the N-terminal half of loop AB. IFN-αs contain two disulfide bonds (Cys-1–Cys-99, Cys-29–Cys-139), whereas human IFN-β contains one disulfide bond (Cys-31–Cys-141). It has been reported that the two cysteine residues forming the disulfide bridge 29–139 (connecting loop AB with loop DE) in IFN-α are critical. Loss of activity results if this disulfide bridge is not present or even if it is displaced by one residue position. The disulfide bridge found in HuIFN-β (Cys-31–Cys-141) connects loop AB (Cys-31) to loop DE (Cys-141) and both of these loops are thought to be important for interaction of the IFN with its receptor. Three domains (amino acids 29–35, 78–95, and 123–140) within the IFN molecule appear to be important in receptor binding. Changes in the amino acid residues in the 78–95 domain may determine the differential specificity of action between IFN-αs and IFN-β. Mutations of only one of the residues at positions 22, 30, 33, 121, 125, 130, and 131 have been reported to increase or decrease the biological activity by more than 10-fold compared to the unmodified, parent protein. The residues at positions 33 and 121 are so critical that even replacement with an amino acid thought to be similar (Arg vs Lys) has a profound effect on activity of the molecule. Site-directed mutagenesis of IFN-α21a/α2c hybrids has shown that the amino acid region 81–95 is important in antiproliferative activity on Daudi (human, lymphoma) cells. More specifically, it was determined that tyrosine (Y) and/or isoleucine (I) at position 86 and tyrosine (Y) at position 90 play a very significant part in IFN-α's antiproliferative effects. There is considerable evidence, beyond that presented here, that even minute changes or differences in the primary sequences could be responsible for a host of biological activities, which could suggest that type I IFNs, rather than being the result of a redundant duplication, in fact, have distinct biological roles in living organisms.

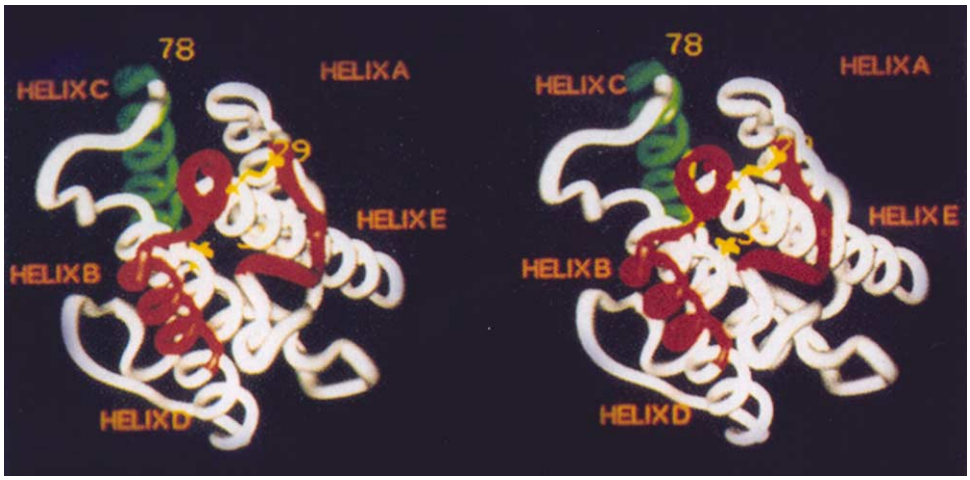

FIGURE 2 Representation of a model of human interferon-α Con (Consensus IFN). Tertiary structure of human IFN-α constructed using the primary amino acid sequence of Consensus IFN and the α-carbon Cartesian coordinates of murine IFN-β. Reprinted from Korn *et al.* (1994) *J. Interferon Res.* **14**, 1–9, with permission.

III. RECEPTORS

The type I interferons (IFN-α, IFN-β, IFN-τ, and IFN-ω) induce different cellular effects, but act through a common receptor complex, IFNAR, present at low levels on the surface of all cell types (100–5000 molecules/cell). The receptor complex consists of two subunits, IFNAR-1 and IFNAR-2. On the basis of modular organization and also sequence alignment with other cytokine receptor chains, IFNAR-1 and IFNAR-2 are members of the class II helical cytokine receptor family. All share conserved structural fibronectin type III (FNIII) "building blocks," forming the extracellular ligand-binding domain. The extracellular portion of IFNAR-2 has two FNIII domains (characteristically partitioned in two β-sheets), each containing 100 amino acids with seven β-strands and connecting loops. The extracellular portion of IFNAR-1 is composed of four fibronectin type III-like repeats, which are composed of two domains separated by a three-proline motif. There is 19% sequence identity and 50% sequence similarity (identity plus conserved amino acid changes) between these two domains. Each domain is composed of approximately 200 residues and can be further subdivided into two homologous subdomains of approximately 100 amino acids. Both IFNAR-1 and IFNAR-2 are glycosylated proteins.

IFNAR-1 and IFNAR-2 contribute to ligand binding to different extents, but both are necessary to form a productive binding site for IFNs. Human IFNAR-2 (HuIFNAR-2, 115 kDa) binds all type I IFNs but with lower affinity and different specificity than the IFNAR complex and has moderate intrinsic affinity for the range of human type I IFNs ($K_d \sim 10^{-9}$ M). Human IFNAR-1 (HuIFNAR-1, 135 kDa) has low intrinsic binding of human type I IFNs ($K_d \sim 10^{-7}$ M) but strongly affects the affinity and differential ligand specificity of the IFNAR complex. When HuIFNAR-1 is co-transfected with HuIFNAR-2, it increases the affinity of the receptor complex for binding most type I IFNs, including IFN-β by approximately 10-fold.

Mature HuIFNAR-1 (after removal of the peptide leader sequence) is a 530-amino-acid integral membrane protein that consists of an extracellular domain containing 409 residues, a transmembrane domain made up of 21 residues, and an intracellular domain composed of 100 residues. Mature HuIFNAR-2 has been isolated as three forms: the full-length receptor chain, composed of 487 amino acids (referred to as IFNAR-2c, 115 kDa) with 251 residues in the cytoplasmic portion, and two shorter forms, one composed of 303 amino acids (referred to as IFNAR-2b, 55 kDa) with only 67 residues in the cytoplasmic portion and one that is a soluble form lacking the transmembrane and cytoplasmic portions (referred to as IFNAR-2a, 40 kDa). Transmembrane domains of IFNAR-1 and IFNAR-2 do not have intrinsic enzyme activities, but their cytoplasmic domains associate noncovalently with tyrosine kinase 2 (Tyk2) and Janus kinase 1 (JAK1), respectively. The importance of both IFNAR-1 and IFNAR-2 for IFN-mediated signaling is highlighted by the observation that in the absence of either chain there is neither high-affinity binding of IFN nor activation of the requisite JAK1/Tyk2 or signal transducers and activators of transcription (STAT) proteins nor biological response.

One of the most intriguing aspects of the function of the type I IFN receptor is its ability to discriminate between the various types and subtypes of IFN and to elicit different biological responses depending upon which ligand is bound. IFN-α and IFN-β interact with HuIFNAR-1 and HuIFNAR-2 differently although they share a common receptor. For example, IFN-β mediates the association of tyrosine-phosphorylated IFNAR-1 and IFNAR-2 (as detected by immunoprecipitation with anti-IFNAR-1 antibodies), whereas IFN-α-1, -α-2, -α-6, -α-7, -α-8, and IFN-ω do not. Previously, the antiproliferative and competitive binding activities of 20 purified components of human lymphoblastoid interferon (IFN-α) were compared with that of recombinant human IFN-α2b on Daudi and AU937 cells. These data suggest that there may be more than one binding site for human IFN-α and/or there may be a multicomponent receptor involved in the biological actions of these molecules. Despite their sequence differences, various type I IFNs probably bind to extracellular portions of IFNAR-1 and IFNAR-2 in a similar manner.

The binding site for IFNAR-2 was mapped mainly on the AB loop and D helix of IFN-α2 and the binding site for IFNAR-1 on the C helix of IFN-α2. However, comparison with homologous cytokines suggests the involvement of the E helix of IFN-α2 in binding of IFNAR-2. Despite extensive studies, the interactions between IFNs and their receptor and the molecular mechanisms underlying the functional differences between IFNs are still unknown.

IV. SIGNAL TRANSDUCTION

Studies on the induction of transcription by IFN-α have provided an understanding of the signal transduction pathways that connect the events from

ligand binding to the type I IFN receptor at the cell's surface to gene activation. The primary signaling pathway initiated by IFN-α is the JAK/STAT pathway. It begins with dimerization of the two receptor subunits induced by IFN binding and the subsequent activation of protein tyrosine kinases. As can be seen from Fig. 3, the two kinases involved in type I IFN signal transduction are Tyk2, which is associated with IFNAR-1, and JAK1, which is associated with IFNAR-2. These kinases then rapidly phosphorylate receptor tyrosine residues, which act as docking sites for STAT SH2 domains. In addition, in the type I IFN system, STAT2 is preassociated with the IFNAR-2 chain of the receptor, and nonphosphorylated STAT1 is also constitutively associated with a more proximal region of IFNAR-2 via the adapter RACK1 (receptors for activated C kinase). This combination of constitutive and receptor phosphotyrosine-dependent binding of STATs leads to efficient phosphorylation of STAT2 and STAT1 by the kinases. STAT1 phosphorylation, however, is dependent on the prior activation of STAT2. The importance of STAT2 to IFN-α-induced signaling is demonstrated by the fact that STAT2 knockout mice are unresponsive to type I IFNs. Normally, IFN-α stimulation also leads to serine as well as tyrosine phosphorylation of STAT1. The phosphorylated forms of STAT1 and STAT2 associate with one another, and the heterodimer interacts with IFN regulatory factor-9 (IRF-9; p48) forming a complex called the IFN-stimulated gene factor 3 (ISGF3). STAT1 homodimers can also be formed. However, ISGF3 is the primary positive regulator of type I IFN-induced transcription and is quickly translocated to the nucleus after formation. This complex associates with a promoter, the interferon-stimulated response element (ISRE), that is located upstream of interferon-responsive genes, and transcription begins. The ISRE responsible for the IFN-α response is a highly conserved region of 12 to 15 bp, found within 200 bp of the transcription start site of most genes that respond to IFNα. In contrast, STAT1 homodimers target gamma-activated sites (GAS).

In addition to STAT1 and STAT2, other STAT proteins (STATs 3, 4, 5, and 6) have been shown to be phosphorylated in particular cell types in response to

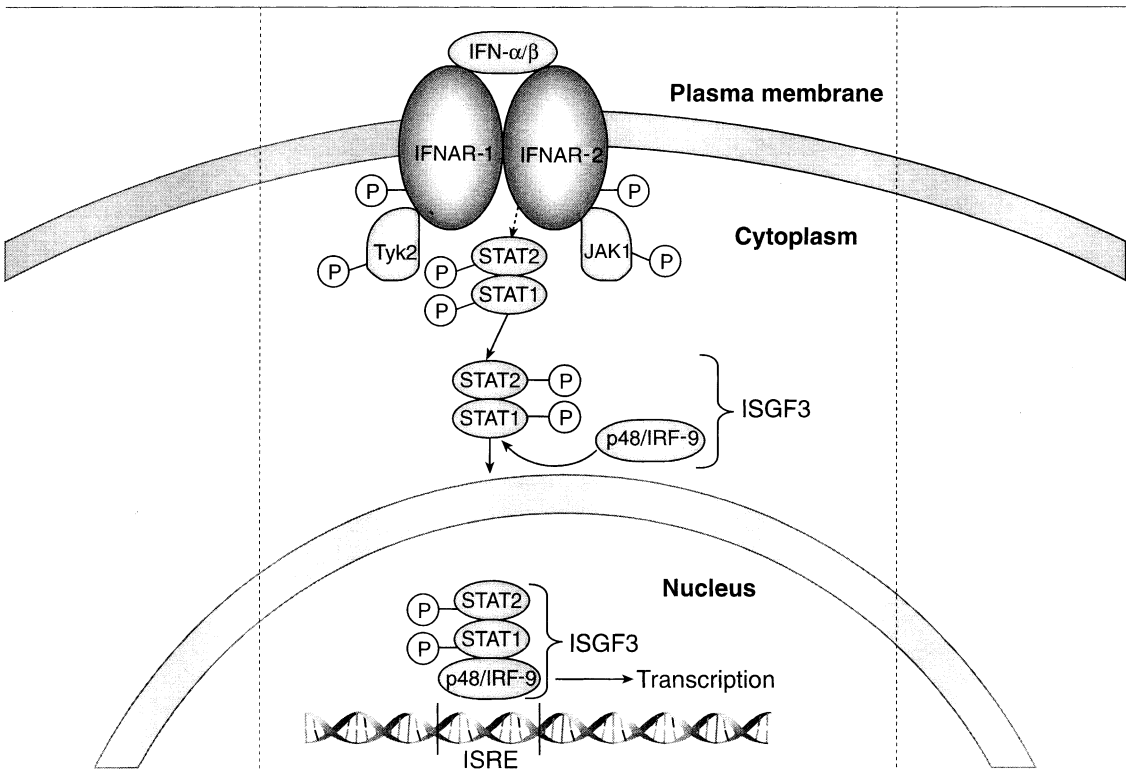

FIGURE 3 Signal transduction mechanism of Hu IFN-α/-β. Interferon binding causes the two subunits of the receptor (IFNAR-1/IFNAR-2) to aggregate, which leads to activation and phosphorylation of JAK1 and Tyk2. These then phosphorylate STAT1 and STAT2. The DNA-binding protein p48 (IRF-9) forms a complex with STAT1 and STAT2 that moves to the nucleus, where it stimulates transcription of genes bearing an interferon-response element (ISRE).

type I IFNs. STAT3 binds to tyrosine-phosphorylated IFNAR-1 and is itself phosphorylated at Tyr-656. The p85 regulatory subunit of phosphatidylinositol 3-kinase (PI-3K) has been shown to bind phosphorylated STAT3, which may be one way to couple activation of a serine kinase cascade to the IFN receptor. STAT4 activation is a convergence point of innate immunity and an adaptive IL-12-mediated response. STAT5 associates with JAK2 and becomes activated. IFNα treatment of Daudi cells leads to activation of both STAT5 and STAT6, and formation of a STAT2:STAT6 heterodimer that associates with IRF-9 has been reported. Although activation of these additional STAT proteins may be important in cell type-specific responses, their exact role in antiviral or even antiproliferative activity of the type I IFNs has yet to be determined.

In addition to the STAT proteins, another key player in type I IFN signaling appears to be PI-3K. PI-3K is a serine kinase consisting of a p85 adapter subunit and a p110 catalytic subunit. It has been shown to associate with IFNAR-1 in the absence of IFN binding. In addition, members of yet another signaling pathway, insulin receptor substrate proteins IRS-1 and IRS-2, regulate activation of PI-3K by IFN-α. There are many downstream targets of activated PI-3K, many of which have a role in cell growth and survival. Activation of the downstream target Akt has been shown to lead to serine phosphorylation and degradation of IκB and subsequent nuclear factor κB activation, which promotes cell survival. The extracellular regulated kinase (ERK) pathway is also downstream of PI-3K. ERK2 and STAT1 were found to co-immunoprecipitate following treatment of cells with type I IFNs. ERK is part of the Ras–Raf–MEK–mitogen-activated protein kinase (MAPK) pathway, which is also involved in promoting cell survival. It has been suggested that Akt or ERK pathways can promote cell survival in the presence of viral infection, and the choice is dependent on the virally induced apoptotic mechanism. The p38 MAPK is another important PI-3K effector pathway. The p38 MAPK appears to be regulated by the small GTPase Rac1, and the Rac 1/p38 pathway has been implicated in IFN-α-induced gene transcription via GAS elements and mediation of growth inhibition. IFN-α suppression of the bcr–abl fusion and inhibition of growth of chronic myelogenous leukemia cells also appears to be dependent on the p38 MAPK pathway. Thus, PI-3K and additional downstream signaling pathways may play a significant role in mediation of the antiproliferative and apoptotic activity of the type I IFNs.

Another family of transcription factors involved in IFN signaling is the IRF family. IRF-1 expression is driven by the GAS element and occurs subsequent to STAT activation. IRF-1 acts as a transcriptional activator at the ISRE, and its function is critical for expression of some IFN-inducible proteins such as guanylate-binding protein and inducible nitric oxide synthase. Another member of this family, IRF-2, is a constitutively expressed transcriptional repressor. Regulation of cell growth has been shown to depend in part on the ratio of IRF-1 to IRF-2, and any change that interferes with the balance of the two factors can result in a significant alteration in cell proliferation. Interestingly, IRF-2 has also been found to antagonize ISGF3, further attenuating type I IFN signaling.

There are additional mechanisms for regulation of JAK/STAT signaling. STAT1 is inactivated by tyrosine phosphatases and degraded by the ubiquitin–proteasome pathway. Regulatory proteins of the suppressor of cytokine signaling (SOCS) family and protein inhibitors of activated STAT (PIAS) also play a role in damping IFN-α-mediated signal transduction. SOCS1 and SOCS3 bind the JAK1 kinase domain and inhibit its activity, and PIAS1 inhibits STAT1-induced gene expression.

Examination of signal transduction from the type I IFN receptor provides insight into the mechanisms responsible for differences in function among IFN-α subtypes as well as other type I IFNs. Another point to consider is that the kinetics of activation of signal transduction molecules may affect observed activity, in that prolonged STAT1 activation in specific cell lines has been associated with enhanced IFN-α antiproliferative activity. Since a variety of signaling pathways are involved in IFN responsiveness, there is also potential for cross talk between pathways. For example, cross-phosphorylation of the IFN-γ receptor has been detected following IFN-α treatment. In T cells, the antiproliferative activity of type I IFNs is dependent on components of the TCR (T cell antigen receptor) signaling cascade, CD45, Lck (lymphocyte cell kinase) and Zap-70 (zeta chain associated protein 70) associating with IFNAR-1. Furthermore, STAT1 and NFAT (nuclear factor of activated T cells) have been found to be preassociated, and type I IFNs have been shown to induce nuclear translocation of NFAT. STAT proteins can also interact with transcription adapter molecules, and IFN-α leads to interaction of STAT2 with p300/CBP (CREB-binding protein, where CREB is cAMP-response element-binding protein).

Thus, the unique activities of particular type I IFNs may be the result of differences in activation or

interaction of the various signal transduction cascades, JAK/STAT, IRF, IRS–PI-3K, ERK, or p38 MAPK, and others associated with IFN function.

V. CLINICAL APPLICATIONS OF HUMAN INTERFERON-α AND -β

A. Human Interferon-αs

The first human interferon-αs, human interferon alfa-2a, recombinant (Roferon A, Hoffmann-La Roche, Inc.) and human interferon alfa-2b, recombinant (Intron A, Schering Corp.), were licensed in the United States in 1986 for the treatment of hairy cell leukemia. Interferon alfa-2a is a recombinant DNA-derived protein prepared from genetically engineered *Escherichia coli* containing the human interferon α-2a gene. This protein is highly purified and has an antiviral specific activity of approximately $2 \times 10^8 \times$ IU/mg protein. It consists of 165 amino acids and has an apparent molecular weight of 19,000. Interferon alfa-2b is also produced from genetically engineered *E. coli* containing a plasmid encoding the human interferon-α-2b gene. It is also highly purified, has a molecular weight of 19,271, and has an antiviral specific activity of 2.6×10^8 IU/mg protein. Subsequently, both of these IFNs have been approved for a variety of clinical indications ranging from chronic myelogenous leukemia to chronic hepatitis C. See Table 2 for the complete list of approved indications in the United States as of March 2002. Some of the side effects of these two products are influenza-like symptoms (e.g., fever, fatigue, myalgia, and chills), and headache, nausea, vomiting, depression, alopecia, and anorexia. The higher the dose, the higher the incidence of severe psychiatric disorders (see their respective package inserts for the complete list of adverse effects).

Pegylated interferon alfa-2b is a covalent conjugate of human interferon alfa-2b with monomethoxy-polyethylene glycol (PEG). The molecular weight of the PEG is approximately 12,000. The average molecular weight of the PEG-INTRON is approximately 31,000. The specific antiviral activity of the product is approximately 0.7×10^8 IU/mg protein. PEG-INTRON (Schering Corp.) is approved for use either alone or in combination with REBETOL (ribavirin, USP) for the treatment of chronic hepatitis C in individuals with compensated liver disease. The dose of PEG-INTRON as a monotherapy is 1.0 μg/kg/week injected subcutaneously (sc). When administered in combination with REBETOL, the recommended dose of PEG-INTRON is 1.5 μg/kg/week. The recommended dose of REBETOL is 800 mg/day in two divided doses. Some major adverse effects include injection site inflammation/reaction, fatigue, headache, rigor, fever, weight decrease, dizziness, nausea, anorexia, neutropenia, myalgia, arthralgia, insomnia, depression, psychiatric disorders, anxiety, alopecia, dyspnea, and some cardiovascular effects (e.g., hypotension, arrhythmia) (see the package insert for the complete list of adverse effects).

PEGASYS, pegylated interferon alfa-2a, is a covalent conjugate of human interferon alfa-2a with a single branched bis-monomethoxy-polyethylene glycol (PEG) chain (approximate MW = 40,000). The apparent average molecular weight of the product is approximately 60,000. PEGASYS (Hoffman–La Roche Corp.) was FDA approved in 2002 as a monotherapy or in combination with COPEGUS (ribavirin) for the treatment of chronic hepatitis C in individuals with compensated liver disease who have not been previously treated with interferon alfa. The recommended dose of PEGASYS is 180 μg/week

TABLE 2 Human Interferons -α, and -β Licensed in the United States

Product	Protein	Indications	Route of administration
Intron-A	Interferon alfa-2b	Hairy cell leukemia, chronic hepatitis B, condylomata acuminata, follicular lymphoma, AIDS-related Kaposi's sarcoma, chronic hepatitis C, malignant melanoma	im, sc, iv, il
Roferon	Interferon alfa-2a	Chronic myelogenous leukemia, hairy cell leukemia, AIDS-related Kaposi's sarcoma, chronic hepatitis C	im, sc
Infergen	Interferon alfacon-1	Chronic hepatitis C	sc
Alferon	Interferon alfa-n3	Condylomata acuminata	il
Betaseron	Interferon β-1b	Multiple sclerosis	sc
Avonex	Interferon β-1a	Multiple sclerosis	im
Rebif	Interferon β-1a	Multiple sclerosis	sc

Note. il, intralesional; im, intramuscular; iv, intravenous; sc, subcutaneous.

for 48 weeks injected subcutaneously (sc) while the ribavirin dosage is 800–1200 mg, twice daily in a split dose. Some major adverse effects include injection site inflammation/reaction, fatigue, neutropenia, anorexia, myalgia, depression, and alopecia (see the package insert for the complete list of adverse events).

Interferon alfacon-1 (Infergen, Intermune) is a recombinant IFN-α that was developed based on a comparison of the sequences of the naturally derived human IFN-α's and targeting the most common sequence elements. It has a very high antiviral and antiproliferative specific activity, 10^9 IU/mg protein. It consists of 166 amino acids and has an apparent molecular weight of 19,434. Interferon alfacon-1 exhibits 88% similarity to human interferon-α2 and 70% similarity to human interferon-β based on an amino acid sequence comparison. Infergen is approved in the United States for the treatment of chronic hepatitis C infection in individuals with compensated liver disease. Adverse effects are similar to those described for other recombinant interferon-αs (see package insert for the complete list of adverse effects).

Interferon alfa-n3 (ALFERON N Injection, Interferon Sciences, Inc.) is the only natural IFN-α licensed in the United States. It is manufactured from source leukocytes induced with Sendai virus and purified by immunoaffinity and size-exclusion chromatography. It consists of multiple interferon-αs, each with approximately 165–166 amino acids. The apparent molecular weights range from 16,000 to 27,000. Interferon alfa-n3 has an antiviral specific activity of 2×10^8 IU/mg protein or greater. ALFERON N Injection is approved in the United States for the intralesional treatment of refractory or recurring external condylomata acuminata in patients 18 years of age or older. Some of the major adverse effects are fever, chills, fatigue, headache, and myalgias.

B. Human Interferon-β

At this time, three human interferon-βs are licensed in the United States: Betaseron (interferon-β-1b; Berlex Laboratories), Avonex (interferon-β1a; Biogen, Inc.), and Rebif (interferon-β-1a; Serono, Inc.). Betaseron, interferon-β-1b is a recombinant DNA-derived product made in *E. coli* that contains the human interferon β-ser17 gene. The antiviral specific activity of this interferon is 3.2×10^7 IU/mg protein. This a nonglycosylated protein with an apparent molecular weight of 18,500. Betaseron is indicated for use in ambulatory patients with relapsing–remitting multiple sclerosis to reduce the frequency of clinical exacerbations. The dosage and route of administration are 0.25 mg sc every other day. Some of the side effects of this product include injection site reactions including necrosis, headache, fever, flu-like symptoms, chills, malaise, decreased neutrophil and white blood cell counts, depression, and suicides/suicide attempts (see the package insert for the complete list of adverse effects). Avonex, interferon beta-1a is produced by recombinant DNA technology using Chinese hamster ovary cells into which the human interferon beta-1a gene was introduced. This interferon is a glycoprotein (166 amino acids) with an apparent molecular weight of 22,500. It has an antiviral specific activity of approximately $2 \times 10^8 \times$ IU/mg protein. Avonex is indicated for the treatment of relapsing forms of multiple sclerosis to delay the accumulation of clinical exacerbations. The dosage and route of administration are 30 μg injected intramuscularly once per week. The major adverse effects include headache, flu-like symptoms, fever, nausea, muscle aches, depression, and suicidal ideation (see the package insert for the complete list of adverse effects). Rebif is also a recombinant DNA-derived human interferon β-1a made in Chinese hamster ovary cells. It is a 166-amino-acid glycoprotein with a molecular weight of approximately 22,500. It has an antiviral specific activity of 2.7×10^8 IU/mg protein. The recommended dose is 44 μg injected 3 times per week sc. It is approved in the United States for patients with relapsing multiple sclerosis to decrease the frequency of exacerbations and delay the accumulation of physical disability. Again, the most common side effects include injection site disorders, influenza-like symptoms, abdominal pain, depression, an increase in liver enzymes, and hematologic disorders (for the complete list of adverse effects see the package insert).

VI. SUMMARY

Interferon-αs and -β were the first cytokines to be discovered in 1957. Over the years, they have served as model systems to understanding receptor interactions and signal transduction. Interferon alfa-2a and Interferon alfa-2b were the first two cytokines licensed for marketing in the United States in 1986. Today these molecules and other interferon-αs are used to treat a wide variety of diseases ranging from hairy cell leukemia to malignant melanoma to hepatitis B and C. Interferon-β has also proven medically valuable, particularly for certain forms of multiple sclerosis. Interferon-τ and -ω continue to be explored to elucidate their biological roles.

Glossary

interferon A family of species-specific vertebrate proteins that confer nonspecific resistance to a broad range of viral infections, affect cell proliferation, and modulate immune responses.

interferon-α A family of highly homologous species-specific interferons, the natural forms of which are derived primarily from either leukocytes or lymphoblastoid cells upon exposure to live or inactivated virus.

interferon-β An interferon produced primarily by fibroblasts in response to stimulation by live or inactivated viruses or by certain synthetic polynucleotides.

interferon-ω First described in 1985 and now recognized as sufficiently distinct from IFN-α to deserve the separate ω-subtype status. It appears to possess comparable biologic activity to many Hu-IFN-αs but its particular function is not understood.

interferon-τ A relatively new class of type I interferon that is not virus inducible but is constitutively produced by the trophectoderm of the ruminant conceptus during a very short period in early pregnancy. This interferon displays high antiviral and antiproliferative activities with a prominent lack of cytotoxicity *in vitro* and possibly *in vivo*.

interferon receptor All type I interferons (α, β, ω, and τ) act through a common receptor complex (IFNAR-1/IFNAR-2). Binding of interferon to its receptor mediates activation of numerous genes through different signal transduction pathways.

licensed interferons Licensure of interferons (or any biologic) in the United States is granted only after the Food and Drug Administration is ensured of its safety, purity, and potency as outlined by regulations set forth in the Code of Federal Regulations (21 CFR 601).

signal transduction The transmission of signals from the exterior of the cell to the interior. The type of signal transduction seen with IFN involves the coupling of ligand (IFN-α,β) and receptor (IFNAR-1/IFNAR-2), with the outcome being alterations in cellular activity and changes in the program of cellular gene expression.

Interleukin-1 (IL-1)

ALBERTO MANTOVANI

Istituto di Ricerche Farmacologiche Mario Negri and University of Milan

Interleukin-1 (IL-1) is the term for two polypeptide mediators, IL-1α and IL-1β, that are among the most potent and multifunctional cell activators thus far described in immunology and cell biology. The spectrum of action of IL-1 encompasses cells of hematopoietic origin, from immature precursors to differentiated leukocytes, vessel wall elements, and cells of mesenchymal, nervous, and epithelial origin. Occupancy of a few receptors, or perhaps only one receptor, per cell is sufficient to elicit cellular responses. The activity of IL-1 overlaps largely with that of tumor necrosis factor (TNF) and other cytokines.

I. INTRODUCTION

The production and action of interleukin-1 (IL-1) are regulated by multiple control pathways, including receptor antagonists and a decoy receptor. The complexity and uniqueness of IL-1 are best represented by the term "IL-1 system." The IL-1 system consists of the two agonists, IL-1α and IL-1β, a specific activation system (IL-1-converting enzyme, or ICE, caspase 1), a receptor antagonist (IL-1ra) of which there are different isoforms, and two high-affinity surface-binding molecules (Fig. 1). This article will focus largely on IL-1 and its receptors, with summaries of the properties of the other elements of the system (IL-1ra, caspase 1).

IL-1 is a member of a multigene family that includes 10 members to date. These molecules are denoted IL-1F1 through IL-1F10, where F stands for family. Receptors and functions have been identified for IL-1F4 (IL-18), IL-1F5, and IL-1F9; the last two molecules are the antagonist and agonist for the same receptor.

II. AGONISTS AND ANTAGONISTS

The mature human IL-1α and IL-1β are polypeptides that share 26% amino acid (aa) identity. Comparison of mature IL-1β from different animal species indicates that the amino acid sequence is 75 to 78% conserved. IL-1α sequences are less conserved among species (60–70%). The primary translation products of IL-1α and IL-1β are 271 and 269 aa long, corresponding to a molecular weight of 30,606 and 30,749, respectively. The IL-1α propeptide is biologically active, whereas the IL-1β precursor is not. Although the sequence contains glycosylation sites, sugars are not important in the biological activity of IL-1. IL-1α may be glycosylated and mannose sites may be important for association with the cell membrane.

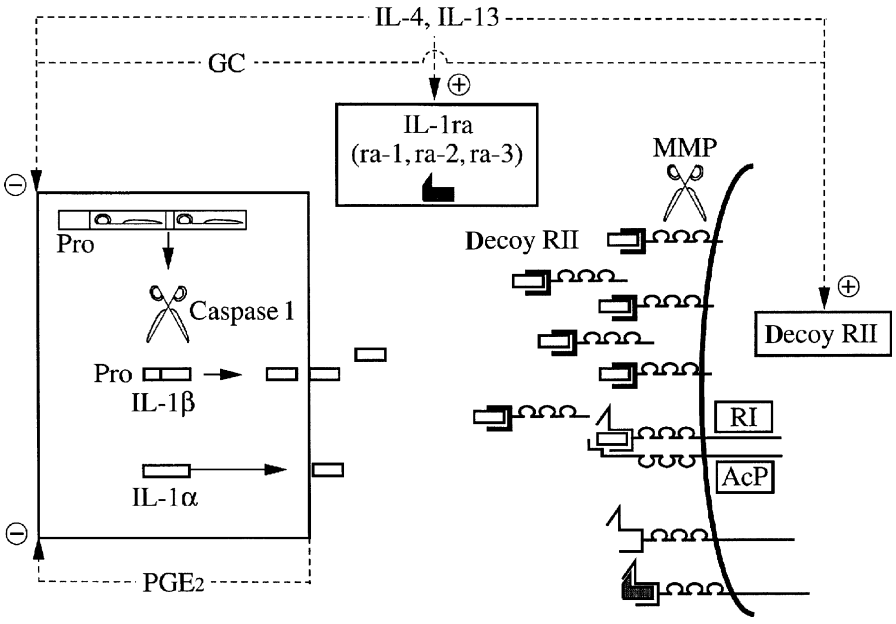

FIGURE 1 An overview of the IL-1 system. GC, glucocorticoid hormones; ra, receptor antagonist. The plus and minus signs indicate stimulation or inhibition of production, respectively. RI, receptor I; RII, receptor II; AcP, accessory protein. Reprinted with permission from "The Cytokine Network and Immune Functions" edited by Théze, J. (1999), copyright Oxford University Press.

IL-1α and IL-1β lack a signal peptide. IL-1α remains mostly in the cytosol and associated with the plasma membrane. The pathway of secretion of mature IL-1β (aa 117–269 of the precursor) is not completely defined and may be the same as that of other leaderless proteins. Cleavage of pro IL-1β to mature IL-1β is mediated by caspase-1, a cysteine protease representative of a novel class of proteolytic enzymes. IL-1α and IL-1β have been crystallized. Despite limited sequence similarity, IL-1α and IL-1β have a similar three-dimensional structure, consisting of a β barrel with four triangular faces that form a tetrahedron.

Multiple forms of IL-1ra have been generated by differential splicing: soluble IL-1ra (sIL-1ra) is a 152 aa protein (p*I* 5.2), secreted in both unglycosylated (18 kDa) and glycosylated (22 kDa) forms; intracellular IL-1ra type I (icIL-1ra I) has been cloned in keratinocytes and consists of 159 aa; it lacks a signal sequence and remains within cells; and icIL-1ra type II contains an extra 21 aa at the N-terminus.

IL-1ra is produced by different cell types, including monocyte–macrophages, polymorphonuclear leukocytes (PMN), and fibroblasts. Keratinocytes and other cells of epithelial origin produce icIL-1ra almost exclusively. The intracellular versions of IL-1ra are likely to represent a reservoir of anti-inflammatory molecules, to be released under conditions of extreme tissue damage.

III. RECEPTORS

IL-1 receptors belong to a complex superfamily of molecules. They activate a signaling cascade starting from the adapter protein MyD88 leading to activation of nuclear factor κB (NF-κB) and activator protein-1 (AP-1) (Fig. 2). Members of the IL-1/Toll-like receptor (TLR) superfamily share a Toll-IL-1 receptor (TIR) domain in the cytoplasmic region, which plays a key role in recruiting the adapter protein MyD88, the first step in a stereotyped signaling cascade leading to NF-κB and AP-1 activation (Fig. 1). The signaling IL-1 receptor complex includes the type I IL-1 receptor (IL-1RI) and the accessory protein (AcP), which have cytoplasmic TIR domains. The genes encoding IL-1RI, IL-1RII, and AcP are located on chromosome 2 (band q12–q22) in humans and in the centromeric region of chromosome 1 in mice. IL-1RI and IL-1RII have different affinities for the three ligands of the IL-1 family. Although results vary between studies, IL-1RI binds IL-1α with higher affinity than IL-1β ($K_d \simeq 10^{-10}$ and 10^{-9} M, respectively). By contrast, IL-1RII binds IL-1β more avidly than IL-1α ($K_d \simeq 10^{-9}$ to 10^{-10} and 10^{-8} M, respectively). IL-1ra binds to IL-1RI with an affinity similar to that of IL-1α, whereas IL-1RII binds IL-1ra at least 100 times less efficiently than IL-1RI. Plasmonic resonance analysis revealed that IL-1β has a slow off-rate from IL-1RII, whereas IL-1ra rapidly dissociates from IL-1RII but not from IL-1RI. Cell-associated IL-1RII did not bind pro-IL-1β, but sIL-1RII did bind it and blocked its processing by IL-1-converting enzyme. The kinetic data are consistent with a decoy function for IL-1RII. Moreover, they indicate that the two anti-IL-1 molecules in the system (IL-1ra and IL-1RII) minimally interfere with each other and actually synergize.

The IL-1RII (68 kDa) is structurally characterized by a short cytoplasmic tail (29 aa) with no TIR domain (Fig. 2). It is the predominant IL-1-binding protein found in monocytes, neutrophils, and B cells. Several lines of evidence suggest that IL-1RII is not required for signaling. Actually, cells that express only IL-1RI and AcP, such as endothelial cells, are exquisitely sensitive to IL-1. Moreover, under no experimental conditions has evidence been obtained that IL-1RII can trans-signal (i.e., in soluble form induce or amplify responsiveness to IL-1, in analogy to IL-6Rα).

Several lines of evidence are consistent with the view that the IL-1RII is a pure decoy for IL-1. The original proposal of the decoy paradigm was based on blocking antibodies to IL-1RII, which amplified responsiveness of myelomonocytic cells to IL-1, as well as on stimulation of expression by anti-inflammatory agents (see below). These observations have been confirmed and extended *in vivo*. Gene transfer experiments have shown that IL-1RII gene transfer blocks *in vitro* cellular responses to IL-1 in diverse cellular contexts. Moreover, as discussed below, transfer of IL-1RII-transfected cells ameliorates collagen-induced arthritis in mice. Finally, genetically modified mice yielded results consistent with the decoy paradigm. IL-1RII was expressed under the control of the human keratin promoter in transgenic mice; keratinocytes from these mice did not respond to IL-1. IL-1RII transgenic mice were resistant to phorbol myristate acetate (PMA)-induced vascular permeability changes and to chronic inflammation caused by repeated topical application of PMA. The effect of IL-1RII was restricted to the skin, with normal systemic inflammatory responses.

In agreement with the view that IL-1RII is a professional anti-IL-1 molecule, poxviruses encode an IL-1RII-like receptor that plays a key role in

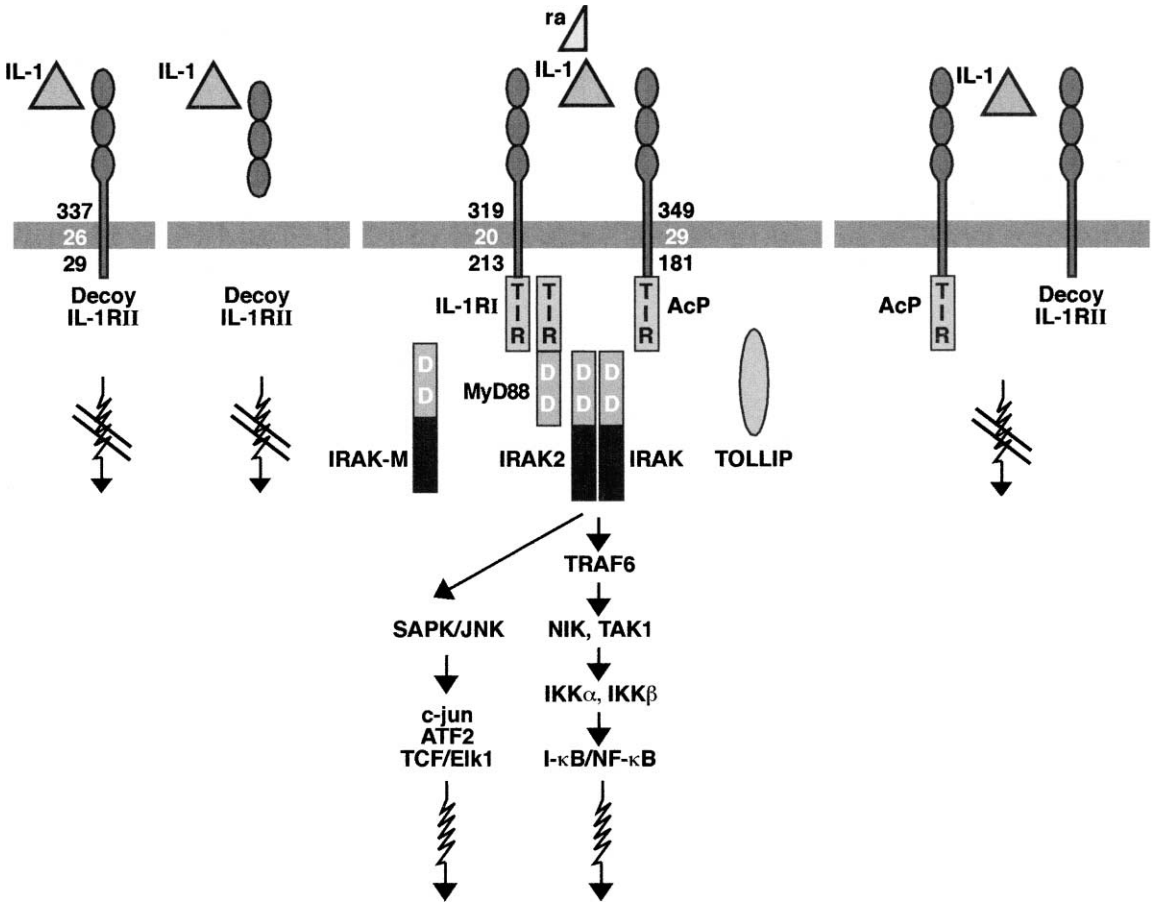

FIGURE 2 The type II interleukin-1 receptor (IL-1RII) as a decoy. The signaling IL-1R complex [IL-1RI and accessory protein (AcP)] activates the MyD88 cascade, leading to activation of NK-κB and AP-1. The cascade consists of adapter proteins (MyD88 and TRAF6), kinases (IRAKS, IKK, and JNK), and a shuttle molecule (Tollip for IRAK). In membrane-bound or soluble form, IL-1RII captures IL-1 and prevents it from forming a signaling receptor complex. In addition, it forms a dominant negative nonsignaling complex with the AcP. ATF-2, activated transcription factor 2; DD, death domain; IL-1ra, IL-1R antagonist; IKK, inhibitor of nuclear factor κB kinase; IRAK, IL-1R-associated kinase; JNK, Jun N-terminal kinase; NK, nuclear factor; NIK, nuclear factor κB-inducing kinase; SAPK, stress-activated protein kinase; TAK, transforming growth factor β-activated kinase; TCF, T-cell factor; TIR, Toll/IL-1R domain; TRAF, tumor necrosis factor receptor-associated factor. the regulation of pathogenicity. In addition to binding IL-1, the IL-1RII forms a complex with the agonist and the IL-1R AcP.

Therefore, IL-1RII acts as a dominant negative molecule for the formation of a signaling receptor complex by sequestering AcP, which is essential for signal transduction (Fig. 2). This dominant negative action probably explains early results obtained in studies in which, after IL-1RII gene transfer, under certain conditions, excess agonist did not completely revert inhibition. In summary, IL-1RII blocks IL-1 *in vitro* and *in vivo* in two complementary ways. First, in membrane-bound or soluble form it acts as a decoy, capturing IL-1 and preventing it from interacting with IL-1RI. Second, it acts as a dominant negative molecule for signaling receptor complexes.

IL-1RII is the main IL-1-binding protein in neutrophils, monocytes, macrophages, and B cells. Monocyte-to-macrophage differentiation results in increased expression of IL-1RII. Endothelial cells and fibroblasts generally have only IL-1RI and IL-1R AcP, whereas other cell types (e.g., T cells and epithelial cells) have a mixture of the two receptors. In addition to being regulated during lineage differentiation, IL-1RII expression is influenced by pro- and anti-inflammatory signals. Glucocorticoid hormones

(GCs) and the anti-inflammatory Th2 cytokines IL-4 and IL-13 induce augmented surface expression and release of the decoy RII (Fig. 1). For example, resting monocytes express $\simeq 1.3 \times 10^3$ molecules per cell. Exposure to IL-13 for 24 h increased the number of surface receptors to 3.5×10^3/cell and induced the release of 12×10^3 sIL-1R molecules/cell. A Stat-6-binding site in the IL-1R promoter could be involved in induction by IL-4 and IL-13. IL-10 does not induce or inhibit IL-1RII *in vitro* but *in vivo* increased circulating levels have been observed after IL-10 treatment in mice. Aspirin increases the levels of sIL-1RI released *in vitro* from mononuclear cell cultures. GCs, IL-4, and aspirin also increase IL-1RII in the circulation and/or tissues after *in vivo* administration. The stimulation of IL-1RII levels by anti-inflammatory signals is consistent with it being a negative regulator of IL-1 activity.

In contrast to anti-inflammatory signals, the two prototypic pro-inflammatory molecules bacterial lipopolysaccharide (LPS) and interferon-γ (IFN-γ) inhibit IL-1RII expression in myelomonocytic cells. LPS causes a rapid (within 30 min) shedding of surface IL-1RII in monocytes, followed by down-regulation of transcript expression. Concomitantly, it stimulates expression of IL-1RI, IL-1R AcP, and the adapter protein MyD88. Stimulation with high concentrations of LPS causes the appearance of incompletely spliced IL-1RI transcripts, whose significance is unclear. PMA has similar effects, inducing also alternatively spliced soluble IL-1R AcP. IFN-γ suppresses IL-1RII mRNA levels and receptor release in monocytes but not in keratinocytes. The reason for the divergent effect of IFN-γ on myelomonocytic cells versus keratinocytes has not been established. It also blocks the IL-4-mediated stimulation of IL-1RII. Therefore, at least certain pro- and anti-inflammatory signals have divergent effects on IL-1RII expression and release in myelomonocytic cells, with inhibition, for instance, by IFN-γ and stimulation by IL-4 and GCs. The IL-1RII balance is a component in setting myelomonocytic cells in a pro- or anti-inflammatory mode.

sIL-1RII is found in culture supernatants and in biological fluids. In normal blood, relatively high concentrations are found, on the order of nanograms per milliliter, presumably reflecting constitutive release observed *in vitro* in cells such as monocytes and neutrophils. An alternatively spliced transcript encoding a soluble version of IL-1 RII has been identified in COS-1 and Raji cells. However, inhibitors of matrix metalloproteinases (MMPs) completely block the induction of IL-1RII release from monocytes, neutrophils, transfected fibroblasts, and hepatocytes exposed to diverse stimuli. Therefore, shedding mediated by an MMP closely related or identical to TNF-α-converting enzyme is the major mechanism of sIL-1RII release (Fig. 2). Shedding is to some extent selective in that PMA induces rapid shedding of IL-1RII but not of IL-1RI.

IL-1RII release is a regulated process (Fig. 2). Augmented surface expression induced by GCs or IL-4/IL-13 is associated with shedding and both are inhibited by IFN-γ. In addition to this default pathway, a defined and restricted set of stimuli cause rapid (in seconds to minutes) shedding mediated by activation of a preformed MMP. These include chemoattractants (e.g., fMLP), reactive oxygen intermediates, TNF, and LPS, but not other pro- and anti-inflammatory cytokines. Shedding of IL-1RII by circulating phagocytes induced by chemoattractants in the early steps of recruitment could prepare cells to respond to IL-1 once they enter tissues and the released decoy IL-1RII can buffer IL-1 leaking in the systemic circulation from sites of inflammation.

Alterations of tissue or body fluids levels of sIL-1RII have been detected in diverse pathological conditions. Increased blood levels of sIL-1RII have been detected in experimental endotoxemia, sepsis, acute meningococcal infection and in patients treated with IL-2, aspirin, or GCs. Overexpression of IL-1RII has been detected in the basal compartment of psoriatic skin, in the context of an imbalance of the IL-1 system. Glomerular overexpression of IL-1RII was associated with the therapeutic activity of IL-4 in experimental glomerulonephritis.

Joint inflammation has been extensively investigated and could represent a target for IL-1RII-based therapeutic strategies. sIL-1RII was present in inflammatory synovial fluids. Gene array analysis of osteoarthritis lesions showed a lack of expression of IL-1RII and IL-1ra. Overexpression of IL-1RII in chondrocytes protected them from IL-1 stimulation. Moreover, transfer of cells transfected with IL-1RII that overexpress and release this molecule resulted in inhibition of collagen arthritis. These results, as well as the binding properties of IL-1RII (high for IL-1, low for IL-1ra; see above), suggest that this molecule may be an ideal therapeutic tool to inhibit IL-1.

IV. CELLULAR SOURCES AND PRODUCTION

Cells of the monocyte–macrophage lineage are the main cellular source of IL-1, though most cell types have the potential to express this cytokine. In the absence of *in vitro* or *in vivo* stimulation, the IL-1

genes are not expressed. Diverse inducers, including bacterial products (e.g., LPS), complement components, and cytokines (TNF, IFN-γ, granulocyte/macrophage colony-stimulating factor, and IL-1 itself), cause transcription (see above), which does not necessarily result in translation. For instance, adhesion causes an accumulation of IL-1 mRNA, which requires a triggering stimulus (minute amounts of LPS) for translation into protein. Similarly, gene expression profiling has recently revealed that chemokines induce IL-1β gene transcription, but that translation requires a second signal.

V. BIOLOGICAL ACTIVITIES

A. Spectrum of Action of IL-1

IL-1 affects a wide range of cells and organs. Its spectrum of action is similar to that of TNF and, to a lesser degree, of IL-6. Induction of secondary cytokines, including IL-6, colony-stimulating factors (CSFs), and chemokines, is involved in many of the *in vitro* and *in vivo* activities of IL-1. The vast phenomenological literature on the activities of IL-1 is concisely summarized here based on target organs/tissues, and the reader is referred to previous reviews for more detailed analyses.

B. Hematopoietic Cells

IL-1 affects the hematopoietic system at various levels, from immature precursors to mature myelomonocytic and lymphoid elements. "Hemopoietin-1" activity was found to be mediated by IL-1α. IL-1 induces the production of CSFs in a variety of cell types including elements of the bone marrow stroma. It acts synergistically with hematopoietic growth factors at various stages of hematopoietic differentiation. IL-1 is active as an hematopoietic growth factor also *in vivo*: it stimulates production of CSFs, accelerates bone marrow recovery after cytotoxic chemotherapy or irradiation, and has radioprotective activity.

IL-1 acts on T and B lymphocytes. In particular, it co-stimulates T-cell proliferation in the classic co-stimulator assay. The AP-1 transcription complex in the promoter of IL-2 represents one molecular target for the co-stimulatory activity of IL-1. The LAF (lymphocyte activating factor) assay has been invaluable for the identification of IL-1, but the actual role of IL-1 co-stimulation in T-cell physiology has not been fully established. Recent data showing that IL-1ra favors the development of Th1-type responses may suggest a role for IL-1 in the generation of Th2-type responses.

IL-1 affects mature myelomonocytic elements. It induces cytokine production in monocytes, although it is a poor inducer in PMN (see above). It prolongs the *in vitro* survival of PMN by blocking apoptosis.

C. Vascular Cells

IL-1 profoundly affects the function of vessel wall elements, in particular, that of endothelial cells. IL-1 activates endothelial cells in a pro-inflammatory, prothrombotic sense. IL-1 induces the production of tissue factor and platelet-activating factor, down-modulates the protein C-dependent anti-coagulation pathway, and induces the production of an inhibitor of thrombus dissolution (PAI-1). IL-1 induces gene expression-dependent production of vasodilatory mediators (nitric oxide, prostacyclin [PG]I2), expression of adhesion molecules, and production chemokines in cultures of endothelial cells. The concerted action of changes in rheology, adhesion, and chemotactic factors underlies leukocyte recruitment at sites of IL-1 production or injection.

D. Neuroendocrine System

Infection and inflammation induce an elevation of blood corticosteroids (CSs) through activation of the so-called hypothalamus–pituitary–adrenal axis (HPAA), very similar to that observed with stress. This is the result of a central action whereby IL-1 stimulates the release of corticotropin-releasing hormone (CRH) by the hypothalamus, which induces ACTH production by the pituitary, ultimately causing a release of CSs in the bloodstream by the adrenals. This release in inhibited by anti-CRH antibodies. The increase in CSs resulting from HPAA activation by IL-1 may have several consequences in view of the wide range of immunosuppressive, anti-inflammatory, and metabolic actions of GC. It should be stressed here that CSs are (as mentioned in Section IV) potent inhibitors of the synthesis of IL-1 (and of other cytokines). They also prevent the hemodynamic shock associated with injection of IL-1, TNF, or LPS and protect against IL-1 or LPS toxicity. Therefore, activation of HPAA may be considered a feedback mechanism to control IL-1 production and toxicity. The fact that adrenalectomized animals are extremely susceptible to IL-1 toxicity strongly supports this hypothesis.

E. The Acute-Phase Response

IL-1 is a key mediator of the series of host responses to infection and inflammation known as the acute-phase response. One of the early acronyms for IL-1 before it was named under the current terminology was LEM (leukocytic endogenous mediator). This was originally identified as a major mediator of the acute-phase response, particularly hypoferremia and induction of acute-phase proteins (APPs).

Hypoferremia seems to be mediated by an effect on neutrophils, which would be stimulated to release lactoferrin to sequester iron in the tissues. It could constitute a "nutritional immunity" against infection since iron is essential for the growth of many bacteria.

The synthesis of APPs is increased during inflammation. APPs include C-reactive protein, serum amyloid component, fibrinogen, hemopexin, and various proteinase inhibitors; these molecules may have protective, anti-toxic, and other functions yet to be defined. The synthesis of some of these proteins (e.g., serum amyloid A) can be directly induced in hepatocytes by IL-1. Other proteins, such as fibrinogen, are induced indirectly through IL-6. Therefore, both IL-1 and IL-6 (like other cytokines) behave like hepatocyte-stimulating factors (cytokines that stimulate liver APP synthesis).

The increased synthesis of APPs is part of a rearrangement of liver metabolism in which the synthesis of "normal liver proteins" is decreased; one such negative acute-phase reactant is albumin, whose gene expression is decreased by IL-1.

F. Central Nervous System

IL-1 is the main endogenous pyrogen. In 1943, Menkins suggested that leukocytes release a pyrogenic substance, "pyrexin," that was subsequently detected in the circulation of febrile rabbits. Human leukocytic pyrogen was purified in 1977 and an immunoassay to determine its presence was developed. It is now clear that the main endogenous pyrogen was IL-1 and that recombinant IL-1 induces fever in experimental animals, an activity shared with other cytokines including TNF and IL-6 (although these are much less potent than IL-1). The pyrogenic action of IL-1 is due to the increased production of prostaglandin (PG). In fact, IL-1 fever is abolished by inhibitors of PG synthesis, and IL-1 directly stimulates prostaglandin E2 release by hypothalamic tissue.

In addition to fever, IL-1 has other effects on the CNS. These include induction of slow-wave sleep and anorexia, typically associated with infections. IL-1 also activates the hypothalamus to produce CRH.

G. Other Effects

It is almost impossible to list all the activities of IL-1. Since it became available as a recombinant protein, a large number of papers have been published reporting very disparate effects of this cytokine. IL-1 has a number of local effects that have been termed "catabolic" and it plays a role in destructive joint and bone diseases. In particular, IL-1 induces the production of collagenase by synovial cells and of metalloproteinases by chondrocytes.

IL-1 also stimulates fibroblast proliferation and collagen synthesis and thus plays a role in fibrosis. It induces a profound hypotension, an effect that is inhibited by a cyclooxygenase inhibitor and in which IL-1 and TNF act synergistically.

Another important action of IL-1 is its toxicity for insulin-producing beta cells in Langerhans islets, supporting a role for IL-1 in the pathogenesis of insulin-dependent type 1 diabetes.

H. Gene-Modified Mice

The development of transgenic or knockout mice for components of the IL-1 system has provided new evidence as to the *in vivo* function of these molecules. IL-1β −/− mice show a reduced acute-phase response to local irritants, whereas the responses to systemic LPS are normal. Gene targeting and overproduction have revealed a critical role for endogenous IL-1ra in animal growth, responses to infection and inflammation, and cytokine regulation. Selective overexpression of IL-1β and the type IR and type II decoy R in skin resulted in pathology consistent with the concept that IL-1 is important in skin pathophysiology.

VI. CLINICAL IMPLICATIONS

IL-1 is the central mediator of local and systemic inflammatory reactions. IL-1 levels in the blood reach relatively modest levels in response to septic conditions, but IL-1ra increases to levels that are orders of magnitude higher. This may represent a feedback control mechanism. Most of the interest generated for IL-1 is for its pathogenic role in septic shock syndrome and rheumatoid arthritis. However, *in vitro* studies, animal models, and results of studies reporting levels of IL-1 in human diseases have indicated other pathologies in which the blockade of IL-1 might be beneficial. These include vasculitis, disseminated intravascular coagulation, osteoporosis,

neurodegenerative disorders such as Alzheimer's disease, diabetes, lupus nephritis, immune complex glomerulonephritis, and autoimmune diseases in general. Inhibition of IL-1 by IL-1Ra, anti-IL-1, or anti-IL-1-R antibodies is protective in various animal models including endotoxin-induced hemodynamic shock and lethality, arthritis, inflammatory bowel disease, spontaneous diabetes in BB strain rats, graft-versus-host disease in mice, heart allograft rejection, and experimental autoimmune encephalomyelitis.

Since TNF is produced concomitantly and IL-1 synergizes with TNF (but not with IL-6) in many systems, it is likely that these two cytokines act in concert in the pathogenesis of these disorders.

IL-1 is a autocrine/paracrine growth factor for acute myeloid leukemia (AML) cells, chronic myeloid leukemia cells, plasmacytoma (via IL-6), and possibly some solid tumors such as ovarian carcinoma. Interestingly, AML blasts usually express IL-1β, but not IL-1ra. Blocking IL-1 using IL-1ra inhibits AML proliferation *in vitro*.

The exploration of the therapeutic potential of IL-1 has provided an opportunity to examine the *in vivo* activity of systemic IL-1 administration in humans. Phase I trials have been conducted with IL-1α and IL-1β in studies ultimately aimed at exploiting the hematopoietic/radioprotective action of these molecules. By and large, the results obtained confirm data from experiments in animals. Systemic (intravenous) IL-1 (1–10 ng/ml) causes fever, sleepiness, anorexia, myalgia, arthralgia, and headache. At doses of 100 ng/ml or higher, a rapid fall in blood pressure occurs.

Therapeutic strategies aimed at blocking IL-1 have received considerable attention in experimental models and in humans. Results obtained with IL-1ra in graft-versus-host disease and in rheumatoid arthritis are encouraging. The IL-1 decoy RII is a logical candidate for blocking the action of IL-1. Preclinical results (e.g., in rheumatoid arthritis in the mouse) are encouraging and this compound is currently undergoing clinical evaluation.

Glossary

chemokines Chemotactic cytokines, with the typical chemokine structure, that interact with seven-transmembrane-domain, G-protein-coupled receptors.

cytokines Soluble non-antigen-specific polypeptides that act as communication signals among diverse cell types.

decoy receptor A receptor that interacts with the ligand with high affinity and specificity but that is unable to signal or to be part of signaling receptor complexes. Decoy receptors act as a sink for the ligand and, in some cases, as dominant negatives for signaling receptors.

interleukins A group of cytokines, with no features that distinguish them from other cytokines.

Interleukin-2

KENDALL A. SMITH
Weill Medical College of Cornell University

Interleukin-2, originally termed T-cell growth factor, was the first cytokine to be isolated, purified, and characterized at the molecular level. Interleukin-2 is a small, globular glycoprotein composed of four amphipathic antiparallel α-helices; it is prototypic of the interleukins as well as the hematopoietic cytokines and

TABLE 1 IL-10 Signaling in Different Cell Types

Cell type	Stats	Interaction with other pathways	Regulation	Effect on the cell
Monocyte	Stat1, Stat3	Inhibits IKK activity and NFkB DNA binding; activates PI3K and p70 S6K that may be involved in proliferation; inhibits p38 MAPK to modulate ARE dependent TNF mRNA translation	Inhibited by IL-1 TNFα, LPS signaling, SOCS1, and SOCS3	Inhibits proliferation, production of inflammatory cytokines, IFN-induced gene expression by inhibiting Stat1 phosphorylation, $p19^{INK4D}$ expression, CD40-mediated activation of ERK1/2, induction of IL-IR, and COX-2 expression; up-regulates expression of CD95 and CD95L, thus promoting apoptosis; up-regulates FcγRI and SOCS-3
Dendritic cell	Stat1, Stat3	Inhibits activation of SAPK/JNK, $p38^{MAPK}$, and ERK2	Antagonized by TNFα and CD40 ligand	Represses TNF-induced changes and modulates CCR expression
B cell	Stat1, Stat3, Stat5	Not described	Not described	Induces differentiation and proliferation; expression of CD32/16, CD2, LECAM-1, heat-stable antigen, and c-fos; and Bcl-2 expression; prevents apoptosis
T cell	Stat1, Stat3	Inhibits Cd28 tyrosine phosphorylation and PI3K recruitment	Not described	Enhances TGF-βR expression on activated T cells, prevents release of T_H1 cytokines, blocks proliferation, enhances Bcl-2 expression, and prevents apoptosis
Neutrophil	Stat1, Stat3	Not described	SOCS proteins	Inhibits mobilization of specific granules to membrane and suppresses production of superoxide
NK cell	Stat1, Stat3	Not described	Not described	Enhances cytotoxicity and proliferation
Mast cell	Stat1, Stat3	Not described	Not described	Inhibits kit expression and reduces TNF induction
Melanoma cell	—	Not described	Not described	Induces proliferation and down-regulates MHC class I and II complex expression
Oligodendrocyte	—	Not described	Not described	Inhibits iNOS expression and promotes survival

TABLE 2 Cellular Function of IL-10

Cell type	Function	
	Immunosuppressive, anti-inflammatory	Stimulation, proliferation
T helper (T_H)	Decreased cytokine synthesis (IFNγ); anergy, immune deviation, generation of suppressor-type cells; inhibits T_H1	Stimulates T_H2
T cell	—	Stimulates maturation and proliferation
Thymocyte	—	Proliferation
Natural killer	Decreased cytokine synthesis (IFNγ)	Increased proliferation, increased cytotoxicity
Macrophage, monocyte	Decreased antigen-presenting cell function, cytokine synthesis (IL-1α, IL-1β, IL-6, IL-8, IL-12, VEGF, MMP-9, TNFα, GM-CSF, NO, H_2O_2), and receptor expression (CD80, CD86, MHC II, IL-1RI, IL-1RII)	—
Dendritic cell	Decreased cytokine synthesis, receptor expression (CD80, CD86, MHC II, MHC I), and APC function	—
Vascular endothelial cell	Decreased receptor expression (ICAM-1)	Increased receptor expression (CD62E)
B cell	T-Dependent responses	T-Independent responses, isotype switching, growth and differentiation, and increased MHC II
Mast cell	—	Stimulates proliferation
Neutrophil	Decreased cytokine secretion	—
Oligodendrocyte	Decreased cytokine synthesis	—

II. GENE AND PROTEIN STRUCTURE

IL-10 is produced by activated T cells, B cells, monocytes/macrophages, mast cells, and keratinocytes. Human IL-10 (hIL-10) is encoded by a single 3.5-kb exon; the mouse IL-10 (mIL-10) gene contains five exons that span 5.1 kb of the genomic DNA, and both genes are located on chromosome 1. Detailed analysis of the mIL-10 gene has revealed that there are possible transcriptional control sequences present in noncoding regions of the mIL-10 genomic sequence. The hIL-10 and mIL-10 cDNA sequences have 80% homology and encode peptides of 178 amino acids, including hydrophobic leader

[a] vIL-10, Viral interleukin-10; cIL-10, cellular interleukin-10.

sequences. Both proteins exist in solution as noncovalent homodimers. hIL-10 is an 18-kDa nonglycosylated polypeptide; mIL-10 is heterogeneously N-glycosylated at a site near the N-terminus, resulting in a mixture of 17-, 19-, and 21-kDa species. A mIL-10 mutant lacking the N-linked site is active and recombinant mIL-10 expressed in *Escherichia coli* retains all known biological activities, thus glycosylation of mIL-10 is not required for biological activity.

The crystal structure reveals that human IL-10 is a tight, noncovalent homodimer and that each monomer contains two intrachain disulfide bonds, between residues 12 and 108 and between residues 62 and 114 (hIL-10 numbering). Each monomer consists of six α-helices containing specific residues (hIL-10 numbering): A (residues 18–41), B (residues 48–58), C (residues 60–82), D (residues 87–108), E (residues 118–131), and F (residues 133–159). Residues A–F tightly associate with the other monomer (A′, B′, C′, D′, E′, and F′) to form two interpenetrating domains. Each domain is composed of six α-helices (A, B, C, D, E′, and F′), four originating from one monomer (A, B, C, and D) and two from the other (E′and F′). The overall topology of the helices bears close resemblance to IFNγ. The two most notable differences between IL-10 and IFNγ dimers are the size and orientation of the domains. In hIL-10, the helix bundles are perpendicular to one another, whereas in IFNγ the domains are oriented at an angle of about 60°. Studies on the crystal structure of IL-10 bound to a soluble receptor (R) complex (IL-10R1) reveal that there are two primary sites for IL-10 and IL-10R interaction.

III. VIRAL IL-10

Several viruses, including Epstein–Barr Virus (EBV), equine herpes virus type 2, orf virus (OV), and human cytomegalovirus, encode IL-10 homologues that have functions similar to those of cellular IL-10 (cIL-10). It is postulated that these viruses might take advantage of the IL-10-like products to suppress production of early immunoregulatory cytokines, leading to ineffective immune responses.

BCRF1 is the EBV homologue of IL-10. This viral IL-10 (vIL-10) exhibits a high degree of DNA and amino acid sequence homology to both mIL-10 and hIL-10. Viral IL-10 is expressed in the late phase of the lytic cycle of EBV and has 85% amino acid identity with hIL-10 and 71% homology with hIL-10 at the DNA sequence level. vIL-10 and cIL-10 have identical immunosuppressive properties, inhibiting IFNγ production, major histocompatability complex (MHC) class II expression, T-cell proliferation, and B-cell IgE production, further reinforcing the notion that IL-10 is an immunosuppressive cytokine.

Viral IL-10 lacks several of the immunostimulatory activities of cellular IL-10 on certain cells. vIL-10 neither effectively enhances class II MHC expression on mouse B cells nor costimulates mouse thymocyte or mast cell proliferation. *In vivo*, it has been shown that cIL-10 can be immunosuppressive or immunostimulatory, whereas vIL-10 is mostly immunosuppressive. Thus, experiments in which mouse tumor cells were infected with recombinant retroviruses expressing mIL-10 or vIL-10 cDNAs show that mIL-10 accelerates and vIL-10 impedes tumor rejection. Experiments also show that rejection of mouse heart allografts is substantially inhibited when the grafts are induced to express vIL-10 but not mIL-10. These observations suggest that vIL-10 has conserved only a subset of the activities of cIL-10, perhaps as a pathogenetic mechanism for successful viral infection. These data also suggest the existence at least two functional domains, only one of which has been conserved by EBV.

The most significant difference in the amino acid sequence of viral and cellular IL-10 is found at the N-terminus. The crystal structure of vIL-10 shows that its structure is similar to that of human IL-10, forming an intercalated dimer of two 17-kDa polypeptides. Viral IL-10 exhibits novel conformations of the N-terminal coil and of the loop between helices A and B compared to hIL-10. It has been suggested that these differences might account for the different activities of vIL-10 and cellular IL-10. Viral IL-10 binds to the IL-10R at least 1000-fold less avidly than does cIL-10, but, like cIL-10, requires the presence of both IL-10R1 and IL-10R2 to induce signaling and immune responses. Mutagenesis of cIL-10 and vIL-10 reveals that the single amino acid isoleucine at position 87 of cIL-10 is required for its immunostimulatory function. Substitution in cIL-10 of isoleucine with alanine, which corresponds to the vIL-10 residue, abrogates immunostimulatory activity for thymocytes, mast cells, and alloantigenic responses but preserves immunosuppressive activity for inhibition of IFNγ production and prolongation of cardiac allograft survival. Conversely, substitution in vIL-10 of alanine with isoleucine converts vIL-10 to a cIL-10-like molecule with immunostimulatory activity. The mechanism of this switch is mostly due to changes in receptor binding affinity.

Human cytomegalovirus encodes a viral IL-10 homologue (cmvIL-10) that has only 27% identity with hIL-10 at the protein level. cmvIL-10 is able to

bind to the human IL-10 receptor and to compete with human IL-10 for binding sites, and requires both subunits of the IL-10 receptor complex to induce signaling and biological function. A new cellular homologue of interleukin-10, AK155, has been identified by transformation of T lymphocytes with *Herpesvirus saimiri*. AK155 protein shows 24.7% amino acid identity and 47% amino acid similarity to hIL-10 and has been mapped to the human chromosome 12q15. The biological function of this homologue is not known. There is also a new molecule, IL-22, that is structurally related to IL-10 and it shares the same IL-10R2 with IL-10. Little is known about the biological activities of IL-22, and it has been described to up-regulate acute-phase reactant production by hepatocytes.

A monomeric form of human IL-10 has been engineered by inserting six amino acids (GGGSGG; G is glycine and S is serine, using the one-letter code) into the D–E loop, connecting the swapped secondary structural elements between Asn-116 and Lys-117. The monomeric form (IL-10M1) is stable under native conditions and is structurally similar to one domain of IL-10. IL-10M1 binds to soluble IL-10R1 (sIL-10R1) with a 1:1 stoichiometry and is biologically active.

IV. IL-10 EXPRESSION

IL-10 is expressed in a variety of cells, including T cells, B cells, macrophages/monocytes, NK cells, keratinocytes, eosinophils, mesangial cells, epithelial cells, and tumor cells. Activated T_H0-, T_H1-, and T_H2-like CD4 + T cells, as well as CD8 + T cells, all express IL-10. CD4 + CD45RA + cells produce low levels of IL-10, whereas CD4 + CD45RA − "memory" cells produce higher levels of IL-10. IL-10 has been implicated in the induction of regulatory or suppressor T_H cell subsets and it also appears to contribute to their effector function.

IL-10 production is induced by many pathogens, which can directly activate monocytes/macrophages [bacterial cell wall components, parasites, fungi, human immunodeficiency virus (HIV)], B cells (EBV), and T cells (human T cell leukemia virus type 1). In the course of severe infections and stress conditions, cytokines, hormones, and arachidonic acid derivatives are released and up-regulate IL-10 synthesis in monocytes, macrophages, and T cells.

Elevated IL-10 expression is associated with human diseases such as septicemia, bacterial meningitis, malaria, rheumatoid arthritis, lepromatous leprosy, visceral leishmaniasis, and lymphatic filariasis. IL-10 protein is also detected in many tumors, such as those in Burkitt's lymphoma, AIDS lymphoma, non-Hodgkin lymphoma, multiple myeloma, melanoma, ovarian cancer, and other intra-abdominal cancers. IL-10 production is regulated by other cytokines. IL-4, IL-13, and IFNγ inhibit IL-10 production in monocytes activated by lipopolysaccharide (LPS). IL-10 also strongly inhibits IL-10 mRNA synthesis, suggesting that IL-10 has autoregulatory activities. In contrast, IL-1, IL-2, IL-3, IL-6, IL-7, IL-12, and IL-15 induce IL-10 production in monocytes, T cells, NK cells, B cells, and mast cells. Tumor necrosis factor α (TNFα) induces IL-10 production in monocytes and mouse liver. IFNα induces IL-10 production in human T cells and monocytes. Transforming growth factor-β (TGF-β) induces IL-10 production in macrophages, mesangial cells, and liver cell lines.

V. IL-10 IN DISEASE STATES

A. Inflammation

IL-10 has protective effects in experimental endotoxemia and rescues mice from LPS-induced toxic shock, which is correlated with reduced levels of serum TNFα. IL-10 inhibits the production of TNFα and macrophage inflammatory protein-2 (MIP-2); regulates hemodynamic parameters, leukocyte–endothelial cell interactions, and microvascular permeability; and reduces mortality in experimental endotoxemia. Mice treated with anti-IL-10 from birth or IL-10-deficient mice are more susceptible to endotoxin-induced shock than are normal mice. Human volunteers receiving IL-10 after endotoxin challenge suffer fewer systemic symptoms and less cytokine production.

B. Inflammatory Bowel Disease

IL-10-deficient and IL-10R2-deficient mice develop chronic intestinal inflammatory disorders and are successfully treated by administration of IL-10, indicating the role of IL-10 in the development of inflammatory bowel disease (IBD) and the effect of IL-10 in the treatment of IBD. Transfer of CD4 + $CD45RB^{high}$ T cells (which produce IFNγ and TNFα) into severe combined immune-deficient (SCID) mice causes IBD, and administration of CD4 + $CD45RB^{low}$ T cells (which produce IL-4 and IL-10) or mIL-10 prevents the development of IBD. CD4 + $CD45RB^{high}$ T cells isolated from IL-10 transgenic mice do not induce IBD but inhibit IBD induced by

wild-type CD4 + CD45RB^{high} T cells. Furthermore, intraperitoneal injection of adenovirus, producing IL-10, successfully prevents experimental colitis in rats, and oral treatment with mIL-10 reduces colitis in mice and prevents colitis in IL-10-deficient mice.

A double-blind, randomized, multicenter trial in humans has been conducted to evaluate the safety, tolerance, and pharmacokinetics of IL-10 in the treatment of Crohn's disease. The results indicate that intravenous bolus injection of IL-10 over 7 days is safe, well tolerated, and results in clinical improvement. Another trial has shown that subcutaneous administration of recombinant human IL-10 (rhIL-10) for 28 days to patients with mild to moderately active Crohn's disease is safe, well tolerated, and clinically efficacious; 23.5% of patients receiving 5 μg/kg of rhIL-10 achieve clinical remission and endoscopic improvement at the end of treatment.

C. Experimental Autoimmune Encephalomyelitis

The effects of IL-10 in the treatment of experimental autoimmune encephalomyelitis (EAE) are controversial, and various reports have yielded conflicting results. Initial studies show that IL-10 mRNA in the spinal cord dramatically rises with the recovery from EAE, and intracerebral synthesis of IL-10 is also increased during the recovery phase of EAE. IL-10-deficient mice develop more severe EAE and do not achieve spontaneous recovery, suggesting an important role of IL-10 in the disease. IL-10 prevents the induction of EAE in Lewis rats and SJL mice on systemic administration during the initial phase of the disease. IL-10 decreases the relapse rate when given with TNFα, and neutralization of IL-10 increases the incidence and the severity of the relapse. Adenovirus-mediated IL-10 gene transfer inhibits development and prevents subsequent relapse of EAE. Murine IL-10 transgenic mice are protected from EAE induced by proteolipid protein (PLP) immunization. Human IL-10 transgenic mice are highly resistant to EAE; this is mediated by suppression of autoreactive T-cell function. In contrast, intravenous injection of IL-10 exacerbates the disease in an adoptive transfer model of EAE. Intracranial injection of IL-10 or IL-10 plasmid does not inhibit EAE. Adoptive transfer of a myelin basic protein (MBP)-specific T-cell hybridoma transduced with IL-10 also does not suppress EAE. Hence, the role of IL-10 in EAE may be related to the route and timing of cytokine administration.

D. Insulin-Dependent Diabetes Mellitus

Systemic administration of IL-10 to adult nonobese diabetic (NOD) mice delays the onset of diabetes, indicating the potential therapeutic effect of IL-10 in autoimmune diabetes. Daily subcutaneous administration of IL-10 to 9- and 10-week-old NOD mice delays the onset and decreases the incidence of diabetes. Combined therapy with IL-4 and IL-10 suppresses T_H1 cytokine production in the islet grafts and inhibits insulin-dependent diabetes mellitus (IDDM) recurrence in syngeneic islet-transplanted NOD mice. IL-10/Fc protein, a long-lived noncytolytic fusion protein, completely prevents the occurrence of diabetes in 5- to 25-week-old NOD mice and the mice remain disease free for a long time after cessation of IL-10/Fc therapy. Intramuscular plasmid injection provides long-term systemic delivery of cytokines. When an IL-10 expression plasmid is injected into the skeletal muscles of NOD mice, the incidence of diabetes is significantly reduced. Intravenous injection of IL-10 plasmid also prevents autoimmune insulitis in NOD mice.

In contrast, transgenic expression of IL-10 on beta cells accelerates the development of diabetes in NOD mice, suggesting a proinflammatory effect of IL-10 in the pathogenesis of autoimmune diabetes. In IL-10 transgenic NOD mice, the incidence of diabetes in the first and second generations is greatly increased, the onset of diabetes is much earlier than in the nontransgenic NOD mice, and histological analysis shows severe insulitis and prominent ductal proliferation. IL-10 transgenic NOD mice back-crossed with NOD.B6 Idd3 Idd10 mice, which have diabetes-resistance alleles at *Idd3* and *Idd10* on chromosome 3 and have a very low frequency of diabetes, results in IL-10 transgenic back-cross mice that develop diabetes. As for EAE, the role of IL-10 in the pathogenesis of autoimmune diabetes is not clear at this time. Its effects may depend on timing, location, and dose of cytokine, along with contributions from other regulatory events.

E. Angiogenesis

IL-10 down-regulates the production of macrophage-derived angiogenic factors such as vascular endothelial growth factor (VEGF), IL-1β, TNFα, IL-6, and matrix metalloproteinase-9 (MMP-9), inhibits angiogenesis, and hence inhibits tumor growth and metastasis. IL-10 stimulates tissue inhibitor of metalloproteinase-1 (TIMP-1) production, inhibits MMP-2 and MMP-9 production, inhibits angiogenesis

in human prostate cancer cells *in vitro*, and significantly increases mouse survival after implantation with IL-10- and TIMP-1-expressing tumors *in vivo*. Transferring the IL-10 gene into Burkitt's lymphoma cells significantly reduces tumor formation in SCID mice, with IL-10 inhibiting VEGF-induced neovascularization and proliferation of microvascular endothelial cells. Local expression of vIL-10 in thrombosed veins decreases thrombosis-associated inflammation and inhibits the expression of cell adhesion molecules such as P- and E-selectin.

The role of IL-10 in angiogenesis has also been studied in a hindlimb ischemia model in IL-$10^{-/-}$ and IL-$10^{+/+}$ mice. In IL-$10^{-/-}$ mice, angiogenesis in the ischemic hindlimb is greatly increased and VEGF expression is also increased. After transferring IL-10 cDNA into IL-$10^{-/-}$ mice, angiogenesis and VEGF expression are significantly inhibited, suggesting an effect of IL-10 on angiogenesis via down-regulation of VEGF expression. Further experiments show that MMP-2 and MMP-9 are increased in the ischemic hindlimb in IL-$10^{-/-}$ mice, and the MMP inhibitor BB-94 abolishes the increase in vessel density and the blood perfusion index, suggesting a role for MMP in angiogenesis.

F. Transplant Rejection

IL-10 prolongs allograft survival in nonvascularized and vascularized transplantation in mice and rats. Adenovirus-mediated IL-10 gene transfer reduces allograft rejection in sheep corneal transplants. Cationic lipid-mediated hIL-10 gene transfer prolongs survival of allogeneic hepatocytes in rats. Intracoronary infusion of an adenoviral vector expressing IL-10 efficiently prolongs graft survival in rabbits. Injection of rhIL-10 down-regulates cytokine-induced neutrophil chemoattractant and prolongs liver allograft survival in rat orthotopic liver transplantation. Intraportal injection of an adenoviral vector expressing IL-10 significantly prolongs survival in orthotopic liver transplantation. IL-10/Fc fusion protein inhibits macrophage-mediated immune responses and prolongs pancreatic islet xenograft survival.

In contrast, infusion of IL-10 in murine recipients of allogeneic bone marrow grafts accelerates graft rejection and increases graft-versus-host disease (GVHD)-induced mortality. mIL-10 inhibits the proliferation of donor spleen cells in the mixed leukocyte reaction (MLR) assay, but cannot reduce morbidity and mortality from GVHD. Postoperative intraperitoneal administration of mIL-10 simulates B-cell and T-cell alloimmune responses and exacerbates allograft rejection in heterotopic vascularized heart transplantation in mice. Subconjunctival or intraperitoneal administration of mIL-10 does not prolong corneal allograft survival and even accelerates rejection.

Viral IL-10 encoded by Epstein–Barr virus BCRF1 open reading frame has the immunosuppressive activity of cellular IL-10 but lacks the immunostimulatory activity and is a more potent immunosuppressant. Plasmid-mediated or adenoviral-mediated vIL-10 gene transfer prolongs allograft survival in nonvascularized cardiac transplantation. Retroviral-mediated vIL-10 gene transfer also prolongs allograft survival, whereas murine IL-10 gene transfer does not prolong graft survival. Similar results are also observed in tumor rejection: vIL-10 inhibits the process of immune rejection in tumors and vIL-10-transduced tumors still grow, whereas mIL-10 causes tumor rejection and inhibits tumor growth. Hence, vIL-10 may act as a more effective therapeutic agent in transplant rejection.

G. Regulatory T Cells

It is currently believed that various types of T regulatory cells (Tr cells) are critical for the inhibition of T-cell responses to antigens and play an important role in immunological tolerance. Several types of Tr cells have been characterized in different experimental models, including Tr1 cells, CD4 + CD25 + cells, T_H3 cells, and others. IL-10 has been related to the differentiation and function of some Tr cells, especially Tr1 cells and CD4 + CD25 + cells.

Tr1 cells result from T-cell priming in the presence of IL-10 and IFNγ and produce large amounts of IL-10 and TGF-β, moderate levels of IFNγ and IL-5, and little or no IL-2 and IL-4. Tr1 cells exert regulatory effects via the production of IL-10 and TGF-β and down-regulate both T_H1 and T_H2 immune responses. The suppressive effects of Tr1 cells are reversed by the addition of anti-IL-10 and/or anti-TGF-β mAb.

CD4 + CD25 + cells comprise about 5–10% of peripheral T cells in naive mice and humans, constitutively express the α-chain of IL-2-receptor, and exert immune regulatory functions in a variety of immune assays. CD4 + CD25 + cells express IL-10 mRNA and secrete IL-10 protein, whereas CD4 + CD25 − cells do not express IL-10 mRNA, even after CD3 stimulation. Some reports have shown that the role of CD4 + CD25 + cells in the control of autoimmune diseases and inflammatory responses is

dependent on IL-10. For example, the production of IL-10 is essential for CD4 + CD25 + cells to prevent colitis in immunodeficient mice; IL-$10^{-/-}$ mice develop colitis in a conventional environment and Tr cells from IL-$10^{-/-}$ mice are not effective in preventing inflammation. However, the role of IL-10 in the inhibitory effect of CD4 + CD25 + cells remains controversial; other reports show that neutralization of IL-10 or IL-10R has no effect on the suppressive effect of CD4 + CD25 + cells.

VI. IL-10 SIGNALING

A. IL-10 Receptor Structure

The IL-10 receptor is a heterodimer composed of subunits known as IL-10 receptor 1 and IL-10 receptor 2); IL-10R2 was formerly known as orphan receptor CRF2-4. The human IL-10R1 gene has been mapped to chromosome 11q23.3. Human IL-10R1 messenger RNA is around 3.6 kb long and encodes a polypeptide of approximately 110 kDa. The predicted amino acid sequences of murine and human IL-10R1s are 60% identical and 73% similar. Although the human IL-10 receptor is species specific, murine IL-10 receptor binds both human and murine IL-10 with comparable affinity. The K_d of binding is in the range of 50–200 p*M*.

Sequence analysis and predicted structure revealed that IL-10 receptor is related to interferon receptors. The polypeptide was shown to be 578 amino acids long, with a putative signal peptide sequence of 21 amino acids, a 215-amino-acid extracellular domain, a transmembrane segment of 25 amino acids, and a cytoplasmic domain of 317 amino acids. Although the calculated molecular mass is approximately 61 kDa, the observed size is around 110 kDa, suggesting glycosylation on at least one extracellular site of the six identified.

Structurally, the extracellular portion of mIL-10R consists of two homologous segments of approximately 110 amino acids. A soluble form of the extracellular domain of hIL-10R1, sIL-10R1, has been cloned and expressed. The soluble receptor is capable of binding hIL-10 and inhibiting its biological activity. From the analysis of this binding, the stoichiometry of the ligand–IL-10R1 interaction has been determined. Crystallographic analysis of the sIL-10R1/IL-10 interaction reveals a complex consisting of two IL-10 dimers and four soluble IL-10R1s. The stoichiometry of the vIL-10:hIL-10R complex has been determined to be the same. Although the domains of sIL-10R1 are structurally similar to IFNγR1, the interdomain angle in sIL-10R1 is around 90°, which is more similar to cytokine class I receptors, rather than the 120° observed for cytokine class II receptors. The topology of each domain is closely related to FBN-III modules that form a sandwich from two antiparallel β-sheets.

B. Receptor Signaling

Functionally important regions of the intracellular domain of the murine IL-10R have been identified using deletion and substitution mutagenesis approaches. Two tyrosine residues (Tyr-427 and Tyr-477) have been found to be important in recruitment and activation of the signal transducer and activator of transcription protein Stat3, but not Stat1 or Stat5. Tyr-427 and Tyr-477 in the murine receptor correspond to Tyr-446 and Tyr-496 in their human counterpart. The sequences surrounding each of the conserved tyrosines have also been found to be highly conserved between murine and human receptors.

The first chain of the IL-10R is capable of binding the ligand on its own and possesses Stat recruitment sites, but it also requires a second chain for initiating a signaling pathway. The second chain of the receptor was originally identified as an orphan cytokine receptor (CRF2-4). The gene was mapped to chromosome 16 in mice and chromosome 21 in humans. The human gene spans more than 30 kb and encodes a 325-amino-acid protein that is 69% identical with its 349-amino-acid murine counterpart. The encoded protein is a transmembrane protein with a 19-amino-acid leader, an extracellular portion of 201 amino acids, a 29-amino-acid transmembrane domain, and a 76-amino-acid intracellular portion. The relatively close location of its gene to the IFNαR gene (less than 35 kb away) and its homology in structure to the interferon receptors suggest that the receptor protein belongs to the interferon class II cytokine receptor family and possibly plays a role in interferon signaling. Unlike IL-10R1, CRF2-4 is constitutively expressed in most cells and tissues and has not been found to be regulated by any stimuli. Interestingly, it has been shown that CRF2-4 also functions as a second chain of the receptor for IL-22, an IL-10 homologue. The importance of CRF2-4 receptor has been further demonstrated in CRF2-4 knockout mice. These mice are developmentally normal but they do not respond to IL-10 and develop chronic colitis and splenomegaly, similar to the IL-10 knockout models. The mice showed normal responses to interferon, suggesting that CRF2-4 is not obligatory for interferon signaling.

C. Jak–Stat Activation and Transcriptional Regulation

Stimulation of T cells and monocytes with IL-10 leads to assembly of the IL-10 receptor complex consisting of the ligand dimer, two IL-10R1 chains, and two IL-10R2 chains, which results in induced proximity between their respective associated Janus kinase (Jak) family members. IL-10R1 has been shown to associate with Jak1, whereas IL-10R2 is associated with Tyk2. Receptor assembly leads to tyrosine phosphorylation of Janus kinase family members Jak1 and Tyk2, but not Jak2 or Jak3. On assembly of the receptor complex, Janus kinases transphosphorylate each other and the intracellular domain of the IL-10R1, leading to recruitment of Stats, predominantly Stat3. Electrophoretic mobility-shift assays revealed that in all cell populations expressing IL-10 receptor, IL-10 stimulation results in activation of Stat1 and Stat3, whereas in pro-B cells expressing IL-10 receptor, Stat5 is also activated.

D. SOCS Regulation

IL-10 is an efficient stimulus for suppressor of cytokine signaling (SOCS-3)/CIS3 induction in neutrophils and monocytes. Incubation of monocytes with IL-10 results in inhibition of gene expression for several IFN-induced gene products, such as IP-10, ISG54, and ICAM-1. This correlates with suppression of IFNα-induced assembly of Stat factors to specific promoter motifs (ISRE and GAS elements) on IFNα- and γ-inducible genes and inhibition of tyrosine phosphorylation of Stat1. Because vanadate, a protein tyrosine phosphatase (PTP) inhibitor, had no effect on inhibition of Stat1 phosphorylation, the effect induced by IL-10 is probably not through SHP1 or other PTPs. Induction of SOCS proteins may therefore be involved in inhibition of interferon signaling. IL-10 has been found to suppress IFNα-activated Stat1 in the liver, possibly through induction of SOCS-2, SOCS-3, and CIS expression.

The IL-10 pathway may also be regulated by other pathways. For example, in addition to Stat3 tyrosine phosphorylation, phosphorylation of Stat3 at Ser-727 plays a role in regulation of transcription. Active MEK kinase 1 (MEKK1) is a mitogen-activated protein kinase kinase kinase (MAPKKK) that activates a c-Jun NH_2-terminal kinase signaling pathway and is induced by growth factors, cytokines, and environmental stress. MEKK1 carries out phosphorylation of Stat3 at Ser-727 *in vitro*, whereas *in vivo*, MEKK1 activates Src and Jak kinases, which phosphorylate Stat3 at Tyr-705. MEKK1 thus may be involved in modulation of IL-10 signaling by growth factors and environmental stress.

E. Downstream Genes

Signaling through the IL-10 receptor activates a number of genes that mediate both anti-inflammatory and proliferative effects induced by IL-10. Activated/memory T cells become refractory to TGF-β-mediated inhibition of proliferation through the down-regulation of the TGF-βRII. TGF-βR expression and inhibitory function can be restored on activated/memory T cells by addition of IL-10. IL-10 has been shown to down-regulate the expression of MHC class I and II complexes and ICAM-1, thus inhibiting human leukocyte antigen (HLA)-dependent antigen presentation and T-cell activation. In monocytes, IL-10 has also been shown to inhibit proliferation directly by up-regulating expression of $p19^{ink4D}$ and $p21^{cip}$. The $p19^{ink4D}$ promoter has been determined to have two Stat3 binding sites. Blocking Stat3 signaling with dominant negative Stat3 or mutant IL-10 receptor prevents induction of $p19^{ink4D}$, but it has no effect on $p21^{cip}$ expression, suggesting that $p21^{cip}$ is regulated through other signaling mechanisms. The antiproliferative effect of IL-10 on macrophages is also exerted through up-regulation of the CD95 receptor and ligand on the monocyte cell surface, leading to apoptosis, and through down-regulation of c-kit protooncogene expression, a protein tyrosine kinase that plays a role in hematopoiesis. In T cells, IL-10 has been shown to induce anergy through inhibition of tyrosine phosphorylation of CD28, thus preventing recruitment of phosphatidylinositol 3-kinase (PI3K) to the receptor.

The anti-inflammatory effects of IL-10 are mediated by down-regulation of production of pro-inflammatory cytokines, and inhibition of cellular responses to mediators of inflammation. In monocytes, IL-10 inhibits the production of IL-1 and TNFα and down-regulates the expression of IL-1RI and IL-1RII. In addition, IL-10 inhibits cyclooxygenase 2 (COX-2) expression in LPS-stimulated monocytes and accelerates degradation of COX-2 mRNA, thus controlling the inflammatory response at yet another level.

Glossary

IL-10R Interleukin-10 receptor complex, composed of the ligand-binding IL-10R1 and the signal-transducing IL-10R2 chains.

Jak–Janus kinase Signaling molecules that bind to the cytoplasmic region and are involved in IL-10R signal transduction.

SOCS Suppressor of cytokine synthesis; inhibitory molecules that bind to receptor docking sites, preventing Stat activation and inhibiting signal transduction.

Stat Kinase signaling molecules downstream of Jak; involved in IL-10R signal transduction and activation of transcription.

Interleukin-12 Family Members

MICHAEL T. LOTZE AND PAWEL KALINSKI
University of Pittsburgh

Interleukin-12 was originally identified as a T-cell-stimulating factor promoting T-cell activation, as a natural killer-stimulating factor enhancing cytolytic activity and interferon-γ production, and as a cytotoxic lymphocyte maturation factor promoting the acquisition of T-cell effector function with interleukin-2.

I. INTRODUCTION

Cloning of both of the subunits of interleukin-12 (IL-12), the p35 and p40 chains in both mouse and human, revealed the close homology of IL-12 to the IL-6 family of cytokines and receptors as well as the extended hematopoietin family. Recent identification

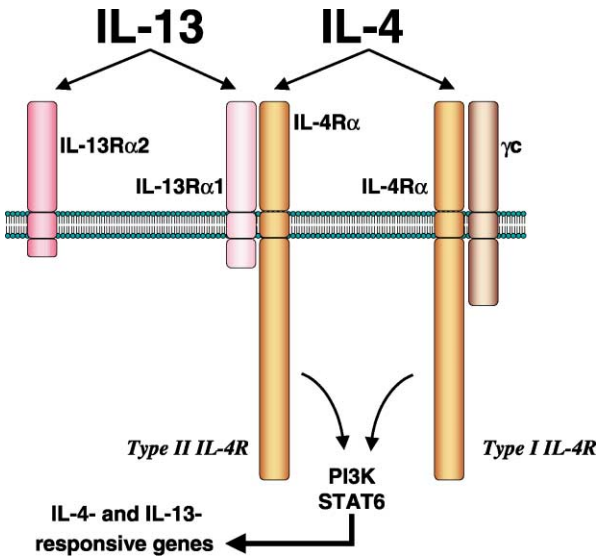

FIGURE 1 IL-13 and IL-4 receptor complexes. IL-13 binds to two different proteins, IL-13Rα1 and IL-13Rα2. IL-13 signaling requires interaction with a heterodimeric complex consisting of IL-4Rα and IL-13Rα1 chains, which is called type II IL-4R since it is also used by IL-4. IL-4 also signals through the type I IL-4R consisting of IL-4Rα and γc chains. The IL-13Rα2, despite having high affinity for IL-13, does not induce the activation of IL-13-responsive genes and acts as a decoy receptor.

and has potent anti-inflammatory effects *in vitro* and *in vivo*. Finally, IL-13 can promote the growth of certain tumors *in vitro* and *in vivo* either directly or indirectly by down-regulating tumor immunosurveillance mechanisms.

II. IL-13 PROTEIN AND IL-13 GENE

Human IL-13 is a cytokine with a molecular mass of ~12 kDa. Two functionally similar IL-13 isoforms consisting of 131 or 132 amino acids have been identified. Mouse IL-13 contains 131 amino acids and has 58% identity with its human homologue. IL-13 contains four potential N-glycosylation sites on four cysteine residues, which pair to form two intramolecular disulfide bonds. The genes encoding human or mouse IL-13 are located on the long arm of chromosome 5q31–q1 or the syntenic region of mouse chromosome 11, respectively, in the same 160 kb cluster of genes encoding IL-4 and IL-5. The IL-13 gene is only 12 kb upstream of the IL-4 gene and both genes together with the IL-5 gene are coordinately regulated in T helper 2 (T_H2) cells.

Polymorphisms in the coding and promoter regions of the IL-13 gene have been identified and are associated with asthma and atopic dermatitis in families belonging to different ethnic groups in Asia, Europe, and the United States. IL-13 protein has only approximately 25% homology with IL-4, but has many structural and functional properties in common with IL-4, which are determined by shared receptor components expressed on various cell types.

III. IL-13 RECEPTOR COMPLEXES

There are two human IL-13-binding proteins: IL-13Rα1 and IL-13Rα2 (Fig. 1). The IL-13Rα1 protein binds IL-13 with low affinity ($K_d \sim 4$ n*M*) but does not bind IL-4. IL-13Rα1 associates with the IL-4Rα chain (CD124) to form a high-affinity receptor that binds IL-13 with a K_d of 30 p*M*. The IL-4Rα chain alone binds IL-4 with relatively high affinity ($K_d \sim 100$ p*M*) but does not bind IL-13. These IL-4Rα/IL-13Rα1 heterodimeric complexes are expressed on many cell types, with a high level of expression in heart, liver, ovary, and skeletal muscle. IL-4Rα/IL-13Rα1 complexes are also expressed on human B cells, human and mouse monocytes/macrophages, basophils, eosinophils, mast cells, endothelial cells, fibroblasts, smooth muscle cells, and airway epithelial cells. In contrast, mouse and human T lymphocytes and mouse B lymphocytes do not express functional IL-13R. Furthermore, IL-4Rα/IL-13Rα1 complexes are also expressed on keratinocytes, ciliated respiratory epithelial cells, heart muscle cells, faveola cells, hepatocytes, gastric glands, sebaceous glands, and sweat glands.

The human IL-13Rα1 chain has 76% homology with mouse IL-13Rα1 at the protein level. The IL-4Rα/IL-13Rα1 complex can also serve as a functional IL-4R (type II IL-4R). This has been demonstrated with T and B cells from X-linked severe combined immunodeficiency patients who have defective common γ chains (γc). The γc is shared with IL-2, IL-4, IL-7, IL-9, and IL-15R and is required for signaling through these receptors. As a consequence, the lymphocytes of these patients do not respond to IL-2, IL-7, IL-9, or IL-15, which causes the severe defects in T- and B-cell functions observed in these patients. However, their B cells respond to IL-4 using the type II IL-4R, indicating that both IL-4 and IL-13 can signal through the IL-4Rα/IL-13Rα1 complex in the absence of a functional γc. This is consistent with the observation that IL-4 and IL-13 signal transduction in the absence of γc occurs in macrophages from γc-deficient mice.

The second IL-13R, IL-13Rα2, has 27% homology with the IL-13Rα1 chain and binds IL-13

with high affinity ($K_d \sim 50$ pM) in the absence of IL-4Rα. The genes encoding IL-13Rα1 and IL-13Rα2 are both located on the X chromosome. Human and mouse IL-13Rα2 proteins have 59% homology. The IL-13Rα2 has a very short intracytoplasmic tail, which lacks the domains required for signaling. This is probably the reason that binding of IL-13 to the IL-13Rα2 chain does not result in cell signaling. IL-13Rα2 is thought to function as a decoy receptor for IL-13. The IL-13Rα2 is expressed on various carcinomas including glioblastomas, ovarian carcinoma, renal carcinoma, pancreatic carcinoma, and acquired immunodeficiency syndrome-associated Kaposi's sarcoma and on fibroblast cell lines. In addition, soluble IL-13Rα2 can be detected in mouse serum. The IL-13Rα2 chain is not expressed at detectable levels on cells of the immune system and normal endothelium.

IV. IL-13 SIGNAL TRANSDUCTION

In hematopoietic cells, binding of IL-13 to the IL-13Rα1 chain results in its dimerization with the IL-4Rα chain and the activation of the Janus kinases JAK1 and tyrosine kinase 2. Subsequent tyrosine phosphorylation of the IL-4Rα chain and the 170 kDa insulin receptor substrate-2 (IL-4-induced phosphotyrosine substrate) provides a docking site for the Src homology 2 domain-containing 85 kDa subunit of phosphatidylinositol 3-kinase in lymphoid cells. This results in the recruitment, phosphorylation, dimerization, and nuclear translocation of signal transducer and activator of transcription 6 (STAT6) and the activation of IL-4-/IL-13-responsive genes in various cells expressing IL-4Rα/IL-13Rα1 chain complexes. IL-13-induced phosphorylation of the IL-4Rα chain and activation of STAT6 are also observed in nonhematopoietic cells such as endothelial cells, fibroblasts, and colon and ovarian carcinoma cells. The requirement for STAT6 in IL-13-mediated signaling was confirmed in STAT6-deficient mice that failed to respond to IL-13. In keratinocytes and lung fibroblasts, IL-13 can also induce the phosphorylation of STAT3.

V. IL-13 PRODUCTION

IL-13 is produced by many different cell types, including T cells, natural killer (NK) cells, NK-T cells, basophils, mast cells, eosinophils, and dendritic cells following activation. In mouse T cells, IL-13 production is restricted to the $CD4^+$ T_H2 and $CD8^+$ T cytotoxic 2 subset. In contrast, IL-13 is produced at relatively high levels by human T_H2 cells and also by T_H0 cells, T_H1 cells, $CD8^+$ T cells, and naive $CD45RA^+$ T cells, albeit at lower levels. Since IL-13 is produced by all single IL-4-producing cells, IL-13 is considered primarily a T_H2 cytokine.

IL-13 production by T cells is further enhanced by IL-4, IL-18, and IL-25. However, IL-4 is not absolutely required for IL-13 production, because IL-4-deficient mice are able to produce IL-13. Production of IL-13 by activated mast cells and basophils following cross-linking of the high-affinity receptor for Immunoglobulin E (FcεRI) likely contributes to the initiation and maintenance of allergic inflammatory responses. IL-13 is also produced by Epstein-Barr virus-transformed B cells, B-cell lymphomas, keratinocytes, Hodgkin/Reed-Sternberg cells, and pancreatic carcinoma cells.

VI. IMMUNOSTIMULATORY AND PROINFLAMMATORY EFFECTS OF IL-13 *IN VITRO*

Like all other cytokines, IL-13 has pleiotropic effects on many different cell types including B cells, monocytes/macrophages, dendritic cells, eosinophils, endothelial cells, synoviocytes, epithelial cells, fibroblasts, smooth muscle cells, and various tumor cells. However, IL-13 does not act on mouse or human T cells. In contrast to IL-4, IL-13 does not support T-cell proliferation and fails to drive the differentiation of naive human $CD4^+$ T cells toward a T_H2 phenotype, which is consistent with the absence of functional IL-13R on these cells.

IL-13 modulates the phenotype of human B cells by up-regulating CD23, CD71, CD72, CD80, CD86, major histocompatibility complex (MHC) class II molecules, and surface immunoglobulin M (IgM). IL-13 has also growth-promoting effects on human B cells stimulated by anti-IgM or anti-D40 monoclonal antibodies (mAbs). IL-13 enhances the production of IgM, IgG, and IgA by human B cells stimulated with anti-CD40 mAbs or CD40 ligand and induces these B cells to switch to IgG4 and IgE synthesis independently of IL-4. Allergen-specific IgE binds to FcεRI on mast cells and basophils. Binding of allergen to receptor-bound IgE results in FcεRI triggering and activation of these cells, leading to the release of mediators of allergic inflammation such as histamines, prostaglandins, leukotrienes, and proinflammatory cytokines. These data indicate that IL-13 may play a role in IgE-mediated allergic diseases (Fig. 2).

IL-13 modulates the phenotype of both human and murine monocytes/macrophages. It up-regulates the expression of various adhesion molecules on

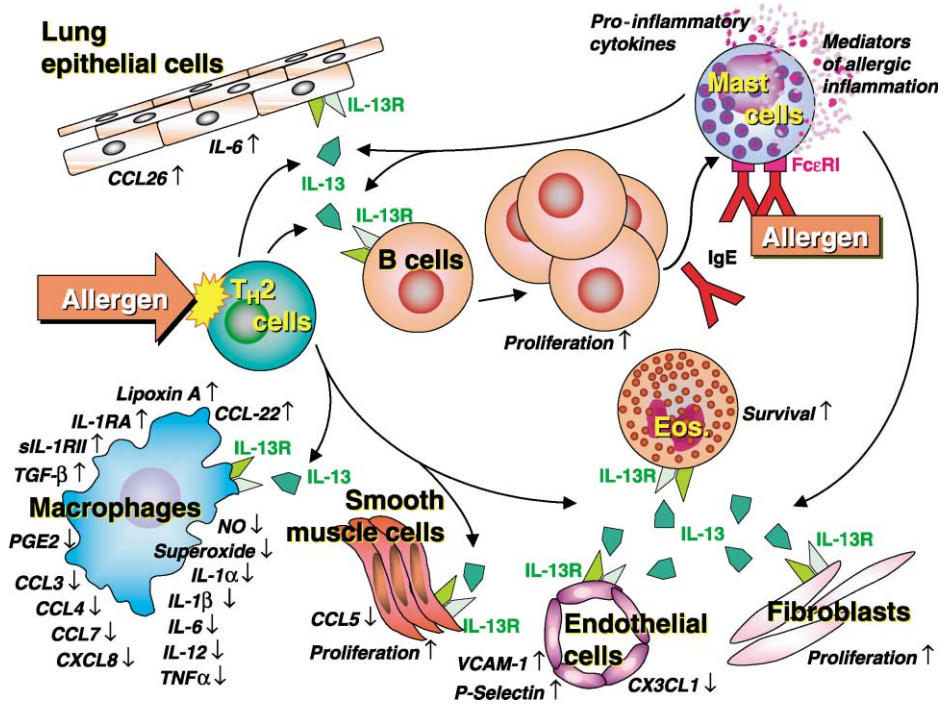

FIGURE 2 Effects of T_H2 cell-secreted IL-13 on various target cells. IL-13, produced by T_H2 cells following specific stimulation (i.e., with allergens), has stimulatory/pro-inflammatory effects on B cells, eosinophils, lung fibroblasts, lung epithelial cells, vascular endothelial cells, lung smooth muscle cells, mast cells, and basophils (not shown). Allergen-activated mast cells (and basophils) release mediators of allergic inflammation, including IL-13, which further exacerbate T_H2 responses (i.e., allergic asthma). On the other hand, IL-13 has anti-inflammatory effects on activated monocyte/macrophages. IL-13-induced changes are indicated in the figure by arrows: up-regulation (↑); down-regulation (↓).

monocytes including CD11b, CD11c, CD18, CD29, and CD49e, suggesting that IL-13 contributes to enhanced extravasation and migration of these cells to sites of inflammation. In addition, IL-13 enhanced the expression of MHC class II molecules and the expression of CD80 and CD86, the ligands for CD28 on T cells, resulting in an enhanced T-cell-stimulating capacity. IL-13 induces the expression of the low-affinity receptor for IgE (CD23) on monocytes, which directs allergen complexes to allergen-specific T cells, thereby enhancing allergic responses *in vitro*. IL-13 enhances the production of the chemokine CCL22 (macrophage-derived chemokine) by monocytes and dendritic cells. Since CCL22 preferentially attracts skin homing T_H cells, this effect of IL-13 may exacerbate cutaneous inflammatory T_H2 processes such as those found in atopic dermatitis. IL-13 directly acts as a chemoattractant for human monocytes. It also enhances the chemotaxis of these cells through up-regulation of the chemokine receptors CXCR1 and CXCR2. Up-regulation of the leukotriene D4 (LTD4) receptor by IL-13 results in enhanced chemotactic responses toward LTD4, which is implicated in bronchoconstriction, mucus production, and chronic airway inflammation in asthma.

IL-13 induces vascular cellular adhesion molecule-1 (VCAM-1) and P-selectin expression on human umbilical vein endothelial cells, which induces adhesion and the subsequent extravasation of eosinophils, T lymphocytes, neutrophils, and monocytes. IL-13 also induces lung epithelial cells and nasal and dermal fibroblasts to produce CCL26 (eotaxin-3), which is a potent chemoattractant for eosinophils in the airways and skin. IL-13 also prolongs the survival of eosinophils directly or through up-regulation of granulocyte/monocyte colony-stimulating factor production by lung epithelial cells. Accumulation of eosinophils at sites of allergic inflammation plays an important role in the pathogenesis of asthma, emphasizing the role of IL-13 in this process. This notion is further supported by the observation that IL-13 inhibits the production of the chemokine CX3CL1 (Fractalkine) by activated vascular

endothelial cells, which reduces the recruitment of NK cells and T_H1 cells and the amplification of polarized T_H1 responses, thereby favoring the development of T_H2-dominated allergic inflammatory responses.

