Testosterone implants are small cylindrical pellets containing 100 or 200 mg of crystalline T. Insertion of T pellets into the subcutaneous tissues of the anterior abdominal wall requires a minor surgical procedure under local anesthesia. The potential advantage of this delivery system is the near zero-order kinetics, which result in stable, dose-dependent testosterone levels without the repeated supraphysiological peak levels of T produced by TE and other similar injectable esters. A single administration of 1200 or 800 mg every 3 months in eugonadal men produced spermatogenic suppression equal to TE 200 mg weekly but fewer metabolic side effects were documented. Recent studies have combined T implants with progestogen (DMPA, oral and implantable desogestrel) and confirmed the synergistic actions between the two steroids in spermatogenic suppression, achieving azoospermia rates equivalent to or better than those achieved with TE alone. This suggests that lower doses of T combined with progestogens may be the optimal approach, which not only achieves maximal suppression of spermatogenesis but also minimizes potential adverse effects. Although the superior pharmacokinetics of T implants are undoubtedly beneficial, the requirement for an uncomfortable and repeated surgical procedure every 3–4 months and a nontrivial implant extrusion rate of 5–10% make this method unsuitable for male contraception either on its own or in combination regimens.

E. Testosterone Patches

Testosterone patches provide noninvasive transdermal self-administered delivery of testosterone when applied daily to the body or scrotal skin. The main limitations include a high incidence (40–60% of subjects) of skin irritation related to the alcoholic excipients employed, the frequent shaving of the scrotum, and poor adhesiveness, particularly in hot weather. Two studies have used a body patch in combination with a progestogen (oral levonorgestrel and desogestrel) and will be discussed below.

F. Testosterone Undecanoate

Testosterone undecanoate (TU) is an unsaturated, aliphatic, fatty acid ester of T that is partially absorbed from the gut lymphatics following oral administration. The currently available oral TU preparation (Restandol) formulated in oleic oil has low bioavailability and variable absorption and requires twice or thrice daily dosing. These problems were highlighted by a study of oral TU and cyproterone acetate (CPA) (see below). The findings suggested that oral TU is currently a poor choice for contraception. Reformulation of oral TU is under way and may produce more reliable pharmacokinetics in the future.

TU has recently been formulated for intramuscular administration in tea seed oil (in China) and subsequently in castor oil (in Germany). This promising

new and as yet unlicensed preparation provides a long-acting testosterone depot (half-life of 33.9 +/− 4.9 days in castor oil) with favorable pharmacokinetic properties. In hypogonadal men, 1000 mg of TU can maintain stable plasma T levels for 12 weeks. TU alone was found to induce azoospermia in 96% of Chinese men (23/24, tea seed oil formulation, 500 or 1000 mg every 4 weeks) and in 57% of Caucasian men (8/14, castor oil formulation, 1000 mg every 6 weeks). Currently, phase III contraceptive efficacy trials are in progress in China using TU alone at 1000 mg every 8 weeks. The combination of TU with a progestogen has also been studied in Caucasian subjects (see below).

G. 7α-Methyl-19-Nortestosterone

7α-Methyl-19-nortestosterone (MENT) is a highly androgenic α-methylated derivative of 19-NT that is not 5α-reduced to DHT. Prostate growth and skin effects (including acne and balding) are dependent on DHT action. MENT may therefore have beneficial androgenic actions without the unwanted effects on the prostate and skin. However, it is currently unclear whether the aromatized metabolite of MENT confers a physiological level and spectrum of estrogenic actions *in vivo*. The potential advantages of this synthetic selective androgen receptor modulator (SARM) are therefore 2-fold: (1) tissue specificity—in nonhuman primates, 19-NT relative potency compared to testosterone is 2-fold in the prostate but 10-fold in suppression of pituitary gonadotropin secretion and (2) the high but differential potency allows lower doses of MENT to suppress pituitary gonadotropins while potentially sparing any prostate stimulation. In theory, the lack of 5α-reduction may also be beneficial in maximizing suppression of spermatogenesis to azoospermia by lowering intratesticular DHT.

MENT has an extremely short half-life. Preliminary studies of small numbers of healthy men using subdermal MENT acetate biodegradable implants confirmed effective gonadotropin suppression and induction of azoospermia in 70% of subjects. There was also maintenance of secondary sexual function. Whether MENT, at doses that can effectively suppress spermatogenesis to the target level, can also prevent or reverse any stimulation of prostate size and maintain bone mass in man remains unproven.

V. GnRH AGONISTS AND ANTAGONISTS

GnRH agonists initially cause an increase in gonadotropin secretion that is followed 2–3 weeks later by marked inhibition. This action is due to the development of desensitization of the gonadotroph GnRH receptor, resulting in the suppression of LH and FSH secretion. Studies in the 1980s and 1990s assessed GnRH agonists alone or in combination with testosterone enanthate and yielded disappointing results. Overall, only approximately one-quarter of men achieved azoospermia with an additional one-third achieving oligozoospermia. The poor suppression is believed to be due to rebound FSH secretion that is presumably independent of GnRH stimulation. Consequently, further study of GnRH agonists as potential candidates for male contraception has been abandoned.

GnRH antagonists are competitive GnRH receptor antagonists that cause rapid suppression of gonadotropins within hours without the initial stimulation seen with GnRH agonists. When combined with T, suppression of LH and FSH is highly effective and sustained. Studies of this combination have shown spermatogenic suppression at least equal to that of TE alone. Furthermore, when the GnRH antagonist Nal-Glu was used to initiate suppression, oligozoospermia (<1 million sperm/ml) could then be maintained with TE at 100 mg once weekly alone. A similar regime of a GnRH antagonist (cetrorelix) and 19-NT was combined and azoospermia was induced within 3 months. However, suppression was not maintained with 19-NT alone. Although these synthetic peptide compounds clearly have contraceptive potential, the disadvantages are their expense and short half-life, requiring daily subcutaneous injection. Side effects encountered have included local skin reactions and pruritus at the site of injection due to histamine release. A new generation of long-acting depots of potent GnRH antagonist preparations (e.g., Abarelix, Ganarelix, and Degarelix) being developed for prostate cancer treatment may have a place in male contraception where rapid induction of spermatogenic suppression can subsequently be maintained by testosterone alone.

VI. PROGESTOGEN/ANDROGEN COMBINATIONS

Exogenous progestogens can inhibit gonadotropin secretion, reduce systemic testosterone levels, and suppress spermatogenesis in men. Combining a progestogen with testosterone exploits the synergistic actions of the two steroids that can be used at lower doses for spermatogenesis suppression. Moreover, some synthetic progestogens may have direct anti-spermatogenic actions in the testis

(e.g., androgen receptor antagonism, inhibition of Leydig cell steroidogenesis, and 5-α-reductase), whereas physiological amounts of T will safely rescue normal androgen-dependent functions.

Four groups of synthetic progestogen are used clinically in women: (1) 19-nortestosterone derivatives (levonorgestrel/LNG, desogestrel/DSG, and dienogest/DNG); (2) 17-hydroxyprogesterone derivatives (medroxyprogesterone/MPA); (3) 19-norprogesterone derivatives (nomegestrel/NOMA); and (4) 17-hydroxyprogesterone or 19-nortestosterone derivatives with anti-androgenic actions (CPA and DNG, respectively). Structural differences between groups account for the different degrees of androgenic and gestogenic actions (Table 1). The different progestogen/androgen combinations studied to date are discussed below (Table 2).

A. Depot Medroxyprogesterone Acetate

Depot medroxyprogesterone acetate (DMPA) has been combined with 19-NT, TE, and T implants. Azoospermia rates in Caucasians were 67 and 59% for 19-NT and TE, respectively. Side effects included weight gain and a decrease in HDL-C. Trials with 19-NT in combination with DMPA in Indonesian men found azoospermia rates of 98% vs 96% for TE alone. The combination of DMPA with T implants achieved azoospermia rates exceeding that of TE alone. There was no significant weight gain or metabolic effects (e.g., on lipid parameters). The main limitation with DMPA use is the prolonged period (up to 6 months) that is often necessary for sperm recovery following cessation of treatment.

B. CPA

CPA has been combined with im TE and oral TU. The anti-androgenic properties of CPA are effected by blockade of T and DHT at the receptor level. This blockade will occur both at the testicular level and systemically. There is also gonadotropin inhibition at the pituitary. The combination of two oral preparations in a true male pill was assessed with oral CPA and TU. Unfortunately, azoospermia occurred in less than 20% of subjects. The reasons for this are most likely related to the inadequate androgen replacement provided by oral TU (see above). CPA at a higher dose (25–100 mg) with TE did result in azoospermia in 100% of men. Furthermore, the time to azoospermia was half that of the TE-alone group (49 days vs 98 days). Though encouraging, a dose-dependent decrease in hemoglobin and body weight was observed in those receiving CPA. These side effects are very likely anti-androgen related. These effects may limit future application of this combination.

C. LNG

LNG has been extensively studied with a variety of androgens. Initially a dose of 500 μg daily with TE confirmed greater sperm suppression than with TE alone (azoospermia rate of 67% vs 33%). Further study with lower doses of LNG (250 and 125 μg) did not compromise sperm suppression rates. Adverse effects were dose dependent and included lowered HDL-C and weight gain. Recently, a TU/LNG combination was compared to TU alone. There was no difference in suppression to azoospermia (50%). Both groups had significant decreases in HDL-C from baseline. A testosterone patch was studied with LNG (250 μg daily) but resulted in only 2 of 11 men suppressing to azoospermia. Most recently, a T patch was combined with long-acting LNG implants, once again with relatively poor sperm suppression (severe oligozoospermia in $<60\%$ of men). A likely reason for the relatively disappointing results compared to

TABLE 1 Pharmacodynamic Properties of Gestogens

		DSG 150 μg	T patch 5 mg	3/6 (50%)	3/6 (50%)
		DSG 300 μg	T patch 5 mg	4/7 (57%)	5/7 (71%)
Kamischke *et al.* (2000)	24 weeks	NETE 200 mg	TU 1000 mg	13/14 (93%)	

Note. DMPA (depot medroxyprogesterone acetate) was administered by a single im injection. CPA (cyproterone acetate) was administered orally once daily. TE (testosterone enanthate) at 100 mg was administered by im injection once weekly. LNG (levonorgestrel) is administered orally once daily. TU (testosterone undecanoate) was administered either orally (80 mg) twice daily or im (1000 mg) every 6 weeks. T patch (testosterone patch) delivers 5 mg/24 h. DSG (desogestrel) is administered orally once daily. NETE (norethisterone enanthate) was administered im every 6 weeks.

[a] Severe oligozoospermia in this paper was defined as <3 million sperm/ml.

[b] One subject was azoospermic at week 12 but had a count of 0.1 million/ml at week 16.

[c] Subjects were commenced on 250 μg daily until week 12. If they had not suppressed to azoospermia at week 12, the dose was increased to 500 μg daily.

[d] One subject dropped out of the trial.

[e] Two subjects dropped out of the trial for personal reasons.

injectable or implantable preparations of T may relate to the unreliable administration or absorption of T so that circulating levels in only the low normal range can be achieved. This highlights the critical role of testosterone in achieving efficient spermatogenesis suppression: a sufficient but not supraphysiological amount of T conveniently delivered with kinetics that can sustain stable plasma levels is required. Currently available preparations fall short of these requirements.

D. DSG

DSG is an oral third-generation progestogen with potent progestational activity and lower androgenicity (see Table 1). These potentially favorable properties led to the study of DSG in combination with TE. DSG has been widely used in the combined female oral contraceptive pill (Marvelon, NV Organon) where no decrease in HDL-C is observed in the women treated. Oral DSG and TE has been shown to produce 100% azoospermia (see Table 2) with certain dose combinations. These results demonstrate the synergistic action of this steroid combination. A 20–25% decrease in HDL-C levels was observed in these studies. One study has assessed doses of DSG (75, 150, and 300 μg) in combination with 300 mg T implants. The treatment phase was short but demonstrated a dose-dependent reduction in sperm counts. The median sperm counts at week 8 (end of treatment) were 24 million, 10 million, and 0.1 million sperm per milliliter in the 75, 150, and 300 μg dose groups, respectively. No effect on HDL-C was evident. Long-term studies would be needed to

further assess this approach. DSG has been combined with a T transdermal patch but similar to the LNG/patch study, sperm suppression was inferior to that seen with other regimens.

E. NETE

Norethisterone enanthate (NETE) is a depot progestogen administered by intramuscular injection converting to the metabolically active norethisterone (NET, Table 1). NET is both aromatized (to ethinylestradiol) and 5α-reduced (to 5α-NET), with androgen receptor binding being 10% that of testosterone binding. NETE and TU have been combined in a 6-week regimen. The potential for reducing the frequency of doses (im injections) is important if a male hormonal contraceptive is to be widely accepted. The results have been very encouraging (see Table 2), with azoospermia in 93% of men. Adverse effects of the TU/NETE combination have included moderate increases in hemoglobin (within the normal range) and decreases in HDL-C.

VII. RESPONDERS AND NONRESPONDERS

There are clear differences in the rates of azoospermia achieved in Asian (Chinese and Indonesian) and Caucasian populations. In the WHO studies, azoospermia was achieved in 90% of Asian men vs 74.3% of European or American men. Greater suppression in Asian men was also seen in the im TU study discussed above (96% vs 57%). The possible explanations for these differences include genetic and environmental influences that are not yet fully understood. Asian men are known to be more susceptible to suppression of both gonadotropins and sperm counts when given a T infusion. Differences in sperm production rates have also been shown in testicular biopsies at autopsy, with Asian men having a lower rate than White or Hispanic men.

Intraethnic variation is seen within Caucasian populations with suppression to azoospermia in 40–70% of men on the WHO trials of TE alone. No correlation was found with physical size, body mass, or baseline biochemical, endocrine, or semen parameters. Differences in 5α-reductase activity were found between oligozoospermic and azoospermic volunteers. The increased 5α-reductase activity found in the oligozoospermic subjects may reflect increased testicular DHT availability. This could be sufficient to provide the stimulus to maintain a residual degree of spermatogenesis in a hypogonadotropic state. Tissue sensitivity to androgen action and androgen metabolism could be relevant in the response to hormone-induced suppression of spermatogenesis. A recent study evaluated the CYP3A4 gene (instrumental to hepatic testosterone metabolism) and the androgen receptor gene in 75 men who had participated in contraceptive trials. No significant difference in genetic polymorphisms for either gene was identified. Further studies with sufficiently large numbers of subjects examining the pharmacogenomics of spermatogenesis may allow the prediction of response and guide the development of hormonal contraceptives of maximal efficacy.

VIII. SAFETY AND ACCEPTABILITY

In a WHO efficacy study, over three-quarters of the couples who participated did so because of dissatisfaction with their current contraceptive method. Furthermore, only 1.5% of volunteers withdrew from the study due to dissatisfaction with the protocol. A large cross-cultural study found that women feel that the responsibility of contraception too frequently falls to them. Over 70% of the women surveyed felt that a male contraceptive pill was a good idea. These facts would suggest that there is an interest and a need for an alternative contraceptive method.

An important aspect of any male hormonal method is that there is a time lag from the start of treatment until sperm suppression is sufficient for contraceptive efficacy. This is because sperm production takes 2–3 months and therefore following gonadotropin suppression a similar period of time is necessary to reach severe oligozoospermia. Vasectomy is an irreversible male method, is commonly used, and has a lag time similar to that of contraceptive efficacy (2–3 months). However, a hormonal method may be preferable to some couples to allow reversibility in the future. A time lag of 1 month applies to the female contraceptive pill and this is also widely accepted by couples in common clinical practice. An important point is that hormonal methods for either the male or the female should be suggested as the sole method of contraception only when the user is in a stable relationship. In this situation, the choice of contraceptive is often planned and a lag time is unlikely to deter users.

Trials to date have treated men with progestogen/androgen combinations for up to 1 year. The data have shown that these regimens are safe over this time period in healthy young men. The main side effects have been weight gain and a decrease in HDL-C. Weight gain appears to be an androgenic effect and is

associated with an increase in lean body mass. The cardiovascular significance of lowered HDL-C is not currently known. It is also likely that these effects would be patient specific as is seen with the female OCP and hypercoaguability, for example. The potential risk of prostate disease when androgen is administered to healthy men is also an area of concern. Essentially, long-term studies are needed to assess this risk. Data from short-term studies to date have demonstrated no association with prostate disease, prostate volumes, or changes in serum prostate-specific antigen. While these risks will continue to be evaluated, in the meantime regimes are chosen to try and minimize androgenic effects. As discussed, the choice of progestogen and the dose of androgen are therefore relevant.

IX. SUMMARY AND CONCLUSIONS

Further understanding of the precise mechanisms of spermatogenesis may provide additional nonhormonal targets for male contraception. The postmeiotic germ cell differentiation and epididymal sperm maturation processes are both potential areas to consider. Public-funded research is at a stage where realization of male hormonal contraception is within our reach. The beginning of participation by the pharmaceutical industry is encouraging and a necessary step leading to product development. A progestogen/androgen combination is most likely to be the first product to be marketed. Further development of long-acting depot formulations or oral and nonsteroidal compounds will provide a variety of contraceptive formulations that will allow men to have a wider choice and encourage acceptability and usage.

Glossary

azoospermia The absence of sperm in the ejaculate.
gonadotropins The pituitary hormones luteinizing hormone and follicle-stimulating hormone.
oligozoospermia A count of <3 million sperm/ml in the ejaculate.
severe oligozoospermia A count of ≤ 1 million sperm/ml in the ejaculate.

Melatonin in Humans[1]

ALFRED J. LEWY AND LAURIE HURTADO VESSELY
Oregon Health & Science University, Portland

Melatonin, a hormone produced by the pineal gland, is secreted in a nocturnal circadian pattern under the control of the endogenous circadian pacemaker. Light exposure and exogenous melatonin can influence the endogenous pacemaker and melatonin secretion; thus, studies in this area may lead to improved therapeutic approaches to sleep-related disorders.

I. INTRODUCTION

Melatonin is the primary product of the pineal gland. The nocturnal circadian pattern of melatonin secretion is controlled by the endogenous circadian pacemaker (ECP) in the suprachiasmatic nucleus (SCN) of the hypothalamus. The ECP is entrained by photic stimuli from the 24-h light/dark cycle. The secretory pattern of melatonin can be used to assess the phase of the ECP. Both bright light exposure and exogenous melatonin can influence the phase of the ECP, which can be put to therapeutic use in a number of clinical situations. Totally blind people often have free-running circadian rhythms that are not entrained to the 24-h day/night cycle. In these blind free-runners (BFRs), the circadian phase drifts each day, causing recurrent insomnia. Properly administered melatonin can advance the circadian rhythms of BFRs, and most of them can be entrained to the 24-h day/night cycle. Sighted people can develop circadian rhythm disturbances as well. Both light and melatonin can be used to advance or delay circadian rhythms that are out of phase due to advanced and delayed sleep phase syndromes, jet travel, shift work, and winter depression (seasonal affective disorder).

II. MELATONIN AS A HORMONE

Melatonin is an indoleamine synthesized from serotonin in two steps (Fig. 1). The conversion of serotonin to *N*-acetylserotonin is the rate-limiting step. Melatonin was first isolated from bovine pineal tissue in 1959 by Lerner and co-workers. It is lipophilic, a property that allows it to pass through cellular and nuclear membranes. The main site of melatonin secretion in humans is the pineal gland, although it may also be synthesized in the retina, lacrimal gland, and gut. Melatonin circulates via the cerebrospinal fluid (CSF) and the bloodstream and then binds to specific seven-transmembrane, G-protein-coupled receptors at various sites, of which the SCN of the hypothalamus is the best characterized. A nuclear receptor for melatonin has also been identified. Melatonin is found diffusely in nature. Although its function in vertebrates is the most clearly defined, it is also found in numerous plants and in lower phyla.

III. CIRCADIAN PHYSIOLOGY

Melatonin's participation in the endogenous circadian system is its most clearly defined role in humans. In all vertebrates that have been studied, the pineal gland is involved in the rhythmic production of melatonin, with active production occurring only at night. In humans, the pineal gland measures between 5 and 7 mm, is shaped like a pine cone, and lies (outside the blood–brain barrier) in the center of the brain, attached by a stalk to the roof of the third ventricle. Melatonin secretion is thought to represent the hormonal signal indicating nighttime darkness. In some nonmammalian vertebrates (including birds, reptiles, amphibians, and fish), the pineal gland contains photoreceptors involved in the regulation of melatonin secretion. This is in contrast to mammals, in which retinal, rather than pineal,

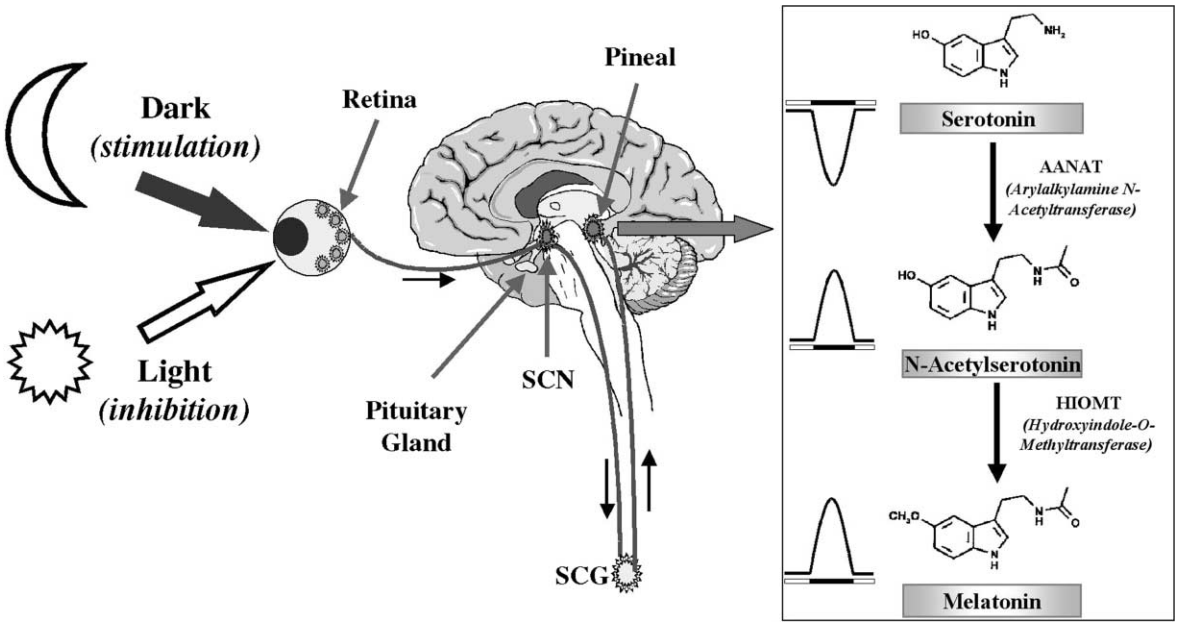

FIGURE 1 Regulation of melatonin synthesis. Melatonin is synthesized in the retina and in the pineal gland. In the pineal gland, melatonin synthesis follows a rhythm driven by the suprachiasmatic nucleus (SCN), the master biological clock, following a multisynaptic path, including, among others, the superior cervical ganglia (SCG). Norepinephrine released from postganglionic fibers activates α_1- and β_1-adrenoceptors in the pinealocyte, leading to increases in second messengers (i.e., cAMP, inositol trisphosphate, diacylglycerol) and in the activity of AANAT, the rate-limiting step in melatonin synthesis. The system is dramatically inhibited by light, the external cue that allows entrainment to the environmental light/dark cycle. The photic signal received by the retina is transmitted to the SCN via the retinohypothalamic tract, which originates in a subset of retinal ganglion cells. The pineal melatonin thus serves as the internal signal that relays day length, allowing regulation of seasonal changes in reproductive physiology and behavior. The pars tuberalis of the pituitary gland interprets this rhythmic signal and generates a precise cycle of expression of circadian genes. Melatonin synthesis in the photoreceptors of the retina follows a similar daily rhythm that is generated by local oscillators.

the demonstration that melatonin inhibited dopamine release from retina through activation of presynaptic heteroreceptors, and the design and synthesis of the first competitive melatonin receptor antagonist luzindole (luz: Spanish for light; indole: basic chemical structure of melatonin). Luzindole (2-benzyl *N*-acetyltryptamine) was designed to mimic light signals by blocking the effects of melatonin, the hormone of darkness.

The first cDNA encoding a melatonin receptor, currently known as Mel_{1c}, was cloned by expression of purified mRNA from *X. laevis* melanophores into mammalian cells in culture. This landmark discovery led to the cloning of the mammalian melatonin receptors Mel_{1a} and Mel_{1b}, belonging to a novel subfamily of seven-transmembrane-domain G-protein-coupled receptors. These mammalian melatonin receptors, currently referred as MT_1 and MT_2, respectively, exhibit distinct molecular and pharmacological characteristics and are localized to different chromosomes (MT_1, 4q35.1; MT_2, 11q21–q22).

A third mammalian melatonin receptor, MT_3 (previously referred to as ML_2), was pharmacologically characterized but is yet to be cloned. The MT_3 melatonin receptor can be activated by both melatonin and its precursor *N*-acetylserotonin and has a pharmacological profile distinct from any other known mammalian melatonin receptor. A protein (quinone reductase II: QR2) purified from hamster kidney was found to have a pharmacological profile identical to that of the MT_3 binding site of hamster brain. Whether the MT_3 and QR2 sites are the same or distinct proteins needs to be further investigated.

The synthesis of new molecules with various degrees of selectivity for MT_1, MT_2, and/or MT_3 melatonin receptors has allowed identification of specific melatonin receptors in native tissues. The recombinant MT_1 and MT_2 melatonin receptors expressed in mammalian cells show picomolar affinity for the radioligands 2-[^{125}I]iodomelatonin and [^{3}H]melatonin, whereas in native tissues the MT_3

melatonin receptor binds melatonin with nanomolar affinity. The MT_1 receptor is pharmacologically characterized by a higher affinity for 2-iodomelatonin and a lower affinity for 6-chloromelatonin than for melatonin. The MT_2 receptor shows similar affinity for melatonin, 2-iodomelatonin, and 6-chloromelatonin. Ligands with higher selectivity for the MT_2 receptor than for the MT_1 melatonin receptor include luzindole and the nonindolic 4-phenyl acetamidotetraline (4P-ADOT) and 4-phenyl propionamidotetraline (4P-PDOT). The affinity of the MT_1 and MT_2 melatonin receptors for *N*-acetylserotonin is approximately 1000 times lower than that for melatonin. By contrast, the *MT_3* melatonin receptor is characterized by similar affinity for *N*-acetylserotonin and melatonin, and shows high selectivity for the agonist 5-methoxycarbonylamino-*N*-acetyltryptamine (5-MCA-NAT).

One important caution in classifying melatonin ligands is that their intrinsic efficacy at initiating (agonist, partial agonist), reducing (inverse agonist), or blocking (antagonist, partial agonist) a signaling response depends on the cellular milieu in each target tissue or cell, the proportion and levels of the different receptor types expressed, the types of G-proteins and scaffolding molecules, and the pharmacological specificity and selectivity for each receptor. For example, luzindole, the first competitive melatonin receptor antagonist discovered, as well as the MT_2 selective ligands 4P-PDOT and 4P-ADOT, are antagonists in the mammalian retina, suprachiasmatic nucleus, and arterial vessels. However, 4P-PDOT acts as a partial agonist in the rat peripheral microcirculation, in that it directly inhibits leukocyte rolling, and in human MT_2 melatonin receptors expressed in mammalian cells, in that it inhibits stimulated cAMP formation. Additionally, both luzindole and 4P-PDOT show inverse agonist efficacy in mammalian arteries and cell lines expressing constitutively active MT_1 melatonin receptors.

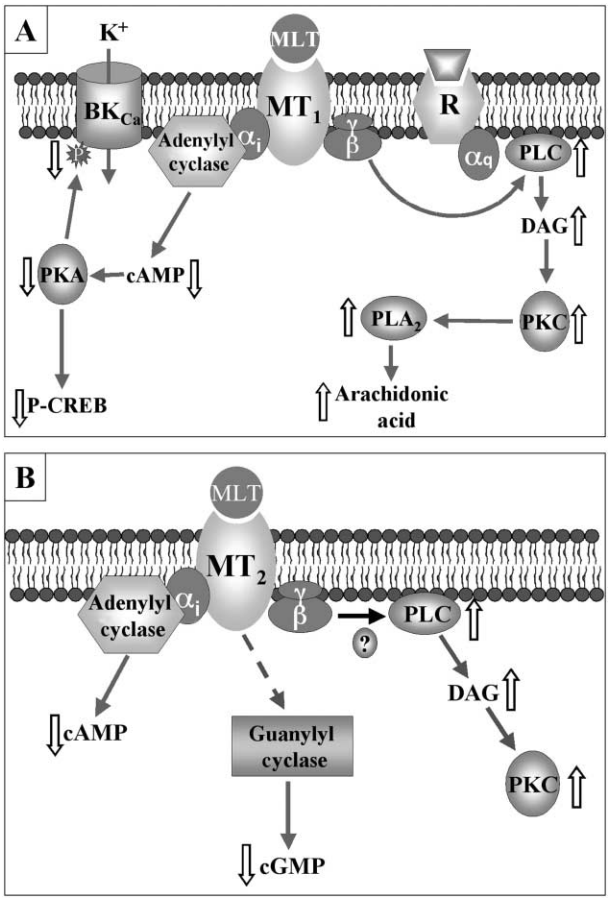

FIGURE 2 Signaling events mediated by activation of MT_1 and MT_2 melatonin receptors. (A) Melatonin (MLT) signals through activation of the MT_1 melatonin receptor via two parallel pathways mediated by the α-subunit [i.e., inhibition of cyclic adenosine monophosphate (cAMP) formation] and the βγ-subunits [i.e., potentiation of phosphoinositide turnover stimulated by a G_q-coupled receptor (R)] of G_i. (B) Signaling pathways coupled to MT_2 melatonin receptor activation. Melatonin-mediated phase shifts of circadian rhythms through MT_2 receptors are mediated by protein kinase C (PKC) activation (the mechanism leading to PKC activation remains putative, however). DAG, Diacylglycerol; PKA, protein kinase A; CREB, cAMP-responsive element binding protein; BK_{Ca}, calcium-activated potassium channel; cGMP, cyclic guanosine monophosphate; R, G_q-coupled receptor (i.e., prostaglandin PGF2α receptor FP and purinergic receptor P2Y).

B. Melatonin Receptor Signaling

1. MT_1 Receptors

Activation of MT_1 or MT_2 melatonin receptors promotes coupling to heterotrimeric G_i-proteins formed by α, β, and γ subunits and to their dissociation into α and βγ dimers (Fig. 2A). The $G_{\alpha i}$ and $G_{\beta\gamma}$ dimers interact with effector molecules involved in the transmission of cell signaling. Our current understanding is that the mammalian MT_1 melatonin receptor signals through the activation of two parallel pertussis toxin-sensitive pathways involving inhibition of adenylate cyclase via coupling to $G_{\alpha i}$ proteins and potentiation of phospholipase stimulation via $G_{\beta\gamma}$ proteins. Activation of the MT_1-melatonin receptor through the $G_{\alpha i}$ proteins ($G_{\alpha i2}$ and $G_{\alpha i3}$) inhibits forskolin-stimulated cAMP formation, protein kinase A (PKA) activity, and

phosphorylation of the cAMP-responsive element binding (CREB) protein. On the other hand MT_1 melatonin receptor activation via the released βγ-subunit potentiates phospholipase C stimulation induced by prostaglandin PGF2α or adenosine triphosphate (ATP) activation of their receptors (FP and P2Y, respectively). Heterologous potentiation of phospholipase C activation through MT_1-generated βγ leads to subsequent stimulation of protein kinase C (PKC) and inositol 1,4,5-trisphosphate ($InsP_3$)-mediated intracellular calcium increase. Activation of MT_1 melatonin receptors potentiates α-adrenergic mediated vasoconstriction by blocking calcium-activated potassium channels (BK_{Ca}) in smooth muscle. This blockade appears to result from decreases in cAMP formation and BK_{Ca} channel phosphorylation. MT_1 melatonin receptor activation also directly vasoconstricts cerebral arteries through blockade of BK_{Ca} channels.