IL-13 interacts directly with primary epithelial cells, fibroblasts, and smooth muscle cells isolated from human lung and induces profound changes of virtually nonoverlapping gene expression profiles in these three airway cell types. In addition, IL-13 promotes the proliferation of lung fibroblasts and lung smooth muscle cells. IL-13 also acts on human mast cells by inducing c-fos and up-regulating intercellular adhesion molecule-1 (ICAM-1) expression, contributing to the activation, enhanced adhesion, and extravasation of these cells. The production of the pro-inflammatory cytokine IL-6 by human microglial and epithelial cells is enhanced by IL-13 (Fig. 2).

VII. IMMUNOSUPPRESSIVE AND ANTI-INFLAMMATORY EFFECTS OF IL-13 *IN VITRO*

In addition to the immunostimulatory and pro-inflammatory activities associated with allergic inflammatory disorders, IL-13 has important immunosuppressive and anti-inflammatory activities. IL-13 inhibits the production of the pro-inflammatory cytokines IL-1α, IL-1β, IL-6, and tumor necrosis factor α (TNFα), the pro-inflammatory chemokines CXCL8 (IL-8), CCL3 (macrophage inflammatory protein 1α, MIP-1α), CCL4 (MIP-1β), and CCL7 (monocyte chemoattractant protein 3), and the chemokine receptor CXCR4 by activated monocytes, alveolar macrophages, and synovial macrophages from patients with rheumatoid arthritis. IL-13 also inhibits IL-12 production by activated monocytes, but priming of these monocytes prior to activation resulted in increased IL-12 production. In contrast, IL-13 enhances the production of the IL-1 receptor antagonist (IL-1RA) and the release of soluble type II IL-1R (sIL-1RII) from activated monocytes and neutrophils. Both IL-1RA and sIL-1RII have anti-inflammatory activities by functioning as IL-1 antagonists (Fig. 2).

The anti-inflammatory effects of IL-13 are further exemplified by its capacity to down-regulate either directly or indirectly various mediators of inflammation. For example, IL-13 induces the expression of 15-lipoxygenase, which catalyzes 15-(*S*)-hydroxy-eicosatetraenoic acid and lipoxin A, both of which inhibit the production of pro-inflammatory leukotrienes. In addition, IL-13 inhibits the function of prostaglandin E2 from arachidonic acid through inhibition of cyclooxygenase induction by activated monocytes. IL-13 also inhibits nitric oxide and superoxide anion production by murine macrophages and activated human monocytes, respectively.

IL-13 down-regulates the expression of the Fcγ receptors CD16, CD32, and CD64 on human monocytes. Down-regulation of CD64 expression correlated with decreased antibody-dependent cellular cytotoxicity. IL-13 may also inhibit the production of CCL5 (regulated on activation of normal T cell expressed and secreted, RANTES) by airway smooth muscle cells, airway epithelia, and endothelial cells. CCL5 is a ligand for CCR3 and CCR5 expressed on T_H2 cells, eosinophils, and monocytes and is a potent chemoattractant for these cells.

VIII. BIOLOGICAL EFFECTS OF IL-13 *IN VIVO*

Both immunostimulatory/pro-inflammatory and immunoprotective/anti-inflammatory effects of IL-13 have been observed *in vivo*.

A. The Role of IL-13 in Asthma

It is well established that IL-13 levels are up-regulated in the lungs, blood, and bronchial alveolar lavage fluid of asthmatic patients. In addition, IL-13 mRNA and IL-13 protein expression levels are enhanced in bronchial biopsies from asthmatic patients. IL-13 levels are also up-regulated in allergic asthma patients following allergen challenge. These observations suggest that IL-13 is associated with human asthma. This notion is supported by several lines of evidence indicating that IL-13 plays a central role in experimental asthma models in mice.

Delivery of IL-13 into the airways causes airway hyperresponsiveness, mucus overproduction, eosinophilia, and airway inflammation, phenomena that reflect the hallmarks of asthma. IL-13 failed to induce this asthma phenotype in IL-4Rα- and STAT6-deficient mice, indicating that IL-13 signaling through the IL-4Rα/IL-13Rα1 complex and subsequently through STAT6 is necessary for the induction of allergic inflammation.

Transgenic mice in which IL-13 is selectively expressed in the lungs developed a comparable asthma phenotype with pulmonary inflammation, infiltrating T_H2 lymphocytes, eosinophils, and macrophages, airway epithelial cell hypertrophy, goblet cell hyperplasia, and enhanced mucus production. In addition, airway fibrosis, airway hyperresponsiveness, and high levels of eotaxin

production are observed in these mice. Enhanced eotaxin production together with IL-5 produced by the infiltrating T_H2 cells is responsible for the airway eosinophilia.

The IL-13-induced airway and peribronchial fibrosis (which is comparable to fibrotic responses observed in remodeled asthmatic airways in human) is in large part mediated through transforming growth factor-β1 (TGF-β1). IL-13 overexpressed in the lungs induces TGF-β1 production predominantly by macrophages. In addition, IL-13 converts latent TGF-β1 to its active form *in vivo*. The pro-fibrotic effects of TGF-β1 were considerably reduced by treatment with soluble TGF-βR, demonstrating that IL-13-induced lung fibrosis is for the most part indirectly mediated by TGF-β1.

IL-13 overexpression in the lungs of STAT6-deficient mice did not result in any pulmonary pathology, confirming that IL-13 signaling through STAT6 is required for the development of the asthma phenotype. Interestingly, reconstitution of STAT6 only in lung epithelial cells is sufficient to restore IL-13-induced airway hyperresponsiveness and mucus overproduction, indicating that the direct effects of IL-13 on lung epithelial cells are sufficient to induce these two hallmarks of asthma. However, restoration of alveolar inflammation and fibrosis was not observed in these mice. Furthermore, these data indicate that IL-13 induces airway hyperresponsiveness independent of inflammation, eosinophilia, subepithelial fibrosis, and airway smooth muscle layer thickening and that the effects of IL-13 on cells other than epithelial cells are required for the development of these pathological processes associated with experimental asthma.

Mice with allergen- or fungus-induced experimental asthma have enhanced levels of IL-13. Blockade of these enhanced endogenous levels of IL-13 by administration of soluble IL-13Rα2, which neutralizes specifically IL-13, and not IL-4, inhibits airway hyperreactivity, goblet cell hyperplasia, and mucus overproduction. IL-13 blockade also inhibits asthma in guinea pigs and dogs. Thus, IL-13 plays a critical role in inducing the asthma phenotype, and compared to IL-4, IL-13 is the dominant cytokine in inducing mucus hypersecretion and airway hyperresponsiveness through direct effects on lung epithelial cells.

In addition to its critical role in asthma, IL-13 expressed in an inducible way in adult murine lungs can cause emphysema, which mirrors human chronic obstructive pulmonary disease. This targeted expression of IL-13 in lung epithelial cells results in enhanced lung volumes and pulmonary compliance, mucus metaplasia, and macrophage-, lymphocyte-, and eosinophil-rich inflammation. Local overproduction of IL-13 induced the expression of matrix metalloproteases (MMPs)-2, -9, -13, and -14 and cathepsins B, S, L, H, and K in lung tissues. Treatment of these mice with a broad-spectrum MMP antagonist or cysteine protease inhibitors strongly reduced lung volume and inflammatory cell influx but had no effect on mucus metaplasia. These data indicate that MMP- and cathepsin-dependent pathways play an important role in IL-13-induced emphysema, but that IL-13, in this setting, utilizes different pathways for induction of airway mucus metaplasia.

B. The Role of IL-13 in Intestinal Nematode Infections

IL-13 has protective effects on mice infected with the gastrointestinal nematodes *Nippostrongylus brasiliensis*, *Ticheris muris*, and *Trichinella spiralis* and induces the expulsion of these worms. IL-13 fails to expel nematodes in IL-4Rα chain- and STAT6-deficient mice, indicating that signaling through IL-4Rα/IL-13Rα1 and STAT6 is required for worm clearance. This signaling pathway is utilized by both IL-4 and IL-13, but studies using an IL-13 antagonist or IL-4- and IL-13-deficient mice have shown that IL-13 is the dominant cytokine for the expulsion of *N. brasiliensis*, whereas either IL-4 or IL-13 suffices to expel *T. spiralis*. Both IL-13 and IL-4 are necessary to clear *T. muris*. The mechanisms underlying nematode expulsion are complex and not fully understood and differ for various nematodes. They include IL-13-induced increased mucus production, enhanced intestinal smooth muscle cell contractility, and activation of mast cell-mediated effector mechanisms.

Although IL-13 provides protection from nematode infections, this protective immunity also causes inflammatory responses, which can be detrimental to the host and are particularly of clinical importance when they develop in the lungs or in the liver. The damaging effect of IL-13 in chronic infections has been illustrated in a mouse model for *Schistosoma mansoni* infection. Mice infected with this helminth develop lung and liver granulomas, which contain large numbers of infiltrating T_H2 cells and eosinophils. Treatment with an IL-13 antagonist results in a reduction in granuloma size and eosinophilia, whereas nearly complete inhibition is observed in IL-4-deficient mice, indicating that both IL-4 and IL-13 contribute to granuloma formation and eosinophilia. However, hepatic fibrosis developing in *S. mansoni*-infected mice is strongly blocked by an IL-13

antagonist, indicating that compared to IL-4, IL-13 is the dominant cytokine responsible for induction of fibrosis associated with chronic infectious diseases.

C. Protective Effects of IL-13 in Autoimmune Diseases

IL-13 down-regulates inflammatory responses by activated monocytes and macrophages. IL-13 also inhibits the production of the pro-inflammatory cytokines IL-1β and TNFα by synoviocytes from patients with rheumatoid arthritis. IL-13 is also effective in the treatment of experimental arthritis *in vivo*. Injection of cells genetically engineered to produce IL-13 reduces the severity and the incidence of collagen-induced arthritis in mice. The beneficial effects of IL-13 in this disease model correlated with reduced TNFα production in the spleen. A similar approach had positive effects on experimental autoimmune encephalomyelitis (EAE). IL-13 reduced the mean duration, severity, and incidence of the disease. These protective effects were mediated by the anti-inflammatory activity of IL-13 on macrophages, which resulted in down-regulation of the disease causing T_H1 responses. IL-13 also inhibits TNFα-induced lung inflammation in guinea pigs and reduces acute lung inflammatory injury induced by intrapulmonary deposition of IgG immune complexes in rats by reduction of TNFα and CXCL2 (MIP-2α) production, ICAM-1 expression, and neutrophil recruitment in the lung. In addition, IL-13 administration reduced the intravascular leak of albumin in this model. Exogeneously administered recombinant IL-13 also increases survival in murine models of endotoxic shock by reducing excessive inflammation and circulating TNFα levels.

IX. EFFECTS OF IL-13 ON TUMOR CELLS

IL-13 is an autocrine growth factor for cutaneous T-cell lymphomas and Hodgkin's lymphoma/Reed-Sternberg cells. Blocking IL-13 activity inhibits the proliferation of these cells *in vitro*. On the other hand, the growth of other types of tumor cells such as gliomas and renal cell carcinomas is inhibited both by IL-13 and IL-4 and requires signaling through the IL-4Rα/IL-13Rα1 chain. These *in vitro* growth inhibitory effects of IL-13 are overcome by transfection of the IL-13Rα2 chain in these cells, which acts as a nonsignaling decoy receptor. In contrast, growth of human breast or pancreas tumor cells expressing high levels of IL-13Rα2 following transfection in immune-deficient mice was strongly inhibited by neutrophil-mediated anti-tumor activity. Restoration of tumor growth was observed on loss of IL-13Rα2 expression. IL-13 has also indirect effects on tumor growth by modulating the immune response. IL-13 produced by NK-T cells inhibited immunosurveillance mechanisms that provided protection from tumor recurrence. Since certain tumors such as gliomas, renal cell carcinomas, and ovarian carcinomas express high levels of the IL-13Rα2 chain, which binds IL-13 with high affinity, the use of IL-13 as a vehicle to deliver cytotoxic compounds into tumors is being explored as a therapeutic modality for these types of cancers.

X. SUMMARY

IL-13 plays an important role in the induction and maintenance of allergic inflammatory processes associated with experimental asthma. IL-13 induces airway hyperreponsiveness, goblet cell hyperplasia, enhanced mucus production, pulmonary inflammation with infiltrating T_H2 lymphocytes, macrophages, and eosinophils, enhanced IgE production, and, on a more chronic basis, airway fibrosis via signaling through the IL-4Rα/IL-3Rα1 complex (type II IL-4R) and the STAT6 pathway. Because IL-13 utilizes the type II IL-4R, it shares many (but not all) of its biological activities with IL-4. However, IL-13 also has clearly distinctive properties. IL-13 is, compared to IL-4, the dominant cytokine inducing airway hyperresponsiveness and mucus overproduction in allergen- or fungus-induced experimental asthma in mice. These effects of IL-13, which represent two of the hallmarks of asthma, are mediated by direct effects on lung epithelial cells. IL-13 is also the dominant cytokine in inducing lung fibrosis, which is largely mediated through the *in vivo* induction and activation of TGF-β. Another major difference between IL-13 and IL-4 is that IL-13, in contrast to IL-4, fails to induce naive human T cells to differentiate into T_H2 cells, which is related to the fact that human and mouse T cells do not express functional IL-13R. Since T_H2 responses are critical for the induction of allergic inflammation and asthma, IL-4 must be considered the dominant cytokine for the induction phase of asthma, whereas IL-13 plays a major role in the effector phase. Both IL-4 and IL-13 are probably required for the maintenance of allergic asthma, but the relative contribution of each of these cytokines in allergic disease and asthma in human remains to be established.

IL-13 also has anti-inflammatory effects *in vitro* and *in vivo*. It down-regulates pro-inflammatory

cytokine and chemokine production by activated monocytes and macrophages *in vitro*. In addition, IL-13 has protective effects in models of rheumatoid arthritis, EAE, and acute lung inflammatory injury. Exogeneously administered IL-13 also increases survival in murine models of endotoxin-induced shock. The beneficial effects of IL-13 in these disease models are mediated through down-regulation of excessive inflammation and inhibition of *in vivo* TNFα production. In addition, IL-13 protects against gastrointestinal nematode infections; in particular, the expulsion of *N. brasiliensis* is solely dependent on IL-13. This protective immunity is associated with excessive inflammatory responses, which in a *S. mansoni* infection model in mice result in lung and liver granulomas and fibrosis, which are predominantly mediated by IL-13. Generally, the most significant function of IL-13 (which distinguishes it from IL-4) is its capacity to regulate the functions of epithelial cells, smooth muscle cells, and fibroblasts on mucosal surfaces. Finally, IL-13 can directly or indirectly affect tumor cell growth. It functions as an autocrine growth factor for T-cell lymphomas and Hodgkin/Reed-Sternberg cells *in vitro*. In addition, endogenously produced IL-13 down-regulates immunosurveillance, resulting in enhanced tumor growth and tumor recurrences in a mouse tumor model.

Based on the current knowledge, it is clear that inhibition of IL-13 would provide a novel way to intervene in allergic asthma, granuloma formation, fibrosis associated with chronic inflammations or nematode infections, and fibrotic diseases in general. In addition, anti-IL-13 therapy could have potential benefits in the treatment of T-cell and Hodgkin's lymphomas and in enhancing tumor immunosurveillance. The large-scale availability of specific IL-13 antagonists such as anti-IL-13 or anti-IL-4Rα chain mAbs or soluble IL-13Rα2 for the treatment of human disease will in the near future allow final conclusions on the role of IL-13 in health and disease to be reached.

Glossary

airway hyperresponsiveness Exaggerated bronchoconstrictor response to a wide variety of endogenous and exogenous stimuli. Airway hyperreactivity is generally assessed by inhalation challenge with metacholine or histamine.

asthma Chronic inflammatory disorder of the airways characterized by recurrent episodes of wheezing, breathlessness, chest tightness, and coughing in response to physical, chemical, or immunological stimuli. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible. The inflammation also causes an associated increase in the existing bronchial hyperresponsiveness. Asthma is frequently associated with atopy.

chemokines Small proteins characterized by the presence of a four-cysteine motif in their primary structure and by their ability to promote chemotactic responses in leukocytes. Chemokines are divided into subclasses (CCL, CXCL, and CX3CL) on the basis of the spacing between their two conserved N-terminal cysteine residues (adjacent cysteines; cysteines separated by a single amino acid; and cysteines separated by three amino acids, respectively). XCL1 is an exceptional chemokine since it lacks two cysteines. Chemokines exert their functions by binding G-protein-coupled seven-transmembrane receptors.

T helper 2 response Reaction of the immune system to certain antigens such as allergens and infectious helminths that results in the generation of memory $CD4^+$ T-cell populations secreting high levels of the cytokines IL-4, IL-5, IL-10, and IL-13 but little or no IL-2 and interferon-γ. T_H2 cells are excellent helpers for B-cell antibody synthesis and promote allergic reactions.

Interleukin-15

THOMAS A. WALDMANN

National Cancer Institute, National Institute of Health, Maryland

Interleukin 15 (IL-15) is a 14 to 15 kDa glycoprotein that is a member of the four-α-helix-bundle family of cytokines. There is widespread expression of IL-15 mRNA in a number of tissues including placenta, skeletal muscle, heart, lung, kidney, fibroblasts, and activated monocytes. IL-15 plays a role in natural killer cell differentiation, T-cell functions, and the host response to intracellular pathogens. Abnormalities of IL-15 expression have been reported in a variety of inflammatory, autoimmune, and neoplastic diseases.

I. INTRODUCTION

Interleukin 15 (IL-15) is a 14 to 15 kDa member of the four-α-helix bundle family of cytokines that is involved in natural killer (NK) cell differentiation, T-cell functions, and the host response to intracellular pathogens. In May 1994, two groups simultaneously described the cytokine, now known as IL-15, based on the ability of culture supernatants from two cell lines, CV-1/EBNA and the human T-cell lymphotropic virus I (HTLV-I)-associated HuT-102 cell line, to stimulate the proliferation of the cytokine-dependent murine T-cell line CTLL-2. As a part of an analysis of the cytokines produced by the retrovirus HTLV-I-associated adult T-cell leukemia cell line, Burton and co-workers reported purifying a NK and T-cell stimulatory cytokine. Simultaneously, the group of Grabstein and co-workers, by analysis of the cell line CV-1/EBNA, identified the same cytokine, IL-15. IL-15 expression is controlled at the levels of transcription, translation, and intracellular trafficking. In particular, in contrast to most cytokines, IL-15 is posttranscriptionally regulated by multiple controlling elements that impede its translation including 11–13 upstream AUGs of a long, >500-nucleotide 5′-untranslated region (5′-UTR), two unusual signal peptides, and the C-terminus of the mature protein. IL-15 uses two distinct receptor and signaling pathways. In T and NK cells, the receptor for IL-15 includes IL-2Rβ and γc subunits, which are shared with IL-2, as well as an IL-15-specific receptor subunit, IL-15Rα. Mast cells respond to IL-15 with a distinct receptor system that does not share elements with the IL-2 receptor. IL-15 plays a pivotal role in the development, survival, and function of NK cells. Although IL-2 and IL-15 share two receptor subunits and many functions, especially in innate immunity, at times they provide distinct and contrasting contributions to T-cell-mediated immune responses. IL-2, through its pivotal role in activation-induced cell death (AICD), is involved in peripheral tolerance through the elimination of self-reactive T cells. In contrast, in general, IL-15 manifests anti-apoptotic actions and inhibits AICD and stimulates the persistence of memory phenotype $CD8^+$ T cells. Abnormalities of IL-15 expression

have been reported in inflammatory, autoimmune, and neoplastic diseases. In particular, abnormally high levels of IL-15 transcription and translation are observed in HTLV-I-associated diseases such as the neurological disorder tropical spastic paraparesis/HTLV-I-associated myelopathy (TSP/HAM). Furthermore, abnormalities of IL-15 expression have been noted in patients with autoimmune diseases such as rheumatoid arthritis and inflammatory bowel disease. Therapeutic agents are being developed to target the receptor and signaling elements shared by IL-2 and IL-15 to provide effective treatment for such autoimmune disorders as well as the leukemia/lymphoma associated with the retrovirus HTLV-I.

II. THE STRUCTURE AND GENOMIC ARCHITECTURE OF IL-15

IL-15 is a 14 to 15 kDa glycoprotein that is a member of the four-α-helix bundle cytokine family. The cDNA defining IL-15 encodes a 162 aa peptide with a 48 aa leader sequence yielding a 114 aa mature protein. Two disulfide cross-links are present at Cys-42–Cys-88 and Cys-35–Cys-85. The predicted folding topology of IL-15 suggests three loops connecting the four helices in an up-up-down-down configuration. The IL-15 gene maps to chromosome 4q31 (human) and to the central region of chromosome 8 (mouse). The IL-15 gene consists of nine exons (exons 1–8 and a newly discovered exon 4a). This exon–intron organization contrasts with the four-exon–three-intron architectural pattern observed with IL-2, IL-4, IL-5, and IL-13.

Human IL-15 mRNA contains a 5′-UTR of at least 500 nt, a mature protein coding sequence of 486 nt, and a 3′-UTR of at least 400 nt. There are two alternative leader peptides, one containing 48 aa and one with 21 aa. The classical long (48 aa) signal peptide that is associated with all secreted IL-15 proteins is encoded by exons 3, 4, and 5 of the human IL-15 gene. The short 21 aa signal peptide is encoded by exon 5 and by an additional 119 nt sequence inserted between exons 4 and 5 (new exon 4a). The two signal peptides share 11 amino acids encoded by exon 5. The introduction of the 119 nt of exon 4a disrupts the 48 aa signal sequence by inserting a premature termination codon and then provides an alternative initiation codon. IL-15 associated with the short 21 aa signal peptide is not secreted but rather is stored intracellularly, appearing in the cytoplasm and nucleus.

III. THE REGULATION OF IL-15 EXPRESSION

A. Regulation of Transcription

IL-2 and IL-15 exhibit major differences in terms of the levels of control of their synthesis and secretion and in terms of their sites of synthesis. IL-2 is produced by activated T cells and its expression is regulated predominantly at the levels of mRNA transcription and message stabilization. In contrast, there is widespread constitutive expression of IL-15 mRNA in a variety of tissues including placenta, skeletal muscle, kidney, lung, heart, fibroblasts, and activated monocytes.

The regulation of IL-15 expression is multifaceted. Modest control occurs at the level of transcription, whereas a dominant control occurs posttranscriptionally at the levels of translation and intercellular trafficking. In terms of transcriptional control, freshly isolated monocytes express a very low level of IL-15 mRNA that is up-regulated when the monocytes are activated with IFN-γ. In addition, infection of monocytes with herpes virus 6 or 7, *Bacillus Calmette-Guerin* (BCG), *Mycobacterium tuberculosis*, *Toxoplasma gondii*, *Mycobacterium leprae*, or *Candida albicans* is associated with an up-regulation of IL-15 mRNA expression. A series of conserved motifs between mouse and human IL-15 5′ regulatory regions, including the transcriptional motifs, nuclear factor κB (NF-κB), interferon regulatory factor-element (IRFE), myb, NF-IL-6, and interferon-α2 (IFN-α2), has been identified. It was demonstrated through the use of a series of reporter assays involving IL-15 promoter deletion mutants that the IRF-E motif is critical for the activation of the IL-15 promoter. Another transcription factor that appears to play an important role in IL-15 transcription is NF-κB acting on an NF-κB motif adjacent to the IRF-E motif.

B. Posttranscriptional Regulation of IL-15 Synthesis

IL-15 is predominantly regulated posttranscriptionally at the levels of translation and intracellular trafficking. Although IL-15 mRNA is widely expressed constitutively, it has been difficult to demonstrate IL-15 within the cells or the supernatants of cells that express such IL-15 mRNA. There are multiple controlling elements that impede IL-15 mRNA translation. Initial studies focused on the 5′-UTR of IL-15 mRNA. In general, the 5′-UTRs of effectively translated messages are short, simple, and unencumbered by AUGs upstream of

the initiation AUG. In contrast to this pattern, the 5′-UTR of the message encoding IL-15 is long and quite complex and includes multiple upstream AUGs (11 or 13 in different human isoforms of the UTR). Kozak emphasized that the presence of such AUGs in the 5′-UTR of mRNAs may drastically reduce the efficiency of their translation. Cells transfected with IL-15 constructs with the 5′-UTR deleted produced approximately 12- to 15-fold more IL-15 than cells transfected with the wild-type construct. Furthermore, using expression constructs that exchanged the signal peptide coding sequences and initiation ATGs of IL-2 with those of IL-15 linked to the alternative mature protein coding sequence, it was shown that the IL-15 long signal peptide was an important factor in the negative regulation of IL-15 expression. Finally, a third negative element was shown to exist in the C-terminus of the IL-15 mature coding sequence or protein. These multiple negative regulatory features controlling IL-15 expression may be required in light of the potency of IL-15 as an inflammatory cytokine that stimulates the expression of tumor necrosis factor α (TNFα), IL-1β, and inflammatory chemokines, which, if indiscriminately expressed, could lead to inflammatory autoimmune diseases. In terms of a more positive role for IL-15, by maintaining a pool of translationally inactive mRNA, cells may respond rapidly to an intracellular infection by transforming the IL-15 mRNA into a form that can be translated effectively, yielding secreted IL-15 that may activate T and NK cells, which could then aid in the host response to the invading pathogen.

C. Intracellular Trafficking of IL-15

The two isoforms of IL-15 generated by usage of alternative signal peptides have different intracellular trafficking patterns. The isoform with the short (21 aa) putative signal peptide is not secreted but appears in nuclear and cytoplasmic compartments, suggesting a biological function for this isoform of IL-15 as an intracellular molecule. The IL-15 associated with the long 48 aa signal peptide is translocated into the endoplasmic reticulum (ER). On translocation, the 48 aa signal peptide may be completely processed or alternatively processed, leaving a residual 3′ element of the signal peptide linked to the mature coding sequence. This latter signal element contains a conserved retention sequence that impedes the trafficking of IL-15 from the ER to the Golgi. Thus, there are impediments to intracellular trafficking that in addition to the impediments to translation are involved in the negative regulation of the synthesis and secretion of IL-15.

IV. IL-15 RECEPTOR AND SIGNAL TRANSDUCTION PATHWAYS

IL-15 uses two receptor and signaling pathways. The type I receptor expressed in T and NK cells is made up of three membrane components. Two of these components, IL-2β and γc, are shared with IL-2; the γc is also shared with IL-4, IL-7, IL-9, and IL-21. In addition, the two cytokines have their own unique cytokine-specific α chains, IL-15Rα for IL-15 and IL-2Rα for IL-2. The IL-15Rα chain, the unique chain of IL-15, is a type 1 membrane protein with a signal peptide of 32 aa, a 173 aa extracellular domain, a single membrane-spanning region of 21 aa, as well as alternative 37 to 41 aa and 21 aa cytoplasmic domains. In contrast to the IL-2Rβ and γc chains, IL-15Rα is not a member of the cytokine receptor superfamily. However, IL-2Rα and IL-15Rα may constitute their own family. IL-15Rα and IL-2Rα have a similar intron–exon organization. Moreover, they are closely linked in both the human (10p15–p14) and the murine genomes (chromosome 2). IL-15 combines with IL-15Rα with a K_d (dissociation constant) of 10^{-11} M, a level 3 logs higher than that of IL-2 for IL-Rα. IL-2Rβ in association with γc is able to bind IL-15 at a lower affinity (K_d of 10^{-9} M) and can induce an IL-15 signal in the absence of IL-15Rα. IL-15Rα has a wide cellular distribution and is expressed in T cells, B cells, monocytes, and thymic and bone marrow stromal cells, as well as in liver, heart, spleen, lungs, skeletal muscle, and activated endothelial cells. The heterotrimeric IL-15 receptor/-signaling pathway in activated T cells utilizes JAK3 and JAK1, as well as STAT-3 and STAT-5. IL-15 uses a distinct type 2 pathway in mast cells. Mast cells respond to IL-15 with a receptor system that does not share elements with the IL-2R but uses a novel 60 to 65 kDa IL-15 RX subunit. In mast cells, IL-15 signaling through this type 2 receptor involves JAK-2/STAT-5 activation rather than the JAK1/JAK3 and STATS-5/STAT-3 system used by IL-15 in activated T cells.

V. BIOLOGICAL ACTIONS OF IL-15

A. IL-15 Actions in the Development, Survival, and Function of NK Cells

IL-15 is important in the development, survival, and activation of NK cells. NK cells are virtually absent

in knockout mice deficient in IL-15 or IL-15Rα. A similar defect in NK development is observed in mice deficient in interferon regulatory factor I (IRF-I), which is required for the interferon-induced transcription of IL-15 mRNA. Similarly, NK cells are deficient in mice lacking IL-2Rβ, γc, and JAK3, a series of elements that are required for IL-15 action. The role of IL-15 in NK development has been studied directly using *in vitro* stromal-independent cultures of hematopoietic precursors. IL-15 is very effective at inducing such bone marrow progenitors to differentiate into NK cells. A similar IL-15-mediated propagation of NK cells from their progenitors was observed in NK cell-deficient $IRF^{-/-}$ mice treated with IL-15. This latter observation supports the view that the defect in such mice is not in the NK cell progenitors themselves but in the induction of bone marrow stromal cell IL-15 synthesis.

IL-15 facilitates the survival of NK cells *ex vivo*, a phenomenon that is associated with the prevention of programmed cell death. This anti-apoptotic action requires B-cell CLL/lymphoma-2 (BCL-2) expression. In addition, IL-15 synergizes with IL-12 to stimulate the production by NK cells of IFN-γ, TNF-α, and granulocyte/macrophage colony-stimulating factor (GM-CSF). Furthermore, IL-15 stimulates the expression of a stimulatory receptor, NKG2D, involved in effective cytotoxic action that is expressed by activated NK cells.

B. Distinct Functions of IL-15 and IL-2 in the Life and Death of Lymphocytes

As might be anticipated from their sharing of the IL-2Rβ and γc subunits in T and NK cells, IL-15 and IL-2 share a number of biological activities including the stimulation of the proliferation of activated $CD4^+$, $CD8^+$, and γδ subsets of T cells. IL-2 and IL-15 also facilitate the induction of cytolytic effector cells including cytotoxic T lymphocytes and lymphokine-activated killer cells. In addition, both IL-2 and IL-15 act as chemokinetic and chemoattractants for T cells. Finally, both cytokines induce the proliferation and synthesis of immunoglobulins (Ig) by human B cells co-stimulated with anti-IgM or the CD40 ligand.

Although IL-2 and IL-15 share many functions, at times they provide distinct and contrasting contributions to the life and death of lymphocytes. IL-2 through its pivotal role in activation-induced cell death (AICD) is active in peripheral tolerance involved in the elimination of self-reactive T cells. IL-15, in contrast, inhibits IL-2-mediated AICD. In addition to their distinct actions in AICD, IL-2 and IL-15 play opposing roles in the control of the homeostasis of $CD8^+$ memory phenotype T cells. IL-15 stimulates the development and persistence of such $CD8^+$ memory phenotype T cells, whereas IL-2 inhibits their survival. Taken together, the reported studies support the view that in terms of their special adaptive immune functions, IL-2 and IL-15 favor opposing actions that tend to emphasize one or the other of two competing goals of the immune response. IL-2, through its contribution to AICD for $CD4^+$ cells and its interference with the persistence of $CD8^+$ memory phenotype T cells, favors the elimination of lymphocytes that are directed toward self, thereby playing a crucial role in the maintenance of peripheral tolerance. In contrast, IL-15, through its inhibition of IL-2-mediated AICD and its positive role in the persistence of $CD8^+$ memory cells, favors the maintenance and survival of $CD4^+$ and $CD8^+$ T cells. Thus, IL-15 contributes to the maintenance of a specific immune response to foreign pathogens.

C. Phenotype of IL-2, IL-2R, IL-15, and IL-15R Knockout Mice

An analysis of IL-2 and IL-2Rα as well as IL-15 and IL-15Rα knockout mice supports these contrasting roles for IL-2 and IL-15 in AICD and in the expression of memory $CD8^+$ cells. IL-2 and IL-2Rα gene-targeted mice manifest the massive enlargement of peripheral lymphoid organs, high levels of IgG1 and IgE, as well as autoimmune disorders, such as hemolytic anemia, inflammatory bowel disease, and infiltrative granulopoiesis, that are associated with impaired AICD. In contrast, IL-15 gene-targeted mice manifest no lymphoid organ enlargement, autoimmune disease, or impaired AICD. Rather, they manifest a marked reduction in the number of NK cells and memory phenotype $CD8^+$ cells. Such mice have a reduced capacity to mount a protective immune response to challenge with infectious pathogens.

VI. ABNORMALITIES OF IL-15 EXPRESSION IN DISEASE

A. Disorders of IL-15 in Autoimmune Diseases

Feldmann and co-workers proposed that TNF-α is at the apex of a cytokine cascade that includes IL-1β, IL-6, and GM-CSF, as well as a series of inflammatory chemokines that are ultimately involved in the development and progression of rheumatoid arthritis (RA). McInnes and co-workers reported

abnormalities of IL-15 in this disease and suggested that IL-15 may precede TNF-α in this cytokine cascade. In murine models, the intra-articular injection of IL-15 induced a local tissue inflammatory infiltrate consisting predominantly of T lymphocytes. In support of the view that IL-15 plays a role in inflammatory arthritis, the injection of an IL-15 antagonist, the soluble form of IL-15Rα, led to the suppression of development of collagen-induced arthritis. Abnormalities of IL-15 were also reported in other inflammatory autoimmune disorders including ulcerative colitis, Crohn's disease, type C chronic liver disease, and sarcoidosis, as well as multiple sclerosis.

B. Aberrant IL-15 Expression in Retroviral Diseases

Increased IL-15 expression has been observed in retroviral diseases and neoplasia. HTLV-I-infected T cells of patients with the neurological disorder TSP/HAM express the HTLV-1-encoded transactivator $p40^{tax}$. The expression of tax leads to the induction of IL-15 and IL-15Rα as well as IL-2 and IL-2Rα expression. The induction of IL-15 and IL-15R expression involves NF-κB and IRF-1 or IRF-4. The *ex vivo* proliferation of HTLV-1-infected T cells in TSP/HAM can be inhibited in part by an antibody to IL-15 or to IL-2 and can be virtually abrogated by the simultaneous administration of antibodies to both cytokines or to both cytokine receptors, suggesting that these two cytokines mediate autocrine/paracrine stimulatory systems as a consequence of HTLV-I infection. IL-15 also appears to play a role in the expression of antigen-specific major histocompatibility complex (MHC) class I-restricted memory phenotype $CD8^+$ cells that participate in the pathogenesis of TSP/HAM. Patients with TSP/HAM were shown using tetramer technology to have from 3 to over 20% of their $CD8^+$ cells as MHC class I-restricted, antigen-specific cells (directed to amino acids 11–19 of the tax protein transactivator). The number of such cells that persisted in *ex vivo* cultures of patient peripheral blood mononuclear cells for 6 days was decreased in the presence of antibodies to IL-15 or to its receptor. This observation is in accord with the view presented above that IL-15 plays a major role in the generation and persistence of antigen-specific $CD8^+$ memory and effector cells. An increased production of IL-15 by HTLV-I-associated T cells is also observed in adult T-cell leukemia (ATL), an aggressive leukemia of mature $CD4^+$ cells that is associated with HTLV-I. Taken together, the evidence supports the view that the retrovirus-induced IL-15 and its private receptor play meaningful roles in the pathogenesis and persistence of both autoimmune and leukemic disorders associated with HTLV-I infection.

VII. THERAPY USING IL-15 OR DIRECTED TOWARD THE IL-15 RECEPTOR OR ITS SIGNAL TRANSDUCTION SYSTEM

The opposing effects of IL-2 and IL-15 on the life and death of lymphocytes have implications for their use in cancer therapy and as a component of vaccines. IL-2 has been approved for use in the treatment of metastatic renal cell carcinoma and malignant melanoma. However, in the presence of IL-2 due to IL-2-mediated AICD, the tumor-specific T cells generated may interpret the tumor cells as self and may not survive. Furthermore, the inhibition mediated by IL-2 on the survival of memory $CD8^+$ T cells directed toward the tumor is not desirable. In contrast, IL-15 with its activation of T cells, its inhibitory action on AICD, and its facilitation of the persistence of memory phenotype $CD8^+$ T cells may be superior to IL-2 in the treatment of cancer and as a component of vaccines.

The majority of therapeutic trials directed toward the IL-2/IL-2R or IL-15/IL-15R systems have focused on the IL-2 receptor α-subunit. Such IL-2Rα-directed therapeutic efforts have met with considerable success in the treatment of leukemia and select autoimmune disorders and in the prevention of allograft rejection. However, efforts targeting IL-2Rα have limitations. In particular, antibodies to IL-2Rα do not inhibit the actions of IL-15, a cytokine that does not bind to this subunit. Another limitation of IL-2Rα-directed therapy is that antibodies directed toward this receptor do not act on resting NK or NK-T cells that express IL-2Rβ and γc but not IL-2Rα. An additional limitation is suggested by our discussion above on the role of IL-2R in AICD where antibody-mediated inhibition of AICD may prevent the generation of peripheral tolerance to the transplantation antigens expressed on the allografts. Due to these limitations in IL-2Rα-directed therapy, IL-15 receptor-directed therapy is being developed for use in organ transplantation protocols and for application in the treatment of autoimmune disorders as well as diseases caused by the retrovirus HTLV-I. The administration of an IL-15 inhibitor, the soluble high-affinity IL-15Rα receptor chain linked to the immunoglobulin Fc element, prevented the development of

murine collagen-induced arthritis and inhibited allograft rejection. Furthermore, an IL-15 receptor antagonist produced by mutation of a glutamine residue within the C-terminus of IL-15 to aspartic acid competitively inhibited IL-15-triggered cellular proliferation. The administration of this IL-15 mutant markedly attenuated antigen-specific delayed hypersensitivity responses in mice and enhanced the acceptance of pancreatic islet cell allografts. Additional IL-15-directed therapeutic approaches have focused on the IL-2Rβ receptor subunit shared by IL-2 and IL-15. A humanized version of HuMikβ1, an antibody directed toward IL-2Rβ that inhibits IL-15 action on T and NK cells, prolonged renal allograft survival in cynomolgus monkeys. In an initial clinical trial, the antibody Mikβ1 is being evaluated in the therapy of patients with T-cell-type large granular lymphocytic leukemia associated with hematocytopenia. The monoclonal large granular lymphocytes involved in this disease respond to IL-15 and express IL-2Rβ and γc but not IL-2Rα. In addition, this monoclonal antibody will soon be evaluated in the treatment of autoimmune diseases in which abnormalities of IL-15 have been demonstrated including rheumatoid arthritis, multiple sclerosis, and TSP/HAM. In conclusion, our emerging understanding of the IL-15/IL-15R system including the definition of the actions that this cytokine manifests that are shared with IL-2 as well as those that are distinct is opening new possibilities for the development of more rational IL-15/IL-15 receptor-directed immune interventions that may be of value in the prevention of allograft rejection, in the treatment of cancerand autoimmune diseases, as well as in the therapy of diseases associated with the retrovirus HTLV-I.

Glossary

activation induced cell death A multistep process involved in peripheral tolerance that is initiated by TCR/CD3 stimulation; there is a subsequent interaction of the induced IL-2 and IL-2R that when followed by TCR/CD3 restimulation leads to the induction of the cell death effector Fas ligand that interacts with the Fas receptor, which culminates in the death of the self-reactive T cell.

adult T-cell leukemia An aggressive malignancy of mature CD3-, CD4-, and CD25- (IL-2Rα) expressing lymphocytes found predominantly in Japan, the Caribbean Islands, and sub-Saharan Africa caused by the retrovirus human T-cell lymphotropic virus I.

human T-cell lymphotropic virus I (HTLV-I) A retrovirus that is found predominantly in Japan, the Caribbean Islands, and sub-Saharan Africa that induces the expression of IL-2 and IL-15 and their receptors and that is the etiological agent of a number of human diseases including adult T-cell leukemia and autoimmune disorders including tropical spastic paraparesis/HTLV-I-associated myelopathy.

tropical spastic paraparesis/human T-cell lymphotropic virus I (HTLV-I)-associated myelopathy A demyelinating neurological disease that is caused by the retrovirus HTLV-I and that is associated with progressive weakness and bowel and bladder dysfunction.

Interleukin-16

KEVIN WILSON, YUJUN ZHANG, HARDY KORNFELD, DAVID CENTER, AND WILLIAM CRUIKSHANK

Boston University

Interleukin-16 (IL-16) was initially reported in 1982 as the first T-cell chemoattractant. IL-16 was isolated from supernatants of mitogen- or antigen-stimulated human peripheral blood mononuclear cells with chemoattractant activity for both human and rat T cells. Based on this activity, IL-16 was originally designated lymphocyte chemoattractant factor; however, its ability to attract immune cells *in vivo* may be secondary to its newly described role as an immunoregulatory molecule for cell motility and activation. This article will discuss many of the current concepts regarding IL-16 gene structure, synthesis, and processing, its biochemical characteristics, and its interaction with CD4. Its potential roles in inflammation and human immunodeficiency virus infection are also discussed.

I. GENE STRUCTURE AND SYNTHESIS

A. Gene Structure

Interleukin-16 (IL-16) is located on chromosome 15q26.1–q26.3 in humans and on chromosome 7 D2–D3 in mice. The IL-16 gene contains seven exons and six introns and encodes a large precursor protein, pro-IL-16, which is enzymatically processed to generate mature (secreted) IL-16 from the C-terminal of pro-IL-16. There is high gene sequence homology for both pro-IL-16 and mature IL-16 when the human is compared with mouse, rat, feline, or simian, greater than 84% for all species. The IL-16 promoter contains two CAAT-box-like motifs and multiple binding sites for GA-binding protein (GABP) and GATA-1, -2, and -3 transcription factors. Two of the motifs constitute a dyad symmetry element that complexes with GABPα and GABPβ. Activation then occurs when the co-activator, CREB-binding protein/p300 (where CREB is Ca^{2+}/cAMP-response element-binding protein), binds to GABPα and induces the IL-16 gene promoter. The promoter lacks a TATA-box.

B. Transcription

The IL-16 message is constitutively expressed at high levels in $>95\%$ of human T lymphocytes and does not appear to be inducible following antigenic or mitogenic activation, suggesting that posttranscriptional modifications are required for translational regulation. In T lymphocytes, the gene is transcribed into mRNA of approximately 2.6 kb, which is capable of undergoing alternate splicing. The message degrades relatively quickly with a half-life of 2 h. Under nondisease conditions, IL-16 mRNA is limited almost exclusively to lymphatic tissue and circulating immune cells. Synthesis of IL-16 is not restricted to T cells because during an inflammatory response *in situ* IL-16 message is also detected in other cell types, such as epithelial cells obtained from the airways of

asthmatics or the footpads of mice undergoing a delayed-type hypersensitivity reaction. Airway epithelial cells do not have constitutive IL-16 message; however, the message is inducible by a variety of stimulants [tumor necrosis factor((TNFα), transforming growth factor-β (TGF-β), and histamine]. A similar profile exists for mast cells where the message is induced following C5a or phorbol myristate acetate (PMA) stimulation and fibroblasts where the message is induced following IL-1β, TNFα, and leukoregulin stimulation. B cells appear to have a constitutive message that cannot be induced further. It is not clear at present why many of the cell types express high constitutive levels of IL-16 mRNA. A possible explanation is that IL-16 is part of a rapid response mechanism as IL-16 secretion occurs rapidly following stimulation of T cells, mast cells, and eosinophils.

C. Translation and Posttranslational Modifications

Translation of the 2.6 kb mRNA results in a 631-amino-acid precursor protein, pro-IL-16 (Fig. 1). Using immunofluorescence and confocal analysis, pro-IL-16 was localized to the perinuclear region of the cytoplasm. Following cleavage by caspase 3, the N-terminal domain is found primarily in the nucleus, indicating cleavage-dependent translocation. Sequence analysis of pro-IL-16 indicates the presence of a casein kinase II (CKII) substrate site; a cdc2 enzymatic substrate site; a bipartite nuclear translocation signal (NLS) domain; two PDZ (PSD-95/Dlg/ZO-1) domains; and a SH3-binding domain. The casein kinase II substrate site, cdc2 kinase substrate site, and nuclear localization signal function together as a CcN motif: a nuclear localization signal regulated by dual phosphorylation. In light of its nuclear localization and the identification of several potential cell cycle-related kinase substrate sites, the N-terminal domain may be important in contributing to the regulation of the lymphocyte cell cycle. Along those lines, Zhang *et al*. have demonstrated that the presence of pro-IL-16 in the nucleus is associated with increased G_0/G_1 cell cycle arrest. This effect is not detected when the CKII substrate site or NLS is mutated. The physiologic importance of these findings has yet to be determined.

D. Neuronal IL-16

A unique form of IL-16, neuronal IL-16 (NIL-16), is found in the cerebellum and hippocampus. Neuronal IL-16 differs from lymphocyte-derived IL-16 in the size and structure of the N-terminal domain. The C-terminal domains of NIL-16 and pro-IL-16 are identical in protein sequence and in association with CD4. Stimulation of granule neurons, which express CD4, with secreted NIL-16 results in the expression of the immediate-early gene, c-*fos*, via a signaling pathway involving protein phosphorylation. The N-terminus of NIL-16, however, is unique as it is approximately twice the size of lymphocyte pro-IL-16 and contains four PDZ domains. It has not been determined whether NIL-16 translocates to the nucleus following cleavage and processing. It has been determined that NIL-16 does interact selectively with a variety of neuronal ion channels. The presence of PDZ domains and the interaction with ion channels are typical of several neuronal intracellular scaffolding proteins. It is hypothesized that NIL-16 may have two roles in the nervous system; extracellularly, mature IL-16 acts to activate $CD4^+$ neuronal cells, and intracellularly, pro-IL-16 may function to anchor ion channels to the membrane.

E. Biochemical Characteristics

The mechanism for IL-16 secretion has not been clearly defined. IL-16 is similar to another

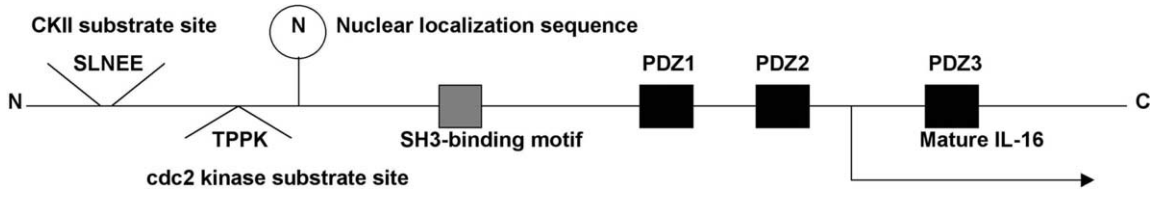

FIGURE 1 Schematic diagram of pro-IL-16. Human pro-IL-16 is a 631-amino-acid protein that contains multiple consensus motifs. There exists a functional CcN motif consisting of a casein kinase II substrate site, a cdc2 kinase substrate site, and a classical bipartite nuclear localization sequence. There are three PDZ domains and an SH3-binding motif. Pro-IL-16 is cleaved by caspase 3. The C-terminal fragment of pro-IL-16 is secreted as mature IL-16. Following cleavage, pro-IL-16 translocates to the nucleus, where it can potentially regulate cell cycle progression.

interleukin, IL-1, in that they both are processed by caspase enzymes and they both lack a consensus secretory leader sequence. IL-1 is secreted by virtue of its interaction with caspase-1, resulting in the formation of a membrane pore. In addition, pro-IL-1 has been shown to translocate into the nucleus following caspase cleavage and affect cell cycle progression. A parallel system for IL-16 secretion has not been identified as yet. It has been determined, however, that the N-terminal may play a critical role in secretion. When the N-terminal 20 amino acids of IL-16 are deleted, there is reduced capacity for secretion. Conversely, when a secretory leader sequence is added, secretion is enhanced.

Biologically active IL-16 is composed of homoaggregates of monomeric peptides. Maximal activity appears with tetrameric formation; however, dimers may also contain some activity. IL-16 monomers lack all IL-16 bioactivity described thus far; however, they are capable of functioning as competitive inhibitors. As both monomeric and aggregated forms of IL-16 are detected in cell supernatants or biological fluids, the presence of the monomer may have some physiological relevance in regulation of IL-16 bioactivity. Each monomeric IL-16 peptide contains a PDZ domain. Typically, PDZ proteins are intracellular proteins that associate with other intracellular proteins and are identified by a conserved G-L-G-F sequence. Although not definitively proven, the PDZ domains likely facilitate autoaggregation. As PDZ proteins are typically intracellular, IL-16 may be the first example of a secreted PDZ protein. Of the 121 amino acids that constitute the IL-16 monomer, the N-terminal 22 amino acids and C-terminal 16 amino acids are not contained within the core PDZ structure and appear to be hinged to facilitate a large degree of flexibility. All described function associated with secreted IL-16 is transmitted by a 4-amino-acid sequence contained in the C-terminal. Synthetic peptides corresponding to the C-terminal sequence, Arg-106 to Ser-109, inhibit all activity of IL-16. When alanine is substituted for Arg-107 in the synthetic oligopeptide, inhibition is lost, suggesting that Arg-107 is essential for IL-16-induced chemotactic activity. These data suggest that the bioactive site on IL-16 is located in the C-terminal end, distinct from the PDZ domain. There is preliminary data to suggest that the N-terminal also contributes to the function of IL-16 through interaction with CD4. Although the N-terminus is not essential for bioactivity, activity is greater when the sequence is present.

F. Species Homology

IL-16 is a highly conserved protein with functional conservation as well in all species examined thus far. Simian pro-IL-16 and human pro-IL-16 are approximately 96% homologous, and the secreted forms of IL-16 for each species are $>98\%$ homologous. There is also intra- as well as interspecies conservation of function. Simian IL-16 has similar function and magnitude of effect whether stimulating simian or human $CD4^+$ T cells. Similarly, murine pro-IL-16 and mature IL-16 demonstrate a high level of homology and functional cross-reactivity with the human protein. In fact, there is functional cross-reactivity and cross-antibody neutralization for all species investigated to date, including rat, sheep, bovine, and feline IL-16. Interestingly, IL-16 was originally identified functionally as lymphocyte chemoattractant factor in 1982, based on its ability to induce migration in both human and rat T cells. These findings suggest that IL-16, along with its interaction with CD4 (see below), represents an evolutionarily conserved molecule with rudimentary roots in the immune system.

II. CELLULAR SOURCES

Initially identified as the major chemoattractant factor produced by $CD8^+$ T cells, IL-16 has now been shown to be a product of a variety of cell types including $CD4^+$ T cells, mast cells, eosinophils, dendritic cells, bronchial epithelial cells, B cells, and most recently, fibroblasts. $CD8^+$ T cells contain constitutively bioactive IL-16 as stimulation with vasoactive amines, such as histamine or serotonin, results in a rapid release of IL-16 that is not altered in the presence of either translation or transcription inhibitors. In addition, $CD8^+$ cell lysates from unstimulated cells contain bioactive IL-16. This suggests that $CD8^+$ T cells have not only constitutive expression of activated caspase 3 but also a mechanism for storage of processed mature IL-16. Antigenic activation of $CD8^+$ cells results in IL-16 production that is sensitive to translation inhibitors, indicating *de novo* synthesis. These data suggest that in $CD8^+$ T cells, two pathways may exist for IL-16 expression. Preformed bioactive IL-16 is stored in vesicles responsive to secretagogues such as vasoactive amine stimulation, and new IL-16 is synthesized and released following T-cell receptor activation. In contrast, $CD4^+$ T cells contain constitutive message and pro-IL-16 but no preformed bioactive IL-16. These cells must be stimulated for 18–24 h with

antigenic or mitogenic stimuli before bioactive IL-16 is detected in the supernatant as a result of caspase 3 processing of pro-IL-16. As IL-16mRNA is constitutively present, the 18 to 24 h period required to produce IL-16 likely also reflects the time required for generation and activation of caspase 3.

The initial observation that airway epithelial cells can produce IL-16 was reported by Bellini *et al*. In their studies, bronchial epithelial cells were obtained by bronchoscopic biopsy from normal, atopic asthmatic, and atopic nonasthmatic volunteers and cultured for 48 h with or without histamine. Only the supernatants from the cell cultures obtained from asthmatics were chemotactic for T lymphocytes and contained IL-16. The induced production of IL-16 by asthmatic epithelial cells was confirmed later using immunohistochemistry and *in situ* hybridization on biopsy lung tissue. In addition to histamine, epithelial cell lines have been reported to produce IL-16 in response to TNFα and TGF-β, as well as following stimulation by Th2 cytokines IL-9 and IL-13.

The most recently identified cell source is the fibroblast. Cultured fibroblasts obtained from all types of tissues sites are capable of generating IL-16 in response to IL-1β, TNFα, and leukoregulin. Cultured fibroblasts appear to have constitutive message but no preformed IL-16 protein. The lack of preformed IL-16 is confirmed by histological studies demonstrating that normal tissue fibroblasts lack IL-16; however, fibroblasts obtained from diseased tissue such as the synovium of patients with rheumatoid arthritis (RA), but not in patients with osteoarthritis (OA), contain high levels of IL-16. In those studies, the synovial lining contained IL-16 message with increased IL-16 protein detected in the synovial fluid.

III. RECEPTOR INTERACTION AND SIGNALING

IL-16 requires the expression of CD4 on T cells to induce a cellular response. A direct interaction between IL-16 and CD4 was first demonstrated in studies in which murine L3T4−T cell hybridoma cells were transfected with the cDNA encoding human CD4. Originally unresponsive to IL-16 stimulation, hybridoma cells expressing CD4 demonstrated IL-16 responsiveness as measured by induction of second messengers and cell migration. The physical interaction between IL-16 and CD4 has been demonstrated by CD4 affinity chromatography and by immunoprecipitation.

The IL-16-binding site on CD4 has recently been determined. High species cross-reactivity suggested a high degree of protein sequence conservation between the active site on IL-16 from different species with its binding site on CD4 from different species. Comparison of the human CD4 amino acid sequence with several different species revealed the D4 domain to be the most conserved. Initially, using peptide inhibition studies, the active site was mapped to the Trp-345QCLLSer-350 sequence within the D4 domain. This was confirmed and further analyzed using regional and point mutational analyses that suggested that both Leu-347 and Leu-348 are essential for induced signaling but that a larger region is required for binding. The binding site on CD4, the proximal region of the D4 domain, is the identical site where CD4 autoaggregates during antigenic activation. Therefore, the presence of IL-16, either in aggregated form or as a monomer, in high enough concentrations prevents CD4 aggregation. Therefore, as a consequence of this interaction, CD4 is sequestered from the T-cell receptor (TCR) complex, resulting in significant alteration of TCR signaling and lymphocyte activation (Fig. 2) (see also bioactivity section). It is this function of IL-16 that appears to predominate in a number of inflammatory conditions.

It does not appear that a co-receptor is necessary to elicit IL-16-induced cellular signaling in T cells and neuronal cells; however, this may not be the case for all cell types. Recent reports have suggested that alternate or co-receptor signaling may be present for both murine monocytes and human dendritic cells; however, identification of an alternative receptor has not been reported. A possible relationship exists between IL-16 signaling and several of the chemokine receptors. IL-16 stimulation of monocyte-derived macrophages results in loss of membrane-expressed CCR5 and CXCR4. In T cells, IL-16 binding to CD4 has been shown to decrease the chemotaxis induced by macrophage inflammatory protein-1β (MIP-1β) binding to CCR5 and stromal cell-derived factor-1α, which binds to CXCR4. As both of these chemokine receptors can physically associate with CD4, the potential exists for a co-receptor relationship with IL-16; however, more studies are required to assess this further.

IL-16 bioactivity is induced only when aggregated into multimeric form, indicating that cross-linking of CD4 is necessary for IL-16-induced intracellular signaling. Further supporting this finding are the observations that oligomerization of CD4 is required for optimization of major histocompatibility complex class (MHC) class II-dependent cell activation and that cross-linking of CD4 by multimeric IL-16 results in the generation of several second messengers not detected by monovalent binding. In lymphocytes,

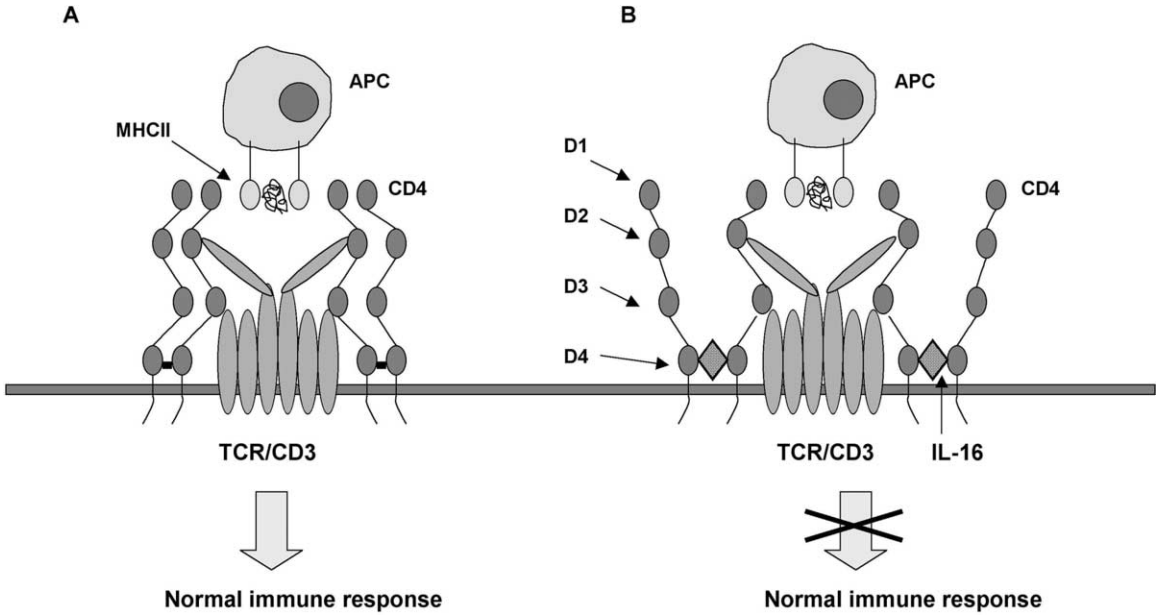

FIGURE 2 Inhibition of TCR-mediated signaling by IL-16. (A) During normal immune responses, an antigen is presented by an antigen-presenting cell (APC) on the major histocompatibility complex class II site (MHCII). The MHCII associates with the D1 domain of CD4. The D3 domain of CD4 interacts with T-cell receptors (TCRs) and CD4 autoaggregates via interaction of the D4 domains, initiating a normal immune response. (B) Interleukin-16 (IL-16) binds to D4 and oligimerizes CD4, changing the steric conformation of CD4. As a result, a normal immune response is inhibited. It is not known whether the mechanism of inhibition is interruption of normal signaling and/or generation of an inhibitory signal.

detectable increases in intracellular calcium, inositol 1,4,5-triphosphate, and phosphorylation of CD4 and $p56^{lck}$ are observed within minutes after stimulation with aggregated IL-16. IL-16 stimulation of monocytes is likely mediated through a Src tyrosine kinase family member, $p59^{lyn}$, and results in activation of the stress-activated protein kinase (SAPK) pathway. Following IL-16 stimulation, SEK-1 (mitogen-activated protein kinase kinase-4) is phosphorylated, resulting in the activation of SAPKs p46 and p54. In addition, c-Jun and p38 MAPK (mitogen-activated protein kinase) are phosphorylated without inducing phosphorylation of MAPK-family members extracellular signal-related kinase-1 (ERK-1) and ERK-2. However, distinct from other signaling pathways involving activation of SAPKs and p38 MAPK in macrophages, there is no apoptosis associated with activation of this apoptotic pathway component. In T cells, IL-16-induced signals are dependent on the interaction of CD4 with another Src tyrosine kinase family member, $p56^{lck}$. This effect was identified by transfecting L3T4 murine hybridoma T cells with CD4 constructs that prevented or allowed interaction with p56lck. IL-16-induced signals were detected only when $p56^{lck}$ physically associated with CD4. Interestingly, $p56^{lck}$ constructs lacking the catalytic SH1 kinase domain functioned normally, indicating that kinase activity was not required for induction of a migratory signal. All signaling was lost, however, when the adapter SH3 domain was deleted. This suggests that a migratory signal induced by an IL-16/CD4 interaction is not transmitted by the enzymatic activity of the SH1 domain, but rather by the SH3 domain.

IV. BIOACTIVITY

IL-16 induces a variety of cellular responses on a number of different $CD4^+$ cell types (Table 1). The bioactivities include induction of cell motility, cell proliferation, and cellular differentiation. In addition, as mentioned above, IL-16 can regulate antigen-induced TCR signaling. Although initially characterized as a chemoattractant selective for $CD4^+$ T cells, it was later determined that IL-16 is a potent chemoattractant for all peripheral immune cells expressing $CD4^+$ including eosinophils, monocytes, and dendritic cells. As a distinction from most of the chemokines, IL-16 can induce migration in naive (inactivated) T cells. In addition to chemoattractant

TABLE 1 Bioactivities of Interleukin-16 in $CD4^+$ Lymphocytes

Mature IL-16
Induces migration/chemotaxis
Regulates immune and inflammatory processes mediated through the TCR
Primes cells for IL-2 or IL-15-induced proliferation
Regulates the responsiveness of chemokine receptors CCR5 and CXCR4
Suppresses HIV-1 and SIV-1 replication
Pro-IL-16
Translocates to the nucleus where it regulates T-cell growth
Neuronal IL-16

Pro-NIL-16 interacts with the mouse brain calcium channel, mbCα1

activity, IL-16 is also a competence growth factor, capable of stimulating cell cycle progression in $CD4^+$ T cells. Stimulation of $CD4^+$ T cells with IL-16 results in up-regulation of surface-expressed IL-2Rα and β, which is associated with progression from a G_0 to a G_1 phase shift in the cell cycle. Cell proliferation does not occur until the cells are stimulated with either IL-2 or IL-15. Stimulation of peripheral blood mononuclear cells with IL-16 followed by IL-2 results in a 1000-fold increase in cell numbers with the expanded cell population being homogenously composed of $CD4^+CD25^+CD29^+CD45RO$ T cells. A similar cell phenotype but with less dramatic expansion is observed when IL-16 and IL-2 are used to stimulate T cells from human immunodeficiency virus (HIV)-infected individuals. In cells that have lost regulated cell growth such as T-cell lines, IL-16 can act as a complete growth factor. $CD4^+$ T-cell lines such as Jurkat and HUT 78 increase their growth rate when stimulated by IL-16. In addition, cells obtained from patients with mycosis fungoides, a common cutaneous T-cell lymphoma, have been shown to have high levels of IL-16 expression. IL-16 stimulation also has an effect on $CD4^+$ pro-B-cell differentiation. Murine bone marrow cells, obtained from aged mice with low levels of circulating mature B cells, stimulated with IL-16 resulted in the differentiation of $CD4^+$ pro-B cells into pre-B cells, the increased expression of RAG-1 and RAG-2, and ultimately, the expansion of the number of pre-B cells in the bone marrow.

Interaction of CD4 with the ligands HIV-1 gp120 or anti-CD4 antibody can induce second messengers and cellular responses such as chemotaxis. The earliest known function for CD4, however, was as a regulatory receptor for TCR-induced activation. Anti-CD4 antibodies were thought to stimulate a "negative signal," resulting in inhibition of TCR signaling and cell proliferation. As a ligand for CD4, IL-16 similarly inhibits antigen-induced TCR signaling. The addition of IL-16 to cell cultures containing a mixed lymphocyte reaction or anti-CD3 stimulation results in inhibition of T cell proliferation. Point-mutated IL-16 is incapable of signaling through CD4 but can still inhibit TCR signaling. This suggests that the interaction with CD4 alone and not signaling through CD4 facilitates the inhibitory activity.

The mechanism by which IL-16/CD4 binding stimulates many cellular responses while inhibiting antigen-dependent stimulation via TCR is becoming more clear. IL-16's interaction with the D4 domain on different CD4 molecules serves to cross-link CD4 and induce cellular signals via activation of phosphatidylinositol 3-kinase, resulting in both a migratory signal and cell cycle progression. If IL-16 interacts with CD4 prior to antigenic stimulation, CD4 is unable to autoaggregate and is unlikely to participate in the formation of a TCR/MHC class II complex. Without CD4's contribution, TCR signaling is significantly less effective and cell activation is reduced or completely inhibited. Binding of IL-16 to a previously activated cell has little effect on the activation state of that cell. Therefore, IL-16's effect to restrict $CD4^+$ T-cell activation is selective for unstimulated T cells. As a consequence of decreased cell activation, cytokine production is also reduced. This is particularly true of the Th2 cytokines, IL-4, IL-5, and IL-13, where IL-16 stimulation results in almost a complete reduction in synthesis (Fig. 3). Th1 cytokines, such as interferon-γ, are less affected. The overall hypothesis for the role of IL-16 in inflamed tissue is less clear. One possibility is that IL-16 contributes to antigen-independent, nonclonal recruitment and priming of $CD4^+$ cells in an inflammatory process. The ability of IL-16 to selectively inhibit chemokine-induced migration would serve to further define the recruited cell population. Although the recruited cells would be responsive to cytokine stimulation (IL-2, IL-15), they would be transiently refractory to antigen-specific activation. The effect would be to increase selectively the number of cells recruited to an inflammatory focus and to further increase the number of viable cells by simultaneously reducing their susceptibility to antigen-specific induced cell death.

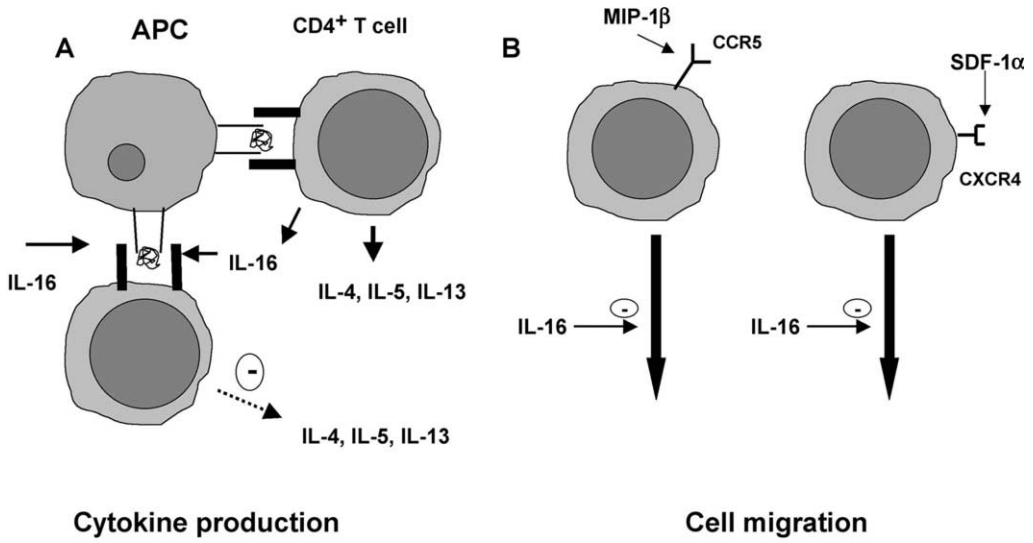

FIGURE 3 Regulatory effects of IL-16 on T-cell recruitment and cytokine production. (A) Following antigen activation, T lymphocytes secrete proinflammatory cytokines such as IL-4, IL-5, and IL-13. IL-16, which can associate with CD4 on unstimulated cells, is also produced, resulting in a reduction or complete inhibition of antigen-induced activation and subsequent cytokine production. There are many other cell sources for IL-16 such as airway epithelium, fibroblasts, and other immune cell types. (B) Binding of IL-16 to its receptor, CD4, decreases chemotaxis induced by several chemokines, in particular, the chemotactic signal generated by macrophage inflammatory protein-1β (MIP-1β) binding to CCR5 and stromal derived factor-1α (SDF-1α) binding to CXCR4.

V. IL-16 AND HIV INFECTION AND INFLAMMATION

A. IL-16 in HIV-1 Infection

As a product of $CD8^+$ T cells, IL-16 was investigated as a potential contributing factor to the anti-HIV-1 viral activity identified by Levy *et al*. Based on this, several studies have identified that binding of IL-16 to $CD4^+$ cells results in suppression of both HIV-1 and simian immunodeficiency virus infection and replication. As IL-16 binds to the D4 domain, distinct from the HIV-1-binding site located in D1, there is no inhibitory effect of IL-16 on HIV-1 binding or internalization. The mechanism for the antiviral activity of IL-16 therefore is different from the mechanism used by RANTES, MIP-1α, and MIP-1β, which bind to CCR5 co-receptor and prevent HIV-1 binding. The inhibitory effect of IL-16 appears to be at the level of transcriptional regulation. Maciaszek *et al*. reported that IL-16 pretreatment of $CD4^+$ lymphoid cells suppressed HIV-1 promoter activity 60-fold. This effect required sequences within the core enhancer, but was not due to the down-regulation of the binding activity of transcription factors such as nuclear factor κB. Therefore, it appears that IL-16 stimulates the activation of a transcriptional repressor that functions through sequences within or immediately adjacent to the core enhancer. Confirmation of this concept was generated when studies revealed that cells transfected with the bioactive portion of IL-16 are resistant to HIV-1 infection. The effect was a result of CD4 engagement by IL-16 on the plasma membrane rather than by intracellular interaction with CD4 prior to surface expression. Several studies have reported that IL-16 is capable of inhibiting HIV even when it is added postinfection. The effects of IL-16 are not limited to T cells. Truong*et al*. reported that IL-16 not only inhibits viral replication but also prevents viral entry in dendritic cells.

The magnitude of viral inhibition for IL-16 is variable depending on the strain of virus; however, for most strains tested there was an average of approximately 50–60% reduction in viral replication. Although the antiviral activity of IL-16 is not as effective as that of many agents currently used in clinical trials, its real benefit may be its ability to facilitate $CD4^+$ T-cell expansion. As discussed earlier, IL-16 stimulation results in up-regulation of IL-2Rα, CD25. This suggests a potential use for HIV therapeutics as an adjunct to IL-2 for immune reconstitution. IL-16 stimulation results in up-regulation of IL-2Rα and imparts IL-2 responsiveness to $CD4^+$ lymphocytes. Thus, IL-16 treatment would be

expected to increase the IL-2R$^+$ population, potentially increasing the effectiveness of exogenous IL-2 and decreasing the required amount of IL-2, thereby reducing the risk of IL-2 toxicity. Expansion of IL-2R$^+$ cells would theoretically also increase TCR diversity. *In vitro* studies have indicated that peripheral blood mononuclear cells obtained from HIV-1$^+$ individuals, cultured with both IL-16 and IL-2, result in an increase in a homogenous CD4$^+$ T-cell population. In addition, preliminary studies have demonstrated that cells from some patients demonstrated renewed antigen responsiveness. Clinically, a pattern has developed correlating HIV disease progression with systemic levels of IL-16. IL-16 levels are low in patients with acquired immune deficiency syndrome, but rise dramatically after treatment with indinavir, concomitant with a rise in CD4 counts. Interestingly, IL-16 levels are higher than the normal range in long-term nonprogressors of disease.

B. IL-16 in Inflammation

Initial characterization of IL-16 bioactivity, induction of cell migration, and priming T cells for proliferation would suggest a pro-inflammatory cytokine. As such, IL-16 has been detected at sites of inflammation in association with a variety of diseases, such as rheumatoid arthritis (RA), asthma, sarcoidosis, systemic lupus erythematosus, inflammatory bowel disease (IBD), delayed-type hypersensitivity (DTH), and Graves' disease. Consistent with the *in vitro* assays indicating pro-inflammatory activity, animal models of IBD, RA, and DTH, where the animals were treated intraperitoneally with IL-16 neutralizing antibodies, there was a significant reduction in parameters of inflammation. However, as with a number of cytokines, its presence in different environments results in the induction of different cellular responses. Although under certain conditions, IL-16 may function as a pro-inflammatory cytokine, recent data have suggested that in inflammation associated with other diseases, such as asthma or RA, IL-16 acts in an immunomodulatory fashion.

Identifying a role for IL-16 in inflammation has focused on diseases characterized by CD4$^+$ infiltrates. Asthma was the first disease to be directly associated with IL-16 production. Bellini *et al*. identified IL-16 in cultures of histamine-stimulated primary epithelial cells obtained from asthmatics, but not from normals. Cruikshank *et al*. challenged asthmatic individuals with antigen, resulting in detection of IL-16 in the bronchoalveolar lavage fluid 4 h postchallenge. IL-16 could not be detected in normal or atopic nonasthmatic individuals, indicating selective production of IL-16 in association with asthma rather than as a result of general inflammation. Subsegmental histamine challenge of asthmatics, but not nonasthmatics, also resulted in the elaboration of IL-16. When biopsies obtained from asthmatics were assessed for immunohistochemical staining and *in situ* hybridization, IL-16 message and protein were detected in the airway epithelium and infiltrating CD4$^+$ cells. There was a significant correlation between the amount of protein and message and the number of infiltrating CD4$^+$ cells. Nonasthmatics had little detectable IL-16 protein or message. The role of IL-16 in asthmatic inflammation is now thought to predominate as an immunoregulatory factor. Intratracheal instillation of IL-16 in a murine model of asthma has indicated a significant reduction in airway hyperreactivity (AHR) as well as a reduction in lung inflammation. Conversely, preliminary studies using an IL-16 $-/-$ knockout mouse have indicated that AHR is significantly increased when these mice are subjected to an OVA model of allergic AHR. These mice also demonstrate an increase in lung inflammation characterized by a cellular influx of T cells and eosinophils. In another animal model, Klimiuk *et al*. demonstrated that the transfer of IL-16-producing CD8$^+$ T cells in a murine model of RA reduces IFN-γ, IL-1β, and TNFα levels by more than 90% and significantly reduces CD4$^+$ T-cell infiltrates, effects that were blocked by co-administration of anti-IL-16. The mechanism for the anti-inflammatory effect of IL-16 in these models has not been clearly defined. The current hypothesis is that IL-16, via its direct interaction with CD4 (see above), limits or completely inhibits CD4$^+$ T-cell activation. Since much of the inflammatory process for these diseases is orchestrated by the CD4$^+$ T cell, alteration in their function would markedly effect downstream events.

IL-16 has been detected in several other diseases; however, its role has not been identified. Immunohistochemical staining of sarcoidosis-associated granulomas from the lymph node and lung reveals high levels of IL-16 staining, with the greatest prevalence in the perivascular areas of lymphocyte accumulation. IL-16 is abundant in the bronchoalveolar lavage fluid of patients with sarcoidosis and tuberculosis. In patients with Crohn's disease, colonic tissue sections show increased IL-16 protein and message compared to uninvolved colonic tissues from the same patients or normal controls. In an animal model of Crohn's disease, anti-IL-16 antibody treatment significantly reduced all parameters of inflammation.

Similarly, using an animal model of DTH, Yoshimoto *et al*. demonstrated that anti-IL-16 antibody treatment significantly reduced granuloma formation in murine footpads.

In summary, IL-16 is a multifunctional cytokine generated by a variety of cell types. In T cells, bioactivities of IL-16 are restricted to surface expression of CD4; however, in monocytes and macrophages there may be an alternative receptor. Expression of IL-16 is primarily limited to T cells during homeostasis conditions, but is dramatically up-regulated at sites of inflammation where it appears to have the capacity to function as either a pro-inflammatory or an immunomodulatory cytokine depending on the surrounding environment. A better understanding of how IL-16 fits into the pathogenesis of inflammation is required as the specificity of IL-16, through CD4, is directed to those cell types that orchestrate much of the inflammatory process.

IL-16 stimulation of T cells, macrophages, and dendritic cells results in a cellular state that retards HIV-1 viral replication. This effect appears to occur through the generation of a transcriptional repressor molecule. The antiviral activity of IL-16 in conjunction with its ability to induce IL-2R in $CD4^+$ T cells suggests that IL-16 may be beneficial in HIV-1 immune reconstitution as an adjunct to IL-2 therapy.

Glossary

casein kinase II (CKII) A ubiquitous protein kinase that phosphorylates over 160 known substrates. Among its many actions, CKII changes the activity of transcription factors, proteins involved in DNA replication and DNA repair (topoisomerase II, DNA ligase), and growth factors (p53, p21).

cdc2 protein kinase A protein kinase that associates with cyclin A or B to form a complex resembling the invertebrate mitosis-promoting factor (MPF). MPF phosphorylates histone-1 protein, disrupting its association with chromatin. It is hypothesized that this provides DNA topoisomerase II access to chromatin, thereby promoting chromatin condensation and advancement to the mitotic phase of the cell cycle. Also, it phosphorylates lamins, impairing their ability to polymerize and leading to nuclear membrane breakdown.

nuclear localization sequence A consensus sequence that is short, is single or bipartite, and contains clusters of basic amino acids. It functions as a nuclear-targeting motif.

$p56^{lck}$ An intracellular tyrosine kinase, from the Src family of tyrosine kinases, that associates with the intracellular portion of CD4 via its unique NH_2-terminal domain. Its presence appears to be essential for CD4 co-receptor activity. However, its tyrosine kinase function is dispensable for certain CD4 functions.

PDZ domain An approximately 90-amino-acid segment with a distinctive three-dimensional shape that contains a binding cleft for protein interaction. The PDZ domain typically allows homologous and heterologous recruitment and assembly into larger protein complexes.

SH3-binding motif A consensus motif, PXXP, where P denotes proline and X denotes an unspecified amino acid. The motif is recognized by Src homology (SH) domains of *Src* and other nonreceptor tyrosine kinases, permitting the SH domain to bind to SH-binding motifs.

Interleukin-18

HIROKO TSUTSUI, TOMOHIRO YOSHIMOTO, HARUKI OKAMURA, AND KENJI NAKANISHI

Hyogo College of Medicine, Japan and Japan Science and Technology Corporation, Tokyo

Interleukin-18 (IL-18) is produced by various types of cells as a biologically inactive precursor and becomes active after cleavage with appropriate enzymes. Playing roles in both the innate and the adaptive immune systems, IL-18 acts not only on NK cells, macrophages, dendritic cells, basophils, and mast cells, but also on T cells and B cells. IL-18 activates both Th1 and Th2 responses. In addition, IL-18 has a wide spectrum of biological actions, a characteristic that has not been shown by other cytokines.

I. INTRODUCTION

Interleukin-18 (IL-18) was discovered as a potent interferon-γ (IFN-γ)-inducing factor in 1995. Its structural properties resemble those of IL-1 and there is some amino acid sequence homology between them. IL-18, like IL-1β, is produced as a biologically inactive precursor and becomes active after cleavage with appropriate processing enzymes, such as caspase-1. The receptor for IL-18 (IL-18R) is composed of two chains, a ligand-binding component, the α chain, and a signaling component, the β chain, both of which belong to the IL-1R family. Furthermore, IL-1 and IL-18 share a common signal transduction pathway. In contrast to its structural homology, IL-18 has biological actions distinct from those of IL-1. IL-1 exerts its actions primarily in the innate immune system, whereas IL-18 plays roles equally in both the innate and the adaptive immune systems. IL-18 acts not only on NK cells, macrophages, dendritic cells, basophils, and mast cells, but also on T cells and B cells. In addition, IL-18 has a wide range of biological functions, a characteristic that has not been shown by other cytokines. IL-18 not only activates Th1 responses but also induces Th2 responses. Because Th1 and Th2 immune responses have been believed to be dichotomous outcomes of adaptive immunity, the finding that IL-18 up-regulates both of them appears to be contradictory and would cause immunological chaos. This may reflect the wide-ranging pathophysiological roles of IL-18 in various immune responses and diseases. IL-18 is profoundly involved in Th1-dependent host defenses against various pathological microbes, such as *Listeria monocytogenes*, a gram-positive intracellular facultative bacterium, *Leishmania major*, an intracellular protozoan, and *Cryptococcus neoformans*, an intracellular fungus. IL-18 plays major roles in the induction and/or activation of autoimmune diseases or inflammatory diseases, including multiple sclerosis and inflammatory bowel disease. Here, we summarize the immunological aspects of IL-18 based on previous reports.

II. MOLECULAR STRUCTURE AND GENE EXPRESSION

Human and mouse IL-18 genes are located on chromosome 11 and chromosome 9, respectively. Human and mouse IL-18 cDNAs encoding precursor IL-18 are composed of 193 and 192 amino acids, respectively, and lack the usual leader sequence that is required for secretion from the cells. Instead, the IL-18 gene contains an unusual leader sequence of 35 amino acids at the N-terminal. The IL-18 gene consists of seven exons, and the first two exons are noncoding. Two promoter regions are located upstream: exon I and exon II. One of them has a PU.1-binding site, suggesting constitutive activation of the IL-18 gene and inducible activation by lipopolysaccharide (LPS). The other exon, containing an interferon consensus site-binding protein-binding site, is activated by IFN-α, IFN-β, and IFN-γ. Based on these characteristics, it is conceivable that macrophages and keratinocytes constitutively express IL-18. The IL-18 gene has a second unique feature.

Cytokine genes usually contain many copies of an RNA-destabilizing element that result in a short half-life of the mRNA for the cytokine. In contrast, the IL-18 gene has at most one copy, presumably resulting in long-lived IL-18 mRNA (described below).

III. PRODUCTION AND PROCESSING

Macrophages, particularly Kupffer cells, store large amounts of proIL-18 under normal conditions. Many cell types, including keratinocytes, dendritic cells, and immune competent B cells, also constitutively express IL-18. This constitutive and continuous production of IL-18 might be caused by the unique gene expression of IL-18 as described above. Therefore, posttranscriptional regulation seems to be quite important for the release of biologically active IL-18.

Two distinct processing pathways have been identified, such as the pathogen-associated molecular pattern (PAMP)-mediated caspase-1-dependent pathway and the Fas/Fas ligand (FasL)-mediated caspase-1-independent pathway (Fig. 1). Both processing machineries are utilized for processing of IL-1β.

On stimulation with LPS, preformed inactive precursor caspase-1 is cleaved into biologically active caspase-1, which cleaves proIL-18 into mature IL-18, eventually leading to the release of IL-18 from macrophages. This process does not always require transcriptional and translational signals, although most cytokines, including IL-1β, require them. In fact, Kupffer cells that constitutively express both precursor IL-18 and precursor caspase-1 can secrete IL-18 but not IL-12, tumor necrosis factor α (TNFα), or IL-1β in the presence of transcriptional or translational inhibitors after being stimulated with LPS. Interestingly, IL-18 secretion from LPS-stimulated Kupffer cells does not require MyD88, although these cells use MyD88 for transduction of cytoplasmic signals required for the production of many other cytokines. Indeed, MyD88-deficient Kupffer cells secrete IL-18 but not IL-12 although Toll-like receptor 4 (TLR4) equally transduces signals for IL-12 and IL-18 secretion. The same scenario seems to be employed by natural infection for this dissociated release of IL-18 and IL-12. *Li. monocytogenes* infection induces elevation of both IL-12 and IL-18 serum levels in wild-type mice. MyD88-deficient mice show elevation of IL-18 but not IL-12. This is also the case for the infection with *Plasmodium berghei*, a pathogenic protozoan in mice.

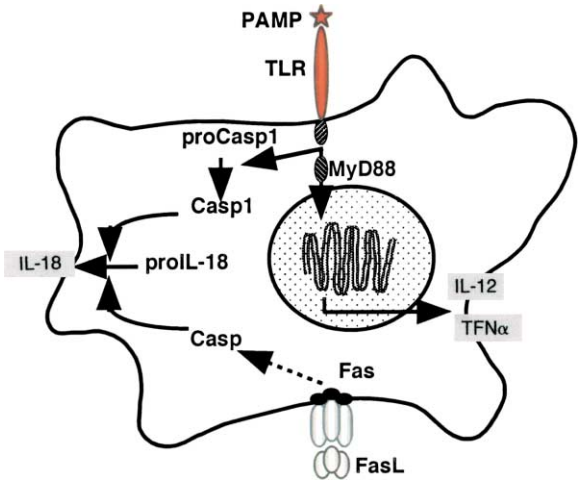

FIGURE 1 Processing of IL-18. Kupffer cells store both IL-18 and caspase-1 (Casp1) as the biologically inactive precursor forms (proIL-18 and proCasp1) under normal conditions. After stimulation with PAMPs, such as LPS, Casp1 is activated independent of MyD88 and then cleaves prepared proIL-18 into biologically inactive mature IL-18, resulting in the secretion of mature IL-18. In contrast, LPS-activated Kupffer cells produce IL-12 or TNFα in a MyD88-dependent manner. On stimulation with Fas ligand (FasL), Kupffer cells release IL-18 independent of caspase-1. However, FasL-stimulated IL-18 secretion is inhibited by caspase inhibitor, indicating that this processing requires a caspase (Casp) other than caspase-1.

A caspase other than caspase-1 is also involved in the processing of IL-18. Kupffer cells isolated from mice that had been treated with heat-killed *Propionibacterium acnes*, a gram-positive bacterium, can secrete IL-18 in response to FasL, whereas those from untreated mice do not. This is because *P. acnes* treatment induces Fas expression on Kupffer cells. *P. acnes*-elicited caspase-1-deficient Kupffer cells can secrete IL-18 after stimulation with FasL, but this is completely inhibited by caspase inhibitors that inhibit caspase-1 or broad caspase activity. This Fas/FasL-mediated IL-18 secretion is observed in mice with acute graft-versus-host disease (GVHD). IL-18 increases in F1 mice ($H2^{bXd}$) that had been transplanted with wild-type splenic cells ($H2^{b}$). In contrast, F1 mice transplanted with *gld/gld* splenocytes ($H2^{b}$) that lack functional FasL do not show elevated serum levels of IL-18. Therefore, at least in acute GVHD mice, IL-18 is secreted on stimulation with FasL.

IV. RECEPTOR AND SIGNAL TRANSDUCTION

Like IL-1R, IL-18R is composed of a ligand-binding α chain and a signaling β chain (Fig. 2). IL-18Rα-deficient lymphocytes do not bind or respond to IL-18. Anti-IL-18Rβ antibodies inhibit lymphocytes to respond to IL-18 both *in vivo* and *in vitro*.

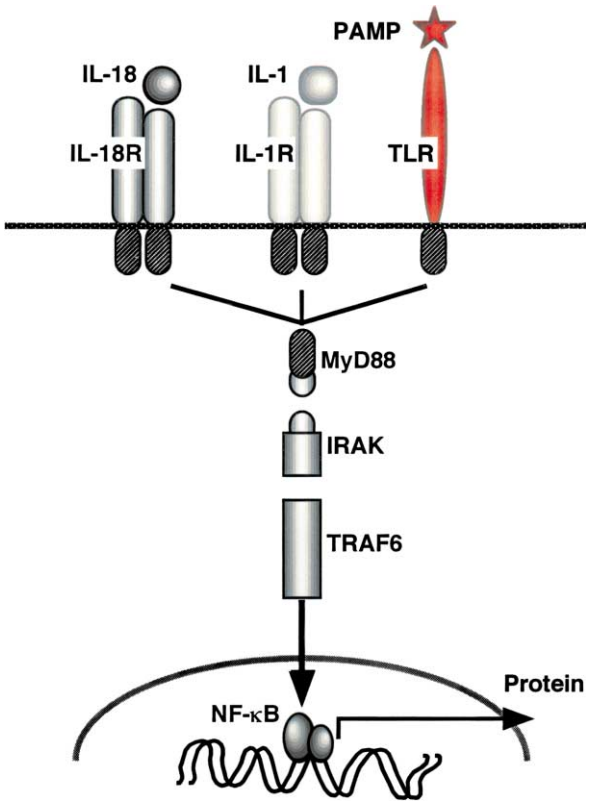

FIGURE 2 IL-18 signaling pathway. IL-18R shares a signal transduction pathway with IL-1R and TLRs. On stimulation with the corresponding ligand, the intracellular domain of each receptor recruits MyD88 to relay a signal, leading to activation of NF-κB.

Freshly isolated murine $CD4^+$ or $CD8^+$ T cells bind with low affinity to IL-18, whereas T cells treated with IL-12 and/or type 1 IFN (IFN-α and IFN-β) bind with high affinity to IL-18. Indeed, the former express a trace amount of IL-18Rα and/or IL-18Rβ, whereas the latter have much larger amounts of both components. Th1 cells, but not Th2 cells, express high levels of IL-18Rα, strongly suggesting that IL-18Rα is a surface marker of Th1 cells. In contrast to T cells, NK cells constitutively express large amounts of IL-18R.

IL-18R shares a signal transduction pathway with IL-1R as well as TLR (Fig. 2). After activation of IL-18R with IL-18, intracellular portions of both chains recruit MyD88 to relay a signal to activate NF-κB, through the sequential activation of IL-1R-associated kinase (IRAK) and TNFR-associated factor (TRAF) 6. Deletion of any gene encoding MyD88, IRAK, or TRAF6 results in failed responses to all the ligands, such as IL-18, IL-1, and PAMPs.

IL-18-binding protein (IL-18BP) is believed to be a natural inhibitor that inhibits binding of mature IL-18 to IL-18R. IL-18BP shows very high binding affinity for IL-18 but has no homology with IL-18Rα or IL-18Rβ. IL-18BP lacks a transmembrane portion, indicating that it is a soluble decoy receptor like the soluble IL-1R type II, which efficiently inhibits binding of IL-1 to IL-1R. IL-18BP is present in serum or urine under normal conditions and is up-regulated by IFN-γ, suggesting a negative circuit between IL-18BP and the IFN-γ, IL-18 product. Although it is not known whether IL-18BP physiologically regulates IL-18 biology, IL-18BP seems to have the potential to be utilized as a therapeutic against IL-18-associated diseases, such as inflammatory diseases, autoimmune diseases, and atopic diseases (described below).

V. BIOLOGICAL FUNCTIONS

One of the prominent characteristics of IL-18 is a wide range biological action. In the immune system, IL-18 has the capacity to activate both Th1 and Th2 responses depending on its cytokine environment, as well as innate immune responses (Fig. 3). In principle,

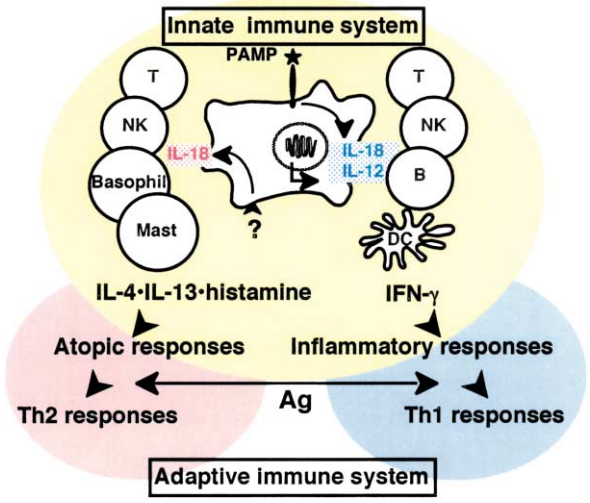

FIGURE 3 Biological functions of IL-18 in the immune system. On stimulation with microbe or microbe products via TLRs, macrophages and/or dendritic cells release IL-18 together with IL-12 (Fig. 1), which activates various types of cells to produce a large amount of IFN-γ, which induces inflammation. Then IL-18 promotes IL-12-committed Th1 responses. If IL-18 producers release only IL-18, Th2-related cytokines are produced, which evokes atopic responses. IL-18 is then involved in Th2-cell development when appropriate antigenic stimulation is present. Thus, IL-18 produces the opposite immunological results depending on whether or not it acts cooperatively with IL-12.

IL-18 stimulates not only conventional constituents of the innate immune system, such as NK cells, macrophages, dendritic cells, mast cells, and basophils, but also adaptive immunity members, such as T cells and B cells, but is dispensable for their T-cell receptor (TCR) and B-cell receptor (BCR) engagement, respectively. These IL-18-responsive cells show immunologically opposite responses depending on whether they encounter IL-18 with or without IL-12. If only IL-18 is released, these cells produce Th2-related cytokines. Such conditions are referred to as innate atopic responses, which would drive adaptive immunity toward Th2 responses if antigenic stimulation works. If IL-18 acts on them together with IL-12, they produce Th1-related cytokines. This is referred to as the innate inflammatory response, which would drive and promote Th1 responses. In natural infection, intracellular microbes induce Th1 responses by two means. One is their PAMPs, which are capable of inducing IL-12 and IL-18 production, and the other is the protein that is presented to naive T cells as a peptide/major histocompatibility complex combination. Under other conditions, IL-18 that is secreted without IL-12 and that is stimulated by unknown molecules directly induces Th2 responses.

A. Roles of IL-18 in Innate Immunity

IL-18 stimulates various constituents of innate immunity to release IFN-γ, particularly in collaboration with IL-12 (Fig. 3). IL-18 together with IL-12 induces very high levels of IFN-γ production by NK cells, dendritic cells, and macrophages. Naive $CD4^+$ T cells and even Th1 cells, although important constituents of the adaptive immune system, also produce a large amount of IFN-γ in response to IL-12 and IL-18 without TCR engagement, indicating that $CD4^+$ T cells also have the capacity to play a role in innate immunity. Although the molecular mechanisms of the synergistic action of IL-12 and IL-18 on IFN-γ production are unclear, IL-12-induced up-regulation of their IL-18R expression might be partially involved in this synergism. Recently, it was demonstrated that Tyk2, an essential JAK kinase for IL-12 signaling, is also required for IL-18-induced IFN-γ production by NK cells. Tyk2-deficient NK cells produce no IFN-γ in response to IL-18, suggesting the possible involvement of Tyk2-mediated signaling in IL-18-induced IFN-γ production. The molecular basis for Tyk2-mediated IL-18 signaling is unknown. As expected, the synergistic action of IL-18 and IL-12 for IFN-γ production is essential for clearance of some types of pathogenic microbes, particularly intracellular pathogens (described below).

IL-18 solely induces production of hematopoietic cytokines, such as IL-3, IL-5, and granulocyte/macrophage colony-stimulating factor (GM-CSF) by $CD4^+$ T cells. Interestingly, IFN-γ-deficient $CD4^+$ T cells produce much more IL-5 in response to IL-18 than wild-type cells, indicating a down-regulatory action of endogenous IFN-γ for IL-18-induced IL-5 production. Daily administration of IL-18 increases circulatory eosinophil numbers in mice, followed by neutrophilia. IL-18-transgenic mice or caspase-1-transgenic mice that spontaneously release mature IL-18 display extramedullar hematopoiesis, particularly in myeloid lineages. However, we do not know whether IL-18 is involved in homeostasis and/or pathogenesis of the hematopoietic system.

IL-18 has the capacity to induce Th2-related cytokine production by $CD4^+$ T cells, NK cells, basophils, and mast cells (Fig. 3). $CD4^+$ T cells produce IL-4 and IL-13 in the presence of IL-2 but without TCR engagement, whereas NK cells produce only IL-13 on stimulation with IL-18. Bone marrow-derived mast cells and basophils express IL-18R and release IL-4, IL-13, and histamine in response to IL-18 in collaboration with IL-3. These cytokines and chemical mediators are major relevant and/or effector molecules that induce atopic phenotypes, such as broncho-constriction and mucous formation in asthma and itching in atopic dermatitis. It is well established that cross-linkage of FcεR I (high affinity receptor for Fc portion of IgE) on these cells by allergen-specific immunoglobulin E (IgE)/allergen is essential for the release of these effector molecules. In contrast, IL-18 can exert these actions without help from allergen-specific IgE/allergen, suggesting abnormal accumulation of IL-18 as a causative factor for atopic diseases.

IL-18, like IL-12, enhances the cytolytic activity of NK cells. In contrast to the synergism of IL-18 and IL-12 in IFN-γ production, there is no synergy in enhancement of their cytolytic activity. IL-18 does not increase production of their cytolytic effector molecules, such as perforin and granzyme B, a serine protease, whereas IL-12 does up-regulate their perforin and granzyme B production, suggesting an up-regulating mechanism of IL-18 distinct from that of IL-12. Unlike IL-12, IL-18 can induce FasL expression on NK cells and Th1 cells. This is also the case for hepatic NKT cells, a subpopulation expressing both NK-cell marker and the TCR.

Like IL-12, IL-18 plays a role in the functional development of NK cells. Both IL-12-deficient mice

and IL-18-deficient mice have comparable numbers of splenic NK cells as wild-type mice. However, the cytolytic activity of IL-12-deficient or IL-18-deficient NK cells against NK-cell targets is decreased compared with wild-type NK cells. NK-cell activity in IL-12 and IL-18 double-knockout mice is most strongly impaired. Interestingly, NK cells from any mutant or wild-type mice equally increase their cytolytic activity in response to IL-12 and/or IL-18, indicating that NK cells do not require endogenous IL-12 or IL-18 for acquisition of responsiveness to IL-18 and/or IL-12.

B. Roles of IL-18 in Th1 Immune Responses

Although IL-18, like IL-12, is a potent factor to induce IFN-γ production, IL-18, unlike IL-12, fails to induce Th1-cell development. $CD4^+$ T cells from IL-18-deficient mice that had been administered heat-killed *P. acnes*, a prototype *in vivo* Th1-cell inducer, show only slight impairment in Th1 development compared with *P. acnes*-primed wild-type mice, whereas $CD4^+$ T cells from *P. acnes*-primed IL-12-deficient mice lack Th1 development, indicating that IL-12 but not IL-18 is a Th1-cell-inducing factor. This is also the case for *Le. major* infection, clearance of which is completely dependent on the intensity of *Le. major*-specific Th1 cells. Because they normally develop into Th1 cells, IL-18-deficient mice with a resistant background show weak susceptibility to *Le. major* compared with wild-type mice with the same background. Indeed, due to their failure in Th1-cell development, IL-12-deficient mice display profound susceptibility to *Le. major.*

C. Roles of IL-18 in Th2 Immune Responses

Although IL-18 was initially recognized as a Th1-activating factor, recent studies show that IL-18 is a potent Th2-cell-differentiation factor. Exogenous IL-18 stimulates $CD4^+$ T cells to develop into Th2 cells on TCR engagement via induction of endogenous IL-4. However, Th2 cells lose responsiveness to IL-18 but retain responsiveness to IL-4, indicating that IL-4 is a Th2-initiating and -sustaining factor but that IL-18 only initiates Th-cell development.

It is noted that $CD4^+$ T cells that have been treated solely with IL-18 are not Th2 cells, indicating that Th2 as well as Th1-cell development definitely requires simultaneous signaling through their TCRs in addition to signals of Th2- and Th1-driving factors, respectively. Interestingly, exogenous IL-18 can up-regulate their CD40 ligand expression, which is essential for inducing IgE production by B cells. Daily administration of IL-18 increases serum levels of IgE in wild-type mice, but not in IL-4-deficient mice, in 2 weeks without any antigen stimulation. IL-18 or caspase-1-transgenic mice that overexpress mature IL-18 spontaneously show high serum levels of IgE, whereas depletion of the Stat6 gene inhibits their high levels of IgE, indicating that accumulation of IgE is dependent on Stat6 in these transgenic mice. This IL-18 induction of IgE is inhibited by anti-CD40 ligand but not by a soluble decoy receptor for IL-13, which inhibits selective biological actions of IL-13 but not IL-4. All the results indicate a requirement of both CD40/CD40 ligand and IL-4/Stat6 but not IL-13 for IL-18-induced IgE induction in mice.

D. Others

IL-18 acts not only on the immune system but also on other systems and physiological processes, such as the endocrine system, the nervous system, and bone metabolism. Under conditions of stress, IL-18 is released from the adrenal gland, suggesting the possible involvement of IL-18 in stress-induced systemic alterations. Osteoblast-derived IL-18 suppresses osteoclast development via induction of GM-CSF production, indicating that IL-18 is an important factor for bone metabolism. Recently, it was shown that intracerebroventricular administration of IL-18 prolongs nonrapid eye movement sleep, suggesting the involvement of IL-18 in sleep control.

VI. PATHOPHYSIOLOGICAL ROLES

Genetic deletion and transgenic techniques have revealed diverse actions of IL-18 in homeostasis of the immune system and various immune system diseases. IL-18 plays important protective roles in host defense against microbial infection or tumor. However, an overabundance of IL-18 is often harmful enough to induce inflammatory or even atopic diseases.

A. IL-18 in Host Defense

As briefly described above, IL-18 is critical for host defense against some types of pathogenic microbes. In particular, IL-18 plays a major role in the clearance of intracellular microbes, such as *Li. monocytogenes*, *Mycobacterium* spp., *C. neoformans*, a pathogenic fungus, *Toxoplasma gondii*, a pathogenic protozoan, and *Le. major.* In the defense against these microbes, endogenous IL-18 as well as IL-12 evokes local and/or systemic inflammatory reactions, eventually leading to the induction of effector molecules, such as

reactive oxygen intermediates and nitric oxide derivatives (Fig. 4).

IL-18 and IL-12 are also essential in expelling some types of viruses. Previously, type I IFN produced by various types of cells was believed to be only the first line against viral infection. However, recent studies have shown that double-stranded RNA activates TLR3 to release various proinflammatory cytokines, which together result in the production of virus-killing substances and/or directly inhibit viral replication (Fig. 4). Depletion of IL-18 renders mice susceptible to some types of viral infection.

B. IL-18 Against Tumors

Like IL-12, exogenous IL-18 induces regression of tumor in mice. However, molecular mechanisms are distinct. IL-12 treatment enhances perforin/granzyme-mediated anti-tumor actions of host cytotoxic cells, and IL-18 elevates FasL expression on effector cells that kill Fas-expressing tumor cells *in vivo*. IL-18 gene therapy is useful to reduce the growth of some types of tumors.

C. IL-18 in Immune Diseases

IL-18 plays critical roles in the development of various types of diseases from Th1-cell-associated autoimmune diseases, inflammatory diseases, and Th2-cell-related atopic diseases (Table 1).

IL-18 promotes various autoimmune diseases. Autoimmune diseases are caused by a disturbance of self-tolerance through unknown mechanisms. IL-18 appears to be involved in local autoimmune diseases associated with Th1 cells. Here, we show several examples.

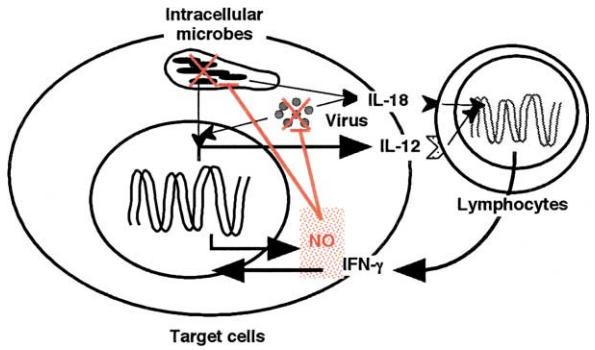

FIGURE 4 Involvement of IL-18 in host defense. Intracellular microbes or viruses stimulate host macrophages presumably through the appropriate TLR to release proinflammatory cytokines, including IL-18 and IL-12. IL-18, in combination with IL-12, activates lymphocytes to release a large amount of IFN-γ, which in turn fully activates macrophages to produce microbicidal molecules such as nitric oxide (NO).

In patients with insulin-dependent diabetes mellitus (IDDM) or nonobese diabetes (NOD) mice, which is a mouse model of spontaneous IDDM, pancreatic beta cells are selectively destroyed, presumably by insulin or insulin-related enzyme-specific T cells that would be depleted in healthy or wild-type mice. Administration of neutralizing anti-IL-18 reduces pathological changes in NOD mice, suggesting that IL-18 is an exacerbating factor for development of IDDM.

Patients with multiple sclerosis, an autoimmune disease of the central nervous system, and mice with experimental autoimmune encepharitis (EAE), which is induced by immunization with neural myelin-derived products, display high serum levels of IL-18 and express activated caspase-1 in their neural lesions. The severity of the disease correlates with the levels of IL-18 in the lesion in the mouse model. Administration of neutralizing anti-IL-18 or caspase inhibitors reduces the disease score in EAE mice.

Many investigators have reported a possible contribution of IL-18 in rheumatoid arthritis, which is a Th1-cell-driven autoimmune disease of the joints. High levels of IL-18 are expressed in the synovia of the patients. This is also the case for a mouse model that is induced by collagen administration.

IBD, especially Crohn's disease, is also associated with IL-18. Lesions in patients with Crohn's disease express the active form of IL-18 and caspase-1. Mice having received trinitorobenzene sulfate (TNBS), a mouse model of IBD, accumulate IL-18 in the colitis lesion. Their disease score parallels IL-18 concentration in the lesion. Furthermore, administration of IL-18BP protects against colitis induced by TNBS, indicating that IL-18 is an endogenous causative molecule for IBD.

IL-18 is profoundly involved in inflammatory diseases, such as septic syndrome and acute GVHD (Table 1). Septic syndrome is initiated by the activation of host innate immunity by the causative bacteria or bacterial products. It is plausible that IL-18 is released via activation of TLRs in septic syndrome. In addition, treatment with neutralizing anti-IL-18 inhibits lethality and/or tissue damage associated with sepsis. In particular, liver injury is prevented by neutralization of IL-18 or depletion of the gene encoding IL-18 or caspase-1. Acute GVHD, a potentially fatal side effect of allogeneic cell transplantation, is tightly associated with the elevation of serum levels of IL-18. The disease severity is also correlated with the level of IL-18.

TABLE 1 Roles of IL-18 in Various Immune Diseases

Types	Examples	Pathological roles	
		Without IL-12	With IL-12
Autoimmune diseases	Insulin-dependent diabetes mellitus	+	++
	Multiple sclerosis	+	++
	Rheumatoid arthritis	+	++
	Inflammatory bowel diseases	+	++
Inflammatory diseases	Septic syndrome	+	++
	Acute graft-versus-host disease	+	++
Atopic diseases	Atopic dermatitis	+	−
	Bronchial asthma	+[a]	−

Note. Endogenous IL-18 (without IL-12) exerts its biological actions to up-regulate (+) the severity of individual immune diseases. Exogenous IL-12 (with IL-12) up-regulates (++) or down-regulates (−) each immune disease.

[a]IL-18 shows reciprocal effects on the disease severity depending on the time points when IL-18 acts.

Atopic diseases are also targeted by IL-18. Transgenic mice that express an excess amount of active IL-18 spontaneously develop atopic dermatitis-like cutaneous changes associated with high serum levels of IgE. In fact, patients with atopic dermatitis have a higher concentration of IL-18 in their sera than do healthy volunteers.

VII. SUMMARY

Various types of cells produce IL-18 as a biologically inactive precursor. On appropriate stimulation, bioactive IL-18 is secreted after cleavage with the appropriate enzymes. IL-18 has a wide spectrum of biological actions. IL-18 with IL-12 potentially forces inflammatory responses by inducing IFN-γ production by various types of cells, whereas IL-18 solely drives atopic responses via IL-4 production by the restricted cell types T cells and basophils. IL-18, whether acting as an inflammation-driving factor or an atopy-inducing element, plays a critical role in host defense but is sometimes involved in various immunological diseases. Furthermore, IL-18 has the potential to modulate nonimmune systems. Future studies, particularly studies on the roles of IL-18 in nonimmune systems, will establish a comprehensive characterization of IL-18, only a part of which we now know.

Glossary

adaptive immune system Consists mainly of T cells and B cells that show hyperdiversity based on their DNA rearrangement and somatic mutation.

atopic disorder Condition resulting from the immediate hypersensitivity based on the abnormal production of immunoglobulin E (IgE) against environmental antigens. Atopic disorders have different clinical manifestations, such as hay fever, asthma, urticaria, or chronic eczema. Antigen, usually called allergen, cross-links allergen-specific IgE bound to FcεRI on mast cells and activates them to release various chemical mediators and cytokines, leading to development of pathological alterations.

autoimmune diseases Diseases that are caused by defects of self-tolerance and are divided into two groups based on their effector mechanisms. Abnormal production of autoantibodies against autoantigen results in immune complex-induced systemic or autoantigen-specific disorders, depending on the properties of autoantibodies. Self-reactive T cells also cause tissue-specific disorders.

caspases Cysteine proteases that cleave corresponding substrates following the aspartate site and are involved in apoptosis and/or cytokine processing. More than 10 members have been identified. Caspase-1, originally termed interleukin-1β (IL-1β)-converting enzyme, has the capacity to cleave biologically inactive precursors IL-1β and IL-18 into the corresponding biologically active forms.

innate immune system The primitive defensive system, including barriers between the inner and the outer environments, defensive proteins in the circulation, and immune competent cells except for T cells and B cells. Recently, it was shown that innate immunity can strictly discriminate microbe products from self-molecules by the corresponding receptors.

Th1/Th2 immune responses On stimulation with antigens, T cells develop into Th1 and Th2 cells in the presence of interleukin-12 (IL-12) or IL-4, respectively. Th1 cells selectively secrete interferon-γ and IL-2 but not IL-4, IL-5, or IL-13, whereas Th2 cells express the inverse cytokine profile. Imbalance or dysregulation of

Th1/Th2 immune responses occasionally determines successful host defense or disease severity.

Toll-like receptor (TLR) The signaling receptor for various microbe products in innate immunity; it is required for discrimination of microbes from self-molecules. TLR is composed of more than 10 members. Each TLR recognizes distinct microbe products called pathogen-associated molecular patterns (PAMPs). All the TLRs examined share a common signaling pathway. On stimulation with PAMPs, the intracellular domain of the corresponding TLR binds to an intracellular adapter molecule, myeloid differentiation factor 88 (MyD88), to relay a signal to activate nuclear factor κB, a transcriptional factor.

Interleukin-22 is an interleukin-9-induced cytokine that is active on B and T lymphocytes, mast cells, and eosinophils. The roles of this

hormones such as growth hormone and prolactin.

I. INTRODUCTION

Interleukin-2 (IL-2), a 15.5-kDa glycoprotein, is functionally confined to the immune system: only antigen-activated T cells produce it and lymphocytes are the only cells that express IL-2 receptors. IL-2 promotes the proliferation, differentiation, and survival of mature lymphocytes, especially T cells. Consequently, IL-2 is obligatory for a physiologic antigen-specific acquired cellular immune response, and it also can promote innate host defenses by activating natural killer (NK) cells. *In vivo*, IL-2 regulates the tempo, magnitude, and duration of the T-cell immune response. As well, because the size of the memory cell pool is dependent on IL-2, the degree of protective immunity is determined in large part by the availability of IL-2. Accordingly, IL-2 is presently in use therapeutically for the augmentation of the immune system in the treatment of cancer and infectious diseases.

The interleukin-2 receptor (IL-2R) was the first of the cytokine receptors to be identified and characterized. The IL-2R is composed of three distinct chains (α, β, and γ), each of which participates in the formation of the binding site for IL-2. The α-chain contributes to IL-2 binding a very rapid association rate; the βγ dimer contributes a slow dissociation rate, making for a very high-affinity binding site ($K_d = 10$ pM).

If a deficiency of IL-2R triggering occurs, either as a result of genetic defects, or pharmacologically, profound immunodeficiencies can be produced. For example, genetic deficiencies of IL-2 or IL-2R α or β chains result in immunodeficiency early after birth, with a later accumulation of activated T cells that do not function properly. It is significant that these phenotypic changes cannot be compensated by other cytokines. Mutations of the IL-2R γ chain results in severe combined immunodeficiency. Given these findings, it is not surprising that pharmacological agents, and therapeutic monoclonal antibodies reactive with the IL-2R that block the IL-2-IL-2R system, are potent immunosuppressives and are the main agents employed to prevent organ transplant rejection.

II. STRUCTURES

Human IL-2 is a small globular glycoprotein of 133 amino acids. There are four antiparallel amphipathic α-helices with one intrachain disulfide bond that is essential for molecular integrity and activity. The high-affinity IL-2R is composed of three noncovalently linked type I transmembrane chains of 55 (α-chain), 75 (β-chain), and 65 (γ-chain) kDa. The α-chain has only 13 intracellular amino acid residues and does not participate in signaling, whereas the β- and γ-chains have large intracellular portions and are responsible for signaling the interior of the cell. The IL-2R binds IL-2 with an extremely high affinity ($K_d = 10$ pM), owing to a rapid association rate contributed by the α-chain ($k = 10^7\ M^{-1}\ s^{-1}$) and a slow dissociation rate ($k' = 10^{-4}\ s^{-1}$) contributed by the $\beta\gamma$ chain heterodimer.

III. FUNCTIONS

The concentrations of IL-2 that bind to IL-2Rs are identical to the concentrations that promote a T-cell proliferative response, i.e., the $K_d = EC_{50}$. Thus, the IL-2 binding and biological response curves are coincident, and there are no "spare" receptors. Moreover, there are a finite number of IL-2–IL-2R interactions that must occur before a cell is triggered to undergo cell cycle progression. Accordingly, the concentration of IL-2 available, the density of IL-2Rs, and the duration of their interaction determine the biological effects of IL-2, and each individual cell responds in a quantal (all-or-none) fashion. The number and duration of intermolecular interactions determine the "strength" of the IL-2–IL-2R signal delivered to the cell. The signaling molecules triggered by the IL2–IL2R interaction include the Janus tyrosine-specific kinases, JAK1 and JAK3, which are activated by the stabilized IL-2–IL-2R complex. Subsequently, the JAKs catalyze the phosphorylation of themselves as well as the β- and γ-chains of the IL-2R, which then serve as docking sites for the signal transducers and activators of transcription (Stat5a and Stat5b). In addition to the JAK/Stat pathway, the IL-2–IL-2R interaction activates the Ras/Raf/mitogen-activated protein kinase (MAPK) and the phosphatidylinositol 3-kinase/Akt pathways, which then are involved in activating transcription factors that are responsible for activating the expression of specific genes that promote cell survival, proliferation, and differentiation. Some of the important genes expressed as a consequence of IL-2 signaling are known; Bcl-2 and Bcl-X, for example, are important in promoting cell survival, and cyclin-D2 is important in promoting progression through the cell cycle. However, many other genes are yet to be discovered.

IV. IL-2 REGULATION OF THE IMMUNE RESPONSE

IL-2 is the principle cytokine responsible for activating the proliferation, differentiation, and survival of peripheral mature T cells once they have become activated by antigen. In particular, IL-2 stimulates a marked proliferative expansion of CD8 + T cells, which are responsible for recognizing and reacting with intracellular infections, such as those caused by viruses. As well, this subset of cytolytic T cells (CTLs), which acquire the capacity to lyse infected target cells, is also active in the destruction of transplanted organs. By comparison, the other major subset of T cells, which express the CD4 surface molecule, differentiate into "helper" cells (T_H cells), by virtue of their capacity to secrete large amounts of cytokines and also to express surface helper molecules. Thus, CD4 + T cells help CD8 + T cells by secreting IL-2. Although CD8 + T cells can also produce IL-2, CD4 + T cells produce approximately 80% of the IL-2 released during an immune reaction. In experimental viral infections, a rapid release of IL-2 promotes a massive expansion of CD8 + T cells, as much as 100,000-fold, within just a few days. However, in mice that have had the IL-2 genes deleted, the proliferative expansion is only ~10% of that observed in wild-type mice. The degree to which antigen-specific T cells expand after a primary antigenic stimulation determines the eventual size of the "memory" T-cell population. Therefore, IL-2 is responsible for the size of this population and for the efficacy of the immune response to reinfection.

IL2 is also responsible for the differentiation that produces CTLs and T_H cells. IL-2 augments the expression of genes that encode cytolytic molecules, such as perforin and the granular proteases (granzymes), and the cytokine molecules that define the so-called T_H1 and the T_H2 cell subsets. Additionally, IL-2 appears to maintain T-cell homeostasis by generating feedback down-regulatory effects, thereby limiting the proliferation and differentiation initiated on the encounter with antigen.

V. IL-2 THERAPY

A. Pharmacodynamics

The pharmacodynamics of IL-2, or how IL-2 affects the cells and tissues of the body, are based on the type and distribution of the IL-2Rs. High-affinity, trimeric ($\alpha\beta\gamma$) IL-2Rs are expressed only transiently on antigen-activated T cells and B cells, whereas they are constitutively expressed by ~10% of NK cells. Because the affinity of the heterotrimeric IL-2Rs is very high (10 p*M*), only very low IL-2 concentrations (<100 p*M*) are necessary to saturate them. By comparison, 90% of NK cells express the β- and γ-chains of the IL-2R, but not the α-chain, so that the K_d is 100-fold higher. This 100-fold difference in affinity, combined with the small number of recently antigen-activated T cells and B cells (<1%), vs NK cells (~10^9 cells/μl), accounts for the main difference in the effects of high doses of IL-2, as have been used in cancer therapy, vs low doses, as used in infectious diseases such as human immunodeficiency virus (HIV) infection. High IL-2 doses result in systemic IL-2 concentrations that saturate most of the IL-2Rs expressed by NK cells, which leads to their activation and their secretion of proinflammatory cytokines, resulting in severe systemic toxicity. In contrast, if the IL-2 doses are lowered, and the systemic IL-2 concentration remains <100 p*M*, only the high-affinity IL-2Rs are saturated, thereby avoiding the activation of most of the NK cells and the attendant toxicity.

B. Pharmacokinetics

The pharmacokinetics of IL-2, or what the body does with the glycoprotein, are dependent on the characteristics of the IL-2 molecule. Because IL-2 is a small (15.5 kDa) globular glycoprotein, it passes freely between capillary and lymphatic endothelial cells; after intravenous administration, it distributes into the total extracellular space, which in a normal adult is about 15 liters. This α-decay phase, due to distribution, occurs with a half-time of ~10 min. Therefore, within 40 min, >94% of the initial peak concentration is dissipated. Subsequently, there is a β-decay due to renal excretion, which has a half-time of ~3 h. After subcutaneous administration, there is a half-time of ~1 h for absorption, followed by renal excretion, so that peak plasma concentrations occur at ~2–3 h and detectable plasma concentrations are still present after 12–16 h. Therefore, low plasma IL-2 concentrations can be maintained by once or twice daily subcutaneous injections. After a subcutaneous or intradermal injection of IL-2, there is a characteristic and classic delayed-type hypersensitivity (DTH) reaction that develops within 24 h. The cardinal signs of inflammation (i.e., rubor, calor, dolor, tumor) are due to the IL-2-activation of NK cells and T cells, which then produce proinflammatory cytokines, leading to the extravasation of plasma and cells at the site of IL-2 injection.

C. Clinical Results

In cancer treatment, IL-2 is used in very high doses (i.e., 150 million units (U)/day) for short treatment intervals of 3–5 days. At these doses, IL-2 causes acute systemic inflammation, with high fever, malaise, myalgia, fatigue, and hypotension. This therapy eventually results in an antitumor response in ~15% of subjects, and ~5% of patients with renal cell carcinoma and malignant melanoma achieve a long-term, complete response.

The treatment of HIV infection is the other major disease category for which IL-2 has been used. In patients with chronic infection and low levels of circulating CD4 + T cells, doses that are ~10-fold lower than those used in cancer therapy have been found to be effective in increasing the concentration of CD4 + T cells. However, these doses are still quite toxic and can be tolerated only for ~5 days. Low-dose daily IL-2 administration is now being tested in conjunction with therapeutic HIV vaccines with coadministration of antivirals, to augment HIV-specific immunity. This has become an important new area for immune-based therapies because the available antiviral drugs are effective in suppressing viral replication, but they do not cure the infection, so that when discontinued the virus begins replicating immediately and a viral relapse occurs almost universally. Consequently, the new therapeutic approaches are designed to augment HIV immune reactivity by boosting the number and function of HIV-specific T cells, especially CD8 + CTLs. A similar approach is planned to test IL-2 for the treatment of chronic hepatitis C virus (HCV) infection.

VI. IMMUNOSUPPRESSIVE THERAPY

The mechanisms of action of the most commonly used immunosuppressive drugs are focused on the prevention of either production or action of IL-2. Glucocorticoid hormones, which have been widely used as immunosuppressives and anti-inflammatory agents for the past 50 years, inhibit the transcription of IL-2 and other cytokine genes. Similarly, the drugs cyclosporin A and FK506 also inhibit IL-2 gene expression, although by blocking slightly different transcriptional activating pathways.

A monoclonal antibody reactive with the IL-2R α-chain has recently been found to be very effective in blocking the IL-2–IL-2R interaction and attenuating the rejection response to renal and cardiac allografts. Also, in combination with rapamycin, which blocks IL-2R signaling, these antibodies have recently been shown to prevent the rejection of pancreatic islet cell grafts used for the treatment of type 1 diabetes mellitus.

VII. SUMMARY

IL-2 is the major mature T-cell growth, differentiation, and survival factor (cytokine) operative in the immune system. It promotes the proliferative expansion and function of antigen-selected T-cell clones and is responsible for the generation of protective immunity and immunologic memory. As a small globular glycoprotein that interacts with high-affinity stereospecific cell surface receptors, it mediates its effects by activating tyrosine-specific kinases and the transcriptional activation of specific genes. In the clinic, it is being used to augment immune responses for the treatment of cancer and infectious diseases, and drugs that block the production or action of IL-2 are effective immunosuppressives.

Glossary

cytokines Cell products that act as hormones, serving to convey messages from one cell to another.

interleukin Term meaning "between leukocytes"; originally coined to describe the first cytokines known to be involved in the regulation of the immune and inflammatory systems.

Janus kinases Class of tyrosine-specific enzymes that function as second messengers; act intracellularly to signal molecules in the cytoplasm and nucleus by catalyzing the phosphorylation of tyrosine residues on target molecules.

signal transducers and activators of transcription (STATs) Molecules that act as second messengers by receiving signals from the cytoplasmic domains of cell surface receptors; on becoming activated, they transform into activators of transcription.

Interleukin-4

WILLIAM E. PAUL

National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda

Interleukin-4 is a type I cytokine that expresses a wide range of biologic functions. Among its most important actions is control of immunoglobulin class switching to IgE and of differentiation of naive CD4 T cells into T_H2 cells. It is the principal regulator of allergic and antihelminthic responses.

I. INTRODUCTION

Interleukin-4 (IL-4) is produced by a subset of CD4 T helper cells (T_H2), by natural killer (NK) T cells, by basophils and mast cells, and by eosinophils. IL-4 mediates its function by interacting with two types of receptors (Rs), both of which utilize the IL-4Rα chain. The type I receptor also utilizes the common γ-chain (γc) whereas the type II receptor utilizes IL-13Rα1. In response to IL-4, IL-4Rα becomes tyrosine phosphorylated and mediates its signaling function by the recruitment of a series of signaling intermediates, including a signal transduction and activation transcription protein (Stat6) and insulin receptor substrate-2 (IRS-2). Regulation of IL-4 expression has potential importance in determining the severity of allergic diseases and, possibly, in controlling destructive autoimmunity.

II. INTERLEUKIN-4 STRUCTURE

IL-4, a typical "short hematopoietin," is a ~20,000-Da glycoprotein consisting of 153 amino acids (in humans) or 140 amino acids (in mice). Its three-dimensional structure is typical of short hematopoietins. IL-4 is a globular protein consisting of four short α-helices, in which the first (A) and second (B) are parallel to one another and connected by a long, overhand loop. The third (C) and fourth (D) helices are parallel to each other but are antiparallel to helices A and B. The α chain of the IL-4 receptor interacts with regions in helices A and C, whereas contact residues for the γc chain of the receptor have been identified on helix D.

III. THE INTERLEUKIN-4 RECEPTOR

The IL-4 receptor uses a typical short hematopoietin receptor chain, IL-4Rα, as a high-affinity binding element and a second polypeptide, either γc (the type I receptor) or IL-13Rα1 (the type II receptor). The type II receptor is also the principal receptor for IL-13. This implies that IL-4 and IL-13 mediate many functions in common. However, the type II receptor is not found on T cells, thus IL-4 is unique in its capacity to induce T_H2 differentiation.

For IL-4 to mediate signaling, it must heterodimerize IL-4Rα with either γc or 13Rα1. A mutation in human IL-4, Y124D (where Y is tyrosine and D is aspartic acid, using the one-letter amino acid code), results in inability to bind to the human γc chain. Because the mutant retains its capacity to bind to IL-4Rα, it is capable of binding but not signaling through the type I receptor and thus is a powerful competitive inhibitor of many IL-4 functions.

The extracellular segment of IL-4Rα consists of two type III fibronectin domains. The membrane distal extracellular domain contains conserved paired cysteines and the membrane-proximal extracellular domain contains a conserved WSXWS motif

cytokine have yet to be fully elucidated, but it appears to be involved in mechanisms controlling immunoregulatory and inflammatory responses, including allergies and asthma.

I. DISCOVERY OF IL-22

Interleukin-22 (IL-22) is one of several recently discovered cytokines with limited primary homology to IL-10. Using a complementary DNA subtraction technique in mouse T cells, the cDNA for mouse IL-22 has been identified as a gene specifically induced by IL-9. A protein encoded by the cDNA that was originally designated IL-10-related T-cell-derived inducible factor (IL-TIF) is now designated IL-22. The protein demonstrates 22% identity to IL-10 and consists of 280 amino acids, including a potential signal peptide. The expression of IL-22 is induced by IL-9 in several cell lines, including BW5147 thymic lymphoma cells, T helper cell clone TS2, and MC9 mast cells, and is also induced by IL-9 or concanavalin A (Con A) in freshly isolated splenocytes. Constitutive expression of the IL-22 gene is detected in thymus and brain. Recombinant IL-22 produced by HEK293 cells transiently transfected with the IL-22 cDNA represents a heterogeneous protein that migrates on gel in the region of 25–30 kDa, indicating glycosylation of the protein. Recombinant IL-22 activates signal transducers and activators of transcription (Stat) factors, predominantly Stat3 and Stat5, in MES13 murine kidney mesangial cells and PC12 rat pheochromocytoma cells.

Human IL-22 has been cloned based on its homology to the mouse orthologue and also as a novel secreted protein. Recombinant human IL-22 expressed in COS cells appears to be a glycosylated secreted protein migrating on gel as several bands in the region of about 25 to 40 kDa. IL-22 mRNA expression is induced in T cells by anti-CD3-stimulation and is further up-regulated by the addition of Con A. It has been reported that activated human and mouse T_H1 rather than T_H2 CD4 + T helper cells produce IL-22. It has also been demonstrated that lipopolysaccharide (LPS) injection *in vivo* stimulates IL-22 mRNA expression in various organs. As a first step in determining biological activities and the receptor for IL-22, several IL-22-responsive cell lines, as measured by Stat activation, have been identified. Rapid Stat activation following treatment with IL-22 is observed in TK-10 renal carcinoma, SW480 colon adenocarcinoma, A549 lung carcinoma, HepG2 and HepG3 hepatoma, HT29 intestinal epithelial cell line, and several melanoma cell lines. Stat3, to a lesser extent Stat1, and in certain cells Stat5 are the transcriptional factors of the Stat family activated in cells after IL-22 treatment. Biological activities of IL-22 are not well defined yet. It has been shown that stimulation of HepG2 human hepatoma cells with IL-22 up-regulates the production of acute-phase reactants such as serum amyloid A, 1-antichymotrypsin, and haptoglobin. Similar effects are observed *in vivo*: IL-22 injection induces production of serum amyloid A in mouse liver. These observations suggest involvement of IL-22 in the inflammatory response. IL-22, in contrast to IL-10, has no effect on LPS-induced production of tumor necrosis factor α (TNFα), IL-1, and IL-6 from freshly isolated human monocytes. Furthermore, IL-22 does not inhibit the action of IL-10 in these assays. IL-22 has no effect on interferon γ (IFNγ) production from *in vitro* polarized T_H1 cells; however, modest inhibitory effects of IL-22 on IL-4 production from T_H2 cells is observed. Administration of murine IL-22 either by intravenous injection or by adenovirus results in systemic effects, i.e., decreased red cell count and serum albumin levels and increased platelet count, serum amyloid A levels, fibrinogen levels, and body weight. Basophilia in the proximal renal tubules is also observed. Further experiments are necessary to elucidate the role of IL-22 in inflammation and in immunoregulation.

II. THE IL-22 GENE

A search for the IL-22 gene led to a surprising discovery. Whereas there is a single copy of the IL-22 gene in the human genome and in genomes of BALB/c and DBA/2 mice, genomes of other mouse strains, such as C57BL/6, FVB, and 129, possess two IL-22 genes, which were originally designated IL-TIFα and IL-TIFβ. Apparently, the gene has been duplicated and two copies are well conserved, demonstrating 98% nucleotide identity in the coding region. The murine genes map to chromosome 10 in the region of the IFNγ gene. The human IL-22 gene is located on chromosome 12 about 90 kb from the IFNγ gene (Fig. 1). The human IL-22 gene and the murine IL-TIFα gene consist of six exons; exon 1 contains a part of the 5′ untranslated region (UTR) and exons 2–5 cover the coding region of the IL-22 mRNA. The murine IL-TIFβ gene, in addition to several single nucleotide variations, contains a 658-nucleotide deletion covering the first noncoding exon and

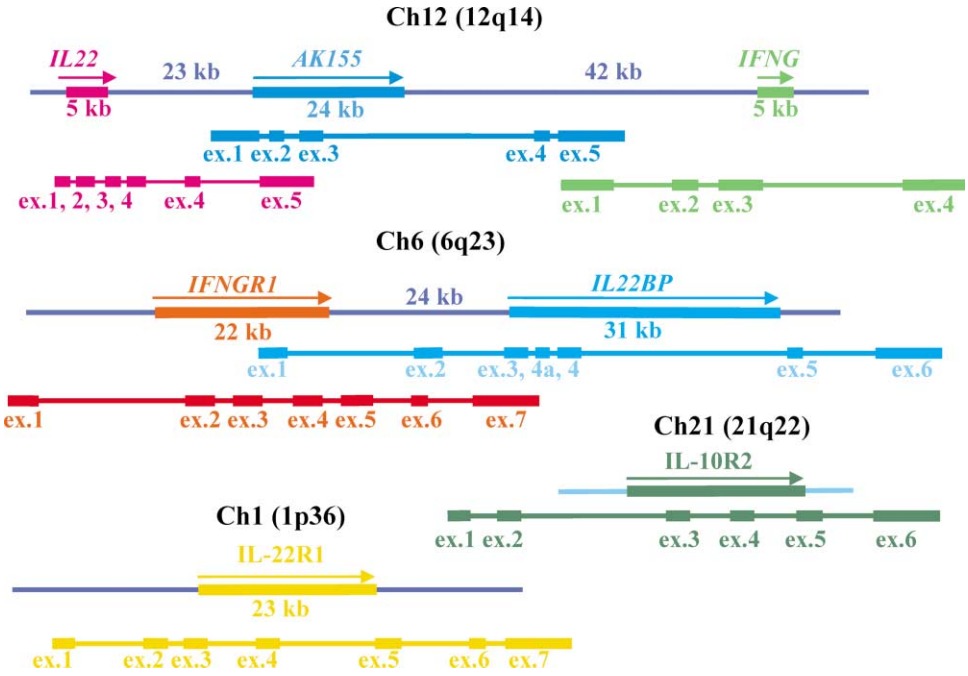

FIGURE 1 Chromosomal localization of the IL-22 gene and genes encoding subunits of the IL-22 receptor complex and the IL-22 binding protein. The IL-22 gene is positioned near the interferon γ (*IFNG*) and *AK155* genes on human chromosome 12 (Ch12). The functional IL-22 receptor complex consists of IL-22R1 and IL-10R2 subunits. Both subunits are common shared receptors for other receptor complexes. IL-22R1 is also a receptor subunit for the IL-20/IL-24 receptor complex, whereas IL-10R2 is also a chain for the IL-10 receptor complex. The IL-22R1 and IL-10R2 genes are mapped to human chromosomes 1 and 21, respectively. IL-22 binding protein is a soluble receptor that acts as an IL-22 antagonist. Its gene (*IL22BP*) is on human chromosome 6 in the vicinity of the *IFNGR1* gene.

a segment of a putative promoter, suggesting that the IL-TIFβ gene is either differentially regulated or not expressed at all.

There are data linking IL-22 to allergy and asthma. IL-22 is induced by IL-9, a T_H2 cytokine active on T and B lymphocytes, mast cells, and eosinophils and thus potentially involved in allergy and asthma. The IL-22 gene and another IL-10-related gene, *AK155*, are located on human chromosome 12q15, where several loci potentially linked to asthma and atopy have been identified by genetic studies, particularly in the 12q13–q23.3 region. The strongest evidence for linkage is in a region near the gene encoding IFNγ. However, the gene for IFNγ appears to be highly conserved (no sequence variations were detected in 265 individuals), suggesting that mutations of the IFNγ gene are unlikely to be a significant cause of inherited asthma. The IL-22 and *AK155* genes are positioned next to the IFNγ gene (Fig. 1) and, thus, are possible candidates for linkage to asthma.

III. THE IL-22 RECEPTOR COMPLEX

Cytokines exert their actions by binding to specific cell-surface receptors, which leads to the activation of cytokine-specific signal transduction pathways. Based on the fact that IL-22 demonstrates homology to IL-10, it is logical to propose that their receptor complexes may share at least structural homology and perhaps receptor subunits. The functional IL-10 receptor complex consists of two chains, the ligand-binding IL-10R1 subunit and a second IL-10R2 subunit that supports signaling through the IL-10R1 chain. Both chains belong to the type II cytokine receptor family. In addition to members with defined functions, i.e., two receptor chains for type I and type II interferons, two receptor chains for IL-10, and the tissue factor that binds coagulation factor VIIa, several orphan receptors belong to this family.

The first step in identifying the IL-22 receptor complex was to rule out the possibility that IL-22

may utilize the canonical IL-10 receptor complex. This was demonstrated by inability of IL-22 to induce Stat activation in IL-10-responsive cells, such as the RAW264 murine macrophage-like cell line and the MOLT-4 human lymphoblast cell line, and also in freshly isolated human peripheral blood mononuclear cells (PBMCs). In addition, IL-22 failed to induce MHC class I antigen expression and Stat1 activation in hamster cells expressing the chimeric human IL-10R1/γR1 chain and the intact human IL-10R2 chain, whereas human IL-10 did. Thus, it became clear that IL-22 requires its own specific receptor complex for signaling, but might share a subunit with the IL-10 receptor complex, particularly the IL-10R2 chain, which is ubiquitously expressed.

Orphan receptors from the type II cytokine receptor family have been examined for being likely subunits of the IL-22 receptor complex. Out of several candidates, only one receptor, a cytokine receptor family type II member (CRF2-9), was capable of binding IL-22 when expressed in monkey COS cells or in Chinese hamster cells, as demonstrated by flow cytometry with an IL-22-Fc fusion protein or by cross-linking, respectively. However, only in COS cells was CRF2-9 able to sustain IL-22 signaling as measured by Stat activation, whereas CRF2-9 expressed in hamster cells did not render them responsive to IL-22. CRF2-9 was designated IL-22R1, or IL-22R. These results suggest that an additional receptor subunit is required to support signaling through IL-22R1 in hamster cells. This subunit might not be expressed in hamster cells or may be species specific, whereas it is endogenously expressed in COS cells. A similar scenario was observed for the IL-10 receptor complex. It was demonstrated that the IL-10R2 chain has limited species specificity: the IL-10R2 chain of mouse, human, or monkey origin can support signaling through the IL-10R1 chain of these species. However, the hamster IL-10R2 chain can support signaling only through mouse IL-10R1, but not through human IL-10R1. Thus, it was hypothesized that IL-10R2 could be a common second chain for both IL-10 and IL-22 receptor complexes. Indeed, when the human IL-10R2 chain is coexpressed with IL-22R1 in hamster cells, the cells become sensitive to IL-22, demonstrating involvement of IL-10R2 in the IL-22 receptor complex. In addition, anti-IL-10R2 antibody completely blocks IL-22-mediated expression of serum amyloid A and luciferase reporter activity in HepG2 cells. Thus, IL-22 requires expression of both chains, IL-22R1 and IL-10R2, for signaling and induction of biological activities. The pattern of IL-22-induced Stat activation in COS cells expressing the IL-22 receptor is characteristic of IL-22 signaling in intact IL-22-responsive cells. The analysis of the IL-22R1 intracellular domain demonstrates that Stat proteins are likely to be recruited through this receptor. There are several tyrosine residues in the IL-22R1 intracellular domain that are potential sites for phosphorylation. Analysis of amino acids surrounding tyrosine residues within the IL-22R1 intracellular domain reveals the presence of four potential Stat3 recruitment sites, the phospho-Tyr-XX-Gln sequence (YXXQ motif). In addition, when the chimeric IL-22R1/γR1 chain (in which the IL-22R1 intracellular domain was replaced by the intracellular domains of the human IFNγR1 chain) was expressed in COS cells, the pattern of IL-22-induced Stat activation changed to that characteristic of IFNγ signaling—only Stat1 DNA-binding complexes were observed. Thus, the activation of Stats is indeed mediated by the IL-22R1 intracellular domain, because substitution of the IL-22R1 intracellular domain with the IFN-γR1 intracellular domain causes a change in the pattern of Stat activation. The use of chimeric receptors also allowed evaluation of responsiveness of cells to IL-22 treatment without knowing IL-22-specific biological activities. In cells expressing the chimeric IL-22R1/γR1 and intact IL-10R2 chains, IL-22 induced IFNγ-like biological responses. Thus, in these cells, in addition to measuring IL-22-induced signaling events (Stat activation), it was also possible to measure IL-22-induced IFNγ-like biological activities, such as major histocompatibility complex (MHC) class I antigen expression.

The IL-22 receptor (Fig. 2) is likely to be structurally homologous to the IFNγ, IL-10, and other IL-10 family cytokine receptor complexes. IL-22 binding is likely to induce oligomerization of two IL-22R1 chains and two IL-10R2 chains. However, the IL-22 receptor complex has a distinct feature: the IL-22R1 chain and the IL-10R2 chain are both capable of binding IL-22 independently. The ability of IL-10R2 to bind IL-22 has been demonstrated by flow cytometry using an IL-22-Fc fusion protein and COS cells overexpressing IL-10R2 alone, and also by cross-linking radiolabeled IL-22 to hamster cells expressing only the human IL-10R2 chain, without the IL-22R1 chain. Thus, both chains of the IL-22 receptor complex can independently bind ligand, whereas in the IL-10, IFNα, and IFNγ receptor complexes only one chain (the R1 chain, which also recruits Stat proteins) can bind ligand in the absence of the other. Nevertheless, in all of these receptors,

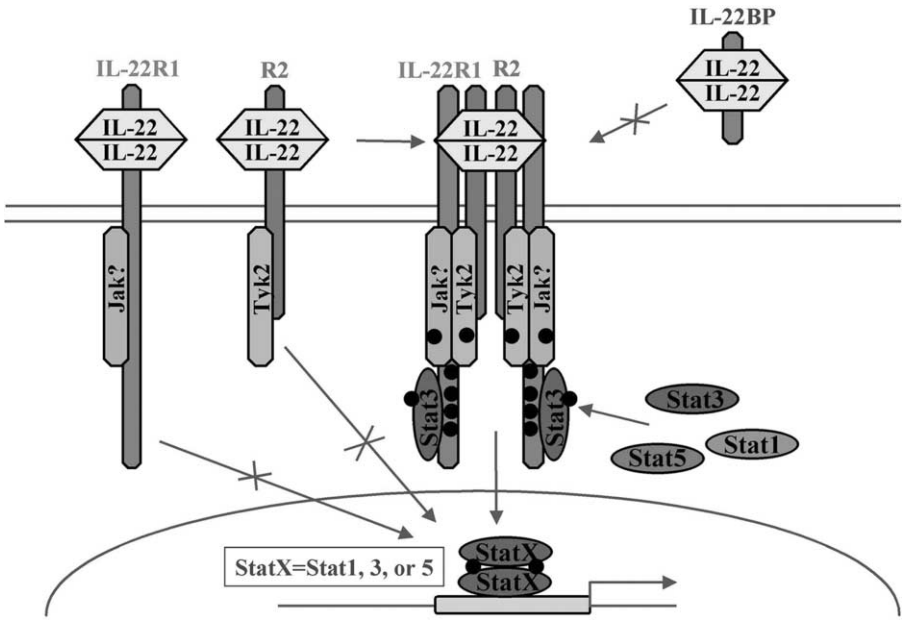

FIGURE 2 Model of the IL-22 receptor complex and signal transduction mechanism. The functional IL-22 receptor complex consists of two receptor chains, IL-22R1 and IL-10R2 (R2), which is likely to be structurally homologous to the functional IL-10 or interferon γ receptor complexes. Both chains can independently bind IL-22, but both chains must be present in the receptor complex to induce signal transduction events. The IL-22 activity can be negatively regulated by the expression of the R2 chain alone because IL-22 binding to the R2 chain does not lead to signaling, preventing shedding of IL-22 into the circulation (local suppression). In addition, secretion of the soluble IL-22 binding protein (IL-22BP) into the circulation can provide systemic inhibition of IL-22 action. Both chains are necessary to assemble the functional receptor complex, which is able to induce signaling after binding IL-22. The IL-10R2 chain is associated with Tyk2. IL-22 activates a set of Stat proteins (Stat1, Stat3, and Stat5).

the second (R2) chains are necessary for signaling. The ability of the IL-10R2 alone to bind IL-22 was particularly surprising because this chain is unable to bind IL-10. Whether this unusual binding is of functional significance remains to be determined. Because IL-10R2 is ubiquitously expressed but is unable to transduce a signal without an additional chain (IL-10R1 or IL-22R1), it is possible that secreted IL-22 will be retained at the site of secretion by being bound to the IL-10R2 chain, providing local action but preventing its action at remote sites. However, this "exception" could become a rule for receptor complexes for other IL-10-related cytokines, for which only the combination of both chains provides receptor complexes with high affinity for a ligand, and each chain alone provides very low binding affinity for a ligand.

In conclusion, it is clear that both IL-22R1 and IL-10R2 chains are required for reconstitution of the functional IL-22 receptor complex; and that the IL-10R2 chain also functions as the IL-22R2 chain. However, sharing of receptor chains between cytokines of the IL-10 family goes beyond the use of IL-10R2 as a second chain in both IL-10 and IL-22 receptor complexes. The IL-22R1 chain combined with IL-20R2, the second chain of the IL-20 receptor complex, could form a functional receptor complex for both IL-20 and IL-24.

IV. EXPRESSION OF THE IL-22R1 mRNA

Expression of IL-22R1 mRNA has been detected by Northern blotting in several normal tissues, including kidney, liver, and pancreas, in which the level of expression was the highest. The fact that the IL-22R1 gene is expressed in normal liver tissue correlates with its functions as a hepatocyte-stimulating factor. The transcript size is approximately 3.0 kb, which is comparable with the size of IL-22R1 cDNA (2.8 kb). Several solid tumor cell lines constitutively express the IL-22R1 mRNA. Among them are colorectal adenocarcinoma SW480, lung carcinoma A549, melanoma G361, hepatoma HepG2, and renal carcinoma Caki-1 and TK-10 cell lines, the

HT29 intestinal epithelial cell line, and the HaCaT keratinocyte cell line also constitutively express IL-22R1 mRNA. It is interesting to note that all cell lines expressing IL-22R1 mRNA are nonhematopoietic tumor cell lines. Because IL-22 induces Stat3 activation in IL-22-responsive cells, and expression of constitutively active Stat3 has been shown to cause cellular transformation, it is possible that in certain cells IL-22 could act as an autocrine or paracrine factor, driving cells to malignancy.

V. NATURALLY OCCURRING IL-22 ANTAGONIST

The fact that IL-22 is capable of binding to the singly expressed IL-10R2 suggests that the activity of IL-22 can be regulated on a local level by sequestering locally expressed IL-22, because IL-10R2 is ubiquitously expressed. However, regulation of IL-22 action is not limited to the local level. Systemic regulation is provided by the soluble receptor, i.e., IL-22 binding protein (IL-22BP).

The use of decoy or soluble receptors for cytokines utilizing members of the type II cytokine receptor family for signaling is rather uncommon. It has been demonstrated only for interferon α (IFNα), in which the human IFNαR2c, one of the functional chains of the IFNα receptor complex, has two splice variants, the membrane-bound IFNαR2b (with a short intracellular domain that appears unable to transduce the signal) and the soluble IFNαR2a form. These various receptor chains are the result of alternative splicing events. The gene encoding the only soluble receptor from the type II family was recently, identified. This novel receptor was originally designated cytokine receptor family type II member 10/X (CRF2-10/CRF2-X). When its function as an IL-22 antagonist was discovered, the protein was renamed IL-22 binding protein (other names include IL-22RA2 and CRF2-s1).

IL-22BP was discovered by searching the sequence of the human genome for genes encoding novel receptors from the type II cytokine receptor family. IL-22BP demonstrates 34% identity to the IL-22R1 extracellular domain. The purified protein migrates on gel as a broad band in the region of about 35–45 kDa, suggesting possible glycosylation of the protein. Indeed, there are five potential sites for N-linked glycosylation (Asn-X-Thr/Ser) in CRF2-10. IL-22BP binds IL-22, as demonstrated by cross-linking of IL-22BP to radiolabeled IL-22 in solution and by binding IL-22BP-Fc fusion protein on IL-22-coated plates. Also, IL-22 is unable to interact with the membrane-bound IL-22 receptor complex in the presence of IL-22BP, as demonstrated by cross-linking. In addition, IL-22BP neutralizes IL-22 activity. IL-22BP inhibits the ability of IL-22 to induce Stat activation in intact A549 human lung carcinoma cells and the ability of IL-22 to induce the expression of the SOCS-3 gene in HepG2 human hepatoma cells; it also blocks luciferase reporter activity induced by IL-22 in HT29 intestinal epithelial cells and neutralizes IL-22 activity in a proliferation assay with BAF3 cells expressing the IL-22 receptor complex. IL-22BP inhibits IL-22-induced activities and signaling in specifically designed IL-22-responsive hamster cells expressing the chimeric human IL-22 receptor complex. The affinity of the IL-22 receptor complex when both IL-22R1 and IL-10R2 chains are present is higher than the affinity of each chain alone. It seems that IL-22BP has even higher affinity for IL-22 binding than the membrane-bound IL-22 receptor complex, because incubation of cells expressing the functional IL-22 receptor complex with IL-22 in the presence of IL-22BP inhibits binding of IL-22 to the cellular receptors. It also appears that the IL-22–IL-22BP complexes are stable and that little or no dissociation of the complexes occurs, because cells incubated for 3 days with IL-22–IL-22BP complexes in conditioned media do not demonstrate IL-22-induced activities. The binding appears to be very specific, because IL-22BP-Fc fusion protein fails to bind to plates covered with bound cytokines from the IL-10 family, including IL-19, IL-20, and IL-24; IL-22BP also fails to neutralize IL-10 activity. Thus, by binding IL-22, IL-22BP blocks the activities of IL-22.

VI. EXPRESSION OF THE IL-22BP mRNA

Because each chain of the IL-22 receptor complex alone is able to bind IL-22, it is likely that IL-22 activity can be negatively regulated by expression on the cell surface of the R2 chain, unpaired by the IL-22R1 chain. Because IL-22 binding to the R2 chain expressed alone does not lead to signaling, it may prevent shedding of IL-22 into the circulation (local suppression). In addition, secretion of the soluble IL-22BP into the circulation can provide systemic inhibition of IL-22 action. Thus, the production of IL-22BP may be one of the mechanisms to regulate IL-22 function precisely (Fig. 2). Because IL-22 has been implicated in inflammation, the expression of IL-22BP in certain tissues can, perhaps, modulate local inflammation. In this light, it is of interest to

note that IL-22BP expression has been detected by *in situ* hybridization in the mononuclear cells of inflammatory infiltration sites, plasma cells, and a subset of epithelial cells. Cells expressing IL-22BP as detected by *in situ* hybridization are observed in several tissues, including placenta, skin, inflamed appendix, lung, gastrointestinal tract, lymph node, thymus, and spleen. Also, strong signals are detected in epithelial cells and some interstitial cells (most likely mononuclear cells) in ovarian carcinoma; however, no signal is observed in normal ovarian tissue. The regulation mechanism of IL-22BP expression is not known. Induction of IL-22BP expression in response to LPS or anti-CD3 antibodies in peripheral mononuclear cells has not been detected. IL-22 stimulation does not induce IL-22BP production. The IL-22BP expression profile generated by Northern blot and polymerase chain reaction (PCR) analysis indicates that IL-22BP is highly expressed in placenta, mammary gland, breast, spleen, skin, and lung, with lower expression in a variety of other tissues such as heart, pancreas, testis, thymus, and prostate. IL-22BP expression is also detected in the digestive system (stomach, small intestine, esophagus, gastro-esophageal, pancreas, duodenum, ileum, colon, and small bowel), female reproductive system (mammary gland, endometrium, and breast), and other systems (lymph nodes, lung, skin, parotid, bladder, bronchus, heart ventricles, and kidney). It is noteworthy, that IL-22BP is expressed in certain tissue-specific tumors such as ovarian, uterine, and rectal cancers, but not in the corresponding normal tissues.

VII. IL-22R1, IL-10R2, AND IL-22BP GENES

Genes encoding receptors from the type II cytokine receptor family are clustered on several human chromosomes. The IL-10R2 gene maps to chromosome 21 along with IFNαR1, IFNαR2, and IFNγR2 genes. The IL-22R1 gene is on chromosome 1. The IL-22BP gene is positioned on chromosome 6 in the vicinity of the IFNγR1 gene in a head-to-tail orientation and is in close proximity to the IL-20R1 gene. IL-10R2, IL-22R1, and IL-22BP genes have similar structural architecture, with two exceptions for the IL-22BP gene: the presence of an additional exon (exon 1) encoding the 5′ UTR and the lack of the two last exons encoding transmembrane and intracellular domains of the IL-22R1 and IL-10R2 chains. Thus, IL-10R2 and IL-22R1 genes contain seven exons. The first exon encodes the 5′ UTR and the signal peptide of the proteins. Exons 2, 3, 4, and 5 encode the extracellular domain of the receptors. Exon 6 encodes the entire transmembrane domain and the beginning of the intracellular domain of the receptors. Exon 7 encodes the rest of the intracellular domain and the 3′ UTRs of the proteins. Numbering of exons is shifted by one in the IL-22BP gene because of the presence of an additional exon, exon 1, encoding the 5′ UTR. Thus, the IL-22BP gene is composed of six exons. The entire first exon and a part of the second exon encode the 5′ UTR. The rest of the second exon encodes the signal peptide of the protein. Exons 3, 4, and 5 and a portion of exon 6 encode the secreted IL-22BP receptor. The rest of exon 6 encodes the long 3′ UTR with the presence of multiple polyadenylation signals. In addition, alternative splicing events either insert exon 4a between exons 4 and 5, creating a longer CRF2-10 splice variant (CRF2-10_L), or eliminate exon 5, creating prematurely terminated short protein (CRF2-10_S). It remains to be determined whether alternative slicing events are regulated and whether splice variants are functional.

Glossary

cytokine receptor family type II Cell membrane protein group that includes interferon receptors, interleukin-10 receptor, coagulation factor VIIa receptor, and several orphan receptors.

interferon Member of a family of proteins, some of which are glycoproteins; when secreted by virus-infected cells, can protect noninfected cells from viral replication.

interleukin Generic term for a group of protein factors that affect primary cells; derived from macrophages and T cells that have been activated.

major histocompatibility complex Genetic regions and encoded antigenic proteins that confer tissue compatibility/incompatibility between donor and recipient cells and tissues.

*University of Medicine and Dentistry of New Jersey—Robert Wood Johnson Medical School • †University of Medicine and Dentistry—New Jersey Medical School • ‡Columbia University College of Physicians and Surgeons

Interleukin-24 (MDA-7) is a member of an interleukin-10 cytokine subfamily. It is encoded by a gene (*mda-7*) that resides in a cluster of genes associated with the interleukin-10 family of cytokines. The gene cluster contains four genes that encode IL-10, IL-19, IL-20, and MDA-7. Because of its growth-suppressive effects, interleukin-24 has antitumor properties in a broad array of tissues; potential therapeutic applications, particularly in combination with other suppressive agents, are under investigation.

I. OVERVIEW OF *mda-7*

Subtraction hybridization has identified a melanoma differentiation-associated gene-7 (*mda-7*) as a novel cDNA displaying inducible expression in the context of irreversible growth arrest and terminal differentiation of human melanoma cells. The *mda-7* gene is expressed in normal melanocytes; expression decreases progressively during the process of melanoma development and evolution, suggesting a potential involvement of this gene in human melanoma progression. When ectopically expressed in a wide variety of cancer cells with diverse genetic defects, *mda-7* induces growth suppression and apoptosis (programmed cell death). In contrast, *mda-7* does not elicit any overt harmful effects in normal human cells. Preclinical human tumor animal models have documented that *mda-7* administered by means of a replication-incompetent adenovirus, Ad.*mda-7*, suppresses tumor formation and cancer progression. Based on these preferential cancer specific growth-suppressive and apoptosis-inducing properties, phase I clinical trials with Ad.*mda-7* in patients with cancer are now in progress. Human *mda-7* encompasses seven exons and six introns and encodes a protein of 206 amino acids. The *mda-7*-encoded protein contains a predicted secretory motif of 49 amino acids, an interleukin-10 (IL-10) signature motif, and belongs to the four-helix bundle family of cytokine molecules most closely related to the IL-10 subfamily (although IL-10 contains six α-helices). The *mda-7* gene maps to human chromosome 1q, at 1q32.2–q41, a genomic area containing a cluster of genes associated with the IL-10 family of cytokines, including IL-10, IL-19, and IL-20. Members of the expanded IL-10 family have distinct functional properties and tissue expression profiles. Experimental evidence documents that the MDA-7 protein is secreted from both normal and tumor cells, and purified MDA-7 protein can bind to IL-20R1 and IL-20R2 receptor complexes, resulting in the activation of signal transducers and activators of transcription (Stat) signaling pathways. Based on its structure, cytokine-like properties, and proposed mode of action, MDA-7 has now been classified as IL-24. Still unanswered and important questions relate to the mechanism by which IL-24 (MDA-7) selectively induces its cancer growth suppressive and apoptosis-inducing effects and the programs of gene expression changes underlying these effects.

II. DISCOVERY

Aberrant programs of differentiation occur frequently in many forms of cancer. A therapeutic approach that offers potential for exploiting this trait in tumor cells involves the use of agents that induce reprogramming of neoplastic cells to a more differentiated state, resulting in a reduction or loss in proliferative ability and tumorigenic potential. In human melanoma cells, treatment with a combination of fibroblast interferon β(IFNβ) and the protein kinase C activator mezerein (MEZ) results in an irreversible loss in growth potential, suppression of tumorigenic potential, and terminal differentiation. Combining this "differentiation therapy" model system with subtraction hybridization allows definition of the spectrum of gene changes that are associated with induction of melanoma terminal differentiation. Initial screening of 73 cDNA clones isolated from an HO-1 IFNβ + MEZ temporally spaced subtracted cDNA library has led to identification of the novel *mda-7* cDNA.

III. ACTIVITIES

Based on the context of its isolation following induction of terminal differentiation in human melanoma cells, it was initially hypothesized that *mda-7* might play a role in human melanoma growth, differentiation, and progression. To test this possibility, HO-1 human melanoma cells were transformed with an expression vector containing the *mda-7* gene under the transcriptional control of a mouse mammary tumor virus promoter (pMAMneo) that responds to dexamethasone (DEX). When appropriately engineered HO-1 clones were grown in a medium containing DEX, *mda-7* was expressed and growth was suppressed. Analysis of *mda-7* mRNA expression in cell lines and in patient-derived tissue demonstrated an inverse relationship between melanoma development and progression and *mda-7* expression. Highest levels of *mda-7* expression were observed in melanocytes and nevi and diminishing expression was found as the primary early radial growth phase (RGP) melanoma progressed to vertical growth phase (VGP) melanoma and then to metastatic melanoma, in which the majority of patient-derived cell lines and tumor samples displayed negligible or no *mda-7* expression. This inverse relationship between melanoma progression and *mda-7* expression, as originally proposed by Jiang *et al.* based on reverse transcriptase and polymerase chain reaction (RT–PCR) studies, has recently been confirmed by Western blotting with MDA-7 antibodies and by immunohistochemistry with patient tissue samples and cells in culture.

Considering the growth suppressive effects of *mda-7* in metastatic human melanoma cells, experiments were performed to determine if this effect is restricted to melanoma or represents a more general property of this gene. Transfection of a wide spectrum of human tumor cell lines with an *mda-7* expression vector, including glioblastoma multiforme, osteosarcoma, and carcinomas of the breast, cervix, colon, nasopharynx, and prostate, reduced colony formation. In contrast, no deleterious effects were observed when *mda-7* was ectopically expressed in normal human cells, including epithelial cells and fibroblasts. To deliver *mda-7* to cancer cells more efficiently, a replication-incompetent adenovirus (Ad.*mda-7*) expressing *mda-7* was constructed. As observed with transfection, Ad.*mda-7* selectively induced a growth inhibitory effect in diverse human cell types but spared a wide spectrum of normal cells, including endothelial and epithelial cells, fibroblasts, and melanocytes. Moreover, when expressed at high levels by adenovirus delivery, *mda-7* selectively induced apoptosis in cancer cells. Initial experiments using breast carcinoma cells indicated that Ad.*mda-7* induced apoptosis in a p53-independent manner and was associated with an increase in the pro-apoptotic protein BAX and a decrease in the ratio of the anti-apoptotic protein Bcl-2 to the BAX protein. Moreover, when breast carcinoma cells were cotransfected with a pMAMneo–*mda-7* vector (permitting controlled *mda-7* expression by dexamethasone and selection for resistance to G418) and a Bcl-2 or Ad.E1B expression vector, *mda-7*-induced growth inhibition was prevented. These findings document that the increase in BAX protein and the decrease in the ratio of BAX to Bcl-2 protein following Ad.*mda-7* infection of breast cancer cells functionally contribute to the process of apoptosis. However, because DU-145 prostate cancer cells, which do not produce BAX protein, and NSCLC H1299 lung carcinoma cells, which do not show up-regulation of BAX expression following infection with Ad.*mda-7*, are also sensitive to the programmed cell death-inducing effects of *mda-7*, it is clear that this cancer-growth-suppressing gene can induce apoptosis in a BAX-dependent or BAX-independent manner. To date, Ad.*mda-7* has been shown to induce apoptosis in multiple cancer subtypes, including melanoma, glioblastoma multiforme, osteosarcoma, and carcinomas of the breast, cervix, colon/rectum, lung,

nasopharynx, and prostate, without affecting normal cells. These experiments confirm that Ad.*mda-7* can induce antitumor effects in specific cancer cells independent of the genomic status of p53, retinoblastoma, p16, Ras, BAX, and caspase 3 genes. In specific cancer cell types, Ad.*mda-7* also induces an alteration in the cell cycle, resulting in an accumulation of tumor cells in the G_2/M phase of the cell cycle, and this alteration in cell cycle regulation may contribute to the antitumor effects of *mda-7*. Based on the broad-spectrum antitumor activity of *mda-7* and its apparent selectivity toward cancer cells without adversely affecting normal cellular physiology, phase I clinical trials have been initiated with Ad.*mda-7* to determine its safety in patients. Initial results with a limited number of patients suggest that *mda-7* is safe and has no unanticipated side effects following Ad.*mda-7* intratumoral administration, and that direct injection into tumors can elicit tumor cell death by apoptosis. In view of these promising initial findings, further studies to define directly the potential cancer therapeutic effects of Ad.*mda-7* in additional phase I and phase II clinical trials are warranted.

An apparent exception to the wide-spectrum antitumor properties of *mda-7* is pancreatic cancer. Infection of human pancreatic cancer cells with Ad.*mda-7* does not alter growth or induce apoptosis. In contrast, the combination of Ad.*mda-7* with antisense phosphorothioate oligonucleotides (PS ODNs), thus targeting the K-*ras* oncogene (which is mutated in 85–95% of pancreatic carcinomas), induces growth arrest and decreased survival by inducing apoptosis uniquely in mutant K-*ras* pancreatic carcinoma cells. Similarly, by blocking K-*ras* expression using an antisense K-*ras* expression vector, thus targeting the AUG region of the K-*ras* gene, the growth and *in vivo* tumorigenic potential of mutant K-*ras* pancreatic carcinoma cells are inhibited. This study provides compelling evidence that a combinatorial approach, consisting of the *mda-7* cancer-specific apoptosis-inducing gene and an oncogenic inactivation strategy, offers potential for developing an effective and rational therapy for pancreatic and perhaps other resistant cancers. Furthermore, this study emphasizes how molecular oncology, based on an understanding of the molecular defects in cancer cells, can be used for defining methods for early diagnosis, prevention, and new and effective therapeutic strategies for treating cancer. These experiments further highlight that, in specific cancers, such as pancreatic cancer, it may be necessary to correct or modify two disparate molecular changes to elicit a biological response that results in growth suppression and apoptosis. By defining the gene changes associated with cancer development and evolution, it may be possible to exploit these defects by correcting and blocking specific cancer-related changes, thereby short-circuiting the cancer cell and inducing its demise.

IV. HUMAN *mda-7* (IL-24) GENE

The human *mda-7* cDNA is 1718 nucleotides long; there is an open reading frame (ORF) encoding a 23.8-kDa protein of 206 amino acids. The major ORF starts at position 275 and terminates at position 895. The predicted open reading frame is flanked by 5′ and 3′ untranslated sequences of 274 and 823 bp, respectively. The 3′ untranslated region (UTR) contains three consensus elements (AUUUA) involved in mRNA stability and three polyadenylation signals, AAUAAA, at −413, −204, and −20, from the first A of the poly(A) tail. The *mda-7* promoter has been isolated and found to be constitutively active in human melanoma cells, and treatment with IFNβ + MEZ does not significantly alter promoter function. In contrast, *mda-7* mRNA levels during terminal differentiation are partly regulated by differential posttranscriptional message stabilization regulated by the AU-rich (ARE) sequences present in the 3′ untranslated region of the *mda-7* cDNA. *In vitro* translation of *mda-7* in a rabbit reticulocyte system produces a protein with an apparent molecular mass of ~24 kDa on sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). Hydrophobicity plot analysis of the MDA-7 amino acid sequence predicts the presence of a hydrophobic stretch encompassing amino acids 25 to 45 of the protein. Analysis of cell lysates from Ad.*mda-7*-infected tumor and normal cells indicates the presence of an approximate 23/17-kDa doublet, suggesting that MDA-7 is processed intracellularly in a similar manner in cancer and normal cells. The first 48 amino acids of MDA-7 contain a potential signal sequence with a consensus proteolytic cleavage site at amino acids 48/49. Considering this arrangement of the primary MDA-7 amino acid sequence, it is predicted that a 23/17-kDa doublet would be generated, and indeed this is the case. Analysis of supernatants from Ad.*mda-7*-infected tumor and normal cells indicates the presence of higher molecular weight MDA-7 proteins, including multiple-sized proteins, presumably resulting from differential glycosylation.

Analysis of DNAs derived from different species by Southern blotting indicates homologous sequences in the genomic DNAs of yeasts, monkeys, bovines, dogs, and cats. The intensity of hybridization in Southern blots reveals that the highest sequence homology occurs between human, Rhesus monkey, and yeast genomic DNAs. Only weak hybridization signals are detected by probing Southern blots containing bovine, dog, and cat genomic DNA with *mda-7*. These findings confirm that *mda-7* is an evolutionarily conserved gene. However, there does not appear to be a yeast homologue of *mda-7*.

Southern blotting demonstrates that *mda-7* is a single-copy gene. Considering its unique presence in the human genome, a PCR-based method employing *mda-7*-specific primers with diploid human fibroblast genomic DNA was used to identify and isolate *mda-7* genomic DNA. This approach resulted in the identification of a 5.5 kbp amplification product containing the *mda-7* open reading frame. This approach plus subsequent screening of a human placental genomic library resulted in identification of a contiguous *mda-7* genomic sequence containing the *mda-7* transcription unit (6.33 kbp). By genomic walking, it was possible to clone an additional 2.2 kbp of the *5′* flanking region, which contains the *mda-7* promoter. The *mda-7* gene comprises seven exons and six introns that conform to the intron–exon consensus splicing signals (GT…AG). The exons range in size from 64 to 889 bp and the introns range from 115 to 1143 bp. Moreover, the *mda-7* cDNA deduced from the human exon sequence information corresponds exactly with the previously reported human *mda-7* cDNA. Sequence analysis of the seven exons from 15 different genomic sources, including non-small-cell lung carcinoma, colorectal, prostate, cervical, and normal peripheral blood leukocytes, identified an exon 4 polymorphism at residue 125 that causes a change in codon usage, resulting in either a histidine or tyrosine residue. The *mda-7* cDNA from human melanoma cells contained histidine at amino acid 125. A single amino acid insertion (Ser-15) in the signal peptide of the published *mda-7* sequence has been reported in colorectal carcinomas. However, this genetic alteration was not observed after sequencing all *mda-7* exons from more than 15 different genomic sources, including the DLD-1 colorectal cancer cell line. Nevertheless, this finding does not rule out the possibility of mutations in other regions of the gene locus.

A panel of rodent–human hybrid DNAs was employed in combination with a PCR amplification-based method to map the chromosomal location of *mda-7*. This approach generated a unique 129-bp human *mda-7*-specific product in positive clones. This approach documented that *mda-7* resides on chromosome region 1q. With the use of the gene-bridge radiation hybrids and the Whitehead Institute/MIT Center for Genome Research (WICGR) mapping server, *mda-7* displayed close linkage to markers WI-9461 (D1S06) and D1S491, which map to the region 1q32.3–q41. In this context, the genomic locus encoding *mda-7* appears to be within an IL-10-related gene cluster containing four genes, including those for IL-10, IL-19, IL-20, and MDA-7, in linear order, spanning 195 kb of genomic DNA. At the present time, the functional significance of this genomic organization is unclear.

Analysis of a large array of normal and cancer cell types demonstrates a lack of *de novo* expression of *mda-7*. An exception is melanocytes, which express both *mda-7* mRNA and protein. To define which normal tissue(s) express *mda-7,* multiple tissue Northern blots containing human tissue poly(A)$^+$ RNAs were probed with an *mda-7*-specific cDNA probe. This analysis confirmed restricted *mda-7* expression in tissues of the immune system, including spleen, thymus, and peripheral blood leukocytes. In addition, treatment of the human K562 erythroleukemic cell line with 12-*O*-tetradecanoylphorbol 13-acetate (TPA), which results in megakaryocyte differentiation, results in the induction of *mda-7* mRNA expression. Experiments with a rat model indicated elevated (9- to 12-fold) levels of *c49a* (a rat gene that encodes a protein with 58.7% overall identity with the human MDA-7 protein) mRNA during wound healing, specifically in areas surrounding the edge of the wound. Representational difference analysis (RDA) resulted in cloning of a mouse gene called *FISP* (IL-4-induced secreted protein), with sequence homology to *mda-7* and the rodent gene *c49a* (identical to a later described *mob-5* Ha-*ras*-induced rat gene). *FISP* is induced specifically as a consequence of induction of differentiation of T cells to T helper (T_H2) cells. Based on functional differences between human *mda-7*, rat *c49a*/*mob-5*, and mouse *FISP*, it appears that these genes are not true homologues but represent closely related members of a gene family

with distinct functions; however, they do appear to have evolved from the same gene.

Although normally restricted to specific cell lineages, *mda-7* mRNA can be induced under appropriate conditions in human cells that are not of melanocytic or hematopoietic lineage. A 24-h treatment of DU-145 (prostate carcinoma), HBL-100 (normal breast epithelial), MDA-MB-157 and MDA-MB-231 (breast carcinoma), NC (normal cerebellum astrocytes), GBM-18 (glioblastoma multiforme), Saos-2 (osteosarcoma), HeLa (cervical carcinoma), and HONE-1 (nasopharyngeal carcinoma) cells with IFNβ and mezerein induces *mda-7* mRNA expression. In contrast, *de novo* expression and induction of *mda-7* are not apparent in additional normal and tumor-derived human cells, including HuPEC (normal prostate epithelial), PC-3 and LNCaP (prostate carcinoma), MCF-7, T47D and MDA-MB-453 (breast carcinoma), T98G (glioblastoma multiforme), and SW613 (colon carcinoma). These results document that *mda-7* is not expressed *de novo* in most normal and cancer cell types, but expression, at least at the level of mRNA, can be induced by IFNβ and MEZ in a spectrum of normal and tumor cell types independent of alterations in classic tumor suppressor genes such as *Rb* and/or *p53*. Further studies are required to understand the significance of the induction of *mda-7* in regulating cellular physiology in normal and cancer cell types.

V. HUMAN IL-24 RECEPTOR COMPLEX

IL-24 (MDA-7) has been shown to have many activities that might be explained by its interaction with two separate receptor heterodimeric complexes. IL-24, IL-19, and IL-20 bind to the IL-20 receptor complex that consists of two chains, IL-20R1 and IL-20R2. The IL-20R1 (IL-20Rα) chain is the cytokine receptor family 2-8 (CRF2-8) chain; whereas the IL-20R2 (IL-20Rβ) chain is the protein also designated DIRS1. Furthermore, IL-24 and IL-20 bind to a second receptor complex with which IL-19 does not interact. This second receptor complex consists of the IL-22R1 and IL-20R2 complex. When activated by the ligands, both receptors signal through Stat3. Because cytokines IL-19, IL-20, IL-22, and IL-24 signal through Stat3, the differences in their activities represent a mystery still to be understood. This paradox is reminiscent of the IFNα/β receptor that consists of the two chains, IFNαR1 and IFNαR2c, thus serving as the receptor for many human ligands (12 human IFNα species, plus one IFNβ, one IFNω, and one IFNκ). Nevertheless, these various interferons demonstrate remarkable differences in activities and signal transduction despite the fact that they function through the same receptor.

VI. IL-24-RELATED MOLECULES

Since the original isolation of the *mda-7* cDNA in a human melanoma differentiation screen, three independently isolated rodent sequences showing significant sequence identity have been reported. The rat c49a sequence was isolated by differential RNA display (DD-PCR) to identify new genes for which expression was correlated with wound healing. Elevated expression was observed in fibroblast-like cells at the wound edge or base, showing a 9- to 12-fold elevated level of expression from 12 h up to 5 days, followed by a gradual decrease to 1.5- to 3-fold over a 6- to 14-day period, compared to control samples. In contrast to the observed growth-suppressive properties of the human sequence, rat c49a appears to be associated with cellular proliferation of fibroblast populations involved in the wound-healing process. No further data with this model have been forthcoming since the initial report. A later study reported the isolation of a sequence identical to c49a, utilizing DD-PCR as a screen to identify oncogenic *ras* target genes. Two types of screens were used, one involving a Rat-1 fibroblast line containing an inducible Ha-*ras* gene and the other utilizing DD-PCR on a Rat-1 line constitutively expressing Ha-*ras* treated or not with the mitogen-activated protein kinase kinase (MAPKK) inhibitor PD98059. A sequence identified in the screen and designated mob-5 was confirmed to be rapidly induced concomitant with induction of the Ha-*ras* gene, identifying it as an early oncogenic *ras* target. This sequence was shown to be rapidly inducible downstream of oncogenic *ras* signaling (but not as a consequence of serum stimulation of starved normal fibroblasts) or to be otherwise expressed in any normal rat tissues examined in the study. The normal physiological role of c49a/mob-5 is presently unclear, though both screens and subsequent analyses indicated an association of expression with proliferative responses, as opposed to observed growth-inhibitory effects induced by ectopic expression of human IL-24. It is possible that these sequences, despite possessing regions of significant amino acid identity with the human

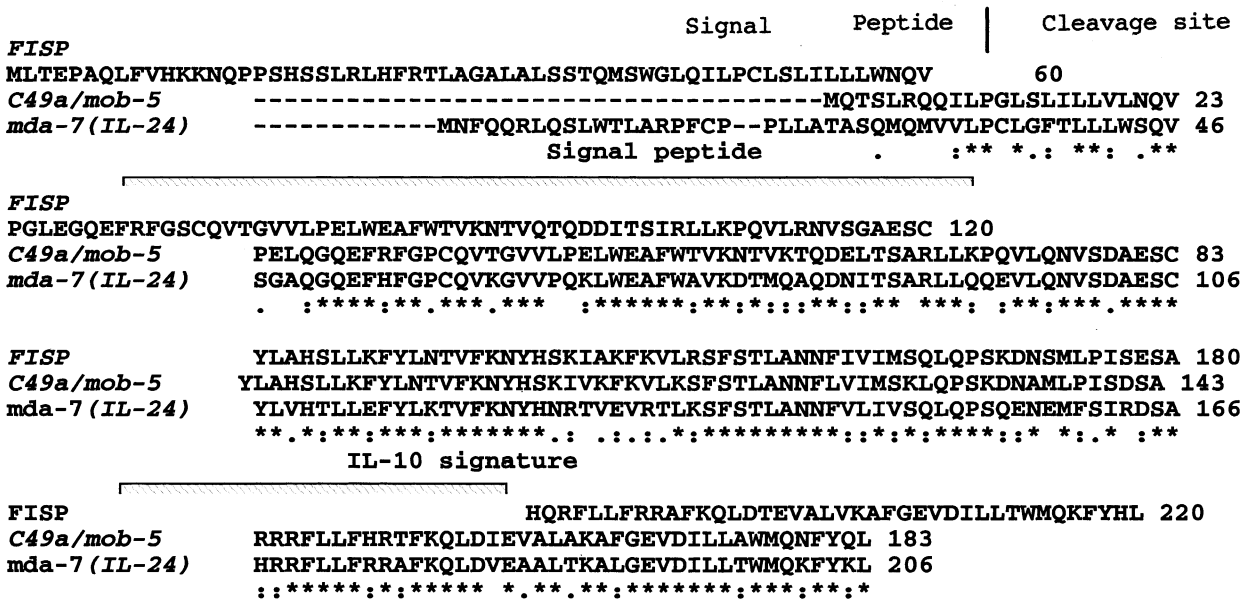

FIGURE 1 Sequence comparison of mouse IL-4-induced secreted protein (FISP), rat c49a/mob-5, and human MDA-7 (IL-24). Multiple sequence alignments using CLUSTAL W (http://www.ebi.ac.uk/clustalw) with amino acid sequences of mouse (FISP), rat (*c49a*/mob-5), and human MDA-7 (IL-24) proteins. The specific regions of note, the secretory signal peptide and IL-10 signature sequences, are indicated under each relevant sequence by a hashed line; the signal peptide cleavage site is indicated by the vertical line. The markings under each multiple alignment have the following correspondence: *, identical amino acid; ●, weakly conserved residue; :, conservative change in amino acid residue; and no marking for an unrelated residue at the respective alignment position.

protein, are related moieties but are functional rodent homologues. This is supported by the observation that the genes appear to have an oppositely acting phenotypic effect. A screen designed to identify genes involved in T helper lymphocyte type 2 (T_H2) cell development resulted in the isolation, by representational difference analysis, of mouse IL-4-induced secreted protein, which showed significant homology to c49a/mob-5 and IL-24 (MDA-7). FISP is expressed selectively in T_H2 cells following culturing of splenocytes, resulting in T_H2 differentiation and not T_H1 lineage determination. FISP is not expressed in normal spleen, thymus, liver, brain, heart, lung, testicle, kidney, or embryo-derived tissues. It appears that, on a functional level, FISP more closely resembles IL-24 than c49a/mob-5 due to its close association with differentiation. It is presently unclear if ectopic expression of FISP results in induction of apoptosis similar to activity displayed by IL-24. In general, it appears that IL-24, c49a/mob-5, and FISP represent closely related sequences comprising a gene family, but remain functionally distinct. Sequence alignment of the proteins shows significant amino acid identity over significant stretches but also several specific residues that are not functionally conserved (Fig. 1). Further structure–function studies are needed to clarify the basis of the differential activity of these molecules.

Glossary

interferon Member of a family of proteins, some of which are glycoproteins; when secreted by virus-infected cells, can protect noninfected cells from viral replication.

interleukin Generic term for a group of protein factors that affect primary cells; derived from macrophages and T cells that have been activated.

***mda*-7** Melanoma differentiation-associated gene.

In Vitro Fertilization

ROGER G. GOSDEN AND WILLIAM E. GIBBONS
Eastern Virginia Medical School

***In vitro* fertilization (IVF) is a technology with wide-ranging applications for treating female and male infertility. To enhance its chances of success, the ovaries are stimulated with gonadotropic hormones to increase the numbers of mature oocytes that are available. Pharmacological suppression of endogenous gonadotropins enables greater control of the cycle and improves success rates. Normally, several embryos are created, but their quality is variable and cytogenetic anomalies are common. To compensate for the difficulty of identifying embryos of high implantation quality, two or more are transferred to the uterus. Nevertheless, only a quarter of treatment cycles are fully successful in young women and fewer in those over 35 years of age. Technology is evolving toward less intervention in the natural cycle and more screening of embryos by preimplantation genetic diagnosis.**

I. INTRODUCTION

Infertility is arguably the most common medical condition worldwide, with at least 1 in 10 couples experiencing involuntary childlessness at some stage in their lives. *In vitro* fertilization (IVF) was pioneered by Robert Edwards and Patrick Steptoe in the 1970s. Although their primary objective was to use IVF to bypass blocked fallopian tubes, it has become a generic reproductive technology for treating many conditions, including male infertility using intracytoplasmic sperm injection. In essence, IVF involves aspirating oocytes from follicles immediately before ovulation, when they should be at the metaphase II stage of meiosis. A few days after fertilization *in vitro* with spermatozoa from ejaculated semen or surgically extracted in severely oligospermic men, the embryos reach the morula and blastocyst stages, when they can be transferred to the uterus.

The original breakthrough in IVF was achieved in natural cycles (Fig. 1a). Nowadays, treatment usually involves ovarian stimulation to increase the harvest of oocytes and improves the chances of producing some embryos with high implantation potential. Many oocytes either fail to fertilize or produce poor-quality embryos, and cells with abnormal numbers of chromosomes are common. Spare embryos of good quality can be cryopreserved for replacement in a subsequent undisturbed cycle or for donation to other patients.

II. ROLE OF GONADOTROPINS IN THE MENSTRUAL CYCLE

At the beginning of each menstrual cycle, a cohort of 10–20 small antral follicles is present. Only one follicle becomes estrogenic and grows toward ovulation and luteinization, and the rest undergo atresia. Emergence of this dominant follicle depends on stimulation by follicle-stimulating hormone (FSH) and luteinizing hormone (LH) and intrafollicular

(where W is tryptophan, S is serine, and X is an unknown amino acid).

The cytosolic domain of mouse IL-4Rα is 785 amino acids in length. The membrane-proximal cytosolic region interacts with the Janus kinase JAK1 (or, in some cases, JAK2); γc has a docking site for JAK3. It is generally believed that the interaction of JAK1 and JAK3 as a result of heterodimerization of IL-4Rα and γc leads to the activation of the Janus kinases and the phosphorylation of key tyrosines in IL-4Rα.

More distally in IL-4Rα, there is a docking site for phosphotyrosine-binding (PTB) domain proteins. In particular, IRS-1 and IRS-2, Shc, $p62^{dok}$, and $p56^{dok2}$ (FRIP) bind to this site when its central tyrosine (Tyr-497) is phosphorylated. The sequence in IL-4Rα that constitutes this site is designated the I4R motif. It is highly homologous to docking sites for PTB domain proteins found in the insulin receptor and the insulin-like growth factor-I (IGF-I) receptor, and many of the same PTB domain proteins dock to these receptors.

Further distally, there are three sites with the motif GYK/QXF (G, glycine; Y, tyrosine; K, lysine; Q, glutamine; F, phenylalanine) that are docking sites for the latent transcription factor Stat6. The central tyrosines of these sites are at positions 575, 603, and 631. There is an immunoregulatory tyrosine-based inhibitory motif (ITIM) in the cytosolic portion of IL-4Rα, centered on a tyrosine at position 713. Phosphorylated ITIMs serve as docking sites for SH2-containing phosphatases (SHP1, SHP2, and SHIP). It has been shown that in the presence of IL-4 SHP1 becomes associated with IL-4Rα, suggesting that this negatively regulates the receptor by dephosphorylating key tyrosines in IL-4Rα or in signaling intermediates.

IV. IL-4 RECEPTOR SIGNALING MECHANISMS

Addition of IL-4 to resting T cells leads to rapid phosphorylation of Stat6; each of the three Stat6 sites in IL-4Rα appears competent to mediate the docking of Stat6 and its subsequent phosphorylation, because abolition of Stat6 phosphorylation is observed only if the central tyrosines of each of the sites have been replaced by phenylalanines.

Phosphorylated Stat6 dissociates from the receptor and dimerizes. The dimer enters the nucleus, where it binds to DNA; a motif to which dimeric Stat6 binds is $TTCN_4GAA$. Transcription mediated as a result of this binding tends to require interaction with other well-characterized transcription factors. These may include c-Jun and Sp-1. Among the genes known to be targets of Stat6 action are the germ-line *IgC*ε gene and the gene for IL-4Rα. Indeed, in Stat6 knockout cells, neither gene is induced in response to IL-4.

Phosphorylation of PTB domain proteins, such as IRS-2, has been implicated in the anti-apoptotic effects of IL-4 in myeloid cells. This appears to be mediated by phosphoinositide 3-kinase (PI3K). Indeed, the regulatory subunit of PI3K binds to phosphorylated IRS-2.

The role of IL-4 in mediating cell growth is less well understood. Although phosphorylated IRS-2 can interact with Grb2 and Sos and thus should be able to induce the Ras pathway, IL-4 is inefficient in activating mitogen-activated protein kinases (MAPKs) in lymphoid cells. Furthermore, IL-4 has recently been shown to enhance the expression Gfi-1, a SNAG domain transcriptional repressor. Gfi-1-overexpressing cells show repression of $p27^{Kip1}$, which is also known to be repressed by IL-4, in a Stat6-dependent manner. Repression of $p27^{Kip1}$ allows cells to enter cycle. Thus, much of the IL-4-dependent growth promotion in lymphocytes may depend on the Stat6/Gfi-1/$p27^{Kip1}$ pathway rather than on signaling through IRS-2.

IL-4 generally mediates its functions in lymphocytes as a costimulant. In T cells, most IL-4 functions, such as T_H2 differentiation, depend on joint stimulation through the T-cell receptor (TCR) and the IL-4 receptor. It is striking that TCR engagement profoundly, although transiently, desensitizes the IL-4 receptor. Within 1 h of stimulation through the TCR, phosphorylation of IL-4Rα, JAK1, Stat6, and IRS-2 is strikingly attenuated. The failure of such cells to respond to IL-4 lasts for ~8 h, after which the cells regain their capacity to respond. The inhibition is not dependent on new protein synthesis and is reversed by MAPK kinase kinase (MEKK) inhibitors, suggesting that extracellular signal-related kinases (ERK1/2) play a major role in the inhibition process.

JAK/Stat signaling is inhibited by a set of suppressor of cytokine signaling (SOCS) proteins. It has been reported that interferon γ (IFNγ) induction of SOCS-1 results in inhibition of IL-4-mediated functions in macrophages and lymphocytes.

V. REGULATION OF IL-4 PRODUCTION

IL-4 is produced by a series of cell types, including T_H2 cells, NK T cells, basophils, mast cells, and eosinophils. T_H2 cells are a polarized set of memory/effector CD4 T cells that have the capacity to produce IL-4 and a series of other cytokines,

including IL-13, IL-5, IL-6, IL-9, and IL-10. Although there are no absolute markers of the T_H2 phenotype, these cells fail to express IL-12Rβ2 and IL-18 receptors and often express the IL-1 receptor analogue T1-ST2. They are more likely to express the chemokine receptor CCR4 and less likely to express CCR5 and CXCR3.

Naive CD4 T cells are capable of producing small amounts of IL-4 in response to TCR/CD28-mediated signaling, but they are not "high-rate" IL-4 producers. Differentiation of naive CD4 T cells into T_H2 cells is optimally achieved by culturing these cells with their cognate antigen and antigen-presenting cells (or with TCR stimulants such as anti-CD3, in association with anti-CD28) together with IL-4 and IL-2. In general, such differentiation is inhibited by IFNγ and possibly by IL-12.

IL-4 plays its role in T_H2 differentiation by acting through Stat6. This leads to the induction of Gata3. Retroviral transduction of TCR-stimulated cells with Gata3 leads to the development of IL-4-producing cells, strongly indicating that Gata3 plays an important role in T_H2 differentiation. Indeed, many of the cytokines that are produced by T_H2 cells have Gata-binding sites in their promoters and elsewhere in the gene. Several such sites have been identified in the *Il4*gene. On the other hand, transduced Gata3 is much less effective than transduced, constitutively active Stat6 in inducing IL-4-producing cells, suggesting that optimal induction of the T_H2 phenotype requires an additional Stat6-inducible factor.

Although IL-4 is very important in T_H2 induction *in vitro*, there are instances in which T_H2 cells develop in the absence of IL-4 or in the absence of IL-4Rα or Stat6. However, in one instance, it was shown that even Stat6 $-/-$ cells that develop into IL-4 producers have up-regulated Gata3, arguing for the importance of Gata3 in IL-4-production.

Physiologically, the source of IL-4 that participates in T_H2 differentiation has been enigmatic. Other IL-4-producing cell types, such as NK T cells and basophils, have been proposed as sources of the IL-4 that plays a role in T_H2 differentiation. There is no convincing evidence implicating basophils or mast cells in this process. It has been suggested that NK T cells may play a role, particularly because of reports that both in models of type 1 diabetes in mice and in human type 1 diabetes, there is a deficiency of NK T cells. In humans in the prodromal stages of type 1 diabetes, a deficiency in serum IL-4 levels has also been suggested.

However, data continue to indicate that IL-4 production by naive T cells may play a role in IL-4-dependent T_H2 development, at least in some settings. There is evidence that naive T cells can transcribe IL-4 and that such IL-4 production is not blocked by anti-IL-4. Further, mice lacking IL-4Rα also produce "early" IL-4, further arguing that such production is a property of naive CD4 T cells rather than previously differentiated T_H2 cells. Finally, cloning experiments indicate that early IL-4 production is a property of the majority of CD4 T cells and does not represent production of large amounts of IL-4 by rare cells.

Intensity of T cell stimulation plays a role in the differentiation of naive CD4 T cells into T_H2 cells. In some well-characterized systems, naive CD4 T cells cultured without added polarizing cytokines tend to develop IL-4-producing capacity when stimulated with low concentrations of their cognate antigens. High concentrations favor the differentiation of these cells into IFNγ-producing T_H1 cells. These dose effects appear to be due, at least in part, to the endogenous induction of an appropriate cytokine environment, because the T_H2 differentiation that occurs in response to low concentrations of antigen is largely inhibited by anti-IL-4 antibody, whereas the T_H1 differentiation that occurs in response to high antigen concentration is blocked by anti-IFNγ.

Dendritic cells may play a substantial role in determining the degree of differentiation of naive cells into T_H2 cells. Highly activated dendritic cells, particularly those that have been stimulated with lipopolysaccharide or through CD40L, produce substantial amounts of IL-12p70, which aids in driving IFNγ production. These two cytokines, acting together or separately, favor the differentiation of naive cells into T_H1 cells and inhibit T_H2 differentiation. Forms of dendritic cell activation that fail to induce IL-12p70, or the loss of IL-12p70-producing capacity by dendritic cells, may render those cells more likely to induce a T_H2 response, because they would be less effective in inhibiting the activity of endogenously produced IL-4 in driving T_H2 differentiation.

VI. IL-4 GENE STRUCTURE AND EXPRESSION

The *Il4* gene consists of four exons distributed over 6.2 kB located on human chromosome 5 at q23–q31 and in the syntenic region on mouse chromosome 11. The gene is in a cytokine complex. Genes *Il13, Il5, GM-CSF*, and *Il3* are linked to the *Il4* gene; *Il13* is located ~11 kB from *Il4*, and a highly conserved element in the *Il4–Il13* intergenic region, i.e., *CNS-1*,

plays a role in regulating the level of expression of both IL-4 and IL-13.

The *Il4* gene appears to be in a closed conformation in naive T cells. The gene displays little evidence of DNase 1 hypersensitivity and most CpGs are methylated. As cells undergo T_H2 differentiation, they show progressive evidence of developing an open conformation in the *Il4* genetic region. The *Il4* gene in T_H2 clones has a series of DNase 1 hypersensitivity sites, most notably in the second intron and downstream of the fourth exon, in a site designated V. The *CNS-1* element also acquires DNase I hypersensitivity. Similarly, T_H2 clones display CpG demethylation and histone acetylation in regions of DNase 1 hypersensitivity, further indicating the acquisition of an accessible conformation. Newly differentiated T_H2 cells show some of the chromatin changes observed in T_H2 clones.

Il4 has been reported to be expressed monoallelically. Using knock-in mice, in which one IL-4 allelic product can be distinguished from the other at the level of individual cells, it has been observed that, in many T_H2 cells, IL-4 encoded by only one of the two alleles is produced. Furthermore, T_H2 clones from heterozygous mice show distinctive ratios of expression of the two allelic products. This translates into distinctive proportions of cells that express the two alleles on stimulation. The ratio of expression of the two alleles is heritable, strongly suggesting that it represents an epigenetic trait, presumably due to distinctive patterns of accessibility of the two alleles in individual T_H2 cells and in the clones derived from them. The biological significance of monoallelism at the *Il4* locus is still not understood. It has been suggested that it relates to the potential of the *Il4* gene to exist in several different conformations, each associated with a distinctive probability of expression. This may represent a particularly effective way to control the proportion of antigen-specific CD4 T cells that can produce IL-4 and thus can engage in productive interactions with B cells, dendritic cells, macrophages, and other cell types.

VII. IL-4 FUNCTIONS

IL-4 receptors are broadly expressed, indicating a wide range of cell types that are potential targets of IL-4 action. The earliest recognized activities of IL-4 were in regulating growth and survival of naive B cells stimulated by cross-linkage of membrane IgM. Indeed, IL-4 was first designated B cell growth factor (BCGF) because of this activity. By itself, IL-4 does not cause the growth of either resting T or B cells, although it is a good survival factor, particularly for resting T cells.

A. Immunoglobulin Class Switching

IL-4 has a major role in controlling the class of immunoglobulin produced in the course of an antibody response. *In vitro*, IL-4, acting with anti-CD40 or with lipopolysaccharide (LPS), causes B cells to differentiate into IgE-secreting cells; when mouse cells are used, IL-4 also promotes the production of IgG1, but when human cells are used, IgG4 production is enhanced. This effect appears to be highly significant at the physiologic level. Mice in which the *Il4* gene, the *Il4R*α gene, or the *Stat6* gene has been inactivated by gene knockout technology have a profound diminution in levels of serum IgE and in IgE antibody responses. They also show defects in IgG1 production, but these are somewhat more variable. IL-4 transgenic mice have heightened serum levels of IgE.

IL-4 acts as a switch factor by regulating the transcription of the germ-line *IgC*ϵ and *IgC*γ1 H-chain genes. The induction of germ-line transcription targets these genes for switch recombination and leads to class switching to the ϵ and γ1 isotypes. Interestingly, these events appear to occur principally in germinal centers. It has recently been shown that the RNA editing enzyme, activation-induced cytidine deaminase, is critical for class switching to occur.

An indication of the relative balance of T_H1/T_H2 differentiation *in vivo* is provided by the ratio of IgG1 to IgG2a in mouse serum. Whereas IL-4 is the principal switch factor regulating IgG1 production, IFNγ regulates IgG2a switching, so that in situations in which IFNγ predominates, a mouse will tend to have a high IgG2a:IgG1 ratio, whereas when IL-4 dominates, there will be a low IgG2a:IgG1 ratio.

B. T_H2 Differentiation

As already discussed in some detail, the most efficient way to induce IL-4-producing T_H2 cells is by priming naive CD4 cells in the presence of IL-4. IL-4 acts through Stat6. Gata3 is induced and plays an important role in the acquisition of the T_H2 phenotype. A high rate of IL-4 production requires c-maf as well as Gata3. IL-4-mediated T_H2 differentiation results in the capacity of cells to produce other T_H2 cytokines, notably IL-13, IL-5, IL-6, IL-9, and IL-10.

In various *in vivo* models, IL-4-mediated T_H2 differentiation appears to play an important role in the pathogenesis of infectious and allergic diseases.

For example, in BALB/c mice, infection with *Leishmania major* leads to progressive disease with increasing lesion size and increasing parasite burden. In general, T cells from the draining lymph nodes of these mice produce substantial amounts of IL-4 and relatively little IFNγ. By contrast, in mouse strains such as C57BL/6, in which infection with *L. major* results in a CD4 T-cell response dominated by IFNγ-producing cells, the infection is resolved. In susceptible strains, neutralization of IL-4 by administration of anti-IL-4 antibody allows recipients to resolve infections with *L. major*. Such mice develop CD4 cell responses dominated by IFNγ production. It is generally believed that anti-IL-4 neutralizes the "early" IL-4 that plays a role in T_H2 differentiation in naive cells.

However, the process may be substantially more complex. For example, when certain strains of *L. major* (e.g., LV39) are used for infection studies, it is seen that both IL-4 and IL-4 receptor knockout mice are susceptible to infection and that anti-IL-4 treatment renders wild-type mice resistant to infection with LV39. This suggests that the presence of IL-4 at low concentrations or possibly at specific times during infection may be important in the development of resistance, independent of the striking role of IL-4 in the acquisition of a susceptible state (see discussion on IL-4 effects on dendritic cells, Section VII,D).

In a model of immune-mediated airway hyperreactivity in mice, IL-4 plays a major role in the induction of the hypersensitive state. Immunization of mice with ovalbumin (Ova) followed by airway challenge with Ova results in bronchiolar constriction, excessive mucus production, and an inflammatory response dominated by eosinophils. Neutralization of IL-4 at the time of initial immunization strikingly diminishes the magnitude of the hyperreactivity to challenge, suggesting that a T_H2 response plays a major role in the immunopathogenesis of this process. By contrast, neutralization of IL-4 at the time of challenge has little or no effect on the magnitude of the resistance to flow in the airway or on the other manifestations of the response. However, neutralization of IL-13 will block airway hyperreactivity and mucus production, although eosinophilia still occurs.

This indicates that IL-4 is critical to induction of the hyperreactive state but that it is not the principal mediator of the effector phase of the airway response. By contrast, anti-IL-13 does inhibit airway hyperreactivity, implying that it is the major effector molecule. Because IL-4 and IL-13 largely use the same receptor on bronchiolar endothelial cells and because direct insufflation of either IL-4 or IL-13 causes airway hyperreactivity, the distinctive actions of IL-4 and IL-13 as effector molecules may be determined by the relative amounts of the cytokines made during the effector phase of the allergic response, rather than by intrinsic differences in their functionalities.

C. IL-4 Inhibits Macrophage Activation

IL-4 exerts potent inhibitory activity on macrophages, where it opposes many of the effector functions mediated by IFNγ. IL-4 inhibits the production of pro-inflammatory molecules that are normally induced as a result of the action of IFNγ alone or in synergy with other stimulants of inflammation. Among the molecules for which synthesis is inhibited by IL-4 are TNFα, IL-1β, IL-12, and IP-10. Furthermore, IFNγ is a potent stimulator of inducible nitric oxide synthase, a key enzyme in the induction of reactive nitrogen species, which are potent antimicrobial agents. IL-4 inhibits this induction as well as the induction of reactive oxygen intermediates and thus opposes macrophage activation. In many instances, IL-4 acts on macrophages with a function similar to that of IL-10. It can be speculated that the role of IL-4 in opposing much of the IFNγ-mediated induction of enhanced microbicidal activity of macrophages may actually represent the function of IL-4 as a regulator of levels of inflammation, which reflects a physiologic effort to control levels of tissue damage during immune responses.

D. IL-4 Plays a Role in Dendritic Cell Differentiation and Maturation

In vitro production of dendritic cells from bone marrow precursors is usually achieved by growth of the cells in a mixture of granulocyte/macrophage colony-stimulating factor (GM-CSF) and IL-4, implying an important role for IL-4 in this process. In general, immature dendritic cells, which are the cells emerging from such differentiation, are excellent in uptake of antigen but require activation both to mediate their optimal antigen-presentation function and to acquire the capacity to produce IL-12p70. Such a combination of functions allows dendritic cells to prime naive CD4 T cells optimally to develop into T_H1 cells. Somewhat surprisingly, Shortman and colleagues have presented evidence that the presence of IL-4 during this maturation phase strikingly

enhances the capacity of dendritic cells to produce IL-12p70 and thus favors T_H1 differentiation. Other have reported that the presence of IL-4 enhances the maturation of monocyte-derived dendritic cells, which preferentially induce T_H1 responses, while exerting a pro-apoptotic effect on plasmacytoid dendritic cells, which have been proposed to enhance T_H2 responses. Indeed, it has been shown in a variety of models, including contact hypersensitivity, *L. major* infection, and cytotoxic T cell destruction of tumors, that IL-4 present at specific times is important in the acquisition of effector function. Analysis of these examples has suggested that the target of IL-4 is an antigen-presenting cell, most likely a dendritic cell. Thus, the *in vitro* data showing a role of IL-4 in acquisition of optimal IL-12p70-secreting activity may be paralleled with a physiologic effect of IL-4 on dendritic cell function.

E. IL-4 Regulation of Cell Migration

IL-4 plays a role in the migration of eosinophils into tissues, which is of central importance in allergic inflammation. It does so in part through the induction of eotaxin-3 production by human vascular endothelial cells; eosinophils home to eotaxin produced by vascular endothelial cells through the action of CCR3 receptors expressed by the eosinophils. IL-4 has also been reported to up-regulate expression of vascular cellular adhesion molecule 1 (VCAM-1) on vascular endothelium, which would further aid in the accumulation of eosinophils in areas of allergic inflammation.

IL-4 also controls migration of B cells; stimulation with lipopolysaccharide or with anti-CD40 plus IL-4 results in marked enhancement of the migration response to BCA-1, SLC, ELC, and SDF-1.

VIII. TARGETING IL-4 FOR THERAPY

Because of the central role IL-4 plays in the induction of allergic diseases and in the production of IgE antibody, it has been regarded as an important target for drug development for these diseases. Thus far, it has been difficult to develop small-molecule inhibitors of the binding of IL-4 to the type I IL-4 receptors, although new approaches in this area should be considered. Alternative approaches have been the use of soluble IL-4 receptors to inhibit IL-4 binding to cell-associated receptors or the use of an IL-4 mutant (Y124D) that acts as a competitive antagonist. Thus far, although there have been preliminary reports of the use of these approaches, there have not yet been any dramatic successes flowing from this effort. Similarly, animal studies have indicated that IL-4 can, in some instances, ameliorate disease-causing autoimmunity. Perhaps the most dramatic effects have been in administration of IL-4 to nonobese diabetic (NOD) mice that express a spontaneous type 1 diabetes. NOD mice that receive IL-4 have a striking amelioration of diabetes. There have also been reports that IL-4 can diminish the incidence and severity of experimental allergic encephalomyelitis, which is often used as a model for multiple sclerosis.

Glossary

IgE Immunoglobulin class that mediates many allergic-type responses; functions by binding to high-affinity FcεRI receptors on mast cells and basophils. When IgE molecules are cross-linked, by binding their cognate antigen, they signal the release of preformed mediators and the synthesis and secretion of cytokines.

interferon γ Cytokine that is a member of the interferon/interleukin-10 family. Mediates a wide variety of cellular functions, particularly the enhancement of the microbicidal activity of macrophages.

Stat6 Latent transcription factor that docks to phosphorylated IL-4 receptor α-chains, becomes phosphorylated, then dissociates from the receptor, dimerizes, enters the nucleus, and binds to specific elements in DNA, where it cooperates with other transcription factors in regulating the expression of IL-4-inducible genes.

T_H2 cells Differentiated form of CD4 T helper cells that have acquired the capacity to produce a set of cytokines that orchestrate humoral immune responses, particularly allergic-type responses. These cytokines include IL-4, IL-13, IL-5, IL-6, and IL-10.

type I cytokines Also known as hematopoietins; four-α-helix-bundle proteins generally secreted by T cells, in response to stimuli mediated through the T-cell receptor. These molecules are recognized by a family of receptors designated hematopoietin receptors.

Interleukin-5

ANGUS J. LAUDER*, ANDREW N. J. MCKENZIE*, AND COLIN J. SANDERSON†

*MRC Laboratory of Molecular Biology, Cambridge, England • †Western Australia Institute of Medical Research

Interleukin-5 is a cytokine produced predominantly by T cells. It is important in inflammatory responses due to its control of eosinophil production and its ability to activate basophils and to modify mast cell secretions. Inhibition of interleukin-5 may be key to therapeutic interventions in certain malignancies and hyperimmune conditions.

I. INTRODUCTION

Interleukin-5 (IL-5) was originally isolated by several groups independently on the basis of two different biological activities. Several years of work identified a B-cell differentiation factor (BCDF) and an eosinophil differentiation factor (EDF) that were subsequently shown to arise from the same protein. Cloning of the human and murine genes led to this factor being named interleukin-5. IL-5 is expressed predominantly by T lymphocytes and encodes a 40- to 45-kDa protein. Although it has been clear for some time that IL-5 is crucial in the development of eosinophils, IL-5 has also been implicated in a range of conditions, such as asthma, cancer, and parasitic infections.

II. GENE AND PROTEIN STRUCTURE

The human IL-5 gene is located in the cytokine gene cluster on chromosome 5q31; the murine homologue is located in the syntenic region of mouse chromosome 11. These regions also contain the respective human and murine IL-3, granulocyte/macrophage colony-stimulating factor (GM-CSF), IL-4, and IL-13 genes. The IL-5 gene consists of four exons and three introns, which encode precursor proteins of 134 and 133 amino acids in the murine and human systems, respectively. The four-exon and three-intron gene structure of IL-5 is also found in the cytokine gene cluster genes encoding IL-4, IL-13, and GM-CSF. There is little sequence conservation between these genes but the conserved exon/intron structure and their chromosomal proximity to each other suggest a common evolutionary origin whereby gene duplication and subsequent sequence divergence led to the evolution of new cytokine genes. The human and mouse IL-5 coding sequences are highly conserved at the nucleotide (77%) and the amino acid (70%) levels, although there are differences in the structures of the two genes. The mouse gene produces a transcript of 1.6 kb, compared to the shorter 0.9-kb human mRNA. This is due to the presence of a number of *Alu*-like repeats and a 738-bp insertion flanked by inverted repeats in the murine sequence.

In both humans and mice, the IL-5 protein precursors are cleaved to generate the 115-amino-acid mature peptide. The IL-5 protein is subject to both O-linked (Thr-3) and N-linked (Asn-28) glycosylation, with an additional N-linked glycosylation site at Asn-55 in the murine IL-5. Glycosylation does not appear to be required for the biological activity of IL-5 because deglycosylated IL-5 retains comparable receptor binding and activity. However, N-linked glycosylation does appear to increase the thermostability of IL-5 and may therefore be important in the function of IL-5. Unusually for cytokine molecules, the active IL-5 protein exists as a dimer joined by two disulfide bridges between conserved cysteine residues. Dimer formation is crucial for the activity of IL-5 because mutation of the conserved cysteine residues blocks not only dimer formation but biological activity as well. X-Ray diffraction studies reveal that each monomer consists of four α-helices arranged in an up/up–down/down topology, forming

a characteristic cytokine fold. This structural arrangement is found in a number of other cytokine molecules, including IL-2, IL-4, GM-CSF, and the human growth hormone molecule. These cytokines exist as monomers, with their four α-helices forming the up/up–down/down cytokine fold. In the case of the IL-5 dimer, rather than each monomer forming a cytokine fold independently, the fourth helix from each monomer supplies the D′ helix, to complete the fold of the other monomer. Even though the D′ helix is supplied by the other monomer, the resulting cytokine fold is homologous to the cytokine folds formed by individual monomers of IL-2, IL-4, and GM-CSF.

The IL-5 protein has also been shown to contain a functional nuclear localization sequence (NLS). Fluorescence labeling of the IL-5 receptor has revealed that in the presence of IL-5 ligand the IL-5 receptor can translocate to the nucleus. Unlike nuclear hormone receptors, for which a clear nuclear signaling role has been defined, the functional significance of IL-5 receptor nuclear targeting is currently unclear.

III. CONTROL OF IL-5 EXPRESSION

IL-5 is expressed predominantly by T lymphocytes and is associated with a T_H2 cytokine expression profile. In addition to T cells, IL-5 expression has also been detected from mast cells, eosinophils, and Epstein–Barr virus-infected B cells. IL-5 gene expression can be activated by a wide range of factors, including parasitic infection, the cytokines IL-2, IL-4, and IL-25, and chemical reagents such as phorbol esters in conjunction with phorbol myristate acetate (PMA). The control of gene expression can be analyzed at a number of different levels. In addition to numerous IL-5 promoter elements that have been reported, regulatory elements exist that co-ordinate expression of multiple genes within the cytokine gene cluster. Located between the IL-4 and IL-13 genes, the conserved noncoding sequence-1 (CNS-1) region was identified by comparison of the mouse and human cytokine gene cluster sequences. Deletion of this 401-bp sequence in mice reduces expression of IL-4, IL-5, and IL-13, resulting in impaired T_H2 responses. IL-4 production in mast cells was unaffected in these mice, suggesting that this element may regulate T_H2 cytokine expression specifically in the T-cell lineage. Although the CNS-1 element appears to regulate these cytokines coordinately, there are many circumstances in which these genes are differentially expressed. For example anti-CD3 stimulation of murine T_H2 clones results in induction of IL-4 and IL-5. However, stimulation of these cells with recombinant IL-2 induces only IL-5 and not IL-4, indicating that different signals can activate subsets of genes from the cytokine gene cluster.

The complex range of signals that affect IL-5 gene expression is reflected at the level of the IL-5 promoter. Numerous promoter elements interact with a range of transcription factors, including members of the GATA, Oct, activator protein 1 (AP-1), NFAT, and Ets families. One of the first regulatory sequences to be identified was the conserved lymphokine element 0 (CLE0), which is not only present in the IL-5 promoter but is also found in the IL-3, IL-4, and GM-CSF promoters. The CLE0 sequence (nucleotides −56 to −42 in humans) is required for IL-5 promoter activity and binds members of the AP-1 and Oct transcription factor families. Upstream of the CLE0 element lie several GATA binding sites, which play a positive role in IL-5 transcription (−70, −152), and a further GATA site (−400), which negatively regulates IL-5 expression. The Ets1 and Ets2 transcription factors have been shown to transactivate a human IL-5 reporter construct through a GGAA motif adjacent to the AP-1 site within the CLE0 element. Ets-mediated transactivation acts with GATA-3 in a cooperative manner to further increase transcription levels. In addition to 5′ control elements, additional positive sequences have been identified 3′ to the IL-5 gene. The mouse downstream regulatory element-1 (mDRE1) is located in the region +4539 to +4585 in relation to the translational start site of the IL-5 gene and has been shown to bind Oct-1 and Oct-2 transcription factors.

Higher order gene regulation at the level of chromatin structure also plays a key role in gene expression. On T-cell differentiation to a T_H2 phenotype, T_H2 cytokine genes become located to transcriptionally active regions of chromatin whereas silenced T_H1 cytokine genes generally become localized to inactive heterochromatin regions. GATA-3 expression has been shown to promote T_H2 differentiation, and, remarkably, ectopic expression of GATA-3 can induce T_H2 cytokine expression in committed T_H1 cells. GATA-3 appears to act as a master switch to induce T_H2 cytokines. The IL-5 promoter contains numerous GATA binding sites that help to mediate its induction under T_H2-promoting conditions. Even though different genes may utilize the same transcription factors, differences in their mode of action may exist. For example, GATA-3 induces both IL-4 and IL-5, consistent with its role as

an inducer of T_H2 differentiation. In the case of IL-5, GATA-3 appears to act directly on the IL-5 promoter. In contrast, GATA-3-mediated IL-4 induction may act through a global T_H2 enhancement and not directly through binding at the IL-4 promoter. Interestingly, activation of IL-4 and IL-5 by GATA-3 requires different regions of the GATA-3 protein. Transactivation of IL-4 requires only the C-terminal zinc finger domain, whereas induction of IL-5 by GATA-3 requires both the N- and C-terminal zinc finger domains, which may reflect a different mode of action.

Many of the transcription factors detailed above are involved in regulating multiple genes, including those of other cytokines. This raises the question as to how gene-specific transcriptional activation is achieved. The use of similar transcription factors may help to coordinate regulation of groups of genes such as T_H2 cytokines. Differences in the number of binding sites, cooperation with other sites, and the different sets of factors activated by different cellular stimuli allow specific regulation of genes within such a group. The potential of gene-specific regulatory sequences/proteins is clearly evident in this respect. Recent evidence has uncovered a pair of interacting palindromic sequences nearly 400 bp apart that positively regulate IL-5 expression. Mutation of the positive regulatory motifs within either of these sequences results in a 60 to 70% reduction in IL-5 expression. These elements form protein/DNA complexes with nuclear extracts from the EL4-23 T-cell line, and although the binding proteins have not yet been identified, elements such as these would help to achieve specific IL-5 expression under conditions in which other T_H2 cytokines may not be induced.

IV. IL-5 RECEPTOR STRUCTURE/ISOFORMS/DISTRIBUTION

The IL-5 receptor consists of α and β chains that, when bound to IL-5 ligand, activate a series of signal transduction cascades. The β chain of the IL-5 receptor is also utilized by the IL-3 and GM-CSF receptors and is therefore known as the βc, or common, β chain. The shared usage of the βc chain explains the partially overlapping functions of these cytokines, such as their ability to promote eosinophil survival. IL-3, IL-5, and GM-CSF compete for receptor binding, presumably due to limiting amounts of the shared βc chain. Each cytokine receptor has a unique α chain that provides specificity, and the distribution of these chains defines the differing biological roles of these cytokines. In the human system, IL-5 receptors appear to be found only on eosinophils and basophils. In mice, in addition to eosinophils and basophils, the IL-5 receptor is also found on activated B cells and on B1 cells from the peritoneal cavity. The α and β chains are both required to generate a successful IL-5 signal. The βc chain contains a large cytoplasmic domain and is essential for signal transduction. Transfection of the α and β chains into the CTLL-2 T-cell line generates a functional IL-5 receptor and enables these cells to proliferate in response to IL-5. However, transfection of the wild-type βc chain with an α chain lacking its cytoplasmic tail generates a signaling-deficient receptor. It is not clear at this time if the small cytoplasmic domain of the α chain interacts directly with the intracellular signaling machinery or if it acts through interaction with the βc chain. Direct interaction of the cytokine-specific α chain with the signaling machinery is an attractive model because it provides a simple explanation for producing IL-3-, IL-5-, and GM-CSF-specific signals. A recent report describes the identification of the first signaling molecule shown to interact with the IL-5Rα. The protein syntenin was shown to interact with the IL-5R α chain but, significantly, not with the IL-3R or GM-CSFR α chains, thereby enabling an IL-5 receptor-specific signal to be generated.

The hIL-5Rα gene encodes a protein of 420 amino acids containing a 20-amino-acid N-terminal signal peptide, a 324-amino-acid extracellular domain, a 21-amino-acid transmembrane span, and a short 55-amino-acid cytoplasmic domain. The common β chain is much larger, at 897 amino acids, and contains a 16-amino-acid signal sequence, a 424-amino-acid extracellular domain, a 27-amino-acid transmembrane span, and a large 430-amino-acid cytoplasmic domain. These receptor proteins belong to the hemopoietin superfamily in which the extracellular domain is a modular structure and each module consists of a seven-β-sheet scaffold. The extracellular domain of the α chain contains three modules. The membrane-proximal module contains a canonical Trp-Ser-Xxx-Trp-Ser (WS-WS) motif that is characteristic of this receptor superfamily. The second module contains conserved cysteine residues that form disulfide bridges within the protein, and the third module contains a WS-WS-like motif. The extracellular portion of the βc chain contains four modules; two contain WS-WS motifs and the other two contain conserved cysteine residues that form disulfide bridges. The cytoplasmic domains of the IL-5 receptor lack intrinsic kinase activity but promote

signaling through the association of numerous signaling molecules and kinases (see Section V).

The IL-5Rα chain in isolation binds IL-5 with low affinity, whereas the βc chain alone has no affinity for IL-5. Interaction of the α and β chains forms the high-affinity IL-5 receptor. Although the IL-5Rα chain is the major partner in ligand binding, interaction of IL-5 with the β chain is also required for signaling to proceed. Mutation of a glutamic acid to a glutamine residue at position 13 of hIL-5 disrupts the normal interaction with the βc unit. This mutant acts in an antagonistic fashion inasmuch that it binds functional receptors but cannot trigger signaling due to disruption of the IL-5 ligand/βc chain interaction. The IL-5R βc chain has been crystallized and the X-ray structure should soon be published, providing additional information on the structure/function of the IL-5 receptor.

Expression of natural IL-5 antagonists has been detected in human eosinophils and in murine B cells. These proteins take the form of soluble IL-5Rα chains and can inhibit the proliferation of IL-5-dependent cell lines. Two soluble receptor transcripts are generated by differential splicing events that remove the soluble-specific exon from its position adjacent to the transmembrane region, producing a truncated protein consisting of the α chain extracellular domain. A soluble transcript accounts for around 90% of the transcripts in mature eosinophils from cord blood, and soluble IL-5Rα may act as a negative feedback mechanism during eosinophil activation. Recent work has suggested that IL-5 may regulate the production of its own receptor, determining the relative proportions of soluble and membrane-bound forms. Through the use of a minigene construct containing the human IL-5 gene it was shown that IL-5 could switch expression from soluble IL-5Rα to the transmembrane (TM)-bound TM-IL-5Rα form. In an eosinophil differentiation assay in the presence of IL-5, TM-IL-5Rα was up-regulated between days 5 and 7, returning to predominantly soluble IL-5Rα chain expression by day 14 of the assay, when mature eosinophils predominated. IL-5 may therefore positively regulate its receptor expression to promote IL-5 signaling during eosinophil differentiation. The mechanism by which expression changes between soluble and membrane-bound forms is not clear.