In the SCN, melatonin increases potassium conductance by activation of an inward rectifier potassium channel (GIRK) Kir3, through a mechanism that may involve activation by the βγ-subunits of the G_i-protein coupled to the MT_1 melatonin receptors. Activation of an MT_1 receptor appears to be involved in melatonin-mediated hyperpolarization of neonatal pituitary cells, as well as in the inhibition of calcium influx through voltage-activated L calcium channels in neonatal rat gonadotrophs. The MT_1 melatonin receptor also couples to pertussin toxin (PTX)-insensitive Qq/11 proteins, leading to the mobilization of intracellular calcium in pars tuberalis cells in culture.

2. *MT_2 Receptors*

Activation of the MT_2 melatonin receptor modulates cAMP and guanosine 3′,5′-monophosphate (cGMP) formation (Fig. 2B). Activation of recombinant MT_2 melatonin receptors expressed in mammalian cells inhibits forskolin-stimulated cAMP formation and directly inhibits cGMP formation through a currently unknown mechanism. In the SCN, melatonin phase shifts circadian rhythms of neuronal firing rate, through activation of a receptor coupled to a pertussis toxin-sensitive G-protein. This response is completely antagonized by selective MT_2 antagonist 4P-PDOT and inhibitors of the protein kinase C. Although the exact mechanism through which MT_2 melatonin receptor activation phase shifts circadian rhythms is not known, it appears to involve phospholipase C (PLC) stimulation, increases in diacylglycerol (DAG) production, and PKC activation.

3. *Melatonin Receptor-Mediated Physiological Responses*

Melatonin plays a key role in a number of physiological, neuroendocrine, and behavioral responses, including regulation of circadian rhythms and sleep; reproduction in seasonally breeding mammals; and visual, cardiovascular, and neuroimmunological functions (Fig. 3). These effects of melatonin are mediated through the activation of high-affinity melatonin receptors identified using radioligand binding, *in situ* hybridization with specific riboprobes or oligonucleotide probes, and immunohistochemistry using receptor-selective antibodies. Functional responses mediated through activation of MT_1 or MT_2 melatonin receptors in target tissues were identified using melatonin receptor-selective and specific ligands, and mice with deletion of the MT_1 receptor.

Melatonin receptors in the neural retina and superior colliculi are targets for the regulation of visual function. Melatonin released locally from retinal photoreceptors or other cells modulate a number of retinal functions, including calcium-dependent dopamine release, pigment aggregation, disk shedding, and phagocytosis. At picomolar concentrations, melatonin inhibits dopamine release through activation of an MT_2 presynaptic heteroreceptor. In the mammalian retina, dopamine mimics light and melatonin mimics the effect of darkness, exerting reciprocal modulation on light- and dark-mediated processes.

In the mammalian SCN, activation of melatonin receptors mediates two distinct functional responses: acute inhibition of neuronal firing by the MT_1 receptor and phase shifts of circadian rhythms by the MT_2 receptor. Both the acute inhibition of neuronal firing and the phase shift of circadian rhythms of activity occur at temporally sensitive times of the day. Neurons in the SCN show the highest sensitivity to inhibition of neuronal firing by melatonin at dusk, suggesting that the MT_1 receptor may play a role in altering the SCN state of excitability as the clock shifts from day to night. Thus, this property of melatonin may underlie the mechanism by which it promotes sleep, possibly by inhibiting neuronal activity in the SCN and/or other areas of the limbic system. By contrast, activation of the MT_2 receptor phase shifts the clock at both dusk and dawn, which coincides with the times of rise and fall of melatonin production. In the fall, as night length increases, the duration of melatonin production also lengthens. It is therefore possible that the MT_2 melatonin receptor

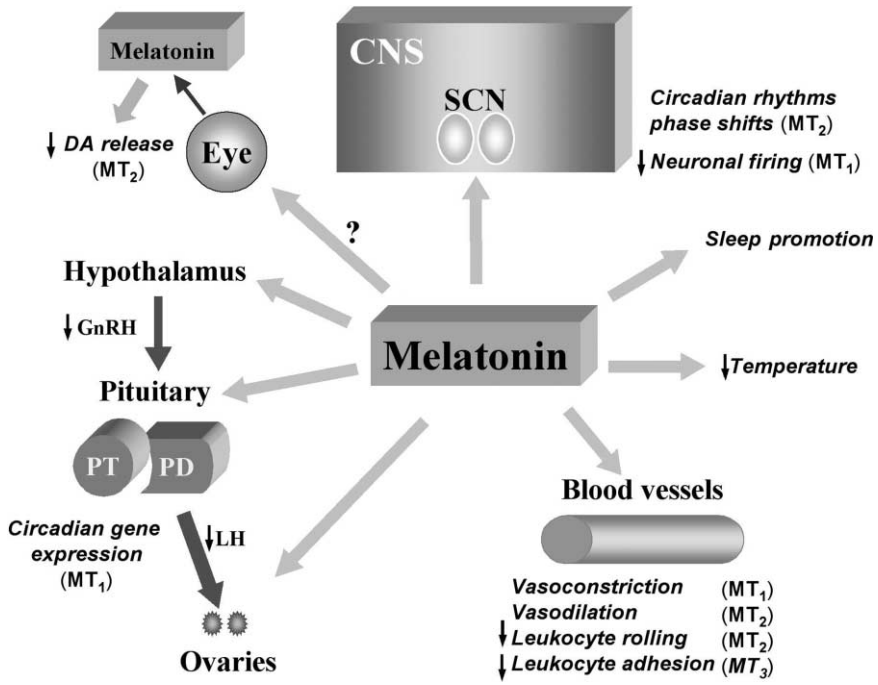

FIGURE 3 Melatonin-mediated physiological responses. Schematic representation of some of the most well-recognized functions of circulating melatonin: circadian behavior, sleep, reproduction, immune system effects, and vasculature effects. Melatonin synthesized in the retinal photoreceptors is secreted locally and is known to inhibit dopamine (DA) release. Melatonin and dopamine can act as signals for dark and light, respectively, mutually inhibiting each other and functioning as major players in the dark/light adaptation process. MT, Melatonin receptor; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; CNS, central nervous system; SCN, suprachiasmatic nucleus; PD, pars distalis; PT, pars tuberalis.

provides photoperiodic information to the clock to maintain synchrony of photoperiodic responses. In summary, activation of MT_1 and MT_2 melatonin receptors may provide important integrated control of distinct aspects of SCN physiology by melatonin.

Nonneuronal melatonin receptors in vascular beds regulate cardiovascular function and temperature. Melatonin, through activation of an MT_1 receptor, potentiates adrenergic constriction in some peripheral arteries, whereas it shows a direct vasoconstrictor effect in cerebral arteries. Further, activation of the MT_2 receptor mediates a vasodilator response in arterial beds. Inflammatory responses follow a diurnal rhythm that appears to be generated by melatonin. Melatonin appears to reduce the acute inflammatory process by inhibiting leukocyte rolling in the microvasculature, through activation of MT_2 receptors, and leukotriene B_4-induced leukocyte adhesion to endothelial cells, through a melatonin receptor with the pharmacological characteristics of the *MT_3* site.

Melatonin regulates reproduction in seasonally breeding animals and the dynamic physiological adaptations that occur in response to changes in day length. As the duration of the dark period changes, so does the duration of the melatonin acrophase, which then serves as the link between the circadian clock and peripheral tissues. In the pars tuberalis of the pituitary gland, the nocturnal secretion of pineal melatonin suppresses expression of the clock gene *Per1* by inhibiting the c-AMP-dependent pathway (receptor–cAMP–CREB phosphorylation–*Per1* gene expression) and simultaneously sensitizes the cAMP signaling pathway. As the levels of circulating melatonin decrease at dawn, the pars tuberalis is released from transcriptional repression, which facilitates the induction of *Per1* gene expression by adenosine, a transmitter that stimulates cAMP production via the A_{2b} adenosine receptor. This may be a general mechanism by which the hormone melatonin regulates gene expression, thus linking the central circadian pacemaker and peripheral tissues, resulting in modulation of circadian and seasonal rhythms.

Studies of the sites and mechanisms by which melatonin regulates reproduction have focused on

the hypothalamus and pituitary as target tissues. Melatonin receptor activation regulates gonadotropin-releasing hormone (GnRH) secretion from hypothalamic neurons, which in turn control the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which alter reproductive function at the level of the gonads. In pituitary gonadotrophs, possibly through activation of an MT_1 receptor, melatonin inhibits GnRH-induced calcium increase and LH secretion. Additionally, the presence of melatonin in ovarian follicular fluid suggests the possibility for a direct effect of the pineal hormone in ovarian function as well.

The MT_2 melatonin receptor appears to modulate responses in various nonneuronal targets. Activation of this receptor was shown to enhance cell-mediated and humoral immunity, to inhibit proliferation of human choriocarcinoma JAr cells (probably by delay of the cell cycle transition from G_1 to S phase), and to decrease the expression of the glucose transporter Glut4 and glucose uptake in human brown adipocytes.

III. MELATONIN RECEPTORS AS THERAPEUTIC TARGETS

Melatonin-mediated activation of the MT_1 receptor in the SCN and/or other limbic system areas may mediate somnogenic effects, and activation of the MT_2 subtype may be involved in the regulation of circadian rhythms. Thus, it follows that MT_2-selective melatonin receptor agonists and/or antagonists may be used to treat disorders involving alterations in the phase of the circadian clock, as observed in depression, blindness, and delayed sleep phase syndrome, or following a rapid change in the light dark/cycle, such as during jet travel and shift work. The use of specific and selective MT_1 and MT_2 melatonin receptor antagonists will help to elucidate the functional role of melatonin in mammals and may prompt development of type-selective analogues for the treatment of insomnia and circadian sleep/mood disorders involving alterations in phase.

Glossary

agonist Ligand with positive intrinsic efficacy that induces a change in receptor conformation, leading to a functional response.

circadian rhythm Endogenous adaptations of physiology and behavior made by organisms in response to day and night cycles [(L) circa = about; dies = day].

constitutive activity The ability of a receptor protein to adopt an active conformation and to signal in the absence of ligand.

G-protein-coupled receptors Seven-transmembrane-spanning receptors, coupled to signal transduction systems utilizing heterotrimeric ($\alpha\beta\gamma$) guanosine triphosphate-binding proteins (G-proteins).

intrinsic efficacy Property of a molecule that changes the conformation of a receptor, leading to a functional response.

inverse agonist Ligand with negative intrinsic efficacy; induces a functional response that is opposite to that of an agonist and decreases basal or constitutive receptor activity.

neutral antagonist Ligand with no intrinsic efficacy; binds to the receptor without inducing a functional response on its own and blocks functional responses mediated by agonists.

partial agonist Ligand with intrinsic efficacy lower than that of the agonist. Partial agonists either activate the receptor, inducing a response, or block the response induced by an agonist.

pertussis toxin Bacterial toxin produced by *Bordetella pertussis*; catalyzes ADP-ribosylation of the α-inhibitory subunit of G_i-protein and abolishes responsiveness of adenylyl cyclase to inhibitory ligands.

photoperiod Annual variation of daily changes in a physiological response that results from exposure of an organism to a natural light/dark cycle. Long photoperiodic responses are associated with longer days and shorter duration of the melatonin peak, because light inhibits melatonin synthesis.

pineal gland Endocrine gland (also called the pineal body) located in the center of the brain; main site of production of the hormone melatonin.

seasonal rhythm Endogenous rhythm synchronized to the time of the year by the natural change in the length of the daily light phase.

suprachiasmatic nucleus Hypothalamic nuclei; major endogenous pacemaker of circadian rhythms in mammals, i.e., the endogenous circadian clock.

Membrane Receptor Signaling in Health and Disease

ALFREDO ULLOA-AGUIRRE,
GUADALUPE MAYA-NÚÑEZ, AND CARLOS TIMOSSI
Instituto Mexicano del Seguro Social, Mexico

The primary function of cell surface receptors is to recognize a specific signal or ligand from among an immense number of chemically diverse substances and to act as signal transducers and amplifiers of the stimulus or message carried by external, systemic, or local stimuli. Extracellular signal-evoked receptor activation triggers a cascade of intracellular events; this usually culminates in a highly specific biological response, either stimulatory or inhibitory, of a given cell function.

I. INTRODUCTION

The three main classes or superfamilies of cell surface receptor proteins are defined according to the way in which they evoke intracellular signaling: (1) by G-protein coupling, (2) by enzyme coupling, and (3) by ion channel linkage. G-Protein-coupled receptors are seven-transmembrane-helix protein molecules that mediate their intracellular actions through the activation of one or more members of the guanine-nucleotide-binding signal-transducing proteins (G-proteins), which carry the information received by the receptor molecule to cellular effectors such as enzymes and ion channels. Activated effectors modify, in turn, levels of particular second messengers that regulate a wide variety of cellular processes. Enzyme-coupled receptors function directly as enzymes or through associated enzymes. Most have a single transmembrane (TM) segment with a ligand-binding site outside the cell and a catalytic site inside the cell. A majority of these receptors are protein kinases or

are associated with protein kinases that trigger a cascade of protein–protein interactions and phosphorylations on activation by their cognate ligands. Finally, ion-channel-linked receptors or transmitter-gated ion channels are multisubunit ionotropic receptor molecules that rapidly mediate signals carried by a small number of neurotransmitters across the synapse of the central and peripheral nervous systems. In these particular receptors, ligand binding leads to opening of an intrinsic pore, through which ions can flow down their electrochemical gradients, transforming a chemical signal into charge flux across the membrane. The activity of a given family or type of membrane receptor can be influenced, positively or negatively, by signaling pathways from other receptors (i.e., receptor cross-talking) in a variety of ways, generating the functional flexibility required by complex systems.

This article focuses on how membrane receptors and their coupled signal transducers evoke intracellular signals in normal and abnormal conditions. Special emphasis is given to the G-protein-coupled receptor (GPCR)–G-protein system, for which nearly 2000 receptors have been cloned since initial cloning of bovine opsin, the photoreceptor of the rod cell.

II. G-PROTEIN-COUPLED RECEPTORS AND G-PROTEINS IN HEALTH

A. GPCRs

G-protein-coupled receptors are a large and functionally diverse superfamily of membrane receptors; they consist of a single polypeptide chain of variable length that traverses the lipid bilayer seven times, forming characteristic transmembrane helices connected by alternating extracellular and intracellular sequences or loops (Fig. 1). Many signaling cascades use this class of receptor to convert external (e.g., photons and odorants) and internal (e.g., neurotransmitters, peptides, and glycoproteins) stimuli to intracellular responses. G-Protein-linked receptors characteristically bind large G-proteins, which in turn act as mediators of receptor-evoked effector activation. The nature of the second-messenger pathways activated in response to ligand binding to a given GPCR is essentially determined by the type of G-protein(s) coupled to the receptor (see later). The regulation of receptor–G-protein signal selectivity and specificity is highly complex and involves the activation of a network of mechanisms and pathways that eventually lead to biological responses. Based on nucleotide and amino acid sequence similarities, the GPCRs can be grouped into three main families: (1) family A, the rhodopsin/β_2-adrenergic receptor-like family, which comprises receptors that respond to a large variety of stimuli, including photons, odorants, neurotransmitters, and glycoprotein hormones; (2) family B, the glucagon/vasoactive intestinal peptide (VIP)/calcitonin receptor-related family, which includes receptors for a variety of peptide hormones and neuropeptides, including parathyroid hormone, corticotropin-releasing hormone, VIP, calcitonin, glucagon, growth hormone-releasing hormone, and secretin; and (3) family C, the metabotropic glutamate/calcium-related family, which includes the taste receptors, the metabotropic glutamate and calcium receptors, the putative pheromone receptors, and the γ-aminobutyric acid (GABA) receptors. Other receptors belonging to the GPCR superfamily are grouped in family D (pheromone-like receptors) and family E (cyclic AMP receptors).

Agonist binding to GPCRs provokes changes in the conformation of the receptor molecule involving particularly the relative positions of the seven-TM domains; the molecular perturbations of the membrane-embedded helices (Fig. 1) are thought to cause changes in the cytoplasmic (i.e., the intracellular loops) face of the receptor, promoting G-protein coupling and activation. Most of the primary sequence homology among the different groups of these types of receptors is contained within the hydrophobic TM domain (particularly for families A and B) or the intracellular loops (for the metabotropic neurotransmitter/calcium receptors). Receptors for small ligands (e.g., molecules that bind to some receptors belonging to family A, such as the retinal chromophore and biogenic amines) characteristically bind the ligand through a pocket or crevice, involving highly conserved residues located in the middle and extracellular third of hydrophobic TM helices. Receptors for small peptides bind their ligands through regions comprising either the extracellular loops or both the TM domains and the extracellular loops, whereas for moderate-sized peptides, binding usually occurs in both the extracellular loops and the amino-terminal segment. For larger ligands, such as the glycoprotein hormone receptors, the binding site usually resides within a large extracellular amino-terminal sequence alone. Similar to peptide receptors belonging to family A, binding of peptide ligands to receptors in family B involves the extracellular loops. In the calcium-sensing and the metabotropic glutamate receptors, the principal determinants for both ligand binding and signal specificity reside in the large amino terminus; receptor

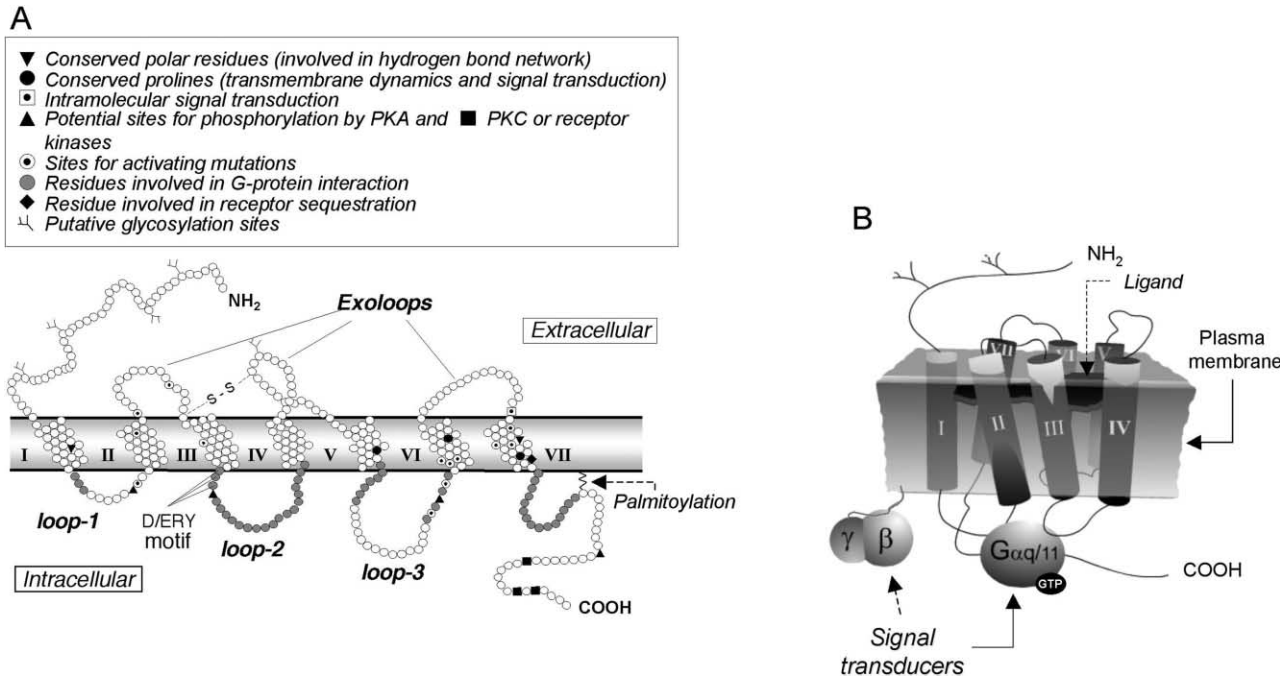

FIGURE 1 (A) Model of the proposed seven-transmembrane-spanning domains of a prototypic GPCR belonging to family A. Some structural characteristics of these particular receptors are shown. The structure also shows the location of some mutations that lead to constitutive activation of the receptor (e.g., glycoprotein hormone, rhodopsin, and adrenergic receptors). Reproduced from Ulloa-Aguirre *et al*. (1999), with permission. (B) Counterclockwise orientation of GPCRs from TM domains I–VII. The closed loop structure is representative of receptors for peptide ligands. In this arrangement, the core is composed mainly of TM domains II, III, V, and VI, whereas domains I and IV are peripherally sequestered. Proximity between helix II and helix VII is characteristic of this family of GPCRs. G-Proteins are closely associated with the intracellular domains.

activation requires, however, interactions of the liganded amino-terminal domain with membrane-associated domains.

In these particular membrane receptors, the G-protein-coupling domains lie within the divergent sequences of their intracytoplasmic domains and/or in residues located in the cytoplasmic face of the TM domains. In fact, mutations in residues located in the intracellular loops or in the TM helices may lead to loss of function or gain of function of the altered receptor (see later). Activation of the receptor and, consequently, of the G-proteins requires not only disruption of intra- and interhelical interactions and the occurrence of TM movements, but also disruption of interactions between specific residues located in the intracellular loops [e.g., in family A receptors, the highly conserved aspartic acid/glutamic acid–arginine–tyrosine (D/ERY) sequence located at the boundary of TM-III and the loop-2 intracellular sequence (Fig. 1)] and residues forming a pocket through interhelical interactions. Thus, agonist binding provokes a series of conformational changes in the receptor molecule that eventually lead to an enhanced accessibility of the G-proteins to the receptor regions involved in G-protein activation.

Several mechanisms regulate the functional level and activity of GPCRs. Continuous or prolonged stimulation of a cell generally results in progressively attenuated responses to subsequent stimulation by the same agonist. This decrease in cellular responsiveness to further stimulation, or desensitization, protects the cell from excessive stimulation. Early desensitization occurs rapidly and involves phosphorylation of residues located in the intracellular domains by second-messenger-dependent activated kinases or by a special class of serine/threonine-specific kinases called G-protein-coupled receptor kinases. The subsequent binding of a group of soluble inhibitory proteins, the arrestins, amplifies the desensitization process and turns off the receptor by impeding its coupling to G-proteins. Arrestins have also been shown to couple GPCRs to the activation of particular types of kinases, the Src-like kinases, and to facilitate the formation of multimolecular complexes,

including components of the mitogen-activated protein kinase (MAPK) and JUN N-terminal kinase (JNK) pathways (see later). In this vein, some adapter proteins bearing PDZ [a 90-amino acid repeat initially recognized in the postsynaptic density (PSD)-95 proteins] or SH2 or SH3 (Src homology) domains (all involved in downstream protein–protein interactions) provide the molecular basis for direct, heterotrimeric G-protein-independent interactions between GPCRs and several intracellular signaling molecules, such as the small G-protein Ras (see later). A more profound receptor deactivation process, long-term desensitization, may be observed after a prolonged time of agonist exposure; long-term desensitization, which involves a decrease in the net complement of receptors specific for a particular agonist, is subserved by several biochemically distinct mechanisms, including receptor down-regulation (i.e., loss in total cellular content of functional receptors) and internalization.

B. Heterotrimeric G-Proteins (Large GTPases)

Extracellular signals received by GPCRs are coupled by G-proteins to the regulation of effector enzymes that provoke generation of second messengers. G-Proteins are signal-transducing molecules belonging to a superfamily of proteins regulated by guanine nucleotides. These heterotrimeric proteins have α-, β-, and γ-subunits that are encoded by distinct genes.

G-Proteins are defined by their α-subunits; G_α-proteins can be divided into four main classes ($G_{\alpha s}$, $G_{\alpha i}$, $G_{\alpha q}$, and $G_{\alpha 12}$), grouped on the basis of amino acid identity and effector regulation. The G_α subunits are highly diverse and their tissue distribution varies, being either ubiquitous (or nearly ubiquitous) or expressed in selected tissues. The $G_{\alpha s}$ class includes $G_{\alpha s}$ and $G_{\alpha olf}$ and is involved in the activation of the various types of the enzyme adenylyl cyclase to enhance the synthesis of the second messenger, cyclic adenosine monophosphate (cAMP), which in turn activates protein kinase A; the $G_{\alpha s}$ subunit may also participate in the regulation of Ca^{2+} and Na^+ channels. The $G_{\alpha q}$ class includes $G_{\alpha q}$, $G_{\alpha 11}$, and $G_{\alpha 14-16}$; proteins of this class are predominantly associated with activation of the enzyme phospholipase $C\beta_{1-4}$, which catalyzes hydrolysis of the lipid phosphatidylinositol 4,5-bisphosphate (PIP_2) to form two second messengers, inositol 1,4,5-trisphosphate ($InsP_3$) and diacylglycerol (DAG). Proteins of the $G_{\alpha q}$ class also activate protein kinase C (PKC). The $G_{\alpha i}$ class includes $G_{\alpha gust}$, $G_{\alpha t}$, $G_{\alpha i}$, $G_{\alpha o}$, and $G_{\alpha z}$, which mediate a variety of effects, such as inhibition of adenylyl cyclase, activation of K^+ channels, Ca^{2+} channel closure, and inhibition of inositol phosphate turnover. Finally, the $G_{\alpha 12}$ class is defined by $G_{\alpha 12}$ and $G_{\alpha 13}$; signaling pathways regulated by these G-proteins include modulation of the sodium–proton exchanger NHE1 as well as regulation of cell growth and differentiation.

The β- and γ-subunits of G-proteins bind tightly to each other in diverse ways; although this diversity may theoretically yield 30 or more different βγ complexes, βγ dimerization is highly specific, allowing for differential effector regulation by unique $G_{\beta\gamma}$ complexes. Both the G_α subunits and the $G_{\beta\gamma}$ dimer play a major role in intracellular signal transduction, and the presence of all components of the heterotrimer is required for a receptor to trigger intracellular signaling.

The G-protein-mediated signaling is initiated on receptor activation (Fig. 2). In the inactive ("off") state, the α-subunit of the heterotrimer is bound to a molecule of guanosine diphosphate (GDP); the GDP-bound G_α subunit can interact with receptors, an association that is greatly enhanced by the $G_{\beta\gamma}$ complex. Activation of a GPCR is followed by activation of the trimeric $G_{\alpha/\beta\gamma}$-protein complex by guanine nucleotide. Receptor-promoted and Mg^{2+}-dependent GDP → guanosine 5′-triphosphate (GTP)

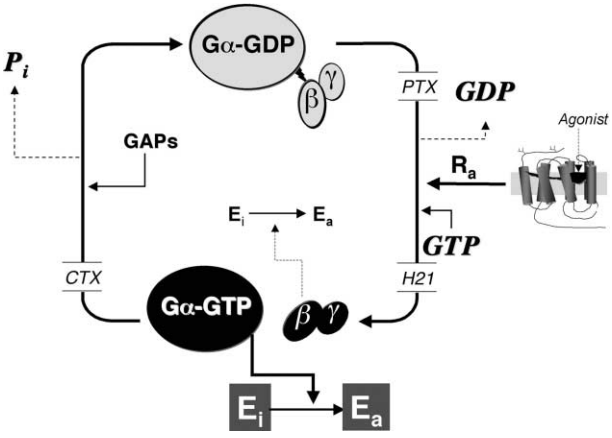

FIGURE 2 Regulatory cycle of a trimeric G-protein. The unoccupied receptor interacts with a specific agonist, leading to the activation of the receptor. Activated receptor (R_a) interacts with the trimeric G-protein, promoting Mg^{2+}-dependent GDP–GTP exchange and subunit dissociation, allowing interaction with effectors (E). The sites of action of pertussis toxin (PTX) and cholera toxin (CTX) are shown (see text for details). The H21 mutation on $G_{\alpha s}$ blocks signal transduction by preventing GTP activation. Inorganic phosphate ion (P_i) is released from GTP. GAPs, GTPase-activating proteins; E_i, inactive effector; E_a, activated effector.

exchange within the G_α guanine nucleotide-binding site leads to a conformational change of the subunit that causes G-protein activation and dissociation of the trimeric complex into G_α-GTP and $G_{\beta\gamma}$ ("on" state). Both of these complexes can then activate or inhibit signaling pathways by engaging in interactions with effectors (enzymes or ion channels); $G_{\beta\gamma}$ activation results solely as a consequence of its release from the $G_{\alpha/\beta\gamma}$ complex. Termination of signaling depends on the intrinsic GTPase activity of the α-subunit, which leads to hydrolysis of GTP to GDP, promoting dissociation of the G_α subunit from effector and reassociation with the βγ dimer, switching the G-protein complex to the "off" membrane-associated state. GTP hydrolysis by G_α is regulated by GTPase-activating proteins (GAPs) specific for a given member of the heterotrimeric G-protein family. Some effectors in G-protein-mediated signaling pathways may act as GAPs on cognate G_α subunits; other proteins, known as *r*egulators of *G*-protein *s*ignaling (RGS proteins), also act as GAPs that selectively and potently deactivate G_α subunits by accelerating the rate of intrinsic GTPase activity.

In addition to involvement in acute signaling functions, GPCRs also induce longer term effects on gene expression and cell proliferation. Signaling pathways involved in cell proliferation are stimulated by several extracellular ligands that transmit signals from the plasma membrane, through the cytoplasmic space, and finally to the nucleus. Similar to tyrosine kinase-linked receptors (see later), GPCRs may activate intracellular signaling in relationship with mitogenic effects. These GPCR-triggered proliferative effects are mediated by G_α-proteins of the $G_{\alpha q}$, $G_{\alpha i/Go}$, $G_{\alpha s}$, or $G_{\alpha 12}/G_{\alpha 13}$ class as well as by the corresponding βγ dimers. Growth-promoting GPCRs activate the mitogen-activated protein kinase cascade and ultimately regulate the expression of genes essential for proliferation. This occurs through mechanisms that may or may not involve the small GTP-binding G-protein Ras. In addition, a family of enzymes closely related to MAPK, the JUN kinases (stress-activated protein kinases), selectively phosphorylate and regulate the activity of the c-JUN protein (a transcription factor that induces the expression of genes linked to growth responses) under the influence of certain GPCRs, an effect mediated by the Ras-related small GTP-binding proteins Rac1 and Cdc42.

From the previous discussion, it is clear that structural alterations in key residues of the receptor molecules or the G-proteins may lead to altered function of the GPCR–G-protein system. Thus, mutations in sites involved in ligand binding usually result in altered receptors that are unable to recognize the signaling molecule and to become activated (loss-of-function mutations), whereas mutations in sites involved in receptor activation or G-protein coupling may lead either to loss of function or to constitutive activation (activation in the absence of ligand; gain-of-function mutations) of the receptor molecule. Other mutations may cause improper folding, altered intracellular trafficking, and reduced membrane expression of the receptor molecule. On the other hand, G-protein function may be altered in a number of disease states as a result of both adaptive and maladaptive mechanisms, including mutations in genes encoding G-protein subunits, changes in expression levels of G-protein subunit mRNAs or proteins, or posttranslational modifications of G-proteins. Both somatic and germline mutations in genes encoding GPCRs and G-proteins have been found to cause human disease. Examples of some of these mutations and their impact on intracellular signaling and cell function are discussed in the following sections.

III. G-PROTEIN-COUPLED RECEPTORS IN DISEASE

Structural alterations in GPCRs lead to abnormal function of the receptor molecule. Diseases caused by such alterations are shown in Table 1.