V. IL-5 RECEPTOR SIGNALING

Although it is the IL-5Rβ chain that activates the majority of the intracellular signaling components, both the α and β chains of the IL-5 receptor are required to transmit the IL-5 signal. On binding of IL-5, the β chain becomes tyrosine phosphorylated, which provides binding sites for proteins that contain conserved Src homology 2 (SH2) domains such as the signal transduction and activator of transcription (Stat5) protein. Many signal transduction proteins utilize SH domains to mediate binding to receptor phosphotyrosine residues. Deletion studies of the β chain cytoplasmic domain have revealed two regions important for the mitogenic signal. The membrane region proximal to residue 517 is sufficient to induce expression of c-Myc and the pim-1 kinase. Residues 626 to 763 of the β chain mediate phosphorylation of the adapter protein Shc, activation of the Ras/Raf/-mitogen-activated protein kinase (MAPK) pathway, and induction of the transcription factors c-Fos and c-Jun. The adapter protein Shc mediates activation of Ras by recruiting the adapter protein Grb2, which binds the son-of-sevenless (Sos) guanine nucleotide exchange factor, which then activates Ras. The region from 626 to 763 also mediates activation of two kinases with key roles in cell division and survival. Deletion of this region abrogates the ability of the β chain to activate phosphatidylinositol 3-kinase (PI3K) and p70S6 kinase. PI3K activates a number of signaling pathways, including protein kinase B (PKB), and contributes to the activation of p70S6 kinase. Activation of PKB protects numerous cell types from apoptosis and p70S6 kinase is not only involved in regulating protein translation but also contributes to regulation of the cell cycle. Although some of these pathways have not yet been shown to be directly downstream of IL-5, evidence from other systems that utilize the common β chain suggests that they are likely to be. For example, PKB, a downstream effector of PI3K, mediates survival downstream of the common β chain containing IL-3R.

The α and β chains both contain conserved proline-rich sequences known as box1 sequences; these are found in a large number of cytokine receptors. In the case of the β chain, the proline-rich sequence lies in the membrane-proximal region, which is crucial for activation of the genes encoding c-Myc and pim-1. Mutation of proline 352 or 355 inhibits the IL-5 mitogenic signal, thus the proline-rich box1 sequence of the α chain is essential for mediating growth signals. Mutation of these proline residues has been shown to abrogate activation of the kinases JAK1 and JAK2 and their downstream target, the transcription factor Stat5. A dominant negative Stat5 protein can inhibit proliferation induced by IL-3, IL-5, and GM-CSF, all of which use the βc chain

and activate JAK kinases as part of their signaling function. In addition to Stat5, IL-5 signals have been reported to mediate activation of the Stat family members Stat1α and Stat3. Co-immunoprecipitation experiments have provided significant information on the role of JAK kinases in IL-5 signaling. JAK2 associates with the hIL-5Rα chain with or without IL-5 stimulation, showing that JAK2 is bound constitutively to the α chain. JAK1, on the other hand, constitutively associates with the βc chain but also becomes associated with the α chain on IL-5 stimulation. In both cases, it is only after IL-5 stimuli that the JAKs become phosphorylated and activated. Although abundant data on JAK/Stat function have appeared recently, the number of defined target genes is still relatively small. Stat5 target genes include JAK2-binding SH2-containing protein (JAB) and the cytokine-inducible SH2 protein (CIS). CIS is a member of the suppressor of cytokine signaling (SOCS) family of proteins, which act as negative feedback controls by suppressing JAK signaling.

It has been known for some time that the cytoplasmic domain of the α chain is required for IL-5 signaling, but it is only in the past few years that specific signaling functions have been defined. In addition to a role in JAK/Stat activation, the α chain has also been shown to interact with IL-5-specific signaling molecules. Using a two-hybrid approach, the protein syntenin was shown to interact with the last 15 carboxy-terminal residues of the IL-5Rα chain but, significantly, not with the IL-3 or GM-CSF α chains, thereby generating an IL-5 receptor-specific signal. Further two-hybrid and co-immunoprecipitation approaches showed that syntenin bound to the Sox4 transcription factor. Sox4 is known to play a role in B-cell development and IL-5 has been implicated in the development of the B1 subset of B cells in the mouse system. Although only published recently, these data may provide a link between the IL-5 receptor and B-cell development. In addition to JAK/Stats, a number of other kinases have been implicated in IL-5 signaling in B cells. For example, IL-5 signals in an early B-cell line were shown not only to activate JAK2 but also to activate B-cell-specific Bruton's tyrosine kinase (Btk). Addition of a gain-of-function mutant of Btk was able to confer IL-5 independence on this cell line. Mice deficient in Btk are immunodeficient (xid) and have vastly reduced levels of circulating Ig due to a block in B-cell development. These mice also have a defect in B1 cell development similar to the IL-5-deficient mice. The B cells from Btk-deficient mice respond poorly to IL-5 in an IgM induction experiment, but eosinophils from these mice respond normally, suggesting that Btk is specifically involved in IL-5 signaling in B cells.

VI. EOSINOPHIL DIFFERENTIATION/PROLIFERATION AND APOPTOSIS

IL-5 was first identified by a number of activities in cell culture, one of which was its ability to promote eosinophil differentiation in bone marrow proliferation assays. Transgenic mice constitutively expressing IL-5 within the T-cell compartment develop a profound eosinophilia that infiltrates the blood, spleen, and bone marrow. These mice retain eosinophilia throughout their lives yet remain apparently normal. This is presumably because the large numbers of eosinophils do not degranulate and cause tissue damage. In the presence of secretory Ig, IL-5 has been shown to enhance eosinophil degranulation and the release of eosinophil-derived neurotoxin (EDN). IL-5 can also increase production of the superoxide anion, a cytotoxic weapon commonly used by the immune system. The reason why degranulation and tissue damage do not occur in IL-5 transgenic mice *in vivo* is unclear. The ability of eosinophils to lyse antibody-coated tumor cells is increased in the presence of IL-5, as is the phagocytic uptake of opsonized yeast particles.

In addition to modulating eosinophil activation, IL-5 can also promote eosinophil chemotaxis and survival. IL-5 has a marked dose-dependent chemotactic effect on eosinophils *in vitro*. In addition, it has also been reported that IL-5 "primes" eosinophils, which then become more responsive to other chemotactic molecules. A possible mechanism for this effect has recently been identified. Comparison of the signal transduction events downstream of chemotactic molecules, such as IL-8 and receptor-activated neutrophil T-cell expression and secretion (RANTES), has shown that activation of the extracellular signal-related kinases ERK1 and ERK2 (MAP kinases) is significantly increased in IL-5-primed eosinophils. Therefore, in addition to promoting eosinophil differentiation and activation, IL-5 may also be responsible for their recruitment to sites of inflammation.

Purified human eosinophils die by apoptosis in cell culture systems. Although IL-3 and GM-CSF promote survival in these systems, IL-5 has a much more potent eosinophil survival activity. Eosinophils from patients with eosinophilic pleural effusions exhibit in culture enhanced survival that can be blocked by addition of anti-IL-5 antibody. IL-5 can inhibit

apoptosis induced by toxic agents such as staurosporine and by physiological mediators such as Fas. IL-5 strongly inhibits Fas-mediated eosinophil apoptosis and this correlates with the prevention of caspase activation. A further study found that IL-5 blocked translocation of the pro-apoptotic protein Bax to the mitochondria and subsequent cytochrome *c* release. Increased expression of Bcl-2 and its family member Mcl-1 has also been proposed as to mediate the IL-5 survival signal. However, although the IL-5-mediated survival effect is clear in these studies, the changes in Bcl-2 and Mcl-1 protein levels are small and their significance remains to be proved. The molecular link between the IL-5R and the apoptotic machinery has not yet been elucidated, although it may well involve PI3K, which is activated downstream of IL-5 and has several known survival functions.

Infection with the parasitic hookworm (*Necator americanus*) in humans and the nematode worm *Nippostrongylus brasiliensis* in mice leads to the profound development of eosinophilia and increased levels of IgE. Using monoclonal antibodies to inhibit IL-4 and IL-5, it has been shown that even though IL-4 is responsible for IgE induction, IL-5 mediates eosinophilia in *N. brasiliensis*-infected mice. IL-5-deficient mice fail to develop eosinophilia in response to *Mesocestoides corti* helminth infection, although basal levels of eosinophils are unaffected. IL-5 deficiency and the resulting lack of eosinophilia do not appear to affect worm expulsion, but potential functions of IL-5 could be hidden by the redundancy within the T_H2 cytokines. Recent evidence suggests that the individual roles of T_H2 cytokines in worm expulsion are only visualized on a background lacking other T_H2 cytokines. For example, deletion of IL-5 alone does not alter *N. brasiliensis* expulsion, but deletion of IL-5 in conjunction with deletion of other T_H2 cytokines has cumulative effects, indicating that each cytokine contributes to the overall response.

VII. BASOPHILS/MAST CELLS

In addition to eosinophils, the IL-5 receptor is also expressed on human basophils. Cultures of human cord blood in the presence of IL-5 stimulates the growth of eosinophils, as expected, but also results in an increase in the numbers of basophils, although to a much lesser extent. IL-5 enhances basophil activation in a manner similar to its role in priming eosinophil activation. Basophils produce histamine and leukotriene, which are released at sites of inflammation. Complement C5a by itself triggers histamine release, although basophils primed with IL-5 show enhanced histamine release and also produce large quantities of leukotriene C4 in response to C5a. IL-5 is also able to promote histamine release in response to the basophil agonists complement C3a, neutrophil-activating peptide 1, and IgE.

Mast cells have also been reported to secrete IL-5 in response to cross-linking of the FcεRI receptor by IgE. In addition, IL-5 may prime mast cells and alter their cytokine production. A study looking at the ability of IL-4 and IL-5 to modify mast cell cytokine production in response to FcεRI cross-linking found that the two cytokines primed mast cells to produce different cytokine profiles. For example, IL-5 priming increased production of cytokines such as tumor necrosis factor α (TNFα), IL-5, and IL-13, whereas IL-4 additionally enhances histamine release. The ability of IL-5 to mediate eosinophil and basophil activation and to modify mast cell secretion indicates that IL-5 is an important mediator of inflammatory responses and may provide a target for anti-inflammatory treatments.

VIII. B LYMPHOCYTES

IL-5 was originally identified due to its ability to induce differentiation and antibody production in murine B cells. Despite this fact, to date, human B cells have not been shown either to express the IL-5 receptor or to respond to IL-5. This is a major species difference that needs to be borne in mind when considering anti-IL-5 therapies. In the mouse, although not active on naive B cells, IL-5 acts in concert with antigen to promote the growth and development of IgM- and IgG-secreting B cells, and in combination with IL-4, IL-5 can promote IgG1 secretion. IL-5 has also been reported to enhance IgA production preferentially in lipopolysaccharide (LPS)-stimulated splenic B-cell cultures. However, in B cells isolated from the gut-associated lymphoid tissue, IL-5 appears to act by increasing IgA expression in switched cells rather than by inducing switching to the IgA isotype. A recent study has provided evidence of a role for IL-5 in switching to the IgG1 isotype. CD38 is widely expressed on B cells, and stimulation of CD38 with the antibody CS/2 protects B cells from apoptosis and induces expression of the IL-5Rα chain. Cross-linking of sIgD + splenic B cells (conventional B cells) with the CS/2 antibody in the presence of IL-5 has been shown to strongly induce IgG1 expression. Significantly, IgM to IgG1 isotype switching events are detected only

after culture and not in the starting population, although this effect has not been proved to be a direct effect of IL-5.

The development of transgenic and knockout mice has enabled the role of IL-5 in antibody responses to be investigated *in vivo*. Deletion of the IL-5 ligand results in mice with a defect in B1 cell development, an inability to produce eosinophilia in response to helminth worm infection, but with apparently normal antibody responses. IL-5Rα-deficient mice also exhibit a decrease in B1 cells (a subset known to express IL-5Rα), but, unlike the IL-5 − /− mice, show reduced levels of circulating IgM and IgG3. Reciprocally, IL-5 transgenic mice show strongly enhanced levels of serum IgM and increased levels of IgA. However, in another line of transgenic mice, no differences in immunoglobulin levels are observed. Analysis of IgA production in IL-5Rα − /− mice reveals reduced levels in mucosal secretions. Closer examination of mucosal effector tissues, such as the intestinal lamina propria, reveals a reduction in the number of sIgA B1 cells at these sites. The B1 cells are a B cell subset that expresses Mac1, in the case of B1b cells, and Mac1 with CD5, in the case of B1a cells. The B1 cells reside mainly in the peritoneal cavity but are also resident in gut-associated lymphoid tissues and are predominantly responsible for the production of natural antibodies that have been linked to the development of autoimmunity. Transgenic overexpression of IL-5 not only increases CD5 + B1 cells but also results in the production of IgM anti-DNA autoantibodies. We have recently produced transgenic mice expressing IL-5 under the control of a B-cell-specific enhancer. These mice produce autoreactive IgG antibodies against nuclear antigens. IL-5 may therefore play a role in the development of autoantibody-mediated autoimmunity.

IL-5-deficient mice produce normal serum antibody levels and comparable specific antibody responses to influenza virus infection. Although the presence of IL-5 may not be essential for antibody responses, a wealth of *in vitro* and *in vivo* data point to a role for IL-5 in stimulating B cells and modifying antibody responses in mice. In contrast, there is no compelling evidence for an effect on B cells or antibody responses in humans.

IX. IL-5 IN DISEASE

The most well-known link between IL-5 and human disease is in the inflammatory disease asthma. IL-5 plays a role in the activation of eosinophils, basophils, and mast cells, all of which are important mediators of inflammation. IL-5 mRNA has been detected in mucosal bronchial biopsies from asthmatic patients. Ablation of IL-5 function by gene knockout or by administration of neutralizing anti-IL-5 antibody abolishes eosinophilia and airway hyperreactivity in some mouse and primate models of asthma, providing a link between IL-5 and the asthmatic phenotype. Preliminary reports from clinical trials of humanized anti-IL-5 antibodies have reported substantially decreased blood eosinophilia in asthmatic patients in response to a single intravenous injection. Although blood eosinophilia is reduced in these patients, there is no effect on airway hyperresponsiveness to histamine. Surprisingly, there is no reduction in lung eosinophils, suggesting that the antibody is not entering the lung tissue and neutralizing locally produced IL-5. Monoclonal antibodies against the common βc chain have been developed such that they simultaneously inhibit IL-3, IL-5, and GM-CSF, and these may be more potent eosinophil inhibitors. Peptide antagonists that inhibit IL-5 have also been reported and together with specific antibodies provide a range of potential anti-IL5 therapeutic agents.

Expression of IL-5 has also been associated with a number of other diseases, including Hodgkin lymphoma and idiopathic hypereosinophilic syndrome (HES). Many cases of HES are believed to be due to defects at a primitive stage of eosinophil differentiation, but a significant number of cases are associated with aberrant T-cell populations expressing large amounts of IL-5. Hodgkin's lymphomas are characterized by malignant Hodgkin/Reed–Sternberg (H/RS) cells. These cells constitute only a small percentage of the tumor mass, with the remainder made up of nonmalignant T cells, B cells, eosinophils, and neutrophils. The reason for the accumulation of these cells around the Reed–Sternberg cells is not known, but studies have implicated the expression of cytokines by the H/RS cells as an important factor. Hodgkin lymphomas are classified according to the associated cellular infiltrates, and certain cases are associated with eosinophilia. Examination of a panel of samples from Hodgkin tumors with associated eosinophilia reveals that the malignant H/RS cells in these cases express IL-5. Expression of IL-5 has also been detected in a number of H/RS cell lines and it may be that IL-5 is important in the development of Hodgkin disease, especially in cases associated with eosinophilia.

IL-5 is an important molecule in inflammatory responses, largely due to its control of eosinophil

production. The development of specific inhibitors of IL-5 function may therefore prove to be useful therapeutic agents in the treatment of diseases such as asthma. The apparent low efficacy of anti-IL-5 monoclonal antibody to decrease airway eosinophils and hyperresponsiveness in asthma patients emphasizes the importance of developing alternatives such as small-molecule antagonists.

Glossary

apoptosis Form of cell death controlled by an array of intracellular molecules, resulting in nuclear DNA degradation and phagocytosis of the cell residua. This process is used in a widespread fashion during development and in the control of lymphocyte differentiation and immune responses.

asthma Atopic disease characterized by the tendency to produce hypersensitive responses to normally innocuous antigens, resulting in lung inflammation due to the degranulation of mast cells and eosinophils and leading to impaired breathing ability.

eosinophilia The presence of highly elevated numbers of eosinophils, white blood cells important in the defense against parasitic infections.

helminth worms Parasites such as *Nippostrongylus brasiliensis*, which pass through the intestine and provoke a strong T_H2-mediated immune response that normally results in clearance of the worms from the system.

isotype switching Process by which a B cell switches from production of an immunoglobulin isotype, such as IgM, to production of another isotype, such as IgA; accomplished by switching to the transcription of an alternative antibody heavy chain C region.

T helper 2 response Immune response mediated by CD4 + T helper 2 (T_H2) lymphocytes that produces the characteristic T_H2 cytokines (interleukins-4, -5, -9, and -13). The T_H2 branch of the immune system is mainly involved in promoting antibody production by B lymphocytes.

[c]Overall homology to the human amino acid.

AF012908), beluga whales (*Delphinapterus leucas*, AF076643), and red-crowned mangabeys (*Cercocebus torquatus*, L26032). In addition, Kaposi's sarcoma-associated herpes-like virus encodes a functional IL-6 homologue called vIL-6 (U67774). The amino acid sequence deduced from the human *IL-6* cDNA reveals that human IL-6 consists of 212 amino acids, with a hydrophobic signal peptide of 27 amino acids and two potential N-linked glycosylation sites (Fig. 1a). Four cysteine residues are found in the human IL-6 amino acid sequence; this motif is conserved among species, including viruses (vIL-6), and also exists in human and mouse G-CSF. In contrast to the human IL-6, the mouse orthologue contains several potential O-linked glycosylation sites instead of the N-linked glycosylation site. The overall homology at the amino acid level in human, animal, or viral IL-6 is summarized in Table 1.

D. Protein

The human IL-6 protein has a molecular mass ranging from 21 to 28 kDa and an isoelectric point of 5.4. IL-6 protein is posttranscriptionally glycosylated and phosphorylated on serine residues. Glycosylation seems not to be necessary for the biological activity of IL-6 because the recombinant IL-6 protein produced by prokaryotes (*Escherichia coli*) appears functional. Human IL-6 is functionally active in mouse cells, but mouse IL-6 is not active in human cells. As shown in Fig. 1b, the X-ray crystal structure of human IL-6 is a four-helix bundle, similar to the crystal structure of many cytokines, with an additional small "helix E." The A and B helices run in the same direction, and the C and D helices run in the opposite direction. The crystal structure of human IL-6 is similar to that of human G-CSF, growth hormone, and other IL-6 family cytokines (see later), including ciliary neurotropic factor (CNTF), leukemia-inhibitory factor (LIF), and oncostatin-M (OSM).

E. Polymorphisms

Many nucleotide variations are found in the human *IL-6* gene. These variations sometimes encode functional polymorphisms. In the 5′ flanking region (Fig. 2), the C/G variation at position −174 influences IL-6 expression. After coronary artery bypass surgery, people with the −174C/C allele show higher plasma IL-6 levels than do people with the −174G/G allele. In addition, a lower frequency of the −174C/C genotype is observed in juvenile chronic arthritis patients than in the normal population. The C/G variation at position −174 is also associated with susceptibility to type 1 diabetes mellitus, but no association with systemic lupus erythematosus in caucasian Germans is observed. However, another *in vitro* study has suggested that IL-6 transcription is cooperatively controlled by complex allelic interactions among polymorphic

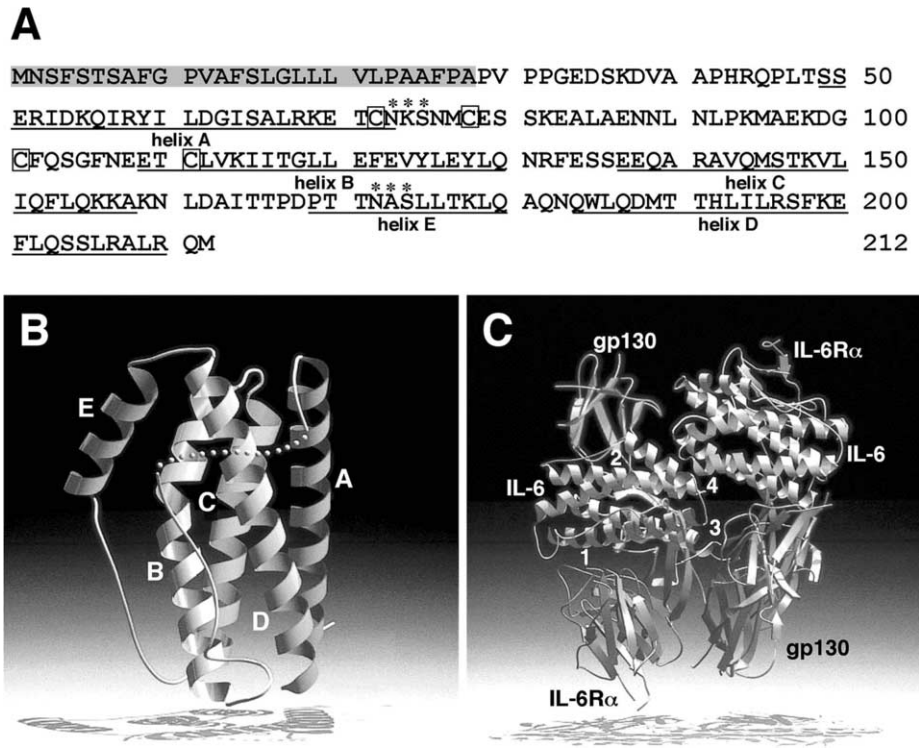

FIGURE 1 Amino acid sequence and X-ray crystallography of human IL-6. (A) The amino acid sequence of human IL-6. Amino acids are denoted using the single-letter code. The signal peptide is shaded, the four-cysteine motif is boxed, and the potential N-linked glycosylation sites are indicated with asterisks. Helices A to E are underlined. (B) The 1.9-Å X-ray crystallography structure of recombinant human IL-6. The N-terminal 18 amino acids of IL-6 that are not visible in the electron density map are indicated with a dotted line. (C) The hexamer model of the IL-6/IL-6Rα/gp130 complex. The proposed binding sites are labeled and correspond to sites 1 to 4 in IL-6. regions in the IL-6 promoter (−596G to A, −572G to C, −392/373 AT runs, and −174G to C) (Fig. 2). Another polymorphism in the fourth intron (G to A at position 4470) appears to correlate with Crohn's disease and ulcerative colitis, although no significant alteration of IL-6 expression has been observed to result from the polymorphism.

III. REGULATION OF IL-6 EXPRESSION

A. Biological Events and Factors Regulating IL-6 Production

In young, healthy animals, serum IL-6 levels are normally low. IL-6 production is rapidly induced in the course of acute inflammatory responses that occur in association with injury, trauma, stress, and infection. Chronic inflammation, which is often observed in many autoimmune diseases, is also associated with increased IL-6 production. Aging also influences the production of IL-6. With advancing age, plasma IL-6 levels increase, a change that is explained at least in part by age-associated diseases. Because estrogens and androgens are known to inhibit IL-6 expression, however, a decrease in the sex hormones with aging may contribute to this increase. Physical exercise such as running and cycling is reported to induce many cytokines, including IL-6, which is the predominant cytokine released from skeletal muscle. Increased body weight (obesity) also correlates with the elevation of IL-6; this is partly explained by the increase in adipose tissue, which is also known to produce IL-6.

Many soluble factors promote IL-6 expression in various types of cells and cell lines. These include serum, cytokines (interferon β, IL-1, OSM, platelet-derived growth factor, TNFα and transforming growth factor-β), complement complex, bacterial components (e.g., lipopolysaccharide, lipoteichoic acid, and unmethylated CpG dinucleotide motif), viral components [e.g., double-stranded RNA

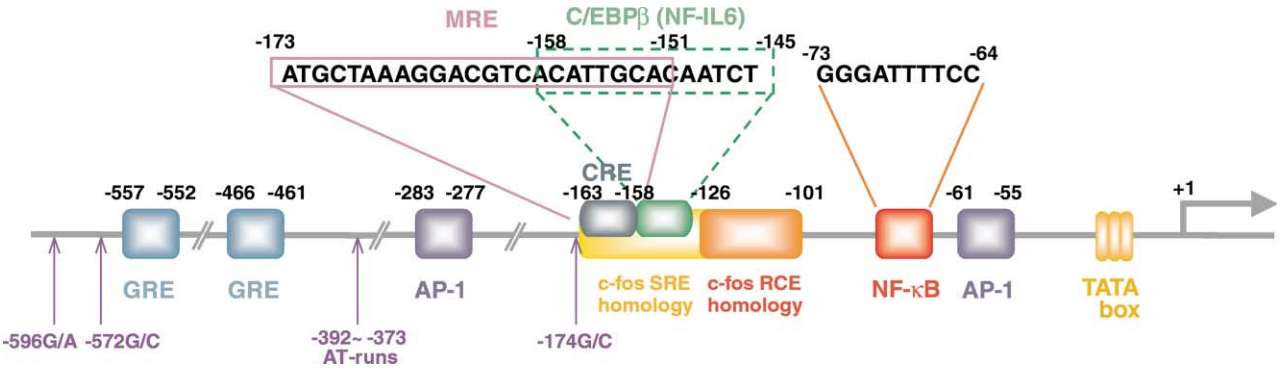

FIGURE 2 A schematic illustration of the 5′ flanking promoter region of the human *IL-6* gene. The nucleotide position of the cis-regulatory elements and polymorphic regions is given relative to the major transcription start site (+1). Functional polymorphisms located in the 5′ flanking region are indicated with arrows. MRE, Multiple response element; see text for other abbreviations.

or poly(I):poly(C)], activators of the cyclic AMP/protein kinase A pathway (forskolin, cholera toxin, and dibutyryl cyclic AMP), phorbol 12-myristate 13-acetate, calcium ionophore A23187, eicosanoid lipid mediators (prostaglandins and leukotriene B4), neuropeptides/neurotransmitters (substance P, epinephrine, norepinephrine, vasoactive intestinal peptide, adenosine, calcitonin, serotonin, and histamine), thrombin, angiotensin II, and others. On the other hand, IL-10, somatostatin, 1,25-dihydroxyvitamin D_3, retinoic acid, glucocorticoids, estrogens, and androgens inhibit IL-6 production in certain cells. Interestingly, IL-4 and IL-13 inhibit IL-6 expression in monocytes, but enhance its expression in osteoblasts.

Cross-linking cell surface receptors, such as the Fcε and Fcγ receptors, T-cell receptor, CD40, CD95 (Fas), and certain members of the integrin superfamily, with an agonistic antibody or specific counter-receptors also stimulate IL-6 production.

B. IL-6-Producing Cells

Many cell types produce IL-6. These include T cells, B cells, polymorphonuclear cells, eosinophils, monocyte/macrophages, mast cells, dendritic cells, chondrocytes, osteoblasts, endothelial cells, skeletal and smooth muscle cells, islet beta cells, thyroid cells, fibroblasts, mesangial cells, keratinocytes, and certain tumor cells. In addition, adipose tissue is a source of IL-6. Neuronal cells, including microglial cells and astrocytes, are also IL-6 producers.

C. Promoter Region of the *IL-6* Gene

As shown in Fig. 2, several potential transcription control elements are found in the 5′ flanking region of the human *IL-6* gene. These include the glucocorticoid-responsive element (GRE), activator protein 1 binding site (AP-1), multiple response element (MRE), c-fos serum-responsive element (SRE) homology, c-fos retinoblastoma control element (RCE) homology, cyclic AMP response element (CRE), nuclear factor for IL-6 expression (NF-IL-6; also known as the CCAAT/enhancer binding protein β, C/EBPβ) binding sites, and the NF-κB binding site. The products of tumor-suppressor genes, p53, and retinoblastoma proteins repress the activity of an *IL-6* promoter fragment containing nucleotides −225 to +13. The human *IL-6* gene contains three copies of a TATA-box and transcription start sites. The preferential utilization of a specific transcription start site in a variety of cells suggests that distinct regulatory mechanisms may be responsible for the *IL-6* gene expression in different tissues.

IV. RECEPTOR AND SIGNAL TRANSDUCTION

A. Molecular Properties of the IL-6 Receptor Complex, IL-6Rα and gp130

IL-6 has high-affinity ($K_d = 40$ to 70 p*M*) and low-affinity ($K_d = 1$ to 6 n*M*) receptors. IL-6 binds IL-6Rα (CD126) alone with low affinity. In the presence of another receptor component, gp130 (CD130), which cannot itself bind IL-6, the ligand/receptor complex shows a 100-fold higher affinity and generates signal transduction. Both receptors possess an immunoglobulin-like domain, a four-cysteine motif, and a Trp-Ser-X-Trp-Ser (WSXWS, where X is any amino acid) motif in the extracellular region. These motifs are conserved among members of the type I cytokine receptor family, including

the receptors for prolactin, growth hormone, many interleukins, leptin, erythropoietin, thrombopoietin, LIF, OSM, CNTF, G-CSF, and granulocyte/macrophage-CSF. The four-cysteine and WSXWS motifs are responsible for the ligand binding and are known as the cytokine-binding module (CBM) (Fig. 3A).

1. *IL-6Rα: Necessary for Ligand Binding*

IL-6Rα, also known as gp80 and CD126, is an 80-kDa single polypeptide chain. Molecular cloning of the human *IL-6Rα* cDNA was achieved in 1988 (database accession, X12830). Mouse (X53802) and rat (M58587) *IL-6Rα* cDNAs have also been identified. The human IL-6Rα consists of 468 amino acids with six potential N-linked glycosylation sites and 11 cysteine residues. The putative mature form of IL-6Rα contains 449 amino acids and consists of an extracellular region of 339 amino acids, a transmembrane domain of 28 amino acids, and a cytoplasmic tail of 82 amino acids. Although the short cytoplasmic domain of IL-6Rα is not important for IL-6 signal transduction in a myeloid leukemic cell line (M1), it functions in the expression of the receptors on the basolateral side of polarized Madin–Darby canine kidney cells. The human *IL-6Rα* gene is located on chromosome 1q21. The mouse and rat *IL-6Rα* genes are on chromosomes 3 and 2, respectively (Table 1). IL-6Rα is expressed on the cell surfaces of leukocytes, hepatocytes, intestinal epithelial cells, cells of the endocrine glands (such as the pituitary and adrenal cortex), and certain cell lines. In addition, dexamethasone treatment up-regulates IL-6Rα expression in

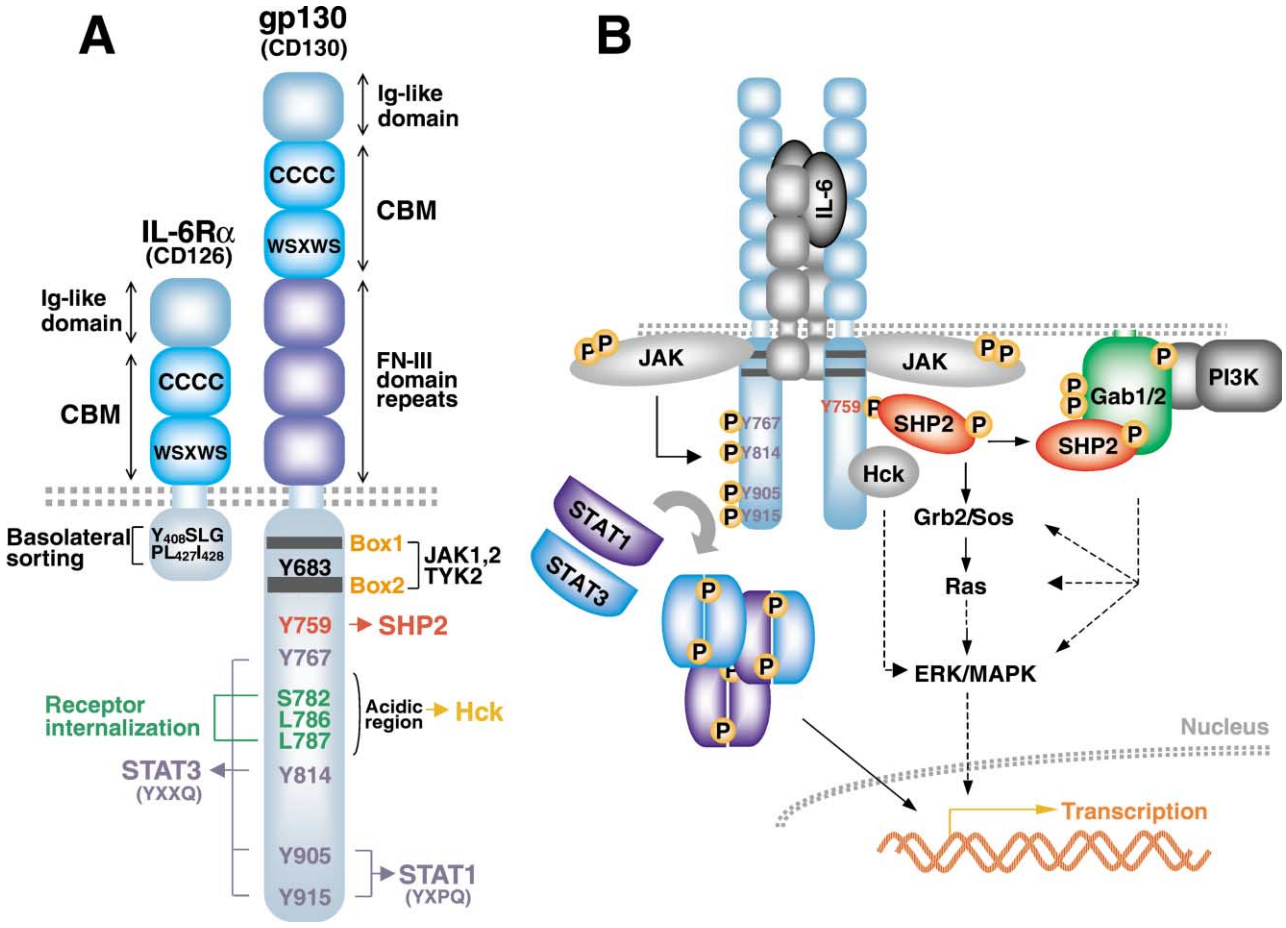

FIGURE 3 Signal transduction. (A) Schematic illustrations of the structures of IL-6Rα and gp130. Amino acid residues are denoted using the single-letter code, followed by the positions of the residues in the human gp130 amino acid sequences. Box 1 and box 2 domains in human gp130 are I^{651}WPNVDP and V^{691}SVVEIEANDKKP, respectively. The acidic domain required for Hck association extends from amino acid 771 to amino acid 811; CCCC is the four-cysteine motif. FN-III, Type III fibronectin; Ig-like, immunoglobulin-like. (B) The intracellular signal transduction pathway generated by IL-6. P, Phosphotyrosine residue; see text for details and abbreviations.

osteoblasts. IL-6Rα expression in naive resting B cells is not detectable but is induced in activated B cells. IL-6Rα has soluble forms that are normally found in the sera and cerebrospinal fluid of healthy individuals, at ~0–50 ng/ml (in women) and ~0.8–1.6 ng/ml, respectively. The soluble forms of IL-6Rα are generated by proteolytic cleavage or alternative splicing of its mRNA, and act in an agonistic manner with IL-6 on cells expressing only gp130. To date, no report describes a phenotype of IL-6Rα knockout mice.

2. *gp130: Necessary for Signal Transduction*

Glycoprotein gp130 has a molecular mass of 130–150 kDa; gp130 has the alternative names IL-6Rβ, CD130, and IL-6 signal transducer. The molecular cloning of human *gp130* cDNA was reported in 1990 (database accession, M57230). The cDNA sequence for mouse (M83336), rat (M92340), rhesus monkey (AF227555, partial sequence), chicken (AJ011688), and African clawed frog (*Xenopus laevis*, AF041845) gp130 has also been reported. The human gp130 precursor contains 918 amino acids. The mature human gp130 contains 896 amino acids and consists of an extracellular domain of 597 amino acids, a membrane-spanning region of 22 amino acids, and a cytoplasmic domain of 277 amino acids. There are 14 potential N-linked glycosylation sites. gp130 has three fibronectin type III domains in the extracellular region. The cytoplasmic domain contains important elements for signal transduction: (1) box motifs, which are necessary for the association with non-receptor tyrosine kinases called Janus kinases (JAKs), and (2) six tyrosine residues (Fig. 3). In humans, there are two chromosomal loci for gp130; one is the genuine *gp130* gene, located on chromosome 5q11, and the other is a pseudogene localized to chromosome 17. The murine and rat *gp130* genes are located on chromosomes 13 and 2q14–q16, respectively (Table 1). The human *gp130* gene has 17 exons separated by 16 introns. The X-ray structure of the extracellular domain of the human gp130 has recently been reported. In contrast to IL-6Rα, gp130 is ubiquitously expressed on the cell surface. Alternative splicing of *gp130* mRNA gives rise to soluble forms; one of these is found in sera at ~210–290 ng/ml (in women) and acts in an antagonistic manner. Another splicing variant of gp130, termed gp130-RAPS (database accession, AB015706), is an autoantigen in rheumatoid arthritis patients. The variant gp130-RAPS also antagonizes IL-6 activities *in vitro*. The disruption of the *gp130* gene in mice leads to embryonic or perinatal lethality, depending on the genetic background of the mouse. Knock-in mutant mouse strains that are defective in gp130-mediated activation of the signal transducer and activator of transcription, Stat3, also die within 1 day after birth. On the other hand, another knock-in mouse that lacks the SH2 domain-containing protein tyrosine phosphatase (SHP2)-binding site of gp130 (Y759, where Y is the one-letter code for tyrosine; see Fig. 3) is born normally and apparently healthy, but displays splenomegaly, lymphadenopathy, and enhanced immunoglobulin production, indicating that Y759 of gp130 has a negative regulatory role(s) *in vivo*.

B. IL-6 Family Cytokines

Glycoprotein gp130 is used as a signal-transducing receptor component by several other cytokines. These include IL-11, CNTF, OSM, cardiotoropin-1, and LIF. Thus, these cytokines are categorized as "IL-6 family cytokines." In addition, a recently identified molecule, novel neurotropin-1 (NNT-1)/BSF-3/cardiotropin-like cytokine (CLC), also uses gp130 as a component for its functional receptors. Because the gp130 signaling component is shared by the IL-6 family cytokines, their functions are largely overlapping.

C. Binding of IL-6 to the Receptor

When IL-6 binds to IL-6Rα and gp130, the molecules form a hexameric complex with a stoichiometry of 2:2:2 (see Fig. 1c). Analysis by means of site-directed mutations of the IL-6 protein has identified the regions required for interaction with the receptor complex and for signal transduction. The region in IL-6 termed "site 1" is important for binding with IL-6Rα. IL-6 mutated at "site 2" or "site 3" can bind to the receptor but cannot generate intracellular signals. The X-ray crystallography of IL-6 has led to a predicted role for the region, designated as "site 4" in the interaction between two IL-6/IL-6Rα/gp130 complexes, in stabilizing the architecture of the signaling complex. A model of the ligand/receptor interaction cascade is as follows: (1) IL-6 binds to IL-6Rα via site 1 in IL-6, forming a heterodimer; (2) the binary IL-6/IL-6Rα complex contacts the gp130 CBM through site 2 and also forms contacts between the C-terminal cell surface domain of IL-6Rα and gp130, resulting in a trimolecular complex with a 1:1:1 stoichiometry that is not yet able to generate intracellular signals; (3) two trimolecular complexes are assembled together via site 3 and the immunoglobulin-like domain of gp130, as well as through site 4, completing the hexamer complex, which is competent for signaling.

D. Signal Transduction Generated by IL-6

Engagement of IL-6 with the receptor induces activation of tyrosine kinases (JAK1, JAK2, and TYK2) that are constitutively associated with gp130 via the box domains. The activated JAKs phosphorylate tyrosine residues in the cytoplasmic domain of gp130 (Fig. 3b). The second phosphotyrosine residue from the plasma membrane (Y759 in humans) is necessary for the recruitment of SHP2. After being recruited, SHP2 is phosphorylated and can then interact with Grb2 (growth factor receptor-bound protein 2), which is constitutively associated with Sos (son of sevenless), a GDP/GTP exchanger for Ras. The activated Ras (i.e., the GTP-form) transmits signals, leading to the activation of an extracellular signal-regulated kinase/mitogen-activated protein kinase (ERK/MAPK) cascade. In fact, a point mutation in the SHP2-binding site (Y759) of gp130 leads to a defect in the ERK/MAPK activation. SHP2 also binds to another adapter protein, Gab1/2 (Grb2-associated binder 1/2), which associates with the p85 subunit of phosphatidylinositol 3′-kinase (PI3K) in a stimulation-dependent manner, resulting in the formation of a tertiary complex, SHP2/Gab/PI3K. The activity of ERK/MAPK is severely impaired in Gab1 knockout fibroblasts stimulated with IL-6/IL-6Rα, indicating a requirement for Gab1 in the gp130 Y759-mediated pathway(s). An Src family tyrosine kinase, Hck, is associated with an acidic region of the cytoplasmic domain of gp130 and modulates the ERK/MAPK activity.

Phosphorylation of any of the four tyrosine residues (Y767, Y814, Y905, and Y915 in humans), all of which lie within a YXXQ motif, is required for the activation (tyrosine phosphorylation) of a transcription factor, Stat3. In addition, Stat1 is activated through phosphotyrosines that lie within a YXPQ motif (Y905 and Y915 in humans). Following phosphorylation, Stat proteins are homodimerized (Stat1/Stat1 and Stat3/Stat3) or heterodimerized (Stat1/Stat3) and subsequently enter the nucleus and activate the transcription of many genes. Stat3 is also phosphorylated on serine residues by an H7-sensitive kinase pathway. This phosphorylation is necessary for the full transcriptional activity of Stat3. Glycoprotein gp130 also receives serine phosphorylation on its cytoplasmic domain (S782 in humans), and the surface expression of gp130 is increased when this serine residue is mutated. Other signaling cascades generated directly through JAKs, such as those involving Stat5 activation, have also been reported.

After binding IL-6, the receptor complex is internalized, independent of its signaling capability. A dileucine motif in the cytoplasmic domain of gp130 (L786 and L787 in humans; L is leucine in the one-letter code) is involved in the efficient internalization of the complex. Molecules that negatively regulate IL-6 signaling have been identified. A protein inhibitor of activated Stat3 (PIAS3) directly interacts with the activated (i.e., phosphorylated) Stat3 and down-regulates the transcriptional activity of Stat3. The suppressor of cytokine signaling (SOCS) family proteins are also negative regulators of IL-6 signaling.

V. BIOLOGICAL ACTIVITIES OF IL-6

A. Molecules Regulated by IL-6

IL-6 stimulates the transcription of a variety of genes through the signal transduction pathways depicted in Fig. 3b. Genes encoding acute-phase proteins are directly regulated by IL-6 via two types of IL-6-responsive elements (see later). The *jun B* gene promoter contains an IL-6-responsive element that consists of a putative Ets-binding site, which has been found to be a Stat3-binding site, and a cyclic AMP-responsive element, both of which are essential for IL-6-induced *jun B* expression. IL-6-responsive elements have also been identified in the promoter region of the *IRF1* and *stat3* genes. Many other genes, such as *C/EBPβ*, *C/EBPδ*, c-*myc*, c-*myb*, *bcl-2*, *p19IND4D*, *pim1/2*, *SOCS/JAB/SSI-1*, and *gp130*, are controlled by the activation of gp130. In addition, metallothionein I, an adapter molecule for the IL-1R/Toll-like-R family (MyD88), IL-4Rα, and tissue-inhibitor of metalloproteinase I are reported targets of IL-6 signaling.

B. Effects on the Immune System

As suggested by its former name, BSF-2, IL-6 acts on activated B cells to promote cell growth and immunoglobulin production, but does not affect naive resting B cells due to a lack of IL-6Rα expression. Consistent with this, IL-6 transgenic mice show massive plasmacytosis and hypergammaglobulinemia. The effect of IL-6 on immunoglobulin production in B cells is dependent on Stat3 activation. In T cells, IL-6 is involved in cell activation, proliferation, and survival. Some of these effects are attributable to the up-regulation of IL-2Rα (CD25) and the induction of anti-apoptotic Bcl-2 family molecules. IL-6 is sometimes categorized as a T helper (T_H) type 2 (T_H2) cytokine, but its effect on the balance between T_H1 and T_H2 is still controversial.

IL-6 in synergy with IL-2 increases the expression of mediators for target cell killing, such as serine esterase and perforin, and thus plays an important role in the functions of CD8-positive cytotoxic T cells. In agreement with these observations, the disruption of the *IL-6* gene in mice results in a reduction in T-cell/thymocyte numbers, a decrease in immunoglobulin production, and a compromised cytotoxic activity of CD8-positive T cells.

IL-6 plays a critical role in protection against both bacterial (e.g., *Listeria monocytogenes*, *Escherichia coli*, and *Candida albicans*) and viral (vaccinia virus) infection, given that IL-6 knockout mice are highly sensitive to these pathogens, and the injection of recombinant IL-6 enhances their resistance. IL-6 is generally grouped as a member of the pro-inflammatory cytokines, but it also has anti-inflammatory characteristics: antigen-induced pulmonary inflammation is exaggerated in mice lacking IL-6 and a lung-specific overexpression of IL-6 protein ameliorates these symptoms. In addition, endotoxin-induced acute inflammatory responses are enhanced in IL-6 knockout mice compared to wild-type animals.

C. Effects on Hematopoiesis

IL-6 induces proliferation of murine pluripotent stem cells in synergy with the action of IL-3. IL-6 triggers dormant progenitor cells to enter the cell cycle, whereas IL-3 supports the continuation of the cell cycle progression. IL-6 also stimulates megakaryopoiesis in concert with stem cell factor and thrombopoietin. IL-6 knockout mice have a reduced number of megakaryocyte progenitors. In addition, IL-6 is involved in granulopoiesis. Mice doubly deficient for IL-6 and G-CSFR show neutropenia that is more severe than that seen in G-CSFR knockout mice. In addition, injection of IL-6 into G-CSFR knockout mice improves granulopoiesis.

IL-6 can arrest the cell cycle and induce differentiation in human (U937) and mouse (M1) myeloid cell lines. The murine M1 cells differentiate into macrophages in response to IL-6. This signal is mediated by IL-6-induced Stat3 activation. Mice overexpressing both IL-6 and IL-6Rα show extramedullary hematopoiesis, which supports the preceding observations.

D. Effects on the Acute-Phase Reaction and Liver Regeneration

The acute-phase reaction is elicited by inflammation associated with infection, injury, and other factors. This reaction aids the body in recovery and helps maintain homeostasis. The acute-phase reaction consists of fever, an increase in vascular permeability, and the production of acute-phase proteins by hepatocytes. The acute-phase proteins are divided into two groups based on their regulating cytokines. IL-6 directly up-regulates the mRNA expression of type II acute-phase proteins through Stat3 activation. IL-6 also contributes to the increase in type I protein levels, which are mainly regulated by IL-1. Intravenous injection of IL-6 rapidly induces the production of the acute-phase proteins in animals. In IL-6 knockout mice, the acute-phase response is lower than in wild-type mice.

IL-6 is known to play a fundamental role in liver regeneration. After hepatectomy in rats, a prompt increase in tumor necrosis factor a (TNFα), followed by an elevation of serum IL-6, is observed. Mice deficient for TNF receptor type I (TNF-RI) are unable to induce the IL-6 elevation after partial hepatectomy. IL-6 or NF-IL-6 (C/EBPβ) knockout mice show an impaired proliferative response during liver regeneration. Injection of IL-6 restores the capacity of the liver to regenerate in TNF-RI or IL-6 knockout mice. These observations indicate that TNFα-induced IL-6 production is essential for liver regeneration.

E. Effects on Bone Metabolism

IL-6 is implicated in osteoclastogenesis. Osteoclast formation is enhanced by ovariectomy in mice, an effect that is negated when an anti-IL-6 antibody or 17β-estradiol is administered to the mice. Consistent with this finding, IL-6 knockout mice are resistant to the bone loss induced by ovariectomy. These findings suggest an important role for IL-6 in the osteoporosis found in postmenopausal women and patients with rheumatoid arthritis.

F. Effects on the Nervous and Endocrine Systems

In situ mRNA hybridization reveals that IL-6 is transcribed at high levels in the hippocampus, hypothalamus, and subcortical structures of the rat brain. In addition, soluble IL-6Rα is detectable in the cerebrospinal fluid in humans. These findings suggest a functional importance of IL-6 in the central nervous system (CNS). In fact, an *in vitro* study showed that IL-6 can induce neurite outgrowth in a rat pheochromocytoma cell line (PC12) pretreated with nerve growth factor. This effect is mediated by IL-6-induced ERK/MAPK activation. The CNS-specific

overexpression of IL-6 protein in mice results in the development of reactive gliosis, and these mice exhibit significant neurodegeneration, which leads to motor problems such as ataxia, seizure, and tremor. In addition, IL-6 knockout mice exhibit delayed recovery of the sensory functions after crush lesions of the sciatic nerve.

IL-6 is reported to modulate the endocrine system via the hypothalamic–pituitary–adrenal axis. Injection of recombinant IL-6 stimulates the release of adrenocorticotropic hormone in a manner independent of the action of corticotropin-releasing hormone. Expression of IL-6Rα on pituitary corticotrophs and in the adrenal cortex supports the direct action of IL-6 on hormone release.

VI. IL-6 AND DISEASES

A number of diseases are reportedly associated with the aberrant expression of IL-6. These include Alzheimer's disease, bronchial asthma, cardiac myxoma, Castleman's disease, cystic fibrosis, inflammatory bowel disease, multiple sclerosis, Paget disease, psoriasis, rheumatoid arthritis, Sjögren's syndrome, systemic lupus erythematosus, and type 2 diabetes mellitus. IL-6 is also implicated in the pathogenesis of osteoporosis. In addition, some other diseases are associated with IL-6 gene polymorphisms. Many tumors, including Kaposi's sarcoma, melanoma, multiple myeloma, and prostate cancer, produce IL-6, which can act as an autocrine growth factor for the neoplasm.

Involvement of IL-6 in the pathogenesis of some diseases has been demonstrated using animal models of the diseases. IL-6 transgenic mice on a BALB/c background exhibit symptoms similar to multiple myeloma. The disease severity of murine models for multiple sclerosis (experimental autoimmune encephalomyelitis), rheumatoid arthritis (collagen-induced arthritis), osteoporosis (induced by ovariectomy), and inflammatory bowel disease (dextran sulfate sodium-induced colitis) is significantly improved in IL-6 knockout mice. Anti-IL-6 antibody treatment ameliorates autoantibody production and prolongs life in an autoimmune-prone (NZB × NZW)F1 mouse strain. By contrast, when twitcher mice, a model of globoid cell leukodystrophy (Krabbe's disease), are crossed with IL-6 knockout mice, the disease symptoms are enhanced. Similarly, antigen-induced pulmonary eosinophilia, an animal model of bronchial asthma, is exaggerated in IL-6 knockout mice.

Results from all of these animal studies indicate that IL-6 and its receptor are likely therapeutic targets for various diseases, and attempts to identify therapeutic approaches are underway. One potential therapeutic agent, an antagonistic, humanized anti-IL-6Rα antibody, is currently being used in a Phase II clinical trial for the treatment of rheumatoid arthritis, Crohn's disease, and Castleman's disease. In addition, adenovirus-mediated expression of IL-6/IL-6Rα fusion protein, which is 100- to 1000-fold more active and thus is called "hyper-IL-6," is being tested for use in clinical treatment of fulminant hepatic failure.

VII. SUMMARY

IL-6 is a multifunctional cytokine that acts on and is produced by many cell types in the body. Although the name "interleukin" literally indicates a substance that is a mediator between leukocytes, IL-6 not only acts on the immune system but also functions in the endocrine and nervous systems. The collective effort of many investigators in different fields has been necessary to disclose the multifunctional aspects of IL-6. In particular, details of the intracellular signaling cascade have been rapidly clarified by many investigators. However, accumulating evidence sometimes reveals contradictory observations; for instance, IL-6 is found to act both as a pro-inflammatory and an anti-inflammatory mediator. The authors of a recent publication on gp130 knock-in mouse strains suggest that these discrepant observations can be explained by the idea that there are variations in the balance between positive and negative intracellular signals generated by a given ligand, leading to different, and sometimes opposite, outcomes *in vivo*.

IL-6 is implicated in the pathogenesis of various kinds of diseases. Elucidation of the detailed mechanism of action of IL-6 will continue to be beneficial for understanding these disorders and for the development of clinical treatments.

Glossary

adapter protein Contains multiple docking sites for other proteins but lacks enzymatic activity; functions as an "adapter" by allowing the assembly of complexes of signaling proteins that generate signal transduction.

5′,3′ flanking region Noncoding region upstream (5′ flanking) or downstream (3′ flanking) of a gene. A cis-regulatory element for gene expression is often found in the 5′ flanking region.

knockout/knock-in mice Mutant mice in which certain genes are disrupted using gene-targeting technology (knockout), or mice in which native genes are changed by the introduction of artificially altered genes (e.g., point mutations) into the endogenous locus (knock-in).

signal transduction Series of intracellular events that link extracellular stimuli (e.g., ligand binding) to the activation of gene transcription.

tyrosine kinase Enzyme that phosphorylates protein tyrosine residues. There are two major types: (1) receptor tyrosine kinases, which penetrate the plasma membrane and possess a kinase domain in the cytoplasmic region, such as the receptors for many growth factors, and (2) nonreceptor tyrosine kinases, which reside in the cytoplasm, such as Src family tyrosine kinases and Janus kinases.

Interleukin-7

HERGEN SPITS
Netherlands Cancer Institute, Amsterdam

Interleukin-7 (IL-7) is a single-chain protein of 25 kDa produced predominantly by epithelial cells, especially keratinocytes and thymic epithelial cells. The functional interleukin-7 (IL-7) receptor consists of two chains, an α chain (IL-7Rα) and a γ chain. The latter polypeptide is denoted γ common (γc) because it is also a component of the receptors for IL-2, IL-4, IL-9, and IL-15. IL-7 plays an essential, nonredundant role in the development of T and B cells in the mouse and of T cells in humans. IL-7 promotes the survival and proliferation of T-cell precursors in humans and mice and of B-cell precursors in mice. IL-7 affects the survival and proliferation of mature T cells but not of mature B cells. IL-7 is important for homeostasis of naive T cells and probably also for the function of mature T cells in the periphery. IL-7 is also essential for the formation of Peyer's patches in the mouse. Data in the mouse suggest that IL-7 may be of clinical benefit by stimulating T-cell development in recipients of hematopoietic stem cell transplantation, but thus far no clinical trials have been performed in humans.

I. THE IL-7 GENE AND PROTEIN

A. IL-7 Gene

Accession numbers for the IL-7 gene are as follows: human gene, M29048; human cDNA, NM_000880; mouse gene, AH_001973; mouse cDNA, X07962; bovine gene, X64540; and swine gene, AB035380.

The human IL-7 gene is located on chromosome 8, bands q12–q13. It is approximately 33 kb long and contains six exons. Murine IL-7 is 56 kb long and maps to chromosome 3.

B. IL-7 Protein

IL-7 is a single-chain glycoprotein of 25 kDa that contains six cysteine residues. The disulfide bonds are essential for the biological activity of the protein. Human IL-7 (152 amino acids and 17.4 kDa) and murine IL-7 (127 amino acids) show 60% sequence homology at the protein level. The human IL-7 gene contains an open reading frame of 534 nucleotides encoding a polypeptide of 177 amino acids with a predicted molecular weight of 17.4 kDa with three potential N-linked glycosylation sites and a signal peptide of 25 amino acids. The murine gene contains an open reading frame encoding a signal peptide of 25 amino acids and a functional protein of 127 amino acids with a predicted molecular weight of 14.9 kDa. The molecular weight of the expressed protein is 25 kDa, due to glycosylation of two potential N-linked glycosylation sites. Both human and mouse proteins contain three disulfide bonds that are indispensable for biological activity.

II. THE IL-7Rα GENE AND THE IL-7 RECEPTOR COMPLEX

A. The IL-7Rα Gene

Accession numbers for the IL-7Rα gene are as follows: human gene: AF043123-9, AF043124-9, AF043125-9, AF043126-9, AF043127-9, and AF043128-9 (these accession numbers denote the different exons); human cDNA, NPI_002185; and mouse cDNA, M29697.

Human IL-7Rα maps to chromosome 5p13. The chromosomal localization of murine IL-7Rα is unknown. Both human and mouse genes contain eight exons and seven introns with a total size of 19 kb in the human and 24 kb in the mouse. The first exon contains the 5′-untranslated region, the signal peptide, and the amino-terminus of the mature protein. The remainder of the extracellular region is encoded by exons 2 to 6. In addition, exon 6 encodes the transmembrane portion of the cytoplasmic region and exons 7 and 8 encode the rest of the cytoplasmic region. The entire 3′-untranslated region is encoded by exon 8. Differential splicing results in mRNA encoding a secreted form of the human IL-7Rα receptor. This form lacks the sequences in exon 6 that encode the transmembrane region.

B. IL-7R Complex

The murine IL-7Rα gene encodes a protein of 439 amino acids with a calculated MW of 49.5 kDa. On T cells, the protein has a MW of 90 kDa. The associated γc chain has a MW of 74 kDa. IL-7Rα is a type I membrane protein with a single transmembrane domain. The extracellular domain contains features of the cytokine receptor superfamily. The cytoplasmic domain with 195 amino acids does not contain consensus sequences of protein kinases. The crystal structure of IL-7Rα has not been determined. Based on the model of the prolactin receptor, intrachain disulfide bridges are most probably formed between the first and second Cys residues and between the third and fourth Cys residues. The receptor contains a WS motif (WSXWS) at the COOH-terminus of the extracellular domain.

III. PRODUCTION OF IL-7

The main cell types that express the gene are bone marrow stroma, thymic stroma, intestinal epithelial cells, and keratinocytes. IL-7 mRNA has furthermore been detected in mature but not immature dendritic cells and dendritic cells derived from CD34 cord blood cells cultured with granulocyte/macrophage colony-stimulating factor and tumor necrosis factor α, but it is not clear whether these cells secrete IL-7. In addition, the gene was expressed in platelets and a megakaryocyte cell line. Various malignant T-cell types express the gene (Table 1).

IV. EXPRESSION OF THE IL-7R COMPLEX

Since IL-7 is important for early T- and B-cell development (see below), it is not surprising that the receptor complex is expressed on T- and B-cell progenitors. In addition, this complex is expressed on mature T cells and furthermore on malignant cells originating from different cell types. They are summarized in Table 2.

V. SIGNAL TRANSDUCTION THROUGH IL-7Rα

A. Kinases Activated by IL-7

The IL-7R complex requires both the α chain and γc for relaying signals. These two chains associate with tyrosine phosphokinases that relay signals triggered by binding of IL-7 to the receptor complex. Tyrosine kinases belonging to the family of Janus kinases (JAKs) are essential for IL-7R signaling. Two Janus kinases, JAK1 and JAK3, associate with the complex. JAK1 binds to IL-7Rα and JAK3 to γc. Both kinases become phosphorylated when IL-7 binds to its receptor, but the extent of phosphorylation of JAK3 is much higher than that of JAK1. In contrast to

Note. DC, dendritic cell; DP, double positive; NK, natural killer; SP, single positive; TCR, T-cell receptor.

JAK3, which is specifically expressed in lymphoid cells, JAK1 is ubiquitously expressed. JAK3 activity and most likely also JAK1 activity are required for IL-7R-mediated signaling during T-cell development. Another kinase that associates with the IL-7R complex is phosphatidylinositol 3-kinase (PI3K). JAK3 appears also to control PI3K activity. PI3K phosphorylates the D3 position of the inositol group of phosphoinositide lipids to generate phophatidylinositol 3-phopsphate [PtdIns(3)P], PtdIns(3,4)P2, and PtdIns(3,4)P3. The last two products are important for cellular proliferation. The enzyme consists of an 85 kDa adapter and a 110 kDa catalytic unit. Upon ligand binding, the p85 unit is tyrosine-phosphorylated and associates with many receptors including the IL-7Rα chain. Stimulation of human thymocytes with IL-7 activates both isoforms of p85, 1 and 2, in human thymocytes. Interestingly, phosphorylation of p85 required JAK3, which was shown to associate with p85. It is probable that two pools of PI3K are activated by IL-7; one is associated with the IL-7Rα chain and another with insulin receptor substrate-1 (IRS-1) and IRS-2. PI3K appears to be important for the survival and proliferation of both T- and B-cell precursors. PI3K associates with the IL-7α chain through an SH2 domain recognition motif (YXXM) spanning residue Y449 in its cytoplasmic domain. Interestingly, this residue was found to be critical for IL-7-mediated proliferation of murine pre-B cells. Induction of immunoglobulin H (IgH) VDJ gene recombination, however, did not require the Y449 residue. These findings indicate that IL-7Rα-transduced signals can control survival as well as proliferation and differentiation through distinct pathways. More recently it was demonstrated that PI3K also mediates the survival and proliferation of human T-cell precursors. The Y449 in the cytoplasmic domain of the IL-7R is important for the survival and expansion of human thymocytes. A dominant-negative mutant of p85 that binds to the receptor but fails to interact with p100 was introduced into human T-cell precursors by retrovirus-mediated gene transfer. This mutant was found to inhibit the survival and expansion of the T-cell precursors in a fetal thymic organ culture but did not inhibit differentiation of these cells.

Recently it was demonstrated that protein kinase B (PKB) can be activated by IL-7. PKB seems to play a central role in PI3K-mediated protection against apoptosis in a wide range of cell types. As activation of PKB as well of PI3K requires residue 449Y, it is very likely that in human T-cell precursors PKB is a downstream effector of PI3K as well. The substrates of IL-7-activated PKB are not yet known. Two sets of observations suggest a role for the p38 mitogen-activated protein kinase (MAPK) in IL-7-mediated proliferation of mature T cells. First, activation of a murine T-cell line by IL-7 resulted in phosphorylation of p38 MAPK, and second, the proliferative response of human T cells was inhibited by the highly selective p38 MAPK inhibitor SB203580. Which signaling pathway activates p38 MAPK is unknown. p21ras is not activated by IL-7 and therefore does not act in this pathway. The same report also documented activation of the stress-activated protein kinase/Jun-N-terminal kinase by IL-7, but there is no evidence that activation of this enzyme is important for the proliferative response induced by IL-7.

B. Transcription Factors Activated by IL-7R Signaling

In general, JAKs phosphorylate the receptor chains, providing docking sites for the SH2 domains of STATs. STATs are recruited to the phosphorylated sites of the receptor and become phosphorylated. The phosphorylated STATs can dimerize, translocate to the nucleus, and stimulate the expression of cytokine-inducible genes. Two studies documented the activation of STAT1 by IL-7. The phenotype of STAT1-deficient mice, however, makes it unlikely that STAT1 plays an essential role in IL-7R signaling *in vivo* as the thymus of these mice is normal and T- and B-cell development proceeds undisturbed. STAT3 and STAT5 have been shown to be activated by IL-7 in several cell types. STAT3 is probably not involved in IL-7R signaling *in vivo*. STAT3 deficiency results in embryonic lethality, preventing analysis of the role of STAT3 in T-cell development in conventional STAT3 $-/-$ mice. Recently, however, mice were generated with a STAT3 deficiency specifically in the T-cell lineage by conditional gene targeting using the Cre-loxP system. Floxed-STAT3 mice were mated with transgenic mice with Cre recombinase under control of the T-cell-specific Lck promoter. Although STAT3 was not expressed in the thymus of these mice, the cellular size of the thymus and distribution of thymic subsets were the same as in control mice. Thymocytes of these mice responded normally to IL-7 *in vitro*. Together these findings indicate that STAT3 is not involved in IL-7-mediated control of T-cell development. IL-7 activates STAT5 in human peripheral blood mononuclear cells and thymocytes. STAT5 was originally identified as a prolactin-induced mammary gland transcription factor. Two STAT5 genes, 5a and 5b, encode proteins that are approximately 95% identical in amino acid sequence. STAT5a and STAT5b differ in their COOH-terminal transactivation domains and display relatively specific actions. STAT5-deficient mice display immunological defects. STAT5a $-/-$ mice have a reduced expansion of peripheral T cells, which is associated with a diminished IL-2-mediated induction of the IL-2Rα chain. STAT5b-deficient mice exhibit a thymus that is slightly reduced in size. In contrast, mice deficient for both STAT5a and STAT5b were reported to have no major decrease in size of the thymus. In addition, the distribution of $CD4^+$, $CD8^+$ single-positive (SP), and double-positive (DP) cells were normal. The reported findings on the phenotype of mice deficient for STAT5a, STAT5b, or both argues against a role for STAT5 isoforms in IL-7-mediated control of T-cell development.

VI. THE FUNCTION OF IL-7 IN DEVELOPMENT AND ACTIVITIES OF T AND B CELLS

A. The Role of IL-7 in Development of TCR$\alpha\beta$ Cells

All lymphocytes are derived from a common lymphoid precursor. Progeny of these cells migrate to the thymus, where they develop into T cells. The earliest murine thymic precursors are characterized by expression of high levels of CD44, but lack the differentiation antigens CD3/TCR, CD4, and CD8. The $CD4^-CD8^-$ double-negative (DN) compartment contains at least four cell populations that can be discriminated on the basis of expression of CD25 and CD44. Development proceeds as follows: CD25 CD44 $\rightarrow$ CD25CD44 $\rightarrow$ CD25CD44 $\rightarrow$ CD25CD44. The latter cells acquire first CD8, followed by CD4 to attain the $CD4^+CD8^+$ DP phenotype.

The thymus of IL-7 mice is reduced in size, but the percentages of CD4CD8 cells and mature CD4 or CD8 single-positive T cells are the same as in the thymus of wild-type mice. The reduced size of the thymus is caused by an inhibition of the transition of CD44CD25 to $CD44^-CD25$ cells. IL-7 is not required at earlier, prethymic stages in the development of lymphoid cells. There is a consensus that IL-7

regulates the size of the early thymic compartment by promoting the survival and probably also the proliferation of early thymocyte precursors. Earlier *in vitro* studies have shown that IL-7 acts as a survival factor for $CD4^{-}CD8^{-}$, in particular, of the CD44CD25 thymocytes. Consistent with these results, IL-7 mice have an increased proportion of DN thymocytes binding annexin-V, a marker for cells undergoing apoptosis. DN thymocytes of IL-7 mice are compromised in expression of the anti-apoptotic protein Bcl-2. In a normal thymus, Bcl-2 shows a biphasic expression pattern: expression is high in DN thymocytes and is down-regulated in DP cells. Bcl-2 is reexpressed in mature SP cells. Bcl-2 expression in the earliest CD44CD25 thymocytes in IL-7 and wild-type mice is the same but IL-7 mice lose Bcl-2 upon progression of differentiation through the CD44CD25 and subsequent stages. The increase in apoptotic cells in IL-7 mice coincides with the decrease in expression of Bcl-2. Moreover, culturing thymocytes of IL-7 mice with IL-7 leads to restoration of Bcl-2 levels. To provide direct evidence for a role for Bcl-2 in IL-7-mediated T-cell development, Bcl-2 has been expressed as a transgene in mice deficient for the IL-7 receptor components IL-7Rα and γc. Although it was found in some studies that transgenic expression of Bcl-2 increased the size of the thymus marginally (two- to fourfold) or even completely compared to the IL-7Rα- or γc-deficient mice without Bcl-2, a recent analysis of a large number of γc −/−, ckit −/− or ckit −/− γc −/− mice failed to observe a rescue of thymic cells by a Bcl-2 transgene. Thus, it is unclear whether Bcl-2 is involved in the IL-7-mediated survival of T-cell precursors.

IL-7 is probably not important for rearrangement at the TCRα or TCRβ loci. Although in two studies it was found that the presence of IL-7 in cultures of T-cell precursors was required for TCRβ rearrangements, these studies could not exclude the possibility that the absence of TCR gene rearrangements was due to a failure of the pre-T cells to survive in the absence of IL-7. Moreover, although there is a delay in the onset of TCRβ rearrangement during embryonic life of IL-7 mice, TCRβ gene rearrangements are normal at birth. In addition, IL-7 mice have TCRαβ cells, albeit in reduced numbers in the spleen. Together these findings argue against an essential role for IL-7 in TCRβ (and α) gene rearrangements.

DN cells in the thymus acquire CD4 and CD8 following stimulation via the pre-TCR. DP cells undergo rearrangements at the TCRα locus and start to express low levels of TCRαβ. These cells are subjected to positive and negative selection through interactions of the TCRαβ and major histocompatibility complex/peptide complexes. This results in the expression of the activation antigen CD69 but also of IL-7Rα and the receptor for stem cell factor. IL-7, probably in cooperation with stem cell factor, maintains survival and induces proliferation of TCRαβ cells that have been subjected to positive selection.

IL-7 is also important for development of human T cells. IL-7 acts as a growth/maturation factor for human thymocyte precursors. Moreover, addition of anti-IL-7 and anti-IL-7R antibodies strongly inhibited human T-cell development in a fetal thymic organ culture system. Development was inhibited at an early stage of development. Genetic defects in the IL-7 system in humans cause severe combined immunodeficiency (SCID) syndromes. SCID patients with defects in γc, IL-7Rα, and JAK3 have been described. A complete γc deficiency in these patients is characterized by an absence of T and natural killer (NK) cells. However, normal numbers of B cells are present in γc-deficient patients. The same characteristics are also observed in JAK3-deficient patients. Two IL-7Rα-deficient patients were reported with normal numbers of NK and B cells but an absence of T cells in their peripheral blood. These data indicate that IL-7 is required for T-cell development, but is dispensable for NK- and B-cell development in humans.

B. The Role of IL-7 in Development of TCRγδ Cells

Although the TCRαβ cells are reduced in number, there are virtually no TCRγδ cells present in IL-7- and IL-7Rα-deficient mice. Both intraepithelial lymphocyte and thymic TCRγδ cells are affected. Defects in rearrangements at the TCRγ locus, in transcription of germ-line and rearranged TCRγ genes and survival of TCRγδ precursors, contribute to the lack of TCRγδ cells in IL-7 and IL-7R −/− mice. TCRγ rearrangements are strongly reduced in two independently generated IL-7Rα mice due to the fact that IL-7 controls TCRγ locus accessibility. It was also reported that transcription of the germ-line and rearranged TCRγ was impeded in IL-7Rα mice. Thus, not only TCRγ locus accessibility but also inhibition of transcription of those TCRγ genes that are rearranged contribute to the lack of TCRγδ cells in IL-7 −/− mice. In addition, IL-7 is important for survival of TCRγδ precursors.

C. The Role of IL-7 in the Function of Mature TCRαβ Cells

It has been reported that mature TCRαβ T cells are compromised in their functional capacities in the absence of the IL-7Rα. The majority of IL-7Rα mice failed to reject an allogeneic tumor, due to a strongly diminished frequency of cytotoxic T lymphocytes (CTL). IL-7Rα T cells were hyporesponsive to TCR-independent stimuli, such as the combination of the phorbol ester phorbol myristate acetate (PMA) and ionomycin. In IL-7 mice, however, T cells responded normally to polyclonal stimuli such as concanavalin A and PMA plus ionomycin on a per cell basis. The T cells of IL-7 mice have not been extensively analyzed for their responses to more physiological stimuli.

IL-7 has strong effects on mature human T cells *in vitro*. It acts as a survival and growth factor for human T cells. Interestingly, IL-7 is directly mitogenic for CD45RA naive human T cells, and culture of these cells results in maintenance of the CD45RA phenotype. IL-7 is involved in the induction of the survival and expansion of T cells after their export from the thymus. IL-7 has the capacity to counteract apoptotic stimuli. For example, it rescues human activated T cells from apoptosis induced by glucocorticosteroids and regulates Bcl-2 and CD25 expression. IL-7 was furthermore shown to up-regulate the expression of CD80 (B7.1) on human T cells, resulting in enhancement of T-cell stimulation by these cells. IL-7 can co-stimulate TCR-mediated activation of T cells, resulting in enhanced IL-2 mRNA accumulation and IL-2 secretion. The effect of IL-7 is in part mediated at the transcriptional level and involves the up-regulation of the DNA-binding activities of nuclear factor of activated T cells and activator protein-1.

It was recently documented that IL-7 mediates homeostasis of naive T cells *in vivo* since IL-7 was required for homeostatic expansion of naive $CD4^+$ and $CD8^+$ T cells in lymphopenic hosts. IL-7 is also required for survival of $CD8^+$ T cells in normal hosts. In addition, IL-7 seems to be involved in homeostasis of memory $CD8^+$ T cells but not of memory $CD4^+$ T cells. Also, in humans there is evidence for a role of IL-7 in T-cell homeostasis. The homeostatic effect of IL-7 may be mediated by the transcription factor lung Krüppel-like factor, since this factor, which is essential for the survival of naive T cells, is induced by IL-7.

D. The Role of IL-7 in Development of B Cells

IL-7 and IL-7Rα −/− mice show severe defects in the development of B cells. A phenotypic analysis of different stages in B-cell development revealed that development of B cells in the bone marrow is arrested in the transition of pro-B cells (B220 CD24 CD43) to pre-B cells (B220 CD24 CD43). Mature B cells that express both B220 and surface IgM were present in these mice but at strongly reduced numbers. IL-&Rα mice have a block at an earlier stage of B-cell development, namely, the transition of pre-pro-B to pro-B cells. Transgenic expression of Bcl-2 does not reconstitute B-cell development in IL-7Rα and γc mice, suggesting that IL-7 induces the differentiation of B cells. Indeed, IL-7 appears to be required for IgH gene rearrangements. It is likely that IL-7 is also necessary for protection against apoptosis and for expansion of early B-cell precursors. Surprisingly, IL-7 is not essential for development of human B cells. SCID patients deficient for either γc or IL-7Rα lack T cells but have near normal numbers of B cells. The reason for this species difference is unknown as a cytokine that controls human B-cell differentiation has yet to be found.

VII. EFFECTS OF *IN VIVO* ADMINISTRATION OF IL-7

The effects of administration of exogenous IL-7 have been studied in various animal models. A general observation in these experiments is a marked stimulation of B-lymphocyte production but increases in T cells, NK cells, and macrophages were also observed. Exogenous IL-7 at an optimal dose can markedly stimulate *in vivo* B lymphopoiesis, eventually resulting in elevated levels of pre-B and B cells. Changes in myelopoiesis were observed after *in vivo* administration of recombinant human (rh)IL-7 to mice. These resulted mainly from the emigration of myeloid progenitors from the bone marrow through the blood to the spleen, liver, and possibly other peripheral organs. This observation suggests that IL-7 modifies the expression of chemokine receptors on myeloid progenitors. It is, in this respect, noteworthy that IL-7 increases the expression of CXCR4, the receptor for stromal-derived factor-1, on thymocytes. In another study, rhIL-7 administration to normal mice caused a pronounced leukocytosis in the spleen and lymph nodes, with increases in B cells, T cells, NK cells, and macrophages. The increased numbers of T cells after IL-7 treatment were primarily the result of an expansion of the peripheral T-cell

population. Interestingly, the T cells from rhIL-7-treated mice have enhanced proliferative responses to various stimuli *in vitro* and were able to enhance an allogeneic CTL response *in vivo*. It was also documented that administration of rhIL-7 to tumor-bearing mice profoundly increased the number of B and T cells and reduced the number of early renal adenocarcinoma pulmonary metastases.

An adverse effect of IL-7 administration in female mice is increased bone resorption. The effect of IL-7 was similar to that observed with estrogen deficiency. Bone resorption is caused through activation of osteoclasts. A recent report documented that IL-7 induced the expression of the osteogenic cytokine receptor activator of nuclear factor κB ligand and possibly other osteogenic factors, leading to the stimulation of osteoclast formation.

IL-7 has also been administered by gene transfer. Murine bone marrow infected with a helper-free recombinant retrovirus expressing the murine IL-7 (mIL-7) gene was used to reconstitute lethally irradiated hosts. Twenty-three percent of mIL-7 retrovirus-infected recipients became moribund within 4–16 weeks posttransplant, with splenomegaly and enlarged lymph nodes. Marked changes in T-cell subsets of spleen and lymph nodes were observed. The size of the thymus was not altered and the proportion of CD4CD8 cells was generally decreased, with corresponding increases in CD4, CD8, or CD4CD8 cells.

VIII. IL-7 AS A POSSIBLE THERAPEUTIC AGENT

The fact that IL-7 stimulates T-cell development and can augment T-cell reactivities *in vitro* has led to the idea that this cytokine may be used to boost development and function of T cells in various clinical settings. IL-7 has been tested in mouse models of infectious diseases and bone marrow transplantation.

A. Infectious Diseases

IL-7 has been tested in various models for its efficacy in treating infectious diseases. IL-7 augments protective immunity against *Toxoplasma gondii* in A/J mice and *Mycobacterium tuberculosis*in Balb-c mice. Moreover, a combination of IL-1 and IL-7 augments immunity against *Listeria monocytogenes*, due to enhanced responsiveness of TCRγδ cells to IL-7. These observations indicate that exogenous administration of human rIL-7 is able to protect mice against acute parasite challenge by stimulating interferon-γ production and augmenting the response mediated by CD8 CTL. However, IL-7 does not always confer a beneficial effect. Treatment of genetically susceptible Balb/c mice with IL-7 at the onset of the infection with *Leishmania major* led to enhanced lesion development and a significantly accelerated death of the animals. This was correlated with a 40-fold increased parasite burden in spleens and lymph nodes. A strong increase in the number of B cells was noted. It was suggested that an enhanced T_H2 response was responsible for the aggravating effect of IL-7 in this model. Administration of IL-7 also aggravated the course of infection with *Schistosoma mansoni*. Consistent with this finding, the growth of the parasite was blocked in IL-7 $-/-$ mice.

B. Bone Marrow Transplantation

Bone marrow transplantation (BMT) is increasingly used in the clinic to promote hematopoietic recovery. The activities of IL-7 on T cells have led to the proposal that IL-7 can be used to overcome immunodeficiencies in certain situations by accelerating T-cell development, by expanding the pool of newly developed T cells, and by promoting the functional maturation of T cells. Administration of IL-7 in this setting would also overcome the blocking effect of irradiation on IL-7 production, presumably by thymic stromal cells. Indeed, several preclinical studies have found that IL-7 could accelerate murine lymphocyte regeneration and acquisition of immune competence following chemotherapy and bone marrow transplantation. IL-7 boosted survival after challenge with influenza virus following syngeneic BMT. Both B- and T-cell responses were stimulated by IL-7. It was also reported that the BMT recipients had thymic hypoplasia and strongly reduced numbers of mature T cells 28 days after syngeneic BMT. When these mice were treated with IL-7, thymic cell numbers were normalized. Moreover, the function of antigen-specific T and B cells was improved. Recombinant human IL-7 was found to accelerate bone marrow engraftment affecting both myeloid and lymphoid compartments. These studies indicate a beneficial effect of IL-7 in autologous BMT. One study, however, suggested that in an allogeneic H2-matched BMT, IL-7 enhanced the responses of the allogeneic T cells posttransplant. This may result in graft-versus-host disease.

C. Anti-tumor Immunity

Most IL-7Rα failed to reject an allogeneic tumor, due to a diminished frequency of CTL, indicating that IL-7

is needed to enable the mature T cells to reject tumor cells. In addition, IL-7 induces *in vitro* growth of murine anti-tumor CTL. A glioma cell line transfected with IL-7 reduced tumorigenicity *in vivo* depending on the amount of IL-7 produced. This reduction in tumorigenicity could be reversed in a dose-dependent fashion by injection of anti-IL-7-neutralizing monoclonal antibody at the tumor site. The response was specific, as other tumors were not rejected and rejection was mediated by CD8 T cells. Co-expression of IL-7 and the co-stimulatory molecule CD80 (B7.1) in mammary adenocarcinoma and a plasmacytoma resulted in a stronger protective response than with either IL-7 or CD80 alone. A protective effect of immunization with IL-7-transfected tumor cells was observed with the plasmacytoma cell line J558L, but in that model CD4 cells rather than CD8 cells were responsible for the protection. Injection of dendritic cells infected with an adenoviral vector harboring IL-7 resulted in a potent anti-tumor response in two murine lung cancer models.

Glossary

interleukin-7 A polypeptide responsible for the differentiation and growth of lymphocytes, in particular of T and B lymphocytes.

interleukin-7 receptor A cell surface-expressed complex consisting of two polypeptide chains that are designated IL-7Rα and γ comma (γc). γc is also part of the receptors for other cytokines.

phosphatidylinositol 3 kinase Kinase that phosphorylates the D3 position of the inositol group of phosphoinositide lipids to generate phophatidylinositol-3 phosphate [PtdIns(3)P], PtdIns(3,4)P2, and PtdIns(3,4)P3. The enzyme associates with the interleukin-7 (IL-7) receptor upon interaction with IL-7. It is important for survival and growth.

signal transducer of activation and transcription (STAT) Following interaction of interleukin-7 with interleukin-7 receptor, STAT5 is activated. Activated STAT5 forms a dimer and is translocated to the nucleus, where it activates several genes important for differentiation.

Interleukin-9

JEAN-CHRISTOPHE RENAULD

Ludwig Institute for Cancer Research, Belgium

Interleukin-9, a cytokine produced mainly by T lymphocytes, was originally identified as a T-cell/mast cell growth factor with a narrow specificity. Interleukin-9 has since been found to be a broadly active cytokine with various targets, including B cells, macrophages, eosinophils, hematopoietic precursors, and epithelial cells. Its main physiological activity seems to be part of antiparasite immune responses.

I. INTRODUCTION

Interleukin-9 (IL-9) was originally purified from helper T-cell supernatants based on its ability to support the growth of a murine T-cell line. Human IL-9 was cloned both by expression cloning of a factor stimulating the growth of a human megakaryoblastic leukemia and by cross-hybridization with the mouse gene. A comparison of the mouse and human IL-9 protein sequences, which are 50% identical, is shown in Fig. 1. Both deduced protein sequences contain 144 residues having a typical signal peptide of 18 amino acids and four potential N-linked glycosylation sites. This glycosylation is responsible for the discrepancy observed between the predicted relative molecular mass (14,150 Da) and that measured for native IL-9 (30,000–40,000 Da). Although recombinant IL-9 produced in *Escherichia coli* recapitulates all *in vitro* IL-9 activities, glycosylation plays an important role in the *in vivo* activity of the protein. Indeed, the half-life of natural IL-9 is reduced more than threefold on desialidation. The sequence is also characterized by the presence of 10 cysteines that are perfectly matched in both mature proteins and a strong predominance of cationic residues, which explains the elevated p*I* measured with purified IL-9.

The human IL-9 gene is a single-copy gene that maps to chromosome 5, in the 5q31–q35 region, in a region of the genome that contains other cytokine genes, including those for other interleukins (IL-3, IL-4, IL-5, and IL-13) and granulocyte/macrophage colony-stimulating factor (GM-CSF). However, in the mouse, the IL-9 gene is not linked to the same gene cluster; it has been localized on mouse chromosome 13, and the IL-3, IL-4, IL-5, and GM-CSF genes are located on chromosome 11. The human and murine IL-9 genes share a similar structure, with five exons and four introns stretching over about 4 kb. The five exons are identical in size in both mice and humans and show homology levels ranging from 56 to 74%. In contrast, no significant sequence homology is found in the introns (except for intron 2, which is also the smallest one). However, 3′ and 5′ untranslated regions show a high level of identity, supporting a possible involvement of these sequences in the transcriptional or posttranscriptional regulation of IL-9 expression. In particular, numerous ATTTA motifs were found in the 3′ untranslated region of both genes. These sequences, frequently noted in cytokine mRNAs, may modulate the stability of the mRNA and thus are thought to be related to the short half-life of these messengers.

The promoter of the IL-9 gene contains potential recognition sites for several transcription factors,

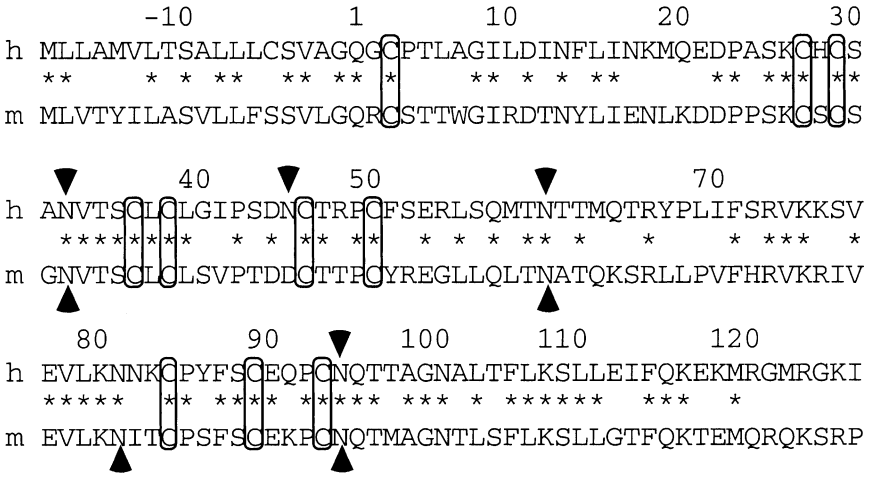

FIGURE 1 Alignment of human and mouse IL-9 protein sequences. Amino acids are indicated in the one-letter code. The 10 cysteine residues of the mature protein are boxed and arrows indicate the potential N-linked glycosylation sites. Amino acids number 1 refers to the N-terminus of the mature mouse protein.

such as activator proteins (AP-1 and AP-2), which could provide a structural basis for the induction of IL-9 expression by phorbol esters. A nuclear factor (NF-κB)-binding site has been also reported to actively regulate IL-9 expression.

II. BIOLOGICAL SOURCES OF IL-9

Activated T helper (T_H2) lymphocytes are the main source of IL-9. Its *in vitro* production by activated spleen cells is inhibited, like that of other T_H2 cytokines, by IL-12, interferon γ (IFNγ), or CpG oligonucleotides. *In vivo*, potent T_H2 stimuli such as anti-immunoglobulin D (IgD)-triggered polyclonal activation and helminth infections also induce IL-9 expression. Conversely, T_H1-promoting factors such as IL-12, type I and type II interferons, and viral infection suppress IL-9 expression in various *in vivo* models. Finally, IL-9 expression nicely reflects T_H2 responses in *Leishmania major* infection, in which susceptible T_H2 responder mice produce IL-9 but resistant T_H1 strains do not.

The mechanisms involved in the regulation of IL-9 production by human T cells have been studied quite extensively *in vitro*. After stimulation of peripheral T cells, IL-9 mRNA expression peaks at 28 h and is completely abrogated by cycloheximide, an inhibitor of protein synthesis, pointing to the involvement of secondary signals in this process. A complex cascade of factors acting in synergy seems to be involved, with IL-2 being required for IL-4 production, both IL-2 and IL-4 being needed for IL-10 production, and eventually IL-4 and IL-10 being required for IL-9 biosynthesis. Other regulatory mechanisms, including IL-1 and transforming growth factor-β (TGF-β) could be involved in IL-9 expression by some T cell lines and tumors.

Another characteristic of IL-9 expression is its association with human T-cell lymphotropic virus type I (HTLV-I), a retrovirus involved in adult T-cell leukemias, which often produces IL-9 constitutively. The tax transactivator of HTLV-I might be implicated in this process through the NF-κB consensus site in the IL-9 promoter. Interestingly, in another system of T-cell transformation by murine polytropic retroviruses, viral infection also resulted in IL-9 expression.

Besides T cells, mast cells represent another source of IL-9. These cells produce IL-9 in response to ionomycin or IgE-antigen complexes. The levels of IL-9 produced by these cells are strongly enhanced in the presence of added IL-10, IL-1, or lipopolysaccharide.

III. IL-9-RESPONSIVE CELLS

A. Mast Cells

Mast cells were among the first identified targets for IL-9 in the mouse system. When primary mast cell lines are derived from hematopoietic progenitors, IL-9 is not sufficient to sustain mast cell growth, but synergistically enhances the proliferation induced by IL-3 or the combination of IL-3 and IL-4. Similar results are obtained by combining IL-9 with stem cell factor (SCF).

In addition to its activity on growth and survival, IL-9 is a potent regulator of mast cell function and differentiation. IL-9 up-regulates expression of the high-affinity IgE receptor in murine mast cell lines. IL-9 is also a major inducer of proteases, including granzyme B and mast cell-specific proteases of the mouse mast cell protease (MMCP) family, particularly MMCP-1, MMCP-2, and MMCP-4. IL-9-induced expression of MMCP-1 may be due to endogenously expressed TGF-β1, because anti-TGF-β antibodies block the effect of IL-9 on the percentage of MMCP-1^+ cells in primary bone marrow-derived mast cell (BMMC) cultures. Other cytokines induced by IL-9 in murine mast cell lines include IL-6, IL-13, and IL-22.

In vivo, IL-9 overexpression induces a massive mast cell infiltration of the gastric and intestinal epithelium, as well as in the upper airways and in kidneys. Injections of antibodies directed against c-kit, the SCF receptor, block mastocytosis in IL-9 transgenic mice. Because a constitutive SCF expression was observed in both IL-9 transgenic and control mice, these observations indicate that neither SCF nor IL-9 is sufficient to induce mastocytosis but that the synergistic activity of these cytokines is responsible for the *in vivo* amplification of this cell population in IL-9 transgenic mice. In a model of *Schistosoma* infection, a decrease in mast cells present in granulomas was reported in IL-9-deficient mice, suggesting that, at least under certain circumstances, IL-9 is required for optimal mast cell responses.

B. T Lymphocytes

Although T lymphocytes were the first identified targets for IL-9, the physiological role of IL-9 for T cells remains puzzling. Human T lymphocytes need preactivation to respond to IL-9, and a significant degree of proliferation can be induced by IL-9 when human peripheral blood mononuclear cells (PBMCs) are preincubated for 10 days with

phytohemagglutinin (PHA). These results suggest that responses to IL-9 require previous T-cell activation.

Several observations point to IL-9 as a potential T-cell oncogene. For instance, 5–10% of FVB mice expressing an IL-9 transgene spontaneously develop lymphoblastic lymphomas. Transfection of mouse IL-9-dependent T-cell lines with an IL-9 cDNA expression vector and injection of these cells into syngeneic animals result in widespread lymphoma development. Similar observations have been reported in a rat model, using an IL-2-dependent T-cell lymphoma that, after infection with murine polytropic retroviruses, became IL-2 independent by induction of an autocrine loop involving IL-9 and its receptor.

In humans, a link between dysregulated IL-9 production and lymphoid malignancies has been initially suggested by the observation that lymph nodes from patients with Hodgkin disease or large-cell anaplastic lymphomas constitutively produce IL-9. Constitutive IL-9 expression is also detected in HTLV-I-transformed T cells and in Hodgkin cell lines.

The role of IL-9 in thymic maturation was studied using human thymic precursor organ cultures, taking advantage of the fact that human progenitor cells from fetal liver or from cord blood can be cultured *in vitro* in thymic lobes from nude mice. Under these conditions, anti-IL-9 receptor antibodies inhibit the growth and differentiation of immature thymocytes, suggesting that IL-9 is involved in normal T-cell development. This observation contrasts with the fact that IL-9 -deficient mice are reported to have a normal thymus. Several possibilities could explain this discrepancy. IL-9 might be critical for human but not for mouse thymus development. The effect of cytokines may also be less redundant in an *in vitro* experimental setting using human precursors and the mouse thymus environment, compared to in a pure murine model. Alternatively, the role of IL-9 in thymic development might also vary between stages of fetal and adult life. In line with this hypothesis, it was shown that fetal murine thymocytes, but not adult thymocytes, proliferate in the presence of IL-9 *in vitro*.

Although IL-9 is specifically produced by T_H2 but not T_H1 cells, its role in the tuning of the T_H1/T_H2 balance *in vivo* remains more elusive. Stimulation of lymph node cells *in vitro* with plate-bound anti-CD3 antibodies induced similar IL-4, IL-5, and IFNγ production in control and IL-9-deficient mice. Also, *in vivo* T-cell-dependent anti-ovalbumin antibody and cytokine production was not altered by IL-9 gene disruption. In IL-9 transgenic mice, IgG1 and IgE concentrations are preferentially increased, as expected from increased T_H2 responses, but IgG2a concentrations are also significantly increased, as in T_H1-like responses. By contrast, in broncho-alveolar lavage from silicotic mice, IL-9 overexpression surprisingly leads to a decreased IgG1/IgG2a ratio, suggesting that T_H1 responses are favored. Finally, analysis of *in vivo* cytokine expression in transgenic mice shows that IL-13 expression is strongly up-regulated in lungs and gut. Altogether, these observation indicate that, if IL-9 actually modulates cytokine production by T cells, this modulation does not fit with a simple inhibition or promotion of a particular T helper subset.

C. Hematopoietic Progenitors

Although human IL-9 was identified as a growth factor for megakaryoblastic leukemia Mo7E, its activities as a hematopoietic growth factor have remained fairly modest. In fact, IL-9 does not seem to be active on normal megakaryoblastic precursors but supports the clonogenic maturation of erythroid progenitors in the presence of erythropoietin. This activity was confirmed by several groups and is reproducibly observed with highly purified progenitors, particularly in synergy with SCF.

D. Monocytes and Macrophages

An anti-inflammatory activity of IL-9 has been demonstrated in experimental septic shock models. Mice infected with *Pseudomonas aeruginosa* are protected against a lethal dose of these bacteria by administration of IL-9. This protection is accompanied by dramatic reductions in serum concentrations of tumor necrosis factor α (TNFα), IL-12, and IFNγ and by a strong induction of IL-10. *In vitro*, IL-9 inhibits the oxidative burst induced by lipopolysaccharide (LPS) in freshly isolated human monocytes and bronchial alveolar macrophages. This activity results from an induction of TGF-β, which in turn inhibits activation of extracellular signal-related kinase (ERK) by LPS.

E. B Lymphocytes

In vitro, IL-9 has only a modest effect on immunoglobulin production by activated B lymphocytes. *In vivo*, although IL-9-deficient mice do not show obvious defects in antibody responses, observations made in IL-9 transgenic mice illustrate the potential

activity of this cytokine in humoral responses. Basal titers of all Ig classes and antigen-specific antibody responses are indeed increased in the serum of transgenic animals. In addition, these mice are characterized by a dramatic increase in the number of peritoneal B1 cells, but not in conventional B cells, suggesting that IL-9 may act preferentially on this particular B-cell population, which is predominantly involved in autoimmunity. However, IL-9 transgenic mice do not have increased levels of autoantibodies, and the expansion of peritoneal B cells in these mice is mainly due to B1b cells, a functionally ill-defined B cell subset that differs from B1a cells by the absence of the CD5 surface marker.

F. Eosinophils

IL-9 overexpression in transgenic mice leads to modest but significant eosinophilia in the blood, peritoneal cavity, and lungs. The mechanisms underlying the effect of IL-9 on eosinophils remain unclear. IL-9 does not induce any eosinophilia in IL-5-deficient mice. This raises the hypothesis that IL-9 induces eosinophilia by up-regulating the expression of IL-5 or its receptor. However, this observation might simply reflect the fact that IL-5 plays a nonredundant role in eosinophil development, independently from any effect of IL-9.

G. Epithelial Cells

Data pointing to lung epithelial cells as important IL-9 targets have been obtained both from IL-9 transgenic mice and from primary lung cultures stimulated *in vitro* with IL-9. Such stimulation induced chemokine secretion and triggered enhanced eosinophil chemotaxis. Moreover, increased levels of eotaxin and MCP-1 were found in lungs from IL-9 transgenic mice by Western blot.

IL-9 action on lung epithelial cells also results in mucin secretion. Lung cells from IL-9 transgenic mice show enhanced expression of the mucin genes *MUC2* and *MUC5AC*, a finding confirmed with human primary lung cultures. The mechanisms underlying up-regulation of mucus production by IL-9 are not clear. The regulation of a murine calcium-activated chloride channel (mCLCA3) gene, *gob-5*, might play a role in this process. Subtraction cloning showed that the *gob-5* gene is up-regulated in the lungs of IL-9 transgenic mice. This gene is also induced in the lungs of allergen-exposed mice, and its human homologue, *Clca1*, is up-regulated by IL-9 *in vitro* in primary lung cultures. Interestingly, transfection of the *gob-5* cDNA in a human mucoepidermoid cell line induced mucus production and *MUC5AC* expression.

IV. IL-9 AND DISEASES

A. IL-9 and Parasite Infections

Infections by helminths induce an immune response characterized by strong IgE production and mucosal mastocytosis resulting from T_H2 cytokine production. During infection with intestinal nematodes, IL-9 production is induced in mesenteric lymph nodes, as are other T_H2 cytokines such as IL-3, IL-4, and IL-5. Interestingly, IL-9 transgenic mice were found to be particularly resistant to these intestinal worms. Conversely, inhibition of IL-9 activity affects the capability of infected mice to expel the nematode *Trichuris muris*.

Schistosoma mansoni infection is another parasite infection model in which IL-9 might play a role. In infected mice, tissue damage is primarily caused by granulomatous inflammation surrounding parasite eggs, whereas the intestine is subject to inflammation elicited by translocation of parasite eggs through the intestinal wall. In this model, IL-9 expression correlates with increased mast cell progenitors during the chronic phase of injection. Analysis of IL-9-deficient mice showed that IL-9 plays an essential role in goblet cell hyperplasia and mastocytosis in pulmonary granulomas induced by *S. mansoni* eggs. However, IL-9 overexpression results in a dramatic increase in mortality of infected mice. Dying animals showed ileum enlargement with muscular hypertrophy, mastocytosis, eosinophilia, goblet cell hyperplasia, and increased mucin expression, pointing to an overwhelming immune response.

B. IL-9 and Asthma

Studies on the inheritance of susceptibility to asthma have pointed to a cluster of candidate genes, including IL-9, on human chromosome 5q31–q33. When DBA/2 and C57BL/6 mice, respectively, susceptible and resistant to experimental asthma, are crossed, susceptibility to the disease correlates with inheritance of the IL-9 gene from the asthma-prone strain. Moreover, IL-9 expression is higher in bronchial hyperresponsive animals. Further support for the role of IL-9 in asthmatic reactions is provided by studies of IL-9 transgenic mice, which show massive airway inflammation with infiltration by mast cells, eosinophils, and lymphocytes. Moreover, a striking epithelial cell hyperplasia is noted with mucus

accumulation and subepithelial deposition of collagen. As a result, these mice show strongly increased airway response to methacoline or 5-hydroxytrytamine, a typical feature of asthma called hyperresponsiveness. Direct evidence for selective increased production of IL-9 in asthmatic airways has been reported using *in situ* hybridization and immunocytochemistry. *In vitro*, allergic children show increased IL-9 expression in response to allergens, as compared to nonallergic controls.

Contrasting reports have been published concerning the possibility of interfering with asthma by blocking IL-9 activity. On the one hand, administration of anti-IL-9 antibodies in a mouse model of allergic asthma significantly inhibited IgE production, pulmonary eosinophilia, goblet cell hyperplasia, and airway hyperreactivity. On the other hand, IL-9 deficient mice showed normal antigen-induced bronchial responsiveness in a similar experimental model.

V. THE IL-9 RECEPTOR STRUCTURE AND SIGNALING

A single class of high-affinity binding sites for IL-9 ($K_d \backsim 100$ p*M*) has been detected on IL-9-responsive murine cells. IL-9 binds to a heterodimeric complex composed of the IL-9 receptor (IL-9R) and the γ-chain of the IL-2 receptor (also called γc, for γ common). The human IL-9R consists of a 522-amino-acid protein with an extracellular domain composed of 233 amino acids, including a WSEWS (W, tryptophan; S, serine; and E, glutamate) motif and typical conserved residues from the hematopoietin receptor superfamily. Antibodies directed against γc completely inhibit the activity of IL-9 without affecting the K_d of IL-9 binding, indicating that γc is required for signal transduction but not for IL-9 binding.

So far, the main function of γc seems to consist of recruiting the tyrosine kinase Jak3, whereas the IL-9R is associated with Jak1. This association of Jak1 with the IL-9R was ascribed to a 98-residue juxtamembrane region of the receptor. On IL-9 binding, both Jak1 and Jak3 become phosphorylated and catalytically active and induce IL-9R phosphorylation on one out of its five tyrosine residues. This single phosphorylated residue acts as a docking site for Stat1, Stat3, and Stat5, three signal transduction and transcription activation factors that, after phosphorylation by the Jak kinases associated with the receptor, form hetero- or homodimers and migrate to the nucleus. Interestingly, mutation of this single tyrosine of the IL-9R abolished both Stat activation and cell growth control by IL-9, including protection against apoptosis and positive as well as negative effects on proliferation.

The role of other signal transduction pathways for IL-9 activities remains more elusive. Opposite observations have been reported concerning the involvement of the ras/mitogen-activated protein kinase (MAPK) pathway. It seems that IL-9 can indeed induce ERK phosphorylation, but that this effect of IL-9 is highly dependent on the cell lines. In Baf3 cells transfected with the human IL-9R, IL-9 induces ERK phosphorylation, and inhibition of this pathway by MAPK kinase (MEK) inhibitors or by dominant-negative Ras isoforms partially inhibits IL-9-induced proliferation.

IL-9 stimulation also involves the phosphorylation of an adapter protein called IRS-2, a feature shared with IL-4 signal transduction, and this pathway has been shown to be critical for growth regulation. Phosphorylation of IRS-2 is not dependent on the phosphorylation of the IL-9 receptor, contrasting with the IL-4 system in which IRS-2 associates with the IL-4 receptor through a phosphotyrosine residue. On IL-9 activation, IRS-2 might become phosphorylated by interacting directly with the Jak1 tyrosine kinase. After phosphorylation, IRS-2 binds the SH2 domain of various signaling proteins, including the p85 subunit of the phosphatidylinositol 3-kinase. The IRS-2 pathway is required for optimal IL-9-dependent proliferative responses, although activation of this pathway is not sufficient to induce proliferation.

IL-9 can also modulate other signaling cascades by regulating the expression of proteins involved in these pathways. This is the case for the NF-κB pathway, because IL-9 induces expression of Bcl-3, a protein that associates with p50/p50 NF-κB dimers. Bcl-3 expression has been shown to inhibit apoptosis in IL-9-dependent cell lines, in line with well-described anti-apoptotic activities of NF-κB. Another example of indirect modulation of signaling cascades by IL-9 is the induction of M-Ras/R-Ras3 in murine T cell lines. This protein shows an amino acid identity of 49 and 46% with p21 H-Ras and p23 K-Ras. Like other members of the Ras family, activated M-Ras is able to regulate cell proliferation and MAP kinase activation.

Negative feedback for signal transduction is a critical process in the regulation of cytokine activities. Cytokine-induced activation of phosphatases is a classical negative feedback mechanism. IL-9 induces

the phosphorylation of the SHP2 phosphatase in a hematopoietic immature cell line. However, IL-9 signaling seems less sensitive to phosphatase-mediated down-regulation than does erythropoietin (EPO) signaling, a characteristic that can lead to more sustained STAT-5 activation and induction of distinct sets of genes.

Another mechanism responsible for negative feedback regulation consists of the induction of genes that code for inhibitors of Jak kinases. A family of such inhibitors has been described, including cytokine-inducible SH2 (CIS)-containing protein, and suppressors of cytokine signaling (SOCS-1, SOCS-2, and SOCS-3). Other SOCS-related proteins have been described but their function remains to be established. In T-cell lymphomas, IL-9 induces the rapid induction of CIS, SOCS-2, and SOCS-3, with a peak after 2 h of stimulation. However, only SOCS-3 is able to inhibit IL-9 signaling, and this effect is seen only when SOCS-3 is overexpressed to IL-9-responsive cells, suggesting that this process is not very efficient in down-regulating IL-9 activities. However, induction of these genes by IL-9 might lead to inhibition of signaling by more sensitive cytokine receptors, suggesting a role in cytokine cross talk rather than in feedback inhibition. A schematic representation of the currently described signal transduction pathways triggered by IL-9 is shown in Fig. 2.

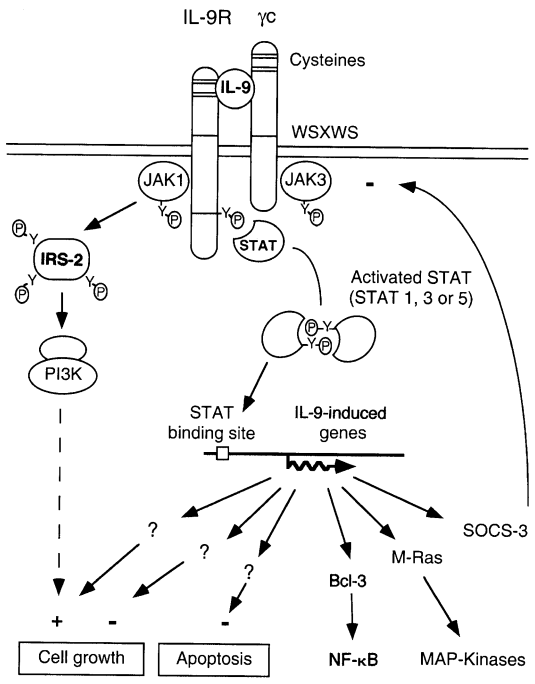

FIGURE 2 Schematic representation of the signal transduction pathways triggered by IL-9.

VI. SUMMARY

IL-9 is a broadly active cytokine with various targets, including B cells, macrophages, eosinophils, hematopoietic precursors, and epithelial cells. Its aggravating role in asthma is probably due to its broad action on the different cells involved in this disease. A potential use of IL-9 *in vivo* stems from its ability to dampen excessive production of inflammatory cytokines by monocytes and macrophages, as has been shown in septic shock following infection with *Pseudomonas aeruginosa*. In view of the induction of IL-10 and TGF-β by IL-9, the ability of this cytokine to modulate autoimmune reactions opens further interesting perspectives for the use and study of this molecule. At the molecular level, IL-9 binds to a complex composed of IL-9R and γc, and most of its activities are mediated by the Jak–Stat pathway.

Glossary

eosinophils White blood cells thought to be important in asthma and in defense against parasitic infections.

helminths Parasitic worms (nematodes) that infect the intestinal tract.

Janus kinases Enzymes that are activated by cytokine receptors; phosphorylate proteins known as signal transducers and activators of transcription, which are normally found in the cytosol but move to the nucleus on phosphorylation and activate a variety of genes.

lymphocytes White blood cells that bear variable cell surface antigen receptors. The two main classes of lymphocytes, B lymphocytes (B cells) and T lymphocytes (T cells), mediate humoral and cell-mediated immunity, respectively.

mast cells Large cells containing granules that store a variety of mediator molecules, including histamine. They have high-affinity IgE receptors, which can trigger degranulation and play a crucial role in allergies.