A. Rhodopsin/Retinitis Pigmentosa

Rhodopsin is the photoreceptor in rod cells; it mediates vision in dim light and is coupled to the retinal G-protein transducin (G_t). Rhodopsin-activated G_t allows light to excite neurons by freeing them from neurotransmitter inhibition. Mutations in rhodopsin lead to misfolding and abnormal trafficking of the nascent receptor protein, causing retention of the mutant protein in the endoplasmic reticulum and death of the rod cells. This causes retinitis pigmentosa, a disease encompassing a clinically variable and genetically heterogeneous group of inherited retinopathies, in which mutated rhodopsin leads to loss of night vision and of the peripheral visual field. Retinal pigmentary changes are characteristic of this disease and result from the release of pigment by degenerating rod cells in the retinal pigment epithelium. Numerous inactivating mutations have been linked to retinitis pigmentosa; mutations in the TM domain, in cysteine residues forming disulfide bonds, or in the carboxyl-terminal domain of the receptor may cause severe or

TABLE 1 Examples of Diseases Caused by Mutations in G-Protein-Coupled Receptors

Disease	Receptor involved[a]	Function[b]
Retinitis pigmentosa	Rhodopsin	↓ or ↑
Color blindness	Red/green opsins	↓
Idiopatic hypogonadotropic hypogonadism	GnRH	↓
Altered gonadal function		
Precocious puberty	LH	↑
Leydig cell hypoplasia	LH	↓
Ovarian dysgenesis	FSH	↓
Altered thyroid function		
Resistance to TSH	TSH	↓
Hyperfunctioning thyroid adenoma	TSH	↑
Multinodular goiter	TSH	↑
Congenital hyperthyroidism	TSH	↑
Nephrogenic diabetes insipidus	Vasopressin	↓
Altered parathyroid function		
Familial (benign) hypocalciuric hypercalcemia	Calcium sensing	↓
Neonatal severe hyperparathyroidism	Calcium sensing	↓
Autosomal dominant hypocalcemia	Calcium sensing	↑
Isolated glucocorticoid deficiency	ACTH	↓
Hirschsprung's disease	Endothelin-B	↓
Jansen-type metaphyseal chondrodysplasia	PTH–PTHrP	↑
Blomstrand disease	PTH–PTHrP	↓
Dwarfism [little (lit) mouselike]	GHRH	↓

[a]GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone; TSH, thyroid-stimulating hormone; ACTH, adrenocorticotropic hormone; PTH, parathyroid hormone; PTHrP, PTH-related protein; GHRH, growth hormone-releasing hormone.

[b]↓, Loss of function; ↑, gain of function.

mild forms of the disease, depending on the location of the mutation. Families with a severe phenotype of retinitis pigmentosa carry a mutation at the site (Lys-296) of chromophore (11-*cis*-retinal) attachment; this alteration disrupts the inactive conformation of opsin, resulting in a constitutively active receptor that activates transducin in the absence of external stimulus (light) and the covalently linked chromophore.

B. Vasopressin Receptor

The function of arginine vasopressin (AVP), a hormone secreted by the posterior pituitary, is to control blood osmolality. AVP controls the reabsorption or water by regulating the number of water channels present in the lumenal surface of the distal tubule and in the collecting duct of the nephron. The antidiuretic effect of AVP is exerted through the vasopressin-2 receptor (V2R), which is linked to the effector enzyme adenylyl cyclase. Inactivating mutations in the V2R lead to nephrogenic diabetes insipidus (NDI), a disease characterized by the inability of the kidney to retain water and concentrate urine. Individuals affected with the X-linked type of NDI bear mutations that alter the structure or expression of the V2R. Vasopressin-2 receptor mutations may be located in either region of the receptor and may interfere with receptor synthesis or with proper AVP binding or efficient coupling to the G_s-protein. This latter alteration usually leads to expression of a partial phenotype of NDI.

C. Gonadotropin-Releasing Hormone Receptor

The receptor for the hypothalamic releasing peptide gonadotropin-releasing hormone (GnRH) is located in the cell surface of the pituitary cells that synthesize the gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH). This receptor is preferentially coupled to the $G_{q/11}$-protein and its activation by GnRH agonists stimulates synthesis and secretion of LH and FSH. Resistance to GnRH by inactivating mutations leads to distinct forms of inherited (autosomal recessive) hypogonadotropin hypogonadism, a disorder characterized by delayed puberty, absence of secondary sexual characteristics, and low gonadotropin and sex-steroid levels. Although inactivating mutations in the GnRH receptor may be distributed along the entire coding sequence of the receptor, they have been mainly

localized within the third to fifth TM domains. These mutations affect ligand binding, signal transduction, and/or processing of the receptor, leading to altered intracellular trafficking and reduced cell surface expression. Mutations of the GnRH receptor may result in a wide spectrum of phenotypes, from partial to complete hypogonadism.

D. Adrenocorticotropic Hormone Receptor

Adrenocorticotropic hormone (ACTH) is an anterior pituitary hormone that, acting via its specific receptor, regulates adrenocortical growth and controls corticosteroid production and secretion. The ACTH receptor (ACTHR) is related to the small subfamily of melanocortin receptors and couples to the G_s–adenylyl cyclase pathway. Hereditary isolated glucocorticoid deficiency, a rare autosomal recessive inherited disease, may result from ACTH receptor unresponsiveness to ACTH. Patients with ACTH resistance, either homozygous or compound heterozygous for inactivating ACTHR mutations, typically exhibit deficient production of cortisol and adrenal androgens in the presence of markedly elevated endogenous plasma ACTH levels. Aldosterone levels are usually normal and respond appropriately to maneuvers that activate the renin–angiotensin axis. Inactivating mutations of the ACTHR leading to familial glucocorticoid deficiency may be scattered throughout the ACTH receptor molecule, affecting receptor structure, membrane expression, ligand affinity, and/or signal transduction. The etiology of familial glucocorticoid deficiency might be heterogeneous and genes other than that of the ACTHR might be involved and may cause the same phenotype.

E. Glycoprotein Hormone Receptors

Glycoprotein hormone receptors have large extracellular domains (300–400 amino acids in length) and bind structurally complex ligands. From the functional point of view, these receptors comprise two halves: an extracellular amino-terminal half (exodomain) and a membrane-associated carboxyl-terminal half (endodomain). Although the exodomain alone is capable of high-affinity ligand binding, interaction with the endodomain [which comprises the seven-TM domains, the three extra- and intracellular loops, the carboxyl-terminal tail, and a short extracellular extension of the first TM domain (Fig. 1)] is necessary to generate and transmit an intracellular signal. In humans, the thyrotropin [thyroid-stimulating hormone (TSH)] receptor and LH receptor are coupled to both the G_s–adenylyl cyclase–cAMP pathway and the G_q–phospholipase Cβ–phosphoinositide/diacylglycerol pathway, whereas the FSH receptor is predominantly coupled to the G_s-protein. All glycoprotein hormone receptors, particularly the TSH and LH receptors, are sensitive to naturally occurring mutations, leading to cell hypo- or hyperfunction.

Thyrotropin is the pituitary glycoprotein hormone that stimulates thyroid development, growth, and function. Thyrotropin receptor gene mutations leading to loss of function of the receptor molecule have been associated with inherited hypothyroidism with TSH resistance; mutations may localize to the amino-terminal region and/or the fourth TM helix of the receptor. Mutations in the amino-terminus usually affect ligand binding, whereas alterations in TM domains may potentially impair receptor membrane expression. Whereas most of the patients with resistance to TSH due to TSH receptor (TSHR) mutations exhibit "compensated hypothyroidism" (i.e., normal serum concentrations of thyroid hormones in the presence of hyperthyrotropinemia), profound hypothyroidism with thyroid hypoplasia may also rarely occur. Reciprocally, mutations leading to constitutive activation of the TSHR and clinical hyperthyroidism may be found at both the somatic and the germ-line levels; the former is usually associated with autonomously functioning toxic (hyperfunctioning) thyroid adenomas, whereas the latter is associated with familial (autosomal dominant) nonimmune hyperthyroidism, a very rare disorder. Both conditions lead to activation of adenylyl cyclase, via G_s, increased cAMP production, and eventually to thyroid hyperplasia or expansion of the adenoma. Spontaneous mutations in the TSHR gene leading to hyperfunctioning thyroid adenomas may be located in the TM domains, the extracellular loops, the third intracellular loop, or, rarely, in the amino-terminus (e.g., Arg310Cys). Exceptionally, activating mutations of the TSHR may be found in multinodular goiter.

The target glands for LH are the gonads, where LH stimulates androgen production by the Leydig cells of the testes and the theca cells of the ovarian follicle. This gonadotropin also stimulates estrogen and progesterone production by the corpus luteum. In the inactivating mutations of the LH receptor (LHR) gene, the altered receptor interferes with the intrauterine development of the male external genitalia, causing a wide spectrum of phenotypic alterations, ranging from extreme forms, in which the patients present as 46, XY females (severe Leydig cell hypoplasia), to milder

forms associated with hypergonadotropic hypogonadism, microphallus, and hypoplastic male external genitalia. Inactivating LHR mutations may be localized in the amino-terminus, the TM domains, or the third intracellular loop. In women, inactivating mutations in the LHR gene may lead to hypergonadotropic hypogonadism, menstrual disorders, enlarged cystic ovaries, and infertility. In the case of activating LHR mutations, the autonomous activation of the receptor causes sporadic or familial pseudo-precocious puberty, a phenotype observed only in males. Somatic activating mutations of the LHR have been found only in Leydig cell adenomas. Activating mutations of the LHR are usually located in the TM domains or in the third intracellular loop of the receptor.

Follicle-stimulating hormone is involved in the regulation and maintenance of essential reproductive processes, such as gametogenesis and follicular development. The target cells of FSH are the Sertoli cells of the testes and the granulosa cells of the ovary. Inactivating mutations in the FSHR gene have been described in selected populations and in some sporadic cases. In females, inactivating mutations in the FSHR cause gonadal dysgenesis and/or premature ovarian failure, whereas in men mutations may provoke poor quality sperm. Inactivating mutations in the FSHR have been identified mainly in the amino-terminal domain, and less frequently in the third intra- and extracellular loops of the receptor. The five mutations reported so far in the extracellular domains altered binding capacity and signal transduction by disturbing the trafficking of the receptor to the membrane, whereas the intracellular loop-3 mutation altered signal transduction but not membrane receptor expression. Only one naturally occurring activating mutation (located in intracellular loop 3) in the FSHR has been identified so far. Nevertheless, other sites for mutations (artificially-induced; not yet described to occur naturally) that may provoke constitutive activation of the FSHR include a leucine in position 460 in the TM-III residue (a residue highly conserved in $\geq 70\%$ of family A GPCRs) and a leucine in position 477 of intracellular loop 2 (a residue present in all human glycoprotein hormone receptors).

F. Parathyroid Hormone/Parathyroid Hormone-Related Peptide Receptor

Parathyroid hormone (PTH) plays a critical role in the regulation of calcium homeostasis in kidney and bone. Its actions are mediated by two closely related GPCRs, the PTH1 receptor, which responds equally to PTH and PTH-related peptide (PTHrP), and the PTH2 receptor, which responds to PTH. Agonist occupancy of these receptors leads to activation of both the G_s–adenylyl cyclase and the G_q–phospholipase C signal transduction pathways. Mutations in the cytoplasmic ends of TM domains II and VI may induce constitutive activity of the PTH/PTHrPR–G_s protein system and thus lead to a rare type of short-limbed dwarfism (called Jansen-type metaphyseal chondrodysplasia) resulting from decelerated chondrocyte differentiation and associated with marked hypercalcemia and hypophosphatemia in the presence of normal serum concentrations of PTH and PTHrP. Parathyroid hormone and PTHrP receptors are also important during fetal skeletal development; signaling through these receptors controls the differentiation of growth plate chondrocytes into hypertrophic cells. Thus, mutations that completely inactivate the PTH/PTHrP receptor may be lethal *in utero*; in fact, mutations resulting in impaired PTH/PTHrP binding (e.g., in the highly conserved Pro-132 amino acid residue of the amino-terminal domain or in the sequence of the fifth TM domain) and in severe receptor dysfunction lead to Blomstrand chondrodysplasia, an autosomal recessive inherited disease characterized by a striking increase in bone density and markedly accelerated skeletal maturation.

G. Growth Hormone-Releasing Hormone

Growth hormone-releasing hormone (GHRH) is a hypothalamic peptide involved in the regulation of the synthesis and secretion of growth hormone, a pituitary hormone that is responsible of regulating growth. Growth hormone deficiency causes short stature and metabolic derangements. The GHRH receptor (GHRHR) is coupled to the G_s–adenylyl cyclase pathway and mutations in the receptor molecule may lead, in humans, to growth failure, analogous to that showed by rodent experimental models bearing a GHRHR gene missense mutation that impairs receptor expression.

H. Calcium-Sensing Receptor

Extracellular calcium is essential for a large array of vital processes and its concentration in extracellular fluids is under strict control by a homeostatic system that includes the kidney, bones, intestines, and the parathyroid and thyroid glands. Extracellular Ca^{2+} sensing occurs through a receptor coupled to the G_q–phospholipase C signaling pathway. Several tissues express this receptor; in the parathyroid gland, the calcium-sensing receptor (CaR) plays a central role in

the regulation of PTH secretion. Loss-of-function mutations in the CaR result in two inherited diseases, familial (benign) hypocalciuric hypercalcemia and neonatal severe hyperparathyroidism; the former results from mutations in only one allele of the CaR gene, whereas the latter arises from mutations in both alleles. Mutations in the benign form of the disease are mainly localized either in the first 300 amino acid residues of the amino-terminal domain or in proximity to TM-I of the receptor. These mutations may cause decreased CaR sensitivity for extracellular calcium or may exert dominant negative actions on the normal receptor, leading to a more severe syndrome.

IV. DEFECTS IN G-PROTEIN-COUPLED SIGNAL TRANSDUCTION

Abnormalities in G-protein function may be caused by: (1) posttranslational modifications of G-proteins by bacterial toxins, (2) mutations (either loss- or gain-of-function mutations) in genes encoding G-proteins, and (3) changes in expression levels of G-protein subunit mRNA or functional protein. Examples of structural alterations in G-proteins leading to abnormal signal transduction are shown in Table 2.

A. Posttranslational Modifications—Cholera Toxin and Pertussis Toxin

Cholera toxin causes adenosine diphosphate (ADP) ribosylation of an arginine residue in position 201 within the GTP-binding domain of $G_{\alpha s}$, markedly reducing the intrinsic GTPase activity of the subunit (Fig. 2), leading to constitutive activity of the protein and increased levels of cAMP independent of the normal extracellular signal. Infection by *Vibrio cholerae* affects the intestinal tract, causing excess fluid secretion by the epithelial cells and massive diarrhea. Pertussis toxin, produced by *Bordetella pertussis*, covalently modifies several subunits of the $G_{\alpha i}$ class by ADP-ribosylation on the fourth cysteine residue from the carboxyl-terminus of the protein, leading to uncoupling of the modified G-protein from the receptor and disruption of signal transduction; this is the mechanism whereby exposure to pertussis toxin causes hypoglycemia and histamine sensitivity.

B. Mutations in the G_{α}-Protein

Germ-line and somatic mutations of the human *GNAS1* gene, located on chromosome 20q13.11, which encodes the $G_{\alpha s}$ protein, have been implicated in abnormal signal transduction and in several clinical disorders. Activating (oncogenic) mutations in this G-protein subunit (specifically in Arg-201 or Gln-227, which lead to inhibition of GTPase intrinsic activity) have been identified as the cause of several disorders, including subsets of growth hormone-secreting pituitary tumors, testicular and ovarian stromal Leydig cell tumors, toxic thyroid adenomas, and the McCune–Albright syndrome, a sporadic disease characterized by increased hormone production and/or cellular proliferation in a number of tissues. Less frequently, $G_{\alpha s}$ mutations may lead to nonfunctioning pituitary and thyroid adenomas, ACTH-secreting adenomas, parathyroid neoplasms, and differentiated thyroid carcinomas. Screening studies of different types of human tumors for mutations in $G_{\alpha i(2)}$ have revealed similar amino acid substitutions in a proportion of ovarian, adrenal, and nonfunctioning pituitary tumors. Conversely, heterozygous germ-line *GNAS1* gene mutations that decrease expression or function of $G_{\alpha s}$ cause Albright hereditary osteodystrophy, a disorder associated with a constellation of developmental defects (including obesity, short stature, bony abnormalities, and mild mental retardation), as well as reduced responsiveness to multiple hormones (including PTH, TSH, and glucagon). Altered expression and/or function of G-proteins may be found in a number of other abnormal conditions, including neuropsychiatric disorders, alcoholism, hypertension, and diabetes mellitus. Defects in G-proteins in such disorders may also be secondary to other alterations in cell function.

V. ENZYME-LINKED RECEPTORS IN HEALTH AND DISEASE

More than 50 receptors belong to the superfamily of enzyme-linked receptors, including the receptors for growth hormone, insulin, cytokines, and growth factors. The enzyme-coupled receptor superfamily can be separated into the following main families: (1) tyrosine kinase receptors, (2) tyrosine kinase-associated receptors, (3) tyrosine phosphatase receptors, (4) guanylyl cyclase receptors, and (5) serine/threonine kinase receptors.

A. Tyrosine Kinase and Tyrosine Kinase-Associated Receptors

Tyrosine kinase receptors are membrane-spanning proteins with large amino-terminal extracellular domains bearing the ligand binding site, a juxtamembrane domain, a protein kinase catalytic domain, and

TABLE 2 Examples of Diseases Caused by Mutations in G_α-Proteins

Disease	G-protein involved/(mutation)	Function[a]
Vibrio cholerae (cholera toxin)	$G_{\alpha s}$ ADP-ribosylation	↑
Bordetella pertussis (pertussis toxin)	$G_{\alpha i}$ ADP-ribosylation	↓
Albright hereditary osteodystrophy, pseudohypoparathyroidism type 1a	$G_{\alpha s}$	↓
Nonfunctioning pituitary adenoma, adrenal and sex cord tumors	$G_{\alpha i2}$ (Arg179Cys/His or Gln205Arg)	↑
McCune–Albright syndrome	$G_{\alpha s}$ (Arg201His/Cys)	↑
Growth hormone-secreting tumors	$G_{\alpha s}$ (Arg201His/Cys or Gln227Leu/Arg)	↑
Nonfunctioning pituitary adenomas, ACTH-secreting adenoma, toxic thyroid adenoma, papillary thyroid carcinoma	$G_{\alpha s}$ (Arg201His/Cys or Gln227Leu/Arg)	↑
Pseudohypoparathyroidism type 1a and testotoxicosis	$G_{\alpha s}$ (Ala366Ser)	↓/↑
Nonfunctioning pituitary adenoma, adrenal and sex cord tumors	$G_{\alpha i2}$	↑

[a] ↓, Loss of function; ↑, gain of function.

a carboxyl-terminal tail. Based on the structure of their extracellular domains, members of this class of membrane receptor can be grouped into 16 subfamilies, which include the platelet-derived growth factor receptor, the fibroblast growth factor (FGF) receptor, the epidermal growth factor (EGF) receptor, the insulin receptor, the nerve growth factor receptor, the hepatocyte growth factor (HGF) receptor, and the vascular endothelial growth factor receptor subfamilies. Receptors belonging to this superfamily dimerize on ligand binding; dimerization is then followed by auto- or transphosphorylation of the receptor, which then interacts with associated adapter proteins or effector enzymes bearing SH2 domains, leading to the activation of a variety of signaling pathways and nuclear factors (Fig. 3). Protein kinase-associated receptors, such as the growth hormone and prolactin receptors, associate with tyrosine kinases belonging to the JAK kinase (for Janus kinase) family. Members of this family phosphorylate target proteins on ligand binding and receptor dimerization, eventually leading to gene transcription; target proteins include the Stat (signal transduction and activation of transcription) proteins. Abnormal or ligand-independent activation of the signaling cascades mediated by tyrosine kinase or tyrosine kinase-associated receptors may lead to altered cell proliferation and tumorigenesis (e.g., some mutated forms of the EGF and HGF receptors) or to severe skeletal dysplasias due to activation of cell cycle inhibitors (e.g., those induced by mutations in the FGF receptor), whereas inactivating mutations may cause abnormal embryogenesis (e.g., the *patch* mutation that affects neural crest development in mice) or to a variety of disorders, such as severe insulin resistance (e.g., leprechaunism and the Rabson–Mendenhall syndrome) and dwarfism (e.g., growth hormone receptor mutations), depending on the particular receptor involved.

B. Tyrosine Phosphatase Receptors

Protein tyrosine phosphorylation and dephosphorylation are mechanisms crucial for the regulation of numerous cellular events. Receptor-like protein tyrosine phosphatases (PTPs) are ligand-regulated phosphatases that participate in intracellular signal transduction by countering the activities of receptors with tyrosine kinase activity. Receptor-like PTPs are subdivided into five types based on common features exhibited by their extracellular domains: (1) type I receptor-like PTPs, represented by the hematopoietic cell-restricted CD45 family (with its corresponding isoforms); (2) type II molecules, such as the LAR-like PTPs [e.g., LAR, PTPσ, and PTPδ in mammals, preferentially expressed (with the exception of LAR) in neurons and implicated in neuronal development], which contain tandem repeats of immunoglobulin-like and fibronectin type III-like domains resembling neural cell adhesion molecules; (3) type III molecules, which exhibit fibronectin type III repeats; (4) PTPα and PTPε, which have a small extracellular domain; and (5) PTPξ and PTPγ, which exhibit amino-terminal carbonic anhydrase-like domains. Many PTPs may be involved in growth defects and diseases. For example, CD45, a PTP receptor present in lymphoid cells, has been shown to be necessary for multiple signaling events in both B and T cells; loss of CD45 in mice has profound consequences for

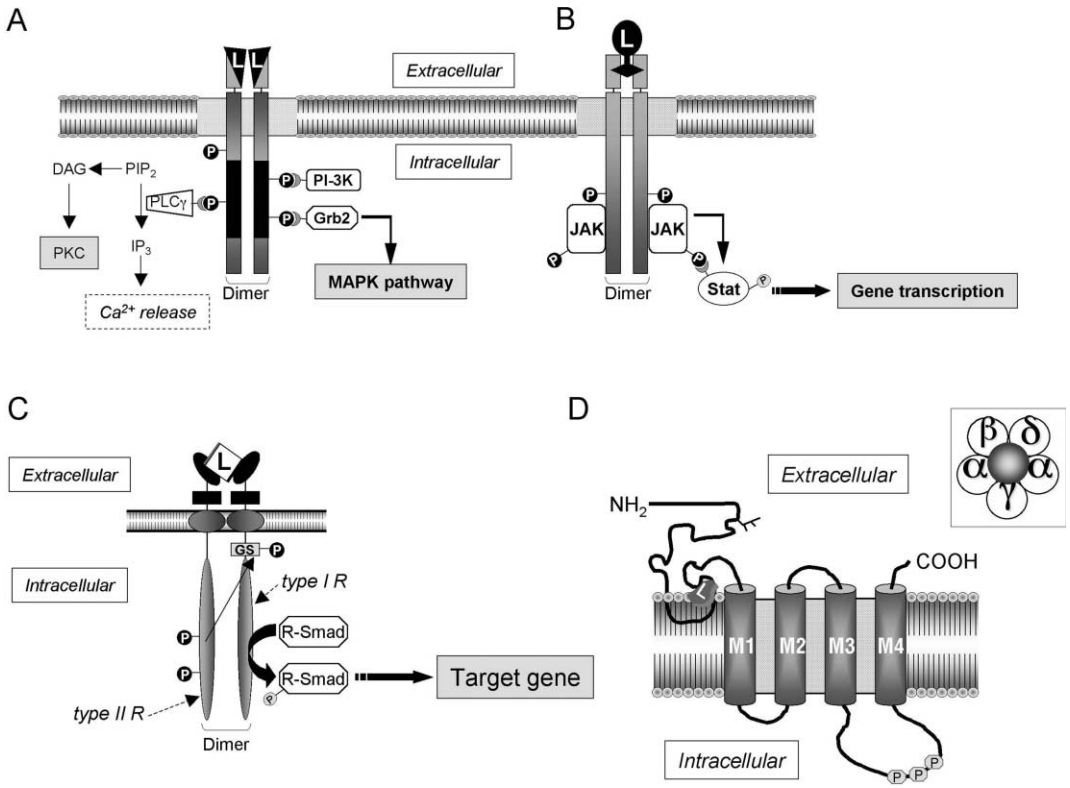

FIGURE 3 (A) Signaling through tyrosine kinase receptors. Ligand (L) (e.g., epidermal growth factor) binding provokes dimerization of the liganded receptor; this is followed by activation of the receptor's intrinsic tyrosine kinase, leading to transphosphorylation of the receptors, docking of SH2 domain-bearing proteins [including Grb2 (growth factor receptor-binding protein 2), phopholipase Cγ (PLCγ), and phosphatidylinositol 3-OH kinase (PI-3K)], and activation of multiple signaling pathways. (B) Activation of intracellular signaling by tyrosine kinase-associated receptors. Ligand (e.g., growth hormone) binding provokes receptor dimerization, recruitment of JAK tyrosine kinase, and subsequently tyrosine phosphorylation of JAK, the receptor, and the Stat (for signal transduction and activation of transcription) proteins; Stats then dimerize and translocate to the nucleus to induce transcription of specific target genes. (C) Signaling through serine/threonine kinase receptors [e.g., the transforming growth factor-β receptor (TGF-βR)]. Binding of TGF-β to its type II receptor in concert with a type I receptor (R) leads to formation of a receptor complex and phosphorylation of the type I receptor, which subsequently phosphorylates a receptor-regulated SMAD (R-Smad) protein. The SMAD, complexed with Smad4, moves into the nucleus and activates TGF-β target genes. (D) Putative transmembrane organization of a ligand-gated ion channel [e.g., the nicotinic acetylcholine receptor (AChR)], showing the four-transmembrane model for this receptor. M, Transmembrane domain; P, potential phosphorylation sites. Inset: Front view of the model of peripheral (muscle) AChR with a pore at the center of the pentamer.

lymphocyte development and signal transduction. Targeted deletion of a LAR-like PTP in mice leads to abnormal neonatal death rates, and targeted homozygous disruption of the *Ptprs* gene (which encodes PTPσ) causes multiple growth defects, including stunted growth, developmental delay, and several neurological disorders.

C. Guanylyl Cyclase Receptors

The single-transmembrane-domain-signaling guanylyl cyclase (GC) receptors have cytoplasmic domains bearing guanylyl cyclase activity; on activation by their cognate ligands, the receptors promote the production of the second messenger cyclic guanosine monophosphate (GMP), which in turn binds and activates a cyclic GMP-dependent protein kinase known as G-kinase, subsequently triggering serine or threonine phosphorylation on specific proteins. The guanylyl cyclase A and B receptors bind natriuretic peptides (involved in the regulation of cardiovascular and renal function), whereas the GC C receptor binds heat-stable enterotoxins. The orphan GC D, E, and F receptors are expressed in

sensory tissues. Nearly 29 genes encoding putative guanylyl cyclases have been discovered in the nematode *Caenorhabditis elegans*, which suggests that numerous guanylyl cyclase receptors still remain to be discovered in mammals. Salt-independent chronic elevation of blood pressure, which corresponds to the phenotype observed in nearly 50% of subjects with essential hypertension, is found in GC A gene-disrupted mice. On the other hand, mice missing the GC C receptor are resistant to Sta, a heat-stable enterotoxin from *Escherichia coli* that is thought to be responsible for diarrhea in adults and infants.

D. Serine/Threonine Kinase Receptors

Transmembrane receptors with serine and threonine kinase activity are distinct molecules that bind members of the transforming growth factor-β (TFG-β) superfamily of related polypeptide growth factors (including TFG-β_{1-3}, bone morphogenetic proteins, anti-Müllerian hormone, and activins) that are involved in a large array of cellular processes, such as growth, proliferation, differentiation, lineage determination, apoptosis, adhesion, and motility. The TFG-β receptor family consists of two subfamilies, type I receptors (formerly known as activin receptor-like kinases) and type II receptors. The TFG-β receptor-mediated intracellular signaling is initiated when the TFG-β type II receptor, which is basally phosphorylated in a ligand-independent manner, binds its ligand and activates via phosphorylation at serine and threonine residues (present within the GS domain, a highly conserved 30-amino acid region) an associated TFG-β type I receptor (Fig. 3). The activated TFG-β receptor complex then phosphorylates and activates proteins of the SMAD family, which in a complex form move into the nucleus and activate TGF-β-responsive genes. Down-regulation or loss of serine/threonine kinase functional receptors, aberrant signal–signal transduction pathways due to Smad alterations, mutations in ligand, or loss of functional genes that control the transcription and translation of TGF-β and TGF-β-related peptides may contribute to the development of several diseases. Because the effects of TGF-β on target cells include negative regulation of cell proliferation, disruption of TGF-β signaling could therefore predispose or even cause cancer (e.g., gastrointestinal cancer, head and neck carcinomas, ovarian cancer, and T-cell lymphoma). Mutations in the anti-Müllerian hormone or its receptor lead to persistent Müllerian duct syndrome, whereas mutations in Gdf5/Cdmp1 (a ligand belonging to the growth and differentiation factor subfamily of TGF-β) result in hereditary chondrodysplasia. Likewise, mutations in Alk1 (a type I receptor) may lead to hereditary hemorrhagic telangiectasia. Finally, SMAD mutations are associated with colon cancer (Smad2 and Smad4), pancreatic cancer (Smad4), and other cancers.

VI. ION-CHANNEL-LINKED RECEPTORS IN HEALTH AND DISEASE

Channels are pores in the cell membrane; ions flow through these pores across the membrane, depolarizing or hyperpolarizing the cell. The ligand-gated ion channels are grouped into two major functional families: (1) the nicotinic acetylcholine (ACh), serotonin, and glutamate-gated ion channels, which allow passage of cations (Ca^{2+}) at excitatory synapses, and (2) the GABA A and GABA C receptor (GABA B receptors are GPCRs) and the glycine-gated channels, which permit passage of anions at inhibitory synapses. At the amino acid sequence level, the nicotinic ACh, serotonin, GABA, and glycine-gated channel subunits are homologous; these receptors assemble as heteropentamers of different gene products and/or splice variants. The glutamate-gated channels differ from the other amino-acid-gated channels in that they are composed of four subunits, each containing three (instead of four) TM segments; these channel receptors may be subdivided according to agonist selectivity into the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), *N*-methyl-D-aspartate (NMDA), and kainate subtypes. The TM segments of these multisubunit receptors are arranged around a large, poorly selective central pore, the properties of which are essentially determined by the amino acid residues forming the second TM segment. In these receptors, ligand binding provokes a transient open-channel state, during which passive flux occurs. The nicotinic ACh receptor is the model for structure–function relationship studies on the superfamily of ligand-gated ion channel receptors and is the best known from the structural and functional points of view. This receptor has an $\alpha_2,\beta(\delta\gamma)$ or $(\epsilon\delta)$ pentameric composition; each subunit has a large extracellular amino-terminal domain, four TM domains, a large intracellular loop between the third and fourth TM domains, and an extracellular carboxyl-terminal domain (Fig. 3). The functional events associated with the ACh receptor include (1) binding of

the neurotransmitter, (1) opening of the channel via rotation of two pore-lining α-helices, which moves the helices apart, (3) conduction across the pore, and (4) desensitization.

Ligand-gated ion channels in the neuronal plasma membrane function as effective, cell surface signal transducers via interactions with a number of extracellularly or intracellularly stimulated protein kinases. Channel phosphorylation may gate the channel, may facilitate interaction with other regulatory PDZ domain-bearing proteins (linking the receptor channel to the cytoskeleton and to appropriate intracellular signal transduction pathways, which may eventually lead to gene expression), and/or may regulate receptor desensitization and clustering. Current evidence demonstrates that ligand-gated cation channels may be additionally located presynaptically on nerve terminals in the peripheral and central nervous systems, where they function to modulate neurotransmitter release. Alterations in the primary sequence leading to modification in gating kinetics may associate with pathological processes or channelopathies. For example, mutation of the extracellular charged arginine ring in the glycine receptor can impair channel function by decreasing the sensitivity of glycine activation, reducing channel conductance, shifting the normal multisubconductance states to lower values, and decoupling ligand binding from channel gating. Mutations in the α_1-subunit of the glycine receptor lead to hyperekplexia (excess startle response), whereas structural alterations in the Ach receptor may cause frontal lobe nocturnal epilepsy (as in those mutations involving the α_4-subunit, which may eventually lead to different alterations in the properties of the ACh-gated channel) or myasthenic syndromes (e.g., slow-channel syndrome). The latter abnormalities arise from delayed closure of the ion channel, ACh receptor deficiency, and short channel open time; these are kinetic abnormalities that lead to high conductance or abnormal interactions of the ligand with its receptor.