T (T_H) helper cells Subsets of T cells that are characterized by the cytokines they produce. T_H1 cells are mainly involved in activating macrophages, whereas T_H2 cells are mainly involved in activating B lymphocytes.

Interleukin-10

YaoZhong Ding, Shuang Fu, Dmitriy Zamarin, and Jonathan Bromberg

Mount Sinai School of Medicine, New York

Interleukin-10 is a soluble protein factor secreted by T cells, B cells, monocytes/macrophages, mast cells, and keratinocytes. It is involved in regulation of immunoreactivity. The general mode of action is in immune suppression, but interleukin-10 may also function in immune stimulation.

I. INTRODUCTION

Interleukin-10 (IL-10) is a key regulator of immune responses. Because of its ability to turn off cytokine production by T cells, IL-10 was originally described as cytokine synthesis inhibitory factor (CSIF). T-Cell stimulation *in vitro* in the presence of IL-10 was also known to lead to long-term anergy and the production of a negative regulatory T-cell subset. Further investigations have demonstrated that the immunosuppressive effects of IL-10 are often at the level of the antigen-presenting cell (APC) and not directly at the level of the T cell. It has also been demonstrated that IL-10 inhibits the immune function of other cell types IL-10 inhibits natural killer (NK) cell production of interferon γ (IFNγ), intercellular adhesion molecule-1 (ICAM-1) expression on activated vascular endothelial cells, and T-dependent responses of B cells. In sum, it has been shown that the predominant effect of IL-10 is to suppress multiple immune responses through individual actions on T cells, B cells, APCs, and other cell types, and to skew the immune response from one T helper (T_H) subset to another (T_H1 to T_H2).

A number of unexpected findings suggest that IL-10 has actions that are more complex than originally proposed. IL-10 can act as a proliferative cofactor for immature and mature thymocytes stimulated by IL-2 plus IL-4. IL-10 can inhibit T-dependent B-cell responses, but not T-cell-independent responses. In fact, IL-10 can act as a B-cell growth factor and support the autocrine growth of B-cell lymphomas. In NZB/W F1 mice, IL-10 stimulates the development of systemic autoimmune disease, which is mediated primarily by B cells, whereas anti-IL-10 monoclonal antibody (mAb) delays the onset of autoimmunity. Likewise, the T_H2 polarization induced by IL-10 enhances the development of granulomata and chronic inflammation. Mice with an IL-10 transgene regulated by an insulin promoter have a pronounced leukocytic infiltrate of CD4 + and CD8 + T cells, B cells, and macrophages, along with activation of the vascular endothelium. Transgenic IL-10 expression in these mice does not prevent or delay autoimmune or alloimmune disease. All of these data suggest proinflammatory functions for IL-10 under some circumstances. In sum, IL-10 is generally considered an immunosuppressive cytokine, but IL-10 may have either immunostimulatory or immunosuppressive effects, depending on the assay, the cell types involved, or other concomitant immune events (see Tables 1–3).

of IL-23 as a p19/p40 heterodimer with potent IL-12-like functions explained why the deficit of T_H1-type responses and cell-mediated immunity is strongly pronounced in p40 knockout mice but is less evident in p35 knockout animals. The IL-12 receptor antagonist (IL-12RA) p40/p40 homodimer plays a T_H2-driving role. Most recently, IL-27 was identified as a member of IL-12 family active at the earliest stages of immunity (Table 1).

II. DENDRIKINES REGULATE IMMUNE REACTIVITY

Studies of the development and regulation of immunity have focused on the critical role of dendritic cells (DCs) in antigen capture and presentation. A second critical aspect of DC function is the induction via cytokine messages of the appropriate immune reactivity, depending on the nature of the pathogen or injury. DCs recruit the appropriate T and B cells, either within secondary lymphoid tissue or at chronic inflammatory sites, based on these additional messages. The array of cytokines and chemokines that are secreted are collectively known as "dendrikines". Many of the approximately 800 cytokines identified to date can directly affect or are made by DCs. Several novel factors including the recently identified IL-12 family members IL-23 and IL-27 have been identified in the past few years. Integrating insights concerning these cytokines into a critical interpretation of the protean biology mediated by these important cells will be necessary to fully limn the context and meaning of the messages delivered by DCs. The cytokines or dendrikines secreted by DCs during the initiation or effector phase of the immune response promote the adaptive immune response. DCs can signal T cells in the absence of exogenous antigen, perhaps using the high surface expression of major histocompatibility complex (MHC) class II molecules to promote interleukin-12 receptor expression on $CD4^+$ T cells and enhance their survival as well as by prompting antigen-independent cytokine gene expression.

Dendrikines and antigens are not unlinked. For example, the development of inducible immunoproteasomes is enhanced in DCs derived from human peripheral blood monocytes after stimulation by maturation signals. These include T-cell mimics such as CD40L (CD154), bacterial mimics such as lipopolysaccharide (LPS) or IL-18, viral mimics such as interferon-α (IFN-α), or pro-inflammatory cytokines [tumor necrosis factor α (TNFα), IL-6, and IL-1β], reflecting presumably those factors that are predominant at the site of danger, damage, or injury. DCs and dendrikines drive naive T-cell expression of the IL-2/IL-15β chain and the common γ chain (γ_C), allowing them to proliferate in response to IL-2 and enhance the response of so-called central memory T cells to IL-7 and IL-15, thus permitting subsequent response to other T-cell growth factors. The distributed network of cells constituting the immune system supports a complex set of interactions dictated in large part by DC production of, and response to, cytokines, regulating the flow of information transfer and recruitment of cells to inflammatory sites.

III. INTERLEUKIN-12p40/p35 HETERODIMER

The IL-12 genes are located on chromosome 5 (5q31–q33) (p35) and on chromosome 3 (3p12–p13.2) (p40). Expression of each subunit is independently regulated. Most cells express p35, either constitutively or after stimulation. In contrast, the IL-12 p40

TABLE 1 IL-12 Family Members

Subunit composition	Name(s)	Receptor interactions	Predominant activity
p35/p40	IL-12; IL-12p70; TSF; CLMF; NKSF	IL-12 β1/β2	Pro-inflammatory NK, CTL, T_H1; enhances IFN-γ production; enhances cytotoxicity; enhances hematopoiesis directly, inhibits indirectly through enhanced IFN-γ production
p19/p40	IL-23	IL-12β1; additional receptor chain	Pro-inflammatory; IL-12-like
p40/p40	p40 homodimer, IL-12 receptor antagonist	IL-12β1/β2, competitive inhibitor of IL-12R	Antagonizes IL-12 receptor interactions
p28/EBI-3	IL-27	WSX-1/TCCR; additional receptor chain	Mediates T_H2-type inflammation (?); promotes clonal expansion of naïve $CD4^+$ T cells

gene is expressed in a far more restricted manner, primarily by antigen-presenting cells (APCs). Biologically active IL-12 can be produced only in cells expressing both the p35 and the p40 chains. APCs, including monocytes, macrophages, and DCs, require additional stimuli to produce the p35 chain, with the presence of the p40 subunit determining its ability to produce IL-12. The amount of p35 produced, however, dictates the amount of IL-12 produced. This complex regulatory pattern is consistent with the crucial role of IL-12 in regulating APC function as well as the subsequent activation, expansion, differentiation, and effector and regulatory functions of T and B cells.

IL-12 production is induced following: (1) direct induction by pathogens. Targeting molecules include CD14, Toll-like receptor-2 (TLR-2), TLR-9, and CD11b/CD18. IL-12 is also produced following phagocytosis of bacteria. Bacterial LPS, whole bacteria (SAC, BCG), nucleic acids including CpG motifs, double-stranded RNA, or poly(IC), particle ingestion, and products from several organisms including *Staphylococcus*, *Mycobacterium tuberculosis*, *Neisseria*, *Yersinia*, *Candida*, *Toxoplasma gondii*, *Listeria monocytogenes*, or *Plasmodium chabaudi* induce IL-12 production. (2) In addition, IL-12 is induced during the interaction of APCs with T_H cells. CD40–CD40L (CD154) interaction induces IL-12 following interaction of CD40L-expressing T_H cells with monocytes, macrophages, or DCs. $CD40^+$ human and murine macrophages interacting with activated $CD40L^+$ T cells or clones are induced to produce and secrete IL-12. Induction of IL-12 production also requires additional surface-bound and soluble factors. TRANCE/TRANCER, RANK/RANKL interactions, and cross-linking of MHC class II by the T-cell receptor or CD4 will induce IL-12 production. IFN-γ and IL-4 do not induce IL-12 by themselves but provide powerful co-stimulating signals, allowing efficient production of this factor. IFN-γ enhances IL-12 production following CD40 engagement or interaction with bacterial products. It has been shown that the presence of IFN-γ during DC maturation results in type 1 polarized DCs with a strongly enhanced capacity to produce IL-12 following subsequent CD40L stimulation. Both IL-1 and IL-4 also enhance CD40L-induced IL-12 production. Paradoxically, however, IL-4 can suppress production of IL-12 and other cytokines following LPS stimulation (Table 2).

The effective induction of high levels of bioactive IL-12 by DCs requires two signals: (1) CD40 ligation and a co-stimulatory cytokine, (2) a bacterial product and IFN-γ, or (3) CD40 ligation and a bacterial product. Such regulation of IL-12 production limits the adventitial induction of autoimmunity. Inhibitors of IL-12 production include cyclic AMP-elevating agents, glucocorticoids, histamine, IFN-α, IL-10, prostaglandin E2 (PGE2), transforming growth factor-β (TGF-β), and several neuropeptides. These peptides all directly suppress IL-12 production in a stable fashion and include calcitonin gene-related peptide, vasoactive intestinal peptide, and pituitary adenylate cyclase-activating polypeptide. IL-12 is enhanced in IL-10-deficient animals and diminished in IFN-γ knockouts.

TABLE 2 Production of IL-12 Family Members in Different Cell Types

Cell type	Production of IL-12 family members
Blood monocytes	Inducible production of small amounts of p35 and p40; secretion of small amounts of p70; inducible expression of EBI-3 and p28
Blood-isolated DCs	Expression of p40 and p35; inducible secretion of p70 enhanced following culture with IFN-γ
Macrophages	Inducible expression of p19, p28, p35, p40, and p70 secretion
Langerhans cells	Secretion of p40 only
T cells	Both p19 and p35; no p40 or p70
Splenic DCs	p40, p35, and p70; low in freshly isolated DCs; high in cultured DCs
Monocyte-derived DCs and bone marrow derived DCs	Inducible p19, p35, p40, p70, EBI-3 and p28; human and mouse secrete IL-23 (p19/p40) or IL-12 (p34/p40) after activation with TNFα, LPS, and anti-CD40 antibody
Neutrophils	Mostly IL-12p40, small amounts of p70
Mesoglia	Low-level production of p40, p35, and p70
Keratinocytes	p40 and p35 expression, p40 secretion, lack of p70 expression
Endothelial cells	Inducible p40, p35, and p70
Trophoblasts	EBI-3 and p28/IL-27 (spontaneous)

A. IL-12 Promotes T_H1 Immunity

IL-12 promotes and sustains T_H1 cell development in murine models where it can be more readily tested. IL-12 deficiency limits the development of protective T_H1 responses to antigens including several pathogens (*Leishmania major*, *Listeria*, and *Mycobacterium*), resulting in progressive uncontrolled infection. In the absence of signal transducer and activator of transcription 4 (STAT4), the distal signaling molecule that is important in IL-12 biology, similar susceptibility to these organisms is noted. Humans lacking the functional IL-12 receptor (IL-12R) demonstrate a similar deficit in T_H1 responses to intracellular pathogens. IL-12 is important for eradicating virus in several murine models, and several viruses including measles virus have developed ways to limit IL-12 production. Animals deficient in p40 or the IL-12Rβ2 demonstrate very limited T_H1 responses. Some elements of antiviral immunity are still intact in this setting, suggesting a number of compensatory mechanisms. Repeated administration of IL-12R attenuates the IFN-γ response, enhances IL-10 production, and reduces the acute toxicity of this agent both in mice and in cancer patients receiving experimental therapy with IL-12.

B. IL-12 Promotes Generation of Cytolytic Activity

IL-12 enhances IL-2-driven lymphokine-activated killer (LAK) activity from human peripheral blood mononuclear cells (PBMCs) and is inhibited by antibodies to TNFα and IFN-γ. IL-12 together with CD80 and IL-6 co-stimulation induces antigen-specific murine cytolytic T cells and, like IL-2, promotes enhanced LAK activity in the PBMCs of human immunodeficiency virus (HIV)-infected individuals. IL-12 is more effective as an enhancer of antigen-specific cytolytic activity and survival (in part through enhanced bcl-2 expression) of cytolytic effectors than it is as a T-cell growth factor. IL-12 up-regulates the expression of perforin, serine proteases, and cytolytic granules.

C. IL-12 Promotes B-Cell and DC Activation and Survival

DCs promote the differentiation of naive (but not memory) B cells in part through IL-12 production. IL-12 also enhances B-cell production of IL-10. IL-12 also enhances the production of IgE. It promotes the nuclear localization of nuclear factor κB (NF-κB), priming murine DCs to produce additional IL-12 and enhance survival. With Flt-3 ligand, it enhances the maturation of Langerhans cells and promotes macrophage recruitment as a chemoattractant.

D. IL-12 Enhances Hematopoiesis and Inhibits Angiogenesis

IL-12 acts directly on early hematopoietic progenitor cells, promoting hematopoiesis. It indirectly suppresses hematopoiesis with associated anemia and neutropenia by inducing IFN-γ and TNFα production *in vivo*, inducing an extramedullary hematopoietic response. Other hematopoietic growth factors [stem cell factor, Flt-3 ligand, IL-3, IL-4, granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor, and erythropoietin] synergize with IL-12 to promote the proliferation and differentiation of bone marrow-derived cells in both mouse and human. It has been shown that IL-12 promotes dendropoiesis within lymphoid and nonlymphoid organs. IL-12 also inhibits angiogenesis in mice, mediated by IFN-γ induction of MIG and IP-10. IL-18 synergizes with IL-12 to limit angiogenesis.

E. Potent Anti-tumor Activity of IL-12

IL-12 is an important mediator of effective anti-tumor responses in virtually every murine model in which it has been tested. Systemic administration prolongs survival and inhibits tumor growth and metastasis formation even if treatment is delayed for up to 3 weeks after tumor injection. Surprisingly, early administration of IL-12 is usually less effective or ineffective. This suggests that T cells need to be selected before IL-12 can mediate its biologic effects. The anti-tumor effect mediated by IL-12 administration depends on local production of IFN-γ and TNFα, and requires both $CD4^+$ and $CD8^+$ T cells. Targeted delivery of IL-12 to the tumor microenvironment by gene therapy reduces the tumor and synergizes with the systemic delivery of IL-2. Using a polycistronic retroviral vector encoding the IL-12 p35 and IL-12 p40 subunits, as well as the neomycin phosphotransferase gene (neo^r), Hideaki Tahara engineered tumor cells to stably secrete nanogram quantities of IL-12; the tumor cells failed to grow when injected into mice. It has also been shown that IL-12 synergized with B7.1 gene delivery.

F. IL-12 in Therapy of Infectious Diseases

IL-12 is effective in a variety of murine infectious diseases involving bacteria, protozoans, mycobacteria, and fungi. IL-12 also mediates resistance to

viral infections including lymphocytic choriomeningitis, HIV, cytomegalovirus, vesicular stomatitis virus, encephalomyocarditis virus, and influenza. IL-12 promotes a protective T_H1 response as well as antibody-mediated protection of *Le. major* in mice, reducing the parasite burden and IL-4 production in the regional lymph nodes. IL-12 treatment of susceptible A/J mice infected with blood-stage *Plasmodium chabaudi* AS decreases parasitemia and enhances survival. IL-12 treatment enhances the resistance of mice to *M. tuberculosis* infection and promotes protective $CD4^+$ T-cell responses.

G. IL-12 in Transplantation

In general, IL-12 treatment of wild-type murine cardiac allograft recipients fails to accelerate and, in some instances, significantly delays graft rejection. Blocking IL-12 promotes murine cardiac allograft rejection but promotes liver allograft acceptance and that of allogeneic myoblasts. IL-12 p40 mRNA expression is increased in heart allografts of tolerant rats conditioned by donor-specific blood transfusion. Tacrolimus and intraportal donor-specific bone marrow infusion down-regulate the expression of IL-12 within transplanted organs. APCs isolated from cervical lymph nodes of mice that accepted corneal allografts produce less IL-12. Acute graft-versus-host disease (GVHD) is a major complication of bone marrow transplantation (BMT) and is characterized by hematopoietic dysfunction, immunosuppression, and histopathological changes in the skin, intestinal mucosa, and liver. IL-12 delivery on the day of BMT inhibits GVHD while preserving graft-versus-leukemia effects and is dependent on expression of Fas by donor T cells. Macrophage IL-12 production after LPS stimulation increased in patients who develop acute GVHD. IL-12 p40 mRNA is expressed only in human kidney allograft biopsies showing acute cellular rejection and in all biopsies with evidence of focal interstitial necrosis. IL-12 levels are elevated in human ischemic lung and IL-12 is not found in stable human lung transplant recipients.

H. Therapeutic Efficacy of Human IL-12 in Clinical Trials

The therapeutic efficacy of IL-12 has been evaluated in multiple clinical trials in patients with cancer (melanoma, renal cell carcinoma, cutaneous T-cell lymphoma, Kaposi's sarcoma) as well as in patients with acquired immune deficiency syndrome, viral hepatitis, and asthma. Its evaluation in patients by the two primary companies developing it, Wyeth and Hoffman LaRoche, has been discontinued because of toxicity and limited effectiveness observed using the dose, route, and schedule that are necessary when it is administered as an outpatient regimen. Objective responses in patients with renal cell cancer, melanoma, and cutaneous T-cell lymphoma were observed. Treatment in an early study, using IL-12 administered at 500 ng/kg daily for 5 consecutive days, resulted in severe neurotoxicity with somnolence and confusion and death in two patients. IL-12 tachyphylaxis is noted as late as 2 weeks after IL-12 administration to patients; similar experiments in mice have revealed apparent protection from acute *rm* IL-12 toxicity by pretreatment with *rm* IL-12. Vaccination of metastatic melanoma patients using *rh* IL-12 and peptide induces only modest enhancement of immunologic responses. Peritumoral injection of IL-12-producing autologous cells was tested with 13/29 patients experiencing a clinical response and with 2/29 having an objective clinical response in noninjected lesions. At doses ≥ 7000 ng/day, a Schwartzman reaction was noted in several patients associated with severe local pain, swelling, and tumor necrosis. This was defined as dose-limiting toxicity. In patients with chronic hepatitis C, antiviral activity of IL-12 comparable to that of other current treatments is noted. Low-dose treatment in HIV patients was not effective and administration of daily doses of 1000 ng/kg *rh* IL-12 resulted in severe adverse events. Trials in asthmatic patients demonstrated a reduction of blood and sputum eosinophil counts with no significant effects on airway hyperresponsiveness or the intensity of late asthmatic reactions.

IV. INTERLEUKIN-12 RECEPTOR

The IL-12 receptor is a dimeric complex with an approximate M_r of 135–210 kDa. Expression cloning studies reveal a β1 chain and a β2 chain, each conferring low/intermediate binding affinity of the complex for IL-12; their combination promotes high-affinity binding. The IL-12Rβ2 chain but not the IL-12Rβ1 chain contains tyrosine residues in its cytoplasmic domain and is required for IL-12 signaling. Co-transfection of the IL-12Rβ1 and IL-12Rβ2 chains into cells yields high-affinity IL-12 receptor sites, allowing IL-12 to promote cell proliferation with an $ED_{50} = 1$ p*M* IL-12 p70. PHA-stimulated T-cell blasts express 1000–10,000 IL-12-binding sites per cell with three different affinities consistent with low-, intermediate-, and

high-affinity IL-12 receptors displaying K_ds in the range of 2–6 n*M*, 50–200 p*M*, and 5–20 p*M*, respectively. In mice, the IL-12Rβ1 chain is responsible for binding IL-12. In human cells, both chains participate in IL-12 binding. The β1 chain interacts with the IL-12 p40 chain and the IL-12Rβ2 chain associates with the IL-12 p35 chain. Antibodies to the receptor inhibit IL-12-induced IFN-γ production and activated T-cell proliferation. IL-23 binds IL-12R, but also acts via additional receptors. IL-27 (EBI-3-p28) binds the WSX-1/TCCR receptor and likely one other, as yet unidentified chain.

A. Cell Types and Tissues Expressing IL-12 Receptor

High-affinity IL-12R is present on activated T and NK cells, on DCs, on human B-cell lines, and on activated human PBMCs or tonsillar B lymphoblasts. Both chains are induced on naive ($CD45RA^+$) and memory $CD4^+$ T-cell clones within 48 h of activation with antigen or anti-CD3 treatment. IL-7 treatment augments expression of the IL-12Rβ1 chain, whereas T_H2 cells express only low levels of the IL-12Rβ2 chain. Expression of the high-affinity IL-12R by activated T cells is reciprocally regulated by IL-4 and IFN-γ. IL-4 inhibits IL-12Rβ2 expression and signaling. IFN-γ promotes expression of IL-12Rβ2 on developing T_H2 cells, but does not elicit IFN-γ production following IL-12 stimulation. Individuals with a mutant IL-12Rβ1 gene display diminished IFN-γ production, and recurrent mycobacterial and *Salmonella* infections. Similarly, IL-12R-deficient mice show a pronounced deficit in the ability to control intracellular infections.

B. Regulation of IL-12 Receptor Expression

IL-4, TGF-β, and IL-10 down-regulate IL-12Rβ2 chain expression, signaling, and biologic effects. PGE2 and dexamethasone inhibit IL-12Rβ1 and IL-12Rβ2 expression. Cholera toxin inhibits the expression of both chains. IFN-γ maintains the ability of cells to signal through the IL-12R *in vitro* and *in vivo*. Differential regulation of IL-12 receptor expression by these factors is involved in the development of T_H1 and T_H2 cells and their stability. The cytokines IL-2, IL-7, and IL-15 induce IL-12Rβ1 expression, whereas the natural killer T-cell ligand α-galactosylceramide induces mRNA for both IL-12Rβ1 and IL-12Rβ2.

C. Signaling Pathways

Distal molecules in IL-12 signaling include Janus kinase 2 (JAK2) and tyrosine kinase 2 (Tyk2), STAT1, STAT3, STAT4, NF-κB, and c-Jun. Cross-linking of the IL-12 receptor results in the activation of the receptor-associated tyrosine JAK2 and Tyk2 kinases, mitogen-activated protein kinase, and the src family lck tyrosine kinase. Tyk2 interacts with the β1 chain of the IL-12 receptor and JAK2 interacts with the β2 subunit. STAT1 can dimerize with either STAT3 or STAT4, and STAT4 can dimerize with STAT3. Only STAT4, but neither STAT1 nor STAT3, is activated directly through the IL-12 receptor. Both IL-12 and IFN-α induce tyrosine phosphorylation and DNA binding of STAT4. IL-12R activates STAT4 in a direct fashion, whereas it binds indirectly via STAT2. STAT4 knockout mice are defective in IL-12 responses with profound defects in T_H1 immunity. T_H2 immune responses predominate. Although T_H1-associated immune responses do occur, they are weaker than those observed in control animals in response to IL-12 or to pathogenic organisms including *Li. monocytogenes*. IL-12 activation of NK cells does not occur in STAT4 knockout mice. IL-12-induced IFN-γ production is diminished and long-term antigen-specific immunity is impaired.

V. INTERLEUKIN-12 RECEPTOR ANTAGONIST—p40/p40 HOMODIMER

The IL-12 p40 chain is expressed by APCs at 10- to 100-fold greater levels than the IL-12 p35 chain, being induced by stimuli similar to those inducing IL-12 p70 expression. Secreted p40/p40 homodimers (IL-12RA) bind to the IL-12R but do not elicit a signal, serving as functional antagonists of the IL-12 receptor. IL-12RA inhibits IL-12-induced murine concanavalin A-blast proliferation, splenocyte secretion of IFN-γ, and NK activation in the mouse *in vitro* and following *in vivo* administration, promoting a T_H2-type response and correlating with IL-10 and PGE2 production. In the mouse, IL-12RA inhibits with an IC_{50} of 1–10 ng/ml. In humans, at least 10-fold higher concentrations are required. IL-12RA is less stable, dissociating in aqueous environments to inactive p40 monomers. Most IL-12-inducing stimuli also induce IL-12RA, sometimes by itself. Production of IL-12RA is noted in several murine tumors, at chronic inflammatory sites, and following ultraviolet irradiation. High levels of IL-12RA in peritoneal fluid from patients with endometriosis may play an IL-12-antagonistic

role, locally inhibiting NK function. Bronchial epithelia, in the setting of asthma, produce IL-12RA, and serum levels increase with age. Production of IL-12RA is induced by PGE2, thereby enhancing the T_H2 response.

VI. INTERLEUKIN-23—p19/p40 HETERODIMER AND ITS RECEPTOR, IL-12Rβ1/IL-23R

The existence of an alternative p40-binding partner interacting with the IL-12 receptor was suggested by the greater defect of p40 null mice than of p35 null mice. The gene encoding this novel partner, p19, is located on human chromosome 12q13 and encodes an 18.7 kDa, 189-amino-acid, four-helical cytokine with five cysteine residues and no N-glycosylation sites. Substantial (70%) homology of the mouse 197-amino-acid p19 protein with a MW of 19.8 kDa was subsequently determined. p19 is most closely related to other members of the extended IL-6 family including IL-6 itself and IL-12 p35 and G-CSF. Like IL-12 p35, p19 must be co-expressed with IL-12 p40; its message is expressed by polarized T_H1 cells and activated macrophages. Both human and mouse monocyte-derived DCs generated in the presence of granulocyte/macrophage colony-stimulating factor and IL-4 secrete IL-23 (p40/p19 complex) after activation (TNFα, LPS, and CD40 ligation).

IL-23 promotes IFN-γ production and strongly enhances the proliferation of activated mouse memory T cells ($CD4^+CD45RB^{low}$) but not naive T cells ($CD4^+CD45RB^{high}$). In humans, IL-23 similarly has a greater effect on activated CD45RO memory than on activated CD45RA naive T cells. Ubiquitous expression of the IL-23 (p19) transgene results in widespread inflammation in multiple organs, runting, infertility, and premature death at 3 months. Lymphocytes, macrophages, and neutrophils are found at inflammatory sites and in the peripheral blood. IL-23 transgenic animals had elevated serum cytokine levels (IL-1, TNFα, and IFN-γ) and increased acute-phase proteins. Limited hepatic expression of IL-23 had no apparent phenotype, whereas transfer of IL-23 transgenic bone marrow into lethally irradiated animals induced the same widespread inflammation.

The p19/p40 heterodimer IL-23 binds to IL-12Rβ1 along with another IL2Rβ homologue, the IL-23R, recently identified by Robert Kastelein and colleagues. IL-23 induces STAT4 signaling in phytohemagglutinin (PHA)-activated T cells.

VII. INTERLEUKIN-27—p28/EBI-3 HETERODIMER AND ITS RECEPTOR, WSX-1/TCCR

The Epstein-Barr virus-induced gene 3 (EBI-3), identified by Elliott Kieff, Mark Birkenbach, and colleagues, is a hematopoietin receptor family member with homology to the p40 subunit of interleukin-12 and to the ciliary neurotropic factor. EBI-3 maps to chromosome 19 (19p13.2–p13.3), near genes encoding the erythropoietin receptor and Tyk2. This gene encodes a 34 kDa glycoprotein lacking a membrane-anchoring motif and is not secreted as a monomer but can be secreted to a very limited extent as a p35-linked heterodimer. The authentic binding partner is p28, a member of the long-chain four-helix cytokines, homologous to p38. The gene encoding human p28 is located on chromosome 16p11 and encodes a 243- or 234-amino-acid cytokine (human and mouse, respectively) with 13 negatively charged glutamic acid residues and no N-glycosylation sites. Several O-glycosylation sites are predicted. p28 is most closely related to IL-11 and CNTF, mimicking NNT-1/CLC binding to the CNTF receptor.

EBI-3 is detected in the spleen and tonsils and at high levels within syncitiotrophoblasts in the human placenta. It is found within the interfollicular zones of tonsil tissue and sinusoidal cells in the perifollicular areas of the spleen. PBMCs express EBI-3 following pokeweed mitogen stimulation. EBI-3 is one of the most prominent genes expressed in activated DCs. Interestingly, expression of the p28 chain peaks at 3–6 h following PBMC activation and then rapidly diminishes, whereas EBI-3 mRNA levels can be identified for up to 72 h.

High levels of expression of EBI-3 are observed in virtually all patients with active ulcerative colitis but only rarely in patients with Crohn's disease. An oxazolone-induced T_H2-mediated inflammatory bowel disease model in the mouse has been noted by Richard Blumberg and Mark Birkenbach to be associated with high levels of EBI-3. EBI-3 knockout mice are protected from T_H2-associated colitis but not T_H1 disease. This suggests that p27 has an active role in sustaining or inducing T_H2-type autoimmunity. Robert Kastelein suggests that IL-27 plays a major role inducing T_H1 immunity by enhancing the proliferation and survival of activated naive $CD4^+$ T cells. He believes its most critical role may be early in T-cell biology during the afferent arm of the immune response and proximal to that of IL-12 and IL-23, which may be sequentially important in T_H1 immunity.

WSX-1/TCCR, expressed on the same chromosome as the IL12Rβ1 chain (chromosome 19), is one of the chains of the functional IL-27 receptor. Initiation of T_H1 responses but not their continuation requires expression of this receptor. Another chain is likely required for signaling but has not been identified.

Glossary

cytotoxic lymphocyte maturation factor This term was initially used to define the ability of interleukin-12 to synergize with interleukin-2, particularly in the presence of corticosteroids, to stimulate cytolytic activity from natural killer (lymphokine-activated killer activity) and T cells.

dendrikines Factors made by dendritic cells and acting on themselves (autocrine activity), on other cells locally in the lymph node or tissues where they reside (paracrine activity), or on immune cells at other distant sites or tissues (endocrine activity). Dendrikines are like lymphokines, soluble factors elaborated by lymphocytes, and like monokines, soluble factors elaborated by monocytes; all of these would be considered cytokines, soluble factors made by one cell and acting on other cells and occasionally acting on themselves.

directed exocytosis The mechanism by which cells can communicate via soluble mediators across an immunologic synapse when they are in close proximity to other cells; cytokines are delivered from a region of one cell adjacent to another, usually after a series of triggering events between the two cells.

Epstein–Barr virus (EBV)-induced gene 3 Dendrikine whose gene product has homology to the p40 chain of interleukin-12, pairing with p19 to create interleukin-27. Induced in B cells following EBV infection and expressed in macrophages and dendritic cells; appears to be important in some chronic inflammatory bowel diseases including Crohn's colitis and possibly associated with pregnancy since it is found in large amounts in human placenta.

interleukin-12 Heterodimeric cytokine of the extended interleukin-6 (IL-6) family of hematopoietins; consists of p35 and p40 noncovalently linked chains with homology to the IL-6 molecule interacting with an extracellular domain of the IL-6 receptor; initially identified in Epstein–Barr virus-transformed B cells and subsequently in macrophages, dendritic cells, and keratinocytes.

interleukin-12 receptor antagonist Homodimeric p40 molecule serving to bind to the interleukin-12 receptor but without agonist activity and blocking the active heterodimer.

interleukin-23 Novel interleukin-12 family member consisting of a common p40 chain as well as a novel p35 homologue, p19; appears to be important in the late stages of inflammation and autoimmunity as a monokine/dendrikine promoting chronic inflammation.

interleukin-27 Novel interleukin-12 family member consisting of p28 and EBI-3 as a heterodimer; appears to be important in the earliest stages of inflammation, particularly in ulcerative colitis, as a monokine/dendrikine promoting activation of naive $CD4^+$ T cells and promoting a T_H1 response.

natural killer stimulatory factor Original functional definition of the biologic activity identified in the laboratory of Dr. Giorgio Trinchieri at the Wistar Institute, capable of enhancing natural killer (NK) cytolytic activity and interferon-γ production from NK cells; subsequently termed interleukin-12.

T-cell-stimulating factor Originally identified by Hermann and Rude as a factor promoting T-cell function, survival, and cluster formation; subsequently identified as being identical to interleukin-12.

Interleukin-13

JAN E. DE VRIES AND JOSÉ M. CARBALLIDO
Novartis Research Institute, Vienna, Austria

Interleukin-13 (IL-13) was first described in 1989 as P600, an mRNA selectively expressed by mouse T helper 2 (T_H2) cells. Its human homologue was cloned 3 years later. Expression of the human cDNA led to the discovery that P600 encoded a cytokine that was designated interleukin-13. IL-13 is produced by various cells of the immune system following activation but is generally considered a T_H2 cytokine. In addition, basophils and mast cells are major producers of IL-13.

I. INTRODUCTION

Interleukin-13 (IL-13) shares many functional characteristics with IL-4, which is related to the fact that the IL-13 receptor (IL-13R) is a heterodimeric receptor consisting of an IL-13-binding chain (IL-13Rα1) and the IL-4Rα chain that binds IL-4. IL-4 utilizes this IL-4Rα/IL-13Rα1 complex (called type II IL-4R) as an alternative IL-4R (Fig. 1). These shared receptor components account for the many overlapping activities of IL-13 and IL-4. However, IL-13 and IL-4 also have clearly distinct activities that are determined by the differential distribution of IL-13R and IL-4R on various cell types. IL-13 plays a critical role in the pathogenesis of asthma, particularly in the induction of airway hyperresponsiveness and overproduction of mucus. IL-13 is also the dominant cytokine in the induction of granuloma formation and tissue fibrosis associated with chronic inflammation. On the other hand, IL-13 has protective effects against gastrointestinal nematode infections

compromise thyroid hormone production, resulting in pathological states of hypothyroidism such as cretinism and goiter.

I. INTRODUCTION

Thyroid hormones, triiodothyronine (T3) and tetraiodothyronine or thyroxine (T4), are essential for normal growth, development, and metabolism, and the effects of deficient or excessive thyroid hormone concentrations are manifested throughout the body. The fundamental components of T3 and T4 are iodine and specific tyrosine residues within thyroglobulin (TG) that provide substrates for iodine attachment. To synthesize thyroid hormones, the thyroid concentrates iodide (I^-) from the circulation and organifies it at the apical membrane to generate iodotyrosines, which are then coupled to form iodothyronines (T3 and T4). The iodinated TG subsequently undergoes endocytosis and proteolysis for release of T3 and T4 into the bloodstream.

The structural organization of the thyroid gland and the distribution of key transporter proteins and enzymes within it ensure that iodine and TG will yield T3 and T4 upon the execution of numerous steps (Fig. 1). The thyroid gland is organized into follicles composed of polarized thyrocytes lining a lumen filled with colloid. The basal aspect of the thyrocyte is in contact with intervening supporting tissue that is rich in blood and lymphatic capillaries, facilitating the uptake of iodide from the blood by the sodium/iodide symporter (NIS) and the release of T3 and T4 into the circulatory system. Pendrin and thyroid peroxidase (TPO) are strategically located within the apical membrane of the thyrocyte, which borders the colloid-filled lumen. Pendrin transports iodide into the follicular lumen positioning it near TG and TPO. In conjunction with hydrogen peroxide, TPO catalyzes the iodination of tyrosine residues on TG to make 3-monoiodotyrosine (MIT) and 3,5-diiodotyrosine (DIT) and then couples the iodotyrosines to form T3 and T4. Hormone-containing TG in the follicular lumen becomes the macromolecular storage site for iodine as well as for thyroid hormone. The thyroid gland is unique among endocrine organs in that the final assembly and storage of hormone occur extracellularly within the colloid of the follicular lumen.

The biosynthesis and secretion of T3 and T4 are stimulated mainly by thyroid-stimulating hormone (TSH) through cyclic adenosine monophosphate (cAMP), in conjunction with insulin and/or insulin-like growth factor 1 (IGF-1). TSH increases the expression of NIS, TG, and TPO and, therefore, T3 and T4 production. Recent studies demonstrate that TG inhibits NIS, TG, and TPO expression, which consequently counteracts the stimulatory effects of TSH to induce T3 and T4 formation.

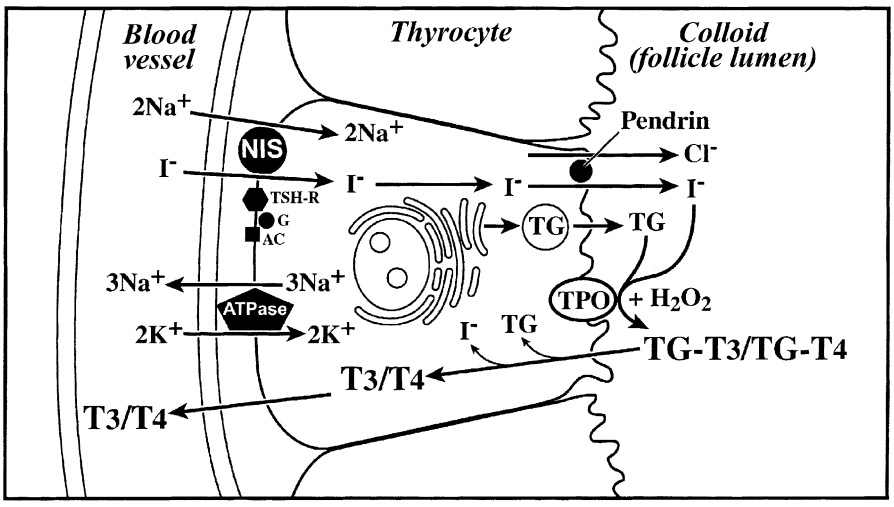

FIGURE 1 Key steps in thyroid hormone biosynthesis including basolateral iodide uptake (NIS, sodium/iodide symporter), apical iodide transport (pendrin), iodination and coupling (TPO, thyroid peroxidase) within thyroglobulin (TG), endocytosis and proteolysis, and hormone release. AC, adenylate cyclase; ATPase, sodium/potassium ATPase; G, G-protein; TSH-R, thyroid-stimulating hormone receptor.

II. SODIUM/IODIDE SYMPORTER: BASOLATERAL IODIDE UPTAKE

The sodium/iodide symporter is a membrane glycoprotein that mediates the uptake of I^- along the basolateral membrane of thyrocytes. NIS couples the inward translocation of two sodium ions down their electrochemical gradient with the inward translocation of one iodide ion against its electrochemical gradient. The energy required to drive this process is provided by the sodium gradient generated by sodium (Na^+)/potassium (K^+) ATPase. NIS is believed to span the plasma membrane 13 times, exhibiting an extracellular amino-terminus and a cytoplasmic carboxy-terminus. The protein exists primarily as a mature ~87 kDa glycosylated peptide. However, the function, membrane targeting, and stability of NIS do not appear to be affected in the absence of glycosylation. Although the exact mechanisms remain to be elucidated, several hydroxyl-containing amino acid residues located in transmembrane segment IX (Ser-353, Thr-354, Ser-356, and Thr-357) appear to play an important role in NIS activity.

In addition to its physiological importance, the ability of NIS to concentrate iodide holds clinical relevance by providing the basis for using radioactive iodine in the treatment and management of various thyroid diseases. For example, radioactive iodine is commonly used to destroy overactive thyrocytes in patients with thyrotoxicosis, to ablate normal and malignant thyroid tissues in patients who have undergone total thyroidectomy for thyroid carcinoma, and to perform whole-body scans for the detection of recurrent and metastatic thyroid cancer. In addition to the thyroid gland, there are several extrathyroidal tissues, including lacrimal and salivary glands, gastric mucosa, and lactating mammary glands, with functional NIS expression. Although the exact role that iodide plays and the factors that modulate NIS expression in these tissues have not been established, the application of radioactive iodine for the treatment of cancers occurring in these extrathyroidal sites is promising.

III. PENDRIN: APICAL IODIDE TRANSPORT

Once within the thyrocyte, I^- is passively transported into the follicular lumen via pendrin. Pendrin is an ~86 kDa chloride/iodide transport protein and is located exclusively at the apical membrane of thyrocytes. Pendrin is the product of the gene responsible for Pendred syndrome, a genetic disorder characterized by sensorineural hearing loss and goiter. Pendrin is characterized by 11 or 12 putative transmembrane domains and is closely related to a family of sulfate transport proteins. However, pendrin does not transport sulfate and, unlike NIS, does not require sodium for its transport of iodide.

IV. THYROGLOBULIN: PROHORMONE

Mature thyroglobulin existing as a dimer is a 660 kDa glycoprotein containing 132 tyrosine residues, some of which are the substrates for iodine attachment to generate T3 and T4. Carbohydrate chain synthesis is initiated once the polypeptide chain of thyroglobulin is produced on polyribosomes of rough endoplasmic reticulum (RER) within the thyrocyte. Enzymes such as protein disulfide isomerase and peptydylprolyl isomerase, as well as several molecular chaperones, including calnexin, BiP, GRP94, and Erp72, ensure that newly synthesized TG leaves the ER properly folded and migrates to the Golgi complex where it undergoes glycosylation and sulfation. Only properly folded and glycosylated thyroglobulin will be allowed to reach the apical membrane of the thyrocyte.

There are various forms of thyroglobulin found within the thyroid gland, including 12S monomers, 17S dimers, and mature iodinated 19S dimers and 27S tetramers. The two monomeric polypeptide chains comprising a 17S dimer are believed to be identical but become heterogeneous following glycosylation and iodination as a 19S dimer. The tetramer is similar in amino acid content to the 19S dimer but contains more iodine and accounts for only 10% of all mature TG. Within the colloid, TG primarily exists as soluble 19S dimers or 27S tetramers. However, 30% of the thyroglobulin contains 40% more iodine and is compacted for storage, rendering it insoluble. This demonstrates that colloid is the extracellular storage site for iodine as well as thyroid hormone.

Tyrosine residues within three consensus sequences (Asp/Glu-Tyr, Ser/Thr-Tyr-Ser, and Glu-X-Tyr) are favored for iodination. There are four major (A through D) and three minor (G, N, and R) hormonogenic sites within TG. Utilization of the different tyrosine residues within the known hormonogenic sites varies with iodine availability, TSH stimulation, and species. Subsequent iodination by thyroid peroxidase at these favored tyrosine residues stabilizes thyroglobulin by oxidation of free sulfhydryl groups and formation of interchain disulfide bonds. This is evidenced by the fact that iodine-poor thyroglobulin dimers readily dissociate.

V. THYROID PEROXIDASE: IODINATION AND COUPLING

Thyroid peroxidase is an ~105 kDa heme-containing glycoprotein that belongs to a family of mammalian peroxidases that includes myeloperoxidase, lactoperoxidase, eosinophil peroxidase, and salivary peroxidase. TPO is located on the apical membrane of thyrocytes where it catalyzes iodination of TG and coupling of iodotyrosines to form iodothyronines attached to TG. However, *in vitro* studies have shown that such functions are not unique to TPO in that lactoperoxidase and myeloperoxidase can also serve as catalysts for both iodination and coupling.

There are currently three forms of TPO that are generated through alternative splicing of the same gene. TPO-1 is the full-length enzymatically active glycoprotein characterized by a catalytic arginine, proximal and distal histidines, and asparagine-linked glycosylation sites. TPO-2, which lacks 57 amino acids from the middle of the sequence, is enzymatically inactive due to the loss of essential histidine and asparagine residues. The third alternatively spliced form is TPOzanelli, which, like TPO-1, is enzymatically active. However, TPOzanelli has a shorter half-life and is less stable than TPO-1 due to a modified carboxy-terminus.

Iodination of tyrosine residues and coupling of iodotyrosines on TG by TPO occur near the apical surface of the thyrocyte at the cell–colloid interface within the follicular lumen and require close proximity of TPO, hydrogen peroxide, TG, and I^-. The oxidation of iodide is coupled to the reduction of hydrogen peroxide because TPO is catalytically inactive in the absence of hydrogen peroxide. Three primary mechanisms of TPO-catalyzed iodide oxidation have been proposed but none has been established. The first mechanism suggests that TPO-bound free radicals of iodide and tyrosine are produced by oxidation to form iodotyrosines. Alternatively, the initial oxidation of I^- to I^+ is followed by iodination of tyrosine. In the third proposal, tyrosine iodination follows oxidation of iodide to hypoiodite. Regardless of the mechanism employed, TPO attaches oxidized iodide to tyrosine residues within thyroglobulin producing MIT and DIT (Fig. 2). Subsequently, TPO couples one MIT residue and one DIT residue to form T3 or two DIT residues to form T4 (Fig. 2). Under conditions of normal thyroid activity and normal iodine supply, a typical molecule of mature 19S TG contains 2.5 T4 residues, 0.7 T3 residues, 4.5 DIT residues, and 5.0 MIT residues.

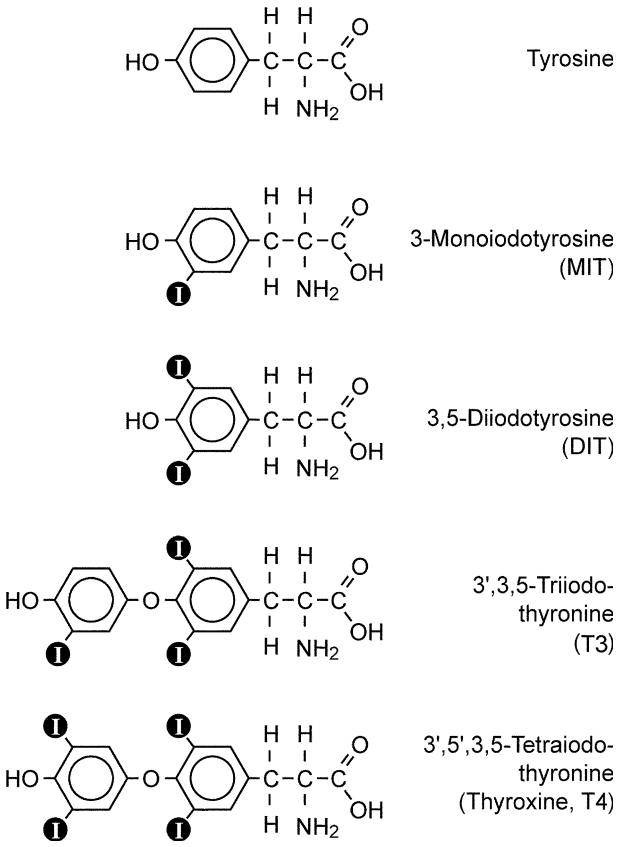

FIGURE 2 Chemical structures of the iodinated tyrosine residues, MIT and DIT, within thyroglobulin, which are then coupled to form T3 and T4.

However, the ratio of MIT to DIT is greatly increased during iodine deficiency, favoring T3 formation.

VI. ENDOCYTOSIS, PROTEOLYSIS, AND HORMONE RELEASE

To facilitate the secretion of T3 and T4 into the bloodstream, thyroglobulin must be processed further within the thyrocyte. Thyroglobulin gains reentry into the thyrocyte primarily by receptor-mediated or nonselective pinocytosis. Coated pits containing thyroglobulin are invaginated to form internalized, coated vesicles. Some species, particularly rats, develop elongated microvilli and pseudopodia, which extend into the follicular lumen to indiscriminately phagocytize and internalize a portion of the adjacent colloid, resulting in the formation of colloid droplets. Once inside the thyrocyte, thyroglobulin takes one of three pathways: proteolysis to release T3/T4, recycling back to the follicular lumen, or transcytosis to the bloodstream. To break

down TG and release T3/T4, TG migrates within the cell to fuse with lysosomes. Lysosomal enzymes such as cathepsin D (aspartic endopeptidase), cathepsins B, H, L, and S (cysteine endopeptidases), and lysosomal dipeptidase I and dipeptidyl peptidase II (exopeptidases) proteolytically cleave iodoamino acids from thyroglobulin. Iodine is then removed from MIT and DIT by an iodotyrosine-specific deiodinase in the thyroid, and the iodide and tyrosine are recycled. A small proportion of T4 is also converted to T3 within the thyrocyte by a thyroidal 5′-deiodinase similar to that found in peripheral tissues. T3 and T4 are then released into the bloodstream where they are transported in association with specific plasma-binding proteins. During pinocytosis, immature thyroglobulin is also internalized. This immature thyroglobulin is recognized by *N*-acetylglucosamine and/or asialoprotein receptors and is targeted for recycling. Finally, a small percentage of thyroglobulin is diverted directly to the bloodstream by a process known as transcytosis.

VII. THYROID-STIMULATING HORMONE AND OTHER REGULATORY FACTORS

Virtually all aspects of thyroid hormone biosynthesis are directly regulated by thyroid-stimulating hormone. TSH is produced by thyrotrophs within the pars distalis of the pituitary gland in response to thyrotropin-releasing hormone (TRH) produced in the hypothalamus. Glucocorticoids, somatostatin, and dopamine inhibit TSH whereas α-adrenergic agonists increase TSH; however, these effects are of importance primarily during pathologic states. TSH increases the synthesis of key proteins expressed in the thyroid gland, including the sodium/iodide symporter, thyroglobulin, and thyroid peroxidase. TSH-mediated regulation occurs mainly by increased expression and activation of the thyroid-restricted transcription factors, thyroid transcription factor 1 (TTF-1), TTF-2, and Pax-8, which are responsible for expression of thyroid-restricted genes. The ultimate result is increased production and secretion of T3 and T4, which themselves inhibit the secretion of TSH and TRH. Most of the TSH effects within the thyroid are mediated by the cAMP–protein kinase A (PKA) cascade, which is initiated following binding of TSH to its receptor on the basal membrane of the thyrocyte. TSH–cAMP–PKA activity also requires the presence of insulin and/or IGF-1. In addition to the increased synthesis of NIS, TG, and TPO, specific consequences resulting from TSH stimulation include

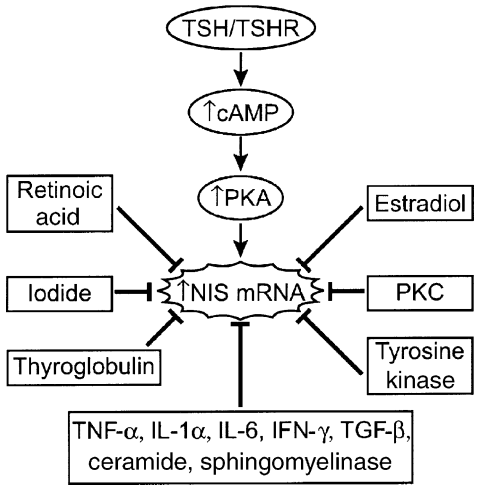

FIGURE 3 Factors affecting sodium/iodide symporter (NIS) mRNA levels in normal thyroid cells. Factors within circles stimulate NIS expression and factors within boxes inhibit NIS expression. cAMP, cyclic adenosine monophosphate; IFN-γ, interferon-γ; IL-1α, interleukin-1α; IL-6, interleukin-6; mRNA, messenger ribonucleic acid; PKA, protein kinase A; PKC, protein kinase C; TGF-β, transforming growth factor-β; TNFα, tumor necrosis factor α; TSH/TSHR, thyroid-stimulating hormone/thyroid-stimulating hormone receptor.

phosphorylation and trafficking of NIS to the plasma membrane, increased glycosylation of TG, increased production of hydrogen peroxide from increased nicotinamide adenine dinucleotide phosphate oxidase, increased pseudopod and colloid droplet formation, increased production of cathepsins B and L, and suppression of TSHR gene expression. In the thyroid gland, the effects of lithium, administered for the treatment of thyrotoxicosis, are believed to be due to the suppression of TSH-stimulated cAMP production.

Follicular thyroglobulin has been shown to counteract the stimulatory effects on the thyroid by TSH through suppressing the expression of TG, TPO, NIS, and TSHR. Follicular TG exerts its actions through suppression of TTF-1, TTF-2, and Pax-8. Follicular TG also inhibits the expression of vascular endothelial growth factor and vascular permeability factor. This results in decreased vascular flow through the thyroidal capillary bed, reducing the availability of iodide for subsequent concentration by NIS. It is reported that the 27S tetramer and poorly iodinated TG have greater suppressive effects than the 19S dimer and highly iodinated TG, respectively. In contrast, the expression of pendrin is up-regulated by follicular TG.

Factors that specifically influence the expression and function of NIS, pendrin, and TPO are important negative regulators in the production of thyroid hormones. For example, perchlorate and thiocyanate are specific inhibitors of NIS. Ouabain inhibits Na^+/K^+ ATPase, effectively removing the energy source necessary for NIS to transport iodide against its gradient. Other factors that affect NIS expression are depicted in Fig. 3. In addition to inhibiting NIS expression, excess iodide inhibits hormonogenesis by preventing TPO from iodinating further tyrosines. TPO is also specifically inhibited by thioureylene compounds such as propylthiouracil, methylmercaptoimidazole, and carbimazole, as well as sulfonamides. Pendrin-mediated chloride transport has been demonstrated to be inhibited by DIDS (4,4′-diisothiocyanostilbene-2,2′-disulfonic acid), furosemide, and probenecid.

Glossary

colloid Gelatinous substance within the lumen of thyroid follicles that contains thyroglobulin with attached iodine and thyroid hormone.

cretinism Developmental condition due to congenital or early-onset hypothyroidism characterized by arrested physical and mental development, dystrophy of bones and soft tissues, and depressed basal metabolism.

goiter Enlargement of the thyroid gland causing a swelling in the front part of the neck that is due to hyperfunction or hypofunction of the thyroid.

molecular chaperones Molecules that are present in virtually all cell types and cellular compartments, and that aid in the proper folding and transport of proteins.

organification Oxidation of iodide and attachment to organic molecules such as thyroglobulin in the thyroid gland by thyroid peroxidase for iodine retention, storage, and hormone production.

sodium/potassium ATPase Physiological membrane-associated protein that pumps two potassium ions into the cell and three sodium ions out of the cell for every adenosine triphosphate that is split to form adenosine diphosphate and inorganic phosphate.

thyrotoxicosis Clinical condition due to overactivity of the thyroid gland and excess thyroid hormone production characterized by rapid heart rate, elevated basal metabolism, goiter, exophthalmia, nervous symptoms, and weight loss.

thyrotropin Hormone secreted by the anterior pituitary that is also known as thyroid-stimulating hormone.

transcription factors Proteins that control gene expression by binding to specific sequences on deoxynucleic acid (DNA) as DNA is transcribed into ribonucleic acid.

acid (OPDA) reductase (see Fig. 1) normally expressed in the pistil, petals, and stamen filaments. Mutant plants dehisce only as the flowers are senescing, a phenotype that can be rescued with exogenous JA. Jasmonates also promote fruit ripening, a phenomenon that is sometimes exploited in the produce industry. Because fruit ripening is commonly attributed to other plant hormones, especially ethylene, plant physiologists were first puzzled by this revelation until it became apparent that jasmonates induce the ethylene-forming enzyme (1-aminocyclopropane-1-carboxylic acid oxidase). In this way, jasmonates could facilitate the coordination of flowering and fruit ripening in response to appropriate developmental and environmental conditions.

Since endogenous jasmonate levels are relatively high in vegetative sink tissues and in developing reproductive tissues, researchers surmised that jasmonates have important roles in regulating source–sink relationships. This role is supported by evidence that jasmonates induce tuberization and deposition of vegetative storage proteins. Jasmonates also effect a trade-off between primary and secondary metabolism, degrading photosynthetic enzymes and inactivating ribosomes while stimulating terpenoid, phenylpropanoid, and alkaloid biosynthesis. This trade-off has important implications for plant productivity and self-defense against herbivores and pathogens.

Many plants require jasmonates for induced systemic resistance to pathogens. Jasmonate-insensitive *coi1* mutants of *A. thaliana* display increased susceptibility to necrotrophic fungi. Spraying wild-type plants with exogenous MeJA increases their resistance to many of these pathogens. Whereas salicylates are primarily responsible for pathogen-induced systemic acquired resistance (SAR), jasmonates have a major role in non-pathogen-induced systemic resistance (ISR). Some studies suggest that SAR, ISR, and wound-induced responses are antagonistic, namely, that the last two compromise SAR against pathogens and vice versa. Such fitness trade-offs have been documented in field and transgenic investigations and are likely related to the fact that salicylates can inhibit jasmonate biosynthesis and vice versa. However, in 2000, van Wees *et al.* showed that simultaneous induction of SAR and ISR in *A. thaliana* results in an additive effect on the level of induced

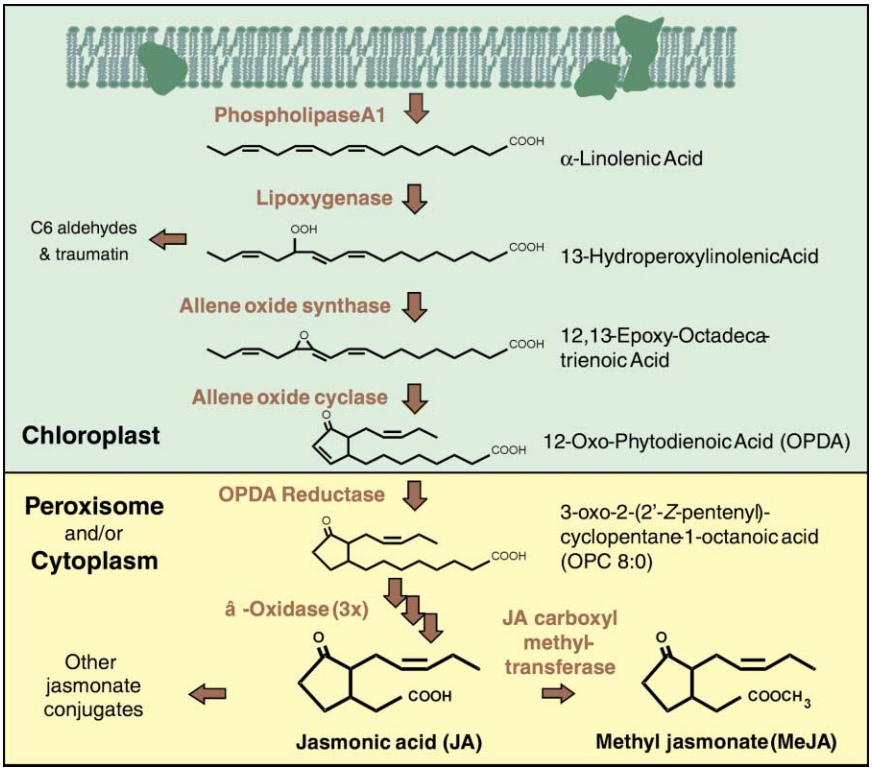

FIGURE 1 Jasmonate biosynthesis via the octadecanoid (or oxylipin) pathway. This pathway involves two or three cellular compartments: chloroplasts, peroxisomes, and/or cytoplasm.

protection against *Pseudomonas syringae* pv. *tomato*. DNA microarray analyses have also revealed a set of 55 genes that are co-induced and another set of 28 that are co-repressed by SA and JA in *Arabidopsis*. Obviously, there is much to learn about the complex cross-talk between these two pathways in mediating plant self-defense.

Jasmonates also affect tritrophic interactions. MeJA and other volatile oxylipins can attract parasitic wasps to herbivorous insect larvae, upon which they lay their eggs. Once these hatch, the wasp larvae parasitize the host herbivore. Clearly, jasmonates have multiple roles in plant defense against multiple enemies.

II. BIOSYNTHESIS

Jasmonates are synthesized from α-linolenic acid (18:3), which is derived from membrane phospholipids, via the octadecanoid pathway (Fig. 1). Enzymes of this pathway have recently been cloned and characterized. Several (phosopholipase A1, lipoxygenase, allene oxide synthase, and allene oxide cyclase) contain chloroplast transit peptides, providing strong evidence for a chloroplast location for the first part of this pathway. Protein localization experiments have confirmed this finding (see below). Evidence for a peroxisomal location of the final steps of this pathway comes mainly from the fact that this organelle is the site of beta-oxidation in plant cells. However, since there are cytoplasmic isoforms of many octadecanoid enzymes, in 1999, Wang *et al.* also proposed a cytoplasmic location of the pathway.

Because these enzymes degrade membrane phospholipids at defined cleavage sites, phospholipase activity is essential for initiating jasmonate biosynthesis. Various candidate phospholipases have been cloned and it has been proposed that they play a role in jasmonate biosynthesis. In 2000, Ishiguro *et al.* identified an *A. thaliana* mutant that was defective in anther dehiscence from which they cloned a phospholipase A1. That this phospholipase is primarily responsible for jasmonate biosynthesis is strongly supported by evidence that it is localized in chloroplasts and that the mutant phenotype can be rescued by exogenous application of linolenic acid or JA.

The release of free α-linolenic acid and addition of molecular oxygen by lipoxygenase results in the formation of 13-hydroperoxylinolenic acid, a precursor for the biosynthesis of jasmonates and other oxylipins. In fact, jasmonates can stimulate oxylipin biosynthesis by inducing the expression of certain isoforms of lipoxygenase and other enzymes of this pathway. The biosynthesis of characteristic combinations of oxylipins may induce specific plant responses to wounding or pathogenesis.

Allene oxide synthase (AOS), an atypical cytochrome P450 with a high turnover rate (1000 min^{-1}), catalyzes the putative committed step in jasmonate biosynthesis. Overexpression of chloroplastic AOS in transgenic flax leads to the accumulation of JA, but does not activate jasmonate-responsive genes. In contrast, overexpression of cytoplasmic AOS does not affect jasmonate levels in nonstressed tobacco plants, lending further support to a plastidic location of the octadecanoid pathway. In tomato, an AOS is targeted to the stromal side of the chloroplast inner envelope. Because 12,13-epoxy-octadecatrienoic acid, the product of the AOS-catalyzed reaction, is unstable, it is likely that AOS is in close proximity to allene oxide cyclase (AOC), the next enzyme in the pathway.

AOC catalyzes the stereo-specific cyclization of 12,13-epoxy-octadecatrienoic acid to specifically form 9*S*,13*S*-12-oxo-phytodienoic acid (OPDA), which has both side chains in the *cis* configuration. Immunohistochemical data suggest that tomato AOC is a soluble protein that resides in the chloroplast stroma. However, localization in the intermembrane space is also a possibility.

OPDA reductase catalyzes the reduction of the double bond in the pentacyclic ring of OPDA, forming 3-oxo-2(2′[*Z*]-pentenyl)-cyclopentane-1-octanoic acid (OPC 8:0). Of the three isoforms identified in *A. thaliana*, only OPR3 catalyzes this reaction. Interestingly, *opr3* mutant plants are still capable of responding to wounding, demonstrating that OPDA and/or other oxylipins have important biological activities commonly attributed to jasmonates.

Three rounds of beta-oxidation culminate in the stereospecific formation of 3*R*,7*S*-jasmonic acid, the *cis* enantiomer. However, 3*R*,7*R*-jasmonic acid (a more stable *trans* configuration) is the biologically active form. Whether this epimerization occurs enzymatically or mainly nonenzymatically remains unknown. Volatile MeJA is produced via JA carboxyl methyltransferase, presumably in the cytoplasm since this *Arabidopsis* enzyme lacks a clear signal peptide. Wounding and exogenous MeJA systemically induce the expression of this gene in leaves and flowers.

Other hormones influence jasmonate biosynthesis by exerting their effects on the expression and activity of octadecanoid pathway enzymes. SA inhibits AOS

gene expression, but reports of its effects on AOS enzyme activity are variable. In contrast, ethylene induces AOS expression and activity. Both of these effects are consistent with observed physiological responses: Salicyclic acid and jasmonates tend to have antagonistic roles, whereas ethylene and jasmonates tend to act synergistically.

III. SIGNAL TRANSDUCTION

The complexity of plant defensive responses, involving extensive cross-talk among jasmonates, SA, and ethylene, has hampered efforts to elucidate jasmonate signaling pathways (see Fig. 2). Receptor and effector molecules remain elusive. It is known that several members of the mitogen-activated protein kinase (MAPK) family are up-regulated by biotic and abiotic stress. One of these is WIPK, a systemic wound-induced protein kinase in tobacco. Overexpression of WIPK in transgenic plants caused an increase in jasmonate levels and activation of proteinase inhibitor expression. However, this result could not be reproduced in another laboratory, perhaps due to the lack of activation by an upstream MAPK kinase. SIPK, a SA-induced protein kinase in tobacco, is induced at even higher levels in wounded plants, but its role(s) in the wound response remains unclear. Constitutive activation of NtMEK2, the upstream MAPK kinase activator of SIPK and WIPK, induces programmed cell death, indicating a role in plant responses to pathogens. Each of these MAPKs is thought to act upstream of jasmonate, inducing the octadecanoid pathway through a process that may also require transient Ca^{2+} influxes.

MAPK cascades may also act downstream of external or internal jasmonates. An *Arabidopsis* MAPK mutant *mpk4* exhibits high SA levels and low-level expression of jasmonate-induced genes. Exogenous JA was unable to induce expression of these genes, suggesting that MPK4 acts downstream of jasmonate. However, in another study, MPK4 activity was up-regulated within 5 min of touching or

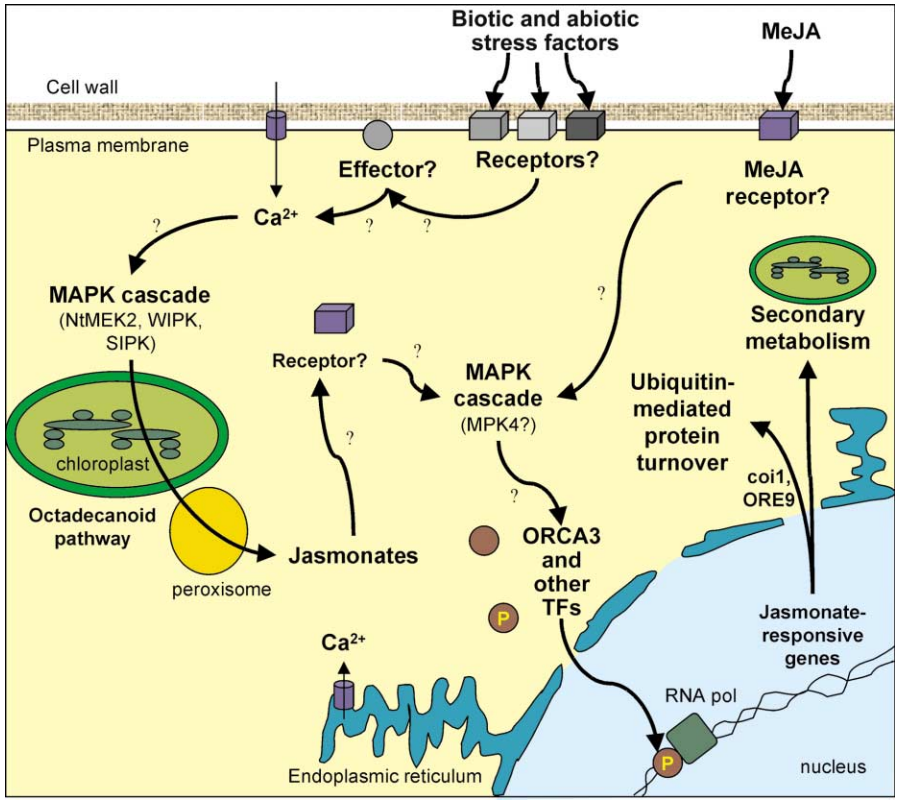

FIGURE 2 A current working model of jasmonate signal transduction indicates the involvement of MAPK cascades in activating jasmonate biosynthesis and action. Many upstream elements of this pathway are still unknown. Also unclear are the complex interactions of various MAPK cascades that are coordinately regulated by environmental stress, jasmonates, salicylates, ethylene, and possibly other hormones.

wounding (much faster than the kinetics of JA accumulation), suggesting that it functions upstream of jasmonate or in a jasmonate-independent pathway. These MAPK cascades may facilitate another level of cross-talk with signaling pathways involving similar cascades, including ethylene, SA, and possibly ABA.

Much of current jasmonate signal transduction research is focused on genomic analyses and characterization of *Arabidopsis* mutants. JA-insensitive mutants include *jar1*, *jin1*, *jin4*, and *coi1*. The affected *coi1* gene encodes an F-box receptor protein that contains a leucine-rich repeat. This family of receptors facilitates transfer of ubiquitin to targeted proteins for proteolysis in proteasomes. Targets of these F-box proteins putatively include proteins that normally repress jasmonate responses. Mutants with constitutively activated jasmonate responses also exist. These include *cev1* and *cex1*. Since the *cev1* phenotype requires *coi1* and *etr1* (the ethylene receptor), it likely encodes a protein that regulates an early step in plant defense involving jasmonate and ethylene signaling. Whether these mutations affect endogenous JA levels is still unknown. Complete elucidation of the pathway awaits characterization of these and other mutants.

Jasmonate signaling pathways converge on a set of transcription factors that regulate gene expression. Terpenoid indole alkaloid (TIA) biosynthesis in *Catharanthus roseus* (Madagascar periwinkle) is regulated by ORCA3, a jasmonate-responsive transcription factor that orchestrates primary and secondary metabolism, and other ORCA proteins. Gel mobility shift assays show that ORCAs interact with upstream elements at the promoters of jasmonate-responsive genes. Overexpression of ORCA3 results in increased expression of key enzymes in the biosynthesis of TIAs and TIA precursors. Plants likely make use of TIAs—including serpentine (a tranquilizer), vinblastine (an anti-tumor drug), strychnine (poison), and campothecin (an anti-neoplastic agent)—and other secondary metabolites in wound healing and self-defense.

IV. SUMMARY

Jasmonates are phospholipid-derived hormones that regulate plant development and responses to environmental stress. They slow normal growth and developmental processes that are sensitive to environmental stress and promote multiple responses to stressful conditions. They also promote flower and fruit development. MeJA, a volatile signal, can alert neighboring plants to biotic and abiotic stresses or even summon parasitic wasps to afflict insect herbivores. Thus, it has interesting ecological and physiological implications. The enzymes that catalyze jasmonate biosynthesis have recently been cloned and characterized. Much of current jasmonate research is focused on elucidating the mechanisms of jasmonate signal transduction, clarifying the mechanisms of cross-talk with other hormones, and identifying the molecular mechanisms of plant self-defense.

Glossary

dehiscence Release of mature pollen grains via degradation of the callose cell wall that surrounds a tetrad of microspores.

elicitors Compounds present in minute quantities in the saliva of herbivores, in the exudates of pathogens, or as degradation products of cell walls that are recognized by receptor proteins. Elicitors induce defensive responses in the affected plant.

environmental stress Biotic (insects, pathogens, etc.) and abiotic (drought, hail, temperature extremes, etc.) factors in the environment that can damage plants due to herbivory, disease, wounding, and physiological maladies (such as water stress).

induced systemic resistance Self-defense mechanism induced by nonpathogenic rhizobacteria that initiates the systemic production of pathogenesis-related proteins, leading to broad resistance against pathogens.

oxylipins Octadecanoid pathway products, including volatile six-carbon aldehydes (hexenal and hexenol), traumatin, cutin monomers, 12-oxo-dodecenoic acid, 9*S*,13*S*-12-oxo-phytodienoic acid, jasmonates, and methyl ester or amino acid conjugates of many of these. Oxylipins can function as signal molecules in plants and/or in attracting parasitic wasps.

systemic acquired resistance Self-defense mechanism induced by pathogen infection that initiates the systemic production of pathogenesis-related proteins, leading to broad resistance against pathogens.

tritrophic interactions Relationships involving species at three different trophic levels within an ecosystem. In the case of jasmonates, these interactions involve wounded plants, herbivorous insect larvae, and parasitic wasps.

Juvenile Hormone Action in Insect Development

KIYOSHI HIRUMA
University of Washington

Insect development is under the control of two hormones, ecdysone and juvenile hormone. Juvenile hormone is a sesquiterpenoid molecule that modulates ecdysone action and functions in prevention of adult differentiation, retention of larval structures, and regulation of ovarian maturation.

I. INTRODUCTION

Juvenile hormone (JH), a regulator of insect development, is synthesized and released by the glandular corpora allata. α-Ecdysone (E) and its precursor are synthesized by the prothoracic glands following stimulation by prothoracicotropic hormone (PTTH), which is produced by neurosecretory cells in the brain and is released from their terminals either in the corpora cardiaca or in the corpora allata in the Lepidoptera. The discussion here focuses on the role of JH in insect development, with particular emphasis on the Lepidoptera, in which this role has been well studied.

The activity of the corpora allata is regulated by humoral factors such as allatotropin and allatostatin as well as by nervous connections. In addition to having multiple functions in blocking adult differentiation, retaining larval structures, and regulating ovarian maturation, JH is a key player for phase

polymorphism in armyworms, aphids, and locusts, and for caste differentiation in termites and ants. Molting is caused by 20-hydroxyecdysone (20E). The action of JH on development is always associated with ecdysone action. JH does not prevent ecdysone action in inducing the molt, but modulates its action. JH in the hemolymph usually binds to the hemolymph JH-binding protein, so that it is protected from metabolism by the general esterases.

II. JUVENILE HORMONE TITERS AND POSTEMBRYONIC DEVELOPMENT

JH is present in the hemolymph throughout the larval (nymphal) life, through the penultimate instar, and its presence causes a larval (nymphal) molt when the 20E titer increases. In the insect subclass Hemimetabola, JH is absent during adult development in the last instar nymph. Its role in the regulation of pupation in the Holometabola is much more complicated (Fig. 1).

A. Hemimetabola

In the cockroach, *Nauphoeta cinerea*, nymphal molts occur when the ecdysteroid titer rises in the presence of JH (Fig. 1). JH application between 5 and 10 days after this ecdysis causes a supernumerary nymphal molt instead of the nymphal–adult molt. Therefore, JH must be absent during the critical period if there is to be a normal transformation to the adult stage. Subsequent exposure to the high level of 20E seen before the adult ecdysis is required for the actual adult development.

B. Holometabola

1. Larval Molt

In the lepidopteran the tobacco hornworm, *Manduca sexta*, rising ecdysteroid titers in the presence of JH cause a larval molt, and the critical period for the presence of JH is at the initiation of the ecdysteroid rise. When the corpora allata are removed from the larva before the critical period of JH for molting (Fig. 1), the larva skips the fifth instar and pupates precociously. The application of JH to the allatectomized larva restores the larval molt, indicating that JH is necessary for this molt.

2. Larval–Pupal Commitment

In the last instar *Manduca* larva, the JH titer declines precipitously because of the cessation of secretion of JH by the corpora allata and the increase of JH esterase activity (Fig. 1), which metabolizes JH to JH acid. JH becomes undetectable by 2 days after the last larval ecdysis. The high JH esterase activity on day 3 is important to remove the trace amount of JH from the hemolymph, allowing the brain to release PTTH. This PTTH is responsible for activation of the prothoracic gland so that it releases a small pulse of ecdysteroid on day 3 to day 4 (consisting of a mixture of α-ecdysone:20E in a 1:1 ratio). The 20E, acting in the absence of JH, causes larval–pupal commitment of the abdominal epidermis. Therefore, this small ecdysteroid peak is also called the commitment peak. In the epidermis, this is accompanied by loss of mRNAs for larval cuticle proteins and synthesis of new mRNAs. In addition, this small ecdysteroid pulse in the absence of JH causes the cessation of the feeding, followed by emptying of the gut contents, which causes the onset of wandering behavior. When a small amount of JH is applied before the peak occurs, the small peak does not appear until the applied JH degrades, and all the events mentioned above are delayed. When a large amount of JH is applied, the larvae molt to gigantic sixth instar larvae (supernumerary larvae). The application of JH during the peak gives rise to various larval–pupal intermediates, but JH has no effect on pupation when applied after the peak. Thus, the switching of the program of larval to pupal occurs during this small ecdysteroid peak in the absence of JH.

3. Pupal Molt

Pupally committed abdominal epidermis can no longer make larval cuticle even if exposed to JH, nor can it make pupal cuticle without exposure to high levels of ecdysteroid. Two days after the larval–pupal commitment of the epidermis and entry into the wandering stage in *Manduca*, there is an ecdysteroid surge along with that of JH (Fig. 1). This molting surge of ecdysteroid causes actual pupal differentiation. The corpora allata at this stage in *Manduca* synthesize and release JH acid, but peripheral tissues such as wing discs produce *O*-methyl transferase, which converts JH acid to JH. This JH is important in coordinating the development of various tissues for normal pupation; some of the tissues, such as wing discs and eyes, develop into adult structures if the JH is removed by allatectomy.

4. Adult Molt

Shortly after pupation in *Manduca*, there is a JH critical period that prevents adult development (Fig. 1). During this period, pupal–adult commitment is completed, probably by the small amount of

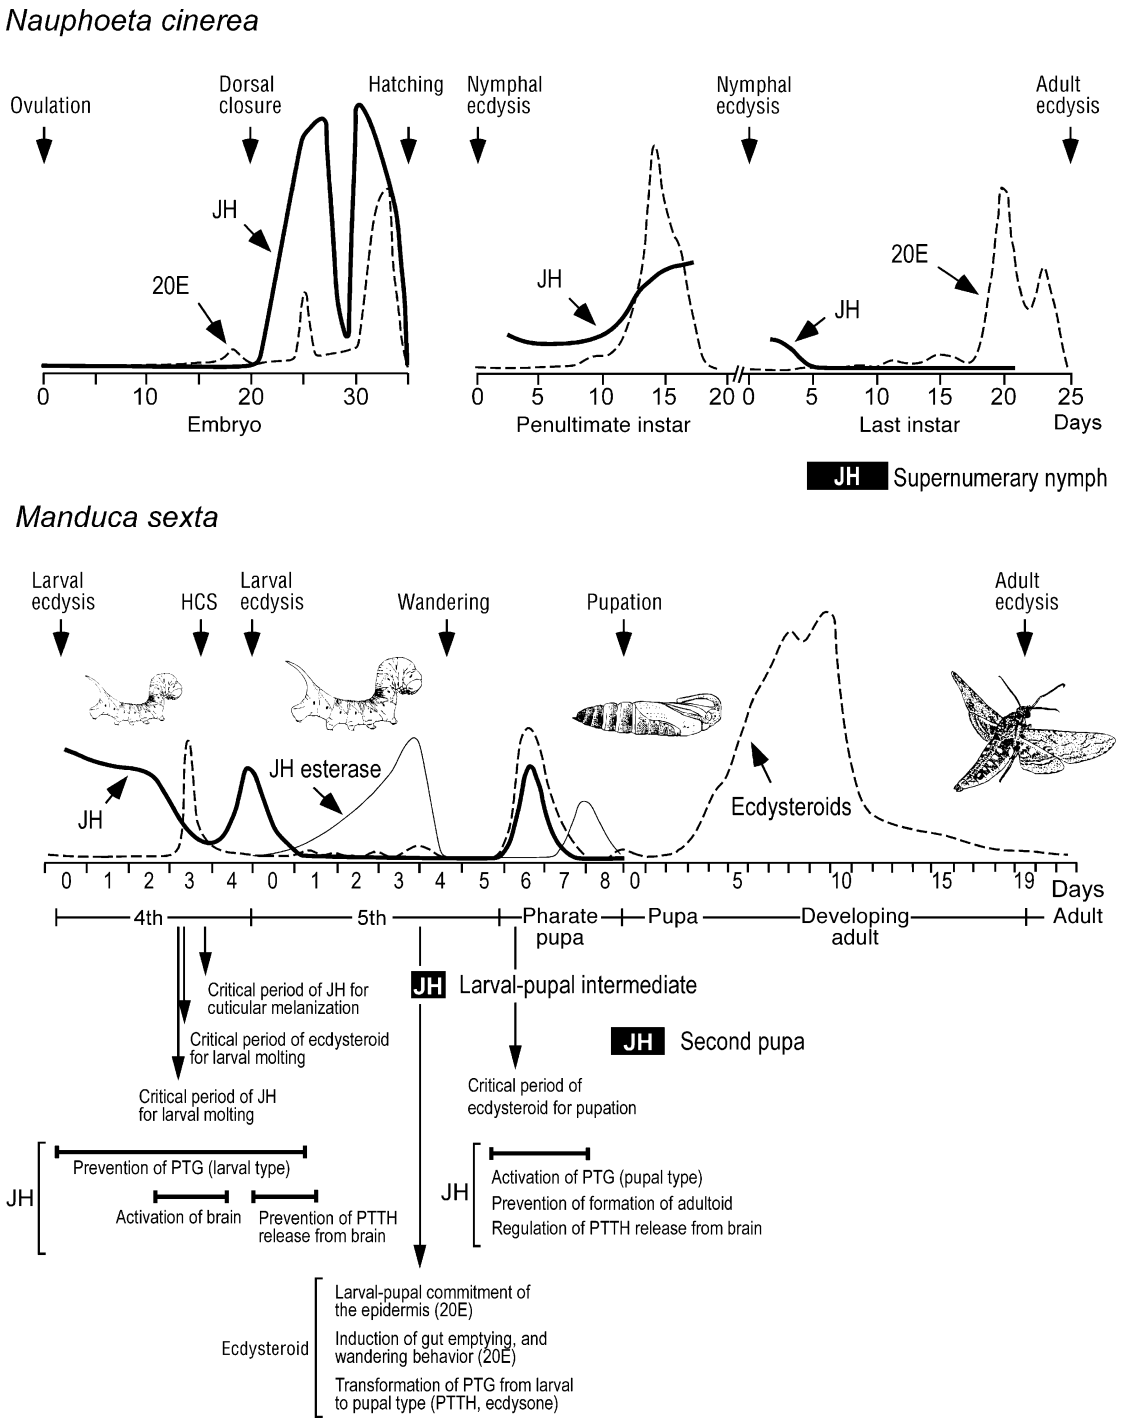

FIGURE 1 Schematic representation of juvenile hormone (JH) and ecdysteroid titers during development in Hemimetabola (*Nauphoeta cinerea*) and Holometabola (*Manduca sexta*), and various events that are caused by each hormone. All of the events in Holometabola are results from studies of both *Mamestra brassicae* and *M. sexta*. The horizontal black bars indicate the critical periods of JH for commitments. 20E, 20-Hydroxyecdysone; PTG, prothoracic gland; PTTH, prothoracicotropic hormone; HCS, head capsule slippage. Redrawn from Lanzrein *et al.* (1985), with permission.

ecdysteroid found at this stage in the absence of JH, and JH prevents this commitment process. After the commitment, the actual adult structures are made by the action of the subsequent ecdysteroid surge, 5 to 10 days after pupation.

III. LARVAL–PUPAL COMMITMENT OF VARIOUS TISSUES

In addition to abdominal epidermis, many other tissues commit to pupal development during the final instar stage. The timing of the pupal commitment and their mechanisms are different from tissue to tissues. In this section, some of the most well-studied representative tissues are discussed.

A. Wing Discs

The cells of imaginal discs, such as wing discs, proliferate throughout larval life; in the final instar they are committed to pupal development. The wing discs are usually pupally committed much earlier than the abdominal epidermis. Thus, when the final larvae are given JH to cause supernumerary larval molt, the resultant larvae very often contain wing discs, which have deposited pupal cuticle. This is because they have already become pupally committed by the time of the application of JH. The pupal commitment of some cells in wing discs of *Manduca* begins 12 to 18 h after the final ecdysis, and all the cells are pupally committed by day 3. The wing discs of the greater wax moth, *Galleria mellonella*, contain high levels of JH esterase activity early in the feeding stage of the last instar larvae, and this esterase breaks down the JH in the discs so that the pupal commitment of the wing discs occurs when the JH titer is declining. The detailed mechanisms of pupal commitment of the wing disc cells are still unknown.

B. Verson's Gland (Dermal Gland)

Dermal glands were first described in the silkworm, *Bombyx mori*, by Verson. Therefore, they are also called Verson's glands in Lepidoptera. They are epidermal derivatives. Verson's glands are composed of three cells (a large secretory cell, a saccule cell, and a duct cell),which are found in each segment and which secrete a cement layer over the epicuticle just at or after ecdysis. The secretory cell produces stage-specific proteins during larval and pupal molts. In *Manduca*, before pupal commitment (ability to make pupal proteins) of the secretory cell, exposure to JH acid in the presence of very small amount of ecdysteroid is required to cause the cells to become competent to commit to make pupal-specific proteins. The actual pupal commitment then occurs between 12 and 36 h after the final larval ecdysis during the decline of JH, possibly in response to a small amount of ecdysteroid. Thus, the cells become committed to pupal development earlier than the abdominal epidermis.

C. Crochet and Proleg

Crochets are tiny hooks on the tips of the prolegs of lepidopteran larvae; they are used to grasp the food plant and to prevent falling away from the stalk, leaf, flower, or fruit. After a larva finds its pupation site during the wandering stage, the prolegs and crochets are no longer necessary. They are larval-specific tissues composed of cells that are destined to die before pupation occurs. In *Manduca*, the crochet-forming cells die before the pupal commitment of the abdominal epidermis, coincident with the decline of JH titer. Because of this earlier commitment, some supernumerary larvae do not have their crochets.

The prolegs are controlled by a set of retractor muscles, the largest of which is the principal planta retractor muscle (PPRM). The PPRM is driven by the PPR motoneuron, but the fate of the PPRM is not influenced by interactions with the PPR, as evidenced by the fact that denervation does not cause its degeneration. Both PPR and PPRM die in response to the molting surge of ecdysteroid, but they are committed to die, at the same time as the larval–pupal commitment of the abdominal epidermis, by ecdysteroid acting in the absence of JH.

IV. ACTION OF JUVENILE HORMONE ON ENDOCRINE SYSTEMS

JH not only modulates ecdysone action on various tissues, but also affects the activities of other endocrine organs that are responsible for molting and metamorphosis—in particular, the brain and the prothoracic gland.

A. Larval Molt

The prolonged high JH titer seen during the penultimate larval instar (Fig. 1) is necessary to cause an increase in ecdysteroid titer at a proper time in both hemimetabolous (*Rhodnius prolixus*) and holometabolous (*Mamestra* and *Manduca*) insects. When JH is removed by allatectomy, the large molting surges of ecdysteroid are drastically depressed, but the application of JH restores these surges. In *Mamestra*, JH apparently activates the brain to synthesize and/

or release PTTH, which then stimulates ecdysteroid synthesis and release by the prothoracic glands.

B. Larval–Pupal Commitment

After the last larval ecdysis, the nature of the brain and prothoracic gland changes dramatically. During the feeding stage in *Manduca*, the secretion of PTTH is strongly inhibited by JH and growth continues if JH is present. Therefore, the decline of JH is important for the brain to release PTTH, which is responsible for the commitment peak of ecdysteroid. This commitment peak does not appear until JH disappears completely. The signal for the decline of JH depends on the weight of the larvae, but the means of recognition of the critical weight is unknown.

After exposure of the commitment peak of ecdysteroid, the responsiveness of prothoracic glands to JH dramatically changes in *Mamestra*, *Manduca*, and *Spodoptera littoralis*. The prothoracic glands before this exposure are inhibited by JH (larval type), but afterward they are activated by JH (pupal type). In *Mamestra*, this transformation is caused by PTTH, which is responsible for the commitment peak and/or α-ecdysone from the prothoracic glands in the absence of JH. Unlike PTTH, the stimulatory action of JH on prothoracic glands appears to be indirect. In *Manduca*, JH causes the fat body to produce a hemolymph protein that enhances the production of ecdysteroids by the prothoracic glands.

C. Pupal Molt

During the pupal molt, JH plays an important role not only for normal pupation but also for the timing of pupation. The removal of this JH by allatectomy delays pupal ecdysis by a day or so in both *Mamestra* and *Manduca*. Because the molting-peak ecdysteroid is also delayed under these conditions, the reappearance of JH at this time is likely important in conjunction with environmental signals that stimulate PTTH release.

V. ROLES OF JUVENILE HORMONE IN EMBRYONIC DEVELOPMENT

Both ecdysteroids and JH are found in freshly laid eggs in the locust, *Locusta migratoria*. The ecdysteroids are inactive conjugates; at times corresponding to the early embryonic molts, these inactive conjugates are converted to 20E and other metabolites. The later ecdysteroid surges are likely a result of the prothoracic glands of the embryo. The JH is wiped out by the JH esterases that appear with the onset of embryonic development, then JH reappears late in embryogenesis, when it is secreted by the embryonic corpora allata. In *Nauphoeta*, two surges of JH appear shortly after dorsal closure (Fig. 1). Application of precocene to destroy the corpora allata of *Nauphoeta* embryos leads to a delay in development, reduced pigmentation of the mandibles and leg bristles, and defects in gut formation, thus the JH in late embryogenesis is necessary for normal development. JH application restores normal development.

JH mimetics applied to insect eggs during early embryogenesis in most insects cause disruption of blastokinesis (the movement of the embryo within the egg so that its dorsal surface is toward the egg shell; more properly known as katatrepsis) and often cause defects in dorsal closure. In the Hemimetabola, such as the locust, the presence of JH at the time of katatrepsis, when JH is not normally present, also causes premature termination of patterning, suppression of growth, and precocious differentiation of the nymphal stage. In the Holometabola, as exemplified by lepidopterans, despite the effect of JH on blastokinesis, there is little effect on growth and differentiation. This lack of effect of applied JH is thought to be due to the earlier appearance of JH during katatrepsis in these embryos. These effects of JH and other considerations have led Truman and Riddiford to hypothesize that during the evolution of complete metamorphosis, the embryos of holometabolous insects showed an advancement in the timing of JH secretion by the embryonic corpora allata. The resultant alteration in tissue patterning and precocious differentiation was then important for the evolution of the novel form of the larva.

VI. DIAPAUSE

Many insects enter diapause at different stages; entry is triggered by environmental cues such as temperature, day length, and humidity. During diapause, the normal progression of growth ceases, yet diapause is not a simple arrest of development, but is an alternative developmental pathway. Usually, diapausing insects are physiologically and biochemically different from the nondiapausing individuals. The programming of diapause is also under the control of hormones. The embryonic diapause in *Bombyx* is induced by a subesophageal ganglion diapause hormone that acts on the ovarioles of females during egg maturation, and the females lay diapausing eggs.

Pupal diapause is caused by arrest of PTTH release, so that the prothoracic glands are not stimulated. JH is a key player in larval and adult diapause. Adult diapause is characterized by the halt of reproduction and is basically due to the cessation of secretion of JH by the corpora allata.

Diapause in last-instar lepidopteran larvae has been well studied. In both the rice stem borer, *Chilo suppressalis*, and the southwestern corn borer, *Diatraea grandiosella*, the JH titer in the hemolymph is high during the diapause, which not only induces diapause but also maintains its status. In addition, the prothoracic glands seem to be inactive. Allatectomy breaks larval diapause and the larvae pupate within 30 days. Larval diapause is artificially induced by the application of JH in these species. In *Diatraea*, the fat body synthesizes a diapause-associated protein in prediapausing and diapausing larvae with high JH titers. This protein has a high affinity for JH, so it may function as a JH carrier protein; furthermore, it is induced by JH application in nondiapausing larvae. A high JH titer also induces the prepupal diapause in the slug moth, *Monema flavescens*.

VII. MOLECULAR ACTIONS OF JUVENILE HORMONE

JH enters the larval epidermal cell in *Manduca* and one-third goes to the nucleus. Photoaffinity-labeled JH I, JH II, and methoprene (a JH mimic) bind to a 29 kDa protein that is found in the larval epidermis. This protein was once considered to be a JH receptor, but further studies have shown only a low-affinity binding protein. It has been reported recently that *Drosophila* ultraspiracle protein (USP) binds JH III and JH III bisepoxide with low affinity (about 4×10^{-7} *M*). JH III and methoprene cannot replace the bacterial phospholipid found in the ligand-binding pocket of recombinant USP, but JH I acid is predicted to fit into this pocket. However, no functional studies of the role of USP as a JH receptor have been reported. There are a number of reports regarding JH-binding proteins. Particularly interesting are the *methoprene-tolerant* (*Met*) gene in *Drosophila* mutants, which have an intracellular JH-binding protein with reduced JH-binding activity. The Met protein is found in the nucleus and has a high degree of similarity to the basic helix–loop–helix Per, Arnt, and Sim (PAS) domain family members. How this is related to JH action is not known. Null mutants show no defect in development, but have delayed and reduced vitellogenesis. Therefore, a JH receptor for insect development is still elusive.

A. Regulation of Cuticular Melanization

Larval pigmentation is under the control of JH in many insects, but there are not many studies at the molecular level. Normally, *Manduca* larvae have a transparent cuticle with black markings. Yet when JH is removed by allatectomy about 30 h before the last larval ecdysis, cuticular melanization occurs in the newly synthesized fifth instar larval cuticle and can be prevented by application of JH (Fig. 1). The melanin is dopamine melanin and is found in granules deposited to the cuticle. Accordingly, dopa decarboxylase (DDC) (converts dopa to dopamine) and granular phenoloxidase (PO) (oxidizes dopamine in the first step of the oxidative path to melanin) are crucial enzymes for this process.

In allatectomized melanizing larvae, the abdominal epidermis produces a granular pro-PO that is incorporated to the new cuticle in the premelanin granules. The pro-PO is later activated by the decline of ecdysteroid titer. The application of JH 25 to 30 h before ecdysis completely prevents the production of this enzyme (Fig. 2). DDC is essential for not only melanization but also for cuticular sclerotization, and its activity and its mRNA increase in response to the decline in the ecdysteroid titer. In allatectomized larvae, the levels are twofold higher than those in nonmelanizing normal larvae (Fig. 2). The excess dopamine is incorporated to the granules deposited in

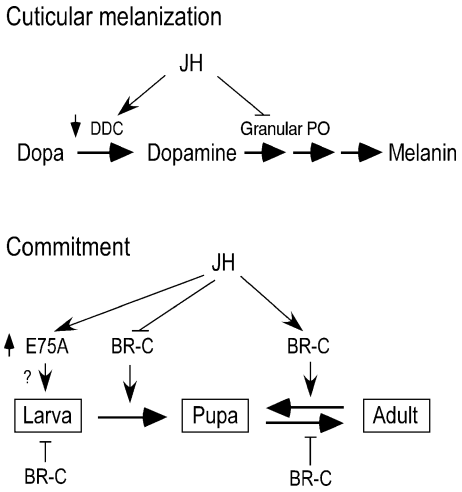

FIGURE 2 Models for molecular actions of juvenile hormone (JH). DDC, Dopa decarboxylase; PO, phenoloxidase; BR-C, broad complex; ↓, induction; ⊥, inhibition.

the cuticle, where activated granular PO is present, so that melanization occurs within the granules. The action of JH on DDC gene expression is thus to modify the amount of gene expression, as is also seen in E75A (see next section), rather than the suppression of new gene expression, as seen in granular PO. The mode of action of JH in both cases is unknown.

B. Regulation of the Ecdysone-Induced Transcription Factor Cascade

Most of the events caused by 20E are through the control of the ecdysone receptor (EcR), but EcR is an inactive receptor and it needs to partner with ultraspiracle protein to be functional. 20-Hydroxyecdysone enters the cells and then the nucleus, where EcR and USP are bound to the DNA. Once 20E binds to EcR, the 20E/EcR/USP complex directly activates the early genes [e.g., E75 and broad complex (BR-C)], the protein products of which in turn activate the late tissue-specific genes (e.g., L71 in the salivary gland) and inhibit the early genes.

Two to three isoforms of EcR and USP are known from various insects, and the receptor levels fluctuate with development. The primary role of JH in morphogenesis is to modulate the ecdysone action, and JH also modulates the ecdysone-inducible EcR and USP expression. Expression of both EcR and USP is up-regulated by 20E in a complex fashion. In the *Manduca* epidermis, the expression of all of the EcR (EcR-A and EcR-B1) and USP (USP-1 and USP-2) isoforms is induced by 20E, but JH prevents this action. The one exception is USP-2, which is unaffected by JH. JH is also known to prolong the half-life of both EcR-A and EcR-B1 proteins.

C. Larval–Pupal Commitment

In the ecdysone cascade, in addition to EcR and USP, JH affects the expression of a few other transcription factors. In *Manduca*, studies of the metamorphic role of these factors show that JH enhances the expression of one of the 20E-induced transcription factors, E75A, in larval epidermis, where it prevents pupal commitment of the epidermis, suggesting that a high titer of E75A is important for maintenance of the larval state (Fig. 2). Another 20E-induced transcription factor, BR-C, is expressed only from the time of pupal commitment through the time of pupation in both *Manduca* and *Drosophila*. In *Manduca*, the appearance of BR-C protein correlates with pupal commitment of the abdominal epidermis on day 3 of the final larval instar, and the prevention of pupal commitment by JH prevents BR-C expression both *in vivo* and *in vitro* (Fig. 2). Expression of BR-C in the abdominal epidermis occurs in a strict spatial pattern that coincides with the loss of the sensitivity to JH. Furthermore, once epidermis is exposed to 20E for 6 h, at which time BR-C mRNA is first detectable, JH can no longer prevent BR-C expression. Similarly, JH cannot prevent the pupal commitment once the cells are exposed to 20E, in the absence of JH, for more than 6 h. The appearance of BR-C mRNA in wing discs also correlates with their pupal commitment. Therefore, BR-C expression is one of the first molecular events underlying pupal commitment of both abdominal epidermis and wing discs. In addition, *Drosophila* mutants that lack BR-C entirely develop normally until metamorphosis, but die before pupation. These observations suggest that BR-C is a key factor for metamorphosis.

A recent breakthrough on the molecular mechanism of pupal commitment has been reported by Zhou and Riddiford, who clearly show in *Manduca* and *Drosophila* that BR-C is a pupal-specifying transcription factor (Fig. 2). Normally, BR-C is present during pupal cuticle formation but is not present during the adult molt. When JH is given just before or after pupal ecdysis in *Manduca*, BR-C mRNA is expressed during the production of a second pupal cuticle. This re-expression of BR-C mRNA can be also induced *in vitro* by exposing the pupal wing to 20E in the presence of JH. In *Drosophila*, the application of JH at pupariation causes the formation of a "pharate adult" with a normal adult head and thorax but a pupal-like abdomen. In these JH-treated insects, BR-C mRNA is re-expressed during adult development in the abdomen but not in the head and thorax. Moreover, pupal cuticle genes are re-expressed and an adult cuticle gene is suppressed in the JH-treated abdomen. These findings show that the abdominal cells are making a second pupal cuticle. The use of transgenic *Drosophila* carrying the various BR-C isoforms under a heat-shock promoter allows determination of the effects of misexpression of each of the four isoforms (Z1–Z4) on pupal cuticle production. Expression of the Z1 isoform at the onset of cuticle production induces re-expression of two pupal cuticle genes and reduces expression of an adult cuticle gene, causing the deposition of a second pupal cuticle. Unlike the JH-treated flies, this induction of a new pupal cuticle occurs in the head and thorax as well as in the abdomen. Interestingly, misexpression of the Z1 isoform during the second larval molt causes premature expression of a pupal cuticle gene and suppresses

expression of a larval cuticle gene. The other isoforms have similar effects on some, but not all, cuticle genes. These findings clearly show that BR-C is indeed a pupal-specifying transcription factor.

VIII. SUMMARY

JH has multiple functions, and a primary role of JH in insect development is to modulate ecdysone action. JH maintains the current commitment of the tissues and cells, whereas ecdysone causes both predifferentiative and differentiative cellular events that are necessary for the molt. Thus, when JH is present, a molt to a larval stage ensues. If JH is absent at the onset of the molt, metamorphosis occurs. Studies of the molecular mechanisms of JH action have been hampered by the failure to isolate its receptor(s). Recently, detailed studies of JH action have begun, and further studies should elucidate new aspects of the action of this unique molecule.

Glossary

allatectomy Removal of the corpora allata, the source of insect juvenile hormone.

allatostatin Neuropeptide that inhibits the biosynthesis of juvenile hormone by the corpora allata.

allatotropin Neuropeptide that activates the biosynthesis of juvenile hormone by the corpora allata.

commitment Capability of the cell to enter a particular stage-specific differentiative program that is elicited during an insect molt. For example, if the epidermis is pupally committed, the epidermis can no longer make larval cuticle, but requires 20E to make actual pupal cuticle.

corpus allatum Gland that synthesizes juvenile hormone.

ecdysis Process of shedding the old cuticle.

ecdysone Generic term denoting the biologically active ecdysteroids that initiate and coordinate an insect molt.

ecdysteroids Compounds in which the steroid nucleus bears a cis-fused A/B ring junction, a 7-ene-6-one chromophore, and a 14α-OH.

Hemimetabola Insect subclass in which insects go through several nymphal stages, then molt directly to the adult stage.

Holometabola Insect subclass in which insects have a pupal stage in their life cycle. There usually are several larval stages followed by a pupal stage, then the adult stage.

20-hydroxyecdysone Biologically active ecdysteroid that induces molting and metamorphosis.

juvenile hormone Sesquiterpenoid compound in insects that has multiple functions, such as the prevention of adult differentiation, the retention of larval structures, and the regulation of ovarian maturation.

molting Process of producing a new cuticle and culminating in ecdysis.

prothoracic gland Tissue that synthesizes ecdysteroids; located mainly in the prothoracic segment in Lepidoptera.

prothoracicotropic hormone Neuropeptide that stimulates prothoracic glands to synthesize ecdysteroids.

transcription factor Protein that regulates the transcription of a gene.

evolutionarily conserved regions. Current conclusions remain, however, tentative, because of the limited number of sequences available.

IV. VITELLOGENESIS

All insects make yolky eggs via the incorporation of the precursor Vg. In the majority of species, Vg synthesis is controlled by JH, and Vg uptake by the oocytes may also be under JH control. In species such as the mosquito *Aedes aegypti*, however, ecdysone appears to be one of the essential hormones that drives this process. In a few species of moths, on the other hand, such as *Bombyx mori* or *Hyalophora cecropia*, vitellogenesis appears to occur without any involvement of known hormones.

Endocrine control of vitellogenesis was first shown for the blood-sucking bug *Rhodnius prolixus* by Wigglesworth through ingeniously designed operations and manipulations based on the biology of this insect. Wigglesworth determined that the corpus allatum, located posterior to the brain, is activated and liberates a gonadotropic hormone following the essential blood meal. Subsequent to this first report, many insect species of several orders had been found to require the corpora allata for egg growth, i.e., vitellogenesis. For several decades the research centered around the brain-controlled corpus allatum activation and/or inhibition; basically, this required the surgical removal and reimplantation of the corpora allata as well as specific brain surgery and the manipulation of environmental conditions such as photoperiods, rearing temperatures or observed mating routines. Then, with the availability of the pure JH, it became feasible to begin an analysis of the details of how this hormone actually may act in the promotion of egg growth. It was shown in 1969 that JH is primarily involved in the *de novo* synthesis of the yolk precursor Vg in the cockroach *Leucophaea maderae*. All species that rely on the corpora allata for egg growth were subsequently found to produce Vg when treated with JH or JH analogues.

Vgs are synthesized on the endoplasmic reticulum (ER) of the fat body as exportable proteins. JH stimulates the incorporation of phospholipids into the ER and thus augments the quantity of ER and the number of available binding sites for the Vg polysomes in the cockroach *L. maderae*. The effect of this augmentation of polysome binding sites is intuitively seen in the increased rate of production of Vg and consequent increase in egg production. Similar observations were made in a few additional species, and it can be assumed that JH-stimulated ER proliferation is a common phenomenon in conjunction with Vg synthesis.

Vg is a *de novo*-synthesized macromolecule under control of JH. Consequently, it is possible to postulate that this hormone is involved in the control of transcription of the Vg gene in the target tissues. Vg mRNAs have been isolated from a few insect species that depend on JH. We assume that the model for transcriptional control of specific protein synthesis, developed for the steroid hormones, is applicable for JH. The search for the presumptive JH receptor has, however, not yet yielded a molecule that could unequivocally qualify for a receptor.

V. OTHER JUVENILE HORMONE ACTIONS

A. Stimulation of Lipophorin Synthesis

The hemolymph protein lipophorin (Lp) is a lipid carrier and functions in the shuttle of lipid reserves between storage sites and flight muscles in flying locusts. It is also known for several insect species that Lp binds lipophilic JH with high affinity, acts as a hormone carrier, and even "protects" the hormone from degradation by circulating JH esterases. The role of lipophorin in facilitation of JH uptake by the target tissues has been discussed, but concrete evidence is not available. Furthermore, JH stimulates an ongoing Lp synthesis and thus augments the titer of Lp in circulation in adult females of the cockroach *L. maderae* and presumably in other species as well. This is presumably beneficial, because more JH molecules can now be sequestered and removed from circulation and thus may serve to increase the half-life of the available JH. A small amount of Lp enters the growing oocytes (presumably nonspecifically) during vitellogenesis and thus contributes to the protein reserves in the egg.

B. Vg Uptake by Oocytes

Throughout the past two decades, there have been anecdotal reports in the literature on JH-stimulated incorporation of Vg into oocytes. Most of these reports rely on correlative observations. Recently, however, reports on a few insect species have provided evidence that Vg uptake by oocytes occurs via receptor-mediated endocytosis that requires the presence of JH.

C. Courtship Behavior

Reproduction in bisexual species often requires mating. Intuitively, it is assumed that courtship behavior is endocrinologically controlled. Numerous correlative lines of evidence that this might be so can be found in early literature. The first experimental evidence that JH is involved in the development of female receptivity was provided by Engelmann in 1960 for the cockroach *L. maderae*. Similar findings have been reported subsequently for other species, and it has been shown that courtship behavior of females and males may be influenced by hormones. Hormones, such as JH, may directly act on the central nervous system, resulting in modified behavior, or may stimulate the production of sex-attractant pheromones that are perceived by the opposite sex. However, it cannot be generalized that this applies to all species and it is reported that JH, for example, may not have any role in courtship behavior in a number of investigated species.

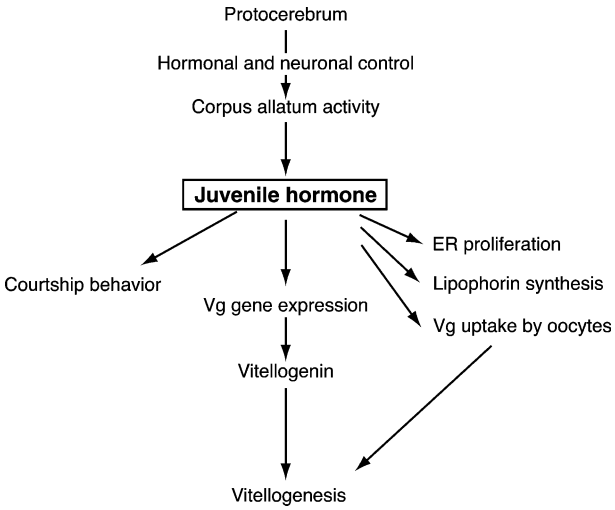

FIGURE 2 Scheme for the central role of juvenile hormone in insect vitellogenesis. ER, Endoplasmic reticulum; Vg, vitellogenin.

VI. SYNERGISM

In species that rely on the presence of JH for vitellogenesis, it is found that this hormone participates in a multiplicity of detailed events, all of which lead synergistically to the production of a mature yolky egg (Fig. 2).

The brain ultimately controls the activity of the corpora allata via hormonal and neuronal pathways, depending on the species and environmental conditions. Control of transcription of the Vg gene is an all-or-none event. The precise details of this process are currently not fully understood. Other aspects of JH involvement in vitellogenesis mostly entail the enhancement of ongoing events.