VII. SUMMARY

Cell surface receptors are signal transducers for water-soluble extracellular signals. There are three main classes of cell surface receptors: G-protein-coupled receptors, enzyme-coupled receptors, and ion-channel-linked receptors. Each class of receptor mediates the signals carried by extracellular ligands through particular mechanisms, most of them involving the intracellular activation of particular protein–protein interaction cascades. G-Protein–coupled receptors mediate their intracellular actions through the activation of G-proteins and specific effector enzymes, whereas enzyme-linked receptors function directly as enzymes or through associated enzymes that, on activation, autophosphorylate or phosphorylate the receptor molecule, subsequently recruiting associated proteins that act as intracellular signal transducers. Ion-channel-linked receptors are protein molecules that convert chemical signals into a charge flux across the cell membrane by opening an intrinsic pore, through which ions flow. Membrane receptors and their associated signal transducers may be altered in a number of diseases as a result of adaptive or maladaptive mechanisms, including mutations in their encoding genes.

Glossary

domain Portion of a protein that has a tertiary structure of its own. In large proteins, each domain is connected to other domains by flexible regions of polypeptide.

effector Molecule that performs an action in response to a stimulus.

guanosine 5′-triphosphate Nucleoside triphosphate used in RNA synthesis and in some energy-transfer reactions. It also plays a special role in protein synthesis, cell signaling, and microtubule assembly.

ligand Any molecule that binds to a specific site on another molecule.

neurotransmitter Small signaling molecule secreted by the presynaptic nerve cell at a chemical synapse; relays a signal to the postsynaptic cell. A neurotransmitter can elicit either excitatory or inhibitory responses on the target synapse.

protein kinase Enzyme that transfers the terminal phosphate group of adenosine triphosphate to a specific amino acid of a target protein.

protein phosphatase Enzyme that removes a phosphate group from a protein by hydrolysis.

receptor Protein that binds a specific extracellular signaling molecule and initiates or blocks a response in the cell.

second messenger Small molecule that is formed in or released into the cytosol in response to an extracellular signal; helps to relay the signal to the interior of the cell.

signaling molecule Extracellular or intracellular molecule that cues the response of a cell to the stimulus of other cells.

signal transduction Process whereby a cell converts an extracellular signal into a biochemical response.

Mutual recognition between a responsive cell and a hormone in the extracellular fluid takes place at their dynamic boundary, the cell surface membrane. This fundamental process, applicable to agonists of diverse structure, lipid as well as peptide, leads to a chain of secondary mechanisms that amplify the impact of selective interception of hormone by receptor. It is now possible to integrate this primary step in the coordinated events that constitute the cellular response.

I. INTRODUCTION

It seems axiomatic that mutual recognition between an agonist in the extracellular fluid and a responsive cell must take place at the cell surface membrane. As first envisioned in the immunologic context by Paul Ehrlich (Fig. 1), extracellular hormones of varied structure, lipid as well as peptide, are now understood to interact with receptors at the outer cell membrane. Examples of the lines of evidence that support this concept, and the criteria for identifying the selectivity, specificity, and affinity of such interaction between the several steroid classes and the specialized protein components of the target cell surface, are presented in this article.

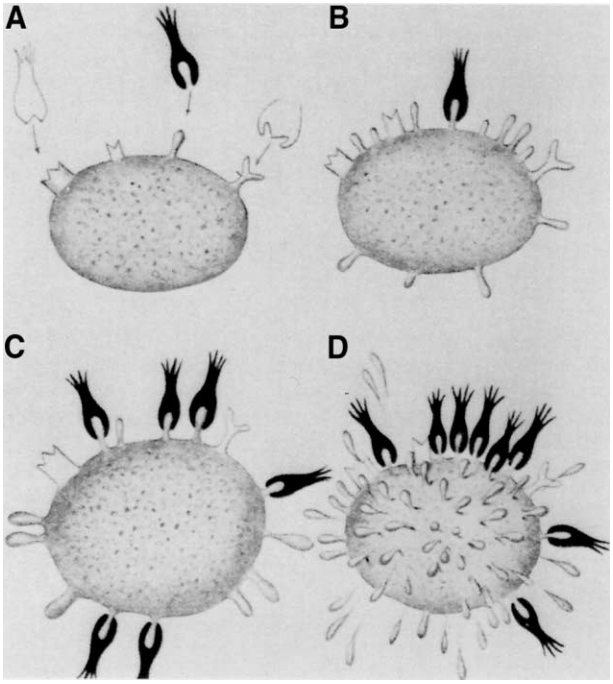

FIGURE 1 Diagrammatic representation of the "side chain" theory to illustrate Ehrlich's concept of specific recognition sites at the cell surface. (A) Complementarity of agonist and receptor. (B) Specific and reversible binding of agonist only to its own receptor. (C) The bound form of receptor is unavailable for providing negative feedback toward its own biosynthesis. (D) This results in overcorrections by regeneration. Reprinted with permission from Ehrlich (1957), with minor paraphrasing of the caption, from the Croonian Lecture, delivered to the Royal Society on 22 March, 1900.

Although the cellular actions of steroid hormones were once postulated to be regulated exclusively by receptors in the cell nucleus, thus permitting selective transcription after ligand binding, this genomic mechanism generally requires hours or days before the effects of hormone exposure are evident. In addition to the latter pathway, steroids also elicit rapid cell responses within seconds of administration. The time course of these acute events lends support to the conclusion that they do not require new gene transcription. Rather, many rapid effects of steroids, termed "nongenomic," appear to be due to specific recognition of hormone at the cell membrane. Hormone–receptor interactions at the surface membrane can initiate a cascade of signaling events that may regulate many cellular functions, both acute and prolonged.

Entry of a steroid hormone into its target cell can be astonishingly swift and requires special strategies to demonstrate its temporal dissociation from binding proper. In some cases, receptor-mediated entry appears to be closely followed by partition into the several intracellular compartments. The available means of such ultrarapid penetration and dissemination are outlined in the following discussions, as is the potential significance of sequential translocation in the overall cellular response. Accordingly, the proportion of total receptor, localized at a given moment in any cellular compartment, whether plasmalemmal, cytostructural, or nuclear, reflects the metabolic history of the receptive cell.

Finally, it is the purpose of this article to survey the transduction mechanisms available to a receptive cell for amplifying and extending the impact of initial surface perturbation by hormone capture. Through such means of communication of the primary hormonal signal, the resultant structural and functional modulations of the several intracellular compartments, including the nuclear compartment, can be coordinated into the totality of the cellular response.

II. SUPRAMOLECULAR ORGANIZATION OF THE SURFACE MEMBRANE AND OCCURRENCE OF STEROID RECEPTORS

Steroid uptake in cells may occur by passive or facilitated diffusion across the plasma membrane or by one of several endocytotic mechanisms. Biophysical studies demonstrate that most steroid hormones are lipophilic molecules that partition deep within the hydrocarbon core of lipid bilayer membranes, even those devoid of receptor proteins. However, steroid hormone agonists also appear to enter target cells by a membrane-mediated process that is saturable and temperature dependent.

A. Membrane Models: from Fluid Mosaic to Lipid Rafts and Signaling Platforms

To understand the nature of steroid receptor association with cell membranes, it is important to consider current concepts of supramolecular organization of the membrane (Fig. 2). The present view of the lateral organization of plasma membrane constituents has been revised significantly from the original fluid mosaic model, wherein membrane proteins were considered to diffuse freely in a sea of lipid, above a critical temperature of 15 °C. With the wide array of molecules known to interact rapidly in receptor signaling, it is difficult to imagine how specific signal transduction could occur if components moved randomly in the lipid bilayer. Rather, new findings suggest the existence of membrane macro- and

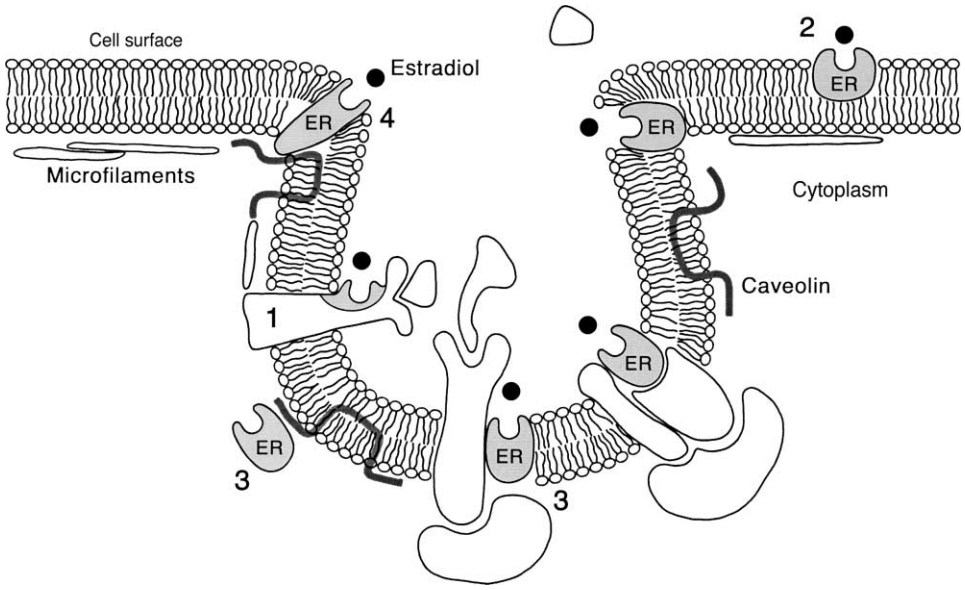

FIGURE 2 Supramolecular organization of plasma membrane and occurrence of estrogen receptors. A model of the surface membrane from an estrogen-responsive cell in the region of a caveolar structure is depicted. Estradiol may interact with one of several different forms of membrane-associated estrogen receptors (ERs). The precise physical and full structural characterization of these molecules remains to be established. The molecules may be known membrane components, such as enzymes, G-proteins, ion channels, or receptors for nonsteroid ligands, with previously unrecognized binding sites for steroids (1); new isoforms of steroid hormone receptors (2); "classical" receptors complexed with other membrane-associated proteins (3); or novel membrane proteins (4). Similar to the ER, the androgen receptor colocalizes with caveolin-rich membrane fractions from target cells, and the androgen receptor directly interacts with caveolin-1 in an androgen-dependent process, providing evidence for a potential physiological role of this interaction. Of note, alternatively spliced transcripts of several steroid receptors occur, and these variant receptors give rise to proteins of different molecular size and, possibly, to modified properties. Membrane insertion of receptors in primary transcript form would likely require one or more hydrophobic regions. ER-α, for example, contains several hydrophobic regions, but it is unknown whether these are sufficient for disposition as an integral membrane protein. Posttranslational modification of receptor protein leading to cell membrane targeting may also occur, including phosphorylation, glycosylation, and/or addition of lipid anchors or other alterations, such as palmitoylation or myristolation.

microdomains that serve to concentrate key signaling molecules for efficient coupling to effectors. The concept of a "signaling platform" has been advanced to characterize a structure in which many different membrane-associated components are assembled in a coordinated fashion.

Evidence now indicates that plasma membrane microdomains, termed "lipid rafts," arise from the phase behavior of lipid components. In the fluid bilayer of the membrane, different lipid species are asymmetrically distributed over exoplasmic and cytoplasmic leaflets of the membrane. In particular, long, saturated acyl chains of sphingolipids cluster in the presence of cholesterol to form a liquid-ordered phase, resistant to detergent solubilization. Saturated acyl chains of glycosylphosphatidylinositol (GPI)-anchored proteins, as well as transmembrane proteins and certain tyrosine kinases, can also occur within these lipid domains. Raft association may concentrate receptors for interaction with ligands and effectors on either side of the membrane, thus facilitating binding during signaling and suppressing inappropriate cross talk between otherwise conflicting signal transduction pathways.

B. Endocytotic Adaptations

Caveolae, literally "little caves," are more specialized raft microdomains that also concentrate and assemble components of several signal transduction pathways (Fig. 2). These membrane structures can be invaginated, flat within the plane of the membrane, detached vesicles, or may be fused together to form grapelike structures and tubules (Fig. 3). Like lipid rafts, caveolae are rich in cholesterol and sphingolipids, but, unlike rafts, they are lined intracellularly with clusters of caveolin protein, a cholesterol-binding molecule that contributes to membrane lipid

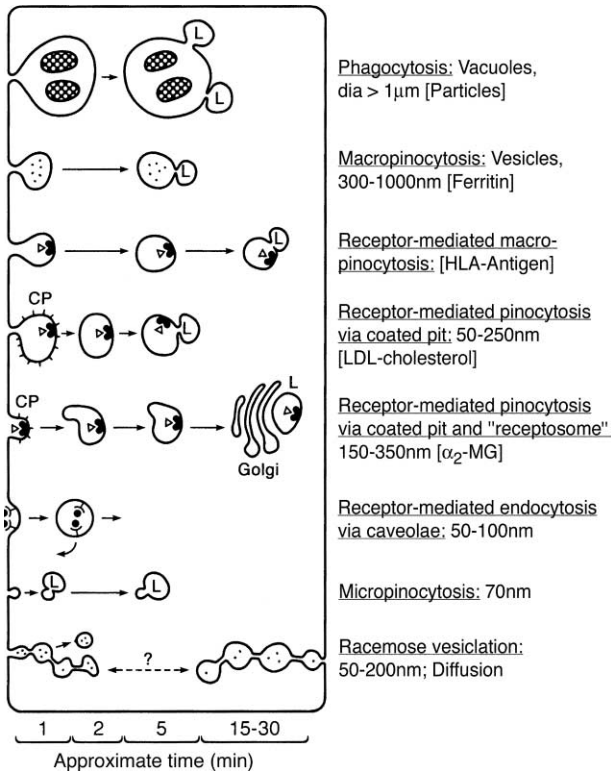

FIGURE 3 Schematic representation of pathways for the internalization of extracellular agonists. Revised from Szego and Pietras (1984), with permission.

organization. The growing list of caveolae-associated molecules constitutes a "who's who" of cell signaling, including receptor tyrosine kinases, G-protein-coupled receptors, protein kinase C, components of the mitogen-activated protein (MAP) kinase pathway, and endothelial nitric oxide synthase (eNOS). In one such example, subpopulations of estrogen receptors are localized to caveolae in endothelial cells, and, in plasma membrane caveolae isolated from these cells, estradiol directly stimulates its receptors, which are coupled to eNOS in a functional signaling module to regulate the local calcium environment and blood vessel contractility.

Clathrin-coated pits are independent membrane invaginations, decorated intracellularly with the protein clathrin. They function in endocytosis of nutrients and certain receptors, such as in receptor-mediated uptake of low-density lipoprotein–cholesterol complexes, and also play an important role in signal transduction. Some agonists may be internalized via either clathrin-coated pits or caveolae, with one pathway apparently providing a default entry mechanism for the other under certain conditions.

Raft-dependent signaling is often coupled with endocytotic uptake mechanisms involving rafts as well as caveolae. Also important in this scheme is the actin cytoskeleton, considered to provide constraints for lateral mobility of lipid microdomains and to function in endocytotic trafficking. Endocytosis is a diverse set of processes that promote internalization of specialized regions of the plasma membrane as well as small amounts of extracellular fluid (Fig. 3). The best understood form of endocytosis occurs at clathrin-coated pits and involves clathrin and the dynamin GTPase, which promotes pinching-off of the endocytotic vesicle. Caveolae also play an important role in potocytosis, a mechanism for uptake of small molecules across the plasma membrane. Finally, some cell types can internalize larger amounts of fluid by macropinocytosis or can take in particulates by phagocytosis (Fig. 3). In most cells, internalized materials are first delivered to early sorting endosomes, which may mature into or be transferred to late endosomes, and, ultimately, to lysosomes. The potential role of the ubiquitin–proteosome pathway in this process remains to be determined.

C. Steroid Receptor Variability

The precise nature of the association of steroid receptors with plasma membranes remains elusive, primarily because full structural characterization of these molecules is incomplete. The task of identifying these membrane-associated steroid receptors is made more challenging by the recent detection of multiple transcript variants of classical "intracellular" steroid receptors, and, in the case of estrogen receptor-α (ER-α), by discovery of a structurally related estrogen receptor form, estrogen receptor-β (ER-β), which is the product of a different gene. Both ER-α and ER-β gene products are expressed in membranes, and both receptors are capable of activating acute and late phases of cellular responses through activation of signal transduction cascades.

Estrogen receptor from target cell plasma membranes is a protein species with high-affinity, saturable binding specific for estradiol. In addition, antibodies to nuclear ER-α recognize surface sites, suggesting that membrane ER has antigenic homology with nuclear ER. Indeed, recent work reveals that membrane and nuclear ERs may be derived from a single transcript. Likewise, properties of membrane glucocorticoid receptors closely resemble those of the intracellular receptor. On the other hand, properties

of the aldosterone receptor, as well as those of the plasma membrane receptor for 1,25$(OH)_2$vitamin D_3, suggest that membrane receptors for these steroids may be distinct from their "classical" intracellular counterparts. Collectively, current findings suggest that membrane receptors for steroid hormones are, in certain instances, transcriptional copies or variants of nuclear receptors, and, in other instances, are products apparently unrelated to these.

Steroid receptors in membranes may also be contained in multimeric complexes with other transmembrane molecules coupled to specific signaling cascades (Fig. 2). In the case of retinoic acid, there may be binding to known membrane proteins, such as mannose 6-phosphate/insulin-like growth factor-II (IGF-II) receptors. Likewise, progesterone congeners bind with moderate affinity to γ-aminobutyric acid type A ($GABA_A$) receptors that comprise ligand-gated ion channel complexes, and pharmacologic levels of estradiol bind with regulatory subunits of independent ion channels in membranes, thus supporting the view that some effects of steroid hormones, at least at high concentration, may be mediated by known membrane receptors with previously unrecognized steroid-binding sites. Finally, despite subtotal ER-α gene knockout, some rapid actions of estradiol still prevail. As with the mixed steroid hormone-binding protein systems known to occur within cells and in their extracellular fluids, it may well be that multiple forms of protein receptors for steroids coexist in plasma membranes, thus complicating efforts to isolate and characterize the individual binding species in this cell compartment. Nevertheless, available evidence suggests that a finite portion of cellular steroid receptors is associated with signaling platforms in specialized microdomains of the plasma membrane.

III. SPECIFIC BINDING OF STEROID HORMONES TO SURFACE MEMBRANES OF RESPONSIVE CELLS

As postulated by Ehrlich in the Croonian Lecture to the Royal Society more than a century ago, the outer surface of a responsive cell is equipped with specialized components, which exhibit exquisite discriminatory capacity toward potential agonist when molecular conformations are mutually complementary (cf. Fig. 1). Indeed, in evolutionary terms, steroid recognition at the surface membrane appears to have been the primary response pathway of the primitive cell. In plant cells, the only known response pathway to steroids is via a membrane-associated receptor that regulates numerous functions in the intracellular economy, including growth and development. In the case of steroid hormones that influence the functions of eukaryotic cells, the fact that such receptor molecules are poised to extract agonist from its plasma protein carrier is directly attributable to primary evidence for noncovalent, and thus reversible, steroid–protein interaction. This property forms the basis for competitive displacement of ligand by excess, or by conformationally competent congeners.

The concept of specific membrane-associated binding sites for steroid hormones has been supported by rigorously controlled observations from many independent laboratories. Evidence is now available for the extended steroid family, which includes the retinoids, thyroid hormone, and digitalis-like steroids (cf. Table 1). The methodologic approaches have also been broad. Representative examples of several of these approaches for estrogen are presented in Figs. 4–6. However, comparable observations are available for other members of the steroid family, especially adrenocortical steroids and vitamin D metabolites (Table 2). Thus, from physical, ultrastructural, immunologic, and molecular probes, as well as direct kinetic analyses of specific binding of isotopically labeled steroid to the surfaces of isolated target cells or to their purified plasma membrane fractions, a large body of evidence now supports this view. Such membrane proteins constitute a fraction of total receptor molecules available at any given moment in the cellular target and have occasionally been overlooked when methods of sufficient sensitivity were not utilized and when signal-to-noise ratio was not taken into account. Especially instructive data are now available for pinpointing the surface orientation of specific receptor proteins for given steroid hormones at their cellular targets (Figs. 4–6). Recent ultrastructural studies have revealed extranuclear immunoreactivity for ER-α associated with membrane sites along dendritic spines and axon terminals of neurons (Fig. 6). Moreover, Fig. 5 reveals incipient receptor-mediated endocytosis in Hep G2 cells. These modern findings confirm the observations of Williams and Baba in 1967, at which time they reported, using electron microscopy and admitted excess of labeled steroids, that [^{3}H]aldosterone and [^{3}H]cortisol associated with plasma membranes of their respective target cells. It is uncanny that report of abrupt stimulation of membrane-associated adenylate

TABLE 1 General, Receptor-Mediated Functions of the Steroid Hormone Superfamily

Hormone	Function
Estrogen	Growth and development of reproductive targets, including breast, bone, liver, and cardiovascular system
Androgen	Reproductive tract functions, patterns of hair growth, and influences on brain and libido in both sexes
Progesterone	Components of reproductive function and behavior, meiosis in oocytes, and acrosome reaction in sperm
Glucocorticoids	Maintenance of integrity of cell membranes; metabolic functions in protein mobilization and gluconeogenesis; neurone signaling; immune and inflammatory reactions, and apoptosis
Aldosterone	Promotion of reabsorption of sodium and excretion of potassium in kidney, colon, and urinary bladder; acute effects on cardiac function and on sodium transport in smooth muscle
Digitalis-like	Inotropic and chronotropic effects on heart; inhibition of Na^+, K^+-ATPase in this and many other tissues
Vitamin D	Regulation of Ca^{2+} and phosphate homeostasis; promotion of differentiation of many cell types
Retinoids	Control of cell growth during embryonic development; antioxidant function promotes integrity of epithelial and many other tissues
Thyroid hormone	Energy expenditure; embryonic development and postnatal maturation of various tissues, including bone and brain

cyclase activity by physiological levels of estrogen appeared in the same year, but these data, as fine red wine, required many years of aging before appealing to the taste of the wider scientific community.

Presently, there has been intensely renewed interest in documenting specific steroid binding to target cell membranes, and current extensions of these data are ongoing. One salient fact emerges from the combined observations, namely, that there is a striking parallel between the initial encounter of steroid, as well as peptide, agonist with the surface of its responsive cell. Such function, critical to unfolding of an orderly sequence of succeeding events through receptor-mediated coupling to further metabolic signals (see below), is also shared by many other regulatory agents, including those that promote growth and development of their target cells, such as the phytohemagglutinins in transformation of small lymphocytes, and, indeed, cytokines generally.

It is important to note emerging data, which suggest that different structural conformations of a given steroid hormone may act as specific agonists for selected cellular response pathways. For example, it is suggested that $1\alpha,25(OH)_2$ vitamin D_3 produces biologic responses through two distinct receptors, one predominant in the surface membrane and the other predominant in the cell nucleus, which are able to recognize different shapes of the conformationally flexible molecule. Accordingly, the functional significance of agonist–receptor interactions at the target cell surface lies in the potential for selective pathway engagement for propagation of this primary signal.

IV. CONSEQUENCES OF RECEPTOR OCCUPANCY: ACTIVATION OF SIGNAL TRANSDUCTION PATHWAYS

Repercussions of receptor activation on the cell surface may be communicated to the farthest reaches of cell structure and function, including the transcriptional events that will eventually unfold in the nucleus. Manifold activities that are amplified over the relatively prolonged intervening period, from receptor binding to transcription, have been studied and documented for decades. In the case of estrogen, which has received the most attention among the steroid hormones in this regard, the time course of such events encompasses several orders of magnitude, leading to its general description as a continuum (Figs. 7 and 8). A similar temporal distribution pattern prevails for responses to glucocorticoids and vitamin D metabolites (Table 2).

Propagation of the minimal information, from the moment of primary capture of hormone at the cell surface, through an orderly cascade of intermediary reactions in other compartments, to the ultimate differentiation or division of the cell so mobilized, begins through recruitment of virtually instantaneous and closely-linked processes within the affected membrane and in its immediate subplasmalemmal environment. Receptor-mediated signal transduction

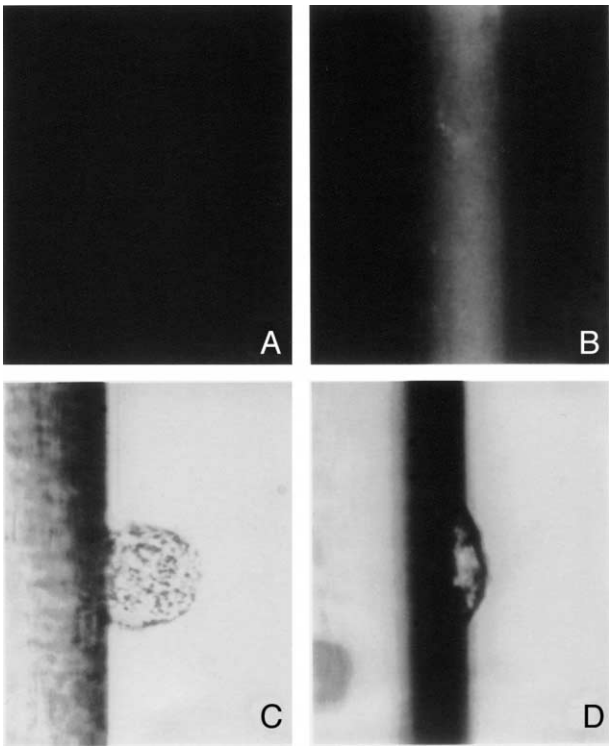

FIGURE 4 Binding of fluorescein isothiocyanate (FITC)-labeled estradiol antiserum and isolated liver cells to estradiol immobilized by covalent linkage to albumin-derivatized nylon fibers. Incubation was conducted at 22 °C with (A) FITC-labeled nonimmune serum or (B) estrogen antiserum, the latter demonstrating availability of the steroid at the fiber surface, as shown in darkfield-UV fluorescence micrographs (original magnification × 100). In independent experiments (C and D), cells derived from liver were incubated with the derivatized fibers in Ca^{2+}/Mg^{2+}-free Ringer solution. Washed fibers with bound cells were photographed with an immersion lens. Some cells appear fairly rounded, whereas others tend to flatten out at the fiber surface (× 850). Reprinted from Pietras and Szego (1979), with permission, *Journal of Cellular Physiology* © 1979.

responses have been identified for essentially all the steroid hormones (Table 3).

A. An Orderly Cascade

It is significant to note the time course of the cellular activities, beginning with the earliest indications of membrane perturbation, which occur within seconds or less, as is seen in the nucleotide cyclase reactions. Here, again, is a significant example of a mechanism shared by steroid and peptide agonists that is particularly well illustrated in neural responses. Acute alterations in Ca^{2+} and in Na^{+}/K^{+} flux are likewise rapid and occur within a framework of wide differences in agonist and end organ. Abrupt changes in phosphorylation mechanisms, some of which are Ca^{2+} dependent, are also recruited. Many of these changes in the cytoplasmic microenvironment, in turn, have profound effects on enzymatic reactions and on cytologic structure, with special reference to protein folding. Thus, amplification of primary hormonal signal is achieved with great conservation of energy and without further input of mass, through a limited number of receptor-mediated transduction mechanisms, linked, in part, through heterotrimeric G-proteins that are integral to the plasma membrane. These remarkably conserved features of hormone action are covered in depth elsewhere within this volume.

In the case of some hormonal responses, interaction at the surface membrane may be sufficient to elicit an alteration in cell function. For example, estradiol can directly stimulate protein kinase C activity in membranes isolated from chondrocytes, and the steroid also modulates calcium-dependent

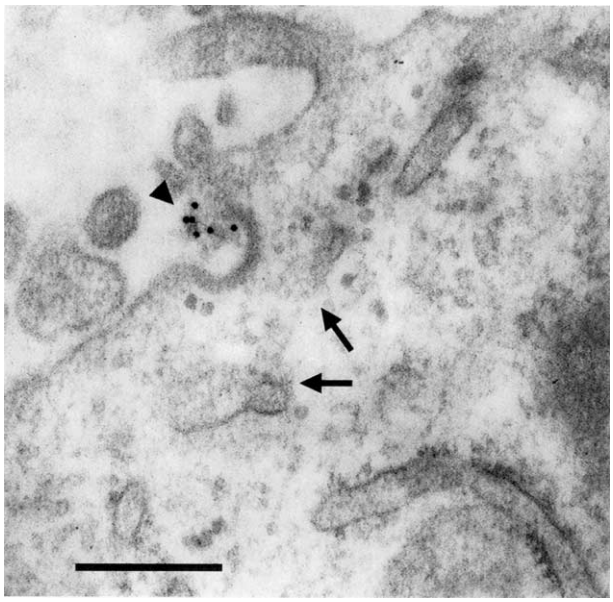

FIGURE 5 Electron microscopic visualization of receptor-mediated specific binding and internalization of 17β-estradiol-17-hemisuccinate:bovine serum albumin (BSA) that had been adsorbed to colloidal gold (E17 BSA:Au) at surfaces of human hepatoblastoma cells. Note binding of ligand to the plasma membrane directly over a potential clathrin-coated endocytotic pit (arrowhead) and intracellular tubulovesicular structures beneath it (small arrows). In control preparations with BSA:Au (lacking derivatization with estrogen; not shown), there is minimal internalization, despite the presence of BSA:Au in abundant extracellular concentrations. eNOS activity associated with its receptor in isolated plasma membranes from endothelial cells. Moreover, estrogens may enhance growth of mammary tumor cells, largely independent of estrogen-responsive element (ERE)-dependent transcription, by stimulating membrane-associated mitogen-activated protein (MAP) kinase pathways. Ligand-independent activation of steroid hormone receptors also occurs and may represent a more primitive response pathway, whereby cross-communication with peptide signaling systems in the cell can directly modulate the activity of steroid hormone receptors. For example, estrogen receptor can be activated in the absence of estradiol through phosphorylation by epidermal growth factor (EGF)-stimulated MAP kinase. Any comprehensive model of steroid hormone action must account for these important cellular interactions.

B. Transitory Alterations in Cellular Architecture and Translocation of Receptor

Among the numerous, acute responses to estrogen recognition in uterine preparations are brief, transitory alterations in cellular architecture, beyond the clear evidence of regional perturbation (cf. Fig. 7); these include incipient vesiculation within the membrane (cf. Fig. 5). These cytoplasmic responses occur within seconds or less, and comprise striking transitory reduction of arrays of microtubules and microfilaments. Indeed, there is considerable evidence that microtubules and the actin cytoskeleton of the cell play an important role in endocytotic trafficking and concomitant signal transduction. In some cases, such remarkable early modifications of target cell structure may play a key role in signal propagation by serving to modulate the relative viscosity of the medium in which the hormone:receptor [H:R] complex is translocated toward, and into, the nuclear compartment.

The microtubular apparatus, with its arboreal array spanning the subplasmalemma and perinuclear/Golgi regions, has been implicated even more directly in the translocation mechanism for the vitamin D_3 receptor in mouse osteoblasts, as well as in the case of cellular targets to glucocorticoids. There are now clear indications that, at least for some

FIGURE 6 Electron microscopic demonstration of localization of immunoreactivity to peroxidase-labeled receptor for alpha isoform of estrogen receptor (ERα) in the hippocampal formation of proestrous rats. Both genomic and nongenomic functions are implicit in the distribution of immunoreactivity. (A) Label is seen throughout the nucleus (N) of a neuron in the hilus of the dentate gyrus, as well as a few patches in the cytoplasm (arrowhead), and also at the plasmalemma (small arrows). (B) In another cell, a dense patch of immunoreactivity is seen in the nuclear envelope; (C) an intensely labeled endosome (En) occurs in the perinuclear cytoplasm near the Golgi apparatus (G). Additional ERα labeling was affiliated with the perikaryal plasmalemma and is apparent in dense patches of reaction product adjacent to several cytoplasmic organelles (B and C). Extranuclear sites revealed with the present methods had not been identified previously by light microscopy. Scale bars, 0.5 μm. Reprinted from Milner *et al.* (2001), by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons.