Glossary

fat body The tissue in insects that is the equivalent of the vertebrate liver.

juvenile hormone Sesquiterpenoid molecules that facilitate retention of juvenile characteristics in larval and nymphal insects and thus prevent metamorphosis. The identical molecules function as gonadotropic hormones in the majority of adult insects by promoting the production of the yolk protein precursor, vitellogenin.

lipophorin A circulating macromolecular protein with a lipid moiety of 10–30%. It functions in transport of lipids and binds and transports juvenile hormone.

vitellin The predominant yolk protein of the eggs. It is immunologically identical to vitellogenin [vitellus (L) = the yolk of the egg].

vitellogenesis Refers to the making of a yolky egg, a process that primarily involves incorporation of vitellogenin into the oocytes and results in production of the complete and mature egg.

vitellogenin A macromolecular protein of the hemolymph. It is the precursor to the major yolk protein vitellin.

Juvenile Hormone Biosynthesis

STEPHANIE SEN, SARA JULL, AND REBECCA WHELCHEL
Indiana University/Purdue University

Several chemically diverse hormones have been implicated in controlling insect development. Of these, one of the most widely studied is the sesquiterpenoid juvenile hormone. The insect order Lepidoptera, which includes all moths and butterflies, is unique in that it produces several homologous juvenile hormones, and the order Diptera produces another derivative.

I. INTRODUCTION

Sesquiterpenoid juvenile hormones (JHs) are neuroendocrine gland products found in insects. The most common chemical form is JH III (Fig. 1); however, the insect order Lepidoptera also produces homologous JH structures, including JH 0, methyl-JH I, JH I, and JH II. An additional JH, JHB_3, which is the C6,7-epoxy derivative of JH III, has been found in the order Diptera. Homologous juvenile hormones are unique structures found only in insects, whereas JH III has been detected in two plant species and the corresponding desoxyderivative of JH III, methyl farnesoate, is an important hormone of crustacea.

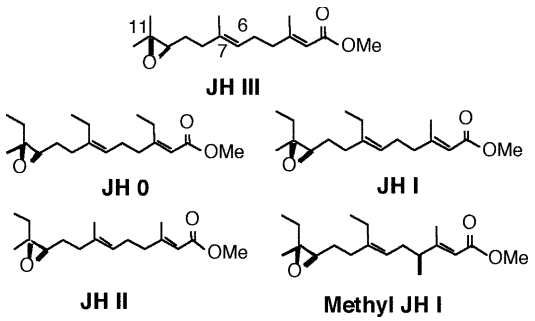

FIGURE 1 Juvenile hormone (JH) structures.

JH biosynthesis is localized within the paired neuroendocrine gland, the corpus allatum (CA). Once made, the hormone is immediately secreted into the hemolymph for delivery to target tissues. An exception to this scheme is found in the male moths *Hyalophora cecropia* and *Manduca sexta*; these animals secrete the acid form of JH from the CA and subsequently make the methyl ester within their accessory gland. Although metabolic localization should simplify the task of identifying the enzymes involved in JH biosynthesis, the corpus allatum gland is minuscule and therefore conventional enzymological techniques are usually impractical.

Both the amounts and the specific structures of JHs produced by an insect species represent a highly orchestrated event. An example of this is seen in the sphinx moth, *M. sexta*. This insect makes JH III and all known homologues, but not all at the same time—the embryonic stage makes JH 0 and methyl-JH I, the larval stages make JH I and JH II, and the adult stage makes JH II and JH III. Because of this complexity, it can be concluded that JH biosynthesis is regulated and that the enzymes involved in JH formation may have unusual substrate specificity. Despite the fact that researchers have been studying JH metabolism for over half a century, there remain significant gaps in our understanding of this important biosynthetic pathway.

II. CARBON SOURCES FOR JH BIOSYNTHESIS

Because all juvenile hormone structures are terpenoid in nature, it is reasonable to suppose that these compounds could be derived from the mevalonic acid (MVA) pathway. Initial studies focused only on confirming this hypothesis, and establishing the existence of alternate pathways, such as methylation of JH III to generate the various JH homologues, did not occur.

A series of elegant *in vivo* and *in vitro* studies were performed utilizing the radiolabeled precursors [^{14}C]acetate, [^{14}C]propionate, [^{14}C]mevalonate, [^{3}H]homomevalonate, and [^{3}H]methionine. Degradative analysis of the metabolites formed indicated that JH III was appropriately labeled by acetate and mevalonate, that homomevalonate was precursor to JH homologues, and that [1-^{14}C]propionate was incorporated into JH I and JH II, the former being radiolabeled at both the C-7 and the C-11 positions. Importantly, L-methionine was incorporated only into the methyl ester moiety of the hormones, thereby establishing that acetyl coenzyme A (coA) and propionyl coA are the carbon sources for JH skeleton production in insects.

Acetyl coA is ubiquitous in nature and can be derived from a variety of metabolic precursors, including carbohydrates, lipids, and amino acids. Propionyl coA is likely to be derived from fewer sources, with metabolic candidates being odd-numbered fatty acid and branched-chain amino acid degradation products. The fact that insect hemolymph contains high concentrations of amino acids would support the latter being the primary source of propionate. Precursors of acetyl coA and propionyl coA have been identified in both lepidopterous and nonlepidopterous insects. Early studies showed that radioactively labeled glucose, valine, and isoleucine were all incorporated into the JH of moths. These results were elaborated on and it has been established that trehalose (a source of glucose) is sufficient to support JH biosynthesis in the cockroach, *Diploptera punctata*. Although amino acids were a poorer carbon source for JH III-producing insects, the order Lepidoptera was found to very efficiently metabolize the branched-chain amino acids isoleucine and valine. The former, which is degraded within the mitochondria to acetyl coA and propionyl coA, was sufficient to support the biosynthesis of JH in these insects. Further evaluation of insect amino acid metabolism indicated that transaminase activity is high in all tissues except the CA of nonlepidopterous insects. This fundamental difference is clearly critical to our understanding of why only lepidopteran insects make juvenile hormone homologues.

III. ENZYMES OF THE MEVALONIC ACID PATHWAY

All animals utilize the MVA pathway for biosynthesis of sterols and terpenes, thus insects are likely to utilize similar, if not the same, enzymes for the construction

of JH. Interestingly, although plants can make the mevalonate precursor isopentenyl diphosphate (IPP) from 2*C*-methyl erythritol-4-phosphate, they also make JH III exclusively from the MVA pathway.

As its name implies, the MVA pathway utilizes mevalonate (Mev) as an important biosynthetic intermediate. This compound is derived from the condensation of two molecules of acetyl coA followed by the condensation of acetoacetyl coA with another molecule of acetyl coA to produce hydroxymethylglutaryl coA (HMG coA) (Fig. 2). These reactions are catalyzed sequentially by the enzymes acetoacetyl coA thiolase and HMG coA synthase, which have been well characterized in a variety of (noninsect) organisms. Mevalonate is produced by the NADPH-dependent reduction of HMG coA by HMG coA reductase. This last step in mevalonate construction is considered to be the rate-limiting step for the MVA pathway. HMG coA reductase is regulated transcriptionally and translationally and its stability/activity are dependent on both phosphorylation and association with endogenous factors. Both sterol and nonsteroidal compounds have been implicated in regulating HMG coA reductase, including the terpenol farnesol, which is an important intermediate of JH biosynthesis.

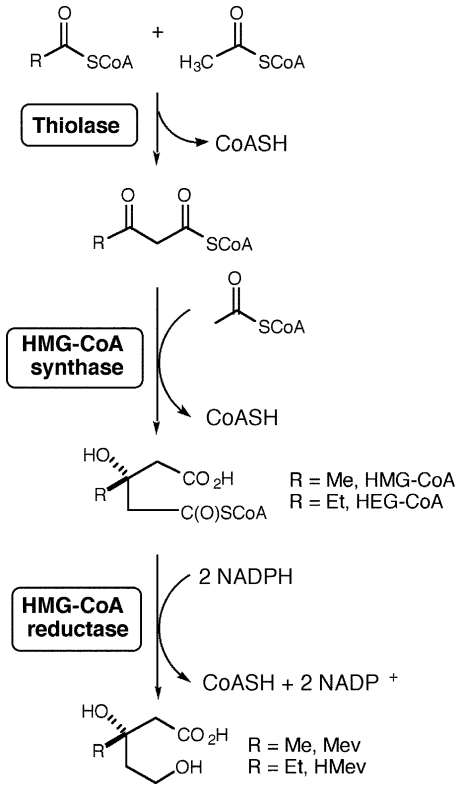

FIGURE 2 Acetoacetyl coenzyme A thiolase, hydroxymethylglutaryl (HMG) coA synthase, and HMG coA reductase.

Both acetoacetyl coA thiolase and HMG coA synthase have been identified in the biosynthesis of JH, although only the latter has been characterized extensively. Using radioactively labeled acetyl coA as substrate and relying on sequential thiolase and synthase activities, HMG coA was produced with corpora allata homogenates of several insect species. The apparent K_m for acetyl coA was 200 μM for *D. punctata* and 400 μM for *Locusta migratoria*. The synthase is strictly cytosolic, is activated by Mg^{2+}, and is inhibited by excess acetoacetyl coA.

Using acetyl coA and propionyl coA as substrates, the formation of both HMG coA and hydroxyethylglutaryl coA (HEG coA) was demonstrated. Compared to rat liver, insect CA homogenates produce more HEG coA, although the nonlepidopterous insect *Schistocerca nitens* made considerably more HEG coA than did the lepidopteran *M. sexta*. Enzyme activity did not parallel the rate of JH release in *D. punctata* and *L. migratoria*, and, for the latter, no loss of synthase activity was observed when the connection between CA and brain was severed. Although the sequence of the CA-specific synthase is not available, two HMG coA synthase (HMGS) genes have been identified in *Blattella germanica*. Both code for functional cytosolic proteins and share considerable sequence similarity with other known synthases. *Blattella germanica* HMGS-1 and HMGS-2 are expressed differentially within the insect and are coordinately regulated with HMG coA reductase in the fat body, but not in the ovaries.

HMG coA reductase (HMGR) has been studied using CA homogenates of several insect species. The enzyme, which is microsomal and requires detergent for activity, catalyzes the stereospecific reduction of (3*S*)-HMG coA to mevalonate using NADPH as cofactor and is inhibited by the anticholesteremic agent compactin. As seen with other HMGRs, activity is dependent on the enzyme's phosphorylation state, and phosphorylation of the reductase by an ATP-dependent kinase renders the enzyme inactive. As expected, the addition of ethylenediaminetetraacetic acid (EDTA) enhanced activity, whereas the addition of $MgCl_2$, ATP, or F^- was inhibitory. HMG coA reductase is most active near neutral pH. An HMGR that is transcribed in the CA of the moth *Agrotis ipsilon* has been recently cloned. The predicted molecular mass of the reductase is 90 kDa and it shows high sequence homology with other animal

HMGRs, including those of *Drosophila melanogaster* and *B. germanica*.

Despite these similarities, the HMG coA reductase of insect CA is different from related enzymes. Antibodies to rat HMGR did not cross-react with the corresponding enzyme in *D. punctata*, suggesting differences in the overall structure of the two animal enzymes. The substrate specificity of HMGR was studied by comparing the reduction of HMG coA to that of HEG coA. Insect HMGR reduced more HEG coA than did rat liver enzyme, although *S. nitens* CA, which produces only JH III, was better able to reduce the homologous substrate, compared to *M. sexta*. In vertebrates, HMGR regulates flux within the mevalonate pathway and is considered the rate-determining step of cholesterol biosynthesis. In contrast, JH does not appear to be regulated by changes in HMGR. Enzyme activity was found to be high at developmental stages that produce little to no JH, and HMGR activity was not modulated by the addition of mevalonate, mevinolin, or farnesol.

The conversion of mevalonate to IPP (Fig. 3) is catalyzed by three sequential ATP-dependent enzymes: mevalonate kinase, phosphomevalonate kinase, and mevalonate diphosphate (MPP) decarboxylase. In relation to JH biosynthesis, these enzymes have been poorly characterized, although studies with fluoromevalonate and the homologous substrate, homomevalonate (HMev), have demonstrated that

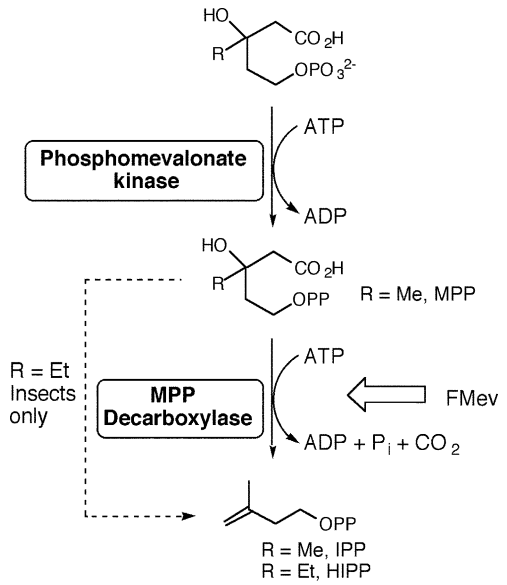

FIGURE 3 Isopentenyl diphosphate (IPP) formation from mevalonate. MPP, Mevalonate diphosphate; HIPP, homoisopentenyl diphosphate; FMev, fluoromevalonate.

there are distinct enzymological differences between insects and other animals. Fluoromevalonate (Fmev) functions as a selective lepidopteran JH antagonist by inhibiting the metabolism of both mevalonate and homomevalonate to JH. Although its precise mode of action is unknown, studies with yeast and rat liver MPP decarboxylase indicate that the compound is phosphorylated and that the corresponding 5-diphosphate derivative functions as the active inhibitor of MPP decarboxylation. The homologous substrate homomevalonate, which is converted to homoisopentenyl diphosphate in *Drosophila* K_c cells and is incorporated into homologous JH structures in Lepidoptera, does not undergo decarboxylation in rat liver and is decarboxylated at one-eighth the rate of MPP in yeast. As seen with each of the earlier steps in JH biosynthesis, it would appear that insect MPP decarboxylase is better able to utilize homologous substrates compared to the analogous noninsect enzymes.

Decarboxylation of MPP provides IPP, which represents the first isoprenoid intermediate of the mevalonate pathway. This compound functions as the building block for all subsequent terpenoid compounds, but to do so it must undergo double-bond isomerization to yield dimethylallyl diphosphate (DMAPP). This reaction is catalyzed by the enzyme IPP isomerase, which has been well characterized in vertebrates, bacteria, and yeast and has been identified in CA homogenates of *M. sexta* and *S. nitens*. The enzyme, which has high sequence homology between organisms, has a molecular mass of 35–40 kDa, requires divalent cations for activity, and possesses active site glutamic acid and cysteine residues that have been implicated in catalysis. The K_m of IPP is 20 μM with purified isomerase of *Bombyx mori*. Although previously considered a strictly cytosolic protein, recent studies in rat liver indicate that the enzyme may reside within the peroxisomes of eukaryotes.

In the context of homologue formation, the substrate homoisopentenyl diphosphate (HIPP) must be efficiently converted to both homodimethylallyl diphosphate (HDMAPP) and (*Z*)-3-methyl-2-pentenyl diphosphate in insects. Using IPP isomerase of pig liver (Fig. 4), (*Z*)-3-methyl-2-pentenyl diphosphate was the major product of HIPP isomerization, whereas only HDMAPP was formed when the reaction was performed with CA homogenates of adult female JH II- and JH III-producing *M. sexta* corpora allata. In the latter system, DMAPP was formed in nearly 10 times greater yield than HDMAPP. These results indicate that although IPP is the preferred substrate of insect

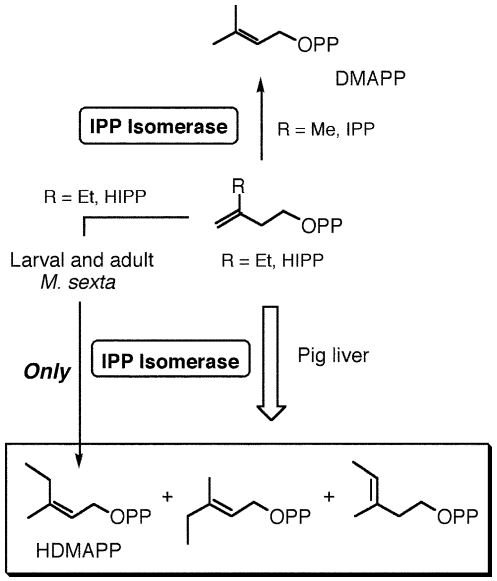

FIGURE 4 Isopentenyl diphosphate (IPP) isomerase of pig liver and *Manduca sexta*. HIPP, homoisopentenyl diphosphate; DMAPP, dimethylallyl diphosphate; HDMAPP, homodimethylallyl diphosphate.

IPP isomerase and methyl-JH I is derived from an isomerase that is similar to that of pig liver, all other JH homologues are derived from another, structurally distinct IPP isomerase.

Once allylic and nonallylic diphosphates are present within the metabolic pool, coupling of these structures will occur to yield the corresponding JH carbon skeletons. This reaction involves the action of a prenyltransferase enzyme, which is likely to be related to farnesyl diphosphate synthase (FPPSase, or FPS). FPS catalyzes the coupling of DMAPP with two molecules of IPP to form FPP as end-product and geranyl diphosphate (GPP) as a tightly bound intermediate (Fig. 5). This enzyme has been well studied in noninsect systems, and the crystal structure of recombinant avian FPS is known. FPSs share significant sequence homology, particularly within domains 2 and 5, which have been shown to possess catalytically important aspartate residues.

Initial studies have focused on the characterization of prenyltransferase from the entire body (minus the gut) of lediopteran insects. Two purified FPSs from *Bombyx mori* are known to posses distinct enzymological properties, including substrate K_m, preferred divalent metal cofactor, and activity in the presence of nonionic detergent. Only one of these synthases efficiently couples homologous substrates, although this activity is not the same as that derived from *M. sexta* CA homogenates. For the latter, a strong preference for the substrate HDMAPP was seen, and both homogeranyl diphosphate (HGPP) and bishomogeranyl diphosphate (BHGGP) were excellent substrates of the prenyltransferase. The intermediacy of (*Z*)-3-methyl-2-pentenyl diphosphate in the biosynthesis of methyl-JH I was established by preparing authentic hormone using purified FPS of pig liver to couple nonallylic substrate with BHGPP.

FPSs from *D. melanogaster*, *B. mori*, and *A. ipsilon* are known. All share significant sequence homology to other FPSs; however, the latter two, which are transcribed in the CA and in other insect tissues, are unusual in that the aspartate-rich region of domain 2 has been modified from DDXXD (X representing any amino acid) to NDIME. It remains to be determined whether the moth clones code for an active prenyltransferase and whether they are involved in JH biosynthesis.

Homologue studies using FPS of pig liver and pumpkin show loose specificity for homologous substrates, and in competition experiments, all possible geranyl- and farnesyl-type structures are formed in essentially equal quantities. Because lepidopteran insects strictly control the structure of JH homologue produced, it can be concluded that FPS related to JH biosynthesis is structurally different from other prenyltransferases.

IV. LATER STEPS IN JH BIOSYNTHESIS

Once the construction of the sesquiterpenoid diphosphate is completed, JH biosynthesis diverges from the mevalonic acid pathway. The last steps of hormone

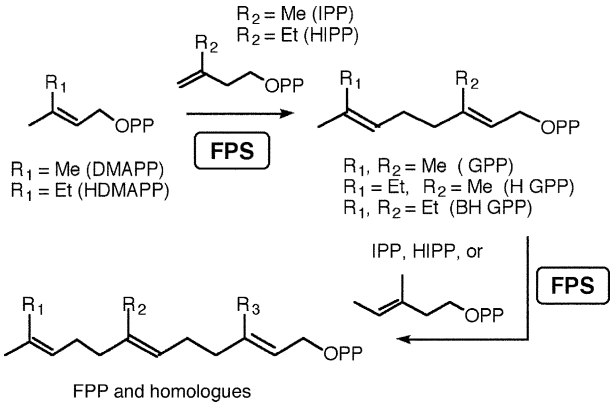

FIGURE 5 Formation of farnesyl diphosphate (FPP) by farnesyl diphosphate synthase (FPS). IPP, Isopentenyl diphosphate; HIPP, homoisopentenyl diphosphate; GPP, geranyl diphosphate; HGPP, homoGPP; BHGPP, bishomoGPP; DMAPP, dimethylallyl diphosphate; HDMAPP, homodimethylallyl diphosphate.

construction involve diphosphate hydrolysis, oxidation at C-1 to yield carboxylic acid, epoxidation of the terminal olefin, and methylation of the acid moiety. The order of methylation and epoxidation appears to be species specific. Lepidopteran insects prepare and methylate JH acid, whereas orthopteran and dictyopteran insects convert methyl farnesoate to JH.

The conversion of FPP to farnesol is mediated by the action of phosphatase. Because there is significant phosphatase activity in CA homogenates, it is likely that the enzymes that perform this conversion are nonspecific. From isoelectric focusing studies on larval CA homogenates, it appears that the bulk of the endogenous phosphatase activity has a pH close to neutral. In comparing the hydrolysis of IPP versus HIPP, both are converted to alcohol with similar efficiency, but HIPP is more slowly hydrolyzed to product, as would be expected given its hydrophobicity.

It is known that both farnesol and farnesoic acid (FA) are precursors to JH III, thus initial studies focused on determining how this oxidation occurred. Incubation of larval and adult *M. sexta* CA homogenates with radioactively labeled farnesol yielded significant quantities of farnesal (Fig. 6). Furthermore, inclusion of the redox cofactor nicotinamide adenine dinucleotide (NAD^+) caused a significant increase in farnesoic acid production. Although activities leading to formation of aldehyde and acid were found in mitochondrial, cytosolic, and, to a lesser extent, microsomal locations of adult CA cells, the conversion of farnesol to farnesal was localized in the cytosolic fraction of larval *M. sexta* CA homogenates. The aldehyde-forming activity, which has an apparent K_m of 1 μM for farnesol, was selectively

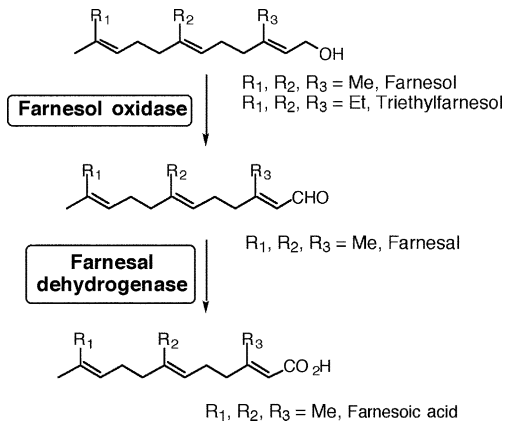

FIGURE 6 Farnesol oxidase and farnesal dehydrogenase.

inhibited by the active-site titrant tetranitromethane. It was not stimulated by the addition of NAD^+, and instead required oxygen for activity. It can be inferred from these studies that two enzymes are required for the conversion of farnesol to FA and that they are formally an alcohol oxidase and aldehyde dehydrogenase, respectively.

The substrate specificity of farnesol oxidase (formally referred to in the literature as farnesol dehydrogenase) has been investigated. Using *M. sexta* adult CA homogenates, geraniol was found to be efficiently oxidized to geranial but the (2Z)-isomer of farnesol and of geraniol (i.e., nerol) was not. Further studies with *M. sexta* larval and adult CA homogenates show that the minimum substrate requirements are a trans-1° allylic alcohol that bears a hydrophobic tail. In comparing the ability of homologous farnesol structures to inhibit farnesol metabolism, it was found that substitution of methyl for ethyl at C-3 caused loss of inhibitory activity. Additionally, metabolism studies indicated that triethylfarnesol (precursor to JH 0) was not efficiently oxidized.

As previously stated, the order of the last two steps in JH biosynthesis is species dependent. In Lepidoptera, epoxidation precedes methylation; interestingly, both *H. cecropia* and *M. sexta* male moths lack JH acid *O*-methyltransferase activity in the CA. In *L. migratoria*, *Blaberus giganteus*, and *P. americana* CA homogenates, FA was found to be a poor substrate of the epoxidase and a buildup of methyl farnesoate (MF) was observed. From these studies it is inferred that it is in another biosynthetic pathway of orthopteran and dictyopteran insects that the MF is formed and subsequently epoxidized to JH III. This would also imply the presence of distinct FA *O*-methyltransferase and JH acid *O*-methyltransferase enzymes.

Both of the *O*-methyltransferases are cytosolic proteins and require *S*-adenosylmethionine (SAM) as cosubstrate. Because of its high polarity and impermeability to cell membrane, SAM must be replaced by L-methionine in whole-gland assays. Typically, high concentrations of L-methionine (200–300 μM) are needed, but *D. punctata* efficiently methylates FA with 10 times lower concentrations, indicating either a more efficient *O*-methyltransferase or methionine adenosine transferase.

In studies concerning the methylation of various carboxylic acids, differences in substrate specificity were observed for the two *O*-methyltransferases. JH acid *O*-methyltransferase of *H. cecropia* appears to be more active toward homologous substrates; thus, racemic JH I acid was more efficiently methylated

than was JH II, and compared to JH I, there was only 15% incorporation of L-methionine into JH III. The enzyme also displayed enantioselectivity, whereby product analysis indicated a large preponderance of the 10R isomer (Fig. 7).

Several structure–activity relationship studies have been performed with locust FA *O*-methyltransferase. The enzyme shows more lax specificity than does the corresponding lepidopteran enzyme, in that a variety of FA and JH acid derivatives serve as substrates. An α,β-unsaturated carboxylic acid possessing a hydrophobic tail of at least two isoprene units appears sufficient for activity, and only electronic perturbation of the C-2, C-3 double bond is detrimental for activity. Because both enantiomers of JH III are efficiently methylated and bishomofarnesoic acid is as good a substrate as FA, the methyltransferase does not show the homologue specificity characteristic of the lepidopteran enzyme.

It appears that regulation of methyltransferase occurs late in the biosynthetic pathway. In *D. punctata*, FA *O*-methyltransferase activity was found to parallel JH titer levels in both the fourth larval stadium and the adult female CA glands. In

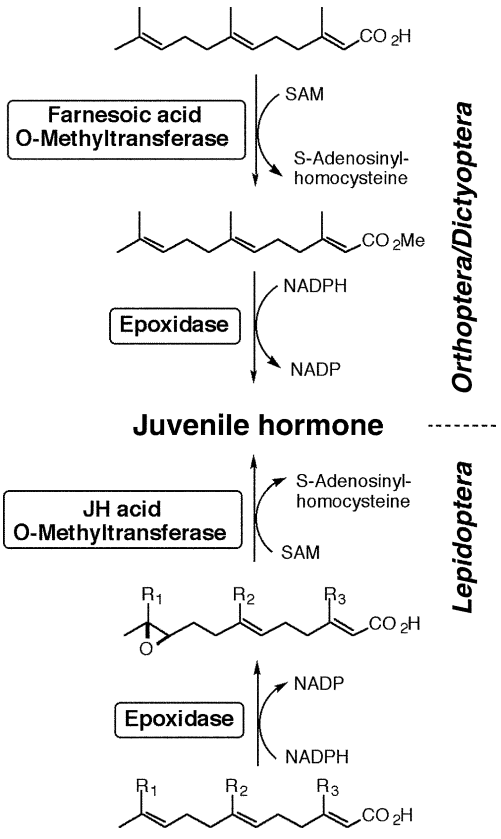

FIGURE 7 Epoxidase and *O*-methyltransferases.

Lepidoptera, methyltransferase activity disappears at the last larval stage such that only JH acid is formed before pupation. These results suggest that JH acid has a hormonal function and should be considered as an additional JH structure.

The epoxidation of FA or MF is mediated by a microsomal NADPH-dependent oxidase. Whether two distinct enzymes exist, as is the case for *O*-methyltransferase, is not known. The enzyme has been characterized in both locust and cockroach CA homogenates. In both cases, MF is the preferred substrate over FA, and the 10R epoxide isomer is formed exclusively. The enzyme is inactivated by a variety of mixed-function oxidase inhibitors, including piperonyl butoxide and methylene blue, and by the cytochrome P450 inhibitor, carbon monoxide. For the latter, activity was regained on white light treatment, as would be expected if photodissociation of CO from a heme center had occurred. Using *L. migratoria* CA homogenates, the apparent K_m for MF and NADPH was 7.7 and 2.6 μM, respectively. Because epoxidase activity comigrated with cytochrome *c* when separating the epoxidase from other endogenous proteins, it was proposed that the epoxidase is a P450 monooxygenase that requires cytochrome *c* (and therefore NADPH) as its redox cofactor.

The isolation of JHB_3 in Diptera indicates that further epoxidation of the C-6, C-7 olefin occurs; however, it is not known whether the same enzyme that is required for JH III biosynthesis is involved.

V. METABOLIC CONTROL OF JH BIOSYNTHESIS

Excluding pathways that involve the degradation of synthesized hormone, JH biosynthesis is regulated in several ways: (1) by changes in concentration of biosynthetic intermediates, (2) by the presence (or absence) of neuropeptides produced in the brain, (3) by modulations in neurotransmitter concentrations and their corresponding receptors, and (4) by changes in cellular ion concentrations. The latter two factors appear to provide a simple on/off switch for the CA, whereas the former two factors appear to effect specific metabolic events of JH biosynthesis.

In *D. punctata*, the addition of exogenous FA caused an increase in JH biosynthesis that was greater than would be expected from its simple incorporation into the metabolic pool. This stimulatory effect, known as FEAR, only occurs at certain stages of development and may therefore represent a biologically relevant feedback enhancement of JH biosyn-

thesis. Acetoacetyl coA was found to inhibit insect HMG coA synthase at low concentrations, and although its overall effect on JH biosynthesis is not know, it is reasonable to conclude that a buildup of this intermediate inhibits mevalonate synthesis. No other intermediates have been shown to cause a regulatory effect on JH biosynthesis, including farnesol, which is known to modulate the stability of HMGR in other organisms and is considered the nonsteroidal feedback inhibitor of the MVA pathway. Because insects lack the ability to make sterols (due to the absence of both squalene synthase and oxidosqualene cyclase), it would seem that these animals have developed an alternate regulatory mechanism for mevalonate synthesis.

The presence of allatostatin (inhibiting) and allatotropin (stimulating) neuropeptides is considered an important regulatory mechanism for JH biosynthesis. Although the mode of allatotropins is not known, the effect of allatostatins on JH biosynthesis in *D. punctata* has been elucidated. The allatostatic effect of the tridecapeptide APSGAQRLYGFGL (amide) was not due to inhibition of acetoacetyl thiolase, HMG coA synthase, or HMG coA reductase. Instead, the site of inhibition was found to be the site of transport of acetyl coA from the mitochondria to the cytosol—specifically, movement of citrate across the mitochondrial membrane and/or conversion of citrate to acetyl coA in the cytosol. Lepidopteran insects show different activity with regard to mitochondrial processing, thus it is not known whether a similar effect is seen in these insects.

VI. SUMMARY

Insects biosynthesize JH by a unique metabolic pathway that is a hybrid between the traditional MVA pathway and a unique insect-specific pathway. JH III and all of the JH homologues are formed in the same manner, although the latter utilize a combination of propionyl coA and acetyl coA as carbon source. Because insects do not make sterols, their ability to modulate the MVA portion of the JH biosynthetic pathway by oxysterols and by farnesol is compromised. Instead, it appears that control occurs earlier and involves the movement of carbon precursors from the mitochondria to the cytosol.

Glossary

homologue Compounds that have a similar core structure but have carbon skeletons that vary by one or more atoms.

juvenile hormone A group of structurally related sesquiterpenoids that are biosynthesized in insects and some plant species. In insects, these compounds control insect growth, development, and female fertility.

mevalonic acid pathway Biosynthetic pathway present in all organisms. Involves a group of enzymes responsible for the production of mevalonate, which is the universal intermediate in terpene metabolism.

Juvenile Hormones, Chemistry of

NOELLE A. GRANGER
University of North Carolina, Chapel Hill

The juvenile hormones are the predominant secretory products of the insect corpora allata, the two tiny glands located behind the insect brain. These versatile hormones inhibit metamorphosis during larval life and act as gonadotropic hormones in the adult, controlling ovarian development and vitellogenin synthesis. They play a role in caste determination in the social insects, in regulation of behavior in honeybee colonies, in polyphenisms of aphids and locusts, and in diapause regulation in larvae and adults.

I. INTRODUCTION

The juvenile hormones (JHs) are generally considered unique to insects and to a few plant species. They are neither steroid nor peptide, but rather possess an acyclic sesquiterpenoid skeleton. The different members of the JH family have methyl or ethyl groups at three branches of the carbon skeleton (C-3, C-6, and C-11) and may have two, rather than one, epoxide moieties (Fig. 1). This article provides an overview of the history of the chemical identification of the juvenile hormones, a description of the genesis of the carbon skeleton of the known members of the JH family, a discussion of the current dogma of JH activity, titers, and degradation, and an introduction to our knowledge of nontraditional JHs.

II. DISCOVERY OF THE CHEMICAL NATURE OF JUVENILE HORMONES

The existence of a juvenilizing factor was originally demonstrated in the mid 1930s by Wigglesworth, who used the term "juvenile hormone." The history of the chemistry of the JHs began in 1956, when Carroll Williams discovered that abdominal tissues of the male *Hyalophora cecropia* moth (Cecropia) contained large quantities of lipid with JH activity, which could easily be extracted into organic solvents. This enabled the isolation and identification of the principal Cecropia JH (now called JH I) by Röller and his colleagues in 1967, through interpretation of mass and spectral data and microchemistry, with tracking of the active moiety by bioassay. The basic structure of this hormone—methyl 10,11-epoxy-7-ethyl-3,11-dimethyl-2*E*,6-tridecadienoate—was confirmed by chemical synthesis. The stereochemistry of the oxirane ring and of the double bond at C-6 was subsequently established as being cis and trans, and Meyer and Hanzmann reported in 1970 that the natural hormone was not racemic. The absolute configurations at the chiral centers (C-10 and C-11) were established in 1971 as 10R, 11S (Fig. 1).

Very shortly after the publication of the structure of JH I, Meyer and his colleagues published the structure of a second Cecropia JH, one that existed in relatively smaller amounts and to which Röller had paid little attention because of its low activity in the bioassay being used. This was JH II, which is structurally identical to JH I with the exception of having a methyl group at C-7 instead of an ethyl group (Fig. 1).

The structure of the third JH, JH III, was elucidated in a different fashion. Rather than extracting large quantities of JH for chemical characterization, Judy *et al*. maintained *in vitro* adult female corpora allata from the tobacco hornworm, *Manduca sexta*, and radiolabeled the gland secretory products by the inclusion of methyl [^{14}C]methionine in the culture medium. Spectral, microchemical, and chromatographic methods revealed that this JH was a

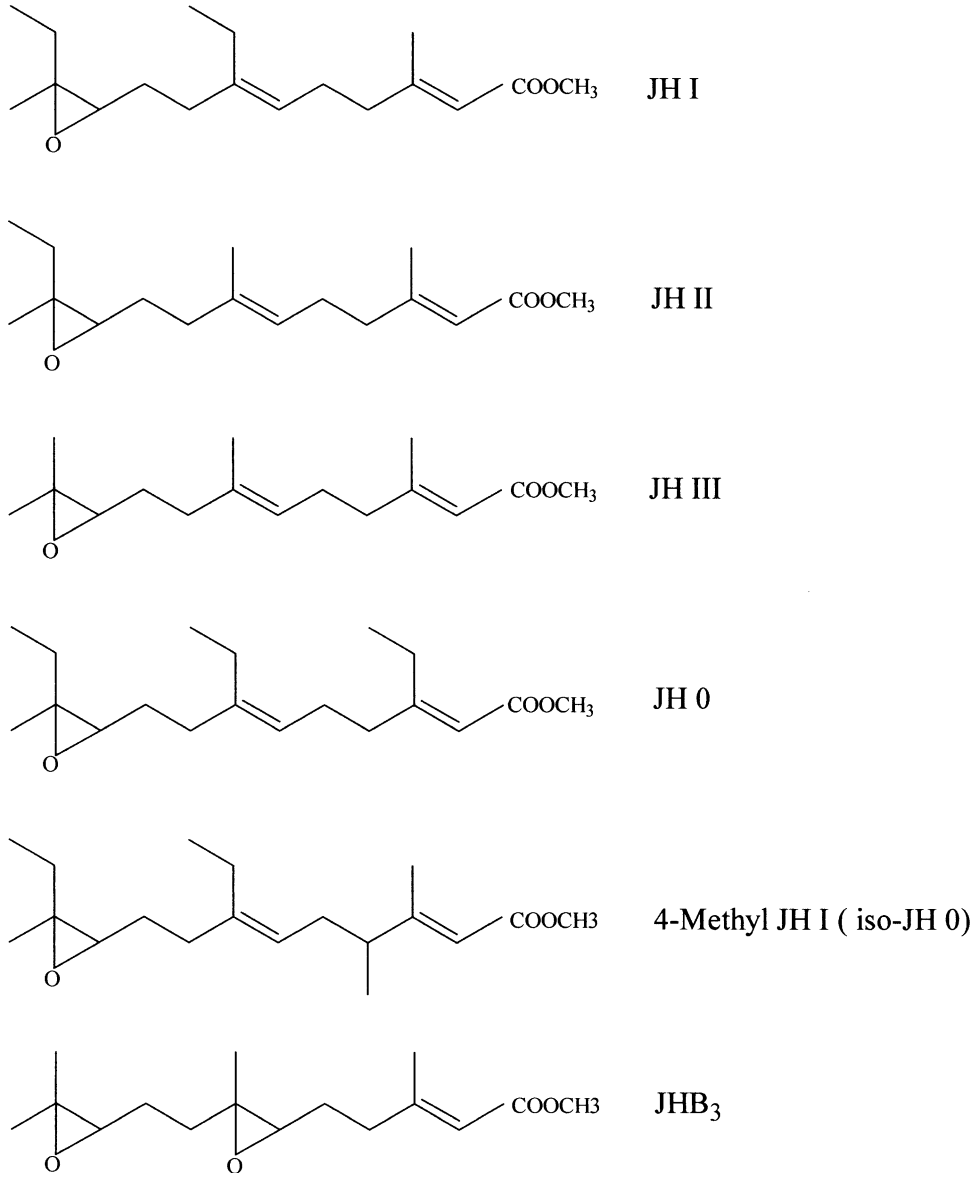

FIGURE 1 Structures of the juvenile hormones, in order of their discovery.

lower homologue of JH II, in which the three branches of the carbon skeleton at C-3, C-7, and C-11 are methyl groups (Fig. 1).

A trihomosesquiterpenoid, JH 0, and an isomer, 4-methyl JH I (iso-JH 0), were identified by Schooley and colleagues in the eggs of *Manduca*. Nothing is known of the functions of these two compounds. Most recently, an active JH bisepoxide (JHB_3) was isolated from incubations of larval ring glands of the fruit fly, *Drosophila melanogaster*, and was identified by chromatographic and gas chromatography/mass spectrometry (GC/MS) analysis (Fig. 1). JHB_3 elicits a response similar to that of JH III in a *Drosophila* bioassay and has been found in several other flies. However, because this homologue is not produced by mosquito corpora allata, JHB_3 may be a JH only in higher Diptera.

The JHs, as acyclic sesquiterpenoid epoxides, are highly unusual molecules. They have now been identified in approximately 100 insect species, representing at least 10 insect orders, although the existence of JHs in the most primitive insect orders (Protura and Diplura) has not yet been determined. JH III is the only, or the predominant, homologue in

most of the species in which JHs have been identified; the higher homologues (iso-JH 0, JH 0, JH I, and JH II) are found only in the more advanced insect orders. In these advanced orders, e.g., the Lepidoptera, different, multiple homologues can be found in the same insect at different times during development.

Plants contain a number of relatively nonpolar compounds that possess JH-like activity in insect bioassays. None of these compounds has been found to closely resemble the JHs in chemical structure, and most of these plant-derived JH mimics affect only a narrow range of insect species. There is only one report of the identification of JH III (and methyl farnesoate, a precursor to JH III; see Fig. 2) in plants, in the sedges *Cyperus iria* and *Cyperus aromaticus*.

III. JH BIOSYNTHESIS

JH III bears a strong structural similarity to the ubiquitous sesquiterpene farnesol, and therefore it is not surprising that the biosynthesis of JH III occurs via the normal terpenoid pathway, involving the sequential head-to-tail linkages of three five-carbon isoprenoid units. The isoprenoid units are formed from acetate via mevalonic acid (Fig. 2). The resulting farnesyl pyrophosphate undergoes esteratic cleavage to farnesol, which is then oxidized to the carboxylic acid. There is a dichotomy in the last two steps in the biosynthetic pathway, depending on the insect species. In Lepidoptera (butterflies and moths), for example, it appears that a 10,11-epoxidase converts the carboxylic acid to the epoxy acid (JH acid), which is then methylated to the methyl ester by an *O*-methyltransferase. In Orthoptera (grasshoppers, locusts, and crickets) and Dictyoptera (cockroaches) the converse appears to be true: epoxidation follows methyl transfer.

The homosesquiterpenoids JH 0, JH I, and JH I are biosynthesized from a mixture of isoprenoid (five-carbon) and homoisoprenoid (six-carbon) units (Fig. 2). Critical work by Schooley and coworkers, using cell-free homogenates of *Manduca* corpora allata, demonstrated that insects are unique in being able to synthesize homoisoprenoid units from acetate and propionate via 3′-homomevalonate (Figs. 2 and 3). Thus the synthesis of JH I would utilize one dimethylallyl pyrophosphate molecule (isoprenoid unit) and two ethylmethylallyl pyrophosphate molecules (homoisoprenoid units) for each molecule of JH I (Fig. 3). A molecule of JH II would incorporate two isoprenoid units and one homoisoprenoid unit, whereas three homoisoprenoid units would form the skeleton of JH 0 (Fig. 4).

The JHs have three unsaturated positions: $\Delta^{2,3}$, $\Delta^{6,7}$, and $\Delta^{10,11}$. The naturally occurring hormones have a 2E,6E 10-cis (JH I and JH II) configuration or a 2E,6E (JH III) configuration. The chiral centers at C-10 and C-11 in the naturally occurring hormones have been assigned a 10R,11S (JH I and JH II) or a 10R (JH III) configuration.

Specificity for the production of a particular homologue appears to be restricted to early enzymatic steps in the biosynthetic pathway. The two terminal steps have been shown to lack substrate specificity in a number of species. The best example is that of *Schistocerca gregaria* (desert locust) corpora allata, which normally synthesize only JH III *in vitro*, but will produce JH I as their sole product when incubated with dihomofarnesoic acid.

IV. JH ACTIVITY

As previously mentioned, the corpora allata of some insects secrete only one JH, whereas others secrete a mixture of two or three. JH III is the principal form of JH found in Coleoptera (beetles), Diptera (flies), Hemiptera (bugs), and Hymenoptera (bees and wasps), although the corpora allata of some species secrete other homologues when incubated *in vitro*. The corpora allata of Lepidoptera are unique in their production of a mixture of JHs, both *in vivo* and *in vitro*. *Manduca sexta* corpora allata synthesize five homologues of JH in different amounts at different times during the life cycle of the moth, and *M. sexta* corpora allata have been shown to secrete three JH homologues *in vitro* (JH I, JH II, and JH III), in addition to their acids. Each of the JHs has a quantitatively different relative activity when bioassayed in insects of different orders, and homologues that are not present in a particular species can nevertheless elicit a typical JH response. There is no evidence to date that JH I, JH II, and JH III elicit qualitatively different physiological effects. The most lipoidal homologues, JH I and JH II, are usually more active in bioassays, compared to JH III, possibly because the greater polarity of JH III makes it more susceptible to degradation. In general, the activities of JH I and JH II are inversely related to their titers *in vivo*—that is, the most potent homologues in the bioassays are present in much lower amounts *in vivo*, compared to JH III. The significance of the mixtures of homologues in any species or at any developmental stage is unknown.

The geometrical configurations of the $\delta^{2,3}$, $\delta^{6,7}$, and $\delta^{10,11}$ positions in the JHs are important to

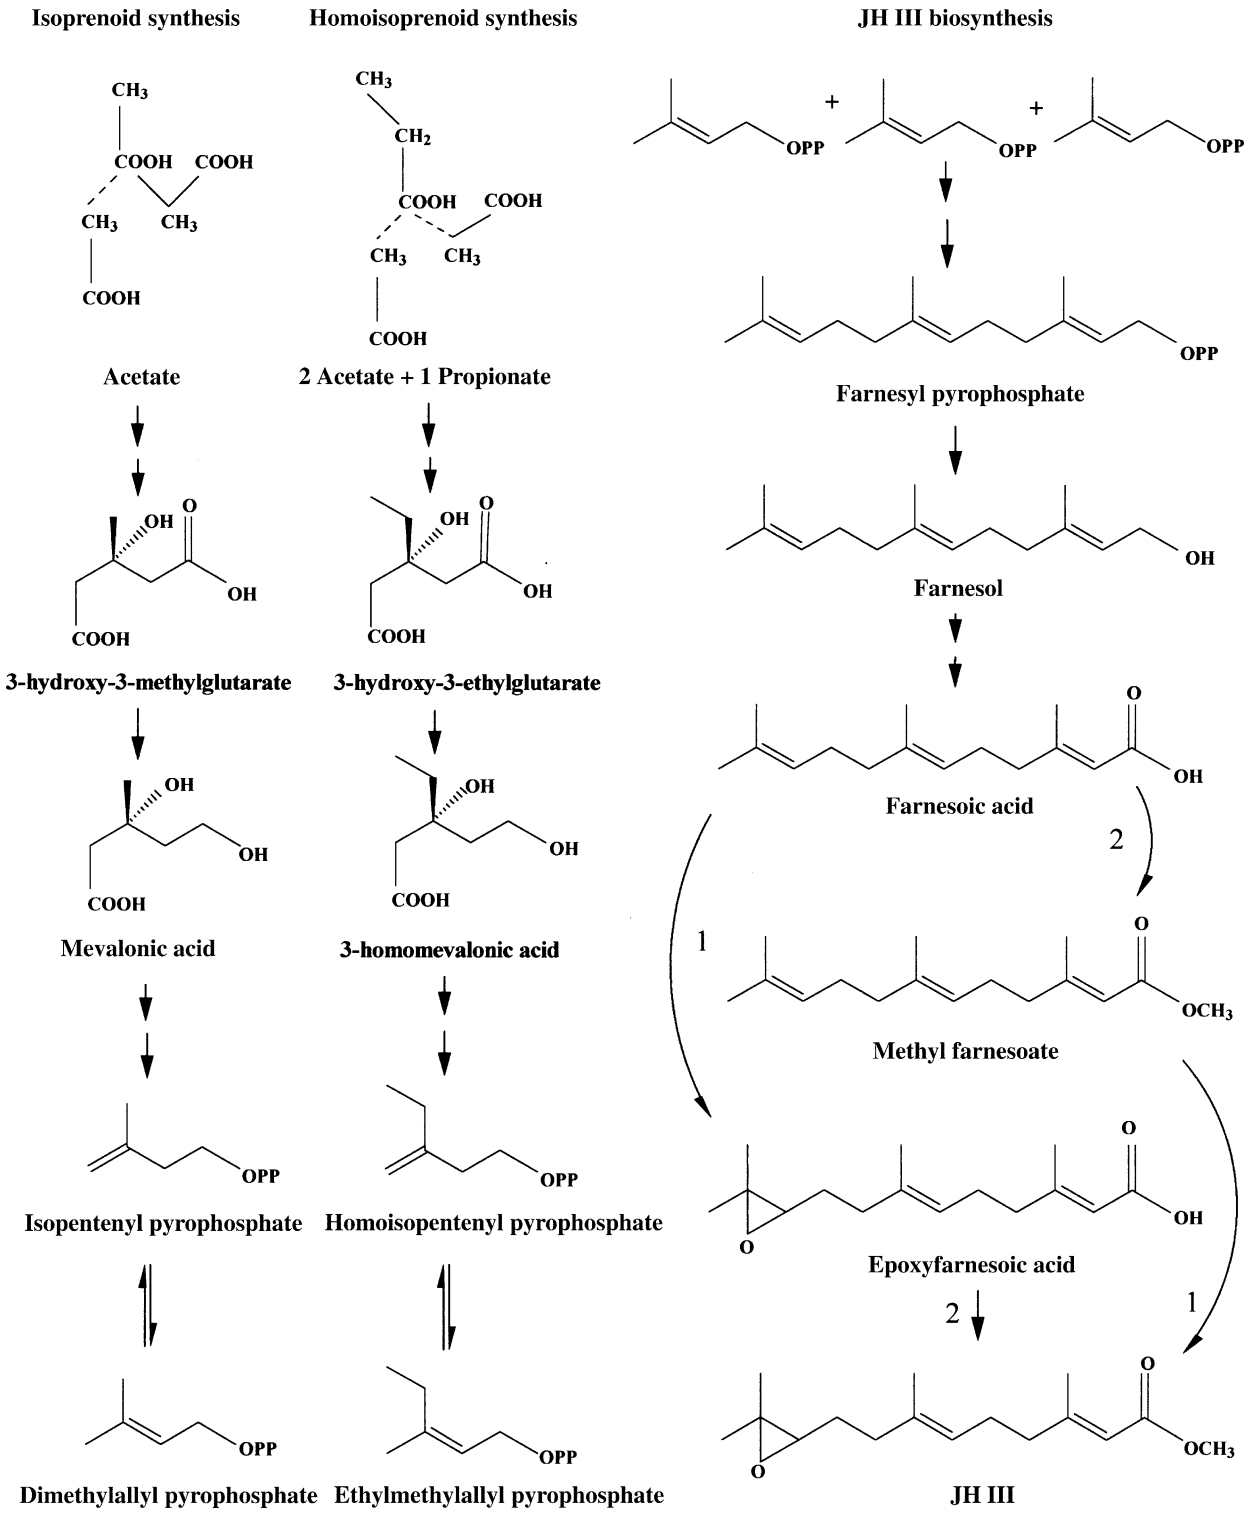

FIGURE 2 Juvenile hormone biosynthesis, showing differences in the sequence of the two terminal enzymatic steps, based on insect order. The production of JH III from farnesoic acid, methyl farnesoate, and epoxyfarnesoic acid involves two enzymes (1, epoxidase; 2, *O*-methyltransferase). It is generally accepted that the sequence 1, 2 occurs in Lepidoptera, and 2, 1 occurs in Orthoptera and Dictyoptera.

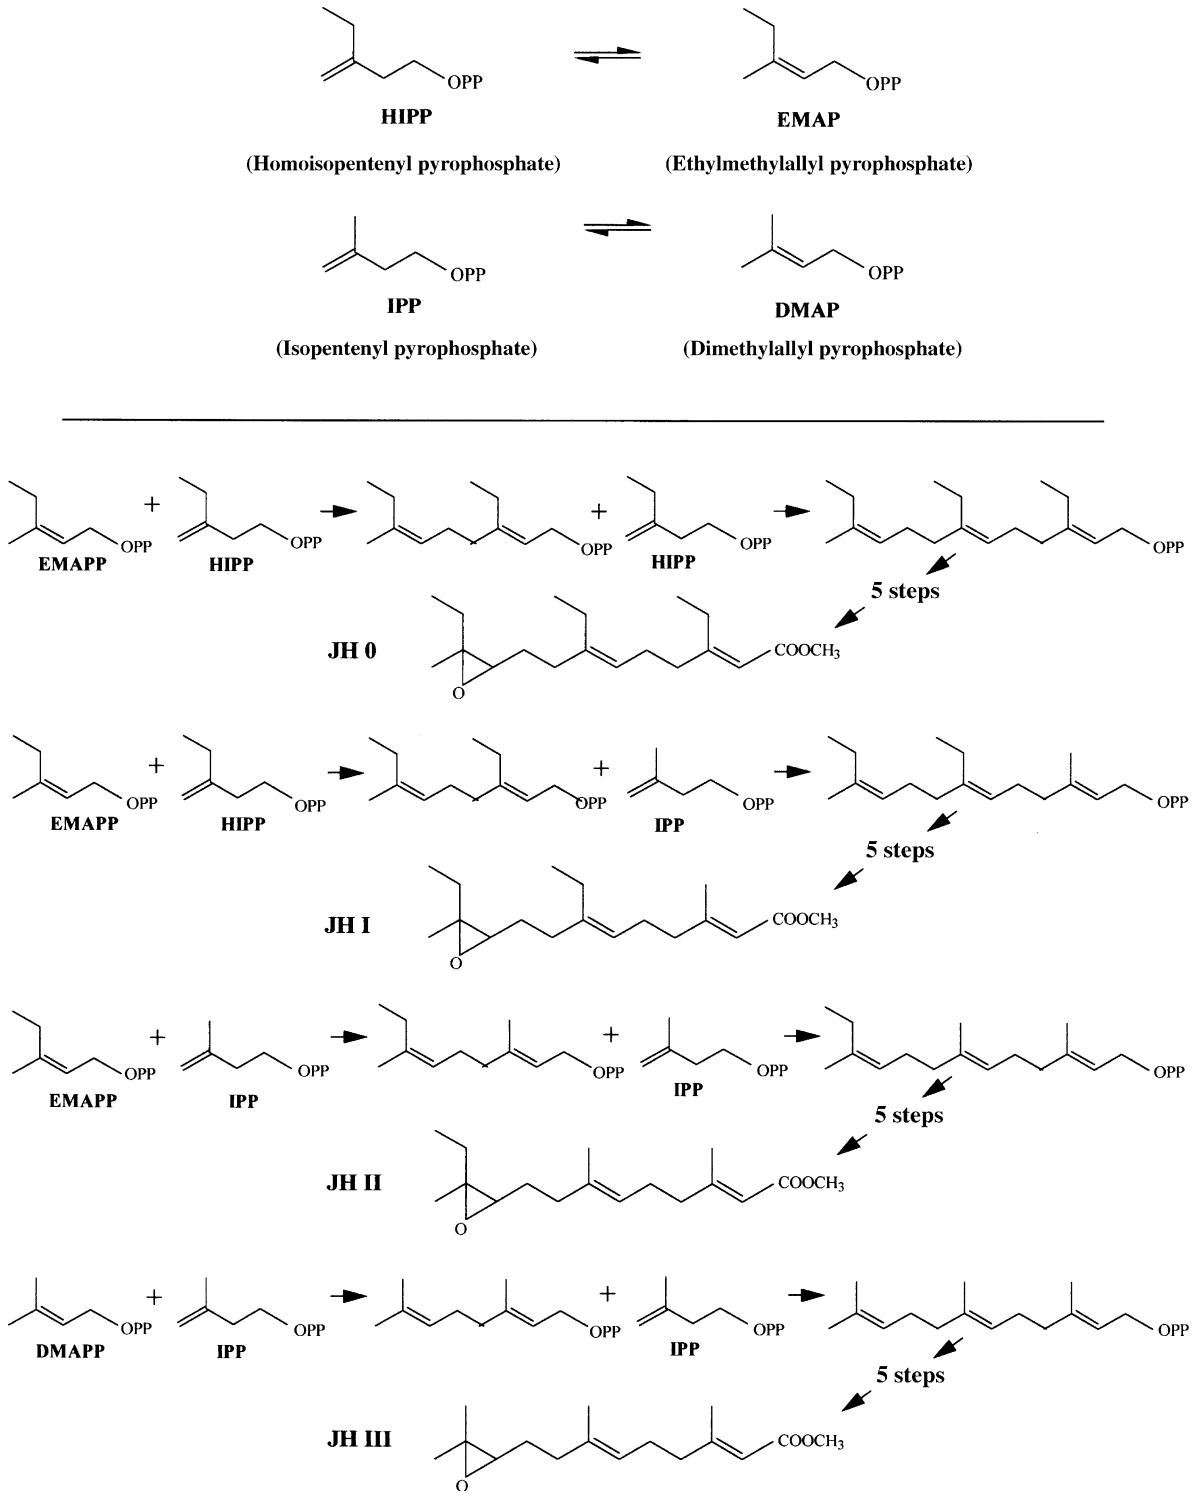

FIGURE 3 Scheme for the biosynthesis of JH 0, JH I, JH II, and JH III from isoprenoid and homoisoprenoid units.

biological activity. The naturally occurring isomers of JH (2E,6E 10-cis for JH I and JH II and 2E,6E for JH III) have been shown to be the most biologically active. Other geometric isomers display varying degrees of decreased activity, with the 2Z,6Z 10-trans isomer (the complete opposite of the natural isomer) having the least activity. The enantiomeric purity of the hormones may also be important for biological activity. For example, only the natural 10R enantiomer of JH III is bound by the JH-binding protein in *Manduca* (see Section VI).

V. JH TITERS

Hemolymph, whole-body, and tissue titers of JH have been determined in a wide variety of species. These titer measurements have shown that different insect species can have vastly different amounts of the JH homologues and that these amounts, measured principally in the hemolymph, change during the course of development. The changes in titer are linked to specific, JH-controlled developmental events. Physiological levels of JH generally range from 10^{-8} to less than 10^{-9} *M*, but higher values have been observed. For example, in the adult female cockroach, *Diploptera punctata*, as much as 10^{-5} *M* has been measured. The significance of differences in JH titers between species and between developmental stages, like the significance of differences in the number and mix of homologues, is unknown.

VI. JH METABOLISM

Thus far, only two definitive pathways for the metabolism of JH have been described: (1) hydrolysis of the methyl ester of JH by hemolymph esterases, yielding JH acid, and (2) hydration of the C-10, C-11 epoxide by microsomal epoxide hydrolases (epoxidases), yielding JH diol (Fig. 4). Three classes of JH-binding proteins (JHBP) have been identified in insects, and it is assumed that most JH in insect hemolymph is bound to these binding proteins and is thus protected from metabolism by nonspecific esterases. Insect fat body is the primary source of a highly stable JH-specific esterase that either metabolizes JH that is bound to JHBP or shifts the equilibrium between JHBP-bound and free JH, increasing the amount of free JH that can be

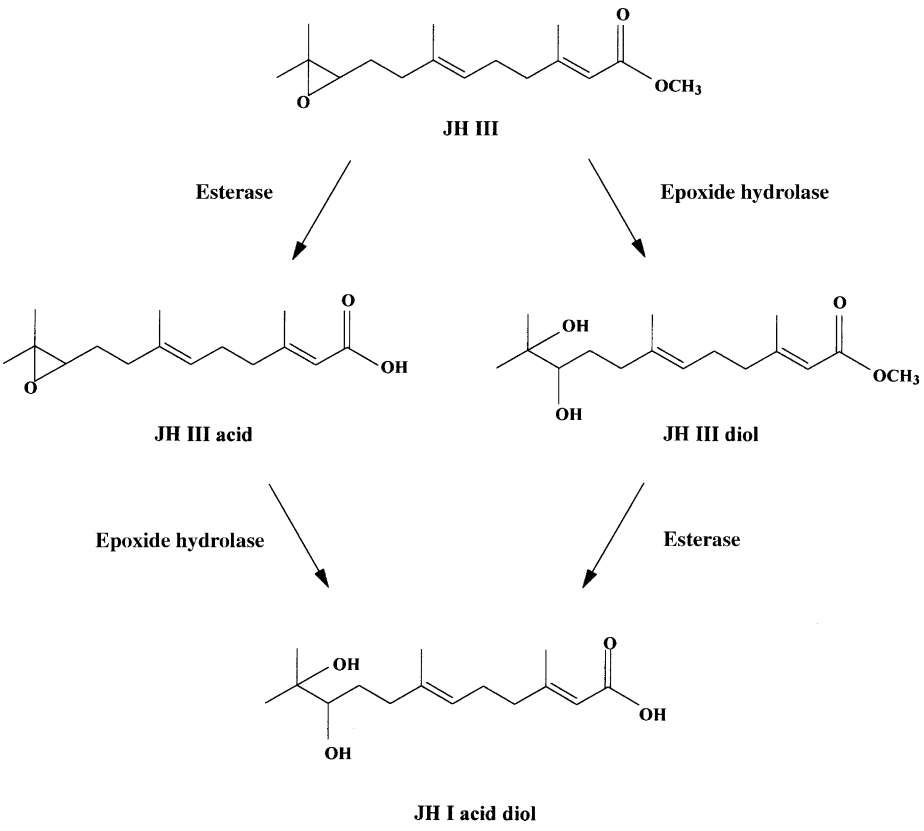

FIGURE 4 Pathways of JH metabolism.

metabolized. In either case, the circulating JH titer would decrease. Current dogma states that JH is metabolized by JH-specific esterase to JH acid, which is then hydrolyzed at the cellular level by epoxide hydrolase, yielding the JH acid diol. Although activity of JH epoxide hydrolase has thus far been assigned a secondary role, recent *in vivo* studies of the metabolism of JH acid indicate that in some species JH diol may be the primary metabolite of JH.

In addition to the primary metabolites of JH (the acid, the diol, and the acid diol), a number of highly polar JHs and/or JH metabolites have been reported, the structures of which are largely unknown. Thus, other pathways for the degradation of JH may exist.

VII. NONTRADITIONAL JHs

JH acids (Fig. 1) have been identified as the products of adult and larval lepidopteran corpora allata. The corpora allata of adult male Cecropia lack the *O*-methyltransferase enzyme and thus synthesize and release JH acids into the hemolymph. JH acid stored in the male accessory gland can be converted to JH by an *O*-methyltransferase. In *M. sexta*, the corpora allata gradually convert from the secretion of JH to the secretion of JH acid during the first 4 days of the last larval stadium. By the time commitment to pupal development is complete, JH acid is the only product. Synthesis of JH resumes in the adult. Based on the situation in Cecropia, it is assumed that JH acid is converted to JH by peripheral tissues, and there is evidence that this occurs in the imaginal discs in *Manduca*. However, there is preliminary information that JH acid may not be a simple degradation product of JH or a precursor to JH in the biosynthetic pathway, but rather is a hormone in its own right. Treatment of Verson's gland in *Manduca* with JH acid or the acid form of a JH analogue, plus a low dose of an ecdysteroid, has been reported to induce metamorphic competency of the gland.

Methyl farnesoate (MF), an intermediary in the biosynthetic pathway of JH (Fig. 2), is released from the corpora allata of a number of insect species and has been reported to synergize the activity of JH II and JH III bisepoxide. Indeed, this molecule is suggested to be the JH of the other class of Arthropoda, the Crustacea. Crustaceans and insects have the same biosynthetic pathway for the synthesis of MF (see Fig. 2), and MF has been isolated from a number of crustacean species, most recently larvae of the barnacle. In spider crabs, from which MF was first isolated, MF has been proposed to control reproduction and to act as the "status quo" hormone, inhibiting metamorphosis. The natural isomer of crustacean MF inhibits metamorphosis in barnacles as well.

Finally, there is evidence that hormones structurally dissimilar to JH have JH-like functions in insects. For example, ovarian ecdysteroids can function as gonadotropins in mosquitoes and other Diptera, as well as in the locust. Thyroid hormones have recently been shown to mimic the action of JH on follicle cells of locust ovary, although the source of these hormones would be exogenous.

Glossary

chirality Chemical nomenclature for an organic molecule, describing the right- or left-handedness of an asymmetric carbon; any carbon with four different groups attached to it is a chiral center.

corpus allatum A typically paired, retrocerebral endocrine gland of a single cell type, which synthesizes and secretes juvenile hormones. The corpus allatum is innervated by nerves from the brain and the subesophageal ganglion.

corpus cardiacum A typically paired, retrocerebral neurohemal organ for the neurosecretory cells of the brain. The corpus cardiacum contains intrinsic neurosecretory cells, which release a variety of neurohormones, as well as the axons of cerebral neuron and neurosecretory cells, which traverse this organ to reach the corpus allatum.

ecdysteroid Member of a family of insect and crustacean steroids responsible for the promotion of molting and growth and development; ecdysteroids are also found in plants.

enantiomers Different compounds with the same molecular formula (isomers) but that are mirror reflections of each other; enantiomers are designated as cis or trans, R or S, or E or Z and occur only when the isomers contain chiral molecules.

isomers Different compounds with the same molecular formula, but differing in the order in which their atoms are joined (structural isomers) or in the arrangement of their atoms in space (stereoisomers, diastereoisomers).

polyphenism The occurrence of several distinct phenotypes or forms in a given species, each of which develops facultatively in response to some cue from the internal or external environment; sequential polyphenism occurs in the metamorphosis of insects (larval, pupal, and adult forms).

racemic Denoting a mixture of optically active compounds (enantiomers), with the mixture itself being optically inactive because it is composed of equal amounts of all the enantiomers; a single enantiomer is optically active because it rotates the plane of a beam of plane-polarized light passing through it.

ring gland Endocrine gland in the higher Diptera (flies) that encircles the foregut and that is composed of fused

corpora allata, corpora cardiaca (which release neuropeptides), and prothoracic glands (which secrete ecdysteroids).

sesquiterpene A class of hydrocarbon compounds having a 15-carbon skeleton, built from five-carbon (isoprene) units that are linked head to tail or in rings; many contain oxygen.

Knockout of Gonadotropins and Their Receptor Genes

CH. V. RAO AND Z. M. LEI

University of Louisville Health Sciences Center

Phenotypes of both gonadotropin knockout and gonadotropin receptor knockout animals have confirmed and extended the knowledge about the role of gonadotropins in ways that were not possible previously. Moreover, LH receptor knockout animals are beginning to serve as important models to further investigate the importance of nongonadal LH actions in the body and how these might be useful in better understanding LH biology and in exploring novel therapeutic applications of hCG in multiple clinical conditions. Complete characterization of knockout animal models can also serve as a guide to what symptoms to look for in patients with corresponding gene mutations.

I. INTRODUCTION

Hormonal ablations created by surgical, pharmacological, or immunological methods have historically provided data on complex interrelationships between gonadotropins and their roles in the

hypothalamus–pituitary–gonadal axis. Cell culture systems have complemented and extended these findings. These approaches have dramatically increased the understanding of the roles gonadotropins play in pathophysiology. There are inherent limitations, however, to each of these approaches as they are nonspecific, variable, and/or incomplete. Gene-targeting technology has allowed generating mice that lack a functional gene, as well as germline passage of the mutation. These animals have provided a great deal of insight into the roles of gonadotropins in pathophysiology and also served to confirm the hypothesis generated by using other approaches. In addition, certain unforeseen phenotypes have emerged. Although both males and females are affected by knockout of the gonadotropin subunit or their receptor genes, this article focuses primarily on the female phenotype. Where applicable, the phenotypes of ligand and receptor knockouts as well as the relevant phenotypes of knockout models for other signaling systems will be contrasted and compared. Finally, the phenotypes of inactivating and activating mutations of the gonadotropin subunits and their receptor genes in humans will also be compared and discussed.

II. FAMILIES OF GONADOTROPINS AND THEIR RECEPTORS

A. Gonadotropins

Luteinizing hormone (LH), follicle-stimulating hormone (FSH), and human chorionic gonadotropin (hCG) belong to the glycoprotein hormone family that includes thyroid-stimulating hormone (TSH). LH and FSH are primarily secreted by gonadotropes in the anterior pituitary gland and hCG is primarily synthesized by syncytiotropoblasts in the human placenta. These hormones, especially hCG, are also produced in small amounts by a number of other normal and cancer tissues.

Members of these families are heterodimers of noncovalently bound α- and β-subunits. The α-subunit is identical, whereas β-subunits, which determine hormone specificity, are different among these hormones except for LH and hCG. These two hormones have similar but not identical β-subunits. The β-subunit of hCG has 30 additional amino acids at the C-terminus carrying four O-linked oligosaccharide chains, which are thought to be responsible for its longer half-life in the circulation compared with LH. Crystal structure studies revealed that LH and hCG contain a so-called cystine-knot motif that is commonly present in a family of growth factors, which include nerve growth factor, platelet-derived growth factor-β, and transforming growth factor-β (TGF-β).

The α-subunit of all the glycoprotein hormones is encoded by a single gene located on human chromosome 6q21.1–q23. A single gene encoding the FSH-β subunit is located on human chromosome 11p13. The β-subunits of LH and hCG are encoded by a gene cluster, which spans approximately 52 kb on human chromosome 19q13.32. The cluster contains one LH β-subunit gene and six hCG β-subunit genes. It appears that only three of the hCG β-subunit genes are transcriptionally active.

B. Gonadotropin Receptors

LH and hCG share the same receptor, whereas FSH has its own receptor. Both receptors belong to the G-protein-coupled receptor superfamily. Members of this family are single-chain transmembrane glycoproteins composed of a large extracellular hormone-binding domain, seven transmembrane-spanning regions, and a relatively small intracellular region, which is coupled to G-proteins. Nucleotide sequence conservation is high in the same receptor from different species. Between the receptors, however, the sequence of the transmembrane region is highly conserved, whereas the sequence of the extracellular domain is much less conserved, which allows for hormone specificity of binding.

The LH receptor is a single-copy TATA-less gene located on human chromosome 2p21. It spans over 70 kb containing 11 exons. The first 10 exons encode the extracellular hormone-binding domain and the last exon encodes the rest of the receptor. The FSH receptor gene is located on the same chromosome, 2p21–p16, and has structural similarity except that it contains only 10 exons. The presence of multiple transcription initiation sites and alternative splicing mechanisms contributes to more than one transcript as is typically seen with these receptors. The size of full-length LH and FSH receptors is very similar, i.e., 80–90 kDa.

Binding of LH, hCG, and FSH to their cognate receptors results in the activation of adenylate cyclase, an increase in cyclic AMP (cAMP) formation, and activation of protein kinase A catalytic subunit, resulting in increased phosphorylation of Ca^{2+}/ cAMP-response element-binding protein and other target proteins and kinases. A single signaling mechanism may not explain all the

actions of gonadotropins. Thus, protein kinase C and mitogen-activated protein kinase, as well as other kinases, and potential cross talk between them may be involved.

C. Gonadotropins' Action

Ovaries are classical targets of LH, hCG, and FSH actions. Thus, they contain high levels of these receptors. Whereas FSH receptors are expressed only in granulosa cells, LH receptors are present in different ovarian cell types. Thus, granulosa and luteal cells contain high levels, whereas stroma, cumulus, surface epithelial cells, oocytes, and blood vessels contain low levels. LH receptors in thecal cells are constitutive, whereas those in granulosa cells are acquired during mid-to-late stages of follicular growth.

FSH actions in granulosa cells result in an increase in aromatase that converts androgens into estrogens. FSH and estrogens work in a synergistic manner to increase granulosa cell proliferation and maturation. During follicular growth, LH first acts on thecal cells to increase the synthesis of androgens, which then diffuse across the basement membrane to reach granulosa cells, where they are aromatized into estrogens. LH, together with estrogens, acts to promote oocyte maturation. LH also triggers follicular rupture and the release of the mature oocyte for capture by the fallopian tube, where fertilization takes place. LH plays an essential role in corpus luteum formation from the ruptured follicle, its subsequent growth and development, and stimulation of progesterone synthesis by small and large luteal cells, which are differentiated from thecal and granulosa cells. The actions of LH in granulosa and luteal cells result in an increased production of steroid hormones, peptide hormones, prostaglandins, and a number of growth factors, cytokines, and proteases.

Research from around the world during the past 15 years has forced a paradigm shift regarding the targets of LH and hCG actions in the body. The new targets include oocyte, early embryo/blastocyst, oviducts, uterus, cervix, placenta, fetal membranes, decidua, umbilical cord, brain, neural retina, spinal cord, skin, mammary glands, adrenal cortex–zona reticularis, urinary bladder, bone, cavernous sinus carotid rete vascular complex, and cells of the immune system. The receptors in these tissues are functional and these functions may explain a number of phenomena that were never previously explained and correct wrong attributions of phenomena to other hormones. Many of the nongonadal LH/hCG actions are beginning to lead to novel biological therapeutic uses of hCG.

Although not much work has been done, FSH may also have nongonadal sites of action. For example, FSH receptors have been found in human myometrium, fallopian tubes, and bovine uterine cervix. FSH can up-regulate LH receptors in myometrial cells just as it does in granulosa cells.

III. LH RECEPTOR KNOCKOUT

A. Generation of Knockout Mice

Targeted disruption of the LH receptor gene by homologous DNA recombination has recently been accomplished by our group as well as by Huhtaniemi's. We used a targeting vector in which a 4 kb DNA fragment containing a portion of the 5′-flanking region and exon 1 of the LH receptor gene were replaced with a neomycin-resistance gene cassette. Upon successful targeting in mouse 129/J embryonic stem cells, they were injected into C57BL/6J blastocysts to generate male chimeric mice carrying the disrupted gene. Some of these mice demonstrated germ-line transmission of the mutation when bred with wild-type females. Southern blot analyses of genomic DNA indicated the correct targeting of the LH receptor gene and the absence of any heterologous recombination. Reverse transcriptase-polymerase chain reaction (RT-PCR), Western blot, and ligand binding assays demonstrated the lack of the receptor transcripts, receptor protein, and ^{125}I-hCG binding in gonads as well as in nongonadal target tissues, indicating complete LH receptor gene inactivation.

Huhtaniemi's group replaced exon 11 and a part of intron sequences surrounding exon 11 with a neomycin-resistance gene cassette. Mutant mice contained truncated receptor transcripts but no functional receptor protein. Nevertheless, the phenotypes of the animals from both research groups were similar.

B. Sexual Development

Inbreeding of heterozygous mice resulted in an expected Mendelian ratio of all three genotypes as well as a balanced sex ratio, indicating that LH receptor gene disruption is not lethal nor does it have any effect on sex determination. Null animals have normal genitalia except that their development was dramatically attenuated. Both adult female and male animals are sterile, indicating that the

LH receptor is critical for postnatal sexual development.

C. Ovarian Development

The null animal ovaries were small and pale with a dramatic reduction in their wet weight. The histology is consistent with an arrest in folliculogenesis at the antral stage, which suggests that follicular growth through this stage is not LH dependent. The absence of large antral and preovulatory follicles and corpora lutea suggests that LH is indispensable for follicular growth, maturation, and ovulation.

Granulosa cells showed an increase in apoptosis and a decrease in telomerase levels, despite the presence of intact FSH signaling, which suggests that LH is an important survival factor. LH receptor inactivation had no effect on ovarian FSH and progesterone receptor (PR) mRNA levels. However, estrogen receptor (ER)-α and steroidogenic acute regulatory protein (StAR) mRNA levels decreased and ER-β mRNA levels increased, indicating that either directly or indirectly LH up-regulates ER-α and StAR and down-regulates ER-β mRNA levels. Reciprocal ER changes in LH receptor-inactivated animals are consistent with the concept that the two ERs may have different roles in regulating ovarian functions. A complete or partial anovulatory phenotype was also seen in ER-α, ER-β, PR, prolactin receptor, cyclooxygenase-2, CAAT enhancer-binding protein β, and cyclin D2 knockouts. The use of Clontech's Atlas mouse cDNA expression arrays revealed altered expression of 17 ovarian genes, approximately equal numbers of which showed a decrease or an increase.

Measurement of serum estradiol and progesterone levels indicated that ovarian steroidogenesis was decreased but not totally abolished. The continued low estradiol levels were probably due to LH-independent synthesis of thecal androgens and their aromatization under the influence of FSH in granulosa cells. The modest progesterone decrease in the face of a dramatic decrease in ovarian StAR levels suggests that an alternate mechanism in progesterone synthesis, not involving StAR, may exist. The dramatic elevation in serum LH levels could be due to a loss of estradiol negative feedback and/or loss of short-loop feedback involving LH control of hypothalamic gonadotropin-releasing hormone. A modest elevation in serum FSH levels could be due to decreased gonadal inhibin secretion.

To determine whether a decrease in steroid hormone levels was responsible for the LH receptor knockout female phenotype, 30-day-old animals were implanted with 21-day slow-release pellets containing 0.1 mg of 17β-estradiol and 5 mg progesterone. The serum hormone levels reached the physiological range and yet ovarian size increased only slightly; otherwise the ovaries remained pale and histologically similar to those of placebo-treated null animals. Injections of pregnant mare serum gonadotropin followed by hCG were unable to induce ovulation. The oocytes retrieved contained germinal vesicles and could not be fertilized *in vitro* by sperm from wild-type animals. Thus, LH signaling is required for final oocyte maturation as well as ovulation; in neither of these cases can lack of LH be compensated for by estradiol, progesterone, or FSH. Concerning the reversal of biochemical changes, only ER-α and StAR, but not ER-β, recovered, suggesting that LH action to up-regulate ovarian ER-α and StAR levels is mediated by estradiol and/or progesterone. The lack of an ER-β change suggests that, either directly or indirectly through other unknown local mediators, LH down-regulates ER-β levels.

D. Reproductive Tract Development and Function

The reproductive tract of null animals was thin and thread-like with a greatly reduced wet weight. The thickness of all uterine layers decreased, stromal and epithelial cells showed no mitosis, and very few endometrial glands were seen.

cDNA expression array analysis revealed that approximately 230 genes showed a decrease and only 2 genes showed an increase in the null mice uterus. The changes were dramatic for some genes and less so for others. A number of genes that showed a decrease came from many gene families in which a change in expression was unexpected. Decreased gene expression after knockout suggests that, either directly or indirectly, LH increases their expression. Conversely, increased gene expression suggests that LH may normally inhibit their expression.

Hormone replacement therapy (HRT) increased uterine size. Computerized quantitative morphometric analysis and proliferating cell nuclear antigen staining showed a restoration of the thickness of all uterine layers and resumption of mitosis in stromal and epithelial cells. The number of endometrial glands, however, remained low, suggesting that LH signaling could be required for their recovery.

To explore genetic response in the uterus of null mice placed on HRT, cDNA expression arrays and semiquantitative RT-PCR were used. The results showed a reversal in both of the genes that increased

(bone morphogenetic receptor protein 1A and insulin-like growth factor-binding protein-3) and in two-thirds of the genes that decreased. The genes that did not respond included those that are known to be critical for uterine morphogenesis, functional differentiation, and receptivity.

Uterine steroid hormone receptor levels responded differently to LH receptor inactivation. Whereas ER-α showed no change, ER-β decreased. The decrease in ER-β could not be reversed by HRT. Levels of both PR isoforms A (PR-A) and B were decreased with a more dramatic decrease in PR-A. HRT completely normalized PR-A but not PR-B. Androgen receptor levels were also reduced and HRT failed to completely reverse this decline. These data suggest that, either directly or indirectly through other unknown mediators, LH differentially regulates uterine steroid hormone receptor levels.

To further test uterine function in null mice following HRT, 60-day-old null mice were placed on 21-day estradiol and progesterone replacement therapy to stimulate uterine growth, followed by ovariectomy and priming with ovarian steroid hormones to make the endometrium receptive to donor blastocyst implantation. Ovariectomized wild-type mice with the same priming were used for controls. Morphological analyses demonstrated that wild-type endometrium contained numerous endometrial glands, displayed typical decidual changes such as edema, hyperemia, marked endometrial cell proliferation, and differentiation, and allowed implantation of donor blastocysts. In contrast, the null animal endometrium showed incomplete decidual changes and implantation of donor blastocysts failed. These differences between the two groups indicate that uterine LH receptors are essential for pregnancy initiation.

Null females had ambiguous vaginal openings and HRT stimulated vaginal growth and development. However, the number of leukocytes remained low, and whether LH signaling is required for their restoration remains to be determined.

E. Mammary Gland Development

The presence of LH receptors in the mammary gland and hCG actions in the differentiation and protection of mammary gland from tumorigenesis have been well documented. LH receptor knockout resulted in complete atrophy of the mammary gland and HRT promoted ductal development and branching. However, the developmental pattern differed from that in normal wild-type siblings. These findings suggest that the actions of LH/hCG could be required for the normal branching pattern.

F. Bone Development

Bone phenotype in LH receptor knockout animals was examined because it appears to be a direct target of LH regulation. The data revealed a decrease in femur density in 8- and 60-week-old null animals and in 60-week-old heterozygous animals compared with wild-type littermates. The femur length decreased only in 8-week-old null females. Twenty-one-day estradiol/progesterone replacement therapy in 30-day-old homozygous females and testosterone replacement in 30-day-old homozygous males did not completely reverse bone phenotype, suggesting that the actions of LH on bone may be required for the normal growth and development of bone.

G. Metabolic Changes

The underdeveloped gonads, reproductive tract, and accessory sex organs of LH receptor knockout animals were covered by excessive fat pads. Accumulation of fat became more pronounced in 1-year-old null animals and in heterozygous animals than in wild-type siblings. This was more dramatic in a subgroup of 1-year-old heterozygous females whose body weight increased by approximately 30% compared with wild-type littermates. Histological examination of gonadal fat tissue from 1-year-old females revealed that an increase in cell size rather than an increase in cell number could be primarily responsible for increased obesity.

H. Consequences of Partial Disruption

Inactivation of one of the alleles of the LH receptor gene had no short-term adverse consequences except for a modest increase in serum FSH levels, the reason for which is not known. It, however, has several long-term adverse consequences. For example, these animals show ovarian failure at an earlier age than wild-type animals, endometria show numerous pathological changes with an enhanced cell proliferation, onset of obesity with some animals becoming extremely obese, and bone loss. That was no apparent correlation between obesity and endometrial pathology.

IV. FSH RECEPTOR KNOCKOUT

A. Generation of Knockout Mice

The FSH receptor gene was disrupted by replacing the 5′-flanking region, all of exon 1, and part of intron 1 with a neomycin-resistance gene cassette, which totally silenced the gene.

B. Postnatal Development and Reproduction

Intercrosses of heterozygous FSH receptor knockout animals produced progeny with an expected Mendelian ratio and approximately equal numbers of male and female animals. Mutant mice were acyclic and sterile.

C. Pituitary Phenotype

Although the wet weight of pituitary gland was not affected, the anterior lobe became enlarged and contained more FSH- and TSH-positive cells, which suggests that these cells may come from the same lineage. Intermediate and posterior lobes appeared normal. Pituitary content and circulating FSH and LH levels were elevated but were normalized by a week of estradiol treatment, indicating that negative feedback regulation is intact at the pituitary level.

D. Ovarian Development and Pathology

Ovaries of 3- to 5-month-old FSH receptor knockout mice were smaller with an arrest in folliculogenesis at the preantral stage. Ovarian stroma contained hypertrophic interstitial cells. Although serum inhibin α levels were not significantly changed, both ovarian and circulating inhibin A and B levels were diminished. Serum testosterone levels were dramatically increased; estradiol and progesterone were markedly decreased. However, ovarian aromatase mRNA and its protein levels were reported to be normal. Analyses of ovarian gene expression revealed that the LH receptor, cyclin D_2, c-kit, steel, ER-α, and ER-β were not changed.

More than 90% of FSH receptor knockout mice developed ovarian cysts and tumors by approximately 1 year of age. The tumors were positive for Leydig cell (3β-hydroxysteroid dehydrogenase and P450c17) and Sertoli cell (Müllerian inhibiting substance and GATA-4) markers. These findings suggest that these are sex cord-stromal-type tumors. In contrast to FSH receptor knockout mice, LH receptor knockout animals, which had elevated serum FSH and increased ovarian inhibin α mRNA levels, never developed these lesions at any age. Mice with ectopic overexpression of LH and a knockout of the inhibin α gene developed ovarian cancers, which suggests that elevation of LH levels and decreased inhibins might contribute to ovarian tumorigenesis in aging FSH receptor knockout animals.

E. Reproductive Tract Development

Null animals have a hypoplastic and imperforate vagina. Vaginal smears showed an absence of cornified epithelial cells. Atrophic uterus contained severely reduced epithelial, stromal, and myometrial layers and less developed endometrial glands. Uterine ER-α and ER-β levels were normal, but PR-A and PR-B levels were diminished. Short-term estrogen replacement therapy demonstrated a full uterine response, suggesting that the uterine phenotype was secondary to estrogen deficiency in FSH receptor knockout mice.

F. Skeletal Abnormalities

FSH receptor knockout females developed compressed vertebrae, resulting in a hunchback appearance. Femur weight was reduced at approximately 1 year of age. X-ray and histological analyses revealed a loss of trabecular bone. Analysis of the bone marrow revealed an accumulation of pre-B lymphocytes that is similar to that of ovariectomized animals, suggesting that skeletal abnormalities may be secondary to estrogen deficiency.

G. Metabolic Changes

Two-month-old animals of three genotypes had similar growth and body weight. However, the weight gain was evident in homozygous and heterozygous animals by 3 to 4 months of age. All FSH receptor knockout females also showed an accumulation of abdominal fat, which was reduced by prolonged estrogen replacement therapy.

H. Consequences of Partial Disruption

Animals with a knockout of one copy of the FSH receptor gene had irregular estrous cycles, delayed conception, reduced litter size, premature reproductive senescence, and ovarian cysts. These data suggest that both copies of a functional FSH receptor gene may be required for full reproductive capacity and that early reproductive senescence seen in certain populations of women might be associated with a copy of a dysfunctional FSH receptor gene.

V. FSH-β SUBUNIT KNOCKOUT

A. Generation of Knockout Mice

A standard gene targeting in embryonic stem cells was used to generate these mice. The replacement-targeting vector was constructed by deleting exons 1 and 2 and most of exon 3 of the FSH β-subunit gene. The mutant mice had no detectable FSH in the circulation.

B. Phenotype Differences from FSH Receptor Knockout Mice

The female phenotype was similar between FSH β-subunit knockout mice and FSH receptor knockout mice. There were differences, however, in the male phenotype. For example, FSH β-subunit knockout males were completely fertile and their serum testosterone levels were normal. FSH receptor knockout males, on the other hand, were subfertile and had lower serum testosterone levels. These differences could be due to the presence of an unknown molecule(s) that might interact with the FSH receptors in FSH β-subunit knockout males. Phenotype differences between ligand and its receptor knockout were also seen in aromatase knockout and estrogen receptor knockout mice.

C. Double Knockout of Inhibin α and FSH β-Subunit

Inhibins, members of the TGF-β superfamily, have been identified as tumor suppressors. One-month-old inhibin α knockout animals develop gonadal sex cord-stromal tumors and die from severe wasting syndrome. These animals often have elevated serum FSH, estrogens, and activin levels. In order to determine the role of FSH in ovarian tumorigenesis, a double knockout (inhibin α and FSH β-subunit genes) was made by crossing FSH β-subunit knockout males with inhibin α knockout female mice. These animals still developed ovarian tumors, but the tumors were slow-growing and less hemorrhagic with minimal cachexia-like symptoms compared with inhibin α knockout mice. Serum estradiol and activin levels and ovarian aromatase mRNA levels were lower in double knockout mice than in inhibin α knockout mice. These findings suggest that FSH is not directly involved in ovarian tumor formation, but indirectly influences gonadal tumorigenesis in inhibin α knockout mice. FSH receptor knockout mice also develop sex cord-type stromal tumors in ovaries, a finding that is inconsistent with the concept that loss of FSH signaling protects against gonadal tumors in inhibin α knockout mice. Thus, the exact role of FSH signaling in gonadal tumorigenesis requires further studies.

VI. NATURAL KNOCKOUT OF GONADOTROPINS AND THEIR RECEPTORS IN HUMANS

A. Mutations in LH/hCG and FSH Receptor Genes

Both activating and inactivating LH/hCG and FSH receptor gene mutations have been described in humans. All the activating mutations were missense and located in the transmembrane region (LH receptor exon 11 and FSH receptor exon 10).

Activating LH/hCG receptor mutation results in severe symptoms in males. The affected males have low to undetectable blood LH levels, elevated testosterone levels, Leydig cell hyperplasia, premature puberty, and onset of spermatogenesis as early as 3 years of age. Female carriers do not seem to have this phenotype. It is not clear why precocious puberty does not occur in females with activating LH/hCG receptor mutations.

In contrast to activating mutations, inactivating mutations are scattered throughout the entire coding regions of the gene. The types include insertion, deletion, nonsense, and missense mutations. All these mutations are autosomal recessive and identified in homozygous and compound heterozygous states. These various mutations result in partial or complete inactivation of the gonadotropin receptor genes. In many respects, the phenotypes of mice with complete inactivating gonadotropin receptor gene mutations resemble those of LH and FSH receptor knockout mice. Males with complete inactivating LH/hCG receptor mutations have abdominal testes and are sterile due to Leydig cell hypoplasia and spermatogenic failure. The external female-like genitalia (pseudo-hermaphroditism) seen in affected males were not seen in LH receptor knockout males. The affected females have normal pubertal development with primary amenorrhea and infertility, absence of preovulatory follicles and corpora lutea, small uterus, and decreased bone mass.

Only one activating FSH receptor mutation has been described thus far. Some men with inactivating FSH receptor mutations were fertile just as FSH-β and FSH receptor knockout mice were. This suggests that FSH is not essential for spermatogenesis. Complete inactivating FSH receptor mutations result in primordial to mature follicles, amenorrhea, and infertility.

B. Mutations in the LH β- and FSH β-Subunit Genes

No germ-line mutation of the α-subunit gene has yet been reported. Targeted disruption of the α-subunit gene results in hypothyroid and hypogonadal states. Mutations in the β-subunit gene of LH and FSH in human are fairly uncommon. In general, the symptoms of affected men and women are less severe than their receptor mutations. Complete inactivation of the human LH β-subunit gene resulted in infertility, absence of Leydig cells, and arrest of spermatogenesis, but affected individuals responded normally to hCG treatment. Variable presentations among women with inactivating mutations of the LH β-subunit gene have been described. The symptoms include infertility, menstrual disturbances, and polycystic ovary syndrome. Men with inactivating FSH β-subunit gene mutations have normal puberty and mild to severe impaired spermatogenesis, but some were fertile. Women with inactivating FSH β-subunit gene mutations, on the other hand, have poor breast development, primary amenorrhea, infertility, low FSH and estrogen levels, and high LH levels.

VII. SUMMARY AND PERSPECTIVES

One of the important findings that emerged from LH receptor knockout studies is gender difference in dependence on LH signaling. In females, it is absolute, meaning that when LH signaling is inactivated, the infertility phenotype cannot be rescued by either ovarian steroid hormones or FSH. In males, on the other hand, testosterone can rescue the infertility phenotype.

FSH is thought to be a principal factor in regulating spermatogenesis. However, FSH β-subunit and FSH receptor knockout mice and men with inactivating mutations were fertile, indicating that FSH is not essential for male fertility. Thus, the strategies to block FSH action for male contraception may not be successful. The findings from LH receptor knockout animals, on the other hand, indicate that LH is essential for spermatogenesis and fertility by increasing testosterone production by Leydig cells.

The phenotypes of heterozygous LH receptor knockout and FSH receptor knockout female mice are unexpected. Although at the age of sexual maturity these animals are indistinguishable from wild-type littermates, they developed early reproductive senescence, obesity, skeletal abnormalities, and endometrial pathology (LH receptor knockout) as they grow old. These findings suggest that both functional alleles of either LH or FSH receptor genes are required for normal reproductive and metabolic functions especially during aging. These findings indicate that certain reproductive and metabolic abnormalities in aging women could be due to allelic inactivation of gonadotropin receptor genes. This prospect holds a great deal of promise in predicting who might be at a greater risk for developing problems during aging.

Knockout of the LH β-subunit gene is not yet available. Thus, LH receptor knockout remains the only model for investigating LH biology using knockout technology. Whether LH β-subunit knockout animals would manifest any phenotypes that would be different from those of LH receptor knockout mice remains to be seen. It should not be surprising, however, if they do, as in the case of FSH-β vs FSH receptor knockout and aromatase versus ER-α and ER-β knockout mice. These differences could come from unknown ligand-activating receptors. Thus, receptor inactivation should give more definitive information than cognate hormone inactivation.

Both LH and FSH have been implicated in the development of ovarian cancer in women. However, the role of FSH has been complicated by the fact that these tumors develop even in the absence of FSH. Moreover, LH receptor knockout animals, which have intact FSH signaling, do not develop any type of ovarian tumor. LH receptor knockout animals could be useful in testing the role of LH in ovarian cancer. For example, if LH is important, then induction of ovarian cancers in LH receptor knockout animals should be very difficult when compared to wild-type or heterozygous siblings.

Double knockouts of LH and FSH receptors should provide further opportunities to test the role of each of these hormones in gonadal and nongonadal functions and tumorigenesis. Tissue-specific knockout is another powerful approach to ascertain gene function. However, this approach results in gene inactivation in only a single cell type, which could create a problem in data interpretation if the gene is expressed in multiple cell types with each contributing to the hormonal response. Despite this limitation, it is an attractive approach to gain additional insights into gonadotropin biology in normal and abnormal reproductive processes.

Glossary

cDNA microarray A method for high-throughput simultaneous analysis of multiple gene expression changes.

cystine-knot motif The motif consists of an internal ring of two cystine bonds linking adjacent antiparallel strands of the peptide chain with the third cysteine passing through the center of the ring to complete the knot.

genotype Gene combination at one specific locus or any specified combination of loci.

gonadotropins A group of glycoprotein hormones that is capable of promoting gonadal growth, development, and function. Usually refers to luteinizing hormone, follicle-stimulating hormone, and human chorionic gonadotropin. Generally, prolactin is not included even though it also has similar effects.

heterozygous Having different alleles at one locus.

homozygous Having identical alleles at one locus.

knockout A genetically engineered mouse in which the endogenous gene is inactivated by homologous DNA recombination.

Mendelian ratio The ratio of progeny with particular phenotypes or genotypes expected accordance with Mendelian law.

phenotype The physical, morphological, or biochemical characteristics of an individual that are determined by the genotype and environment.

receptor A protein on the cell surface or inside the cell that is activated by cognate hormone binding. There is no clear-cut difference between cell surface and intracellular receptors for the same hormone. Thus, the same receptor may be found in both locations mediating different biological effects.

by the placenta in pregnancy and leptin levels are high in pregnancy, although the physiologic function of this hyperleptinemia of pregnancy remains unclear. Serum leptin levels in humans peak at night several hours after the largest meal of the day and reach a nadir in the morning. Leptin production by fat cells in culture is stimulated by insulin and glucocorticoids and is inhibited by counterregulatory hormones (those that antagonize the actions of insulin-e.g., adrenaline) and their intracellular signaling mediators (Fig. 1). The regulation of leptin production by indicators of acute nutritional status such as insulin (feeding → increased insulin → increased leptin) and counterregulatory hormones (fasting → increased counterregulatory hormones → decreased leptin) makes teleological sense. The stimulation of leptin production by glucocorticoids appears counterintuitive in this light, however, because circulating glucocorticoids are important mediators of the stress and starvation responses. Indeed, although plentiful data suggest that insulin is a critical mediator of increased leptin production *in vivo*, the diurnal pattern of leptin levels and numerous other data argue against an important role for circulating glucocorticoids in the stimulation of leptin production. In contrast, adipocyte-produced autocrine- or paracrine-acting glucocorticoids could be involved (Fig. 1); the production of glucocorticoids by adipocytes increases with the accumulation of triglycerides, and mouse models with increased glucocorticoid production specifically in adipocytes have elevated leptin levels.

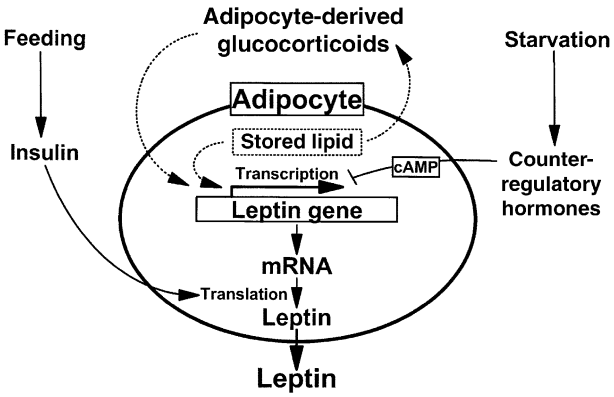

FIGURE 1 Regulation of leptin production in the adipocyte. In the adipocyte, leptin gene transcription is inhibited by the increased levels of cellular cyclic adenosine monophosphate (cAMP) produced by starvation-induced counterregulatory hormones (such as adrenaline). Insulin increases leptin protein synthesis by increasing the translation of leptin mRNA. Lipid stores in the adipocyte also regulate leptin mRNA synthesis; although the details of this process are poorly understood (dashed lines), part of this effect may be mediated by the production of autocrine-acting glucocorticoids by the adipocyte when lipid storage is increased.

A constitutive pathway mediates leptin secretion from adipocytes; leptin secretion is not altered acutely and changes in the rate of leptin secretion result primarily from regulation of leptin synthesis. Glucocorticoids increase leptin gene transcription and insulin stimulates leptin synthesis primarily by increasing the rate of translation of leptin mRNA into protein, whereas counterregulatory hormones decrease leptin gene transcription, reducing levels of leptin mRNA. Integrating this information, then, circulating leptin levels reflect adipose mass (reflecting long-term energy stores) modified by circulating levels of insulin (reflecting recent food intake) and counterregulatory hormones (reflecting lack of recent food intake).

IV. LEPTIN RECEPTORS AND SIGNALING

A. Leptin Receptor Isoforms

The cloning of the leptin receptor (LR) revealed at least five isoforms of the receptor (LRa–LRe) that are alternatively spliced products of the same gene. The leptin receptor is a type I cytokine receptor containing a conserved fold in the ligand-binding extracellular domain and a single transmembrane domain. Each leptin receptor isoform contains the same first 14 exons of the leptin receptor gene (encoding the majority of the extracellular domain of the receptor and the full leptin-binding region); LRe contains only these exons and is secreted. LRa–LRd contain an additional three common exons encoding a short membrane-proximal portion of the extracellular domain, a transmembrane-spanning region, and 28 common intracellular amino acids. Each of these transmembrane forms contains an alternatively spliced exon 18 that encodes intracellular tails of various lengths (LRa, 33 amino acids; LRb, 301 amino acids; LRc, 40 amino acids; and LRd, 31 amino acids).

The extracellular domains of these membrane-spanning leptin receptors mediate dimerization of the leptin receptor in the absence of ligand (leptin). Leptin binding is thought to alter the conformation of the receptor in such a way as to transmit a signal to the intracellular tail of the receptor. Like other class I cytokine receptors, the leptin receptor has no intrinsic enzymatic activity, but mediates signals via a constitutively associated protein tyrosine kinase (Jak2 in this case). Although each of the membrane-spanning LR isoforms contain a critical conserved Box1 motif

required for Jak2 association and signaling, all but LRb lack other motifs that are required for effective Jak2 interaction and activation; hence, only LRb mediates effective signaling. The conformational change induced on ligand binding results in close apposition of the individual Jak2 kinase molecules associated with each monomer of the LRb dimer, leading to Jak2 transphosphorylation and activation and thence to the tyrosine phosphorylation of LRb (Fig. 2).

B. The Long-Form Leptin Receptor, LRb

Much of what is known about LR signaling centers around the so-called long form of the leptin receptor, LRb, with its 301-amino-acid intracellular tail and full Jak2-binding region. Not only is it readily apparent that the long intracellular tail of LRb is likely to mediate downstream signals effectively, but also the original *db* mutation alters a splice site that effectively deletes LRb, replacing it with LRa. The *db/db* phenotype is similar if not identical to the phenotype of leptin deficiency that is observed in *ob/ob* mice. Thus, although the function of the other LR isoforms remains obscure, LRb mediates physiologically important leptin signals. The expression of LRb is also highly regulated; in the brain, high concentrations of LRb are found in few locations (to a great extent in hypothalamic nuclei that are known to integrate body energy status with the control of feeding and neuroendocrine function). LRb may also be expressed in a limited manner in a number of peripheral tissues, although the physiologic relevance of this expression remains unclear.

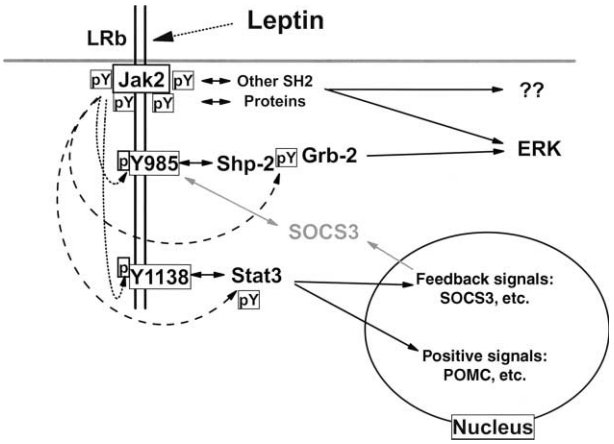

FIGURE 2 Leptin receptor signaling. Leptin binding to the long form of the leptin receptor (LRb) results in the rapid activation and tyrosine phosphorylation of the associated Jak2 tyrosine kinase. Once activated, Jak2 then mediates the phosphorylation (dotted lines) of Tyr-985 (Y985) and Tyr-1138 (Y1138) on the intracellular tail of LRb. Each phosphotyrosine residue becomes a docking site to recruit specific downstream signaling molecules. Phosphorylated Tyr-1138 mediates the binding of the latent cytoplasmic form of the transcription factor, Stat3; Stat3 is then phosphorylated (dashed lines) by the activated Jak2, leading to nuclear translocation of Stat3 and its transcriptional activation. Once in the nucleus, Stat3 mediates transcription of leptin effectors, such as proopiomelanocortin (POMC), as well as the feedback inhibitor, SOCS3. Phosphorylated Tyr-985 mediates the binding of Shp-2, which also becomes phosphorylated by Jak2 (dashed lines), allowing the recruitment of Grb-2 and the activation of the extracellular-related kinase (ERK) signaling cascade. At long times after stimulation, when SOCS3 protein levels have increased, SOCS3 binding to phosphorylated Tyr-985 inhibits all facets of LRb signaling (shaded lines). Downstream signaling proteins likely interact with tyrosine phosphorylation sites on Jak2 as well, although these are poorly characterized.

Receptor–tyrosine kinase complexes (such as LRb–Jak2) signal by inducing the phosphorylation of tyrosine residues in the signaling complex. These phosphotyrosine residues, each in its own unique amino acid context, then become docking sites for downstream signaling proteins that contain specialized phosphotyrosine-binding domains, such as SH2 domains. Each SH2 domain recognizes phosphotyrosine in the context of specific surrounding amino acids; thus, although tyrosine phosphorylation acts as the molecular switch for SH2 domain binding, the amino acid sequence surrounding the phosphotyrosine determines which SH2 domain-containing proteins are recruited.

In addition to its complete Jak2-association domain, the intracellular domain of LRb contains two tyrosine phosphorylation sites, Tyr-985 and Tyr-1138 (Fig. 2); no other LR isoform contains intracellular tyrosine residues. During leptin stimulation, phosphorylated Tyr-1138 mediates the recruitment and activation of the SH2 domain-containing signal transduction and activation of transcription (Stat3) factor. Activated Stat3 mediates the transcription of important neuropeptide mediators of LRb action, including proopiomelanocortin (POMC) and the inhibitory suppressor of cytokine signaling (SOCS3) protein. During acute stimulation, phosphorylated Tyr-985 recruits the SH2 domain-containing tyrosine phosphatase, Shp-2, which controls the activation of the extracellular signal-regulated (ERK) serine kinase cascade. Phosphorylated Tyr-985 also mediates the binding of SOCS3 to the activated receptor, presumably mediating feedback inhibition of LRb during prolonged leptin stimulation (after LRb/Stat3-driven transcription has increased cellular

SOCS3 levels). In addition to these signals that are mediated by tyrosine phosphorylation sites on LRb proper, the activated LRb-associated Jak2 tyrosine kinase also possesses leptin-stimulated tyrosine phosphorylated residues that mediate some components of the leptin signal.

C. The Function of Short and Secreted Forms of the Leptin Receptor

The physiologic and biochemical signaling functions of the short and secreted forms of the leptin receptor are less clear than are those of LRb. There are no known mutations in the leptin receptor gene that specifically affect one or more of the non-LRb isoforms without also perturbing LRb. Much of the phenotype of a strain of *db/db* mice that lacks all leptin receptor isoforms (db^{3J}) is rescued by neural expression of an LRb transgene, however, suggesting only minor roles for these other LR isoforms in the control of physiology. It is not clear, however, whether the failure of this LRb transgene to completely restore normal leptin action results from the lack of other LR isoforms in this model, or is merely due to the expression of this LRb transgene at nonphysiologic levels or locations in these mice.

The ability of the short transmembrane forms of LR (LRa, LRc, and LRd) to mediate physiologically meaningful intracellular signals remains unclear. Although each of these LR isoforms contains the critical Box1 motif required for Jak2 interaction, other sequences that are likely to be required for high-affinity interaction with Jak2 are absent from these receptors and these isoforms are devoid of potential sites of tyrosine phosphorylation. The conservation of these receptor forms across species suggests some function, however, and roles for these receptors in leptin transport, leptin clearance, or LRb inhibition have been proposed; there are few data to address definitively the validity of these proposed functions.

Circulating leptin receptor, not bound to plasma membranes, is also present in mammals. Some of this soluble receptor is the product of LRe mRNA, and some appears to result from cleavage of membrane-bound forms of the leptin receptor. This circulating receptor has a similar affinity for leptin binding as do the membrane-bound forms of the LR, and much of this circulating receptor appears to reside in complex with leptin. Circulating LR is increased in pregnancy (as are serum leptin levels). Possible roles for circulating LR include providing a circulating reservoir for leptin, stabilizing leptin, or decreasing the availability of leptin for membrane-bound forms of the leptin receptor.

V. LEPTIN AND THE ENDOCRINE STARVATION RESPONSE

A. Introduction

Undernutrition evokes a set of physiologic responses geared toward increasing caloric intake, redirecting metabolic fuels, and decreasing energy expenditure (the so-called starvation response). Although many of the details remain unclear, starvation inhibits hypothalamic neurons (e.g., thyrotropin-releasing hormone neurons) that would otherwise stimulate the secretion of anterior pituitary factors (e.g., thyroid-stimulating hormone), which would in turn stimulate endocrine end organs (e.g., thyroid gland) (Fig. 3). Similarly, other hypothalamic neurons (e.g., corticotropin-releasing hormone neurons) are activated, resulting in increased release of different anterior pituitary factors (e.g., adrenocorticotropic hormone) that stimulate other endocrine end organs (e.g., adrenal cortex). Other hypothalamic neurons are similarly regulated during starvation to inhibit

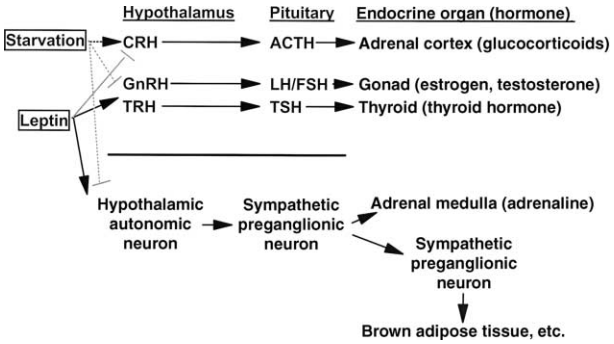

FIGURE 3 Leptin and the endocrine starvation response. Undernutrition, as in starvation, acts on specific sets of neurons in the hypothalamus; these neurons release factors that control endocrine function via the anterior pituitary. Starvation thereby activates the production of glucocorticoids by the adrenal and blocks the production of thyroid and gonadal hormones. Starvation also inhibits the hypothalamic neurons that activate the sympathetic nervous system, blocking the production of adrenaline by the adrenal gland and inhibiting the action of sympathetic neurons on target tissues such as brown adipose tissue. Leptin acts to oppose the starvation response at the level of these hypothalamic neurons. CRH, Corticotropin-releasing hormone; ACTH, adrenocorticotropic hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone; TRH, thyrotropin-releasing hormone; TSH thyroid-stimulating hormone.

the sympathetic nervous system. Many aspects of the starvation response are mimicked by the absence of leptin action (as in *ob/ob* or *db/db* mice), and many aspects of the starvation response can be partially or completely blocked by treatment with exogenous leptin. Indeed, the central theme of leptin function is to communicate the sufficiency (or by its lack, the insufficiency) of body energy stores to the central nervous system (and potentially other tissues).