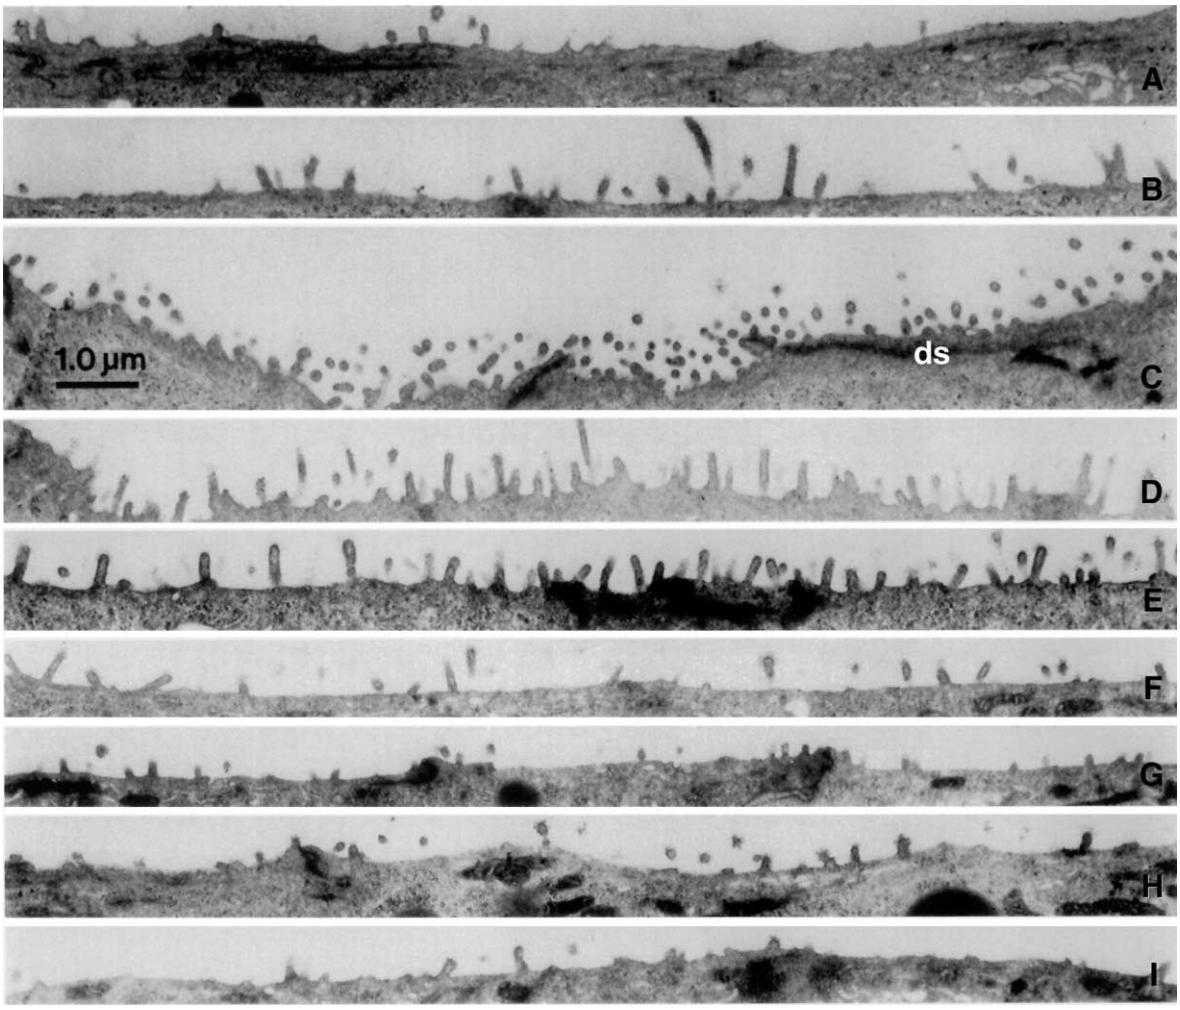

FIGURE 7 Low-magnification electron micrographic views of lumenal surfaces of uterine epithelial cells of ovariectomized rats at brief intervals after iv administration of control vehicle (A) or $E_2\beta$, 0.5 µg/100 g body wt (B–I). The relative paucity of microvilli in a control preparation is in contrast to the striking onset and progressive enhancement of these structures at 35 (B), 45 (C), 80 (D), and 120 (E) s after exposure to hormone *in vivo*. (F–I) Cell surfaces at 5, 10, 15, and 30 min, sequentially, reveal the remarkable subsidence of the mivrovillus activity. Thus, by 30 min after estrogen (I), the degree of lumenal surface investment with microvilli closely resembles the relatively quiescent control state (A). ds, Desmosomes. steroid hormones, a significant portion of the hormone:receptor complex occurs in vesicular form (cf. Figs. 5–7), with the potential for fusion with other organelles.

C. Sequential Distribution of Hormone

Because of the extreme speed of entry, the temporal association of steroid hormone with a surface receptor and its ensuing distribution in target cells have been difficult to demonstrate without appropriate precautions to eliminate nonspecific membrane-perturbing influences. These precautions include strict omission of serum and phenol red from media; use of incubation temperatures at 23 °C rather than the customary 37 °C, but not below 15 °C, when lipid components of membranes assume a rigid conformation; and, above all, sampling at very short intervals. Indeed, because of lack of appreciation by many investigators of these precautions, cumulative evidence of such association had been overlooked by some for decades.

An especially telling analysis of the [^{3}H]estradiol-17β translocation mechanism is available, using analytical cell fractionation at progressive time periods, beginning within 10 s of exposure.

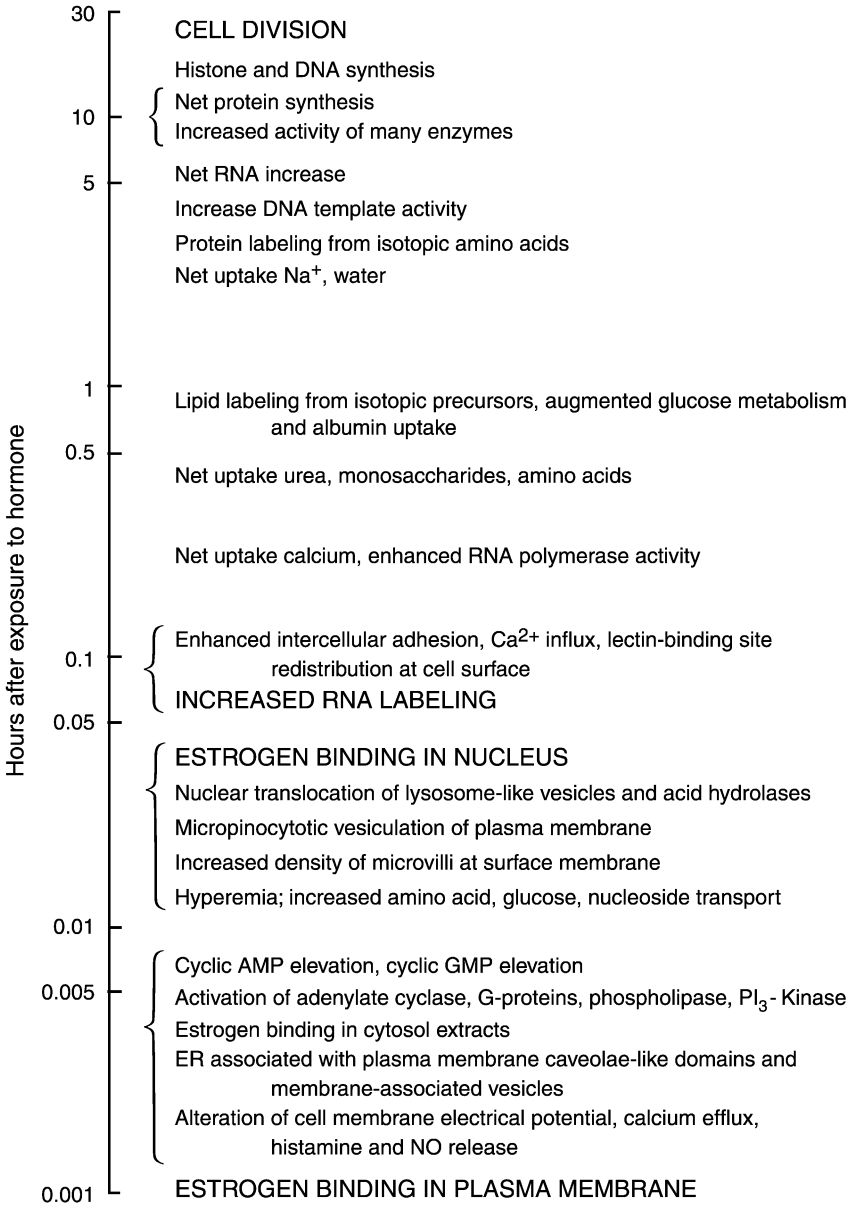

FIGURE 8 Schematic representation of time course of responses of uterus to estradiol-17β. Times shown on the logarithmic scale refer to onset of unequivocal change from baseline values. Thus, times indicated are dependent in part on sensitivities of the various analytic methods applied and on the somewhat arbitrary selection of initial time points for observation in the several experimental protocols. Revised from Szego and Pietras (1984), with permission.

Estradiol-17β interacts specifically with membrane proteins in uterine cells and undergoes rapid internalization in nanometer-sized endocytotic vesicles, resulting in delivery of a portion of the steroid hormone and its associated receptor protein to the cell nucleus and nuclear protein matrix. Quantitative analyses of the postnuclear supernatant prepared from uterine cell homogenates incubated under the strictest estrogen-free conditions indicate that a significant portion of specific estrogen-binding sites is internalized from plasma membranes in vesicular form. Concomitant with a decline in plasmalemmal and presumptive endosomal fractions, a significant amount of labeled hormone occurs in Golgi and lysosomal compartments before the peak in nuclear accumulation. These observations demand further

pursuit with due regard for the scrupulous techniques required.

V. MEMBRANE SIGNALING AND THE CELLULAR RESPONSE TO STEROID HORMONES

A. Compartmentation in the Cellular Economy

Without some form of communication between the events at the cell surface and the relatively remote nucleus, separated as it is from all else in the cell by a double membrane, the coordinated response of growth or differentiation could not be achieved. Indeed, there is rapidly growing evidence that there is close synergism between the receptor-mediated, virtually instantaneous activities at the plasma membrane and their considerably delayed effects within the nucleus. Clearly, mechanisms exist for transfer of information, as well as matériel, between the two major cell compartments.

Separation of potential reactants by structural barriers of variable degree of penetrability is a primitive yet thermodynamically efficient means of maintaining a poised system. Such a system is capable of rapid responses to changes in the environment if specialized surface components can detect and capture minute amounts of specific regulatory agents. In the fullest sense, the steroid-hormone target cell is just such a system.

The initial stages of the primary response may constitute physicochemical alterations in conformation that promote propagation of signal, with the speed of the phase changes reminiscent of the child's game of cat's cradle. The information gap between the cell surface and the boundaries of the other cellular organelles, most notably, the nucleus, is then closed, with variable rates of speed, by a chain of ordered secondary reactions originating from the coupling of liganded receptor to other cell signaling proteins (cf. Figs. 8 and 9).

Now, under certain conditions, these transduced responses, in a closely coordinated system of interdependent pathways, forward the expanded signal toward the nucleus and the enhanced genomic activities to come. There have been significant advances in demonstration of hormone and/or receptor in vesicular form, in close perinuclear array at very early times after surface binding and before substantial concentrations occur within the nucleus. The specific means by which the formidable nuclear barrier is crossed have not yet been identified in the hormonal context. However, there are strong indications of organellar intervention and membrane fusion in hormone:receptor complex transport and, in specific cases, delivery through compound lysosomal pathways. At the same time, the ionic, enzymatic, and energy-generating functions, recruited in coupled fashion in the cytoplasm, prepare the responsive cell for its expanding metabolic requirements.

The genomic hypothesis of steroid hormone action has generally prevailed as the exclusive mechanism since 1961, the year in which the seminal concepts of Jacob and Monod electrified the scientific community. As is presented in other articles in this volume, in the interval between 1961 and the present, extraordinary accomplishments by a broad array of molecular biologists have extended and clarified the details of these concepts for understanding the late nuclear repercussions of a number of steroid hormones at their cellular targets, while unfortunately overlooking the well-documented responses attributable to signal at the cell surface. It was inevitable that the emphasis on the critical and novel activities triggered at the nuclear level would overshadow the parallel observations being made on receptor-mediated signals emanating from the primary recognition site, the cell membrane.

Recent advances now permit greater focus on the acute signals and their systematic transduction. This renewed outlook restores the necessary balance to our understanding of steroid hormone action, and integrates the contribution of each set of functions into a more complete whole (Fig. 9). Moreover, in the case of some hormone responses, the primary interaction at the surface membrane may be sufficient of itself to elicit a cascade of intracellular signals to specifically alter cell function.

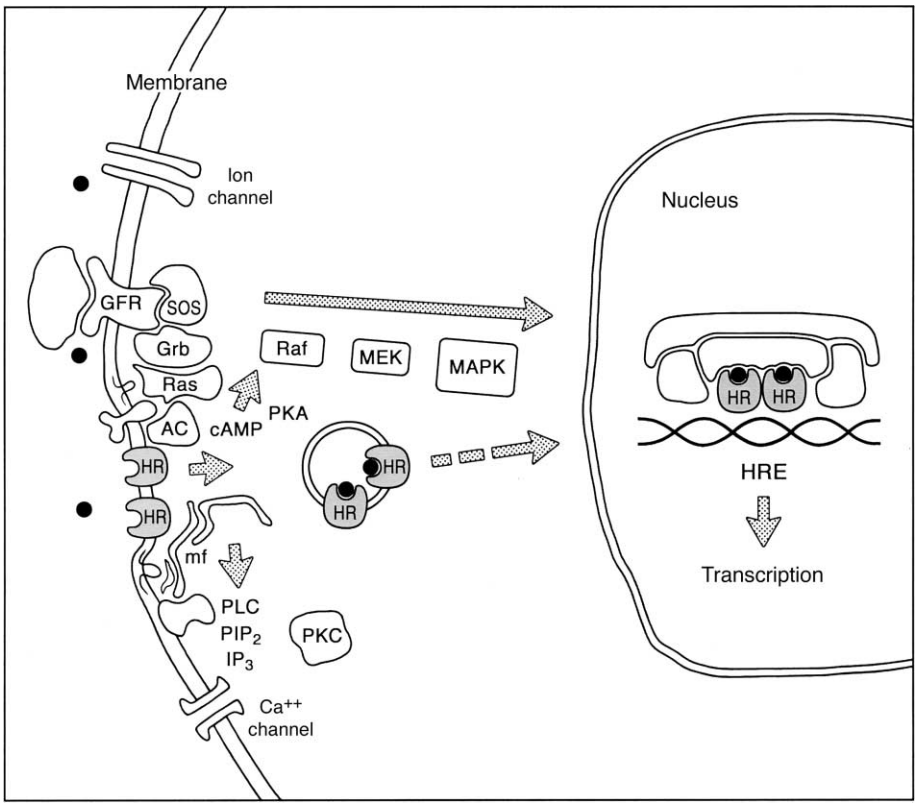

FIGURE 9 The response as continuum: signal transduction mechanisms leading to the full sequence of receptor-mediated responses of the target cell to steroid hormone. Postulated mechanism of action of a steroid hormone (●) in target cells with a steroid hormone receptor (HR) is shown. The steroid ligands first bind to membrane-associated receptors (cf. Fig. 2). The liganded membrane receptor may affect one or more of several pathways, including phospholipase C (PLC) or protein kinase C (PKC) signaling, leading to modulation of ion channels and enhanced flux of ions, notably Ca^{2+}; interaction with peptides or growth factor membrane receptors (GFR) and their immediate signaling partners (SOS, Grb, Ras); or activation of MAP kinase cascades (Raf–MEK–MAPK) or G-proteins and nucleotide cyclases (AC), with generation of cyclic nucleotides (cAMP) and modulation of protein kinases (PKA). These primary membrane interactions may promote physical alteration of the steroid receptor, such as phosphorylation, via steroid-induced or ligand-independent pathways. In some cases, steroid receptors then associate with vesicular structures and microtubule–microfilament (mf) elements in the cell interior and thus gain access to other subcellular compartments. Liganded steroid receptor in the nucleus may promote association of the receptor with co-activator proteins and with specific hormone-responsive elements (HRE) in DNA, leading, in turn, to initiation of selective gene transcription. The wide array of cell responses to steroid hormones may occur as a consequence of synergistic feed-forward circuits, whereby steroids activate cell membrane signaling pathways that act, in turn, to enhance the transcriptional activity of specific receptors in the nucleus.

B. Direct, Membrane-Initiated Responses Seemingly Uncoupled from the Cytoplasmic Cascade: The Dual Functions of Surface Receptor Activation

What is not yet clear, except under the special circumstances noted below, is the question of the inexorability of the full sequence of transduction steps from cell surface recognition to genomic activation, and, thereby, to growth or differentiation. Is there a briefer, less extensive pathway—essentially only an abbreviated sequence—that leads to altered cell functions, including those related to the increase in number of osmotically-active particles at a very early stage of structural changes in membrane "permeability"? As already noted briefly, one such example that comes immediately to mind is the localized liberation of nitric oxide, which is secondary to an instantaneous surge of Ca^{2+} and which occurs in response of endothelia to estrogen; these coupled events result in rapid vasodilation, thus clearly bypassing the hours-long, metabolically

expensive transduction pathway leading to nuclear arousal. Such a truncated pathway may parallel only one or two early steps of the full sequential transduction route. The local effects of estrogen on electrophysiological activities of neurons are another obvious case in point. In the instances noted, there is distinct evolutionary advantage to such a shortcut. In fact, there are circumstances currently being identified, indicating that the two response-sequence stages, full and partial, coexist side by side, thus supporting acute, as well as delayed, responses to a surface signal, independently and in parallel.

Accordingly, the functions of the surface receptor are twofold. Both lead to coordination of the activities of more distal organelles. One such function is *complementary* to the more remote and time-delayed events at the genome, through communication of information, both signals and matériel, from the extracellular environment. The second function *supplements* the more delayed and metabolically demanding activities at the genome, through shortcut of the latter. Instead, signals transduced from receptor engagement of steroid ligand at the external cell surface are converted, independently of genomic activities, to sharply immediate and readily reversible stimuli, such as those eliciting changes in nervous activities and vasomotor functions—these being of evolutionary significance for survival. These dual capacities of surface receptor activation underlie perfect adaptation of the receptive cell to the processing of information from its external environment on two independent/interdependent tracks: acute and more prolonged (Fig. 9).

VI. SUMMARY

Rigorously controlled experimental data, originating from the work of investigators dispersed worldwide, demonstrate that steroid hormones are first intercepted by specialized proteins associated with the surface membrane. Recognition occurs by features of mutual structural conformity, as predicted from principles of physics and chemistry applied to cell biology. For estrogen and glucocorticoid, such receptor molecules at the cell surface have been found to share homology with the nuclear forms, whereas this is not the case for vitamin D metabolites, aldosterone, or thyroid hormone in the limited numbers of tissues examined. Such information is generally lacking for other members of the steroid superfamily.

Capture of steroid agonist from the extracellular fluid is attributable to the competitive advantage of the cellular receptor, because its affinity for ligand is several orders of magnitude higher than that of the carrier proteins in the circulation. This demonstrates that agonal:receptor interaction is reversible, and conforms to the laws of mass action.

Once effective concentrations of hormone are so bound, the cell surface undergoes virtually instantaneous but transitory structural reorganization. These primary interactions may trigger a cascade of specific cellular responses. Thereafter, a portion of the hormone:receptor complex is internalized, generally within seconds or less, through one or more endosomal mechanisms.

Communication and coordination among the several specialized cellular organelles of the targeted cell are achieved by signal transduction processes that propel the hormone:receptor complex or other specific membrane-associated signaling partners toward and into the nucleus. These combined activities are succeeded by the late stages of the response continuum at the genomic level. The outcome is the totality of response in the context of the whole cell, through synergic functions of its organellar constituents.

Glossary

genomic A process related to gene transcription and its regulation.

nongenomic A process independent of RNA transcription.

organelle An intracellular, membrane-bounded compartment (e.g., mitochondrion, Golgi, lysosome, endoplasmic reticulum with membrane-bound ribosomes, nucleus) with specialized functions, reflecting division of labor within cells.

receptor-mediated endocytosis Cellular entry of agonist via a specialized region of the cell where receptor molecules, capable of specifically binding hormones, are localized. Such a region may also be rich in specialized proteins, such as caveolin. Induced invaginations may be pinched off from the outer membrane, becoming endosomes—vesicular channels for signal transduction.

signal transduction A signal is a message relayed from one site to another, in the molecular language of the cell.

The primary signal, in the hormonal context, originates from binding of the agonist (active agent, the hormone) to receptor protein at the surface of the target cell. Signal transduction involves message conversion (translation) from one molecular "language" to another, to be "read" elsewhere in the cell—e.g., surface interactions subsequent to hormonal impact lead to abruptly altered intracellular levels of substances with catalytic activities, such as Ca^{2+}, cyclic nucleotides, and phosphokinases (which shuttle phosphate between critical proteins, altering their structure and behavior). Thus, signal transduction, like a molecular relay, advances the hormonal message, both temporally and spatially, among the cell organelles, like a lighted fuse, progressing toward output at the terminal.

steroid A family of lipid structures related to the parent substance, cholesterol, which is modified by enzymes in certain tissues that synthesize highly active products with hormonal functions, such as estrogen and progesterone in ovary, testosterone in testis, and cortisol in the adrenal cortex (see Table 1).

Mineralocorticoid Biosynthesis

EDUARDO N. COZZA AND LAURA B. MATKOVIC
Universidad de Buenos Aires

Biosynthesis of adrenal gland steroid hormones takes place in the adrenal cortex. Adrenal steroid hormones are grouped into three main types, mineralocorticoids, glucocorticoids, and androgens (sex steroid hormones). Mineralocorticoids are synthesized in the zona

glomerulosa, whereas glucocorticoids and sex steroid hormones are synthesized in the zona fasciculata and zona reticularis, respectively. The biosynthetic pathway that leads to production of adrenal steroids begins in all cases with cholesterol.

I. INTRODUCTION

The primary mineralocorticoid in all animal species is aldosterone; the main glucocorticoid, however, depends on the species. In effect, cortisol plays the role of primary glucocorticoid in humans and in porcine and bovine species; the main glucocorticoid in mice and rats is corticosterone. Because cortisol is a 17α-hydroxylated steroid, this glucocorticoid is produced only by species expressing 17α-hydroxylase in the zona fasciculata.

In all cases the biosynthesis of adrenal steroids starts with cholesterol, which is incorporated into adrenal cells through binding of cholesterol-enriched lipoproteins to their specific cellular membrane receptors. These occupied receptors are then internalized. In lipoproteins, cholesterol is largely esterified and is then intracellularly deesterified in lysosomes. Free cholesterol is available for immediate use in steroid biosynthesis or is reesterified and stored in intracellular lipid droplets. Cholesterol can also be synthesized in the adrenal cells from acetate, although this source does not seem to be relevant for steroid biosynthesis.

The biosynthesis of aldosterone in adrenal zona glomerulosa cells is usually divided into early and late pathways. The early pathway reactions wholly transform cholesterol into 11-deoxycorticosterone (DOC); in the late pathway reactions, mitochondria transform DOC into aldosterone.

Free cholesterol, obtained by the action of specific esterases, is incorporated into adrenal mitochondria and is cleaved by mitochondrial (inner membrane facing the matrix) cytochrome P450 side chain cleavage (SCC) via two hydroxylations at positions C-20 and C-22 of the 27-carbon cholesterol molecule; this is followed by excision of a fragment, C-22 to C-26. The product, pregnenolone, is a 21-carbon steroid, the precursor from which all C_{18}, C_{19}, and C_{21} steroids are produced. The numbering of the carbon positions in C_{21} steroids is shown in Fig. 1.

Two kinds of reactions, hydroxylations and dehydrogenations, occur in the metabolic pathways that produce mineralocorticoid hormones from cholesterol. Dehydrogenases catalyze the oxidation of the cholesterol molecule through loss of two

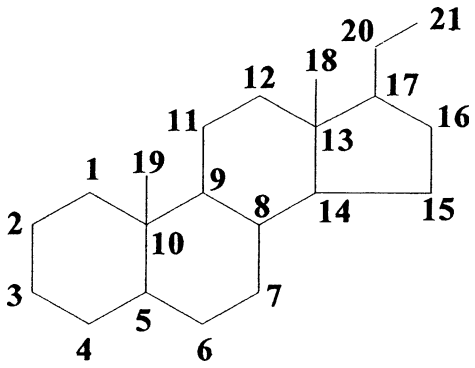

FIGURE 1 Carbon numbering in C_{21} steroids.

hydrogen atoms, using nicotinamide adenine dinucleotide (NAD) as cofactor; dehydrogenases are mainly found in the microsomal subcellular fractions of adrenal cells. Enzymes of the cytochrome P450 family mediate hydroxylations. Some of these P450 cytochromes (P450 SCC, 11,18-hydroxylase/aldosterone synthase, CYP11B1, and CYP11B2) are localized in inner mitochondrial membranes and others (21-hydroxylase, 17α-hydroxylase) are in microsomes.

Cytochrome P450 enzyme systems are protein complexes consisting of an electron transfer chain that takes reduction equivalents from the reduced form of NAD phosphate (NADPH), which is thus converted to NADP, provoking reduction of intermediate specific proteins. These proteins finally pass the electrons to the heme group of cytochrome P450. Trivalent iron in cytochrome P450 molecules is thereby transformed into the ferrous form, which has high affinity for molecular oxygen; divalent iron is then oxidized to the ferric form and iron-bound oxygen is reduced. These steps yield water and a hydroxyl group that is incorporated into the steroid molecule, provoking its oxidation. This last step takes place at the active site of the enzyme (cytochrome P450 protein).

Although this general mechanism is adapted to both microsomal and mitochondrial cytochrome P450-mediated hydroxylations, the intermediate proteins between NADPH and the cytochrome P450 molecule are different. The electron transfer chain for mitochondrial cytochrome P450 contains adrenodoxin reductase, which uses the flavin adenine dinucleotide ($FADH_2/FAD^+$) couple as cofactors and the sulfur protein adrenodoxin; in microsomes only one protein is present. The mitochondrial hydroxylating cycle is shown in Fig. 2.

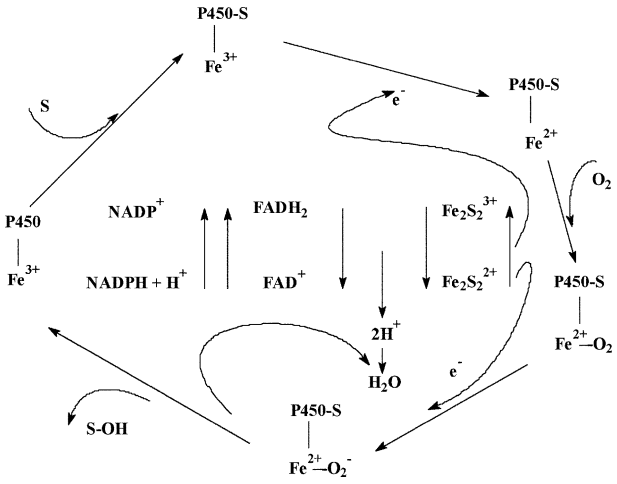

FIGURE 2 Mitochondrial hydroxylating chain. S, Steroid; P450, cytochrome P450.

Cytochrome P450 was so named because the large peak at 420 nm (Soret band due to heme absorbance) of the cytochrome P450 absortion spectrum is shifted to 450 nm in the presence of CO, which binds to reduced heme and competes with oxygen for binding to the iron. As stated before, steroidogenic P450 cytochromes are bound to inner mitochondrial membranes, facing the matrix, or to microsomal membranes. The former can be solubilized in water after treatment with appropriate detergents, whereas microsomal P450 cytochromes are difficult to remove and to obtain in aqueous solution.

II. THE Δ^4 PATHWAY

The biosynthetic pathway from pregnenolone to aldosterone is able to occur through 3β-ol-Δ^5 or 3-keto-Δ^4 pathways, the last one being considered as the normal or main pathway. In the Δ^4 pathway, pregnenolone leaves the mitochondria and is converted to progesterone. The conversion of pregnenolone to progesterone is catalyzed by the enzyme 3β-ol-dehydrogenase Δ^5/Δ^4 isomerase; the process consists of dehydrogenation at the hydroxyl group of C-3 of pregnenolone, yielding a keto group, with subsequent migration of the double bond from C-5–C-6 to C-4–C-5 (product, progesterone). 3β-ol-Dehydrogenase Δ^5/Δ^4 isomerase is the key enzyme for switching from the Δ^5 to the Δ^4 pathway (see below).

As shown in Fig. 3, progesterone is then metabolized to 11-deoxycorticosterone; this is accomplished by microsomal cytochrome P450 21, which introduces a hydroxyl group at position C-21 of the substrate. DOC behaves as a mineralocorticoid, but is not as potent as aldosterone.

The last step of aldosterone production is mitochondrial and involves the conversion of DOC to aldosterone by means of three hydroxylations, one on C-11 and two subsequent hydroxylations on C-18. The overall result of these three hydroxylations is inclusion of a hydroxyl group at C-11, followed by transformation of the methyl group at C-18 to an aldehyde group (aldosterone).

The enzyme involved in the conversion of DOC to aldosterone is species dependent. Bovine and porcine adrenal glands express the cytochrome P450 11β/18-hydroxylase/aldosterone synthase, whereas human, rat, and mouse adrenal glands express cytochrome P450 CYP11B2. Both enzymes catalyze the three hydroxylation steps in glomerulosa cells of each species, but the difference is that, apparently, cytochrome P450 11β/18-hydroxylase/aldosterone synthase is also expressed in bovine and porcine adrenal fasciculata cells, but without producing aldosterone. In other words, aldosterone synthase activity of this enzyme seems to be inhibited in the fasciculata. In contrast, species expressing CYP11B2 in glomerulosa cells produce a different cytochrome P450, CYP11B1, for 11β- and 18-hydroxylations of DOC in adrenal fasciculata cells.

DOC is thus transformed into corticosterone by 11β-hydroxylation and is further hydroxylated at C-18 to yield 18-hydroxycorticosterone, which is finally 18-hydroxylated once again to produce aldosterone. The mechanism by which aldosterone is obtained in this last step deserves special attention. The hypothetical product after one hydroxylation at C-11 and two 18-hydroxylations is 18,18-dihydroxycorticosterone, which has the same oxidation state as aldosterone. The more recognized hypothesis is that this last steroid is largely unstable, suffering loss of water between both hydroxyl groups at C-18, yielding the C-18 aldehyde group of aldosterone.

III. ALTERNATIVE PATHWAYS

Other authors have postulated that the above-stated sequence of hydroxylations, at 11β, C-18, and C-18, followed by dehydration, is flexible, and that there are alternative pathways. One of the possibilities is that DOC is first 18-hydroxylated, yielding 18-hydroxy-11-deoxycorticosterone, followed by hydroxylation at C-11 and C-18, and finally by dehydration. Another likely sequence (Fig. 4) is hydroxylations at 11β and C-18, followed by dehydration, and finally hydroxylation at C-18. In this case, the product after

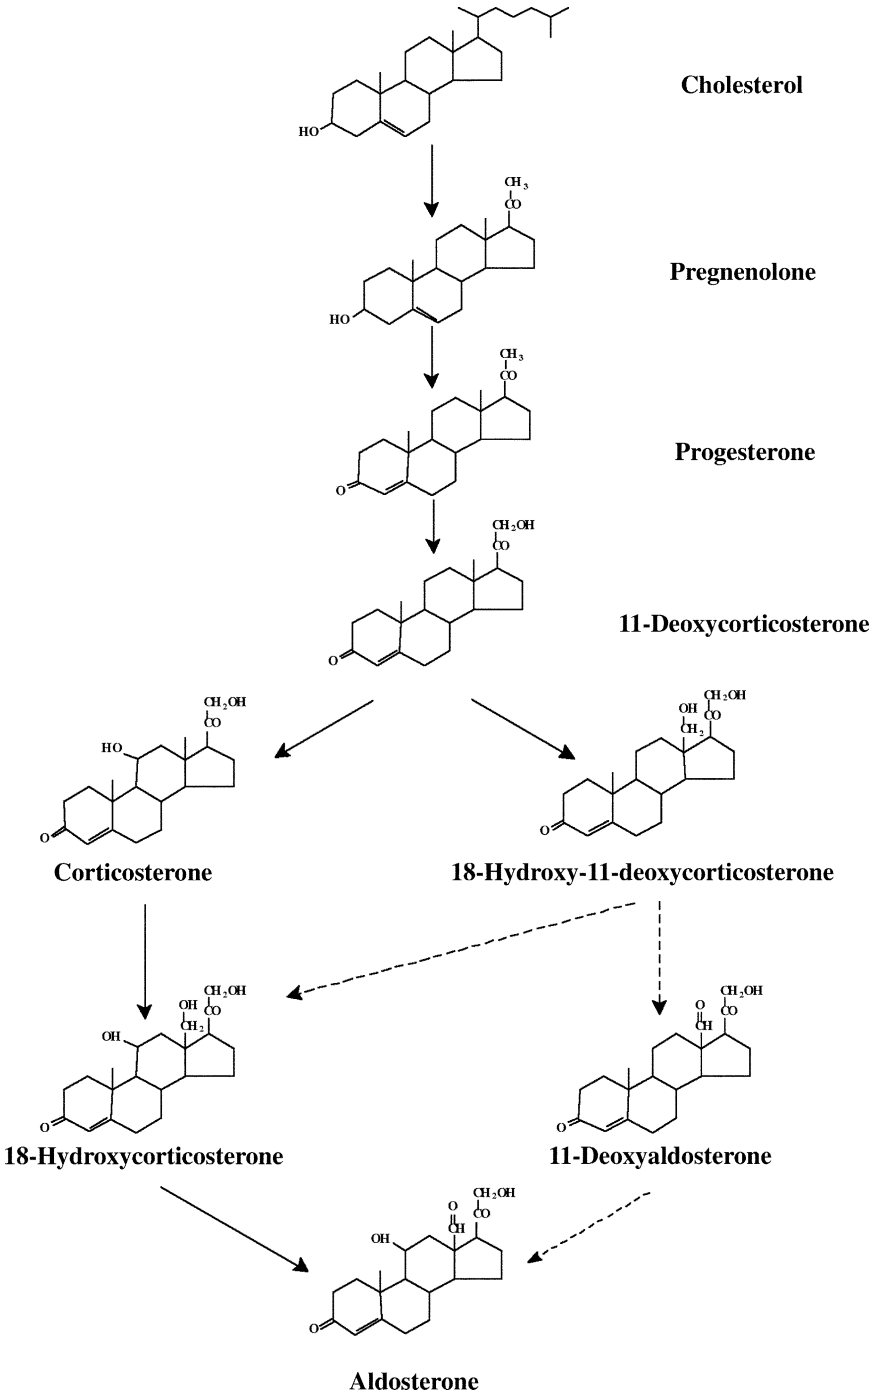

FIGURE 3 Main biosynthetic pathways to aldosterone.

the dehydration step is 11β,18-epoxycorticosterone, also named 18-deoxyaldosterone, which is the substrate for the final 18-hydroxylation. In addition, loss of water occurs by dehydration of hydroxyl groups at C-11 and C-18, rather than of the two hydroxyl groups at C-18.

IV. STRUCTURE OF ALDOSTERONE

Structural analysis of aldosterone, either synthetic or natural, i.e., isolated from incubation media or blood, presents practically no evidence of the presence of a free aldehyde group at C-18. Further, has been

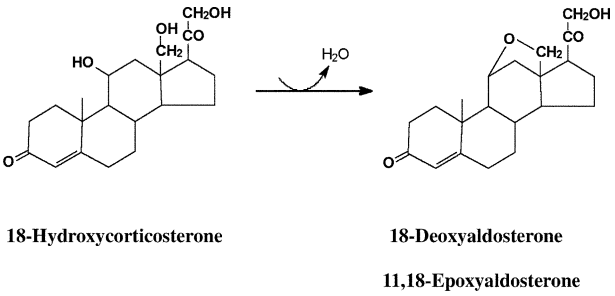

FIGURE 4 Transformation (dehydration) of 18-hydroxycorticosterone.

established by gas/liquid chromatography and mass spectrometry (GLC–MS) and nuclear magnetic resonance (NMR) (^{1}H and ^{13}C) that aldosterone exists in cyclic forms (Fig. 5).

The monocyclic form of aldosterone is obtained by the attack of the negatively charged oxygen atom of the hydroxyl group at C-11 on the positively charged carbon atom of the carbonyl group of the aldehyde at C-18. As a consequence of this reaction 11,18-oxygen-bridged monocyclic aldosterone is obtained, with a hydroxyl group at C-18. It is important to remark that this form of aldosterone could be considered the 18-hydroxylated derivative of 11,18-epoxycorticosterone (see above). In other words, the monocyclic form of aldosterone may be obtained directly, without passing through free-aldehyde stage, by hydroxylation at C-18 of 18-deoxyaldosterone. Within this framework it is possible to hypothesize a relationship between the second alternative biosynthetic pathway mentioned above and the monocyclic form of aldosterone.

The bicyclic form of aldosterone is then obtained when, similar to the previously described process,

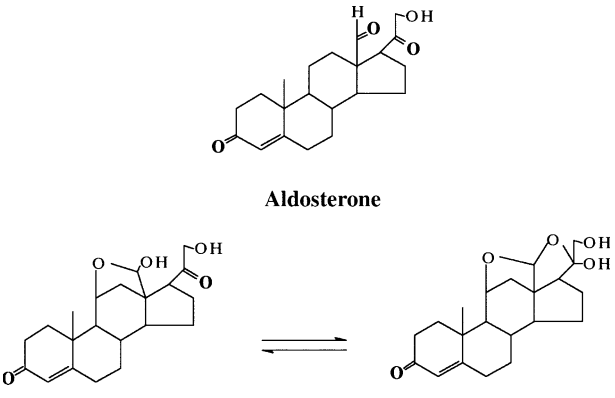

FIGURE 5 Open (upper structure), monocyclic (lower left structure), and bicyclic (lower right structure) forms of aldosterone.

the oxygen of the hydroxyl group at C-18 of the monocyclic structure of aldosterone attacks the carbon of the carbonyl group at C-20. This reaction produces a bicyclic form consisting of a C-11–oxygen–C-18 ring, a C-19–oxygen–C-20 ring, and a hydroxyl group at C-20. This characteristic formation of cyclic structures is not exclusive to aldosterone; other steroids, such as 18-hydroxycorticosterone (a precursor of aldosterone in the main pathway), have the ability to form a C-18-oxygen-C-20 cyclic form, via attack of the hydroxyl group at C-18 on the carbonyl group at C-20, also introducing a hydroxyl group in the cyclic product. Open forms of 18-hydroxycorticosterone are practically nonexistent in ordinary solutions, including biological fluids.

Of particular interest is the behavior of these steroids in acidic media. Aldosterone and 18-hydroxycorticosterone yield dimeric structures when placed in acidic solutions. 18-Hydroxycorticosterone is also converted to 11,18-epoxycorticosterone under the same conditions. All of these products present much higher hydrophobicity, compared to their mother compounds. The relationship between these responses to acidic media and the biosynthesis of mineralocorticoids (aldosterone) is still unclear, but it is possible to speculate that less polar forms of these steroids favor their transport across cellular membranes (plasmatic, microsomal, and mitochondrial). Acidic conditions *in vivo* may exist in particular regions near proton pumps and/or in some organelles. In any case, it is also likely that specific enzymes catalyze the reactions obtained *in vitro* with acidic media.

V. 18-HYDROXYCORTICOSTERONE TO ALDOSTERONE

The conversion of 18-hydroxycorticosterone to aldosterone, i.e., the last step of the main biosynthetic pathway, can be freshly analyzed with respect to the structural characteristics described in the previous section.

18-Hydroxycorticosterone, the immediate precursor of aldosterone, needs a C-18 hydroxylation and dehydration, in order to be converted to the mineralocorticoid. Two questions arise: Do these reactions take place on open or on cyclic forms of the steroids? What is the biosynthetic sequence: C-18 hydroxylation followed by dehydration, or loss of water first, and then hydroxylation at C-18?

The more abundant structure of 18-hydroxycorticosterone is its C-18-oxygen-C-20 cyclic form (Fig. 6), whereas aldosterone and 11,18-epoxycorticosterone have C-11-oxygen-C-18 cyclic structures.

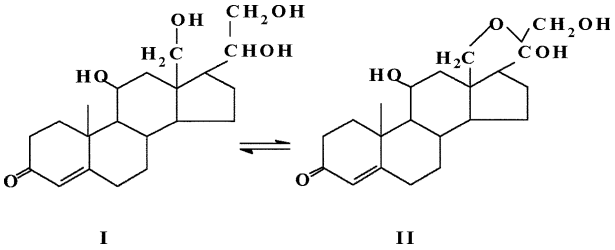

FIGURE 6 Open (I) and monocyclic (II) forms of 18-hydroxycorticosterone.

The previously mentioned alternative pathway described the transformation of 18-hydroxycorticosterone to 11,18-epoxycorticosterone (an acid-catalyzed dehydration) and, finally, aldosterone (C-18 hydroxylation). This alternative pathway is promoted when the 11,18-epoxy form is isolated from incubation media and by the presence of the same oxygen-bridged structures in 11,18-epoxycorticosterone and aldosterone.

VI. 18-OXOCORTISOL AS MINERALOCORTICOID

As a mineralocorticoid, aldosterone is involved in renal sodium reabsorption, as opposed to atrial natriuretic peptide (ANP), which regulates sodium plasma levels. Thus, aldosteronism is a classic cause of hypertension. Glucocorticoid-suppressible aldosteronism (GSA), also known as glucocorticoid-remediable aldosteronism, is characterized by large decreases in aldosterone plasma levels and blood pressure after administration of glucocorticoids (dexamethasone).

18-Oxocortisol isolated from the urine of a subgroup of patients with GSA was found to be responsible for hypertension through its mineralocorticoid activity. The structure and pathway for the biosynthesis of 18-oxocortisol are still unclear. Structure analysis of 18-oxocortisol in comparison with cortisol, corticosterone, and aldosterone eliminated the idea that cortisol, in its conversion to 18-oxocortisol, requires the same transformation pathway that yields aldosterone from corticosterone, i.e., the conversion of the methyl group at C-18 to a C-18 aldehyde (see Fig. 7).

The normal enzymatic group of 17-hydroxylating species regulates adrenal cortex biosynthesis of cortisol in the zona fasciculata and of aldosterone in the zona glomerulosa. Within this framework, the possibility of interaction between cortisol and aldosterone synthase is not obvious. One hypothesis addressing this is based on the existence of a transitional zone between both zonae, in which fasciculata and glomerulosa cells are found together. The larger the transitional zone, the higher the plasma 18-oxocortisol level. This hypothesis is supported by the fact that aldosterone synthase very efficiently transforms cortisol (used as substrate) into 18-oxocortisol in *in vitro* incubations. 18-Hydroxycortisol, a putative intermediate between cortisol and 18-oxocortisol (similar to 18- hydroxycorticosterone in the transformation of corticosterone into aldosterone; see above), was also isolated from those incubations, and exhibited a high degree of mineralocorticoid activity.

A second and more recent and accepted hypothesis is based on the existence of an "abnormal" enzyme in the zona fasciculata; it produces 18-oxocortisol from cortisol, catalyzing the same kind of reactions seen with aldosterone synthase and corticosterone. This enzyme would be the product of a chimeric gene formed by the crossover of genetic material containing the promoter and some

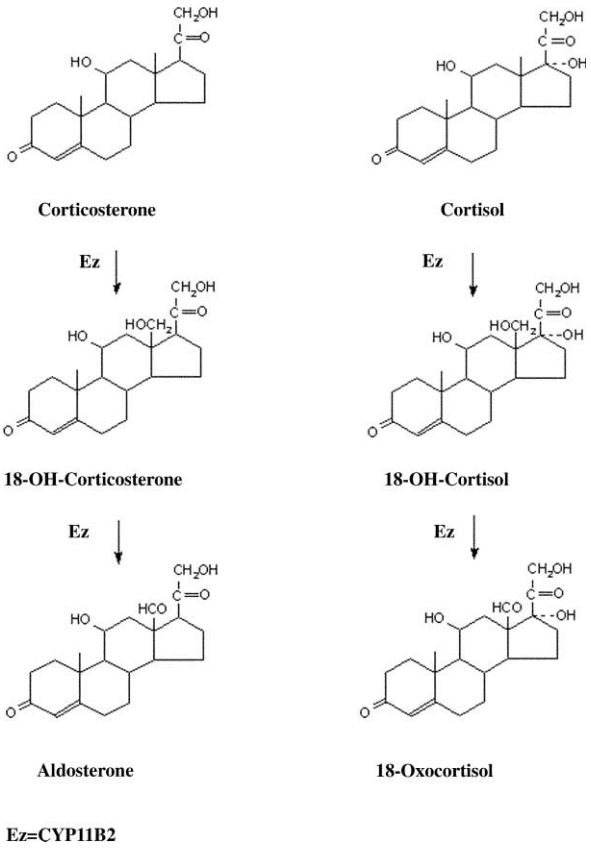

FIGURE 7 Transformation of corticosterone and cortisol to aldosterone and 18-oxocortisol, respectively.

of the first exons of the CYP11B2 gene and some of the last exons of the CYP11B1 gene. As a result of this polymorphic gene, the enzyme obtained contains the catalytic properties of CYP11B2 and the adrenocorticotropic hormone (ACTH)-responsiveregulation of CYP11B1. However, this abnormal enzyme was found only in some patients carrying GSA, and not in all of them. This field is still open to future studies.

VII. THE Δ^5 PATHWAY

In the toad *Bufo arenarum* it has been well demonstrated that aldosterone biosynthesis takes place via a complete 5-ene pathway rather than via the 4-ene pathway mentioned before. The model for this toad species postulates that the main pathway for aldosterone biosynthesis involves the following sequence: cholesterol, pregnenolone, 21-hydroxypregnenolone, 11,21-dihydroxypregnenolone, Δ^5-aldosterone, and aldosterone. This sequence indicates that the main difference between the 4-ene and 5-ene pathways is that, in the 4-ene scheme, the conversion of the 3β-hydroxy-5-ene group to the corresponding 3-oxo-4-ene derivative (catalyzed by the enzyme 3β-hydroxysteroid dehydrogenase/isomerase) takes place at the level of, or close to, pregnenolone, whereas in *B. arenarum* this transformation is the last step in aldosterone biosynthesis. The enzymatic machinery for aldosterone biosynthesis in this amphibian has not yet been elucidated.

VIII. EXTRA-ADRENAL BIOSYNTHESIS OF ALDOSTERONE

The adrenal zona glomerulosa is the main locus for the biosynthesis of aldosterone. However, this mineralocorticoid is also synthesized in other tissues, i.e., in the central nervous system (mainly hippocampus, cerebellum, and brain cortex), heart, kidney, and vascular system. Because the quantities of aldosterone biosynthesized in these tissues are around 100 times lower than in adrenal cortex, it is postulated that the mode of action of the mineralocorticoid in nonadrenal organs is autocrine (acting on the same cell) or paracrine (acting on the closest cells), rather than systemic (being secreted to blood). As an example, aldosterone produced by vascular smooth muscle cells mediates, in an autocrine manner, angiotensin II-stimulated cell proliferation. Independently of the particular role of aldosterone in each case, the general overview of aldosterone biosynthesis is that it is believed to be focused on cardiovascular homeostasis.

The biosynthesis of aldosterone in extra-adrenal tissues has been demonstrated to be carried out by the same enzymatic machinery found in the adrenal zona glomerulosa. Expression and activity of CYP11B2 in the nervous system, heart, kidney, and vascular system have been revealed by different experimental approaches in many animal species.

IX. REGULATION OF ALDOSTERONE BIOSYNTHESIS

Although the main goal of this article is to describe the biosynthesis of aldosterone, a brief discussion of regulation of its formation is in order. The function of aldosterone is to stimulate sodium resorption from the distal renal tubule; water is passively resorbed with the sodium. The major stimuli for aldosterone secretion are hypovolemia (low blood volume), hyponatremia (low serum sodium levels), and low renal perfusion pressure. However, none of these stimuli directly affects the zona glomerulosa; instead, they are channeled through the kidney, because it has the most to lose if blood pressure falls too much. Under this last situation, the kidney is not able to remove wastes from the body.

Juxtaglomerular cells (JCs) possess a sensor for sodium concentration and renal perfusion pressure. Blood volume, however, is monitored by the sympathetic nervous system, which stimulates JCs. Any one of the three parameters sensed by JCs stimulates the secretion of renin from the same cells. Renin is a proteolytic enzyme that converts angiotensinogen, an α_2-globulin made in the liver, to angiotensin I, an inert decapeptide. Then, in the lung, angiotensin-converting enzyme (ACE) removes two amino acids from angiotensin I to form the active angiotensin II. Angiotensin II is a potent vasoconstrictor and stimulator of aldosterone secretion from glomerulosa cells. Thus, low blood pressure, hyponatremia, and hypovolemia are corrected. Angiotensin II may also be converted to angiotensin III by a specific protease at the site of binding to angiotensin II receptors, in adrenal zona glomerulosa cells. Angiotensin III is also active. It is important to remark that intracellular renin/angiotensinogen/ACE/angiotensin II systems (renin/angiotensin system for short) have been reported in several cell systems, including glomerulosa cells.

The basic mechanism of action of angiotensin II in glomerulosa cells involves increased Ca^{2+} influx, and activation of phospholipase C. This last enzyme in turn hydrolyzes phosphoinositol, which is converted

to active inositol 1,4,5-trisphosphate ($InsP_3$) and diacylglycerol (DAG). $InsP_3$ releases Ca^{2+} from intracellular stores, and DAG activates the Ca^{2+} and phospholipid-dependent protein kinase [also named protein kinase C (PKC)]. Although high Ca^{2+} concentrations are accepted as mediators of angiotensin II-stimulated aldosterone secretion, the involvement of PKC is controversial.

When glomerulosa cell cultures are exposed to high concentrations of potassium (6–15 m*M*), the secretion of the mineralocorticoid is significantly augmented. In this case, it is believed that the intracellular renin/angiotensin system in glomerulosa cells is responsible for potassium-induced augmentation of aldosterone secretion. The initial event produced by potassium is probably related to membrane potential, which is mainly dependent on the concentration of sodium and potassium and the transport of ion through the cell membrane. In this respect, Na^+,K^+-ATPase maintains extracellular high concentration of sodium and intracellular high concentration of potassium, and inhibition of this enzyme, for example, by ouabain, provokes depolarization of cell membranes and subsequent activation of voltage-dependent calcium channels, and stimulation of aldosterone secretion. Angiotensin II inhibits Na^+,K^+-ATPase. In the case of extracellular high concentrations of potassium, Na^+,K^+-ATPase is activated. The mechanism by which the intra adrenal renin/angiotensin system is activated is unclear.

Vasopressin [also named antidiuretic hormone (ADH)], adrenomedullin, α-melanocyte-stimulating hormone (α-MSH), and endothelin-1 (ET-1) also stimulate the secretion of aldosterone, but to a much lower degree compared to angiotensin II and potassium. However, according to recent reports, endothelin potentiates angiotensin II- and ACTH-mediated stimulation of aldosterone production.

Adrenocorticotropic hormone, a product of a proopiomelanocortin protein such as MSH, is a potent acute stimulator of aldosterone secretion. ACTH is the main physiological regulator of glucocorticoid biosynthesis, and its secretion is inhibited by high glucocorticoid plasma concentration by means of a feedback mechanism at the level of the pituitary gland. Although from the physiological point of view there is not a clear relationship between ACTH and aldosterone, glomerulosa cells express ACTH receptors at a higher concentration (receptors/cell), compared to the corresponding fasciculata cells. At high levels, ACTH and angiotensin II stimulate aldosterone secretion to a similar degree. However, in long-lasting (chronic) exposures, ACTH reduces aldosterone levels, after the initial augmentation, to control levels, or even below control levels. Histological observations have determined that after chronic treatment with ACTH, the zona glomerulosa is reduced and the zona fasciculata is expanded. This result is not surprising because, for example, ACTH induces 17α-hydroxylase in the adrenal glands of cortisol-producing animal species. In addition, the pathophysiological importance of ACTH in the regulation of mineralocorticoids is underlined by the existence of ACTH-dependent, aldosterone-secreting, adrenal adenomas. The mechanism of action of ACTH involves production of cyclic AMP, and activation of cyclic AMP-dependent protein kinase A (PKA). Other mechanisms involving protein kinase C and extracellular calcium influx are well known and accepted.

Glossary

cytochrome P450 Heme protein with hydroxylase activity. The number 450 refers to the wavelength of maximal absorbance of the CO-cytochrome complex.

Δ^4 pathway Biosynthetic pathway with majority of 3-keto-4-ene structures as intermediates.

Δ^5 pathway Biosynthetic pathway with majority of 3β-ol-5-ene structures as intermediates.

mineralocorticoid One of the main steroid hormones synthesized by the adrenal cortex. Its function is focused on regulation of electrolyte balance through stimulation of renal sodium retention.

steroid Member of a family of organic compounds derived from cholesterol. The basic steroid structure consists of cyclopentane perhydrophenanthrene.

Mineralocorticoid Disorders, Genetic Basis of

IAN MARSHALL AND MARIA I. NEW

New York Presbyterian Hospital—Weill Medical College of Cornell University

Mineralocorticoid biosynthesis and metabolism are affected by certain genetic disorders. In 11β-hydroxylase, 17α-hydroxylase, and aldosterone synthase enzyme deficiencies, the production of aldosterone is decreased, with elevation of mineralocorticoid precursors prior to the enzymatic block. Alternatively, aldosterone production can be increased, as occurs in glucocorticoid-remediable aldosteronism. The binding of aldosterone to the mineralocorticoid receptor (MR) may be altered as in pseudohypoaldosteronism, with resistance to aldosterone action at the MR. Finally, there can be binding of an agonist to the MR, with increased mineralocorticoid action as occurs in apparent mineralocorticoid excess.

I. INTRODUCTION

Mineralocorticoids are hormones whose function is to regulate the transport of electrolytes across epithelial surfaces. The major circulating mineralocorticoid, aldosterone, is a steroid hormone that is synthesized in the adrenal cortex and functions primarily in the maintenance of electrolyte equilibrium, which contributes to the stabilization of blood volume and blood pressure. Aldosterone binds to the mineralocorticoid receptor (MR) in its main target tissues, thereby promoting active sodium transport and excretion of potassium.

II. SYNTHESIS AND ACTION OF MINERALOCORTICOID HORMONES

Aldosterone is synthesized exclusively in the zona glomerulosa of the adrenal cortex in a series of enzymatic steps from cholesterol (Fig. 1). Its intermediate precursors, deoxycorticosterone (DOC), corticosterone (B), and 18-hydroxycorticosterone (18-OHB), have some mineralocorticoid activity and are synthesized in all three adrenocortical zones; 18-OHB is synthesized predominantly in the zona glomerulosa and its secretion correlates with that of aldosterone. In addition to being 11β-hydroxylated to B, DOC can be 18-hydroxylated to 18-OHDOC, which is then 11β-hydroxylated to 18-OHB (Fig. 2). These three final steps in aldosterone synthesis are catalyzed by the P450 enzyme aldosterone synthase.

Because aldosterone is not stored in the adrenal glands to a significant degree, its production is regulated by changes in activity of one or more biosynthetic enzymes. The primary stimuli for these changes are the renin–angiotensin system and serum potassium ion concentration (Fig. 3). There are a number of minor modulators including adrenocorticotropic hormone (ACTH), sodium ion, dopamine, atrial natriuretic peptide, β-adrenergic agents, serotonin, somatostatin, and vasopressin.

III. MINERALOCORTICOID RECEPTOR

Aldosterone binds to two different receptors, the high-affinity type I receptor and the more abundant low-affinity type II receptor. The type I receptor that has been identified as the mineralocorticoid receptor was first cloned in 1987 and consists of a 984-amino-acid protein that is encoded by a gene on chromosome 4. It is expressed predominantly in

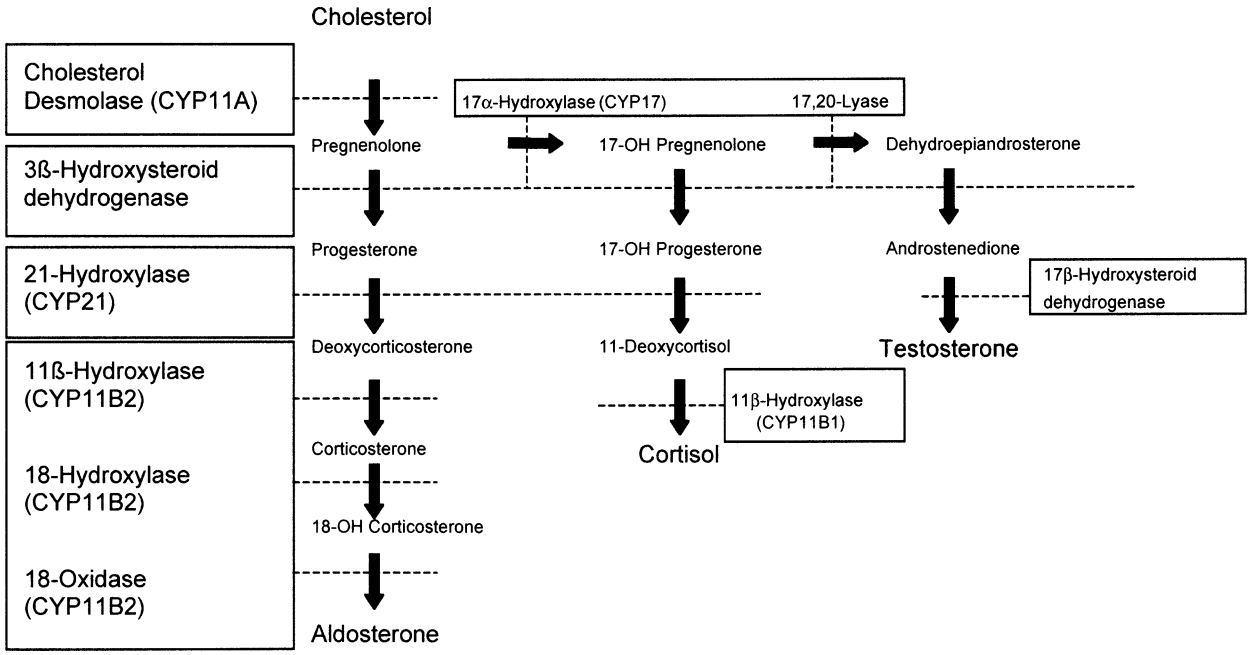

FIGURE 1 Pathway of steroid biosynthesis. In addition to being 11β-hydroxylated to B, DOC can be 18-hydroxylated to 18-OHDOC. Reprinted with permission from New, M. I., and White, P. C. (1995). Genetic disorders of steroid hormone synthesis and metabolism. *In* "Genetic and Molecular Biological Aspects of Endocrine Disease," (R. Thakker, ed.), pp. 525–554. Ballière Tindall, London.

sodium-transporting epithelial cells of the kidney, the colon, and the exocrine glands (salivary and sweat glands), but also in nonepithelial tissues such as mononuclear leukocytes, the central nervous system, large blood vessels, and the heart. Aldosterone and cortisol have equal affinities for the MR and since normal circulating cortisol levels are 100- to 1000-fold higher than that of aldosterone, it would be expected that the ability of aldosterone to bind to the receptor would be limited. The intracellular enzyme 11β-hydroxysteroid dehydrogenase type 2 is co-expressed with the MR in renal tubular cells and catalyzes the conversion of cortisol to cortisone. This reaction protects the MR from saturation by cortisol and other glucocorticoids and therefore maintains the specificity of the MR.

Aldosterone promotes sodium conservation in its target tissues by interacting with the MR through activation of the amiloride-sensitive sodium channels (ENaC) and the Na^+,K^+-ATPase pump. It acts by binding to an intracellular receptor, and as a hormone–receptor complex, it interacts with hormone-responsive elements of the DNA. The interaction leads to the expression of specific proteins, whose candidate targets are the ENaC channels and the Na^+,K^+-ATPase pump.

IV. GENETIC DISORDERS

A. 11β-Hydroxylase Deficiency

Defects in 11β-hydroxylation result in virilizing congenital adrenal hyperplasia (CAH), often accompanied by hypertension. The abnormal adrenal steroid serum profile exerts a net mineralocorticoid effect, altering renal function and causing sodium retention and volume expansion.

A deficiency of enzyme 11β-hydroxylase is inherited as an autosomal recessive disorder, caused by inactivating mutations in the CYP11B1 gene located on chromosome 8. The gene consists of 9 exons, with the majority of mutations appearing to be random point mutations identified in exons 2, 6, 7, and 8. Although the enzyme defect is found in approximately 1 in 100,000 live births, the disease frequency is much higher in a consanguineous group of Moroccan Jews, where it occurs in 1 in 5000–7000 live births.

11β-hydroxylase catalyzes the conversion of DOC to corticosterone in the mineralocorticoid pathway and 11-deoxycortisol to cortisol in the glucocorticoid pathway. A deficiency of the enzyme with resultant low plasma cortisol leads to chronic elevation of ACTH, with subsequent increased

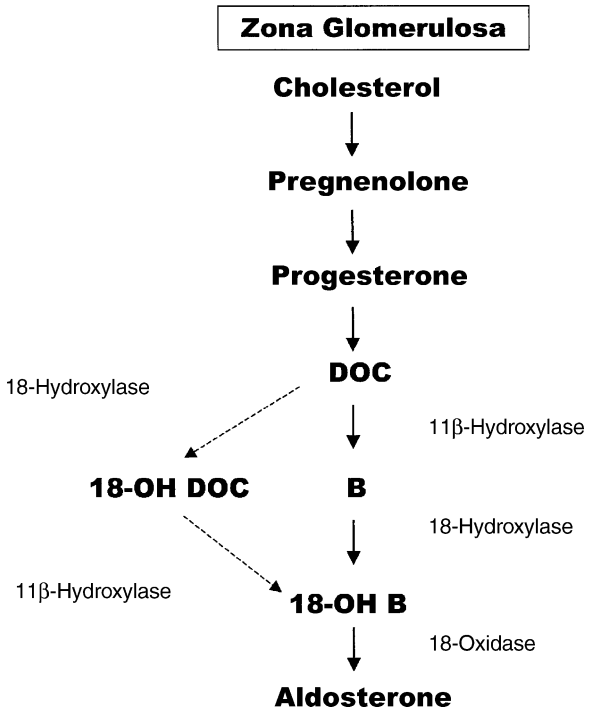

FIGURE 2 Synthesis of aldosterone in the zona glomerulosa.

synthesis and secretion of steroid intermediates proximal to the 11β-hydroxylase block and their non-11β-hydroxylated products. Accumulation of these precursors produces the typical phenotype that characterizes this disorder. Excessive production of DOC and its metabolites exerts a net mineralocorticoid effect. Sodium retention and volume expansion occur, with suppression of renin production. Hypertension occurs in approximately two-thirds of untreated patients, appears infrequently in infancy, and is variable in childhood. Hypokalemia is variable, developing concomitantly with sodium retention. Aldosterone production is low, secondary to low plasma renin activity and low serum potassium concentrations.