B. Feeding, Metabolic Rate, and Fuel Distribution

Leptin regulates the intake and storage of metabolic fuels. Rodents and humans deficient in leptin or leptin action are morbidly obese. The obesity of leptin deficiency results in part from a vast increase in food intake (compared to controls with intact leptin action) in combination with decreased metabolic rate. The absence of leptin action enhances the central orexigenic (eating) response and initiates an energy-conserving alteration in metabolic rate, which is consistent with the idea that leptin represents a signal of energy repletion. In rodents, decreased metabolic rate in leptin deficiency seems to result from combined reductions in thyroid function, sympathetic activity, and locomotor activity (Figs. 3 and 4). In rodents, a great deal of this metabolic/sympathetic activity is mediated via the thermogenic brown adipose tissue, which is absent in adult humans. Depressed sympathetic function is also detectable as decreased blood pressure in the absence of leptin action. The decrease in sympathetic tone in the absence of leptin is likely exacerbated by the concomitant hypothyroidism of leptin deficiency, because thyroid hormone mediates a permissive effect on catecholamine signaling.

Defects in leptin function also increase glucocorticoid levels in rodents (Figs. 3 and 4); elevation of glucocorticoid hormones effectively redistributes energy from protein (e.g., muscle) to fat (e.g., adipose and fat deposits elsewhere). Indeed, adrenalectomy in rodents with defective leptin action greatly ameliorates the obesity syndrome, suggesting that some elements of the leptin-deficient obesity syndrome may be secondary to high glucocorticoid levels.

Each of these leptin effects (increased sympathetic and thyroid function and repression of glucocorticoids) is mediated centrally. Leptin acts in the hypothalamus to regulate signals to autonomic centers in the brain and the production of hypothalamic releasing hormones such as corticotropin-releasing hormone and thyroid hormone-releasing hormone (Figs. 3 and 4).

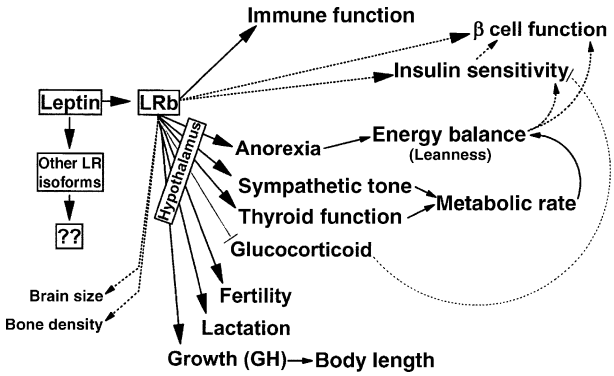

FIGURE 4 Leptin and the control of physiology. Although the actions of leptin on other leptin receptor (LR) isoforms are unclear, leptin activation of LRb controls a broad set of physiologic outputs, many via the hypothalamus. Leptin activates the growth and reproductive axes and permits lactation in postpartum females. Leptin also promotes anorexia (failure to eat). Combined with the increased metabolic rate that leptin promotes via increases in sympathetic tone and thyroid function, leptin regulates the energy balance. Leptin suppresses the stress/starvation hormones of the glucocorticoid family. Although the mechanisms are less clear (and potentially less direct; dashed lines), leptin also promotes large brain size and increased bone density. Leptin aids in controlling the storage and release of glucose by directly and indirectly controlling insulin sensitivity and insulin secretion (via the pancreatic beta cell).

Leptin, of course, is not the only controller of thyroid and glucocorticoid status. Hence, the rarity of humans lacking leptin or the leptin receptor combined with the relatively heterogeneous genetic background of humans compared to experimental rodent models complicates analysis of the endocrine/metabolic function of leptin in humans, in which the variation in so-called normal values is high and abnormal levels are generally defined by stark contrasts provided by diseases of hormone absence or unregulated hormone production. Even so, there are hints that leptin-deficient humans may be marginally hypothyroid and have mildly elevated levels of glucocorticoids.

C. Reproduction

Reproduction requires an enormous investment of energy, especially in females, who must nourish offspring both *in utero* and postpartum (via lactation); the availability of stored energy (fat) should then critically influence fertility. Indeed, society is

replete with anecdotes of impaired fertility in females with low body fat reserves (e.g., highly trained athletes or individuals with eating disorders). Leptin clearly plays a critical role as a signal of energy repletion to the reproductive system in females. Not only is leptin deficiency inextricably linked with impaired female fertility across all species studied, but also the fasting-induced decrease in fertility in rodents is blunted with leptin therapy. Male fertility is decreased by leptin deficiency, but not as much as in females, consistent with the vastly greater energetic demands of reproduction in females. In addition to the effects of leptin on postpubertal reproductive function, there has been some suggestion that leptin levels may influence the progression through puberty, although leptin is clearly not the only pubertal signal in mammals. The presence of normal numbers of quiescent follicles in leptin-deficient animals and the ability of leptin receptor-deficient gonads to function under the control of exogenous or endogenous (after transplant into normal animals) gonadotropins suggest that leptin does not control reproductive function by directly regulating the gonad. Leptin regulates reproductive function by indirectly stimulating the function of gonadotropin-releasing cells in the hypothalamus (Figs. 3–5).

The ability to treat leptin-deficient animals with leptin and so restore reproductive function has enabled the study of postfertilization reproductive function in the absence of leptin. Although there are no data from humans, leptin is clearly not required for the maintenance of pregnancy or parturition in rodents, because withdrawal of leptin postcoitus does not alter the successful completion of pregnancy or delivery of pups. Interestingly, however, the pups of these leptin-deficient mothers generally die soon after birth, without detectable milk in their stomachs. The ability of these pups to survive with wild-type foster mothers suggests a defect in lactation in leptin-deficient animals and, by extension, a role for leptin in the control of the energetically costly process of lactation (Figs. 3 and 4). Indeed, continuation of leptin therapy throughout pregnancy and postpartum permits lactation, suggesting that lactation failure in these animals is not a developmental problem, but is secondary to a hormonal signal mediated by leptin. One reasonable hypothesis is that leptin signals nutritional status to the neuroendocrine centers in the hypothalamus that control the release of prolactin by the pituitary, permitting prolactin secretion only when sufficient energy is available and leptin is present.

In humans, although it is clear that leptin regulates female reproduction (leptin- and leptin receptor-deficient human females are infertile), the specific role of leptin in puberty, parturition, and lactation has yet to be determined. It is also possible that nutritional signals other than leptin may participate in the regulation of reproductive function in humans and other mammals.

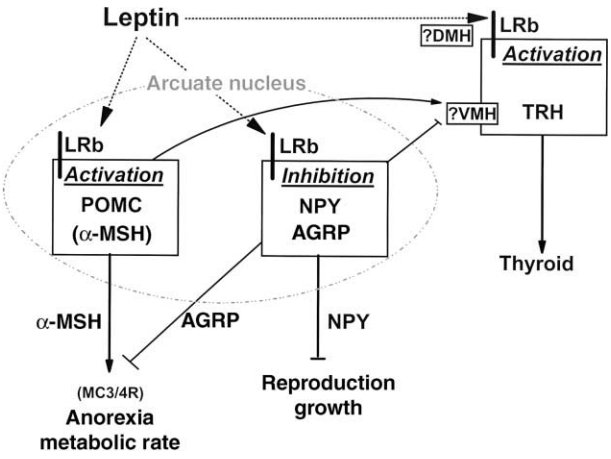

FIGURE 5 Leptin action in the hypothalamus. Leptin stimulates proopiomelanocortin (POMC)/α-melanocyte-stimulating hormone (MSH) neurons in the arcuate nucleus of the hypothalamus to activate the melanocortin receptors (MC3R, MC4R) and to promote anorexia and increased metabolic rate. At the same time, leptin acts to inhibit the arcuate neurons expressing neuropeptide Y (NPY) and agouti-related protein (AGRP). Normally, AGRP antagonizes the action of α-MSH and NPY blocks reproduction and growth; hence, leptin acts to permit reproduction and growth by inhibiting this neuron. Leptin may activate the thyroid-stimulating thyrotropin-releasing hormone (TRH) neurons in the dorsomedial hypothalamic (DMH) nucleus directly and may indirectly activate TRH neurons in the ventromedial hypothalamic nucleus (VMH) by the action of the POMC/α-MSH and NPY/AGRP neurons. These leptin-mediated increases in thyroid function likely contribute to leptin-induced increases in metabolic rate.

D. Growth

Nutritional inputs are also critical for the generation of a large body; this is seen anecdotally in the increased height of first-generation Americans compared to their forebears, who developed under lower nutritional standards. It makes teleological sense to expend less energy generating (and maintaining) a large body in the face of undernutrition. As might be expected, leptin also plays a role in the control of linear growth (Fig. 4). Rodents devoid in leptin or leptin action are shorter than are wild-type mice, and leptin-deficient humans are shorter than would be predicted based on the heights of their parents. As for

reproduction, the regulation of linear growth by leptin is mediated centrally, by the hypothalamus, although leptin may not be the unique nutritional signal to the growth axis.

The finding that animals with defects in leptin action have decreased bone density at an early age suggests that leptin may control bone mass (Fig. 4). One possibility is that leptin may indirectly regulate bone mineral content by influencing reproductive hormone and glucocorticoid levels; direct pathways (e.g., via leptin action on the bone remodeling system) as well as other indirect pathways may exist, however.

Interestingly, rodents devoid of leptin action also have decreased brain size; because a great deal of energy is required to generate and maintain a large brain, the hypothesis that leptin acts as a nutritional signal to control the expenditure of energy in the brain makes teleological sense as well. The mechanism by which leptin regulates brain size is unclear (i.e., via the hypothalamic growth axis or by some other mechanism). Although this possibility remains untested, the developmental delay noted with severe undernutrition in humans suggests that the role for leptin in regulating brain development could be conserved in humans.

E. Integration of Neuroendocrine Function in the Hypothalamus

The mechanisms by which leptin acts in the central nervous system to control neuroendocrine function are becoming clearer. LRb is expressed in several hypothalamic nuclei, each with its own functions, as well as in a few other locations in the brain. LRb-expressing hypothalamic nuclei generally cluster in the basomedial region historically known as the "satiety center" (based on the overeating phenotype exhibited in animals following ablation of these areas). In contrast, the lateral hypothalamus (the corresponding "feeding center," the ablation of which causes anorexia) expresses no LRb. In addition to regulating feeding, the basomedial hypothalamic nuclei that express LRb regulate neuroendocrine function (including autonomic nervous system function and hormone secretion by the anterior pituitary gland).

In the basomedial hypothalamus, the arcuate nucleus expresses the highest concentrations of LRb found anywhere in the body. In this region, LRb is expressed in two sets of chemically distinct neurons (Fig. 5): (1) those that also express POMC, the precursor for the melanocortin α-melanocyte-stimulating hormone (α-MSH), and (2) those that co-express neuropeptide Y (NPY) and agouti-related protein (AGRP). Each of these neuropeptides performs distinct physiological functions. α-MSH secretion results in [via its binding to the melanocortin (MC) receptor-3 and -4 isoforms on target neurons] suppressing appetite and increasing metabolic rate. AGRP antagonizes the α-MSH/MC receptor interaction to increase appetite. NPY mediates myriad effects via several NPY receptor isoforms and suppresses the reproductive and growth axes as well as increasing appetite. Leptin activates POMC/α-MSH neurons, while hyperpolarizing and inhibiting NPY/AGRP neurons.

In addition to regulating arcuate neurons, leptin also acts on neurons in other hypothalamic nuclei: Leptin activates a subset of neurons in the dorsal medial and ventral medial hypothalamic nuclei that may also contribute to the regulation of appetite, among other things. Leptin also activates neurons in the parvocellular paraventricular nucleus, but this appears to be mediated indirectly via connections with projections from the arcuate and dorsal medial nuclei. The neurons in all of these nuclei are those that control neuroendocrine and autonomic nervous system function. Recent data suggest that α-MSH projections from the arcuate nucleus to the paraventricular nucleus contribute to the regulation of the autonomic nervous system by leptin.

Arcuate LRb neurons may regulate thyroid function (α-MSH stimulating and NPY repressing) by synapsing on hypothalamic thyrotropin-releasing hormone (TRH)-expressing neurons in the paraventricular nucleus, and leptin may directly regulate TRH-containing neurons in the dorsomedial nucleus, as well (Fig. 5). Less clear are the central mechanisms by which leptin controls adrenal cortical function, lactation, bone density, and/or brain size (Fig. 4).

VI. LEPTIN ACTION OUTSIDE THE CNS

A. Introduction

Because the highest concentrations of LRb are found in the central nervous system (CNS), especially in the basomedial hypothalamus, it has been widely assumed that little, if any, physiologic leptin function is mediated by direct action on sites outside of the CNS, but rather that the effects of leptin at these peripheral targets are mediated indirectly via the CNS. This initial paradigm has been challenged by a number of studies in a variety of nonneural tissues and, although not all peripheral tissues may be direct targets of leptin action, good evidence exists for direct leptin action on a number of tissues.

B. Immune Function

It has been recognized for some time that nutritional status regulates immune function; because mounting an immune response requires the energetic investment to expand large populations of immune cells, it stands to reason that this response would be placed under some nutritional constraints. As might be expected, leptin controls at least some part of this nutritional input. Indeed, *ob/ob* and *db/db* mice display a number of immune defects, ranging from thymic atrophy and altered T helper cell (T_H1/T_H2) ratios to impaired wound healing. It is possible that some elements of this immune suppression of leptin deficiency are secondary to CNS or neuroendocrine outputs (such as elevation of glucocorticoid levels), but LRb-expressing immune cells have been detected and leptin directly promotes the proliferation of some lymphocyte and macrophage populations, suggesting direct leptin action on at least some immune cells (Fig. 4).

C. Insulin Action

The high incidence of diabetes in most animal models of leptin deficiency or leptin receptor deficiency and the correlation of obesity (leptin resistance) with insulin resistance and type 2 diabetes have prompted a great deal of research on the actions of leptin in the classic targets of insulin action (liver, adipose, and muscle) and in insulin-producing pancreatic beta cells. Although leptin deficiency does not correlate perfectly with type 2 diabetes (the few identified humans deficient in leptin action are not diabetic, and the penetrance of diabetes in rodents is importantly affected by genetic background), it is clear that leptin can play an important role in the progression to insulin resistance and diabetes (Fig. 4). Rodents with genetically impaired leptin action, for instance, progress to frank diabetes at a much higher frequency than do similarly obese rodents with genetic lesions in other systems (such as the melanocortin system). Furthermore, rodents and humans with severe lipodystrophy or lipoatrophy (lack of body fat) display leptin deficiency, enormously elevated serum lipids, and severe insulin resistance and diabetes. Leptin therapy abolishes or ameliorates the insulin resistance, elevated serum lipids, and diabetes without altering the primary lack of adipose tissue.

A number of studies have suggested a potential role for leptin in the regulation of insulin secretion from pancreatic beta cells (Fig. 4). LRb mRNA has been demonstrated in the beta cell and functional data suggest that the presence of this message may be physiologically relevant. Leptin stimulates the activation of Jak2 and Stat3 in these cells. Furthermore, direct treatment of cultured beta cell lines and primary pancreatic islets with leptin results in acutely decreased insulin secretion; as in the arcuate NPY/AGRP neuron, leptin inhibits the cell membrane ATP-regulated potassium channel to hyperpolarize the cell.

Leptin also stimulates the phosphorylation of Stat3 and other receptor-proximal signals in adipose and muscle tissue. Leptin treatment of rodents stimulates gene expression in adipose tissue; this action of leptin on adipose tissue may be mediated indirectly via the central nervous system, however. Additionally, leptin activates the adenosine monophosphate (AMP)-regulated protein kinase (AMPK) in skeletal muscle; two pathways appear to mediate this action: a rapid, direct pathway and a slower pathway mediated via the central nervous system. Although leptin-stimulated AMPK activation in skeletal muscle represents a recent discovery with unknown relevance to physiology, contraction-stimulated AMPK activation in muscle increases glucose uptake into the myocyte, suggesting a potential role for this leptin signal. In the liver, little evidence exists to suggest direct action on hepatocytes, although systemic leptin administration has dramatic effects on liver physiology. Indeed, leptin administration to leptin-deficient *ob/ob* or lipodystrophic mice and lipodystrophic humans reverses the excessive buildup of hepatic triglyceride and dysregulated glucose output associated with lipodystrophy syndromes.

VII. SUMMARY

Leptin is secreted by fat cells as a signal of body energy stores; it serves to integrate the control of energy flux and to regulate the initiation of energy-intensive processes such as growth and reproduction. Thus, leptin deficiency results in increased eating, dysregulation of body energy distribution, and elements of the endocrine starvation response (decreased growth, infertility, etc.). LRb mediates most (if not all) leptin action, and a majority of leptin effects, even in peripheral tissues, depend on leptin action in the central nervous system. We have learned a great deal about leptin function in the years since its initial description, but a great deal remains to be understood about the molecular biology and physiology of leptin.

Glossary

adipocyte Specialized triglyceride-storing cells found throughout the body, commonly known as fat cells. In addition to being an important site for the storage and

release of metabolic energy, adipocytes are the primary source of circulating leptin.

autonomic nervous system Collectively, the sympathetic and parasympathetic nervous systems. The sympathetic nervous system readies the body for action, mobilizing energy stores; actions of the parasympathetic nervous system predominate in energy uptake and storage. The sympathetic nervous system acts on some targets via direct contact of nerves with these tissues, but also mediates systemic effects by promoting release of adrenaline from the adrenal medulla. Elevation of sympathetic nervous system activity increases heart rate, blood pressure, etc.

diabetes Specifically, diabetes mellitus. The syndrome that results from lack of insulin action, either due to absolute lack of insulin (type 1 diabetes) or the inability to produce enough insulin to overcome insulin insensitivity (type 2 diabetes).

endocrine system The network of all hormones. Many endocrine organs (tissues that secrete hormones) are controlled by the action of stimulating factors released by the anterior pituitary gland. The anterior pituitary cells that secrete stimulating factors are regulated by release factors that are secreted into the portal circulation of the pituitary by hypothalamic neurons.

glucocorticoids Cholesterol-derived steroid hormones (e.g., corticosterone) that are the primary product of the adrenal cortex. Some glucocorticoids are produced in adipose and other tissues, as well. Glucocorticoids bind to nuclear glucocorticoid receptors to modulate transcription of target genes. Glucocorticoids are often referred to as catabolic steroids, promoting the breakdown of cellular proteins and potentiating the effects of counterregulatory hormones.

hormone A substance secreted by cells into the extracellular milieu to communicate with other cells. Most hormones work at long distances via the circulation, but may also act on the cell that secreted them (autocrine action) or on nearby cells (paracrine action).

hypothalamus The part of the diencephalon in the subconscious brain that integrates various environmental stimuli to regulate motivation, physiology, and endocrine function. The hypothalamus contains nerve centers (nuclei) that regulate the autonomic nervous system and that regulate the production of pituitary releasing factors. It lies at the base of the brain, overlying the pituitary gland, and is connected to the pituitary gland by a stalk and a specialized portal circulation that carries releasing factors to the anterior pituitary.

melanocortins Peptide hormones (e.g., α- and γ-melanocyte-stimulating hormones and adrenocorticotropic hormone) derived from the precursor protein proopiomelanocortin. Following their release, melanocortins mediate intercellular signaling by binding and regulating one or more of the four known melanocortin receptors on the surface of target cells.

receptor A molecule that binds specifically to a hormone and generates a signal to mediate the action of the hormone.

tyrosine kinase An intracellular signaling enzyme that functions by transferring a phosphate group from ATP to tyrosine residues in substrate proteins. Phosphorylated tyrosine residues transmit downstream signals by recruiting signaling proteins that contain specialized phosphotyrosine-binding domains.

Leptin Actions on the Reproductive Axis

PAOLO MAGNI AND MARCELLA MOTTA
Università degli Studi di Milano

Leptin, a peptide hormone mainly secreted by adipose tissue, represents a signal of satiety and increased energy expenditure, with important actions at the level of the hypothalamus. In addition, leptin participates in the regulation of reproductive processes, playing a role in pubertal development and adult reproductive function. Changes in plasma leptin levels may be involved in the reproductive impairment of anorexia nervosa and obesity. Therefore, leptin may be regarded as a link between modulation of energy expenditure/food intake and the reproductive function.

I. INTRODUCTION

The discovery of leptin, a peptide hormone mainly secreted by the adipose tissue, has provided new insights on the mechanisms controlling food intake and energy expenditure in mammals. One major function of leptin is to inform the central structures controlling energy metabolism, e.g., the hypothalamus, on the status of energy stores, represented by fat mass. Recently, the spectrum of leptin actions has been expanded, and the involvement of this hormone in the control of reproduction has been closely studied.

Leptin is now regarded as a possible link between modulation of energy expenditure/food intake and the reproductive function. In mammals, this function is dependent on energy availability. The crucial physiological observation that these two processes are reciprocally associated in experimental animals, as well as in the human species, in both physiological and pathological conditions dates back over 50 years. The existence of common mechanisms, hypothesized in the early 1970s, suggests that a threshold body fat content is required for the onset of puberty and for maintenance of normal reproductive functions in adult women. Thus, low energy stores are associated with signals leading to increased food intake and reduced energy expenditure, but also to a reversible reproductive impairment. Acute modifications of energy balance are known to modulate the hypothalamic–pituitary–gonadal axis. In several species, fasting and caloric restriction result in suppression of pulsatile luteinizing hormone (LH) secretion, via an inhibition of the gonadotropin-releasing hormone (GnRH) pulse generator, consequently causing infertility. Similarly, excessive energy storage and obesity may interfere with the correct regulation of the reproductive axis. Defective circulating leptin, due to an inactivating mutation of the leptin gene, has been described in the *ob* mouse, which has a phenotype that includes severe and early-onset obesity, extreme insulin resistance, hyperphagia, reduced energy expenditure, and infertility in both sexes. The administration of leptin to *ob* mice results in the reestablishment of fertility, with normalization of body weight and food intake. These findings clearly suggest an important role for leptin in the modulation of reproduction, along with that related to food intake and energy expenditure.

II. SITES AND MECHANISMS OF ACTION OF LEPTIN

Leptin achieves most of its metabolic and reproductive effects by interacting with specific receptors located in the central nervous system, mainly in the hypothalamus (Fig. 1). More specifically, leptin

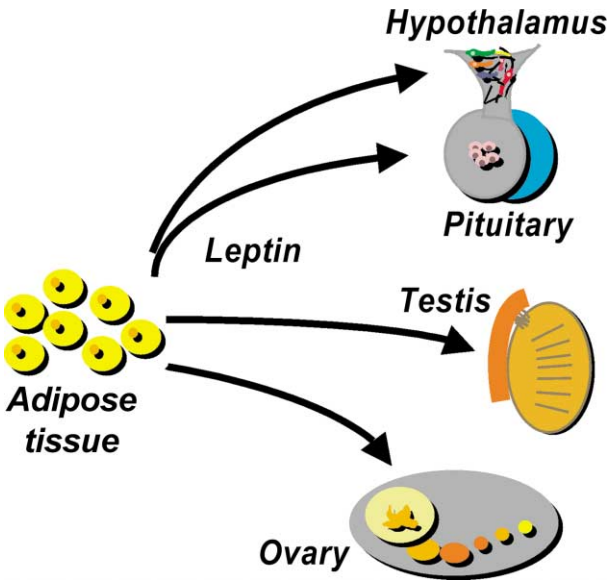

FIGURE 1 Central and peripheral sites of action of leptin for the modulation of reproduction. Leptin, secreted by adipose tissue, acts at multiple levels of the reproductive axis, eliciting different effects on reproduction depending on its concentration in the blood.

receptors are present in four hypothalamic nuclei, i.e., medial hypothalamic, paraventricular (PVN), arcuate (ARC), ventromedial (VMN), and dorsomedial (DMN) nuclei. Leptin receptors, similar to class I cytokine receptors (gp130-like), possess a single transmembrane domain. The six identified isoforms, OB-Ra–OB-Rf, differ in the length of their intracellular domain (Fig. 2); the long isoform, OB-Rb, is abundantly expressed in the hypothalamus.

Leptin modulation of food intake, as well as of the GnRH–gonadotropin system, is believed to be transduced by neurons not only possessing leptin receptors, but also expressing different neuropeptides, i.e., corticotropin-releasing hormone, melanin-concentrating hormone, agouti-related peptide (AGRP), galanin, neurotensin, the most well-studied neuropeptide Y (NPY), and the proopiomelanocortin (POMC) derivatives, suggesting an action of leptin through the activation of these receptors. For instance, administration of leptin to rats results in a down-regulation of NPY gene expression, a reduction of food intake, and an increased energy expenditure. Because NPY is also involved in control of the reproductive function, it is possible that some actions of leptin related to this function might operate at the hypothalamic level through the NPY reproductive network that includes the ARC–median eminence–medial preoptic area. The interplay between NPY and leptin is also suggested by the observation that a cross of NPY knockout mice with *ob* mice decreases the degree of obesity present in the latter.

Inhibitory actions of leptin on food intake are also significantly mediated by signals transduced by melanocortin receptors, and particularly by the MC3 and MC4 receptor isoforms. POMC-deficient mice and humans are hyperphagic, obese, and leptin resistant. However, no major alterations of the reproductive axis or fertility are observed in MC3 receptor-, MC4 receptor-, and NPY-deficient mice: this is suggestive that either these systems do not mediate the reproductive effects of leptin, or, alternatively, that compensatory mechanisms are operative in these animals.

Leptin receptors are also localized at the pituitary level (Fig. 1), and leptin increases gonadotropin secretion and plasma levels in the rat, independently of its hypothalamic action. Messenger RNA transcripts encoding the leptin receptor are present in adult rat pituitary, human fetal pituitary, pituitary adenomas, and ewe anterior pituitary. In addition, a leptin receptor protein is expressed in 29 and 90% of the gonadotropes of the pars distalis and the pars tuberalis of ovine anterior pituitary, respectively; both OB-Rb and leptin are also expressed in normal and neoplastic human pituitary tissue. These data suggest that leptin has the potential to regulate pituitary function via endocrine, paracrine, and/or autocrine mechanisms. Moreover, high concentrations of leptin inhibit pituitary cell proliferation in human and rat pituitary cell lines. Consequently, leptin might directly and positively influence

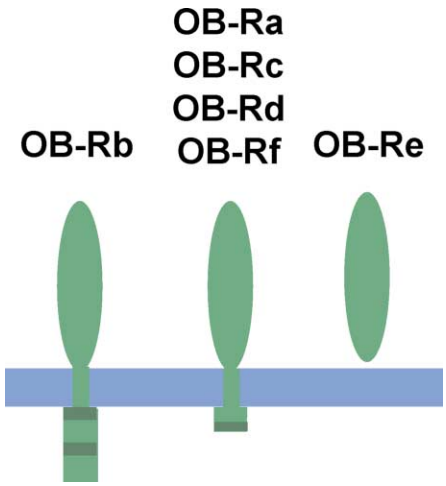

FIGURE 2 The six leptin receptor isoforms. Due to differential RNA splicing, leptin receptors are present in different membrane and soluble (OB-Re) isoforms.

the functions of the gonadotropes by amplifying the stimulatory actions on the hypothalamus–pituitary–gonadal (HPG) axis exerted at the hypothalamic level; in addition, leptin might be involved in the regulation of the growth and differentiation of pituitary cells.

The presence of leptin receptors in peripheral structures of the reproductive system, namely, testis and ovary (Fig. 1), suggests that, in addition to the hypothalamus, leptin may exert its action also on these peripheral organs (see following sections).

III. LEPTIN AND PUBERTAL DEVELOPMENT

The obese and leptin-defective *ob* mouse displays a marked reproductive immaturity in both sexes, with reduced gonadal and uterine weights, low follicle number, and low gonadotropin levels. All these parameters are corrected by leptin administration in male and female *ob* mice. Thus, leptin seems to act as an initiating and permissive factor for puberty, as observed also in normal mice and rats. On the other hand, it is difficult to correlate the complex mechanisms of puberty with modifications of putative single signals such as leptin. Food restriction is known to delay pubertal onset, whereas refeeding abolishes this delay. In addition, murine and human genetic models of leptin deficiency fail to enter puberty, and treatment with leptin can establish a pulsatile secretory pattern of gonadotropins that is characteristic of early puberty. On the other hand, the female transgenic skinny mouse, an *in vivo* model of chronic hyperleptinemia in the absence of adipose tissue, enters puberty precociously. Data regarding the effects of leptin administration on pubertal onset are controversial: intracerebroventricular leptin administration prevents the delay in vaginal opening induced by chronic food restriction in the rat. By contrast, artificially raised leptin levels are not sufficient to abolish the delay of pubertal onset caused by food deprivation. The occurrence of inactivating mutations of the leptin gene, as observed in the *ob* mouse, are extremely rare in humans; however, the few such cases reported confirm that leptin plays an important role linking adiposity and reproduction. In particular, adult female and male patients with the Arg105Trp replacement in the leptin gene are obese and are characterized by primary amenorrhea and prepubertal status, respectively. This observation also supports the concept that leptin is not only a permissive factor for the reproductive function in the adult, but might also represent a metabolic gate for the beginning of puberty, suggested by the peripubertal rise of plasma levels of the hormone in both sexes.

Age seems to represent an important factor that brings about a significant effect on serum leptin concentrations from prepuberty into early puberty. The sexual dimorphism in leptin concentrations becomes evident only after puberty (Fig. 3). In males, leptin levels rise throughout childhood, reach a peak in the early stages of puberty, and then decline, whereas they increase steadily during pubertal development in females. Consequently, adult leptin levels are three to four times higher in females than in males (Fig. 4). The reason for this postpubertal sexual dimorphism in leptin levels is not clear. After puberty, serum testosterone and testicular volume are inversely related to leptin levels in males, whereas in females, when adjusted for adiposity indexes, estradiol is directly correlated with leptin levels. These observations indicate that androgens and estradiol might account, at least in part, for the gender differences in circulating leptin levels. This is also supported by *in vitro* studies showing that androgens and estrogens inhibit and stimulate leptin expression and release from human adipocytes in culture, respectively. Thus, puberty represents a turning point in the sexual dimorphic relationships between the reproductive axis and leptin by determining the

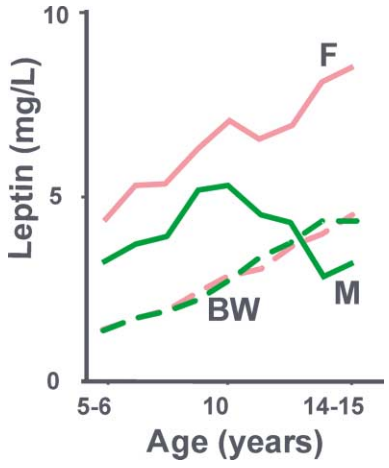

FIGURE 3 Sexually dimorphic leptin levels in puberty. In male (M) and female (F) children, plasma leptin levels (solid lines) rise with age and body weight (BW; dashed lines), but in males there is a decrease to adult levels once testosterone production begins in the testis. Modified from Horlick M. B., *et al.*, (2000), Effect of puberty on the relationship between circulating leptin and body composition. *J. Clin. Endocrinol. Metab.* 85(7), 2509–2518, Copyright The Endocrine Society, with permission.

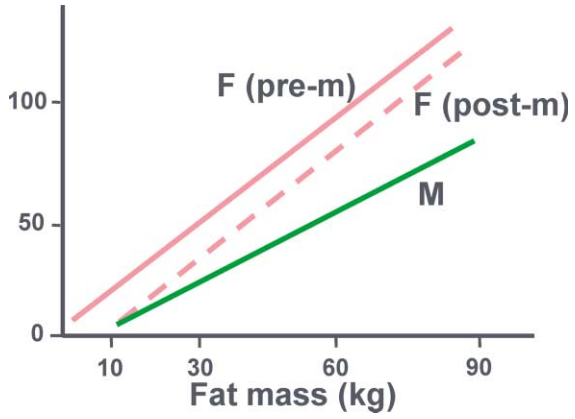

FIGURE 4 Sexually dimorphic leptin levels in adults. Plasma leptin levels are proportional to fat mass, but are higher in premenopausal (pre-m) women than in postmenopausal (post-m) women and in men (M). Modified from Rosenbaum, M., *et al.*, (1996), Effects of gender, body composition, and menopause on plasma concentrations of leptin. *J. Clin. Endocrinol. Metab.* **81**(9), 3424–3427, Copyright The Endocrine Society, with permission.

steroid milieu that leads to a different regulation of leptin secretion in the sexes.

IV. LEPTIN AND MALE REPRODUCTION

Leptin receptors are present in the rat and mouse testis and Leydig cells. Leptin exerts a rapid and dose-dependent inhibition of LH-stimulated testosterone production in rat Leydig cells in culture. Human chorionic gonadotropin (hCG)-stimulated testosterone suppression is accompanied by a parallel reduction of androstenedione levels and a concomitant rise in the precursor metabolites 17-OH-progesterone, progesterone and pregnenolone, compatible with a leptin-induced impairment of 17–20 lyase activity. In addition, leptin inhibits testosterone secretion from adult rat testicular slices incubated *in vitro*, but not from prepubertal testes. These observations indicate that leptin has the potential to modulate the paracrine network that controls gonadotropin-stimulated testicular steroidogenesis, which is analogous to its actions in the ovary.

A negative correlation between plasma testosterone and leptin exists also in humans. In particular, hypogonadal men display higher levels of leptin that are normalized after androgen replacement therapy. Obese subjects, as a group, show raised levels of leptin in blood and reduced androgen concentrations. In obese men, the inhibitory effect of leptin on hCG-stimulated testosterone production appears at concentrations within the range of circulating leptin levels. In addition, the degree of the androgen reduction is related to the amount of fat mass and also to leptin levels. The androgen response to hCG stimulation is impaired in obese men; it is possible that leptin excess might play an important role in the development of reduced androgen production in male obesity.

Immunohistochemical studies demonstrate that mouse testis germ cells express leptin receptors in a stage- and age-dependent manner. Furthermore, *in vitro* treatment of isolated seminiferous tubules with leptin leads to Stat3 phosphorylation, which indicates that OB-R is functional and capable of signal transduction in germ cells. These data suggest that leptin might have additional testicular effects, possibly on the proliferation and differentiation of germ cells, and that the lack of its action(s) might be locally involved in the pathogenesis of infertility observed in leptin-deficient mice.

V. LEPTIN AND FEMALE REPRODUCTION

Leptin receptor expression is abundant in the ovary. Studies conducted on thecal and granulosa cells show that leptin has a negative effect on ovarian steroid production, both in rodent and bovine models. In particular, leptin inhibits insulin-induced progesterone and 17β-estradiol production by isolated bovine granulosa cells, it prevents insulin-induced progesterone and androstenedione secretion in bovine ovarian thecal cell, and it blocks the hormonally stimulated release of 17β-estradiol by rat granulosa cells in culture. Incubation of granulosa cells from fertile women with leptin significantly reduces the production of 17β-estradiol stimulated by follicle-stimulating hormone and insulin-like growth factor I. These observations indicate that leptin, at concentrations commonly found in obese women, has the potential to interfere with estradiol production by the dominant follicle *in vivo*. In addition, an excess of leptin might alter the ovarian response to local tropic stimuli, produced by the dominant follicle. If elevated leptin levels interfere with the development of the dominant follicle and reduce estradiol production, there would be no adequate trigger for LH secretion, which would result in anovulation. In agreement with this observation, administration of leptin in immature gonadotropin-primed rats and exposure of intact rat ovaries to leptin lead to a marked decline (three- to fourfold) in ovulation rate. All these observations might explain, in part, the high incidence of

reproductive dysfunction in obese women and the improvement of anovulation after weight loss.

A putative role of leptin has been proposed in the pathophysiology of polycystic ovary syndrome (PCOS). Insulin resistance and hyperinsulinemia are frequently found in patients with PCOS, although insulin is able to stimulate leptin synthesis and secretion from adipocytes *in vitro*. However, the available data are controversial, and the reports are of increased or unchanged leptin levels in PCOS patients. To evaluate the importance of leptin in female fertility, serum and follicular fluid leptin levels have been measured in different categories of patients: women who succeeded and women who failed in becoming pregnant after assisted reproductive cycles, and patients with PCOS. It was found that lower follicular fluid leptin concentrations are a predictor of pregnancy success, both in normal women and in those with PCOS. However, plasma and follicular fluid leptin levels, after adjustment for body mass index (BMI) and age, are again not significantly higher in the PCOS group than in normal controls. These data are compatible with the hypothesis that when intraovarian concentrations of leptin are high, they might reduce estradiol production and interfere with the development of the dominant follicle and oocyte maturation, thereby contributing to the pathogenesis of female infertility frequently found in obese women.

Pregnancy represents an important challenge in terms of energy metabolism. Several observations suggest the involvement of leptin in this process. Leptin and the related receptors are expressed in the placenta; during pregnancy, especially in the second and third trimesters, serum leptin levels are elevated in both animal models and humans and drops sharply after delivery. Interestingly, the elevated leptin levels during pregnancy cannot be attributed solely to gestational weight gain and increase in BMI. Instead, this increase is mainly the result of other factors, which include the secretion of placenta-derived leptin and the soluble form of its receptor into the maternal circulation, as well as changes in the levels of hormones that might stimulate leptin secretion (e.g., insulin, estrogens, and hCG). Pregnancy-induced hyperleptinemia is not associated with a decrease of food intake or with an increase of energy expenditure, suggesting that the functional reason for elevated leptin is not yet fully understood. In addition to being a site of leptin synthesis, the placenta is a site of abundant leptin receptor expression, both the long signaling and short transporting isoforms. It is possible, therefore, that placenta-derived leptin might play a paracrine and/or autocrine role in placental-fetal physiology. Placenta-derived leptin might act as an important growth factor for the fetus and/or a signal of energy status between mother and fetus. In addition, the reduction in leptin levels seen after delivery might play a role in the reduced fertility found during the period of lactation.

VI. LEPTIN INVOLVEMENT IN REPRODUCTIVE IMPAIRMENT IN EATING DISORDERS

Human obesity is often associated with reproductive disturbances. In this condition, the excessive fat mass might negatively affect the reproductive axis through an altered secretion of at least two known adipose products, leptin and estrogen. However, the picture observed in common human obesity seems much more complex than in several rodent models of obesity. In obese patients, plasma leptin levels are usually proportional to fat mass and thus are elevated; however, in spite of this, an excess of adipose tissue is maintained, leading to the hypothesis of a sort of leptin resistance that cannot be overcome by the high plasma levels of leptin. Leptin might have a dual effect on reproduction, and the major site of action may differ depending on its circulating levels in the blood (Fig. 5). The positive action of leptin at the hypothalamic–pituitary level might be crucial as a trigger of puberty, and might play a predominant role in conditions with abnormally low plasma concentrations, such as in subjects with very low BMI (anorexic patients) or in patients with homozygous mutations of the leptin gene. Conversely, in obesity, central leptin receptors, which are sensitive to

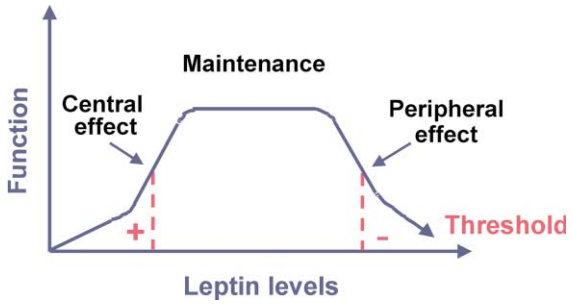

FIGURE 5 Proposed dual action of leptin on reproductive function. Leptin concentrations above a minimal threshold are necessary in the hypothalamus to activate the reproductive axis. Leptin excess above a certain threshold, such as is found in obesity, might impair gonadal steroidogenesis and have deleterious effects on reproduction. Modified from Caprio *et al.* (2001), Copyright Elsevier Science, with permission.

extremely low hormone concentrations, are protected from hyperleptinemia by the saturable transport system of the blood–brain barrier, whereas peripheral leptin receptors are directly exposed to high ligand concentrations, with possible negative effects on gonadal steroidogenesis. It can be hypothesized that a specific and narrow range of leptin concentrations is necessary to maintain a normal reproductive function in both sexes, and that concentrations below or above these thresholds might interfere in opposing ways with the function of the reproductive axis. In any case, the interactions between leptin and the reproductive system appear to be bidirectional, because there is an effect on fertility not only by plasma leptin levels but also by gonadal function (i.e., gonadal production of sex hormones), which modulates leptin synthesis and secretion.

VII. CONCLUSIONS

The discovery of leptin and its related receptors has provided new insights into the pathophysiology of reproduction. It is well established that leptin acts at various levels of the reproductive system, involving different tissues and multiple biochemical pathways. The effect of leptin on reproductive function seems to be determined by different thresholds of activity, depending on its site of activity. In conclusion, leptin appears to accomplish several requirements, linking the regulation of energy balance and the control of reproduction. Future studies in this field should address physiological issues, such as the complete spectrum of the pleiotropic actions of leptin, as well as pathological problems. In this regard, it might be of great interest to test whether leptin or leptinomimetic agents may be useful in correcting metabolic and reproductive dysfunctions that often are simultaneously present in a patient affected by obesity or by eating behavior disorders such as anorexia nervosa or bulimia nervosa.

Glossary

gonadotropin-releasing hormone Hypothalamic peptidic hormone stimulating the secretion of gonadotropins.
leptin Cytokine-like peptide composed of 146 amino acids, mainly secreted by adipocytes.
leptin receptors Exist in several isoforms and are similar to class I cytokine receptors.
neuropeptide Y A 36-amino-acid neuromediator of appetite and other functions.
ob mouse Leptin-defective mouse model of obesity.
polycystic ovary syndrome Disease characterized by obesity, insulin resistance, ovarian dysfunction, and cutaneous symptoms.

the phenotype of LIF knockout mice. The mice show impairments in several systems, including reproduction, the hypothalamic–pituitary–adrenal (HPA) axis, the nervous system, and the immune system.

II. RECEPTOR USAGE IN THE GP130 FAMILY

The gp130 cytokines assemble receptor complexes that contain multiple receptor components, including at least one molecule of gp130. The extracellular domain of gp130 includes a cytokine-binding domain (CBD), also referred to as cytokine-binding module (CBM), cytokine-binding homology region (CHR), or cytokine receptor-like domain (CRD); this domain contains the characteristic four conserved cysteines in the N-terminal fibronectin type III module and a WSXWS motif (using the single-letter amino acid code, W is tryptophan and S is serine; X is any amino acid) in the C-terminal fibronectin type III module. The CBD is sandwiched between an N-terminal immunoglobulin G (IgG)-like domain that plays a role in ligand recognition and three C-terminal fibronectin domains that are adjacent to the plasma membrane (Fig. 2).

With the exception of viral IL-6, gp130 cytokines require additional receptor components in order to activate gp130. IL-6 and IL-11 utilize the receptor specificity subunits, IL-6Rα and IL-11Rα respectively to generate high-affinity complexes with gp130. The cytoplasmic domains of specificity subunits are short or absent, suggesting that they do not contribute to signal transduction. Specificity subunits can usually function *in trans* as soluble receptors. The importance of specificity subunits is that their restricted expression determines which cell types respond.

To form high-affinity receptor complexes, LIF requires an additional transmembrane gp130-related subunit, LIF-R (sometimes referred to as LIF-Rβ). LIF-R resembles gp130 except that LIF-R contains an additional CBD on the N-terminal side of the IgG-like domain. LIF-R is detected as a 190-kDa component on sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE), whereas gp130 migrates more rapidly, ranging from to 130 to 150 kDa. CT-1 can also directly activate complexes of gp130 and LIF-R. A specificity subunit for CT-1 has been proposed but has not yet been cloned. At very high concentrations, CNTF can directly activate gp130/LIF-R, but at low concentrations the specificity subunit CNTFRα is required to activate the complex. CNTFRα is a glycophosphatidylinositol (GPI)-linked receptor that is primarily expressed on neurons. CNTF lacks a signal sequence and is not normally secreted. A secreted ligand for CNTFRα/gp130/LIF-R has been recently identified. CLC is secreted when bound to cytokine-like factor-1 (CLF), a soluble receptor that contains a CBD and an IgG-like domain. The CLC/CLF complex activates gp130/LIF-R in the presence of membrane-anchored CNTFRα. CLC can also be secreted when bound to CNTFRα.

In humans, OSM can activate either gp130/LIF-R complexes or gp130 in combination with another related transmembrane component, OSM-R. OSM-R resembles LIF-R except that the N-terminal CBD contains only a single fibronectin type III module. In mice, murine OSM will activate only gp130/OSM-R. If human OSM is expressed in mice, gp130/OSM-R is not activated; instead, gp130/LIF-R is activated. The large number of gp130 cytokines that activate LIF-R/gp130 complexes complicates the interpretation of the biological activities of exogenous LIF.

III. RECEPTOR ENGAGEMENT BY LIF

LIF is active in bioassays at low concentrations, displaying EC_{50} values below the picomolar level. LIF binds to the LIF-R subunit with an affinity of 1–5 n*M*. The affinity is converted to about 50 p*M* by the recruitment of gp130 into the receptor complex. The higher affinity of the complex reflects a reduction in the off rate. Size-exclusion chromatography indicates that the stoichiometry of the complex is likely to be a trimer of LIF, LIF-R, and gp130. There is a pronounced species specificity to receptor activation by LIF. Human LIF will activate both human LIF-

R/gp130 and murine LIF-R/gp130 complexes with high affinity. In contrast, murine LIF is only a very weak agonist for human LIF-R/gp130.

The crystal structure of LIF has provided a basis for rational mutagenesis of LIF. Two receptor-binding sites have been identified. The gp130 molecule binds to a site in the middle of the A- and C-helices of LIF, referred to as site II. Site II is topologically similar to the region where the second growth hormone receptor binds in the growth hormone/growth hormone receptor complex (Fig. 1). LIF-R binds to site III at the N-terminus of the D-helix. Site III is topologically unrelated to the receptor-binding sites on growth hormone. Because the two receptor recognition sites on LIF, sites II and III, are topologically separate, disruption of site II creates a LIF-R antagonist that occupies LIF-R in nonproductive complexes that fail to recruit gp130. LIF-R antagonists constructed in this way are useful reagents for inhibiting LIF-R activation. Residues in the region equivalent to site I on growth hormone do not appear to be essential for LIF-R or gp130 binding. Site I is occupied on some of the other gp130 cytokines by the specificity subunits IL-6Rα, IL-11Rα, and CNTFRα. In terms of the receptors, particular amino acids in the CBD of gp130 and the IgG-like domain of LIF-R have been suggested to participate in LIF binding. Confirmation awaits the crystal structure of the full complex.

IV. SIGNAL TRANSDUCTION

LIF-R and gp130 rely on intracellular Janus tyrosine kinases (JAKs) that bind to the cytoplasmic domains of the receptor components near the plasma membrane (Fig. 3). Three of the four JAKs (JAK1, JAK2, and Tyk2) can be activated by LIF, but JAK1 is the most important for LIF signaling. Receptor oligomerization by LIF results in JAK activation and receptor autophosphorylation. Phosphorylated tyrosines subsequently recruit signal transducers and activators of transcription (Stats), primarily Stat3, and to a lesser extent, Stat1. The Stats are then phosphorylated by JAKs, triggering the release of Stats from the receptors. The phosphorylated Stats dimerize and are translocated to the nucleus, where they can influence transcription. Stat3 targets include the acute-phase genes in hepatocytes, transcription factors such as Jun B and c-Fos, and the neuropeptide vasoactive intestinal peptide (VIP). The activation of Stat3 underlies the ability of LIF to synergize with

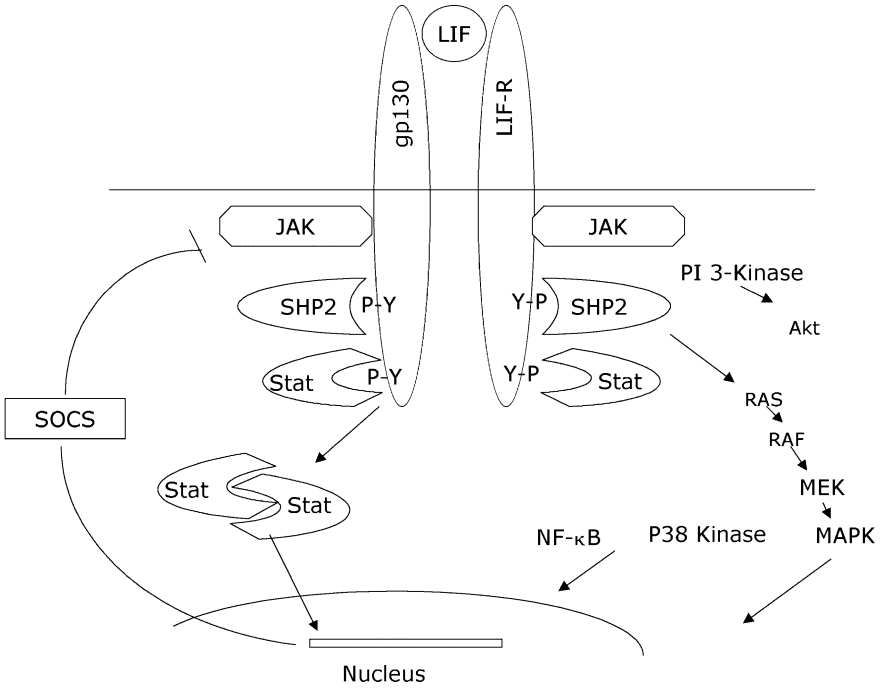

FIGURE 3 Signal transduction pathways activated by leukemia inhibitory factor (LIF). Aside from the JAK/Stat pathway, the precise routing of signals is poorly defined in most cell types (see text for discussion).

growth factors that activate the Smad transcription factors. For example, LIF and bone morphogenetic protein-2 (BMP-2) activate synergistically the glial fibrillary acidic protein (GFAP) promoter to enhance astrocyte differentiation. One of the general targets of Stat3 is the transcription of molecules that inhibit active JAKs, such as suppressor of cytokine signaling-1 and-3 (SOCS-1 and SOCS-3).

LIF-R/gp130 autophosphorylation also results in activation of the Ras/mitogen-activated protein kinase (MAPK) pathway, possibly via SHP2 (SH2 domain-containing protein tyrosine phosphatase-2) binding to SH2-containing adapter proteins. Stat3 activation and MAPK activation appear to work together in supporting proliferation. In BAF cells transfected with LIF-R/gp130, Stat3 provides an anti-apoptotic signal and MAPK provides a mitogenic signal. LIF activation of phospholipase C-γ (PLC-γ), phosphatidylinositol 3-kinase (PI3K), nuclear factor κB (NF-κB), and p38 kinase can also be observed in various cell types. For example, NF-κB is required for the promotion of survival of primary sensory neurons by LIF-R ligands. By utilizing chimeric receptors, it is possible to compare the signals generated by gp130/gp130, gp130/LIF-R, and gp130/OSM-R complexes. The comparisons indicate that although there is overlap in pathway activation, there is specificity as well. Hence the equivalence or nonequivalence of gp130 cytokines is assay dependent.

V. LIF GENE ORGANIZATION AND EXPRESSION

A. Species

LIF homologues have been sought in many species in the hope that they will maintain embryonic stem cells that can be used to create transgenic animals. LIF sequences have been identified in tissues from humans, mice, rats, hamsters, pigs, American minks, cows, muskrats, and even the marsupials, brushtail possums. Although LIF has not been identified in chickens, chickens make a cytokine called growth-promoting activity (GPA) that resembles CNTF in structure and activity, but is secreted. Frogs have been shown to have factors with sequences that resemble those of gp130 and LIF-R, but the extent of ligand conservation is not yet clear.

B. Chromosomal Location

In humans, the LIF gene is located at 22q.12 and is near the gene for a related family member, OSM, suggesting that both products are a result of recent

gene duplication. The human and mouse LIF genes are about 80% identical in amino acid sequence and both genomes show the LIF/OSM synteny.

C. Transcripts

LIF transcripts are composed of three exons (Fig. 4). Only the last two exons contribute to the mature peptide. The first exon determines the nature of the signal sequence and therefore influences the localization of the protein. At least three different versions of the first exon can be selected by alternative splicing. In mice, one of the versions, the M-form, has been associated with the expression of LIF in the extracellular matrix, and the D-form has been associated with diffusible expression. An additional form, the T-form, which completely lacks a signal sequence and the N-terminus of the mature peptide, produces a truncated version of LIF that is cytoplasmic. Similar transcripts have been identified in human tissues, although in humans the M-form lacks an in-frame methionine and gives rise to a mixture of secreted and cytoplasmic forms of LIF. The three alternatively spliced versions of LIF are expressed in different ratios by different cell types, suggesting that the splicing is regulated. Transgenic mice overexpressing murine LIF M-form or D-form under the same promoter develop different phenotypic abnormalities, indicating that the manner of presentation may be important in shaping the biological activity.

D. Expression

LIF expression is kept under tight temporal and spatial control. LIF transcripts have been detected in many tissues in mice, including (at least) heart, liver, pituitary, pancreas, breast, uterus, gut, germ cell, kidney, normal pigment epithelium, cartilage, lung, lymphocytes, monocytes, osteoblastic cells, bone marrow stromal cells, and thymus. However, strong expression of LIF is restricted in healthy mice to the uterine endometrial glands of pregnant females just prior to implantation. Strong LIF expression is also detected in affected tissues following infection, inflammation, and injury. For example, LIF is elevated in synovial tissues in rheumatoid arthritis, the bronchoalveolar lavage of patients with acute respiratory distress syndrome, the urine of patients undergoing acute rejection after kidney transplantation, and in the early stages of contact dermatitis. The cellular sources of LIF include cells of the immune system, such as monocytes/macrophages and T cells, as well as stromal cells, such as fibroblasts, muscle cells, keratinocytes, epithelial cells, synoviocytes, chondrocytes, osteoblasts, neurons, Schwann cells, and astrocytes. Inducers of LIF expression include bacterial products and other cytokines, such as IL-1, IL-6, IL-16, and tumour necrosis factor (TNF), as well as reproductive hormones. LIF expression is typically local; only in the event of septicemia does LIF rise substantially in serum.

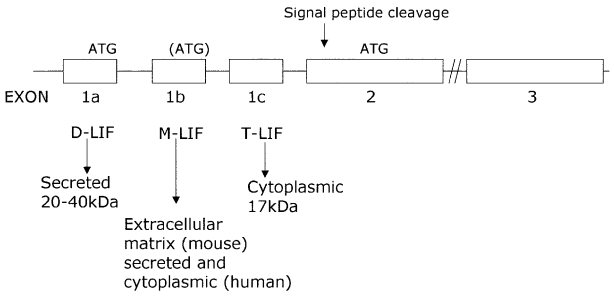

FIGURE 4 The leukemia inhibitory factor (LIF) gene contains three exons. The mature protein is encoded within the second and third exon. The first exon determines the nature of the signal peptide and hence the cellular localization of the protein. The first exon is alternatively spliced, giving rise to three transcripts. In humans, the in-frame ATG in the second exon is missing in the M-LIF form and alternative translation initiation sites are employed.

VI. *IN VITRO* ACTIVITIES OF LIF

Both gp130 and LIF-R are expressed by most tissues and cell lines. Hence, LIF is active in a wide variety of biological assays, evoking cellular responses that include proliferation, differentiation, protection from apoptosis, inhibition of differentiation, and gene activation. Table 2 lists a sample of *in vitro* activities in a range of cell types. Of the numerous activities, the neurotropic activities of LIF have attracted strong interest from clinicians as a way to support neurons in degenerative diseases. Provided that the appropriate receptor components are present, activities similar to those of LIF will often be observed with other gp130 cytokines. There are currently only a few examples *in vitro* for which the identities of the signal-transducing subunits (gp130, LIF-R, and OSM-R) have been shown to make a qualitative difference.

VII. *IN VIVO* ACTIVITIES OF LIF

A. Systemic LIF Elevation

Experiments in mice have revealed that prolonged elevation of LIF wrecks havoc on the body. Mice

TABLE 2 *In Vitro* Activities of LIF[a]

Cell type	Activity
Embryonic stem cells	Prevents differentiation
M1 leukemic cell line	Differentiation
Macrophages	Chemotaxis
Hematopoietic progenitors	Proliferation of primitive and committed myeloid progenitors, megakaryoctes
Osteoblasts	Proliferation, survival, differentiation
Adipocytes	Differentiation, inhibits lipoprotein lipase
Fibroblasts	Increases TIMP1, proliferation
Synoviocytes	Increases cytokine production
Chondrocytes	Increases TIMP1, IL-1β
Endothelial cells	Increases protein S, inhibits proliferation
Myoblasts	Proliferation
Cardiac myocytes	Survival
Hepatocytes	Induces acute-phase proteins
AtT-20 (pituitary corticotrophs)	Increases POMC expression, ACTH, and growth hormone secretion
Lung epithelial cells	Increases cytosolic phospholipase A_2
Keratinocytes	Increases cytokine production
Spinal cord precursors	Neuronal and astrocytic differentiation
Sensory neurons	Survival
Sympathetic neurons	Increases acetylcholine synthesis and decreases catecholamines synthesis

[a]The list of *in vitro* activities for LIF presented here includes a small selection of the large number of activities observed following LIF application to different cell types and tissues.

implanted with LIF-secreting cells become cachectic and hypermotile and ultimately die after 6–8 weeks of treatment. Both subcutaneous fat and abdominal fat are completely depleted. The mice also display thymus atrophy, osteopetrosis, calcification of skeletal and heart muscles, and numerous other pathologies. Injecting LIF daily for 2 weeks results in a milder phenotype; however, at high doses, behavioral changes, loss of body fat, and thymus atrophy still occur. Megakaryocyte and platelet levels are also elevated. Most of the symptoms of the LIF-treated mice can be understood in terms of the *in vitro* activities of LIF on different cell types.

B. LIF − /− Mice

Experiments in which LIF is overexpressed *in vivo* may offer more insight into the consequences of generalized LIF-R activation than true LIF function in which LIF expression is restricted temporally and spatially. LIF knockout mice are more informative, with the caveat that the extent (if any) to which LIF *in vivo* functions are masked by redundancy with other gp130 cytokines is unknown. So far, the double knockouts with IL-6 − /− mice and CNTF − /− mice demonstrate only very modest phenotypic synergy, but that may not be true for other gp130 cytokines.

Two different groups described LIF − /− mice in the early 1990s. Despite expectations of a lethal deficit in embryonic stem cells, the mice were viable but smaller than their wild-type littermates.

1. Implantation

LIF − /− males are fertile and LIF − /− females are infertile. The fertility defect derives from a maternal defect in implantation. LIF −/− blastocysts implant successfully when transplanted into foster wild-type females, whereas even wild-type blastocysts fail to implant into foster LIF − /− females. Introducing exogenous LIF into LIF − /− females throughout the period of normal implantation restores implantation. Additional work has carefully defined the spatial and temporal expression of LIF, LIF-R, and gp130 during the establishment of pregnancy, but the functional role of LIF in implantation is still poorly defined. Low LIF production is also associated with reduced fertility in humans, indicating that increasing LIF might aid fertility in some women.

2. Hematopoiesis

The stem cell compartment and the immune responses of LIF − /− mice are abnormal. The numbers of

pluripotent stem cells in the spleen and the bone marrow of the mice are reduced, but the overall numbers of nucleated cells in the spleen and bone marrow and the numbers of circulating mature red cells and platelets are normal. This suggests a reduction in the stem cell pool rather than a reduction in the ability of hematopoietic cells to differentiate. Indeed, LIF − /− stem cells developed normally when introduced into an irradiated host, arguing that the deficiency derives from the microenvironment for supporting stem cells in the LIF − /− mice and not from the stem cells. The thymic T-cell responses to concanavalin A (Con A) and allogenic stimulation are also strongly reduced in the LIF − /− mice, indicating alterations in the thymic epithelium. Wild-type animals reconstituted with LIF − /− stem cells regain normal T-cell responses, again suggesting that the deficiency derives from the stromal microenvironment.

Subjecting the LIF − /− mice to specific models of injury and inflammation has yielded a number of differences from wild-type mice, especially at the interface of the immune system, the endocrine system, and the nervous system. A few of the conditions tested and the resulting findings are described in the following sections.

3. Nerve Injury and Inflammation

LIF is essential for neuronal and muscle repair following trauma. For muscle, the absence of LIF reduces the size of muscle fibers, probably by reducing the proliferation of myoblasts. For neurons, the absence of LIF changes their intrinsic growth status. Normally, conditioning lesions enhance the growth status of neurons. If the sciatic nerve is axotomized *in vivo* 2 weeks before dorsal root ganglion (DRG) neurons are transplanted into culture, the conditioned neurons will show increased neurite outgrowth in culture. In such a model, neurons from the LIF − /− mice fail to demonstrate conditioning. Furthermore, when regeneration is measured after a nerve crush, peripheral nerve regeneration in the LIF − /− mice is impaired. The LIF − /− sensory neurons fail to progress out of the crush site, whereas neurons from wild-type mice penetrate beyond the crush site into the distal nerve stump. The lack of regeneration is consistent with an intrinsic defect in the ability of LIF − /− neurons to extend neurites. However, an extrinsic change in the inflammatory cell infiltrate may also have shaped the behavior of the LIF − /− neurons.

In a separate study of LIF − /− mice, following nerve crush, inflammatory cells infiltrated the nerve more slowly compared to the infiltration in wild-type mice. The slowed inflammatory response was also observed when the brain cortex of LIF − /− mice was lesioned. Both microglia and astrocytes were slow to respond in the LIF knockout. Although LIF appears to be pro-inflammatory within the nervous system, that is not true everywhere. Injection of complete Freund's adjuvant (CFA) into the footpad of an adult LIF − /− mouse resulted in increased edema and cellular infiltration compared to wild-type mice. Local introduction of LIF via an injection of an adenoviral vector expressing LIF suppressed the inflammation. The disparate effects of the absence of LIF on cellular infiltration in the nerve injury model and the CFA footpad model argue that the function of LIF in the cytokine networks must be different in each of the models.

4. Hypothalamic–Pituitary–Adrenal Axis

LIF plays an important role in regulating the hypothalamic–pituitary–adrenal (HPA) axis in response to psychological stress or inflammation. When adrenocorticotropic hormone (ACTH) is measured, LIF − /− mice display lower basal levels compared to wild-type mice. Injection of CFA into the tail vein or injection of turpentine into the hindlimb muscle fails to elicit in LIF − /− mice a normal rise in ACTH and corticosterone. In these models of inflammation, in intact mice, LIF expression is highly induced in the hypothalamus and weakly induced in the pituitary. The critical LIF activity is the induction of proopiomelanocortin (POMC) expression and ACTH secretion in the pituitary.

VIII. SUMMARY

LIF is a four-helical bundle cytokine that belongs to the gp130 family of cytokines. Along with several other members of the family, LIF activates receptors composed of the signal-transducing components, LIF-R and gp130, which activate the JAK–Stat pathway. The sharing of receptor components accounts for the redundancy in activities observed with other family members *in vitro*. Most cell types express LIF-R and gp130, but their responses to LIF are varied, including proliferation, survival, prevention of differentiation, differentiation, and gene activation. LIF is highly expressed in the endometrial glands of pregnant mice; otherwise, it is only weakly expressed except in inflammation and tissue injury. Experiments with LIF − /− mice demonstrate an essential role of LIF in implantation, generation of a normal stem cell compartment, repair of nerve

injury, control of inflammation, and the regulation of the HPA axis.

Glossary

cytokine-binding domain Conserved domain in the extracellular region of type I cytokine receptors; composed of two fibronectin type III modules that can function as a ligand-binding pocket.

gp130 Signal-transducing receptor component shared by a large family of cytokines, including interleukin-6 and leukemia inhibitory factor.

immunoglobulin-like domain Domain of about 100 amino acids; predicted to adopt a seven-stranded immunoglobulin-like fold that in cytokine receptors has been shown to participate in ligand binding.

Janus tyrosine kinases Family of cytoplasmic protein tyrosine kinases; bind to the cytoplasmic domains of cytokine receptors and are activated on ligand binding.

leukemia inhibitory factor receptor Signal-transducing receptor component; closely related to gp130 and binds leukemia inhibitory factor with nanomolar affinity.

signal transducers and activators of transcription (Stats) Family of receptor-binding transcription factors that are translocated to the nucleus when phosphorylated by Janus tyrosine kinases.

Src homology 2 domain-containing protein tyrosine phosphatase-2 Key protein in transducing signals from cell surface receptors to the nucleus; functions as an adapter as well as a phosphatase.

suppressor of cytokine signaling (SOCS) Family of proteins characterized by a central SH2 domain and a suppressor of cytokine signaling box that mediates negative feedback by inhibiting Janus tyrosine kinases.

Ligand Modification to Produce Pharmacologic Agents

EUGENE N. BUSH

Abbott Laboratories, Illinois

Cellular communication in biological systems is based on receptor targets for naturally produced chemical ligands. Natural ligands may have limitations with regard to efficacy and specificity. Structural modifications of natural ligands may alter activity and pharmacokinetic characteristics. Conformationally restricted compounds can show improved selectivity. Systematic chemical substitutions and random screening procedures may result in ligands with a spectrum of activity from antagonist to full agonist, as well as specificity at the receptor target.

I. GENERAL CONCEPTS OF CHEMICAL COMMUNICATION

Chemical communication is utilized at several levels within a multicellular organism. Certain organs or tissues (endocrine glands) contain specialized neuroendocrine cells that produce and secrete chemical agents into the extracellular fluid in response to a stimulus. These naturally produced molecules diffuse into the general circulation and reach target cells at sites distant from the site of secretion, serving as ligands to mediate communication at the target cell receptor. Intercellular communication may also be more discrete. Secreted paracrine (local mediator) factors, including peripheral and central nervous system neurotransmitters, have local effects on nearby cells; autocrine factors are secreted by and affect the same cell. Many chemical mediators are not secreted by cells—rather, they are formed within and are recognized by targets within the same cells.

A pharmacologic agent or drug is a compound that, when administered to an organism, produces an effect on a specific function or process. A drug is an exogenous agent, one that originates from outside of an organism. Many pharmacologic agents are synthetic analogues of natural substances that act on specific receptor targets. Pharmacologic agents alter a specific natural process in an organism either by mimicking the effect of an endogenous beneficial or pathological chemical or by blocking the effect of a native compound. A natural compound may be present in abnormally large amounts in a disease state. Cushing's disease, for example, results from overproduction of glucocorticoid hormones (cortisol) by the adrenal cortex, and Graves' disease is characterized by overproduction of thyroid hormones. In other circumstances, an endogenous ligand may not be consistently elevated during a disease, yet blockade of the receptor for the ligand may still be beneficial. For example, β-adrenergic blockers can decrease cardiac rate and contractility in a patient with hypertension, but the elevated blood pressure cannot be attributed to excessive β-adrenergic stimulation. In other circumstances, the endogenous ligand may be lacking or absent. This is the basis of treatment of type 1 diabetes with insulin, because pancreatic beta cells do not adequately produce and secrete insulin. Hormone replacement is also used in treatment of hypothyroidism, Addison's disease (lack of cortisol production by the adrenal cortex), diabetes insipidus (lack of antidiuretic hormone), and postmenopausal osteoporosis (lack of estrogen). Similarly, hormone replacement may be used for therapeutic effects when there is no obvious lack of endogenous ligand, such as the in the use of growth hormone to promote longitudinal growth in adolescents with short stature. Receptor over- or underexpression or altered signal transduction may also be present in a disease state, and thus the normal quantity of natural ligand is not sufficient.

II. RECEPTOR CLASSIFICATION

The receptor concept was first proposed by Langley in 1907 to explain the means by which the natural toxin curare could selectively block contraction of skeletal muscle. Prior to the development of technology for the determination of protein and genetic sequences, the existence of many different specific receptors could be inferred and categorized from the responses of cells to specific chemical stimuli. Currently, the definitive classification of receptors is based on amino acid sequence, although posttranslational modifications such as glycosylation or sulfhydryl cross-bridge formation may also regulate receptor activity and/or specificity. Receptors are grouped into superfamilies and families based on sequence or structural homologies, the endogenous ligand, the activity of selective agents that mimic or block the endogenous ligand, and the cellular second-messengers systems used by these receptors (Table 1).

Many receptors are integral plasma membrane proteins with a binding site for the ligand present on the outer cell surface. The guanosine triphosphate (GTP) binding proteins, or G-proteins, are adapters for signal transduction between receptors and many different intracellular transduction systems. Specific G-protein complexes bind to these receptors and regulate signaling proteins such as adenylate cyclase

TABLE 1 Receptor Superfamilies Based on Structural Similarities

Superfamily	Structural feature	Example	Second messenger
G-protein coupled	Single chain, seven transmembrane-spanning domains	Rhodopsin, α- and β-adrenergic subtypes, angiotensin II, FSH, GnRH, MC4	Adenylate cyclase (increase or decrease cAMP), phospholipase C (increase IP3 and diacylglycerol)
Ligand-gated ion channels	Multiunit oligomeric complex	Nicotinic acetylcholine, GABA	Ions (Na^+, K^+, Ca^{2+})
Receptor tyrosine kinase	Heteromeric, activation via autophosphorylation of tyrosine	Insulin, IGFs, epidermal growth factor	Tyrosine-phosphorylated proteins
Receptor protein tyrosine phosphatase	Binding sites for phosphotyrosine residues	PTP1B, LAR	Dephosphorylated proteins
Cytokine receptor	Multiple forms families—single-transmembrane protein	GH, PRL, EPO, TNFα, IL-6, leptin	JAK (tyrosine kinase)–Stat
Intracellular hormone receptor	Single chain, hetero- and homodimers	Steroids, thyroid, retinoic acid, PPARγ	DNA binding and transcription

and phospholipase C. The G-protein-coupled receptors (GCPRs) are a large family of receptors that share the common structural feature of a single protein chain with seven transmembrane-spanning domains. Knowledge of common amino acid sequences of transmembrane domains has led to identification of a number of genes that encode previously uncharacterized receptors for which neither the endogenous ligand nor physiological role was known. The inventory of known endogenous peptide and protein ligands has also been expanded through the appreciation of structural homology. Many newly described receptors may be potential therapeutic targets, and this strategy may lead to identification of promising new drug targets as the human genome is fully characterized. Furthermore, the genomic strategy based on sequence homologies to known receptors is not restricted to the GPCRs.

Many receptors are classified as hormone-responsive or ligand-gated ion channels. These receptors are not configured as a single chain like the GCPR, but are instead an oligomeric complex of proteins with at least one ligand recognition element and one ion-specific pore. Both the ligand-binding site and the ion pore contribute to selectivity. In the presence of a ligand, the pore is either opened or closed, thereby regulating ion flux, electrical potential, and other cell processes. The nicotinic receptors at the neuromuscular junction control the interaction of actin and myosin through regulation of sodium ion flux and intracellular calcium ion mobilization. There are specific receptors in pancreatic beta cells that bind sulfonylurea analogues and stimulate the secretion of insulin by closing adenosine triphosphate (ATP)-sensitive K^+ channels; these have been the target for oral hypoglycemic agents for decades.

Receptor tyrosine kinases directly phosphorylate tyrosine residues in their own intracellular domain, as well as several signal transduction/adapter proteins, including the insulin receptor substrates (IRS1–IRS*x*). Insulin and the insulin-like growth factors are examples of this receptor type. Receptor protein tyrosine phosphatases dephosphorylate receptors and molecules of signal transduction. Inhibition of these may lead to improved receptor tyrosine kinase signal transduction and to new agents for treatment of diabetes. Activation of these phosphatases may be useful for treatment of cancers and immune disorders.

Cytokine receptors are configured as a single protein chain with one transmembrane domain that does not possess intrinsic tyrosine kinase activity. These receptors associate with and activate the Janus kinases (JAK) and signal transducers and activators of transcription (Stats). Examples of ligands for cytokine receptors are growth hormone, prolactin, interleukin-6 (IL-6), and leptin.

There are also receptors that are present in one or several intracellular compartments in membrane-bound or soluble form. The intracellular receptor superfamily includes all of the steroid hormone (estrogen, androgen, progesterone, glucocorticoid, mineralocorticoid, and vitamin D) receptors. Many of these are not exclusively receptors for a single ligand; rather, their binding to ligand and activation may be modulated by signals from cell surface receptors as well. In this respect, the estrogen receptor is the best characterized, but other steroid receptors are similarly modulated by cell surface messengers.

Thyroid hormone and vitamin A (retinoic acid) receptors form heterodimers with the retinoic acid X receptor (RXR), which binds the 9-cis form of retinoic acid, permitting dual regulation of receptor activity by the ligands for each receptor. The intracellular receptors have DNA-binding domains and activate or inhibit the transcription of specific genes that possess a hormone response element (HRE), a site where the activated intracellular receptor can bind.

Receptors confer specificity, and it is assumed that receptors are the most favorable targets for therapeutic intervention. Although other components of signal transduction may not bind extracellular ligands directly, they specifically recognize and bind to the receptors and other specific downstream molecules of signal transduction. These transducers may also be suitable targets for new specific drug development. Examples of these targets are ligand-regulated transcription factors; mitochondrial, nuclear, and vesicular structural and functional proteins; genes (DNA); and gene transcripts (mRNA).

III. PHARMACODYNAMIC CONSIDERATIONS

If nature has designed a ligand molecule with high affinity and an ability to activate its target, then why is there a need to alter it? First and foremost, not all situations require complete activation of a ligand-dependent response. In many situations, partial activation, partial inactivation, or a complete blockade of a receptor target will lead to a desired response.

A ligand that activates a receptor, leading to a response, is considered an agonist (Fig. 1). In most cases, there is a direct relationship between the concentration of compound and the magnitude of the response. At higher concentrations, a maximum effect is reached and further increases in concentration do not lead to a greater response. The magnitude of the maximum effect of the agonist relative to the natural ligand is the intrinsic activity of the agonist, usually expressed as a percentage. In case the natural ligand is not known, the maximum effect of another reference compound may be used. The concentration of agonist that produces 50% of the maximum response (effective concentration) is designated the EC_{50}. The ratio of EC_{50} values for different ligands that produce activation of the receptor is an indicator of relative potencies.

Full activation and blockade are not the only events that result from a ligand–target interaction. Some agents do not possess the intrinsic activity of the natural ligand in all cells and tissues. These partial agonists will produce only a partial activation of their receptor, and in the presence of a full agonist they will behave more like antagonists. Tissue differences in intrinsic activity may be associated with a compound, producing a tissue selectivity even when the same receptor is present in multiple tissues. Another issue is that the receptors may associate with other elements of signal transduction, even in the absence of ligand. These receptor systems may possess basal constitutive activity, and the presence of an inverse agonist will decrease the basal activity mediated by the receptor.

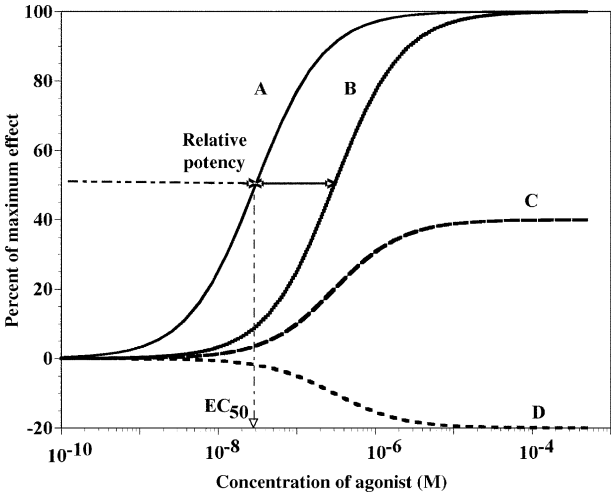

FIGURE 1 Agonist concentration–response. The curves are fit to the equation $E = ([A]IA)/([A] + EC_{50})$, where E is the effect, [A] is agonist concentration, IA is the intrinsic activity of the agonist, and EC_{50} is the agonist concentration associated with a half-maximum response. The EC_{50} for curve A is $3 \cdot 10^{-8}$ M, and for B, C, and D is $3 \cdot 10^{-7}$ M. Curves A and B represent full agonists, where A is 10-fold more potent than B. Curve C is a partial agonist with 40% of maximum intrinsic activity. Curve D is an inverse agonist acting on a receptor with constitutive activity, resulting in a 20% decrease in activity.

An agent that prevents activation of the receptor by an agonist is considered an antagonist (Fig. 2). Whereas an agonist presumably results in some conformational change that promotes interaction with a second-messenger system, an antagonist binds but does not favor a productive interaction with second messenger, even though the receptor may be induced to bind to the next element of signal transduction. Endogenous antagonists for some receptors have been identified. The agouti-related protein (AGRP) is an antagonist of melanocortin receptors in the hypothalamus. Antagonist activity, like agonist activity, is not all or none. If the antagonist binds to the same binding site as the

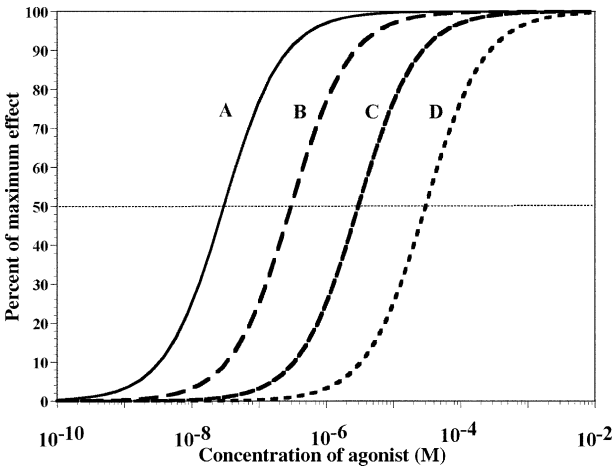

FIGURE 2 Antagonist evaluation. The response to agonist A is blocked in the presence of antagonist, requiring greater concentration of A to produce an effect. Curve A is agonist alone, B is agonist in presence of 10^{-7} *M* antagonist, C is agonist plus 10^{-6} *M* antagonist, and D is agonist plus 10^{-5} *M* antagonist.

agonist, they may compete with the agonist for these sites. Increasing concentrations of agonist increase agonist accessibility to the binding sites, thereby surmounting the effect of the antagonist. There is a parallel rightward shift in the concentration–response curve of the agonist in the presence of a competitive, reversible antagonist. If one calculates the ratio of EC_{50} values in the presence vs absence of the antagonist, and compares these concentration ratios vs the concentration of antagonist at each ratio via linear regression, there is ideally a linear relationship between the agonist concentration ratio and the antagonist concentration (Fig. 3). By extrapolation, the concentration of antagonist that produces a twofold increase in the agonist requirement to reach a 50% response is determined. The negative logarithm of this concentration of antagonist is the pA_2, a measure of the affinity of an antagonist for the receptor. The pA_2 values for different antagonists of the receptor may be compared in order to describe relative antagonist activities quantitatively.

The interactions between a ligand and receptor are not usually covalent. Rather, the molecules associate via thermodynamically favorable hydrogen bonds, dipole and ionic interactions, and hydrophobic interactions, via functional groups on the ligand and the receptor (Table 2). The overall affinity between ligand and receptors is the product of several individual interactions between functional groups. Although each of these individual interactions is relatively weak, a high affinity and practically irreversible interaction is possible as a result of the interactions between many functional groups.

There are at least two divergent approaches to structural modification when an endogenous ligand is known. First, one can start with the native hormone structure, making structural analogues with conservative, systematic changes. Changes in structure that affect affinity or activity may help to identify important functional groups, and groups that stabilize the three-dimensional configuration of the ligand such that the receptor-interacting functional groups are favorable or optimum for interaction with the receptor. A second approach is to construct a library of compounds, and screen compounds without preselection based on structural similarity to the hormone. Hits would then be further modified to optimize activity. These two strategies are not mutually exclusive and may be used together at various stages in a cycle of structure identification and refinement.

A linear peptide hormone such as glucagon, somatostatin, or gonadotropin-releasing hormone (GnRH) may have considerable flexibility. A conservative substitution of one D-amino acid for the glycine in position 6 of GnRH results in greatly improved affinity and *in vitro* potency, due to induction of a beta turn in an otherwise extended molecule, and bringing the ends into close proximity. Covalent crossbridges between amino acid sidechains or amino- to carboxyl-terminal cyclization will result in a even more rigid structure. Octreotide and

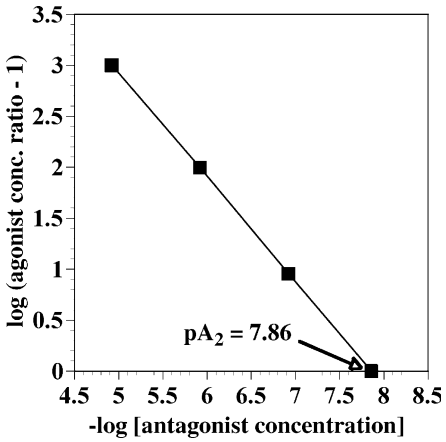

FIGURE 3 Schild plot. The ratio of concentration of agonist required to produce a 50% of maximum effect in the presence of antagonist over the EC_{50} for the agonist is decremented, log transformed, and compared to the negative log of the concentration of antagonist. The *x* intercept is the pA_2, the negative log of the concentration of antagonist that results in a twofold increase in agonist EC_{50}.

TABLE 2 Functional Groups Important for Ligand–Receptor Interactions

Interaction	Functional group	Energy of interaction (ΔH, kcal mol^{-1})
H^+ bonding	Carboxyl, amino	~1 in aqueous solution
Dipole	OH, ether, ester, amide	1
Hydrophobic	Aliphatic, aromatic	Entropy driven
Covalent	Several, including C–C	100

Octreoscan are cyclic somatostatin analogues used for treatment and diagnosis of neuroendocrine cancers. Alternatively, part or all of a peptide backbone can be replaced with a rigid nonpeptide lattice in order to maintain the important functional groups in a favorable configuration for receptor interaction. This approach has led to the development of several nonpeptidic antagonists of the peptide hormone receptors (for example, the GnRH receptor).

Another reason for searching for novel, synthetic ligands is that the endogenous ligand may be nonselective. The endogenous catecholamines norepinephrine and epinephrine activate a multitude of α- and β-adrenergic receptor subtypes. A further complication is that several receptor subtypes may coexist in the same tissue, making it difficult or impossible to evaluate a specific receptor interaction. For this reason, it is desirable to express a single subtype in a cell line to avoid the confusion of multiple receptors interacting with a ligand. In order to develop a specific ligand for a single receptor subtype, it is necessary to test ligand affinities for the other related and unrelated receptors, also expressed individually in cell lines.

In addition to the systematic alteration of the ligand molecule and testing the affinities and activities at the natural receptor either in explanted tissue or expressed in host cells, it is valuable to probe the structure of the receptor. This can be accomplished with techniques such as site-directed mutagenesis and with chimeric receptors to determine the functional groups that participate in the interactions with agonist and antagonist ligands as well as those that are important for signal transduction. This approach has been used for characterization of the GnRH, melanocortin-4, and thyrotropin-releasing hormone (TRH) receptors, the β-adrenergic and α-adrenergic receptor subtypes, and many others.

There may be an issue of species-specific interactions, particularly with ligands that are very dissimilar to the native ligand. Some of the functional groups in these molecules in the vicinity of the binding site may take advantage of interactions that are not utilized by the native ligand, when there may be differences in the primary structure of the receptor. If the ultimate goal is to identify novel ligands for new drug development, it may be necessary to screen the compounds with a human receptor, because ligands may have very different effects in human vs animal species targets. It also may be difficult to assess the efficacy of a human-specific compound with *in vivo* testing in animals. The β_3-adrenergic receptor is an example of the problems associated with species specificity, in that several highly selective agents developed in rodents are not as selective in humans. However, human receptor selectivity is also a problem in the evaluation of nonpeptide GnRH antagonists.

Some targets require pulsatile rather than continuous activation in order to maintain receptor concentration as well as the postreceptor transduction system. For example, GnRH is released into the hypophyseal portal circulation as a synchronized secretion from a diffuse neural network in the median eminence. The frequency of this oscillation is approximately once per hour in humans. Idiopathic hypogonadotropic hypogonadism may result from inadequate or absent GnRH secretion. Pulsatile administration of GnRH can stimulate pituitary gonadotropin release, thereby restoring gonadal function and maturation. In contrast, the continuous administration of GnRH or a GnRH agonist will produce an initial burst of gonadotropin release from the pituitary, followed by a decrease in pituitary GnRH receptor concentration, gonadotropin biosynthesis and storage in the pituitary, and low concentration of gonadotropins in the circulation. This leads to suppressed gonadal steroid production. The chronic effect of GnRH agonist administration is essentially the same as the response to a GnRH antagonist, although the antagonist response is immediate.

The biphasic response to GnRH agonists also illustrates the need for comparison of acute vs chronic effects of administration of a ligand. Single-dose testing requires a relatively small quantity of compound and may produce an *in vivo* response. However, the response to a single dose may not

predict the effect of chronic administration. Agents that produce a receptor desensitization or altered transcription may require treatment for several days or longer, and the chronic effect may not be clearly predicted by the single-dose response. An example is the activation of the peroxisome proliferator-activated receptor-γ (PPAR-γ) in adipose tissue by the thiazolidinedione rosiglitazone. In the Zucker fa/fa rat model of extreme insulin resistance, rosiglitazone leads to an increase in insulin sensitivity accompanied by decreased basal plasma insulin concentration, and an increase in adipose tissue and skeletal muscle insulin sensitivity mediated by increases in cell surface glucose transporters. The decrease in circulating insulin and improved glucose transport *in vivo* do not reach a nadir until 4 days of treatment. Agents that produce chronic weight reduction may not suppress appetite or cause a sudden weight loss on acute administration. Anorexigenic agents such as dexfenfluramine and dextroamphetamine may produce acute suppression of appetite and weight loss, but chronic treatment does not result in persistent effects despite continued administration due to development of tolerance. The tolerance may be target dependent or ligand dependent, and it is important to establish this distinction in a drug discovery research program.

There are often alternatives to development of a novel ligand for a specific target, because physiological systems are often controlled by a cascade of regulatable processes. The biosynthesis, storage, release, and removal of the endogenous ligand may be controlled by other targets. Type 2 diabetes is the result of an inadequate production of insulin and accompanying insulin resistance. The sulfonylurea oral antidiabetic agents facilitate insulin release. Insulin-sensitizing agents such as metformin or rosiglitazone affect targets downstream of the insulin receptor. Some targets may be better suited for activation or blockade with exogenous agents or may offer more specific control of a physiological process.

IV. PHARMACOKINETIC CONSIDERATIONS

Much of the research directed toward the identification and characterization of high-affinity, selective ligands is performed with cell cultures or in subcellular fractions. In these systems, a ligand placed into a culture medium has rapid access to receptors, and the ligand concentration can be maintained relatively constant. Except for ligands that must penetrate into cells in order to reach their molecular target, there are no diffusion barriers. This situation is very different from the fate of a ligand *in vivo*. Because a ligand must reach its target at a sufficient concentration, for an adequate period of time to achieve receptor activation or blockade, it is not surprising that many compounds with great affinity for specific receptors are ineffective in whole animals. The delivery of a compound to its site of action depends on pharmacokinetic considerations.

A. Absorption

The primary route of administration for drugs is the oral route. In order for a ligand to be absorbed from the gastrointestinal tract, it must dissolve in the aqueous intestinal contents and pass through or between the gastrointestinal epithelial cells. *In vitro* permeability models, such as flux through caco2 colonic cancer cells, can be used to predict absorption from the intestines. In general, large molecules, including peptides and proteins, are rapidly digested in the gastrointestinal lumen. Many small molecules are also unsuitable for oral administration, due to poor permeability or rapid degradation.

Injectable formulations provide the most direct route for systemic delivery of poorly absorbed ligands. An infusion pump can be used to provide either continuous delivery or, in situations in which continuous administration is not effective due to receptor desensitization, many discrete pulses. If long-term continuous delivery of ligand is required, a sustained-release formulation may be utilized. For example, long-acting neutral protamine Hagedorn (NPH) insulin and depot formulations of GnRH agonists or antagonists will release ligand for hours to months, respectively. Many steroid hormones are poorly absorbed when given orally, and in some instances this may be surmounted via structural modification. For example, 17-α-ethynyl-estradiol is orally bioavailable, whereas 17-β-estradiol is not. Formulation may be an important issue, because dissolution and solution properties can determine rate of absorption. The concentration of compound in solution may also be an important consideration, because the delivery of a concentrated solution of compound may not result in the same effect as the same dose in a more dilute solution. For example, several GnRH antagonists will aggregate or gel in aqueous solutions above approximately 1 mg/ml. This results in an uncontrolled sustained release formulation with a much longer duration of action than a dilute solution, both administered at the same dose.

B. Distribution

Distribution of ligands into target tissues is required. An apparent volume of distribution can be calculated from the ratio of concentration of drug at time of dosing (C_0) determined by extrapolation and the dose, assuming that the ligand is uniformly distributed (Fig. 4). A large volume is associated with lower plasma concentrations compared to a low volume, assuming equivalent rates of elimination. The receptor may be readily accessible from the circulation, so the concentration in plasma approximates the concentration in the target tissue. Alternately, the receptor may be in a distinct compartment—for example, the majority of neurons in the brain that are separated from the circulation by a blood–brain barrier. It may be more relevant to measure the concentration of drug in the target tissue when possible, because the concentration in the plasma may be much different than the local concentration at the target. For ligands intended to reach intracellular targets, either a large distribution volume or a facilitated or active transport is required. In general, the apparent volume of distribution is directly proportional to lipophilicity. The liver will also extract highly lipophilic agents from the circulation prior to elimination. Protein binding may also influence distribution. A drug that is very highly bound to proteins in the circulation will often have a high plasma concentration and a small distribution volume. Many hormones bind to carrier proteins; only the free or unbound ligand is available to the receptors. A carrier-bound ligand can be delivered selectively to sites where the carrier is modified or degraded, leading to local release of active ligand. For example, insulin-like growth factor-I (IGF-I) is bound by several IGF-binding proteins. The binding proteins are degraded by specific proteases secreted by IGF-responsive tissues, leading to localized delivery of free IGF-I.

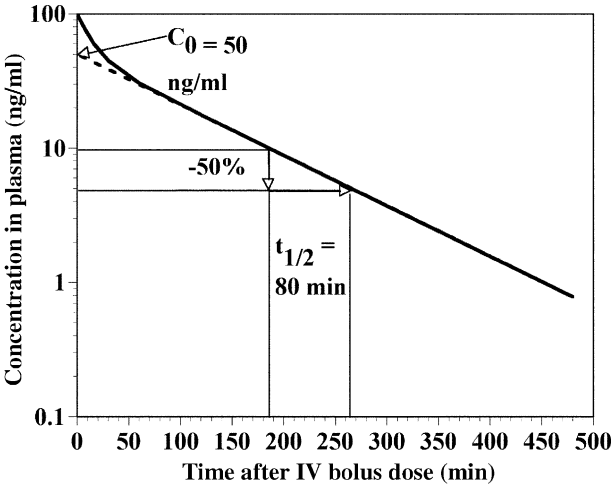

FIGURE 4 Elimination of a single intravenous bolus dose of 20 μg/kg at time zero. The log of the concentration of compound in the circulation decreases over time. Terminal plasma half-life ($t_{1/2}$) is the time required for the concentration of compound to decrease by 50% during the log-linear elimination phase. This initial rapid decline in concentration is attributed to distribution of compound. These data can be fit to a two-compartment model: $C = C_0(e^{-k-1t} + e^{-k-2t})$, where C is the concentration of compound at time t, C_0 is the initial concentration determined by extrapolation, and $k-1$ and $k-2$ are the distribution and elimination rate constants, respectively. The volume of distribution (V_D = dose/C_0) is 400 ml/kg. The area under the curve estimated from the 0- to 480-min time course is 6777 ng ml^{-1} min, and the whole-body clearance is 2.95 ml kg^{-1} min^{-1}.

C. Elimination

The liver and kidneys are responsible for the removal of both endogenous and exogenous ligands from the circulation by excretion and metabolism. Whether an agent is excreted intact or is biotransformed, the compound is cleared from the circulation. The time required for the plasma concentration to decrease by 50% is the plasma half-life (Fig. 4). Many endogenous ligands have short half-lives, in the order of minutes, and one major goal of structural modification is to decrease the elimination rate, prolonging the compound's presence so that convenient once or twice daily dosing is feasible. The sites of metabolic inactivation can be predicted by *in vitro* metabolism studies with liver slices and microsomal preparations. In some cases there will be active metabolites of a ligand. Under these circumstances, the metabolites may not have the same degree of specificity for the intended target as does the parent ligand, so an *in vitro* testing strategy for development of highly specific agents may be foiled by *in vivo* biotransformation.

The area under the curve (AUC) in the plot of plasma concentration vs time is a quantitative measure of the exposure to compound. Measurement and comparison of the AUC do not require compartmental modeling, as is the case for apparent volumes of distribution and half-lives. Whole-body clearance is the measure of the rate of disappearance of drug, determined from the ratio of the dose divided by the AUC. It is the volume of blood or plasma that is cleared of compound per unit time, and, like AUC, it does not require the assumption of a compartmental model. Although clearance cannot be readily attrib-

uted to physiological filtration and flow rates, they may be used for comparison. A compound with a very high clearance—for example, greater than cardiac output—is probably not a feasible drug candidate. Even a clearance greater than hepatic blood flow may be prohibitively high. The dosing interval, the mode of delivery (i.e., continuous vs intermittent), and possibly even the route of administration are dependent on the clearance. A final caution is that there are species differences in pharmacokinetics, just as there are differences in receptors. It is not always possible to make accurate predictions of pharmacokinetic characteristics in humans based on animal studies.

D. Other Considerations

A therapeutic target may be discrete, and local rather than widespread effects may be desirable. In some cases, such as with beta agonists and glucocorticoids administered via inhalation for treatment of asthma, or local treatment of pain or inflammation with local anesthetics or glucocorticoids, the intended site of action is readily accessible. An ideal agent for local administration would not be biologically available for systemic effects. Chemotherapy for solid tumors with specific cytotoxic or cytostatic agents may affect rapidly dividing cells throughout the body, and it would be desirable to restrict the effects of treatment to the therapeutic target. Local targets may be used to both identify and treat these diseases, such as with the somatostatin analogue octreotide (Octreoscan), which is used for delivery of radionuclide scanning agents for diagnosis of neuroendocrine cancers, as well as for cytostatic treatment of diseases such as breast cancer or advanced-stage prostate cancer resistant to androgen deprivation.

In vivo pharmacodynamic testing may often be conducted in a species in which a model can be established. Mice are often used for *in vivo* testing, partly because the compound requirements are minimized relative to larger species. In addition, many new targets have been validated by characterization of the phenotypes associated with over- and underexpression in mice; this may lead to testing of leads in either wild-type or genetically altered mice. A problem of false negative information may arise if the pharmacokinetic characteristics of the compound in mice are not favorable or representative. For example, leuprolide acetate administration via daily subcutaneous injection of as much as 8 mg/kg/day does not suppress testosterone in male mice, although it is effective in male rats or dogs at less than 0.1 mg/kg/day. Lupron 1 Month Depot will decrease testosterone in mice at 1–2 mg/kg/day, but is effective in rats or dogs at less than 0.1 mg/kg/day. The antitumor efficacy of this agent against human prostate cancer cells injected into nude mice will be dictated by the host, rather than by the cells.

Another topic related to pharmacokinetics is the stability or shelf life of a formulation of ligand. If the ligand binds appreciably to surfaces, precipitates, forms gels or complexes, oxidizes, hydrolyzes, supports microbiological growth, or is otherwise altered, suitable formulations must be developed prior to valid evaluations either *in vivo* or *in vitro*.

V. SUMMARY

Receptor targets for chemical ligands mediate communication in biological systems. The natural ligands may have limitations with regard to efficacy and specificity. In some cases the target is known but the endogenous ligand is not. Systematic chemical substitutions and random screening result in a spectrum of activity from antagonist to full agonist, as well as specificity at the receptor target. Current technology makes it possible to clone and express human receptors in cell culture and to study individual receptor subtypes without confusion or contamination by other subtypes. Structural modifications of the natural ligands may alter activity and pharmacokinetic characteristics. Conformationally restricted compounds may improve selectivity. Synthetic analogues may interact with functional groups on the receptor other than those that bind the natural ligand, and may result in a species-specific compound.

Glossary

affinity The degree of attraction between a ligand and a specific receptor. It is based on a high degree of structural complementarity between the ligand and the binding site of the receptor.

intrinsic activity The maximal response caused by a drug in a tissue preparation relative to the endogenous ligand or another reference compound, if the endogenous ligand is not known. A full agonist causes a maximal response and a partial agonist causes less than a maximal response. The terms "intrinsic activity" and "efficacy" are often used interchangeably, although efficacy requires both intrinsic activity and potency.

ligand A molecule that is bound by another molecule, i.e., a target molecule or a receptor. The binding between the ligand and its target molecule is usually not covalent and does not usually result in a chemical alteration of the ligand. However, the interaction triggers changes in

the target molecule that lead to changes in function in the target cells.

pharmacokinetics The study of the kinetics of drugs in humans, animals, and *in vitro* test systems, including the processes of absorption, distribution, metabolism, and excretion.

potency The dose or concentration of a drug required to produce an effect. The relative potencies of two or more ligands are determined from the ratio of concentrations or doses required to produce the same effect. By convention, EC_{50}/ED_{50}, or the concentrations/doses producing a 50% of maximum effect, are usually compared.

receptor A target molecule or an organized assembly of molecules. A receptor has a binding site for a ligand and usually possesses other structural and functional domains for interaction with itself, its surroundings, and other molecules of signal transduction to transfer information, leading to a change in function.

Lipoprotein Receptor Signaling

DANIEL LASKOWITZ AND SALVATORE V. PIZZO
Duke University

Since their original description by Brown and Goldstein, lipoprotein receptors have been recognized as playing an integral role in cholesterol homeostasis. This family of receptors is responsible not only for binding and internalizing lipoprotein-containing particles for use within the cell, but also for regulation of endogenous cellular cholesterol metabolism and synthesis. In addition to this role in cholesterol regulation, it is now known that several members of this family of receptors are capable of initiating signaling cascades. Convergent experimental and clinical evidence suggests that these signaling capabilities may mediate important biological processes, including normal central nervous system development and the brain response to injury, immune regulation, and atherogenesis. Increased insight into the mechanisms of lipoprotein signaling may increase our fundamental understanding of the biology of these multifunctional receptors

and holds the promise of novel therapeutic strategies for human disease.

I. THE LDL FAMILY OF RECEPTORS

The presence of the low-density lipoprotein (LDL) receptor on the surface of cells is essential in maintenance of extracellular and membrane cholesterol homeostasis. The mature LDL receptor is a highly conserved cell membrane glycoprotein consisting of five distinct domains, including a short cytoplasmic tail, a transmembrane domain, an O-linked sugar domain, an epidermal growth factor (EGF) precursor homology domain, and a ligand-binding domain.

The cytoplasmic domain of the LDL family of receptors is composed of a stretch of approximately 50 amino acid residues that are required for internalization of the receptor–ligand complex. The tetrapeptide NPXY is one of the short sequences that targets LDL receptors to coated pits on the surface of cells for subsequent internalization. Although the cytoplasmic tail of the LDL receptor family has been traditionally thought of in the context of endocytosis and lysosomal trafficking, it may actually serve a dual function. Recent evidence suggests that this domain is a key in initiating signaling events by binding a family of cytoplasmic adapter and scaffolding proteins. These adapter proteins interact with the cytoplasmic tail of the LDL receptor family proteins and initiate signal transduction pathways that involve tyrosine and mitogen-activated protein (MAP) kinase-mediated cellular events involved in cell adhesion, activation, and cytoskeletal organization. Interestingly, the binding of these adapter proteins inhibits the endocytosis pathway, suggesting a possible regulatory mechanism.

The transmembrane domain of the LDL receptor family consists of approximately 25 hydrophobic amino acids. Although this domain plays a primary role in membrane anchoring, recent evidence supports the hypothesis that this region also plays an important role in transducing the signal initiated by receptor–ligand interaction across the plasma membrane.

The O-linked sugar domain of the LDL receptor is a serine- and threonine-enriched stretch of 58 amino acid residues located just outside of the plasma membrane. A majority of the hydroxyl side chains are glycosylated in a posttranslational process whereby galactosyl and sialyl residues are added to the O-linked *N*-acetylgalactosamine moiety. Despite the fact that the structure of this domain has been clearly delineated, the function of the O-linked sugar domain remains unclear. One plausible hypothesis is that this region facilitates receptor–ligand interactions by physically extending the receptor-binding domain into the extracellular milieu.

The EGF precursor homology domain is a common feature of all of the receptors in the LDL family. This domain is composed of approximately 400 amino acids and lies immediately adjacent to the ligand-binding site. As suggested by its the name, this domain contains amino acid sequences that are similar to those present in EGF. Two of these EGF repeats are located in tandem near the amino terminus, whereas the final repeat is located at the carboxyl terminus of the EGF homology domain. The remainder of this domain is composed of five sequences, each comprising approximately 50 amino acids that contain the consensus tetrapeptide YWTD. Although the function of this domain has not been fully defined, deletion of this sequence impairs pH-dependent LDL disassociation from its receptor and subsequent recycling of the receptor.

Finally, the ligand-binding domain protrudes into the extracellular milieu and mediates the interaction between the receptor and lipoproteins containing apolipoprotein E (apoE) or apolipoprotein B-100. The amino terminus includes a stretch of 292 amino acids containing seven LDL receptor type A (LA) repeats arranged in tandem. This area is highly enriched in cysteines and folds into a structure exposing clusters of aspartic acid and glutamic acid residues on its surface. These negatively charged regions are found at the carboxyl terminus of each of the seven repeat units. The electrostatic interactions between these negatively charged patches and positively charged regions of the lipoprotein subunits apoE and apolipoprotein B-100 are believed to play an important role in facilitating receptor–lipoprotein interactions. In general, repeats two through seven are believed to act in concert to facilitate receptor binding with apolipoprotein B-100, whereas repeat five is necessary for apoE binding.

In the years following the original description of LDL receptor–ligand interactions, several related proteins have been described in the LDL receptor family. These receptors include the very-low-density lipoprotein (VLDL) receptor, the gp330/megalin receptor, the apoE receptor 2 (ER2), and the LDL receptor-related protein (discussed in detail in Section II). These receptors share structural homology to the LDL receptor, including the EGF domain, O-linked sugar domain, and cytoplasmic region, with one or

more short sequences mediating receptor internalization via coated pits.

In addition to their function in cholesterol metabolism, recent attention has focused on the ability of the LDL family of receptors to initiate signaling cascades. These receptors may be particularly important in the central nervous system, and converging clinical and experimental evidence suggests that the LDL receptor family is involved both in normal brain development and response to injury. For example, although inactivation of the either the VLDL receptor gene or the ER2 gene does not result in obvious neurological abnormalities, a recent study demonstrated that simultaneous targeted disruption of the ER2 and VLDL receptor genes resulted in a distinctive neurological phenotype. During the second week of life, these double-knockout mice developed failure to thrive, progressive ataxia, and tremor. This neurological abnormality was progressive, and animals rarely survived beyond 3 to 4 weeks of age. At autopsy, the brains of these animals exhibited distinctive histological abnormalities, including the loss of the normal cellular organization in the hippocampus and cerebellum.

Surprisingly, these developmental anomalies were identical to those previously identified in mice lacking the reelin or mDab1 genes. Reelin is a large extracellular protein that regulates the neuronal migration that forms the radial glial network during development. mDab1 (so named because of similarity to the *Drosophila disabled* gene product) is a cytoplasmic adapter protein that functions downstream of reelin. mDab1 interacts with several neuronal membrane proteins, including LDL receptors, presumably through interaction with the NPXY internalization motif present in the cytoplasmic tails of this receptor. Mice deficient in mDab1 develop a neurological syndrome that is similar to reeler and VLDL receptor/ER2 double-knockouts mice, characterized by migrational abnormalities in cerebellum and cortex, resulting in progressive ataxia and hindlimb weakness. Thus, it appears that the VLDL receptor and ER2 share overlapping roles as obligatory components of the reelin/disabled pathway involved in normal neuronal migration. The exact mechanism by which this occurs remains unclear, as neither the VLDL receptor nor ER2 contains a kinase domain, although it has been speculated that members of the LDL receptor family recruit adapter proteins and kinases into the receptor complex, as has been described in other signaling pathways.

The role of the LDL receptor family in central nervous system (CNS) development is not limited to the ER2 and VLDL receptor. Recently, it was reported that mice deficient in megalin (another member of the LDL receptor family) demonstrate holoprosencephaly, another disorder of neuronal migration. Although the molecular basis for this outcome is poorly defined, these results strongly suggest that the LDL family of receptors is important for CNS development and function. Thus, more than two decades after the original classic articles describing the structure and function of the LDL receptor in the context of cholesterol metabolism, we are only beginning to learn of the diverse biological properties that this multifunctional receptor family plays in cellular communication and signal transduction.

II. LOW-DENSITY LIPOPROTEIN RECEPTOR-RELATED PROTEIN

Following modification by lipoprotein lipase and the association of apolipoproteins, VLDLs become chylomicron remnants. These are cleared from blood by a receptor-mediated mechanism in the liver. Although recognized as distinct from the LDL receptor, the chylomicron remnant receptor also has a high affinity for apoE and recognizes the remnant particles via this incorporated subunit. In 1988, this remnant receptor was cloned and dubbed the LDL receptor-related protein (LRP). Subsequent analysis has demonstrated that the LRP is present in a variety of tissues, including liver, kidney, placenta, and brain. The pool of LRP receptors in the liver is critical for catabolism of a number of proteins, whereas in brain it is postulated to play an important role in normal development of the CNS and response to neurological disease.

LRP is a large receptor with a primary sequence of 4525 amino acids (molecular weight of $\sim$600,000), and it bears many structural similarities to other members of the LDL receptor family. This receptor is posttranslationally cleaved, yielding a heavy chain of molecular weight 515,000 and a light chain of molecular weight of 85,000. The latter subunit is tethered in the membrane. Like the LDL receptor, the extracellular domain of LRP includes a cysteine-enriched ligand-binding domain and an EGF precursor homology domain that probably functions in the acid-dependent dissociation of ligand from the receptor. Unlike the LDL receptor, however, the O-linked sugar domain is not present in the extracellular portion adjacent to the membrane. As with all of the members of the LDL receptor family, LRP, through its light chain, is a transmembrane protein that is

anchored by a single transmembrane segment. The cytoplasmic tail of the protein is 100 amino acids long, approximately twice as long as the LDL receptor, and contains the NPXY motif; however, unlike the LDL receptor, this sequence is not important for receptor-mediated endocytosis. Rather, endocytosis of LRP depends on the presence of a YXXL motif. The latter motif is also known as the immunoregulatory tyrosine activation motif (ITAM) and is found in receptors that participate in antigen presentation. Its potential significance in LRP will be considered next.

LRP is capable of a number of important functions, including immune regulation, atherogenesis, and the clearance of structurally diverse and toxic ligands. LRP has relatively broad binding characteristics and is considered to be a multiligand receptor. A variety of physiologically important ligands that are bound to LRP are targeted to coated pits then internalized, dissociated in endosomes, and degraded in lysosomes. LRP has multiple, independent binding sites for these ligands, and it is believed that lysosomal degradation is mediated by the EGF precursor homology domain. Binding of a ligand to a receptor-binding domain without an intact EGF homology domain may allow the bound ligand to be recycled with the receptor rather than entering the lysosomal degradation pathway. Thus, it appears as though the ultimate fate of a ligand bound to LRP is determined in part by its binding site on the receptor.

A further understanding of the complex biology of LRP was made possible when it was discovered that LRP is identical to the previously characterized α_2-macroglobulin (α_2M) receptor. *In vivo*, the proteinase inhibitor α_2M circulates in blood at a very high concentration (1–5 μM). On binding of proteinases to α_2M, the molecule undergoes a conformational change, exposing a receptor recognition site present in each of its four identical subunits. This so-called activated form of α_2M is designated α_2M^*. α_2M is capable of inhibiting the function of proteinases of all four mechanistic classes. *In vitro* treatment of α_2M with ammonia or methylamine results in a similar conformation change, resulting in a form of α_2M^* that also binds to LRP. The fact that either a proteinase or a small nucleophile triggers similar conformational changes in α_2M^* is unusual; it is the result of an internal γ-glutamyl-β-cysteinyl internal thiolester bond in each of the four α_2M subunits. This bond ruptures when proteinases bind to α_2M or can directly react with small nucleophiles such as ammonia or methylamine, also rupturing the bond. As already noted, LRP has broad ligand specificity and it appears to function in the clearance and internalization of a number of ligands, including *Pseudomonas aeruginosa* exotoxin A. In fact, endocytosis via the LRP is requisite for *Pseudomonas* toxicity, and cell lines deficient in this receptor are resistant to *Pseudomonas* cytotoxicity. LRP also binds to tissue and urokinase-type plasminogen activator complexes with plasminogen activator inhibitor-1. The list of other LRP ligands is very long, including LDL, lactoferrin, lipoprotein lipase, tissue factor pathway inhibitor, matrix metalloproteinases, factor VIII light chain, thrombospondin, and antithrombin III–thrombin complexes. Receptor-associated protein (RAP) is an unusual "ligand" for LRP and other members of the LDL family. RAP is not found in the extracellular environment. It is believed to function as an intracellular chaperone that promotes proper folding of LRP and prevents it from binding ligands before LRP reaches the cell surface. When cloned RAP is added to the external environment of cells that have LRP on their surface, it blocks the binding of all known ligands to this receptor.

In the past several years, studies have demonstrated that LRP can target delivery of antigens to antigen-presenting cells. This subsequently results in activation of the immune system. These antigens, however, must be in complex either with α_2M^* or heat-shock proteins. Complexes with antigens are formed as a result of coincorporation of these proteins into α_2M during the course of proteinase activation. Complexes with heat-shock proteins probably are produced intracellularly—for example, in tumor cells—and are shed during cell death. The occurrence of ITAM in LRP is, therefore, quite intriguing. This sequence is present in other receptors that bind and internalize antigens complexed to various carrier proteins. It appears to be essential both for endocytosis and the activation of signaling cascades critical for antigen processing.

In addition to its role in binding and clearing such structurally and functional diverse ligands, there is now abundant evidence that the LRP is capable of initiating a signaling cascade. For example, on binding of the LRP to endogenous ligands such as lactoferrin, *Pseudomonas* exotoxin A, or lipoprotein lipase, a signaling cascade is initiated, resulting in increased intracellular free Ca^{2+}, $[Ca^{2+}]_i$, and inositol phosphates, including inositol (1,4,5)-trisphosphate ($InsP_3$) via a pertussis-toxin sensitive G-protein. Apolipoprotein E may also serve as an endogenous ligand capable of signaling via this receptor. In fact, a recent observation suggests that both the intact apoE holoprotein and the peptides derived from the apoE

receptor-binding region are capable of initiating signaling cascades that result in increased $[Ca^{2+}]_i$ and $InsP_3$ turnover in murine peritoneal macrophages. This signal is mediated by a pertussis-toxin sensitive G protein and is blocked by RAP and Ni^{2+}, characteristic properties of LRP-dependent ligand binding and signal transduction. These effects are likely to be biologically relevant given the known immune-modulating functions of this receptor, and there are now a number of observations demonstrating immune abnormalities in apoE-deficient mice.

There are a number of suggested mechanisms whereby LRP may contribute to the process of atherogenesis. In response to cholesterol loading, macrophages secrete large amounts of apoE, which is available to incorporate into lipoproteins at the site of developing atheromatous lesions. It has been postulated that this can trigger a secretion/recapture mechanism in which secreted apoE-enriched lipoproteins are locally cleared and internalized by LRP-expressing macrophages, facilitating development of the plaque and the transition of macrophages into lipid-laden foam cells. Independent of its role in cholesterol homeostasis, the ability of LRP to initiate signal transduction in resident macrophages may also have important biological consequences in atherogenesis. For example, there is an increasing understanding that inflammatory processes are important in the development of atheromatous plaques. LRP modulates cellular immune responses, and it has been speculated that apoE–LRP interactions may modulate atherogenesis by regulating macrophage activation and inflammation at endothelial surfaces in areas of plaque development. This is consistent with observations that the early atheromatous plaques in apoE-deficient mice are associated with up-regulation of interleukin 6 (IL-6), vascular adhesion molecules, and increased numbers of CD4 lymphocytes, which are critical for activation of immune responses. It is also consistent with observations that macrophage-specific expression of apoE reduces atherosclerosis in apoE-deficient mice independently of systemic cholesterol levels.

Thus, the ability of LRP to initiate cellular signaling mechanisms may ultimately prove to be an important factor in diverse clinical disease processes. Interestingly, the receptor-competent form of α_2M^* also initiates a signaling cascade in macrophages, but it is believed that this signal is not initiated via LRP. Instead, there appears to be a distinct receptor, dubbed the α_2M signaling receptor (α_2MSR), which is capable of initiating signal transduction independently of ligand internalization. These two receptors may be differentiated by a variety of functional characteristics, including competition with RAP and Ni^{2+}. As noted above, both block ligand binding to LRP; however, neither affects α_2M^* binding to α_2MSR (Table 1). The biological role of this newly described receptor remains unclear, although it has been the focus of considerable recent investigation.

III. SCAVENGER RECEPTORS AND LDL RECEPTOR BIOLOGY

Following exposure to cholesterol, macrophages become filled with cholesterol ester and assume the morphology and functional properties of foam cells. Although the uptake of cholesterol by subendothelial macrophages has long been recognized as important to atherogenesis, it was unclear for many years how this process occurred, because there did not appear to be clear evidence that cholesterol was internalized by LDL receptors. This quandary was resolved by the demonstration of macrophage scavenger receptors that are capable of mediating the endocytosis of modified cholesterol. These scavenger receptors have a particularly high affinity for acetylated LDL and were originally dubbed acetyl-LDL receptors. However, it was subsequently recognized that they could bind a relatively broad range of ligands, including oxidized-LDL, polyribonucleotides, polysaccharides, and anionic phospholipids. In recognition of their ability to bind and clear such structurally diverse ligands, they have been renamed scavenger receptors. Although the exact structural determinants that confer recognition by the scavenger receptor have not been fully elucidated, it is known that polyribonucleotides will

TABLE 1 Functional Characterization of Ligand Binding to LRP vs α_2MSR[a]

bind with high affinity only if they are capable of forming a stable, four-stranded helix.

Two scavenger receptor isoforms have been described as representing alternative splicing of a common gene. Expression of both type I and type II scavenger receptors has been detected *in vivo*, primarily on resident tissue macrophages. The scavenger receptor is a homotrimeric integral membrane protein, with each monomer composed of approximately 450 amino acids. The receptor has six distinct domains, of which the first five domains are identical between the type I and type II receptors. These include a short cytoplasmic tail of approximately 50 amino acids located at the amino terminus; a single transmembrane domain; a juxtamembrane spacer region of approximately 45 amino acids; an extracellular α-helical domain, and a collagen-like domain containing approximately 24 Gly-X-Y triplet repeats, with the Y position primarily occupied by proline or lysine residues. The primary structural difference between the type I and type II scavenger receptors occurs in the final extracellular ligand-binding domain located at the carboxyl terminus. Here, the type I receptor has an 11-residue stretch that is highly enriched in cysteine residues (SRCR domain), whereas the type II receptor has a truncated carboxyl terminus composed of approximately 6–17 amino acids. Despite this difference in the ligand-binding domain, both types of receptors have a comparably broad range of ligand-binding specificity.

As already noted, scavenger receptors facilitate the endocytosis of cholesterol by subendothelial macrophages and the subsequent formation of foam cells. Support for the role of the macrophage scavenger receptor in atherogenesis is strengthened by the fact that scavenger receptor mRNA has been colocalized with atheromatous plaques; oxidatively modified LDL is ubiquitous in atheroma; and *in vitro* expression of scavenger receptors in macrophages causes massive uptake of cholesterol and a cellular morphology similar to that seen *in vivo*.

In addition to its role in atherosclerosis, the scavenger receptors may participate in cellular adhesion. This hypothesis is based on the observation that monoclonal antibodies directed against scavenger receptors are capable of blocking the adhesion of macrophages to an artificial substrate. Such a role may explain why these receptors are more highly expressed in resident tissue macrophages as compared to circulating monocytes. A third biological role postulated for scavenger receptors is in host defense. In particular, several gram-negative bacterial endotoxins bind to both type I and type II scavenger receptors and are cleared from the circulation in this fashion. Scavenger receptors also bind lipoteichoic acid, which is expressed on the surface of many gram-positive pathogens. Given the ability of the scavenger receptors to bind constituents of both gram-positive and gram-negative bacteria, it has been suggested that scavenger receptors served as a primitive form of host defense that arose early in the evolution of the immune response by recognizing oxidatively damaged pathogens as "non-self" and facilitating their clearance.

As with LRP, recent attention has focused on the signaling properties of scavenger receptors. It appears as though different subtypes of scavenger receptors may mediate distinct pathways. Interestingly, these pathways may even occasionally have opposing biological properties. For example, oxidized-LDL binds preferentially to one class of macrophage scavenger receptors, initiating a signaling cascade characterized by pertussis-toxin-sensitive hydrolysis of phosphoinositides and elevations in $[Ca^{2+}]_i$. This has the downstream effect of suppressing a number of genes mediating the inflammatory response, including tumor necrosis factor α (TNFα), interleukin-1α (IL-1α), monocyte chemoattractant protein-1 (MCP-1), and nitric oxide release triggered by exposure of macrophages to lipopolysaccharide (LPS). Oxidized-LDL induces these anti-inflammatory effects in part by inhibiting the binding of the transcription factor nuclear factor κB (NF-κB) to its cognate binding site in the TNFα promoter.

In contrast, ligands such as maleylated bovine serum albumin (maleyl-BSA) and the polynucleotide poly(I:C) bind to a distinct macrophage scavenger receptor characterized by a relatively high number of receptor sites (2×10^6/cell) and low affinity (K_d of 4.9 μM). Binding of ligands to this receptor has predominantly pro-inflammatory effects, with up-regulation of genes encoding MCP-1, TNFα, and IL-1β. Thus, maleyl-BSA and oxidized-LDL appear to bind distinct scavenger receptors and initiate discrete second-messenger pathways with opposing biological effects. Although binding of either ligand initiates hydrolysis of phosphoinositides, activation of phospholipase A_2, and elevation of $[Ca^{2+}]_i$, the scavenger receptor for oxidized-LDL is coupled to a pertussis-toxin-sensitive G-protein, whereas that for maleyl-BSA is not, and binding of oxidized-LDL initiates more extensive and prolonged spiking of $[Ca^{2+}]_i$ than does binding of maleyl-BSA. Although not yet well understood, such so-called oscillatory

patterns trigger different cellular responses other than single spikes in $[Ca^{2+}]_i$.

Of note, not all ligand–scavenger interactions initiate a signaling cascade. For example, acetyl-LDL and malondialdehyde-LDL appear to bind a third discrete class of scavenger receptor, characterized by a low number of receptor sites (~20,000/cell) and high affinity (K_d of 9.6 nM). Binding of acetyl-LDL, however, to this receptor does not initiate a signal transduction pathway. Thus, it appears that there are at least three classes of receptors that can be functionally distinguished by ligand-binding and signaling properties: high-affinity acetyl-LDL; low-affinity maleyl-BSA; and oxidized-LDL scavenger receptors. The cloning of these receptors has also revealed at least three distinct classes of scavenger receptors. The scavenger receptor A (SRA) avidly binds acetyl-LDL, maleyl-BSA, polynucleotides, and polysaccharides. Two subtypes of scavenger receptor A, SRA-1 and SRA-2, have been cloned. Both have short amino-terminal cytoplasmic tails that do not contain known signaling sequences. Scavenger receptor B (SRB) binds to acetyl-LDL but not to polysaccharides or polynucleotides. A third type of scavenger receptor (SRC) is not expressed in mammals but has been identified in *Drosophila melanogaster*. It is clear that the biological properties of scavenger receptors extend beyond their ability to clear chemically modified and oxidized ligands. Better characterization and insight into the signaling properties of these multifunctional receptors may well yield insight into their role in inflammation, cell adhesion, and atherogenesis.

IV. THE EXPANDING NEUROBIOLOGY OF apoE

The recent observations that an apoE isoform is linked to functional outcome in a number of neurological diseases has led to a resurgence of interest into its ability to initiate a signaling cascade in macrophages and neurons. Apolipoprotein E is a 299-amino-acid protein that is a constituent of VLDLs, high-density lipoproteins (HDLs), and chylomicron remnant particles. There are three common human isoforms of apoE, designated E2, E3, and E4, which differ by single amino acid substitutions at positions 112 and 158, i.e. E3 (Cys112Arg158), E4(Arg112Arg158), and E2(Cys112Cys158). Apolipoprotein E is the primary apolipoprotein produced by brain, which is its largest extrahepatic source. Interest in the neurobiology of apoE intensified after the observation that the *APOE4* allele increased susceptibility to the development of sporadic and late-onset Alzheimer's disease (AD). Initial efforts to understand the role of apoE in AD were focused on disease-specific mechanisms, such as interactions with β-amyloid or tau. However, there is accruing evidence to suggest that presence of the *APOE4* allele may play a deleterious role in modifying outcomes not only from AD, but also from a diversity of acute and chronic neurological diseases, including intracranial hemorrhage, stroke, multiple sclerosis, and traumatic brain injury.

These observations have led to intensified efforts to understand the neurobiology of apoE in human disease. It has recently been realized that biologically relevant concentrations of apoE are capable of initiating a signaling response in neurons, presumably via the LRP. Consistent with these observations, we have recently created a family of peptides derived from the receptor-binding region of apoE (residues 130–155) and have demonstrated that a signaling response can be initiated in a CAD neuronal cell line on exposure to either human recombinant apoE or apoE peptidomimetics. This signaling response is characterized by the intracellular mobilization of calcium, $InsP_3$ turnover, and activation of protein kinase C (PKC), and appears to be specific to peptides containing residues 146–149 (Table 2). Moreover, the ability of both these peptides and the intact apoE to signal is blocked by the preincubation of cells with RAP, implicating LRP as the putative signaling receptor (Fig. 1).

Based on this evidence, it appears plausible that that the ability of apoE to initiate a signaling response in neurons may mediate an adaptive response to CNS injury. In fact, several studies have demonstrated that apoE initiates neurotrophic responses to promote

TABLE 2 Neuronal Ca^{2+} Signaling Induced by apoE-Mimetic Peptides[a]

Apolipoprotein E residue	10 μM	100 μM
apoE (130–149)	+	++
apoE (133–149)	–	++
apoE (130–146)	–	–
Scrambled apoE (133–149)	–	–

[a]Apolipoprotein E (apoE)-mimetic peptides were taken from the sequence identified as containing the receptor recognition site, amino acids 130–149. The ability of these peptides to elevate $[Ca^{2+}]_i$ in fura-2AM-loaded differentiated, neuronal CAD cells was studied by digital imaging microscopy. Neither the scrambled peptide nor the peptide in which residues 146–149 were truncated retained the ability to initiate neuronal calcium responses.

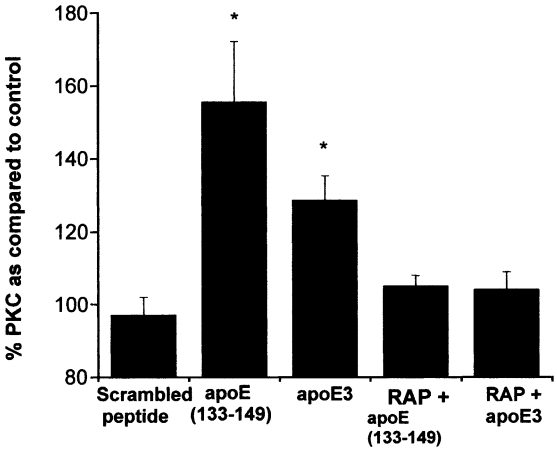

FIGURE 1 RAP blocks protein kinase C (PKC) activation by apolipoprotein E (apoE) and mimetic peptide. The CAD neuronal cell line was differentiated for 5 days in serum-free medium, then stimulated with the indicated ligand for 40 min at 37 °C. Incubation was stopped by addition of ice-cold homogenization buffer. PKC activity was assayed by phosphorylation of the PKC substrate histone IIIs, using [γ-^{33}P]ATP. Receptor-associated protein (RAP) was preincuabted with cells for 40 min at a concentration of 250 μM prior to addition of ligand. Results are presented as percent change in PKC activity as compared to control (no stimulation) values in cell lysate $\pm$ standard deviation. There was a statistically significant ($^*p < 0.05$) increase in PKC activation following stimulation with either apoE3 or apoE(133–149). Preincubation with RAP blocked this response.

neurite outgrowth and survival. The exact mechanisms by which this occur remain to be defined, although both direct neurotropic effects and indirect interactions with growth factors and extracellular matrix proteins have been described. The hypothesis that apoE plays an important role in the CNS by virtue of it ability to initiate a signaling cascade is also consistent with the observations that ER2/VLDL receptor double knockouts and megalin knockout mice have developmental abnormalities resulting from impaired neuronal migration, as described previously. The nature of the isoform-specific roles that apoE3 and apoE4 play on neurons remains to be elucidated, although several recent reports have demonstrated that there may be discrete signaling pathways that are isoform specific. For example, apoE4 but not apoE3 stimulates the transcriptional activity of a cyclic AMP-response element-binding protein, resulting in the activation of an extracellular signal-regulated kinase cascade in hippocampal neurons. Such an isoform-specific novel signaling pathway may provide insight into the role of this polymorphism in human disease.

Another possible mechanism that would explain the role of apoE in modulating the CNS response to acute and chronic brain injuries is that this protein down-regulates the glial response to injury. The brain has a limited repertoire of responses to both acute and chronic injury, and the cornerstone of the brain inflammatory response is activation of microglia, the CNS resident macrophage. Glial activation results in the secretion of glutamate, proteases, and reactive oxygen species, all of which promote secondary neuronal injury in both acute and chronic diseases of the CNS. A role for apoE in modulating the function of microglia would be consistent both with the experimental evidence to date and with the clinical observations implicating apoE in neurological disease. In fact, both apoE and mimetic peptides derived from the receptor-binding region have been demonstrated to initiate a signaling cascade in macrophages and to down-regulate glial activation in cell culture models and *in vivo* paradigms of brain injury.

Thus, it is becoming increasingly clear that lipoprotein receptors play diverse roles that extend beyond cholesterol homeostasis. The ability of lipoprotein receptors to initiate signaling cascades enables them to participate in a variety of biological responses, including neuronal development and response to CNS injury, host immunity, and atherogenesis. A better understanding of these signal transduction cascades will no doubt play an important role in developing novel therapeutic intervention for a variety of human diseases.

Glossary

epidermal growth factor homology region A domain common to all receptors of the low-density lipoprotein family; adjacent to the ligand-binding site.

low-density lipoprotein Molecule that is a mixture of lipid and protein, characterized as having a density of 1.019–1.063 g/cm^3 and a particle size of 180–250 Å.

low-density lipoprotein receptor Specific receptor for low-density lipoproteins; the first identified member of a large receptor family.

low-density lipoprotein receptor-related protein A receptor that binds many different ligands, including low-density lipoproteins; a member of the low-density lipoprotein receptor family.

mitogen-activated protein kinases Crucial enzymes in signal transduction pathways. Despite their name, they are activated by the binding of ligands to cell surface receptors. Examples of ligands are growth factors, hormones, and proteins that bind to members of the low-density lipoprotein receptor family.

protein kinase C Family of serine/threonine protein kinases that are activated by Ca^{2+} and/or phospholipids in

response to extracellular signals. Kinases phosphorylate their substrates, generally promoting activation.

Luteinizing Hormone (LH)

MARGARET A. SHUPNIK
University of Virginia

The pituitary gonadotropins, luteinizing hormone and follicle-stimulating hormone, play a central role in mammalian reproduction, controlling the production of the sex steroids and gametogenesis. Synthesized and secreted from the same pituitary gonadotrope cells, both hormones share several structural characteristics. However, the two hormones bind to different receptors on their target organs, the ovaries and testes, have distinct biological functions, and are subjected to differential physiological regulatory mechanisms. This article focuses on the secretion of luteinizing hormone as well as its biological actions in the gonads.

I. INTRODUCTION

Recent gene disruption studies as well as naturally occurring biological mutations have confirmed the critical role of luteinizing hormone (LH) in stimulating

steroidogeneis in the ovaries and testes. A lack of LH results in infertility in both males and females and inappropriate patterns of LH secretion may result in subfertility. The pulsatile secretion of LH is regulated by secretion of the hypothalamic peptide gonadotropin-releasing hormone (GnRH) as well as by levels of the sex steroids 17β-estradiol (E2), progesterone (P), and testosterone (T) (Fig. 1). The steroids may act indirectly to regulate LH via actions on the hypothalamus to alter the GnRH pulse generator, or directly at the level of the pituitary gonadotrope to influence gonadotropin synthesis and sensitivity to steroids and GnRH. The relative importance of each site of steroid regulation may vary between species, and in the female complex dynamic interactions between sex steroids, the hypothalamus, and the pituitary are of critical importance in orchestrating the reproductive cycle and normal fertility. The focus of this article is on synthesis of LH, biological actions of LH in males and females, and physiological regulation of LH by steroids and hypothalamic peptides.

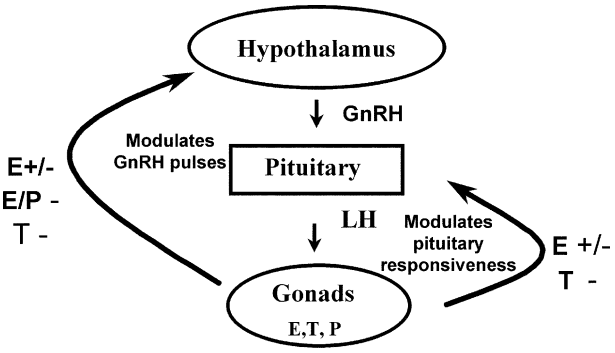

FIGURE 1 Regulatory hormonal feedback loops in the hypothalamic–pituitary–gonadal axis. Secretion of pituitary luteinizing hormone (LH) is stimulated by hypothalamic gonadotropin-releasing hormone (GnRH) pulses, which vary in frequency and amplitude with physiological state. LH secretion is favored when GnRH pulse frequency is higher, and is increased with higher amplitude pulses. LH binds to specific membrane receptors on the Leydig cells in the testes, and on the theca and granulosa cells in the ovaries, to stimulate the production of the sex steroids 17β-estradiol (E), testosterone (T), and progesterone (P). The steroids promote development of eggs and sperm in the gonads and have many other biological effects on other target tissues, including actions on the hypothalamus and pituitary in the regulation of LH secretion and subunit gene expression. Estradiol, progesterone, and testosterone bind directly to receptors in the pituitary gonadotrope. In the hypothalamus, E may act directly on GnRH neurons through the estrogen receptorβ isoform, but all steroids may act indirectly through other hypothalamic neurons that subsequently influence GnRH release. High physiological T concentrations suppress hypothalamic GnRH pulses and the pituitary response to GnRH. At the pituitary level, E increases the number of GnRH receptors and increases responsiveness of the LH genes to GnRH, but can also directly suppress LH secretion in humans. Estradiol treatment alone increases GnRH pulse frequency but decreases pulse amplitude, whereas E plus P suppresses GnRH pulses.

II. STRUCTURE, SYNTHESIS, AND SECRETION

LH belongs to a family of glycoprotein hormones consisting of LH, follicle-stimulating hormone (FSH), the pituitary hormone thyrotropin, and placental chorionic gonadotropin (CG), which is expressed in humans and horses. In each case, the hormone consists of two noncovalently associated subunits: the α-subunit is identical in all family members and a unique β-subunit (LHβ, FSHβ, CGβ, and thyrotropinβ) provides biochemical and biological specificity to the intact hormones. The two LH subunits are encoded by separate genes located on different chromosomes, and transcription of the subunit genes for the intact hormone must be coordinated between the different transcriptional units. In the mouse, the α-subunit gene is located on chromosome 4, with the single LHβ gene on chromosome 7. In humans, the α-subunit gene is located on chromosome 21, and the human LHβ (hLHβ) gene is located in a gene cluster on chromosome 19 containing one copy of hLHβ and six copies of both bona fide and pseudogenes for hCGβ. This suggests that the hLHβ and hCGβ genes are closely related, and in fact the proteins have significant (83%) homology. The hCGβ gene coding region is believed to have evolved from the hLHβ gene through a frameshift mutation in the last exon that extends the reading frame for 29 additional amino acids at the C-terminus. The promoter regulatory regions of the gene, however, are quite different, and hCGβ gene expression is modulated very little or not at all by the changes in hypothalamic peptides and steroids that are critical in determining LH subunit gene transcription.

Both LH subunits and CGβ are glycosylated, and these modifications play a role in both hormone half-life in the serum and biological activity on the LH receptor (LH-R), which also binds CG. As secreted proteins, the glycoprotein hormone peptides are translated from their mRNAs as prohormones containing a hydrophobic sequence at their N-termini, which are cleaved as peptides are modified to add complex sugars, combine with their designated subunit partner, and are packaged into secretory

granules. The mature α-subunit protein from human tissues has 92 amino acids and contains two N-linked sugars, whereas the hLHβ protein has 121 amino acids and one N-linked sugar modification. The 145-amino-acid hCGβ protein contains two N-linked glyclosylation sites and, in the C-terminal extension region, four additional O-linked glycosylation sites not contained in hLHβ. This structural modification of hCGβ results in a much longer half-life of the intact hCG in serum relative to hLH, and plays an important role in the greater biological potency of hCG at the LH/CG receptor. In general, both intact hormone and some free (i.e., uncombined) α-subunit can be detected in secretory granules in the pituitary or placenta and in serum. There does not appear to be any physiological role for the free α-subunit, and the uncombined protein contains an additional O-linked sugar; it is not known whether this is a result of processing that occurs because there is additional α-subunit available or if this serves some other regulatory function.

In adult humans and animals, LH secretion is rhythmic and has a fairly consistent pattern of one pulse approximately every 90 min in males, but varies both in frequency and in amplitude throughout the reproductive cycle in females. LH secretion (Fig. 2) is generally lower during the early phase of the female ovarian cycle, but rises as the follicle develops and estrogen and P levels begin to increase, culminating in an LH "surge". The surge of high levels of serum LH that occurs midcycle in females is critical for ovulation. After ovulation, when the egg is released, the corpus luteum synthesizes P and E2; this stage of the ovarian cycle is correlated with a low level of LH secretion (Fig. 2). Variations in LH secretory patterns occur in response to alterations in the secretion of the hypothalamic peptide gonadotropin-releasing hormone and in levels of the sex steroids, E2, P, and T, as part of the long endocrine feedback loops (Fig. 1) regulating reproduction and fertility. GnRH is secreted episodically into the portal circulation that links the hypothalamus and pituitary gland. Stimulation of LH and FSH secretion is frequency dependent, with more rapid pulse frequencies (30- to 90-min intervals) generally favoring LH and slower pulse frequencies (120-min or longer intervals) generally favoring FSH. Steroid feedback to regulated LH levels may occur at the level of the hypothalamus, to alter GnRH pulse frequency, or at the level of the pituitary gland, to modulate either LH synthesis or the response of the gland to GnRH. In males, steroid feedback is generally negative, whereas in females both positive feedback prior to the LH surge and negative feedback during the rest of the ovulatory cycle are important for normal fertility.

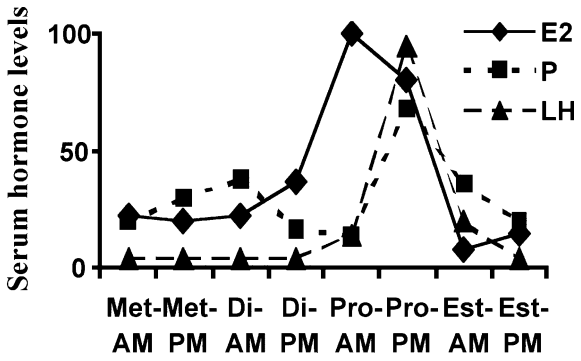

FIGURE 2 Serum levels of luteinizing hormone (LH) and steroids during the female rat reproductive cycle. Levels of LH, progesterone (P), and 17β-estradiol (E2) are plotted relative to 100% of maximal levels secreted during the 4-day rat estrous cycle, measured at 9 AM and 6 PM on each day of the cycle. Follicular development occurring during diestrus (Di) and proestrus (Pro) results in rising E2, increased GnRH receptor number, and an increased GnRH pulse frequency, leading to a surge of LH and P. After ovulation in the late afternoon of proestrus, corpora lutea formation during estrus (Est) and metestrus (Met) secretes sufficient levels of E2 and P to suppress GnRH pulses and thus LH.

III. BIOLOGICAL ACTIONS ON TESTES

LH plays a critical role in endocrine function of the adult testes, acting on the Leydig cells to promote the production of the sex steroid testosterone, which is required for normal sperm production and fertility. In the mouse, α-subunit gene expression is detected fairly early in development, on day embryonic day 10.5 (E10.5), whereas LHβ is not expressed until day E16.5 and FSHβ is not expressed until E17.5 of the 20- to 21-day gestational period. Thus, neither LH nor FSH secretion occurs prior to the prenatal development of the testes, and normal male sexual differentiation and genital development occur in the absence of circulating pituitary gonadotropins. This point has been substantiated by gene disruption studies in mice in which the common α-subunit gene is "knocked out" by insertion of an artificial DNA sequence, and no α-subunit protein is made in either the gonadotropes or the thyrotrope cells that synthesize thyrotropin. Homozygote knockout males have normal sexual differentiation and genital development but are both hypothyroid and hypogonadal, with no circulating LH, FSH, or T, and are infertile. The mice have decreased testis size with normal

epididymis and vas deferens; however, the seminal vesicles are atrophied, consistent with the lack of serum T, and there is a block in spermatogenesis at the first meiotic division. The directed disruption of the LHβ gene specifically in an animal model has not been reported. However, mutations in the gene for early growth response protein-1 (Egr-1), a transcription factor required for LHβ gene expression, can result in a functional loss of LHβ and serum LH and subsequent infertility in males under certain conditions. Male infertility results if the Egr-1 mutation is severe and targets both the N-terminus and the DNA-binding domain of the protein, but not if the Egr-1 targets the DNA-binding region alone. Because the first mutation also affects expression of the LH receptor gene, both LH synthesis and action as well as other potential unknown molecules and pathways are affected. A recent report described the phenotype of mice in which the LH-R gene was disrupted, resulting in spermatogenic arrest and severe underdevelopment of internal and external genitalia, including abdominal testes, disarray of seminiferous tubules, diminished number of Leydig cells, and low T. Testosterone treatment resulted in descended testes and larger penis size as well as resumption of spermatogenesis, but the mice remained infertile.

In humans, a short period of high levels of gonadotropin secretion after birth in both sexes occurs during the first 3–4 months; this is followed by a period of suppressed gonadotropin levels until puberty. There are no known human gene deletions for the LHβ gene or for the LH-R. However, several inactivating mutations in these genes confirm that a functional loss of LH results in extremely low to absent T production, Leydig cell hypoplasia, absence of the development of male secondary sexual characteristics, and infertility. Rare cases of activating receptor mutations in boys result in precocious puberty and high levels of gonadotropin-independent testosterone.

LH acts through a serpentine (seven-transmembrane) domain G_s-protein-coupled membrane receptor. Biological activity is primarily dependent on G_s stimulation of adenylyl cyclase and increased intracellular cAMP, which then activates protein kinase A (PKA) and subsequently several other enzymes. In males, LH-Rs are located primarily on the Leydig cells in the testes, which produce all of the testicular T. This T production, along with the FSH-induced androgen-binding protein produced in the Sertoli cells, maintains the high androgen concentrations required for spermatogenesis (Fig. 3). The production of the sex steroid occurs by modification of precursor

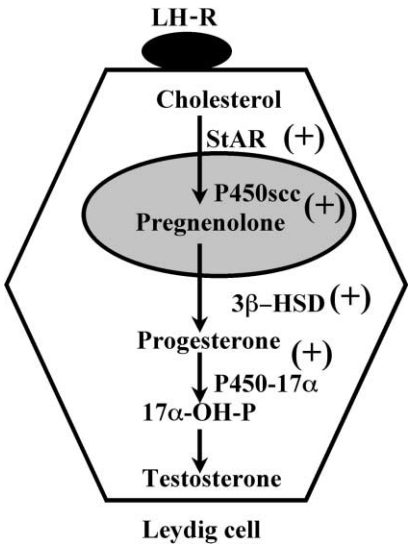

FIGURE 3 Luteinizing hormone (LH)-stimulated steroid synthesis in Leydig cells in the testes. The testes contains several cell types, including the Leydig cells, which contain LH receptors and produce testosterone, and the Sertoli cells, which synthesize a testosterone-binding protein that acts to maintain the high testosterone concentrations required for spermatogenesis. LH stimulates (+) the transport of the cholesterol precursor into the mitochondria, indicated by the gray oval, by the steroidogenic acute regulatory (StAR) protein, and several enzymatic steps in the mitchondria and endoplasmic reticulum that modify the cholesterol backbone to the final product. These steps include P450 side chain cleavage enzyme (P450scc), which converts cholesterol to pregnenolone; 3β-hydroxysteroid dehydrogenase/isomerase type I(3β-HSD), which converts pregnenolone to progesterone; and 17α-hydroxylase/17,20 lyase (P450-17α), which acts on pregnenolone to produce 17α-OH progesterone (17α-OH-P), a precursor of the androgens androstenedione and testosterone.

cholesterol esters in several steps by cytochrome P450 enzymes that are contained in the mitochondria and endoplasmic reticulum. LH stimulation of steroidogenesis occurs at several sites and includes induction of steroidogenic acute regulatory protein (StAR) synthesis and phosphorylation. Although the entire molecular mechanism of StAR activity is not yet clear, it facilitates the overall rate-limiting step in steroidogenesis, the transfer of cholesterol from the outer mitochondrial membrane to the inner mitochondrial membrane. Cholesterol is then modified by the actions of the P450 cholesterol side chain cleavage enzyme (P450scc; CYP11A), the key and rate-limiting enzyme in steroidogenesis, which removes the six-carbon cholesterol side chain to form pregnenolone. Pregnenolone is further metabolized to P by the actions of the endoplasmic reticulum enzyme

3β-hydroxysteroid dehydrogenase/isomerase type 1 (3β-HSD1), and production of the androgens androstenedione and testosterone is further catalyzed by a cascade initiated by the P450 17α-hydroxylase/17,20 lyase enzyme (P450-17α; CYP17). In addition to its actions on StAR, LH also stimulates the production and activity of the steroidogenic enzymes P450scc, 3β-HSD1, and P450-17α, at least partly by stimulating transcription of the enzyme genes through the cyclic adenosine monophosphate (cAMP)-activated transcription factor, cAMP response element binding (CREB) protein, and related family members. Thus, LH stimulates many if not all of the steps leading to androgen synthesis. Activating mutations in the human LH-R have been found to result in precocious puberty in young boys, presumably because the LH-R increases intracellular cAMP concentrations in the absence of ligand, stimulating StAR and the steroidogenic enzymes.

IV. BIOLOGICAL ACTIONS ON OVARIES

The ovary, the site of both steroid synthesis and egg or ovum production, is a complex tissue and its physiology will not be covered in detail here. Steroid synthesis in the ovary occurs in ovarian follicles, which contain two types of steroidogenic cells, the granulosa and the theca cells (Fig. 4); these cells lie on either side of the follicular basement membrane, whereas interstitial cells are contained between the follicles. Granulosa cells contain receptors for both FSH and LH, whereas the theca cells contain receptors for LH alone. The effective physiological production of the two main female sex steroids, P and 17β-estradiol, requires cooperation between the two cell types. LH plays a critical role in inducing the levels and activity of StAR, the main transport protein for moving cholesterol into the mitochondria for enzymatic modification, and the rate-limiting step in steroidogenesis in both granulosa cells and theca cells. FSH induces LH receptors on the granulosa cells of the follicle, and gonadotropin (either LH or FSH) treatment results in increased CYP11A activity, leading to increased P production. Progesterone cannot effectively be modified to E2 within the granulosa cells. Instead, it is transported to the theca or interstitial cells, where it can either enter the circulation or serve as a substrate for the CYP17 enzyme, which converts P to 17-OH progesterone, a precursor of the androgens androstenedione and T. Testosterone serves as the substrate for E2 via the enzyme aromatase (P450arom; CYP19), which is not expressed in theca cells. Estradiol synthesis requires

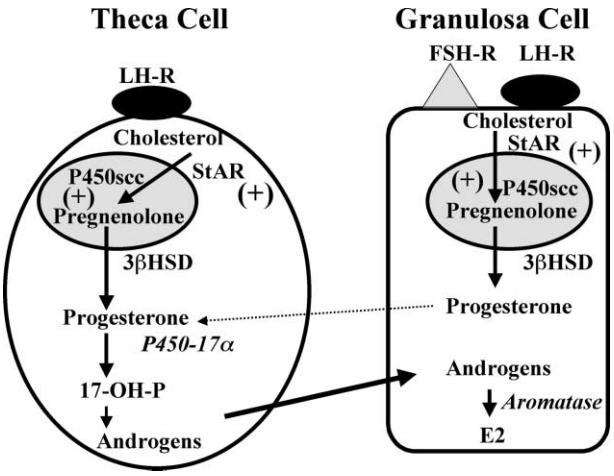

FIGURE 4 Luteinizing hormone (LH)-stimulated steroid synthesis in ovarian cells. Production of progesterone and 17β-estradiol (E2) from cholesterol precursors requires cooperation of the granulosa cells, which contain both LH and follicle-stimulating hormone (FSH) receptors (LH-R and FSH-R), and the theca cells, which contain only LH receptors. Both cells can synthesize progesterone. However, only theca cells contain the enzyme 17α-hydroxylase/17,20 lyase (P450-17α), which modifies progesterone to 17-OH progesterone (17-OH-P), a precursor of the androgens androstenedione and testosterone, and progesterone from either theca or granulosa cells may be used for this purpose. Only granulosa cells contain aromatase, which converts androgens to E2. FSH induces LH receptors as well as the side chain cleavage enzyme (P450scc;), which converts cholesterol to pregnenolone in the mitochondria. LH stimulates (+) the transport of the cholesterol precursor into the mitochondria by stimulating the steroidogenic acute regulatory (StAR) protein, as well as mitochondrial P450scc activity, in both granulosa and theca cells, but other enzyme activities in the endoplasmic reticulum are not stimulated. Enzymes unique to a specific cell type are shown in italics.

transport of the testosterone from the theca to the granulosa cells, where it is converted to E2 by CYP19. The theca cells also contain StAR and the enzymatic machinery to produce P, so androgens made in the theca cell can arise from either granulosa cell- or theca cell-produced P. The vast majority if not all E2 production occurs in the granulosa cell. LH does not appear to have much influence on CYP17 and CYP19 levels, which rise in rodent models prior to the LH surge. In fact, these enzymes are critical in providing the increased serum E2 levels that are required for the LH surge.

The increased level of LH-R on the mature follicle makes it highly sensitive to LH, and the LH surge signals the rupture of the follicle and ovulation. After ovulation, the granulosa cells from

the ruptured follicle undergo the process of luteinization and form the corpus luteum (CL), an endocrine structure that synthesizes the E2 and P secreted during the next phase of the ovarian cycle, referred to as the luteal phase of the cycle in humans. LH is required for the development of the CL; however, this structure and steroid synthesis in the rodent ovary are maintained during pregnancy by pituitary prolactin and by uterine prolactin-related molecules. In humans, the CL contains LH-R, and LH could maintain CL steroidogenesis. However, negative steroid feedback results in lower serum LH, and the maintenance of the CL in early pregnancy occurs through hCG, which is produced by the trophoblast cells of the placenta and acts on the LH/CG-R in the CL.

The importance of LH in the ovarian cycle and fertility is underlined by several gene knockout models and naturally occurring human mutations. Female mice with disrupted α-subunit genes are infertile, with a failure of the vaginal orifice to open, small ovaries with no antral follicles or corpora lutea, thin uteri, and severely depressed E2 levels. Introduced mutations in the mouse gene for early growth response protein-1,a transcription factor required for LHβ gene expression, result in a functional loss of LHβ and serum LH and subsequent infertility. The animals with these mutations have normal follicular development, because this occurs under the influence of FSH, but there is no ovulation or subsequent corpus luteum development. Steroid synthesis can be induced by gonadotropin (LH or hCG) administration. Disruption of the LH-R in female mice results in ambiguous vaginal opening, dramatically decreased ovarian and uterine weights, arrested follicular growth, dramatically decreased StAR levels, and decreased E2. Estradiol and progesterone replacement therapy in these animals results in normal vaginal development, but has no effect on ovarian morphology, and animals remain infertile. Thus, steroids cannot replace LH actions for ovarian morphology or overall fertility, and LH likely plays additional roles in this process. Hypersecretion of LH in female mice, as engineered in a transgenic mouse model, results in enlarged, cystic, and hemorrhagic ovaries, elevated T:E2 ratios, and infertility due primarily to anovulation.

In humans, LH-R-activating mutations identified to date do not cause precocious puberty in females, because the receptors still respond with higher activity to the high levels of serum LH required to cause ovulation. Inactivating LH-R mutations in women do not interfere with the development of primary and secondary sexual characteristics, but result in low levels of E2 and P and in the absence of ovarian corpora lutea, thus resulting in infertility. Women with polycystic ovarian syndrome (PCOS) are infertile or subfertile and are hyperandrogenic. Many PCOS women have elevated LH/FSH levels, but it is uncertain whether this helps drive the higher serum androgens or is the result of inappropriate steroid feedback at the hypothalamus and pituitary.

V. REGULATION BY GnRH

The single most important physiological determinant of LH secretion in mammals is the hypothalamic decapeptide gonadotropin-releasing hormone, and animals or humans lacking GnRH do not secrete gonadotropins and are infertile. GnRH is secreted episodically into the vessels of the hypophyseal portal system linking the hypothalamus and the pituitary; it acts on specific seven-transmembrane G-protein-coupled GnRH receptors (GnRH-Rs) on the membrane of the pituitary gonadotrope. Pulsatile secretion of GnRH, defined by both pulse frequency and amplitude, is critically important in determining the amount and identity of the gonadotropin secreted. Rapid GnRH pulse intervals lasting 30 to 90 min favor LH secretion, and longer pulse intervals favor FSH secretion. Both LH and FSH are synthesized in the same cells, although a population of gonadotropes will contain cells that primarily contain one of the two hormones, and the mechanism by which cells sort secretory vesicles to release primarily LH or FSH is unknown.

The intermittent nature of the GnRH signal is essential in maintaining gonadotropin secretion. Elegant studies in primates and sheep, using direct physical sampling of GnRH secretion or direct administration of GnRH into the portal system, have shown that sustained exposure to high concentrations of GnRH reduces the response of the gonadotrope cells to subsequent GnRH stimulation. This process of homologous desensitization of the GnRH receptors (GnRH-R) leads to subsequent suppression of gonadotropin secretion and occurs even within the time frame of endogenous GnRH pulses. The mechanism of desensitization is not known; it may involve both reduction in receptor number and uncoupling of the GnRH-R from its regulatory G-proteins, $G_{\alpha q}$ and $G_{\alpha 11}$, and the loss of downstream signaling. GnRH binding activates phospholipase C, protein kinase C (PKC), and

mitogen-activated protein kinase (MAPK) and results in increased intracellular calcium concentrations due to calcium influx through voltage-dependent L-type calcium channels and release from intracellular stores. Desensitization has been shown to diminish the GnRH response through all of these signaling cascades. The mechanism for GnRH-R uncoupling has not been defined. In other G-protein-coupled receptors, this process usually involves receptor phosphorylation in the third intracellular loop or the C-terminal tail. The GnRH-R lacks a C-terminal intracellular tail and does not have significant amino acid homology with these receptors in the third intracellular loop, suggesting that desensitization may occur at some point after receptor binding and activation.

In addition to effects on LH secretion, GnRH pulse frequency has profound effects on the transcription rates of the all of the gonadotropin subunit genes, as well as the GnRH-R, as shown in rats *in vivo* and in rodent pituitary cells in culture. Continuous GnRH or rapid pulses (one pulse every 8 or 30 min) preferentially stimulate α-subunit mRNA and gene transcription; intermediate pulse frequencies (one pulse every 30 to 60 min) preferentially stimulate the LHβ subunit gene and increase levels of GnRH-R and LHβ subunit mRNA. GnRH pulses have a less robust effect on FSHβ mRNA levels and gene transcription, and occur only at slow pulse frequencies (one pulse every 120 or 240 min). This may reflect the fact that the FSHβ gene is also regulated by gonadal and pituitary peptides such as activin, inhibin, and follistatin, which have little if any effect on LHβ and may reduce the importance of regulation by GnRH. The stimulation of the GnRH-R by GnRH is reflected in increased GnRH binding to pituitary cell membranes at times leading up to the LH surge, and this helps explain the "priming" effect of GnRH pulses on GnRH-R.

Because the gonadotrope contains only one type of GnRH-R, the mechanism by which frequency-dependent signals are decoded at the level of the receptor and sensed differentially by the gonadotropin subunit genes has been a subject of much conjecture and investigation. Possible points of GnRH regulation include preferential sensitivity to different signaling pathways recruited by varying pulse frequencies, different gene targets such as DNA sequences and transcription factors, or both. Unfortunately, there is no current cell model system that maintains the strict GnRH pulsatile dependency required *in vivo* for gene expression, and dependence on differential intracellular signaling pattern activation for subunit gene activation has been difficult to confirm. There are also differences in DNA sequences of the promoters of the LH subunit genes from various species (humans, rats, mice, and bovines), allowing for potential species-specific differences in gene regulation between model systems. GnRH-stimulated transcription of the human and rodent α-subunit gene requires both calcium influx and MAPK activity, whereas activation of the LHβ genes from several species has been reported to require preferentially either calcium influx, PKC, or various MAPK family members. However, because intermediate to high GnRH pulse frequencies stimulate the expression of the GnRH-R as well as LHβ and the α-subunit, the LH genes are maximally stimulated when GnRH-R concentration is high, and FSHβ is maximally stimulated when GnRH-R concentrations are low. These data have been verified in cells that have artificially engineered levels of GnRH-R, and this has led to the hypothesis that the higher levels of GnRH-R activate some additional signaling pathway, perhaps associated with G-protein βγ subunits that either preferentially stimulate the LH subunit genes or silence the FSHβ gene.

It is clear that the two LH subunit genes from any one species have both common and divergent gene regulatory regions, and that the divergent regions likely contribute to the differential regulation by GnRH. Both subunit genes bind transcription factors that direct gene expression to the pituitary gonadotrope, but are not required for hormonal regulation. Prominent among these common factors is steroidogenic factor-1 (SF-1), which plays a central role in the expression of many genes in reproductive and steroidogenic (gonads and adrenals) tissues. SF-1-dependent genes include those encoding the α-subunit, LHβ, and the GnRH-R; animals in which the SF-1 gene is disrupted are infertile.

GnRH regulation of the subunit genes utilizes pathways with at least some degree of species specificity. Stimulation of the human α-subunit gene requires a cyclic AMP response element (CRE), which binds several members of the CREB protein family. These transcription factors are phosphorylated posttranslationally, and thus are activated, by multiple protein kinase enzymes. The kinases are modified and activated by several signaling pathways stimulated by GnRH, including PKC, MAPK, and calcium. The rat and mouse α-subunit genes do not contain CREs, and although the DNA sequences necessary to confer a GnRH response have been identified, the proteins binding to

them have not. The LHβ genes from several species require the transcription factor Egr-1, mentioned previously, for LHβ expression. Egr-1 protein synthesis is dramatically stimulated by GnRH through the PKC pathway. The protein can also be posttranslationally modified and activated by GnRH signaling cascades, resulting overall in increased binding of Egr-1 to the LHβ gene promoter and in stimulated LHβ mRNA and protein levels. The rat, but not the bovine, LHβ gene also requires gene promoter sequences that bind specificity protein-1 (Sp-1), a protein similar to Egr-1, for full stimulation, and the two regions are proposed to cooperate by binding additional co-activator proteins.

Regulation of LH subunit gene activity through specific divergent GnRH response elements and transcription factors cannot explain the pulsatile GnRH control of this process. Rhythmic transcription is at least partly due to secondary induction of enzymes or other proteins that subsequently act in opposition to GnRH. Sophisticated molecular biology techniques have identified numerous GnRH-induced genes, including those for signaling molecules, transcription factors, and adapter proteins, that could serve this function. For example, Egr-1 stimulates not only the LHβ gene, but also the gene for a MAPK phosphatase, which opposes and limits the actions of the MAPK activated by GnRH. GnRH also stimulates synthesis of Nab-1 and Nab-2, proteins that bind to Egr-1 and alter its biological activity. Thus, GnRH can induce proteins that initiate the stimulatory LH response as well as help to extinguish it.

VI. REGULATION BY OTHER HYPOTHALAMIC PEPTIDES

Although several additional peptides have been reported to stimulate or inhibit LH secretion, or to modify the effects of GnRH on LH stimulation, none of the peptides has the central physiological role of GnRH in controlling LH serum levels. The majority of information on their biological effects is derived from animal models, particularly rats, and effects of nearly all the peptides can be either positive or negative, depending on the particular animal model or endocrine state. Galanin and oxytocin stimulate LH secretion, and hypothalamic release of both, as well as neuropeptide Y (NPY), is highest in rats during proestrus when LH secretion rises. The stimulatory effects of oxytocin and NPY are greatest in the presence of E2 and are inhibited in the presence of P. Direct effects of NPY on pituitary cells have been difficult to demonstrate, emphasizing the importance of the physiological interactions between the various hypothalamic peptides, steroids, and GnRH *in vivo*. Pituitary adenylyl cyclase-activating peptide (PACAP) stimulates LH release from isolated pituitary cells and augments the GnRH stimulatory effect. PACAP is released into portal blood and is also synthesized in anterior pituitary cells. PACAP stimulation of intracellular cAMP levels and cross talk with GnRH signaling pathways contribute to the stimulatory actions of PACAP on the gonadotrope. The gonadotrope cells contain high-affinity receptors for PACAP and oxytocin, allowing them to act at low physiological concentrations. In contrast, the pituitary contains a small number of high-affinity NPY-binding sites that are often masked by a large number of lower affinity sites. NPY treatment increases GnRH binding to rat pituitary cells, thus increasing GnRH effectiveness.

Two peptide types, substance P and the opioids, have been reported to suppress GnRH stimulation of LH secretion under specific physiological states. Substance P binding sites exist on rodent and human pituitary tissues. The number of substance P receptors varies during the rat estrous cycle and is inversely related to the number of GnRH binding sites. Substance P inhibits GnRH-stimulates LH release from cultured rat or human pituitary cells but potentiates the response in pig cells, thus demonstrating some species-specific responses. Opioid peptides, particularly β-endorphin, are secreted into portal blood in a temporal pattern inversely related to GnRH secretion. The opioids act at the hypothalamus to inhibit GnRH secretion, and this is their most important physiological effect on the hypothalamic–pituitary reproductive axis. However, β-endorphin can also suppress GnRH-stimulated LH release by acting through μ- and δ-opioid receptors on rat pituitary cells. Inhibition is not observed in E2-treated pituitary cells, but is observed in the presence of P. The opioids are also synthesized in the anterior and intermediate pituitary lobes, allowing for paracrine regulation of the gonadotropins.

VII. REGULATION BY SEX STEROIDS

Serum LH levels are closely correlated with those of the sex steroids, E2, T, and P. The steroids may act indirectly at the level of the hypothalamus to regulate the amplitude and frequency of GnRH pulses. Alternatively, direct steroid effects can occur at the

level of the pituitary to modulate LH subunit gene expression, GnRH-R levels, and the response of the pituitary gland to other peptides and steroids that modulate GnRH responses. Because T may be aromatized to E2, T may have biological actions through its own androgen receptor (AR) or through the estrogen receptor (ER). Negative feedback of the steroids with respect to LH in males and females is dramatically demonstrated after gonadectomy, when LH levels rise manyfold. Elevated LH levels are also observed in aging humans, particularly postmenopausal women with low E2 levels, and in animal models in which the ARs and ERs are mutated or disrupted. Positive steroid (E2) feedback is demonstrated in females at the time of the proestrus or midcycle surge in LH, leading up to ovulation. Steroid modulation in both cases requires actions at the hypothalamic level, but some pituitary actions of steroids are noted in both cases.

The pituitary gonadotrope contains receptors for E2, androgens, and P, and these steroids all influence LH synthesis and secretion. Estradiol treatment increases the level of GnRH-R, stimulates rat LHβ gene transcription, and stimulates the human α-subunit gene responsiveness to GnRH through effects on CREB phosphorylation. Estradiol also induces the synthesis of P receptors (PRs). All these responses contribute to positive steroid feedback in females prior to the LH surge and increase pituitary responsiveness to GnRH. In contrast, high physiological levels of T generally have suppressive effects on LH synthesis. These responses are due to direct androgen action rather than to conversion to E2, as verified by administration of aromatase inhibitors or use of the nonaromatizable androgen dihydrotestosterone (DHT). Testosterone or DHT suppresses human α-subunit gene expression directly and blunts stimulatory responses of the LH subunit genes of several species to GnRH. Testosterone also reduces the LH response to GnRH in human studies.

The sex steroids exert profound control over the GnRH pulse pattern, affecting both frequency and amplitude. Thus, they play a critical role in determining gonadotropin secretion, the female ovarian cycle, and the fertility of both sexes. In females, rising serum E2 from the developing ovarian follicle decreases the amplitude of GnRH pulses and raises the baseline secreted between pulses, with either no effect or an increase in GnRH pulse frequency; overall, in rats at proestrus, sustained GnRH release during the hormonal surge in maintained. Estradiol also induces PR expression in the hypothalamus, allowing a response to P and E2 secreted from the mature follicle and corpus luteum after ovulation. Progesterone, in the presence of E2, slows GnRH pulse frequency and overall GnRH secretion, thus suppressing LH secretion. High levels of sustained E2 or T also suppress GnRH pulses, reducing the rise in gonadotropins noted after gonadectomy in animals or humans. Sustained E2 plus P treatment suppresses the hypothalamic–pituitary axis and ovulation very efficiently, and is the basis for oral contraception.

High physiological levels of T suppress GnRH pulse amplitude in humans, based on lower LH pulses in response to GnRH, and suppress GnRH secretion in rats and sheep. However, in women with polycystic ovarian disease, the inappropriately high serum T levels are often associated with elevated serum LH. Testosterone levels in these women are lower than those found on men and women with suppressed GnRH secretion. In this case, T may interfere with P action on the hypothalamus to reduce GnRH pulse frequency. LH secretion will thus be favored. Administration of androgen antagonists restores the sensitivity of the women to estrogen plus P suppression of LH. Thus, the levels of the sex steroids relative to each other can also influence GnRH pulses.

The mechanisms by which the steroids modulate GnRH neurons have been the subject of much debate, because it has been difficult to detect steroid receptors within them. However, GnRH neurons of several species have now been found to contain ERβ, a recently identified estrogen isoform, allowing for direct estrogen actions, and PR has been detected in a small subset of these neurons in some species. Steroid effects could occur through direct effects on the GnRH neurons, or indirectly through steroid-responsive cells adjacent to the GnRH neurons, to modulate secretion of other peptides and small molecules such as nitrous oxide, opioids, serotonin, and dopamine, which subsequently regulate GnRH release. In either case, steroids can act to regulate transcription of genes for neurotransmitters or their synthetic enzymes or receptors, or may activate other intracellular signaling pathways to have nongenomic effects. For example, E2 acutely opens potassium channels and hyperpolarizes GnRH neurons, and kinase inhibitors block some of these effects. It is likely that both direct and indirect steroid mechanisms play a role in regulating GnRH pulse patterns.

VIII. SUMMARY

LH secretion from the pituitary gonadotrope cell is controlled by interplay between the circulating levels of estradiol, progesterone, and testosterone and the

specific pattern of hypothalamic-secreted GnRH pulse frequency and amplitude. Steroids regulate LH synthesis and the synthetic and secretory responses to GnRH. In females, a surge of E2 and LH is required for ovulation and fertility, whereas GnRH and gonadotropin secretion are suppressed in the presence of constant E2 and P. Luteinizing hormone plays a central role in stimulating the production of the sex steroids in the ovary and testes, through transport of the cholesterol precursor and stimulation of the steroidogenic enzymes. LH secretion and functional LH receptors on the gonads are required for normal fertility in both males and females.

Glossary

gonadotropin-releasing hormone A 10-amino-acid peptide synthesized and modified from a large protein precursor and secreted in intermittent pulses from the hypothalamus; acts on specific gonadotrope G-protein-coupled receptors to stimulate gonadotropin synthesis and secretion.

gonadotropins Two related, but functionally distinct, peptide hormones (luteinizing hormone and follicle-stimulating hormone) synthesized and secreted from the gonadotrope cells in the mammalian pituitary. These hormones bind to receptors on the gonads, the ovaries, and testes, and individually influence either sex steroid production (primarily luteinizing hormone) or the development of eggs and sperm.

G-protein-coupled receptors Membrane receptors, also called seven-transmembrane, or serpentine, receptors; bind peptides or small molecules on the cell surface and bind intracellularly with small three-subunit G-proteins, the activity of which is regulated by GTP cleavage and phosphorylation. The G_α subunit communicates directly with and activates other intracellular signaling cascades to increase levels of cyclic AMP, phospholipids, and intracellular Ca^{2+}. The $G_{\beta\gamma}$ subunits were originally thought to be inert, but have recently been shown to activate protein kinase pathways distinct from that of the G_α subunits.

mitogen-activated protein kinases Dual protein kinase enzymes activated by phosphorylation of specific threonine and tyrosine residues in response to binding to G-protein-coupled and growth factor receptors. The biological activities of the kinases are opposed by phosphatases, enzymes that dephosphorylate either the threonine or tyrosine and inactivate the kinase.

protein kinase C Serine/threonine protein kinases that are activated by phospholipids and by increases in intracellular Ca^{2+}, and in response to extracellular signals from membrane-bound receptors.

steroidogenesis Enzymatic process of synthesizing sex steroids from cholesterol precursors, occurring in steroidogenic tissues such as the ovaries and testes. The process can occur only in cells that contain the steroidogenic acute regulatory protein, a transport protein that brings the cholesterol ester to the inner mitochondrial membrane for modification, and specific cytochrome P450 enzymes, which are located in the mitochondria and endoplasmic reticulum. The enzymes contain heme and reduce molecular oxygen, incorporating one atom specifically into the substrate as a hydroxyl group.

Luteinizing Hormone Receptor Signaling

PREMA NARAYAN AND DAVID PUETT
University of Georgia

A critical component of the reproductive axis in males and females, the luteinizing hormone receptor (LHR) is required for phenotypic male sexual differentiation of the 46,XY fetus, gonadal steroidogenesis in adult testes and ovaries, and ovulation. The major signaling pathway of this receptor in response to the gonadotropins, human luteinizing hormone and human chorionic gonadotropin, is believed to be that of intracellular cAMP production, although recent findings suggest the involvement of other signal transduction pathways in certain target cells. This article reviews the intracellular signaling pathways associated with LHR in hormone-dependent and hormone-independent activation, the latter, for example, arising from mutations of the LHR gene that promote constitutive receptor activation. The cellular mechanisms for signal attenuation at the level of LHR are also discussed.

I. INTRODUCTION

The luteinizing hormone receptor is a member of the glycoprotein hormone receptor subfamily, which includes the follicle-stimulating hormone receptor and the thyroid-stimulating hormone receptor. This small subfamily belongs to the larger family of rhodopsin-like seven-transmembrane G-protein-coupled receptors, which are defined by an N-terminal extracellular domain, seven transmembrane helices linked by three intracellular and three extracellular loops, and a C-terminal cytoplasmic tail. A defining characteristic of the glycoprotein hormone receptors is the presence of a large, glycosylated extracellular domain that is composed of leucine-rich repeats; this extracellular region serves as a high-affinity ligand-binding domain.

The luteinizing hormone receptor (LHR) binds the two homologous and structurally similar gonadotropins, pituitary-derived luteinizing hormone (LH) and placentally secreted human chorionic gonadotropin (hCG). These two hormones are glycosylated heterodimers that share a common α-subunit and contain a hormone-specific β-subunit. In early development, LHR activity is essential for the maturation of fetal Leydig cells and the production of testosterone during male sexual differentiation. In adults, LHR function is required for male and female reproductive physiology. For example, in males, LHR regulates the production and secretion of androgens from the testis in response to LH. In females, LHR associated with the theca and granulosa cells of the ovary promotes follicular development and regulates the production of sex steroids in response to LH. Moreover, the action of high levels of LH produced during the midcycle LH surge triggers ovulation. Following ovulation, LHR associated with the luteal cells in the corpus luteum is responsible for the production of progesterone, a process also under the control of LH. In the event of fertilization, LHR in the corpus luteum is activated by hCG secreted by the syncytiotrophoblast cells of the placenta, resulting in the production of progesterone, which are essential for the maintenance of pregnancy. Therefore, LHR occupies a central role in the fundamental processes of development and reproduction, and precise regulation of the signaling pathways activated by LHR is vital to these processes.

II. SIGNALING VIA THE cAMP PATHWAY

Binding of LH or hCG to LHR on the cell surface activates a cascade of intracellular events that are ultimately responsible for the modulation of steroidogenesis in the gonads. The predominant intracellular signal transduction pathway that mediates the tropic effects of LH and hCG, thus regulating steroidogenesis in gonadal cells, is the cyclic adenosine monophosphate (cAMP) pathway (Fig. 1A). This is also the predominant pathway that is activated in heterologous cells (e.g., HEK293, COS-7, and CHO) expressing LHR. On ligand binding, LHR interacts with the stimulatory $G_{\alpha s}$, resulting in activation of the membrane-bound adenylyl cyclase, leading to an elevation in the levels of the intracellular second messenger, cAMP. cAMP activates protein kinase A (PKA), which subsequently activates transcription factors by phosphorylation. The most well-studied factors are the cAMP response element binding protein (CREB) and the coregulatory CREB-binding protein (CBP). Transcription of many of the steroidogenic enzymes, when activated, results in the production of testosterone in males and estrogen and progesterone in females.

Although this signaling pathway has been well established, it may not be the only pathway that mediates all the actions of LHR. Recently, an increasing body of evidence has accumulated suggesting that additional signal transduction pathways radiating from this linear cAMP pathway may be responsible for the proliferation and differentiation of cells in the gonads. For example, PKA and the G-protein βγ-subunits can activate the mitogen-activated protein kinases (MAPKs), key regulatory enzymes that are implicated in a number of cellular functions, including proliferation, differentiation, control of cellular morphology, and apoptosis. Additionally, it has been demonstrated that in L cells expressing LHR, the G-protein βγ-subunits can activate other signaling cascades by activating phospholipase C-β (PLC-β; see later).

In addition to the well-established activation of the steroidogenic enzymes by LHR, ovulation triggered by the binding of LH to the large numbers of LHRs present in the granulosa cells of the preovulatory follicle initiates diverse signaling pathways radiating from the cAMP pathway. Although the details of these pathways remain to be elucidated, the end result is induction of gene expression of many immediate-early transcription factors and expression of a number of genes that mediate ovulation and differentiation of the granulosa cells of the ovulatory follicle to the luteal cells of the corpus luteum.

III. SIGNALING VIA THE PHOSPHOINOSITIDE PATHWAY

At high hormone concentrations and high receptor densities, LHR can activate PLC-β and protein kinase C in addition to the adenylyl cyclase/protein kinase A pathway. LHR couples to $G_{\alpha i2}$, and the βγ-subunits of G-proteins released from either $G_{\alpha s}$ or $G_{\alpha i2}$ can activate PLC-β (Fig. 1B). PLC-β, in turn, cleaves the inositol 1,4,5-trisphosphate ($InsP_3$) moiety from phosphatidylinositol 4,5-bisphosphate (PIP_2) with the retention of 1,2-diacylglycerol (DAG) in the membrane. $InsP_3$ enters the cytoplasm and binds to receptors on the endoplasmic reticulum, resulting in the mobilization of intracellular calcium stores. DAG, in concert with phosphatidylserine and calcium, activates protein kinase C. Increases in intracellular $InsP_3$ and calcium have been observed in ovaries and in nongonadal cells (L cells, COS-7 cells) transiently or stably transfected with LHR. The extent to which LHR can activate the PLC pathway likely depends on receptor density and the levels of G-proteins present in the different cells. At present, the extent to which the PLC pathway is responsible for mediating LHR activation of steroidogenesis in the ovary and testis is unclear. Perhaps it operates at certain stages during the ovarian cycle when LH levels are greatly elevated.

IV. LIGAND-INDEPENDENT SIGNALING

Several mutations identified in the LHR gene produce receptor proteins with altered amino acid sequences. Many of these amino acid substitutions render LHR in a constitutively activated state so that the signaling pathways are functional in the absence of hormone, whereas other mutations render LHR inactive such that the receptor is unable to signal even in the presence of hormone. Activating mutations were first identified in young boys with familial or sporadic gonadotropin-independent precocious puberty, characterized by increased testosterone and Leydig cell hyperplasia, with no obvious phenotype in females. The phenotypes of the inactivating mutations in males range from incomplete to complete pseudohermaphroditism with low testosterone levels and Leydig cell hypoplasia. In females, a milder phenotype of primary amenorrhea is observed.

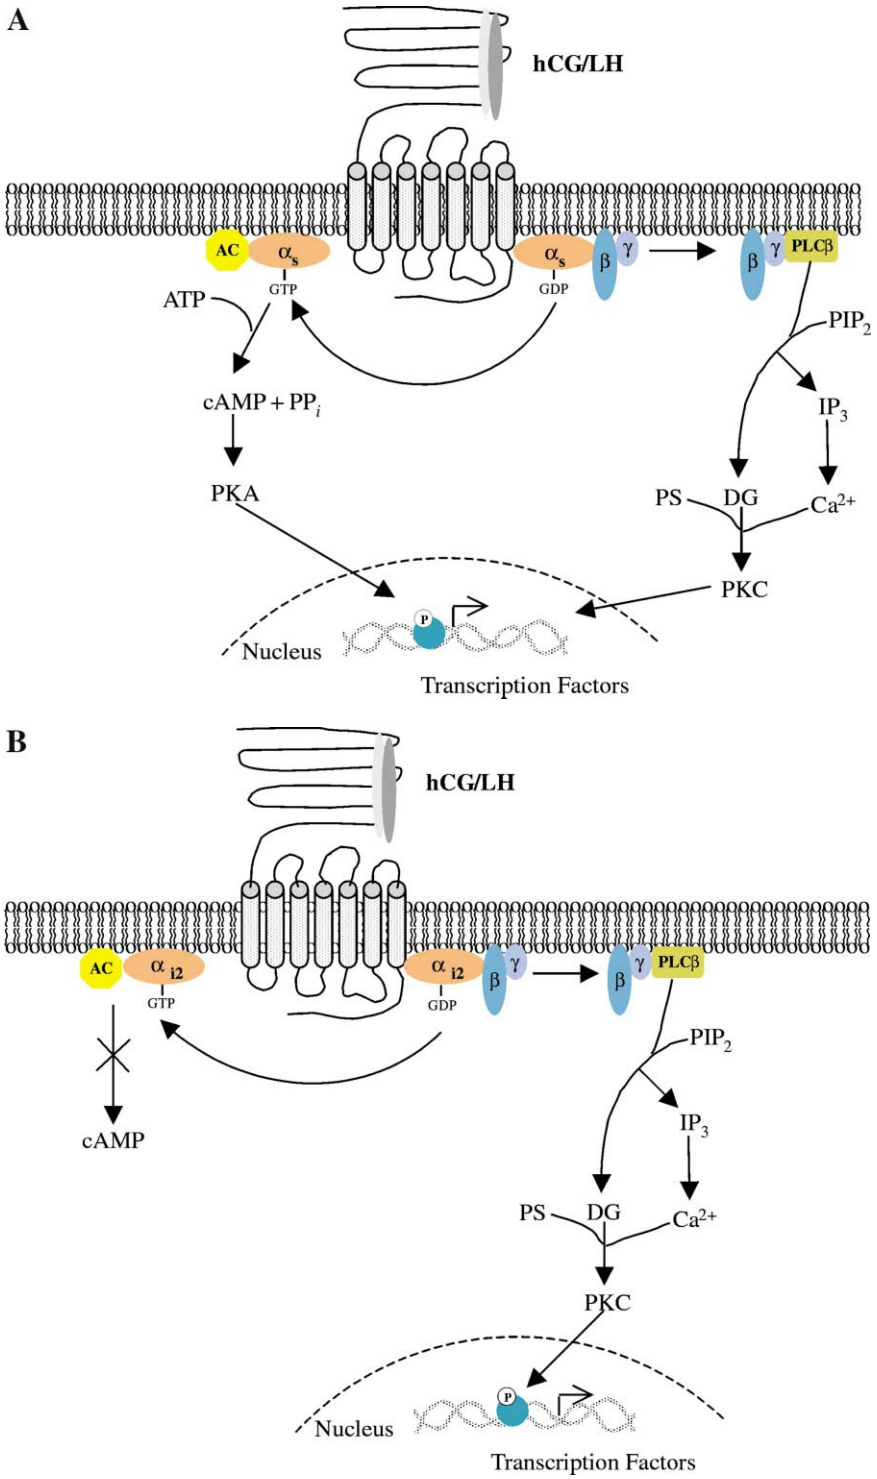

FIGURE 1 Signaling pathways mediated by the luteinizing hormone receptor (LHR). (A) The cyclic adenosine monophosphate (cAMP) pathway. Binding of human chorionic gonadotropin (hCG) or luteinizing hormone (LH) to the membrane-bound LHR converts the inactive guanosine diphosphate (GDP)-bound $G_{\alpha s}$-subunit to the active guanosine triphosphate (GTP)-bound form. This is followed by the activation of adenylyl cyclase (AC), an increase in intracellular levels of cAMP, and activation of protein kinase A (PKA); the G-protein βγ-subunits can potentially activate protein kinase C (PKC). Phosphorylation of nuclear transcription factors by PKA or PKC results in the transcription of

The activating mutations are present in transmembrane helices 1, 2, 3, 5, and 6, with the majority present in helix 6. The signaling properties of these mutant receptors have been examined by *in vitro* transfection experiments. These studies demonstrated that the mutations activate the cAMP pathway in the absence of hCG or LH. Some of the mutant receptors were able to respond to additional ligand with a further accumulation of cAMP whereas others were maximally activated and refractory to additional hormone. Many of the activating mutations also stimulate the phosphoinositide pathway, resulting in an increase in the basal level of $InsP_3$. Presently, it is unknown if additional pathways are activated by the mutant receptors and the effects, if any, of these pathways on the manifestation of the mutant phenotypes have not been elucidated.

V. SIGNAL ATTENUATION

Attenuation of LHR receptor signaling is accomplished by a combination of two processes, receptor desensitization and receptor internalization or sequestration. Much of our current knowledge of these processes is derived from studies on the prototypical G-protein-coupled receptor (GPCR), the β_2-adrenergic receptor. Desensitization of this receptor involves the rapid (minutes after receptor activation) phosphorylation of the cytoplasmic C-terminal portion of the receptor by a specific GPCR kinase. This phosphorylation event promotes the binding of arrestin proteins that thereby facilitate the uncoupling of the receptor from the G-protein, terminating the signal. Arrestin-bound GPCR is internalized into vesicles via clathrin-coated pits. Most GPCRs then undergo dephosphorylation and are recycled to the plasma membrane, where they can again interact with their ligand (resensitization). Alternatively, GPCRs are degraded in lysosomes, resulting in a decrease in the number of cell surface receptors. This process of down-regulation occurs after prolonged exposure to ligand and occurs more slowly than rapid internalization.

Many of the molecular details of signal attenuation of LHR are similar to those described for the β_2-adrenergic receptor, although there are also many important differences. The C-terminal intracellular portion of LHR contains four serine residues that are major sites of phosphorylation. The role of phosphorylation in LHR signal attenuation, however, appears less important. Studies performed in porcine ovarian follicular membranes found no evidence that phosphorylation mediates desensitization. On the other hand, studies performed with rat LHR in transfected HEK293 cells showed that inhibition of agonist-induced phosphorylation delays the time course of LHR uncoupling but does not prevent it. Internalization of the hCG–LHR complex is mediated via clathrin-coated pits by a pathway that requires nonvisual arrestins and dynamin. In contrast to most GPCRs, arrestin binding to LHR is not dependent on phosphorylation. In addition, the internalized rat LHR is not recycled, but the hCG–LHR complex is delivered to the lysosomes, wherein both hormone and receptor are degraded. An exception to this rule is the hCG–hLHR complex in which the majority of the receptor is recycled rather than degraded by the lysosomal pathway. Therefore, the processes of internalization and lysosomal degradation of the agonist–LHR complex are important in the attenuation of hormone-mediated cAMP accumulation and down-regulation of LHR.

VI. SUMMARY

LHR expressed primarily in the testis and ovary has a vital role in male and female reproduction by regulating cell proliferation, cell differentiation, ovulation, and steroid hormone production. The large N-terminal extracellular domain of LHR is the high-affinity binding site for LH and hCG. Agonist binding initiates a signaling cascade beginning with an accumulation of intracellular cAMP, which mediates the activation of PKA, followed by activation of transcription factors, culminating in changes in gene expression and synthesis of steroid hormones. Activation of the phosphoinositide pathway also occurs at high hormone concentration. Attenuation of LHR-mediated signaling is achieved by a combination of receptor uncoupling and down-regulation.

---

specific genes. (B) The phosphoinositide pathway. LHR also couples with $G_{\alpha i2}$ to inhibit cAMP production indicated by X. The $\beta\gamma$-subunits activate membrane-bound phospholipase C-β (PLC-β) which hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_2) to inositol 1,4,5-trisphosphate ($InsP_3$) and 1,2-diacylglycerol (DAG). Note that PIP_2, DAG, and phosphatidylserine (PS) are membrane bound and are shown here as intracellular merely for ease of representation. $InsP_3$ can increase intracellular Ca^{2+}, and DAG-activated PKC can regulate gene transcription.

There is much that is not known about LHR activation and signaling. The precise nature of the interaction between LHR and the G-proteins is not understood. Although it is clear that cAMP is important in LHR-mediated signaling, there is increasing evidence that additional pathways may be involved. For example, recent studies suggest that LHR may stimulate the MAPK pathway and this activation may be important in the modulation of LH-induced steroidogenesis. Furthermore, it is becoming increasingly apparent that signaling cascades are not linear but form a network of interacting pathways. cAMP coordinates multiple and divergent pathways, and the integration and control of these pathways are essential in the regulation of diverse functions such as cell proliferation and cell differentiation. The challenge is in unraveling the LHR-mediated pathways in the normal functioning of the ovary and testis, as well as in pathophysiological conditions.

Glossary

adenylyl cyclase A membrane-associated enzyme responsible for converting adenosine triphosphate to adenosine-3′,5′-cyclic monophosphate. The enzyme is regulated by several G_α proteins.

cyclic adenosine monophosphate A major intracellular signaling molecule that is regulated by a number of extracellular effectors. It is synthesized from adenosine triphosphate via adenylyl cyclase and is metabolized to adenosine monophosphate by cyclic nucleotide phosphodiesterase.

G-proteins A family of heterotrimeric (α, β, and γ) guanosine triphosphate (GTP)-binding proteins, the α-subunit of which exhibits GTPase activity. On activation by G-protein-coupled receptors, the guanosine diphosphate (GDP)-associated α-subunit exchanges GDP for GTP and dissociates from $\beta\gamma$. The G_α–GTP complex regulates the activity of membrane-associated enzymes, e.g., adenylyl cyclase and phospholipase C.

phosphoinositides A family of lipid molecules important in intracellular signaling. The minor membrane component, phosphatidylinositol 4,5-bisphosphate, is hydrolyzed by phospholipase C to yield inositol 1,4,5-trisphosphate and 1,2-diacylglycerol. The former compound is responsible for release of intracellular calcium stores, and the latter component functions with phosphatidylserine and often calcium to activate protein kinase C.

phospholipase C A member of the family of phospholipases responsible for the hydrolysis of phosphatidylinositol 4,5-bisphosphate to inositol 1,4,5-trisphosphate and diacylglycerol. Enzymatic activity of the phospholipase C-β isoform is regulated by subunits of the G-proteins.

protein kinase A A serine/threonine protein kinase, also denoted as cyclic adenosine monophosphate (cAMP)-dependent protein kinase, containing two regulatory (R) and two catalytic (C) subunits. On binding of cAMP by the R subunits, the C subunits dissociate and phosphorylate a variety of intracellular proteins containing the consensus sequence Arg-Arg-X-Ser/Thr-Y, where X is generally a small amino acid residue and Y is a large hydrophobic residue.

protein kinase C A family of serine/threonine protein kinases that are activated by phospholipids and often calcium. The form involved in intracellular signaling is regulated by phosphatidylserine, diacylglycerol, and calcium.

FIGURE 1 Three-dimensional structure of human MIF, viewed down its threefold axis of symmetry.

known proteins that display any three-dimensional structural similarity to MIF are the mammalian enzyme dopachrome tautomerase and the bacterial enzymes 4-oxalocrotonate tautomerase (4-OT) and 5-carboxymethyl-2-hydroxymuconate isomerase (CHMI). A dopachrome tautomerase activity for MIF was discovered serendipitously during an investigation of intermediary steps in melanin biosynthesis, which involves the conversion of 2-carboxy-2,3-dihydroindole-5,6-quinone (L-dopachrome) into 5,6-dihydroxyindole-2-carboxylic acid. While using D-dopachrome (a nonphysiologically relevant stereoisomer) as a negative control in this reaction, a novel enzyme that could convert D-dopachrome to 5,6-dihydroxyindole-2-carboxylic acid was purified. This protein was established to be MIF. MIF and D-dopachrome tautomerase share only 27% sequence identity; however, MIF shares structural similarities with D-dopachrome tautomerase, 4-OT, and CHMI, in that each protein has an N-terminal proline with an unusually low pK_a that can act as a catalytic base to effect tautomerization. These structural studies have provided much impetus for the hypothesis that MIF is an enzyme; however, a physiologically relevant substrate for MIF has not been convincingly identified nor has site-directed replacement of the catalytically active Pro-1 with other residues consistently eliminated MIF's pro-inflammatory activities.

III. IMMUNE CELL PHYSIOLOGY

Although MIF was described first as a T-lymphocyte-derived factor and then as a pituitary secreted protein, other cell types are also important sources of MIF. An investigation of hypophysectomized mice, which lack a pituitary source of MIF, revealed significant levels of circulating MIF during the acute phase of the host response to endotoxin. This led to the identification of the macrophage, which is exquisitely sensitive to endotoxin, as an important producer of MIF *in vivo*. Monocytes/macrophages, like the corticotropic cells within the pituitary gland, contain significant quantities of preformed MIF that can be rapidly released on stimulation. This is in contrast to other macrophage-derived, pro-inflammatory cytokines such as IL-1β and tumor necrosis factor α (TNFα) that require *de novo* mRNA synthesis and protein production before secretion occurs. MIF secretion from macrophages not only is rapid; it occurs in response to endotoxin concentrations that are 10- to 100-fold lower than those required to induce TNFα production. MIF protein also is produced by T lymphocytes, eosinophils, and activated endothelial cells.

Current views favor a dominant role for MIF in the innate immune response. Gram-negative endotoxin, gram-positive exotoxins, hemozoin (malaria pigment), and the pro-inflammatory cytokines TNFα and IFN-γ induce the release of MIF from monocytes/macrophages. Once released, MIF exerts potent autocrine and paracrine effects, promoting macrophage and T-cell activation and pro-inflammatory cytokine release. MIF is also a potent inducer of the cyclooxygenase 2 (COX-2) pathway [arachidonic acid, COX-2, prostaglandin E2 (PGE2)] and of the expression of matrix metalloproteinase-2. Thus, it is not surprising that the blockade of MIF by the use of monoclonal antibodies inhibits the development in experimental animals of several inflammatory diseases such as arthritis, glomerulonephritis, and septic shock.

MIF administration exacerbates endotoxin-induced toxicity, whereas immunoneutralization of MIF rescues mice from lethal endotoxic shock and reduces circulating TNFα levels by up to 50%. The pivotal role played by MIF in the pathogenesis of endotoxic shock has been confirmed by experiments carried out in $MIF^{-/-}$ mice in which the degree of resistance to endotoxin lethality observed was similar to that obtained by MIF immunoneutralization. Recent studies also have provided clinical evidence for systemically elevated MIF levels during sepsis and other generalized inflammatory conditions. The time course of MIF expression in plasma in septic shock patients parallels that of cortisol, and a significant correlation has been noted between elevated MIF levels on hospital admission and occurrence of death.

MIF also is an important regulator of adaptive immunity. Stimulation of primary T cells with anti-CD3 antibody or superantigen induces MIF mRNA expression and protein secretion. Neutralization of

T-cell-derived MIF with specific anti-MIF antibodies inhibits both anti-CD3 and superantigen-induced IL-2 secretion and reduces T-cell proliferation by 40–60%. *In vivo*, treatment of mice with anti-MIF antibodies inhibits antigen-driven T-cell proliferation and reduces the expression of antigen-specific IgG production. A role for MIF in the shaping of the adaptive immune response also is supported by expression studies using T_H1 and T_H2 T-cell subsets. In parallel to effects observed *in vivo*, it was found that, although both subsets of T cells express MIF, secretion is predominantly increased in activated T_H2 clones. Furthermore, studies using MIF knockout mice ($MIF^{-/-}$) have revealed that antigen-stimulated lymph node cells from $MIF^{-/-}$ mice produce higher levels of IL-4 and IFN-γ than those from wild-type mice. These data would favor a role for MIF in the development of T_H2-driven antibody production, at least in some settings.

In an unexpected twist, MIF was found to be specifically released from immune/inflammatory cells as a consequence of glucocorticoid stimulation. Glucocorticoids normally inhibit pro-inflammatory cytokine expression, but secreted MIF functions in a regulatory capacity to "override" or counterregulate the immunosuppressive effects of glucocorticoids on immune/inflammatory cell activation and pro-inflammatory cytokine release. Inhibition of the anti-inflammatory and immunosuppressive properties of glucocorticoids may largely explain MIF's global pro-inflammatory effects, and an emerging body of data indicates that MIF's position within the cytokine cascade is to act in concert with glucocorticoids to control the setpoint of the immune and inflammatory response. It has been considered that MIF neutralization may offer a powerful therapeutic strategy for the treatment of inflammatory and autoimmune diseases, particularly those that are characterized by resistance to steroid therapy or by steroid dependence. By removing the counterregulatory agent of glucocorticoid action (i.e., MIF), MIF neutralization could decrease the steroid requirement for a number of diseases and even allow the host's natural glucocorticoid response to more effectively control an overactive inflammatory response.

IV. HYPOTHALAMIC–PITUITARY–ADRENAL AXIS

Immunocytochemical and immunohistochemistry techniques have shown that MIF is contained within secretory vesicles in corticotropic cells of the anterior pituitary gland. MIF protein accounts for approximately 0.05% of total pituitary protein, a level comparable to that of the classical pituitary hormones ACTH and prolactin (0.2 and 0.08%, respectively). Within corticotropic cells, MIF resides in specific granules, both alone and co-localized with ACTH. The precise contribution of the pituitary to total plasma MIF levels is unclear, but when mice receive an injection of endotoxin as a model of infective stress, there is a significant decrease in the pituitary content of MIF protein, a concomitant rise in plasma MIF levels, and a slower, time-dependent increase in pituitary expression of MIF mRNA. Other cell types also express MIF protein, however, so ambient plasma levels may reflect a collection of MIF secretions from different tissues rather than from a single, dominant organ source.

The release of MIF from the pituitary together with ACTH is somewhat paradoxical, as ACTH stimulates glucocorticoid release from in the adrenal cortex, which then acts to down-regulate the inflammatory response. The glucocorticoid-antagonistic activity of MIF likely represents a mechanism by which the host maintains a functioning immune response during situations of high endogenous glucocorticoid production such as severe trauma, stress, or life-threatening infection. Increased levels of glucocorticoids act to maintain glucose and electrolyte homeostasis during the so-called "flight or fight" response, but these glucocorticoids also can act deleteriously to suppress the immune response. MIF that is released systemically from the pituitary or by activated cells at the site of infection would counterbalance the anti-inflammatory and immunosuppressive effects of glucocorticoids. The precise outcome of this response—resolution and tissue repair versus excessive inflammation and tissue damage—would be the result of an interaction between MIF and glucocorticoid action on target cells.

MIF secretion from corticotropic pituitary cells can be induced by stimulation with corticotropin-releasing factor (CRF) and requires lower concentrations of CRF than those required to induce ACTH secretion. Interestingly, CRF also has been shown to be a potent inducer of MIF gene transcription in murine pituitary cells. A functional analysis of the MIF gene-promoter region using rodent pituitary cells has demonstrated that CRF-induced MIF expression is dependent on a cyclic AMP-responsive element-binding protein.

MIF protein and mRNA also are expressed in the cortex of the adrenal gland. As in the pituitary, the adrenal MIF content decreases following systemic

administration of endotoxin and this is followed by MIF resynthesis. This type of response—decreased tissue content followed by resynthesis and induction of MIF mRNA—is not unique to the pituitary or the adrenal, but can be observed after endotoxin challenge in other MIF-expressing tissues including the spleen, the lung, the kidney, and the liver.

V. GLUCOSE HOMEOSTASIS AND ENERGY METABOLISM

Energy metabolism is regulated by a complex network of endocrine, paracrine, and autocrine mediators acting between the liver, pancreas, muscle, adipose tissue, and brain. This network is subject to dramatic changes during stress, infection, and illness. A hypermetabolic response that is characterized by profound alterations in carbohydrate metabolism frequently develops in the host as a consequence of severe infection or trauma. If not counteracted, over time this response leads to metabolic wasting and death. These metabolic effects are believed to be mediated by stress-induced changes in circulating hormones and by the expression of inflammatory cytokines produced by immune cell activation. MIF also plays a prominent regulatory role in the metabolic features of the host response to stress.

Immunohistochemical staining of the pancreas has localized MIF to the cytoplasm of the insulin-producing beta cells within the pancreatic islets, and an increase in glucose concentration can induce the release of MIF protein *in vitro*. Immunoneutralization of MIF inhibits the first and second phases of insulin secretion by 39 and 31%, respectively, in an isolated rat islet perfusion system, whereas MIF addition increases glucose-induced insulin secretion by 140%. These data indicate that MIF is a positively acting, autocrine/paracrine regulator of glucose-induced insulin release. Stress-induced elevations of circulating glucocorticoid levels are known to induce a hyperglycemic state that increases the need for insulin so as to ensure appropriate glucose homeostasis. High circulating MIF levels may be beneficial in this context by augmenting pancreatic islet insulin production, thereby counterbalancing the hyperglycemic effect of glucocorticoids.

TNFα was once called "cachectin" for its ability to induce muscle catabolism and wasting. Treatment of myotubes with TNFα results in a depletion of MIF from intracellular pools, the release of MIF into the supernatant, and an increase in MIF mRNA transcription. Stimulation of cultured myotubes with MIF initiates an increase in the production of fructose-2,6-bisphosphate, the most potent allosteric regulator of glycolysis that acts by activating phosphofructokinase-1. An increase in the cellular secretion of lactate, the end-product of anaerobic glycolysis, also occurs. Both of these properties were originally ascribed to cachectin/TNFα. Anti-MIF inhibits these effects of TNFα *in vitro* and *in vivo*, indicating that autocrine-acting MIF is a downstream effector of the catabolic actions of TNFα.

MIF also is expressed constitutively in adipocytes and its expression appears to be dependent on glucose and insulin levels *in vitro*.

VI. REPRODUCTIVE TISSUES

A systematic analysis of tissue MIF protein and mRNA levels has demonstrated MIF expression in the reproductive organs. In the testis, MIF expression is localized to the androgen-producing Leydig cells. The testicular interstitial fluid also contains significant amounts of MIF. The addition of MIF to Leydig cells results in a dose-dependent suppression of inhibin production by seminiferous epithelium, suggesting a paracrine role for MIF in Sertoli cell regulation. Interestingly, Leydig cell ablation does not lead to a loss of MIF in the testis, but to a switch of the site of MIF production from Leydig cells to Sertoli cells and spermatogonia. In the epididymis, MIF expression also is observed in the epithelial cells of the epididymal caput. MIF is present in seminal plasma in high concentrations of 1–10 μg/ml and likely arises from the prostate gland where the protein has been observed to be expressed within the epithelial cells. $MIF^{-/-}$ male mice do not display any apparent dysfunction in their reproductive capacity, suggesting that the contribution of MIF to male reproduction either is not crucial or can be compensated for by other molecules.

MIF mRNA has been found in the oviduct, the uterus, and the granulosa cells of the ovary. Uterine mRNA levels change during pregnancy, suggesting an influence by the endocrine changes of pregnancy. $MIF^{-/-}$ female mice also appear to reproduce normally.

VII. MOLECULAR MECHANISMS OF ACTION

MIF is directly pro-inflammatory by activating or promoting cytokine expression (TNFα, IL-1β, IL-2, IL-6, IL-8, IL-12, IFN-γ), nitric oxide release, and matrix metalloproteinase-2 expression, and by inducing the COX-2 pathway. Interestingly, much of the COX-2-inducing activity of IL-1β on synovial

cells can be inhibited by anti-MIF, indicating that MIF is a downstream effector of IL-1β action in these cells. MIF also plays an important role in regulating both the setpoint and the direction of the inflammatory response by counteracting the anti-inflammatory and immunosuppressive effects of glucocorticoids. Specifically, MIF counteracts the glucocorticoid-induced inhibition of inflammatory cytokine secretion in macrophages, T cells, and synovial fibroblasts. Although there are substantial data to support roles for MIF as an inflammatory cytokine and an endocrine hormone, the precise role of many of MIF's specific "inflammatory" versus "endocrine" activities in the pathophysiology of different inflammatory or autoimmune diseases remains to be established.

Several studies suggest that an interaction between MIF and a receptor on the surface of target cells is essential for MIF's activities. Perhaps the strongest of these data are those that have shown that exogenously added MIF, as well as endogenously released MIF, induces the proliferation of quiescent fibroblasts. This response is associated with sustained activation of the p44/p42 [extracellular signal-related kinase variants 1 and 2 (ERK1/2)] subfamily of mitogen-activated protein (MAP) kinases and is dependent on the activity of protein kinase A. Neither the p38 family nor the JUN N-terminal kinase (JNK)/stress-activated protein kinase family of MAP kinases is stimulated by MIF. The ERK1/2 MAP kinase signaling cascade results ultimately in the phosphorylation and activation of cytoplasmic phospholipase A_2 ($cPLA_2$). $cPLA_2$ is a critical mediator of inflammatory responses and its product, arachidonic acid, is the precursor for the synthesis of prostaglandins and leukotrienes. Interestingly, $cPLA_2$ also is a target for the anti-inflammatory action of glucocorticoids, and the ability of MIF to activate $cPLA_2$ is one mechanism by which MIF regulates the immunosuppressive effect of glucocorticoids on cells. In support of this hypothesis, MIF is able to counterregulate glucocorticoid inhibition of $cPLA_2$ activation and arachidonic acid release from cells. $cPLA_2$ is an important point of interaction between MIF and glucocorticoids, as the product of $cPLA_2$, arachidonic acid, is required for the activation of JNK and efficient translation of TNFα mRNA.

Another mechanism by which MIF may counterregulate the effects of glucocorticoids is via the transcription factor nuclear factor κB (NF-κB). NF-κB is a critical regulator of the inflammatory response and regulates the expression of over 60 genes for pro-inflammatory cytokines and cell adhesion molecules. Glucocorticoids have been reported to enhance the synthesis of inhibitor κB (IκB), a cytoplasmic binding protein that inhibits the translocation of NF-κB to the nucleus. Recent studies have shown that MIF inhibits the ability of glucocorticoids to induce IκB synthesis in human peripheral blood mononuclear cells. Thus, by blocking glucocorticoid-induced IκB activity, MIF promotes the translocation of NF-κB into the nucleus and enables the expression of a cellular pro-inflammatory response.

The innate immune response also is kept in check by specialized counterregulatory mechanisms such as apoptosis or programmed cell death. Defective apoptosis of macrophages may lead to an exaggerated inflammatory response, and increased T-cell apoptosis has been considered to contribute to clinical immunosuppression in the late phase of septic shock. Recent data have linked the action of MIF to the inhibition of p53, an important tumor suppressor gene and mediator of apoptosis. MIF can sustain macrophage survival and pro-inflammatory function by suppressing activation-induced, p53-dependent apoptosis. Thus, an important action for MIF in this regard would be to prolong the life span and the activity of monocytes/macrophages during inflammation. This particular mechanism could explain the important defect in macrophage responses and innate immunity that has been reported for $MIF^{-/-}$ mice.

The lack of information regarding the molecular identity of a cell surface receptor for MIF has led several investigators to consider alternative or "nonclassical" modes of action for this extracellular mediator. It has been shown recently that MIF may directly affect the transcriptional activity of activator protein-1 (AP-1)-responsive genes via an interaction with the intracellular protein, Jab-1. AP-1 is a DNA-binding transcription factor that forms a heteromeric complex with the Fos and Jun oncoproteins. It has been proposed that Jab-1 stabilizes the binding of AP-1/c-jun complexes to AP-1 promoter sites. Jab-1 also binds to, and promotes the degradation of, $p27^{Kip1}$, a protein that halts the cell division cycle. A biologically significant interaction between MIF and Jab-1 was demonstrated *in vivo* and shown to result in the inhibition of Jab-1 binding to c-jun, thus destabilizing the formation of activated AP-1 complexes. The binding of MIF to Jab-1 resulted in reduced degradation of $p27^{Kip1}$ and an inhibition of the growth-promoting properties of Jab-1 in fibroblast cells. As AP-1 has been shown to be an important regulator of several pro-inflammatory genes, this mechanism appears to contradict the pro-inflammatory and mitogenic activities described for MIF. However, a

characteristic feature of MIF action is its bell-shaped dose–response curve with respect to several biological phenomena, suggesting that low versus high MIF levels may have distinct regulatory mechanisms.

VIII. SUMMARY

The protein mediator known as MIF has emerged as a critical mediator of various inflammatory, endocrine, and metabolic responses. MIF is expressed almost ubiquitously by tissues and regulates cell activation, proliferation, and apoptosis. The cellular release of MIF is regulated by a variety of specific stimuli, and systemic levels of MIF vary as a consequence of different infective or inflammatory stressors.

Glossary

cytokine A protein that is secreted in a regulated fashion by cells of the inflammatory and immune system and that delivers signals to other cell types.

mitogen-activated protein kinases A functional family of kinases that mediate cellular responses to extracellular signals.

Male Hormonal Contraception

C. Hay and F. C. W. Wu

University of Manchester, United Kingdom

The goals of hormonal male contraception should include (1) reversible and consistent suppression of spermatogenesis to a level compatible with temporary infertility and (2) maintenance of physiological androgen-dependent sexual and metabolic functions. This article discusses different types of male hormonal contraceptive preparations, including androgen-only preparations, alternative testosterone preparations, GnRH agonists and antagonists, and combinations of progestogen and androgen. Their efficacy and safety are also examined.

I. INTRODUCTION

The world population reached 6 billion people for the first time in 1999, representing an increase in population of 4.4 billion since 1900. If the current average birth rate of 3.3 children per woman is maintained, the world population will approach 19 billion people by 2100. This degree of overpopulation is likely to outstrip the world's resources, leading to poverty, famine, and pollution. Provision of effective methods of contraception can slow the current rate of population expansion, thereby avoiding some of these potential consequences. Birth control has also been desirable to individuals for centuries. Female barrier methods have included fruit, paper discs, and brandy-soaked sponges used by French women in the 18th century. The 18th century also saw the first use of condoms made from animal intestine. Other widely used methods have included periodic abstinence and coitus interruptus. A revolution in contraception occurred in the 1960s with the advent of the female oral contraceptive pill (OCP). This hormonal method is highly efficacious, with a first-year failure rate of 1.8% compared to 12% for condoms. Condoms do have the advantage of protecting against sexually transmitted diseases (STDs). However, their efficacy (both in protecting against STDs and in contraception) is hampered by incorrect usage. Vasectomy is highly effective but is essentially an irreversible method. The female OCP is highly efficacious but may be contraindicated or poorly tolerated in some women. Effective family planning requires adequate education of contraceptive users. Consideration of the individual couple's circumstances and requirements is crucial to selecting the most suitable methods. There are limitations with all the existing methods. The development of a male hormonal contraceptive should therefore provide an important additional reversible method for men in stable relationships to share the risks of contraception more equitably between both partners. Interest in using a new male hormonal contraceptive has indeed been shown in 50–70% of men surveyed in Edinburgh (Scotland), Cape Town (South Africa), and Hong Kong.

II. BASIC PRINCIPLE OF HORMONAL SUPPRESSION OF SPERMATOGENESIS

Spermatogenesis is a complex process that begins with the mitotic division of a self-renewing stem cell population to form diploid germ cells or spermatogonia. These spermatogonia periodically differentiate into primary preleptotene spermatocytes, which then initiate meiosis. The primary spermatocytes result in spermatids. Round spermatids are mitotically inactive but go through a complex transformation (spermiogenesis) to differentiate into elongated spermatids and spermatozoa. Spermiogenesis involves DNA condensation, replacement of nucleosomal histones by protamines, and loss of virtually all cytoplasm with development of the proteolytic enzyme-rich acrosome cap and a flagellum capable of propelling beating movements connected by a mitochondria-rich midpiece. Mature elongated spermatids, embedded in Sertoli cell cytoplasm, are eventually released (spermiation) into the tubular lumen as spermatozoa. The entire sequence and duration of each step encompassed in the formation of spermatozoa from primary spermatogonia are species-specific biological constants; in humans, it takes approximately 74 days.

A sufficient testosterone (T) concentration in the seminiferous tubules is critical to the maintenance of normal spermatogenesis. The intratesticular T concentration is normally 50–100 times higher than that in the systemic circulation. The drive for testosterone production is provided by luteinizing hormone (LH) released from the anterior pituitary. LH acts on Leydig cells in the testis to stimulate androgen synthesis from cholesterol via a series of steroidogenic enzymes. In addition to testosterone, follicle-stimulating hormone (FSH) is required for the initiation and maintenance of quantitatively normal spermatogenesis. Secretion of both LH and FSH is stimulated by pulsatile gonadotropin-releasing hormone (GnRH) from the hypothalamus. This intermittent GnRH signal avoids

desensitization of the pituitary gonadotrophs and maintains physiological episodic gonadotropin secretion. Negative feedback of testosterone at both the pituitary and the hypothalamic levels suppresses LH and FSH, whereas inhibin B and follistatin regulate FSH secretion (Fig. 1). Potential inhibitors of this system include testosterone, progestogens, gonadotropin-releasing hormone agonists (GnRH agonists), and GnRH antagonists, all of which (via different mechanisms) suppress both LH and FSH. Inhibition of gonadotropins will therefore abrogate both testosterone production and spermatogenesis simultaneously. When agents other than testosterone are used to suppress spermatogenesis, there will be a requirement for androgen replacement to prevent a deficient state. Thus, hormonal male contraception based on suppression of gonadotropins creates the need for exogenous testosterone replacement to maintain extratesticular secondary sexual functions, e.g., libido. In principle, exogenous testosterone on its own appears to be the ideal hormonal contraceptive. However, as discussed below, the supraphysiological doses required to suppress spermatogenesis consistently may be undesirable clinically. Current thinking deems that nonandrogenic anti-gonadotropic agents combined with physiological androgen replacement is the preferred approach to effect hormonal male contraception even though potentially more complex regimens are required.

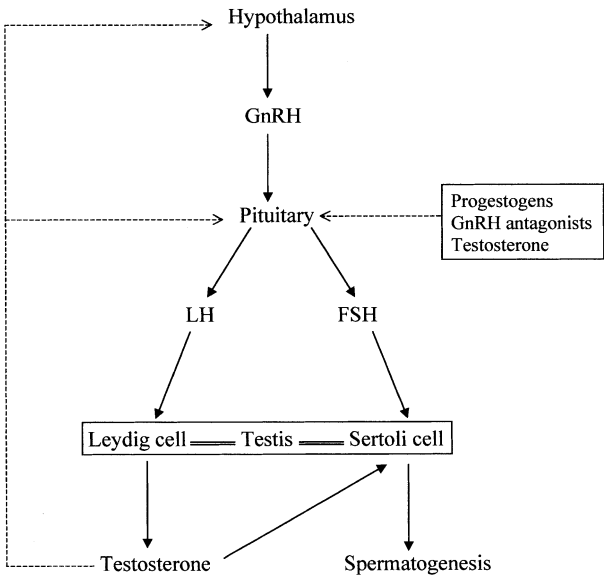

FIGURE 1 The hypothalamic–pituitary–gonadal axis. Solid arrows show the pathway of spermatogenesis promotion and the dashed arrows show inhibitory influences. Endogenous testosterone acts via negative feedback pathways to inhibit both GnRH release from the hypothalamus and gonadotropin release from the pituitary. Exogenous sex steroids and GnRH analogues reversibly manipulate this physiological response.

III. ANDROGEN-ONLY PREPARATIONS

The principal androgen in men is testosterone, which is 5α-reduced to the more potent dihydrotestosterone (DHT) and aromatized to estradiol. Testosterone is rapidly degraded by first-pass metabolism in the liver following oral or systemic administration. Chemical modification of androgen preparations is therefore necessary to reduce hepatic breakdown and prolong the duration of therapeutic action. Oral preparations currently available have a relatively short half-life and frequent dosing is required. Prolongation of the half-life is achieved by formulation of T esters in lipid vehicles that are administered by intramuscular injection.

In the 1970s, studies using intramuscular testosterone enanthate (TE) confirmed that supraphysiological doses of testosterone induced azoospermia in 40–70% of Caucasian males. These studies demonstrated a relationship between the extent of spermatogenesis suppression (sperm concentration) and contraceptive failure (pregnancy) rate. The pregnancy rate for azoospermia was 0.8 per 100 person years (95% confidence interval of 0.02–4.5) comparable to female injectables, increasing to 8.1 (2.2–20.7 per 100 person years) for oligozoospermia (0.1 to 3 million/ml). The overall efficacy Pearl Index was 1.4 (0.4–3.7) pregnancies per 100 person years, which is comparable to the female oral contraceptive pill and is better than the typical first-year failure rate of condoms (12%). These studies therefore offered proof of the principle that hormonal suppression of spermatogenesis can be an efficacious and reversible contraceptive for men. These studies also showed that acceptable targets of suppression to ensure effective contraceptive protection are azoospermia and severe oligozoospermia (<1 million sperm/ml).

The androgen-only approach had two drawbacks: (1) unsatisfactory pharmacokinetics of the injectable T esters currently available, which required weekly intramuscular injections and resulted in widely fluctuating levels of testosterone, and (2) high doses (causing supraphysiological T levels) of T were required to induce and maintain adequate suppression of spermatogenesis. The androgen-related side effects encountered included acne, weight gain, behavioral changes, lowered high-density lipoprotein cholesterol (HDL-C), and increased hematocrit. For these reasons, alternative strategies have been sought.

IV. ALTERNATIVE TESTOSTERONE PREPARATIONS

A. Testosterone Buciclate

Testosterone buciclate is a long-acting ester developed specifically for male contraception by the World Health Organisation (WHO) and the National Institute for Child Health and Human Development (United States). To date, only one dose has been assessed, in which 1200 mg produced azoospermia in 3/8 volunteers. Further studies are currently in abeyance due to formulation problems and concerns of genotoxicity with the buciclate side chain.

B. 19-Nortestosterone

19-Nortestosterone (19-NT or nandrolone) is a long-acting ester with potent androgenic effects and a high progestational activity (10 times that of T) but it is not aromatized. 19-NT has been shown to suppress LH and FSH effectively with full maintenance of androgen-dependent functions. With the combination of both androgenic and progestational activity, the potential for 19-NT to provide contraception as a single agent has been considered. Small trials with 19-NT alone or in combination with depot medroxyprogesterone acetate (DMPA, see below) have confirmed that azoospermia is induced without any symptoms of androgen deficiency (despite low T levels).

C. Testosterone Microspheres

Testosterone microspheres are biodegradable polyactide-glycolide spheres containing testosterone and exhibit first-order absorption kinetics. A single dose of 315 mg administered by intramuscular (im) injection to hypogonadal men can maintain T levels in the normal range for 10–11 weeks. Recently, reformulation by another company has allowed subcutaneous administration. The pharmacokinetics in this small study were similar to those of the im microsphere preparation. Additional study of this novel mode of testosterone delivery is needed to further assess both efficacy and safety.

D. Testosterone Implants