The precursors that accumulate in the glucocorticoid pathway are channeled into the androgen pathway and result in prenatal virilization, with varying degrees of genital ambiguity in the affected newborn female. Males and females may manifest signs of androgen excess at any phase of postnatal development, with progressive virilization, including precocious pubic hair, advanced somatic and epiphyseal development, and induced central precocious puberty later in childhood.

Treatment of 11β-hydroxylase deficiency consists of glucocorticoid replacement; this approach is effective because (1) it fulfills systemic steroid (glucocorticoid) requirements and (2) by providing feedback inhibition of ACTH release, it reduces the drive on the adrenal for the synthesis and secretion of precursor steroids. Therapeutic control is achieved by careful clinical monitoring, particularly in children when the dosage is continually adjusted, with particular avoidance of suppression of linear growth from overdosing.

Identification of the mutations affecting CYP11B1 has permitted prenatal diagnosis and subsequent treatment of the affected female fetus. This is achieved by the administration of dexamethasone to the pregnant mother by 8 weeks gestation to suppress excess adrenal androgen secretion and prevent virilization should the fetus be an affected female. Karyotyping and diagnosis by genetic analysis require chorionic villus sampling at $10\frac{1}{2}$ to 12 weeks or later by amniocentesis at 15 to 18 weeks gestation. If the fetus is determined to be a male or an unaffected female, treatment is discontinued. Otherwise, treatment continues to term.

B. Aldosterone Synthase Deficiency

Deficiency of the aldosterone synthase enzyme, which catalyzes the three steps in the conversion of DOC to aldosterone (Fig. 1), results from mutations in CYP11B2, the gene that encodes this mitochondrial cytochrome P450 enzyme. Two types have been described. Type 1 results from deficiency of the 18-hydroxylase enzyme and is usually characterized biochemically by reduced levels of 18OHB and very low levels of urinary aldosterone metabolites. Type 2, which is characterized by increased levels of 18OHB and reduced urinary levels of aldosterone metabolites, results from deficiency of 18-oxidase enzyme.

Aldosterone synthase deficiency presents in infancy with renal salt wasting, which can lead to dehydration, shock and even death if not adequately treated. Infants can also present with failure to thrive. Plasma renin activity is increased secondary to low aldosterone levels. Cortisol synthesis is unaffected.

Patients are treated with mineralocorticoid replacement therapy in addition to sodium supplementation. Often, replacement therapy is not required after childhood when compensatory extrarenal salt-conserving mechanisms mature with age.

C. Glucocorticoid-Remediable Aldosteronism

Glucocorticoid-remediable aldosteronism (GRA) is a familial form of low renin hypertension, which is inherited as an autosomal dominant disorder.

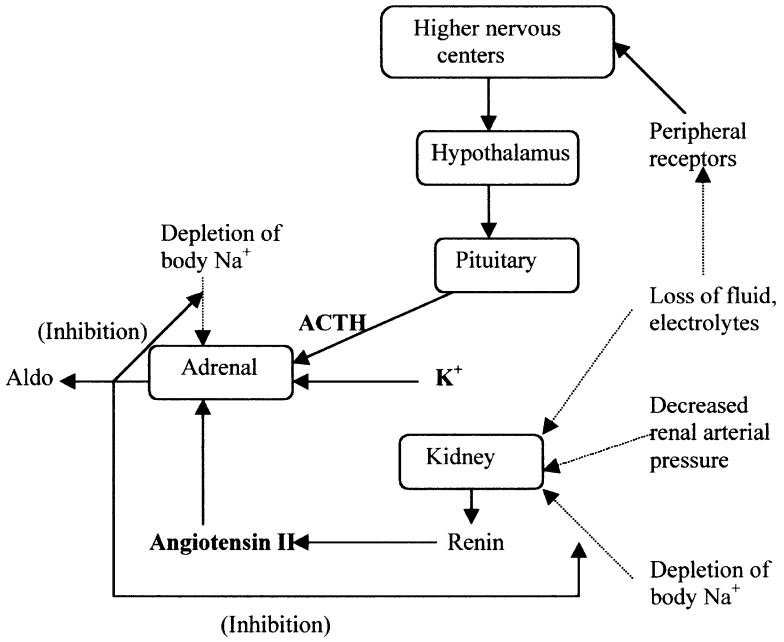

FIGURE 3 Control of the renin–angiotensin system. Reprinted with permission from Speiser, P.W., and New, M.I. (2002). Hormonal hypertension in childhood. *In* "Manual of Endocrinology and Metabolism, Third Edition" (N. Lavin, ed.), pp. 163–179. Lippincott Williams & Wilkins.

The disease is characterized by hyperaldosteronism and excessive secretion of two normally rare steroids, 18-oxocortisol and 18-hydroxycortisol. The presence of these two steroids suggests the simultaneous presence of 17α-hydroxylase and aldosterone synthase activities, which are normally limited to the zona fasciculata and the zona glomerulosa, respectively. Although there are clinical features similar to those found in other forms of primary hyperaldosteronism, the unique distinguishing feature of GRA is the complete and rapid suppression of aldosterone oversecretion by dexamethasone (glucocorticoid) administration.

GRA produces a volume-expanding, salt-sensitive form of low renin hypertension. Although hypertension is invariably present, hypokalemia and metabolic acidosis may be absent. Additionally, children demonstrate normal growth and development, which distinguishes this disorder from the aforementioned 11β-hydroxylase deficiency and apparent mineralocorticoid excess, discussed below.

Circadian measurement of plasma steroids in GRA patients has revealed that not only is aldosterone produced in excessive amounts, but is also high following ACTH stimulation, suggesting a zona fasciculata origin.

Other factors in addition to elevated aldosterone levels may be involved in the etiology of hypertension in this disorder. Whereas ACTH given in the dexamethasone-suppressed state reestablished the hypertension of the untreated state in GRA patients, aldosterone replacement alone in large doses over 5 days did not reestablish hypertension. Replacement of aldosterone, DOC, and 18-hydroxy-DOC in amounts restoring pretreatment levels of these steroids also failed to restore hypertension. Thus, a significant proportion of the hormonal effect in GRA hypertension may be derived from other ACTH stimulable steroids.

Qualitative steroid abnormalities in GRA have been identified, but the summed mineralocorticoid effects of these steroids at their physiological levels fall far short of the total mineralocorticoid effects observed. The steroids specific for GRA and identified as the 17α-hydroxylated analogues of 18-hydroxycorticostrone (18-OHB) and aldosterone, namely, 18-hydroxycortisol and 18-oxocortisol, respectively, suggest that the inner cortical zones, which express 17α-hydroxylase and are ACTH responsive, are responsible, thereby indicating a particular defect in adrenal zonation. An explanation for the elevated aldosterone and its unusual regulation by ACTH has been provided by genetic studies that have shown that a chimeric gene is created by misalignment of chromatids and unequal crossing over between genes during meiotic reduction in gametogenesis.

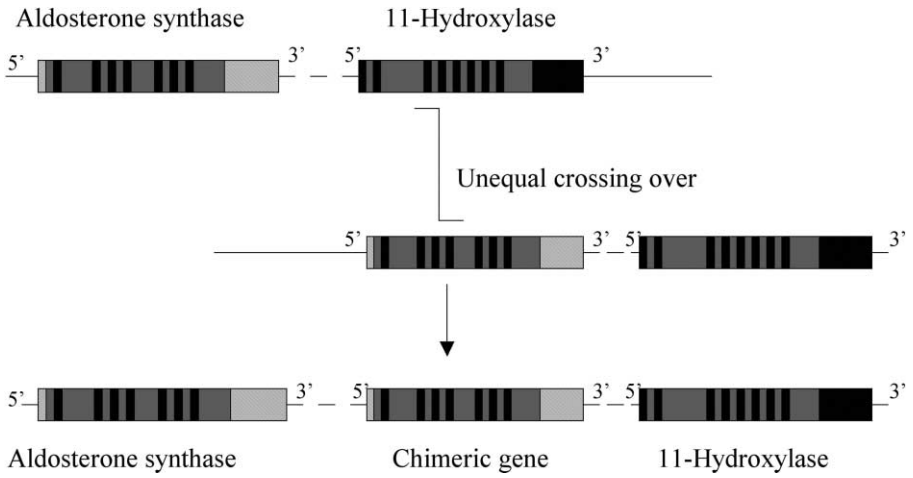

FIGURE 4 Formation of chimeric gene product by misalignment of chromatids and unequal crossing over between genes during meiotic reduction in gametogenesis. Reprinted from Lifton, R. P., Gharavi, A. G., and Geller, D. S. (2001). Molecular mechanisms of human hypertension. *Cell* **104**, 545–556, with permission of Elsevier.

This occurs between the genes for CYP11B1 (11β-hydroxylase) and CYP11B2 (aldosterone synthase), which reside within a 30 kb stretch on chromosome 8. In affected individuals, a chimeric gene that has aldosterone synthase activity is produced but it is regulated by ACTH rather than by angiotensin II (Fig. 4).

Children with GRA are treated with glucocorticoids, and resolution of their hypertension usually occurs within 2 weeks after initiation of therapy. The response to glucocorticoids is variable in adults, often requiring the additional use of antihypertensive medications, such as spironolactone, which blocks the action of aldosterone at the mineralocorticoid receptor. Amiloride and triamterene have also been used in GRA patients.

D. Pseudo Hypoaldosteronism Type I

Pseudo hypoaldosteronism type I is characterized by loss-of-function mutations that cause defective sodium transport due to the inability of aldosterone to exert its end-organ effect. Two genetically distinct forms have been identified, the autosomal dominant form and the recessive form.

The autosomal dominant form, also known as mineralocorticoid resistance, is caused by mutations in the MR of the kidney. As a result, aldosterone has no effect on the MR in the kidney. The disorder presents in infancy with salt wasting, dehydration, and failure to thrive, but does have a variable clinical presentation ranging from asymptomatic cases to severe salt wasting. Owing to the absence of responsiveness to aldosterone, there is markedly elevated plasma renin activity, with paradoxically elevated plasma and urinary aldosterone. Mineralocorticoid resistance is treated with sodium supplementation, which can often be discontinued after infancy as the salt loss may improve with age. Family members can be clinically asymptomatic but biochemically affected and can be identified by their plasma renin levels and aldosterone response to salt deprivation.

The recessive form of pseudo hypoaldosteronism results from loss-of-function mutations in one or more of the genes encoding the α-, β-, and γ-subunits of the amiloride-sensitive ENaC, which is present in the kidney as well as in the colon, sweat glands, salivary glands, and lungs. This disorder presents in early infancy with salt wasting, due to profound urinary sodium loss leading to hyponatremia, and is accompanied by hyperkalemia and metabolic acidosis. Because salt loss can occur from multiple organs, the presentation of the recessive form can be life-threatening if the disorder is unrecognized in the neonatal period. Biochemically it is also characterized by elevated plasma renin and aldosterone levels. Furthermore, children with this disorder can present with increased frequency of respiratory tract illnesses due to defective sodium-dependent liquid absorption in the airways. Treatment includes lifelong salt supplementation, often with the addition of potassium-binding resins to maintain normokalemia.

Gain-of-function mutations that affect the ENaC result in sodium retention, hypokalemia secondary to potassium wasting, and metabolic alkalosis, a disorder known as Liddle's syndrome

(pseudo hyperaldosteronism). Liddle's syndrome is an autosomal dominant form of hypertension, characterized by suppressed plasma renin and aldosterone levels.

E. Apparent Mineralocorticoid Excess

Apparent mineralocorticoid excess (AME) is a form of hypertension caused by mutations in the HSD11B2 gene, which result in a deficiency of the 11β-hydroxysteroid dehydrogenase (11β-HSD) type 2 enzyme. The 11β-HSD type 2 enzyme maintains the specificity of the MR for aldosterone by catalyzing the conversion of cortisol to cortisone in the same cells in which the MR is expressed.

AME is a rare autosomal recessive disorder, having been identified in only approximately 60 patients over the past 20 years. To date, most patients with AME who have undergone molecular genetic analysis are homozygous for one of the different mutations, with only 3 compound heterozygote patients.

AME usually presents in early life with low birth weight and postnatal failure to thrive, hypertension, and persistent polyuria and polydipsia. The disorder is characterized by hypokalemic alkalosis, hyporeninemia, and undetectable serum concentrations of aldosterone. The diagnosis of AME can be made biochemically by measuring the ratio of urinary cortisol metabolites to cortisone, often measured as an increase in the sum of the urinary tetrahydrocortisol (THF) and allotetrahydrocortisol, divided by the concentration of tetrahydrocortisone (THE) [(THF + 5αTHF)/THE]. This ratio, which is normally 1.0, is elevated in patients with AME, with a predominance of THF.

The treatment of AME is primarily directed at the correction of hypokalemia and hypertension. Spironolactone, an MR receptor antagonist, is the medication of choice. Addition of potassium-sparing diuretics may be beneficial, but patients can become refractory to therapy. A reduction in dietary sodium and supplemental potassium can be beneficial.

F. 17α-Hydroxylase Deficiency

17α-Hydroxylase deficiency is an extremely rare disease that has been identified in approximately 120 patients worldwide. The deficiency of 17α-hydroxylase results from mutations in the enzyme cytochrome P450C17, which functions both as steroid 17α-hydroxylase and as 17,20-lyase. The structural gene for cytochrome P450C17 has been mapped to chromosome 10q24.3. Deleterious mutations have been identified in numerous cases of 17α-hydroxylase deficiency.

The enzyme deficiency causes diminished production of cortisol and sex steroids, whose production requires the 17,20-lyase function of the same 17α-hydroxylase enzyme (Fig. 1). Both the adrenals and the gonads shared the enzyme defect, resulting in decreased biosynthesis of all androgens and estrogens. Untreated 17α-hydroxylase deficiency in females at pubertal age results in primary amenorrhea and lack of development of secondary sex characteristics. Male (46,XY) patients present with an undervirilized (i.e., infantile female) sexual phenotype at birth and, later, failure of pubertal development.

Reciprocal elevation of ACTH secondary to low cortisol increases synthesis via the 17-deoxy pathway, notably of the steroids DOC and corticosterone. As in 11β-hydroxylase deficiency, the formation of aldosterone is reduced secondary to suppressed renin as a result of excess DOC.

Because of massive overproduction of corticosterone, which is a weak glucocorticoid with serum concentrations 30 times normal, patients with this disorder rarely present with symptoms of adrenal insufficiency in early infancy. Diagnosis is often made in a young female or apparent female presenting at pubertal age with primary amenorrhea or lack of development of secondary sexual characteristics. There can be associated hypertension and hypokalemia at diagnosis. Alternatively, these latter findings may constitute the primary presentation at any age.

Treatment consists of glucocorticoid replacement in prepuberty to normalize elevated circulating mineralocorticoids and sex steroid replacement as appropriate for the phenotypic sex starting at pubertal age. In 46,XY patients, the testes may be abdominal, inguinal, or labial; if sex assignment is male, the gonads may be preserved. If the patient is reared as a female, estrogen replacement induces development of female secondary sexual characteristics and stimulates the increase in bone mass that normally occurs during puberty.

V. SUMMARY

Adrenal steroid hormones are among the many factors regulating blood pressure. Mineralocorticoid abnormalities can cause clinical conditions such as hypertensive congenital adrenal hyperplasia due to 11β-hydroxylase deficiency, 17α-hydroxylase/17, 20-lyase deficiency, and glucocorticoid-remediable aldosteronism. An inborn deficiency of the enzyme 11β-hydroxysteroid dehydrogenase can also explain

the hypertension found in apparent mineralocorticoid excess. Because many of these disorders can be life-threatening, making a specific diagnosis can aid in designing an effective therapeutic regimen. Furthermore, understanding the etiology of the mineralocorticoid disorder can help in identifying other affected family members and in providing anticipatory management and genetic counseling in inherited disorders.

Glossary

aldosterone Principal mineralocorticoid hormone produced in the adrenal cortex. Primary function is sodium reabsorption in the distal renal tubule.

amiloride-sensitive epithelial sodium channel This channel consists of three homologous subunits, α, β, and γ, and mediates the reabsorption of sodium in the distal renal tubule.

11β-hydroxysteroid dehydrogenase type II An enzyme that is expressed predominantly in the kidney and catalyzes the conversion of cortisol to cortisone.

mineralocorticoid A steroid synthesized in the adrenal cortex that regulates electrolyte balance. Aldosterone is the principal circulating mineralocorticoid.

mineralocorticoid receptor The specific receptor for steroid hormones with mineralocorticoid activity.

renin–angiotensin system One of the principal regulators of the aldosterone biosynthetic pathway.

Mineralocorticoid Effects on Physiology and Gene Expression

ANIKÓ NÁRAY-FEJES-TÓTH AND GÉZA FEJES-TÓTH
Dartmouth Medical School

Mineralocorticoids, named for their ability to maintain the homeostasis of two important minerals, sodium and potassium, are a class of adrenocortical hormones. The major physiological effect of mineralocorticoids is to promote sodium retention and potassium excretion.

I. INTRODUCTION

Although the daily secretion rate of the adrenal gland mineralocorticoids is very low, i.e., only about 1/100th of that of glucocorticoids, this small amount is essential for life. In the absence of mineralocorticoids,

such as occurs in Addison's disease, a life-threatening electrolyte and water imbalance develops.

The two main mineralocorticoid hormones are aldosterone and 11-deoxycorticosterone (DOC). The most potent mineralocorticoid, aldosterone, is produced by the zona glomerulosa of the adrenal cortex. Aldosterone was isolated in the early 1950s from a lipid extract of the adrenal cortex.

II. PHYSIOLOGICAL EFFECTS OF MINERALOCORTICOIDS

Aldosterone has two major physiological functions: (1) it regulates the total amount of sodium in the body and, consequently, the extracellular fluid volume and (2) it regulates potassium homeostasis. Normal plasma sodium concentration is 136–145 m*M*; normal plasma potassium concentration is 3.5–5.0 m*M*. Changes in sodium levels lead to changes in plasma osmolality. Changes in plasma potassium levels alter membrane potential and, consequently, have major effects on excitatory tissues, such as those in the muscles, the heart, and the nervous system. Therefore, the levels of sodium and potassium in the plasma must be tightly regulated.

The main target site of aldosterone is the kidney, but aldosterone also affects sodium and potassium excretion by the colon and the salivary and sweat glands. In the kidney, the primary target segment of aldosterone is the cortical collecting duct. Mineralocorticoid effects on sodium and potassium transport take place in the major cell type of this nephron segment, the principal cells. A model of the cellular transport mechanisms involved in sodium reabsorption and potassium secretion by "tight" epithelia is shown in Fig. 1. Sodium enters the principal cells from the urine, through lumenal sodium channels (which are sensitive to the diuretic, amiloride), via the sodium electrochemical gradient; it is extruded from the cells by a Na^+- and K^+-transporting ATPase ("sodium pump") located in the basolateral membrane. The basolateral Na^+,K^+-ATPase also creates the driving force for potassium to exit from the cells into the urine via lumenal K^+-selective channels.

Aldosterone stimulates active sodium reabsorption from the urine into the blood by a complex action, which results in increased activity of Na^+,K^+-ATPase as well as in increased conductive capacity of lumenal sodium channels. Although the effect of aldosterone on Na^+,K^+-ATPase is most likely due to direct stimulation of transcription of new mRNAs for this enzyme, the effect on sodium channels is more

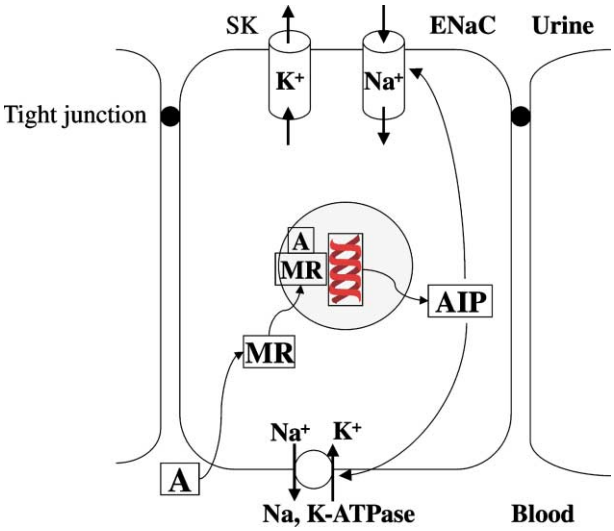

FIGURE 1 Model of aldosterone action in epithelial cells. Aldosterone (A) binds to mineralocorticoid receptors (MR), and the MR–aldosterone complex binds to specific hormone response elements on the DNA. Interaction of the activated MR with hormone response elements leads to changes in the transcription of specific, aldosterone-induced proteins (AIP). The AIPs modulate the activity and/or trafficking of the two most important effectors of aldosterone action, the epithelial Na^+ channel (ENaC) present in the apical membrane and the basolateral Na^+,K^+-ATPase. Activation of the Na^+,K^+-ATPase also creates the driving force for K^+ to exit from the cell to the tubule lumen though apical K^+-selective channels, which may explain the increased K^+ secretion following aldosterone. The tight junctions are impermeant for Na^+ and K^+, thereby preventing paracellular movement of the transcellularly transported ions.

complex. The effect in this case includes an increase in the activity of pre-existing Na channels in the apical cell membrane, as well as an increase in the absolute number of channels in the apical cell membrane (see later).

Mineralocorticoid effects on Na transport in amphibian epithelia (which are frequently studied model systems) are usually divided into "early" and "late" phases. (It should be pointed out that the existence of these two phases in the mammalian collecting duct has not been clearly established.) The early response takes place about 0.5–3 h after hormone addition, and is probably mediated by activation of pre-existing apical membrane Na^+ channels. The late phase (several hours to several days after hormone addition) involves new Na^+ channel synthesis, Na^+,K^+-ATPase molecules, and secondary effects on K^+ and H^+ transport.

Because water movement follows passively that of sodium, an increase in sodium reabsorption

necessarily results in an expansion of extracellular fluid volume and an increase in blood pressure. Therefore, chronic overproduction of aldosterone leads to pathological conditions accompanied by hypertension.

Although the main physiological effect of aldosterone is stimulation of Na^+ reabsorption, aldosterone also regulates the excretion of potassium by increasing K^+ secretion from the blood into the tubular lumen. This action takes place predominantly in the principal cells of the cortical collecting ducts. The exact cellular mechanism underlying the K^+-secreting response elicited by aldosterone is still not clear, but probably the bulk of the effect is mediated through an increase in the activity and expression of the basolateral Na^+,K^+-ATPase. Increased pumping of Na^+ out of the cell is coupled to increased pumping of K^+ into the cell. This event creates a favorable electrochemical driving force for K^+ to exit from the cell into the lumen through K^+-selective ion channels (SK channels). The hypothesis that aldosterone increases the number of K^+ channels in the apical membrane of cortical collecting duct cells by directly increasing their level of expression has not been confirmed. Thus, although it is widely acknowledged that aldosterone regulates renal K^+ handling, the question if this is only a secondary effect, coupled to its regulation of Na^+ reabsorption, is still open.

In addition to its effects on sodium and potassium transport, aldosterone also enhances the excretion of H^+ ions in the collecting ducts. H^+ transport takes place in the minor cell type of the collecting duct, the intercalated cells. The mechanisms by which aldosterone regulates acid secretion are not clear, and it is still debated whether aldosterone has a direct effect on the intercalated cells by increasing the expression of the H^+-ATPase, or whether the enhanced H^+ secretion is merely a consequence of the lumen negative voltage, created by increased sodium reabsorption in principal cells. Whatever the exact mechanism, the effect of aldosterone on acid secretion is probably not a major physiological regulatory function.

III. RECEPTORS THAT MEDIATE MINERALOCORTICOID EFFECTS

Aldosterone, like other steroids, exerts its effects through binding to intracellular receptors, called mineralocorticoid receptors (MRs). Mineralocorticoids, like other steroids, enter the cell by passive diffusion. Ligand binding induces a structural change, i.e., activation, in the MR. The activated MR then interacts with specific regulatory segments, hormone response elements (HREs),on the chromatin. This interaction results in an increase (or decrease) of the transcription of specific genes. MRs are present in target tissues in the renal collecting duct system, the colon, and the sweat glands, for example; in addition, they can be found in the heart and in the muscular walls of vessels, as well as in the brain, where their function is still not clear.

The MR is a member of the nuclear receptor superfamily. Nuclear receptors are ligand-dependent transcriptional regulators that contain a highly variable N-terminal domain, a highly conserved DNA-binding domain, and a conserved C-terminal ligand-binding domain (LBD). Transcriptional activation function (AF) is localized to both the N-terminal region (AF-1) and the LBD (AF-2). The DNA-binding domain contains two type II zinc fingers, which anchor this domain to HREs.

Nuclear receptors bind to only one of two possible consensus sequence half-sites on DNA. These two half-sites can combine in various orientations and with different spacing, allowing binding of head-to-head, head-to-tail, or tail-to-tail receptor homo- or heterodimers. However, the diversity of HREs is insufficient to account for the observed spectrum of specificity in gene regulation by individual nuclear receptors. For instance, the MR, the glucocorticoid receptor (GR), and the androgen and progesterone receptors have identical DNA binding specificity but mediate very different biological actions. It should be noted that thus far no HRE has been identified that can distinguish between MR and GR. Thus, a central question in the biology of nuclear receptors is how distinct patterns of gene regulation are initiated by receptors with identical DNA sequence recognition profiles. It is logical to assume that receptor-specific actions are mediated through receptor-specific protein–protein interactions, but solid experimental evidence to support this hypothesis is still lacking.

In mineralocorticoid target tissues, in addition to MRs, GRs are also expressed. Although both types of receptors have high affinity for their respective ligands, they exhibit poor selectivity between endogenous glucocorticoids and aldosterone. In addition to glucocorticoids, the GR also binds aldosterone, although with lower affinity than cortisol. It was even more surprising to find that the MR *in vitro* has the same affinity for cortisol as for aldosterone ($K_d = 0.5–1.0$ n*M*). Because the plasma level of cortisol is from 100- to 1000-fold higher than that of aldosterone, the obvious question

is how aldosterone can act as the physiological mineralocorticoid hormone in the presence of much higher concentrations of cortisol, which, in theory, should occupy all MRs. To explain this paradox, Funder and Edwards proposed that aldosterone selectivity of the MR is vested in the enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD). This enzyme catalyzes the dehydrogenation (oxidation) of the 11-OH group present in every biologically active glucocorticoid. The resulting oxidized glucocorticoid metabolites (such as cortisone or 11β-dehydrocorticosterone) are biologically inactive because they do not bind to the MR. Thus, 11β-HSD rapidly inactivates endogenous glucocorticoids (but not aldosterone; see later) in mineralocorticoid target cells. This hypothesis was proved right when a second isoform of 11β-HSD (referred to as 11β-HSD2) was characterized in aldosterone target cells. 11β-HSD2 has an unusually high affinity for endogenous glucocorticoids (K_m in the nanomolar range) and catalyzes exclusively dehydrogenation, i.e., inactivation of glucocorticoids. Subsequently, the cDNA of 11β-HSD2 was cloned, and it turned out that 11β-HSD2 has very low degree of similarity to the type 1 isoform of 11β-HSD. 11β-HSD1 is expressed ubiquitously, and *in vivo* (mainly in the liver) it mediates activation of the inactive oxidized glucocorticoids to their active forms.

11β-HSD2, by lowering the intracellular levels of active glucocorticoids, protects the target cell MR from being occupied by glucocorticoids; thereby ensuring that aldosterone can act as the physiological mineralocorticoid hormone. Consequently, 11β-HSD2 has been called the "guardian of the MR." For such a protective mechanism, it's a prerequisite that the physiological ligand of the MR is not a substrate for this enzyme. Indeed, although aldosterone can exist in two forms (as an aldehyde and a hemiacetal), in the blood it occurs predominantly as a hemiacetal. In this molecule, the 11β-OH group forms a ring with the 18-aldehyde group and therefore 11β-HSD2 cannot oxidize the 11β-OH group in aldosterone.

The importance of 11β-HSD2 becomes clear if we consider the severity of the syndrome that develops if this enzyme is inactive: in the congenital disease of apparent mineralocorticoid excess (AME), aldosterone levels are low, but all the symptoms of hyperaldosteronism are present (high blood pressure, low plasma K^+ concentration, low plasma renin activity). This paradox occurs because deficient 11β-HSD2 activity in the kidney leads to high intracellular cortisol concentrations, which saturates the MRs and exerts mineralocorticoid activity. An acquired, milder form of 11β-HSD2 insufficiency occurs in patients who consume large amounts of licorice. The active ingredient of licorice, glycyrrhetinic acid, is an inhibitor of 11β-HSD2.

The critical importance of the MR in mediating the physiological effects of mineralocorticoids is clear from experiments with genetically engineered animals with targeted elimination of the MR (MR knockout mice) and from studies of patients with hereditary mutations of the MR. Homozygous MR knockout mice die a few days after birth due to pseudohypoaldosteronism; patients with loss-of-function mutations of the MR, survive, but also develop pseudohypoaldosteronism.

IV. MINERALOCORTICOID-INDUCED GENES AND PROTEINS

There is a general agreement that mineralocorticoids stimulate Na^+ reabsorption by changing the transcriptional activity of specific genes. However, the exact mechanism(s) and the genes involved are just beginning to be uncovered. The two most important effector molecules in aldosterone-induced Na^+ reabsorption are (1) the epithelial Na channel (ENaC) present in the apical (lumenal) membrane of Na^+-absorbing cells and (2) the basolateral Na^+,K^+-ATPase (see Fig. 1).

A. Epithelial Na Channel

The key event in transepithelial Na^+ transport in the collecting duct and other aldosterone target cells is Na^+ uptake, from lumen to cell, through ENaCs. ENaCs consist of three homologous subunits: α, β, and γ. ENaCs residing in the apical membrane of native epithelia are thought to consist of heterotrimeric complexes; however, the exact stoichiometry of the subunits in the apical membrane is still debated.

The critical role of ENaC in the regulation of Na homeostasis is demonstrated by at least two inherited diseases associated with mutations in ENaC subunits. Certain mutations in the β or γ subunits lead to Liddle's syndrome, characterized by constitutively elevated Na^+ reabsorption, and, as a consequence, hypertension, whereas loss-of-function mutations in ENaC lead to severe Na depletion and hypotension.

Although observations from several laboratories strongly indicate that aldosterone increases the *de novo* synthesis of ENaC subunits, there is no consensus about the subunit in which changes occur, the tissue-specificity of this effect, and, most importantly, the temporal correlation of the induction in

ENaC subunit mRNA with apical Na^+ permeability. It seems likely that the early increase in apical Na^+ permeability is mediated by postsynthetic modifications (such as phosphorylation or methylation) that enhance the translocation of ENaC subunits to the apical membrane or activate pre-existing channels in the apical membrane. Recent evidence strongly suggests that an important regulation of Na^+ reabsorption occurs via increased surface expression of ENaC subunits in the apical membrane. This effect is probably due to an enhanced rate of exocytosis of ENaC molecules.

B. Na^+,K^+-ATPase

In Na^+-transporting epithelia, a basolateral Na^+,K^+-ATPase is responsible for pumping Na^+ out of the cell and K^+ into the cell, against their electrochemical gradients. By this action the Na^+,K^+-ATPase maintains the driving force for Na^+ to enter the cell via apical ENaCs. A regulatory role for aldosterone on the Na pump has been well established by studies in both amphibian and mammalian epithelia. Aldosterone was shown to stimulate the activity of Na^+,K^+-ATPase by rapidly increasing its mRNA and protein synthesis in amphibian cells. However, this rapid increase in mRNA and protein levels has not yet been unequivocally demonstrated in mammalian cells. Thus, the question as to whether the observed increase in Na^+,K^+-ATPase activity and expression is secondary to changes in intracellular Na^+ concentration (as a consequence of increased Na^+ permeability of the apical membrane) following aldosterone is still unanswered. In addition to increasing the synthesis of Na^+,K^+-ATPase, aldosterone might also increase translocation of the enzyme into the basolateral membrane, an action that would be analogous to increased insertion of ENaCs into the apical membrane.

C. Early Aldosterone-Induced Genes

The observation that the Na-absorbing effect of aldosterone, at least in mammalian cells, seemed much faster than the increased rate of synthesis of ENaC or Na^+,K^+-ATPase suggested the existence of early, aldosterone-induced genes. According to a generally accepted hypothesis, the products of these genes would mediate the increased activity or trafficking of ENaC.

Although early studies on two-dimensional gels detected several aldosterone-induced proteins (AIPs), these proteins remained unidentified. However, a new and exciting development in the search for mediators of aldosterone action is the recent identification of two aldosterone-induced early gene products: serum- and glucocorticoid-induced kinase and K-ras2.

1. Serum- and Glucocorticoid-Induced Kinase

Serum- and glucocorticoid-induced kinase (sgk), a serine/threonine kinase, was originally identified as the product of a gene that is rapidly induced by dexamethasone in mammary epithelial cells, but until recently, no function was ascribed to this kinase.

In cultured rabbit cortical collecting duct cells, synthesis of sgk mRNA and protein is rapidly induced by physiological doses of aldosterone; this occurs as well as in the rat collecting duct and colon following *in vivo* aldosterone treatment. In two cell lines (M1 and in A6 cells) that originate from collecting ducts but do not express MRs, glucocorticoids transcriptionally up-regulate sgk, with a concomitant increase in amiloride-sensitive Na^+ transport. Coexpression of sgk in *Xenopus* oocytes with ENaCs results in a three- to sevenfold increase in amiloride-sensitive current. This is not due to a nonspecific effect on vesicular traffic, because sgk does not increase surface expression of the K^+ channel, ROMK.

The sgk-induced increase in Na^+ current in oocytes is due to an increase in the number of ENaCs present in the plasma membrane and not to changes in the open probability or kinetics of ENaCs. This effect resembles that of aldosterone in epithelial cells. Mutational analysis of ENaCs and *in vitro* studies suggest that the effect of sgk on ENaC surface density is not mediated by direct phosphorylation of ENaC subunits. Thus, it seems that sgk regulates a protein involved in the vesicular traffic of these transporters, rather than the transporters themselves. Endogenous targets of sgk phosphorylation that mediate its biological effects have not yet been identified.

Although sgk is regulated at the transcriptional level by steroids, its activity is regulated by phosphorylation via a phosphatidylinositol-dependent pathway. Activation of phosphatidylinositol 3-kinase (PI3-kinase) leads to activation of two other kinases, phosphoinositide-dependent kinase 1 (PDK1) and PDK2, which, in turn, activate sgk. Because insulin and other hormones that stimulate the PI3-kinase pathway are able to stimulate Na^+ absorption, sgk might serve as a more general mediator of the hormonal regulation of Na^+ transport rather than as a mediator of aldosterone action alone.

2. K-ras2

The small G-protein K-ras2 has been shown to be induced in amphibian A6 cells by high concentrations

of aldosterone. This effect is most likely mediated by the glucocorticoid receptor, because A6 cells do not express functional MRs. Although the effects of K-ras2 on Na^+ currents in oocytes are inconclusive, antisense oligonucleotide and overexpression experiments in A6 cells suggest a possible role for this gene in corticosteroid-induced Na^+ transport. The role of K-ras2 in the mammalian collecting duct has not been established, and because the expression of K-ras2 mRNA is not induced by aldosterone *in vivo*, its physiological significance in mineralocorticoid action, at present, is uncertain.

3. Other Early Effects of Aldosterone

There is also evidence that the action of aldosterone is accompanied (and possibly mediated) by increased carboxymethylation of proteins, including that of βENaC. Synthesis of the key enzymes involved in this reaction is not increased by aldosterone, but their activity is. This raises the possibility that an aldosterone-induced early gene is responsible for the activation of these enzymes.

V. NONCLASSICAL ALDOSTERONE TARGETS

In addition to its effects on ion transport in epithelial cells, aldosterone, under certain conditions, has been shown to have effects in other tissues, such as the brain, the heart, and vascular smooth muscle cells. These effects include elevation of blood pressure following intracerebral ventricular infusion of aldosterone, increase in salt appetite, interstitial fibrosis in the heart, and rapid effects on the activity of the Na/H exchanger. The identity of the receptors that mediate such effects of aldosterone are still unclear; in certain cases the effects might occur via MRs that are "unprotected" by 11β-HSD2, and in other cases "nonclassical" membrane receptors and "nongenomic" effects have been implied. No such membrane receptor for mineralocorticoids has been cloned, and the significance of these receptors and actions is not yet known.

VI. SUMMARY

The primary function of aldosterone, a mineralocorticoid synthesized in the zona glomerulosa of the adrenal glands, is to stimulate the reabsorption of sodium from renal tubular fluid in the distal nephron of the kidney. A concomitant excretion of potassium and hydrogen occurs, in part due to the lumen (tubule) negative potential difference generated by active sodium transport.

Aldosterone exerts its effects through intracellular mineralocorticoid receptors. Aldosterone- activated receptors bind to specific elements on the chromatin, inducing the transcription of specific mRNAs. Although mineralocorticoid and glucocorticoid receptors serve different biological functions, aldosterone and cortisol have similar affinities for the mineralocorticoid receptors. Because the plasma concentration of aldosterone is about 1/1000th that of cortisol, in aldosterone target tissues (the renal collecting duct and salivary and sweat glands) the enzyme 11β-hydroxysteroid dehydrogenase type 2 inactivates glucocorticoids, leaving the aldosterone molecules without competition, and thus able to bind to their receptors. The congenital absence of this enzyme develops into a fatal condition, known as apparent mineralocorticoid excess.

The main effectors of aldosterone action on Na^+ reabsorption are the epithelial Na^+ channel, expressed in the apical membrane of Na^+ reabsorbing cells, and the basolateral Na^+,K^+-ATPase. Aldosterone increases the expression of both of these proteins. In addition, aldosterone rapidly increases the insertion of active ENaC subunits into the apical membrane and might activate ENaCs already present in the apical membrane.

Serum- and glucocorticoid-induced kinase, a serine/threonine kinase, has been recently identified as the product of an early-induced, aldosterone-regulated gene. This kinase is capable of increasing ENaC current and insertion of ENaC molecules into the plasma membrane and thus is probably an important mediator of the early effect of aldosterone on Na^+ reabsorption.

Glossary

aldosterone The main mineralocorticoid hormone.

epithelial sodium channel Specific ion channel consisting of α, β, and γ subunits, expressed in the apical membrane of Na^+-reabsorbing epithelia.

11β-hydroxysteroid dehydrogenase An enzyme that catalyzes the oxidation of hydroxy groups in the 11β position of steroids. 11β-HSD2, the second isoform of this enzyme, has high affinity for endogenous glucocorticoids and is expressed specifically in aldosterone target cells.

hormone response element Regulatory DNA sequence in the promoter region of a gene; interacts with factors that bind hormone receptors, altering transcription of specific genes.

mineralocorticoids Hormones produced by the adrenal cortex; regulate sodium and potassium homeostasis.

mineralocorticoid receptor The specific target tissue receptor for mineralocorticoids. It has high affinity

(K_d, <1 n*M*) for aldosterone and for endogenous glucocorticoids such as cortisol.

serum- and glucocorticoid-induced kinase A serine/threonine kinase that is regulated transcriptionally and posttranscriptionally; its mRNA and protein expression is rapidly induced by aldosterone.

Mineralocorticoid Receptor, Natural Mutations of

MARIE-EDITH RAFESTIN-OBLIN, JÉRÔME FAGART, AND MARIA-CHRISTINA ZENNARO

Xavier Bichat, INSERM U478, Paris, France

The mineralocorticoid hormone aldosterone produces its effects through the mineralocorticoid receptor (MR), which, like other members of the nuclear receptor family, is a ligand-activated transcription factor that induces or represses specific target genes. Natural mutations in the gene coding for the MR can lead to either a loss-of-function or a gain-of-function.

I. INTRODUCTION

Aldosterone (Fig. 1), the mineralocorticoid hormone secreted by the adrenal gland, is a key regulator of sodium homeostasis and plays a central role in blood pressure regulation. Aldosterone produces its effects through the MR, which is expressed in the epithelial cells that line the distal tubule of the kidney, the distal colon, and the ducts of salivary and sweat glands. In these cells, MR-dependent sodium reabsorption is mediated by the apical epithelial amiloride-sensitive sodium channel (ENaC) and the basolateral Na^+, K^+-ATPase (Fig. 2). It is now clear that ENaC and Na^+, K^+-ATPase are not early aldosterone-induced proteins, and an active search for such proteins is currently in progress. Serum- and glucocorticoid-regulated kinase (sgk) has emerged as one such possible primary aldosterone-induced protein.

Aldosterone and another adrenal gland hormone, cortisol (the major glucocorticoid hormone in humans), bind to the MR with similar affinities; however, in epithelial cells, aldosterone is ensured access to the MR by the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), whereas 11β-HSD2

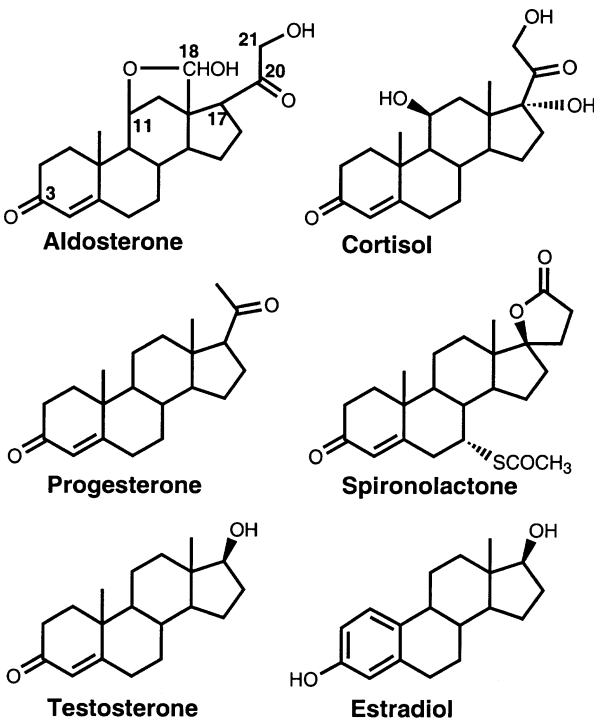

FIGURE 1 The key mineralocorticoid, aldosterone, and structurally similar compounds. Spironolactone is an aldosterone antagonist.

metabolizes cortisol to cortisone, which has no affinity for the MR. The MR is also expressed in some nonepithelial cells, such as the neurons of the hippocampus and the myocytes of the heart. However, the mechanism underlying the mineralocorticoid specificity of these cells is not clear.

Abnormalities in aldosterone secretion and in the production of steroids that activate the MR and mutations of 11β-HSD2, MR, or ENaC all affect the sodium balance in epithelial target cells. This article focuses on the mechanism of action of the MR and on the receptor mutations that have a functional impact.

II. THE MINERALOCORTICOID RECEPTOR AS MEDIATOR OF ALDOSTERONE ACTION

The MR belongs to the nuclear receptor superfamily that includes the other steroid hormone receptors as well as receptors for thyroid hormone, vitamin D, and retinoic acid and numerous orphan receptors. Like the other nuclear receptors, the MR contains several functional domains (Fig. 3). The N-terminal part of the protein harbors an autonomous activation function. The cysteine-rich central region, containing approximately 90 amino acids, is the DNA-binding domain (DBD). This region is the one most completely conserved in the nuclear receptors; it contains two zinc finger structures, in which each zinc atom is coordinated by four cysteines. These structures are responsible for DNA–receptor interaction and dimerization. The sequence between the DBD and the ligand-binding domain (LBD), called the hinge region, is probably involved in the ligand-induced conformational changes of the receptor. The C-terminal part of the receptor, a large region containing approximately 250 amino acids, mediates numerous functions, including ligand binding, interactions with heat-shock proteins and transcriptional coactivators, dimerization, nuclear targeting, and hormone-dependent activation.

The human MR gene contains 10 exons. Two different 5′-untranslated exons (1α and 1β) are transcribed to form two distinct mRNA isoforms, MRα and MRβ, which encode the same protein. Exon 2, which contains the MR translation start site, encodes the N-terminal part of the receptor, exons 3 and 4 encode the DBD, and exons 5–9 encode the hinge region and the LBD (Fig. 3).

The crystal structure of the LBD has been solved for several receptors, either in their unliganded state (apo-receptor) or in their agonist-associated state (holo-receptor). A common fold organization has been described in which 11 to 12 α helices and one β turn are arranged as an antiparallel sandwich fold, in a three-layer structure surrounding the ligand-binding cavity. In the holo state the LBD is more compact and

the helix 12 harboring the ligand-induced activation function is folded back toward the core of the LBD, creating an interface suitable for coactivator binding. It has not yet been possible to purify and crystallize the MR. Nevertheless, a three-dimensional model of the LBD of the human MR has been constructed using the crystallographic data for another member of the nuclear receptor superfamily as a template. Validation of the model by site-directed mutagenesis has made it possible to describe the organization of the MR LBD, to pick out the amino acids that delimit the ligand-binding cavity, and to identify those amino acids that interact with the polar functions of aldosterone. The 3-ketone moiety is anchored by Gln-776 and Arg-817, the 20-ketone moiety is anchored by Cys-942, and the 18- and 21-hydroxyls establish hydrogen bonds with Asn-770 (Fig. 4).

The aldosterone-dependent activation of gene transcription is thought to be a multistep process. In its unliganded state, the MR is found predominantly in the cell cytoplasm as a hetero-oligomeric complex in association with the heat-shock protein Hsp 90. The MR–Hsp 90 interaction appears to be required to maintain the receptor in a nonfunctional state and to fold the MR LBD in a ligand-binding-competent state. Aldosterone binding induces a change in the receptor conformation, thus allowing the associated proteins to dissociate and permitting the recruitment of transcriptional coactivators. Within the nucleus, the aldosterone-associated receptor binds as a dimer to hormone response elements in the promoter region of target genes and initiates hormone-mediated transcription through specific interactions with the transcriptional machinery.

The contact between Asn-770 in helix 3 and the 21-hydroxyl group of aldosterone is crucial for the activation of the MR. In the absence of this contact, the MR remains in an inactive state—indeed, progesterone and the drug spironolactone, both of which lack the 21-hydroxyl group (Fig. 1), are potent mineralocorticoid antagonists.

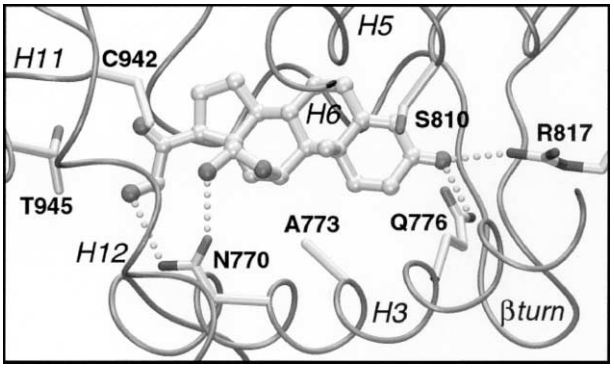

FIGURE 4 Aldosterone docking within the ligand-binding domain of the human mineralocorticoid receptor.

III. ACTIVATING MUTATIONS OF THE MINERALOCORTICOID RECEPTOR

A missense mutation in the MR LBD, resulting in the substitution of leucine for serine at codon 810 (MR_{L810}), has been detected in a 15-year-old boy with severe hypertension, suppressed plasma renin activity, and low serum aldosterone. Examination of the patient's family revealed that 11 MR_{L810} carriers all developed hypertension before they were 20 years old, a rare trait in the general population, whereas the other members of the family had unremarkable blood pressure. All pregnancies among patients known to harbor this mutation have been complicated by a dramatic exacerbation of their hypertension, combined with the complete suppression of their

renin–angiotensin system. Aldosterone levels, which are normally increased during pregnancy, were undetectable.

The MR_{L810} function measured in cis–trans cotransfection assays, revealed a constitutive activity of MR_{L810} that is not detected for the wild-type receptor (MR_{WT}). This activity, observed in the absence of any added steroid, may contribute to the hypertension in patients harboring this mutation. Several steroids have been tested for their ability to activate MR_{L810}. Estradiol and testosterone, steroids with a 17β-hydroxyl group (Fig. 1), activated neither MR_{L810} nor MR_{WT}, whereas steroids with a 21-hydroxyl group, such as aldosterone and cortisol, activated both MR_{WT} and MR_{L810}. Surprisingly, steroids without the 21-hydroxyl group did activate MR_{L810}, but they displayed antagonist properties when bound to the MR_{WT}. This is the case for the antihypertensive drug spironolactone (a synthetic steroid with a 17γ-lactone), and as a result, its use is contraindicated for MR_{L810} carriers. Progesterone also activates MR_{L810}, and in this regard has the same potency as aldosterone. Progesterone levels normally increase 100-fold in pregnancy, and so it is likely that this hormone is responsible for the severe hypertension that is developed during pregnancy by MR_{L810} carriers. The mechanism of early-onset hypertension in men is unclear. It has been suggested that 17α-hydroxyprogesterone may contribute to hypertension in men, because it is present at levels similar to those of aldosterone; furthermore, this derivative of progesterone is able to activate MR_{L810}.

The mechanism of MR_{L810} activation is distinct from that of MR_{WT}. In a three-dimensional model of MR_{L810}, the side chain of Leu-810 in helix 5 projects into the ligand-binding cavity, thus making possible van der Waals contacts between Leu-810 and Ala-773 in helix 3. The implication of these contacts in the MR_{L810} activation process was demonstrated in a site-directed mutagenesis study. Mutant receptors with amino acids bearing a short side chain at position 810 or 773 were not activated by a progesterone derivative, whereas MR_{L810} was activated by the compound. The fact that the interaction between the steroid 21-hydroxyl group and Asn-770 becomes dispensable when a helix 3/helix 5 contact is created suggests that these contacts are interchangeable for receptor activation. Such a helix 3/helix 5 contact is present in the crystal structures of the progesterone and androgen receptors, with a methionine and a glycine at the position corresponding to Leu-810 and Ala-773 in the MR_{L810}. The conservation of this contact and its role in the MR_{L810} activation by steroids lacking a 21-hydroxyl suggest that it is significant in activating nuclear receptors.

IV. LOSS-OF-FUNCTION MUTATIONS OF THE MINERALOCORTICOID RECEPTOR

Pseudohypoaldosteronism type 1 (PHA1) is a rare inherited disease involving mineralocorticoid resistance characterized by severe neonatal salt loss accompanied by hypotension, despite high aldosterone levels. Affected patients also have marked hyperkalemia and metabolic acidosis and are resistant to the administration of exogenous mineralocorticoids. Treatment consists of salt supplementation, which can sometimes be discontinued after a variable period of time.

There are two forms of PHA1, autosomal recessive and autosomal dominant; in other cases, PHA can be sporadic. The recessive form, with severe and recurrent life-threatening episodes of salt loss, is caused by homozygous loss-of-function mutations in genes encoding the subunits of the amiloride-sensitive ENaC. The autosomal dominant form and the sporadic cases manifest with a milder clinical picture, and in these forms, salt loss gradually improves with age. Heterozygous mutations in the MR have been identified in four autosomal dominant cases and in one sporadic case (Fig. 3). These mutations include a nonsense mutation at position 1831 (Δ1831T), introducing a premature stop codon at position 537 (R537Stop). Two single base pair deletions (Δ G1226 and ΔT1597) introduce frameshift mutations, leading to a premature stop codon; the resulting proteins lack the entire DBD and LBD. A single base pair deletion in the intron E splice donor site changes the consensus sequence, suggesting that this mutation results in aberrant splicing. A missense mutation resulting in the substitution of proline for leucine at codon 924 (MR_{P924}) was found in a Japanese family with the dominant form of PHA1. *In-vitro* functional assays revealed that, unlike MR_{WT}, MR_{P924} is not activated by aldosterone. Replacement of leucine by proline at position 924 has been proposed to affect receptor dimerization. Nevertheless, a change in receptor conformation cannot be ruled out, because the introduction of a proline within helix 10 could indeed alter the helical structure. Another frameshift mutation was detected in a sporadic case of PHA1. This mutation (InsC2871) affects the C-terminus of the LBD, introducing a new 54-amino acid sequence from codon 958 (the first stop being located at position 1012). Although the ligand-binding capacity of this mutant has not been investigated, it is likely

that modification of the extremity of the MR LBD could impair the ligand-binding capacity of this mutant, as has already been reported for truncations or point mutations in this region.

V. SUMMARY

Aldosterone is involved in the regulation of sodium homeostasis and plays a role in the regulation of blood pressure. It acts by binding to the mineralocorticoid receptor, a ligand-activated transcription factor that belongs to the nuclear receptor family. Loss-of-function mutations of the mineralocorticoid receptor have been identified in several patients with autosomal dominant or sporadic pseudohypoaldosteronism type 1. On the other hand, there has also been a description of a mineralocorticoid receptor activating mutation that causes early-onset hypertension exacerbated during pregnancy. This mutation modifies the selectivity of the receptor, so that progesterone and the antimineralocorticoid drug spironolactone become potent activators of the mutant receptor. This identification of naturally occurring activating and inactivating mutations of the mineralocorticoid receptor highlights its central role in the regulation of blood pressure.

Mineralocorticoid Receptors

JOHN W. FUNDER

University of Melbourne and Prince Henry's Institute of Medical Research

Mineralocorticoid receptors are members of the steroid/thyroid/retinoid/xenobiotic/orphan receptor family of transcription factors, most closely linked in terms of sequence and

subcellular mechanism of action with the glucocorticoid receptor, the androgen receptor, and the progesterone receptor.

I. INTRODUCTION

Although the time-honored definition of a mineralocorticoid hormone is that of promoting unidirectional transepithelial sodium transport, mineralocorticoid receptors (MRs) are found in varying abundance in both epithelial and nonepithelial tissues. In addition, MRs have equivalent affinity for aldosterone, the physiologic mineralocorticoid, and the physiologic glucocorticoids (cortisol and corticosterone), which circulate at ~1000-fold higher plasma levels. In classical mineralocorticoid target tissues, aldosterone access to MRs involves the expression of high levels of the enzyme 11βhydroxysteroid dehydrogenase type 2 (11βHSD2), which converts cortisol and corticosterone to their cognate, receptor-inactive 11-ketosteroids. In several nonepithelial tissues, 11βHSD2 is also co-expressed with MRs, consistent with such tissues (vascular smooth muscle, amygdala, and placenta) also being physiologic aldosterone target tissues. In other nonepithelial tissues, MRs are unprotected and thus presumably essentially always occupied by glucocorticoids: the function of such MRs remains obscure. Similarly unexplained to date is the differential effect of MR occupancy between 11βHSD protected and unprotected tissues. In protected tissues, cortisol and corticosterone mimic the effect of aldosterone, if and when they can access MRs, whereas in unprotected tissues, the glucocorticoids appear to function as MR antagonists and inappropriate occupancy by aldosterone may have very deleterious effects. Possible roles for glucocorticoid-occupied MRs as monitors and modulators of intracellular redox status are proposed.

II. BACKGROUND

The hormone aldosterone was first isolated and characterized in 1953, and distinct MRs were identified 2 decades later. From the very first studies it was clear that MRs had a disconcertingly high affinity for the physiologic glucocorticoids, which circulate at orders of magnitude higher concentrations; it also became rapidly apparent that MR expression was not confined to classic aldosterone target tissues (kidney distal tubule, distal colon, sweat gland, and salivary gland) but was seen in a variety of nonepithelial tissues such as brain, heart, and vascular smooth muscle cells (VSMCs). In classical epithelial aldosterone target tissues, MRs are expressed at modest levels (~10,000 molecules/cell), as is the enzyme 11βhydroxysteroid dehydrogenase at much higher levels (~3.5 million molecules/cell). 11βHSD2 operates to convert receptor-active cortisol and corticosterone to their receptor-inactive 11-keto congeners, in the process generating NADH from its obligate co-substrate NAD; aldosterone is not similarly metabolized, as its 11βhydroxyl group cyclizes with the signature CHO (aldehyde) group at C-18, forming an 11,18-hemiacetal and thus protecting aldosterone from enzymatic attack and allowing it preferential access to MRs.

Immunocytochemical studies have shown that both unliganded MR and 11βHSD2 are extranuclear, but that on binding steroid the MR translocates to the nuclear compartment and binds to palindromic 15-mer response elements apparently shared with the glucocorticoid receptor (GR), progesterone receptor (PR), and androgen receptor (AR) and generally termed glucocorticoid-response elements. Many facets of the subcellular action of aldosterone have been assumed by inference from studies on GR/PR/AR, for several reasons. First, MRs are unstable in broken cell preparations, particularly in the absence of added molybdate, and thus are difficult to work with. Second, an effective aldosterone antagonist (spironolactone) was developed 40 years ago, and thus the impetus to develop antagonists by cellular and molecular screening was lacking. Finally, and most importantly, until relatively recently aldosterone appeared to be a relatively unidimensional hormone (sodium homeostasis), and the roles of the obviously more complex but still considered cognate "mineralocorticoid" receptor were tarred with the same brush. In the sections to follow, the clearly important epithelial roles of aldosterone and MR will be presented, focusing on areas that remain incompletely explored or enigmatic. Subsequently, the physiology (or currently, often the pathophysiology) of both protected (e.g., VSMCs) and unprotected (e.g., cardiomyocyte) MRs will be discussed. Finally, a possibly unifying hypothesis for MRs occupied by glucocorticoids, reconciling the apparently opposing actions in the two tissue types, will be put forward.

III. EPITHELIAL MR AND THE PHYSIOLOGY OF ALDOSTERONE ACTION

As previously noted, MRs are expressed at modest levels in particular cells (e.g., principal cells in the renal collecting tubule) of established aldosterone

target tissues. Aldosterone acts via MRs to regulate genes coding for pump subunits, channel subunits, or enzymes that activate them to increase sodium transport from the tubular lumen into the cell. As such, aldosterone forms a crucial endocrine link in a negative feedback loop, with its levels increased by sodium deficiency or loss, lowered plasma volume, or high potassium intake. Without aldosterone, animals require a high-salt diet to survive, with many species including human needing mineralocorticoid replacement therapy in addition; similarly, the MR knockout mouse dies ~10 days postpartum unless supplementary sodium is given.

In evolutionary terms, the drive was almost certainly that of retaining relatively scarce sodium in terrestrial environments. Accordingly, multiple mechanisms to elevate aldosterone secretion rate have evolved; in addition to the well-recognized effect of angiotensin II, potassium intake has been shown to be a powerful, independent elevator of aldosterone production. Redundancy of this sort is clearly an evolutionary advantage in the context of a commonly low sodium, the high potassium intake of a largely vegetarian diet, and the intercurrent fluid and electrolyte losses seen with a high incidence of diarrheal disease. In such a context, the evolution of a specific aldosterone synthase (CYP11B2) in the zona glomerulosa of the adrenal cortex—or, in some species, of conditions favoring aldosterone synthase activity of CYP11B1, the mechanisms of which are currently unknown—is of survival advantage, if aldosterone synthesis can be yoked to sodium status, as is obviously the case. In addition, the evolution of an aldosterone-specific MR (which does not appear to have been the case) or of mechanisms allowing aldosterone to selectively access and activate a less selective receptor is a necessary second part of such a control system.

In terms of evolution, MRs appear probably to have substantially antedated aldosterone synthase. If the MR is compared with the GR, its nearest homologue, the area of highest identity (90%) is the relatively short (66–68 aa) DNA-binding domain; in the ligand-binding domain, the extent of identity is 57%, and in the N-terminus <15%. In addition, the genes for the two receptors are located on different chromosomes. In contrast, aldosterone synthase and the glucocorticoid-specifying enzyme CYP11B1 lie adjacent to one another on chromosome 8 and are 94% identical over the whole coding region. The most common explanation offered for such a finding is one of relatively recent gene duplication, and the inference is that the more complex (CYP11B2, aldosterone synthase) derives from the less complex (CYP11B1). On the other hand, there is no formal proof of this, with its corollary that aldosterone followed corticosterone in evolutionary time and that MR preceded its "cognate" ligand.

Two other points need to be made regarding the classical epithelial MR. First, it is clear from studies in which 11βHSD2 is blocked by licorice ingestion or carbenoxolone administration, or is congenitally defective as in the syndrome of apparent mineralocorticoid excess, that the physiologic glucocorticoids mimic the effect of aldosterone when they occupy the MR in such circumstances. Similarly, when 11βHSD2 is absent or blocked, "pure" glucocorticoids selective for the GR and with no affinity for the MR will mimic the effect of aldosterone on urinary electrolytes, for example, providing further evidence for the pivotal role of 11βHSD2 in conferring steroid selectivity on aldosterone target tissues. An inference of the equivalent MR activity of mineralocorticoids or glucocorticoids in such circumstances is that on entering the nucleus the steroid–receptor complex is able to recruit a similar range of co-activators, although studies in this area for the MR are just beginning, lagging well behind comparable findings for other receptors.

In this context, however, another question arises. Unless 11βHSD2 acts as a physical constraint to the access of glucocorticoids to the MR, unlikely given its localization on the endoplasmic reticulum, it is inevitably a less than perfect protective mechanism, with its efficiency at reducing glucocorticoid access determined by the relative concentrations of enzyme and receptor and their (loosely speaking) relative affinity for the ligand. A rough calculation gives a figure of ~5% for corticosterone and ~15% for cortisol, as the amount of unmetabolized glucocorticoid that "leaks" past the protective enzyme to the receptor. In such circumstances, what the enzyme does is reduce active glucocorticoid receptor by approximately an order of magnitude—which would mean that cortisol/corticosterone concentrations postenzyme were still ≥10-fold those of aldosterone and that MR would be ≥90% occupied by glucocorticoid.

That this is not merely a rough estimate is shown by *in vivo* [^{3}H]aldosterone-binding studies in adrenalectomized rats. Rats were injected with tracer plus RU486 (to exclude [^{3}H]aldosterone from the GR), alone or with increasing half-log doses of nonradioactive aldosterone or corticosterone. Fifteen minutes later the animals were killed, and MR occupancy—by tracer or by added nonradioactive

steroid—was determined in heart, hippocampus, kidney, and colon. In heart, corticosterone was ~30% as potent as aldosterone in binding the MR, consistent with the known differences in receptor affinity (corticosterone 3 × aldosterone) and plasma binding (corticosterone 10 × aldosterone). In the kidney, which unlike the heart expresses 11βHSD2, corticosterone was ~3% as potent as aldosterone, consistent with the enzyme adding another order of magnitude in specificity—but also with the bulk of the renal MRs being occupied under normal conditions by corticosterone, as predicted from the rough mathematical calculations.

One possible explanation for this apparent conundrum lies with the often forgotten co-substrate for 11βHSD2, i.e., NAD. If the enzyme is operant, in addition to converting hydroxyl to ketosteroids it is generating high levels of NADH. In a series of studies on the GR, it has been shown that thioredoxin binds to the DNA-binding domain and that a GR–dexamethasone complex is or is not transcriptionally active depending on the redox state of the cell. A similar scenario for glucocorticoid–MR complexes would thus explain why such complexes are inactive in the presence of ambient high levels of NADH, as is the case when the enzyme is operant, or become active when the enzyme is blocked. If such a redox dependence holds for glucocorticoid–MR complexes, as appears to be the case for GR–glucocorticoid complexes, then presumably an aldosterone–MR complex is not equivalently redox-sensitive, reflecting some otherwise minor differences between occupied MRs depending on the ligand. Whether or not this redox dependence holds awaits experimental investigation; in its absence, and in the meantime, there remains a continuing conundrum in terms of the selectivity of action, rather than binding, of epithelial MR.

IV. CO-EXPRESSION OF MR AND 11βHSD2 IN NONEPITHELIAL TISSUES

Until recently, it appeared that 11βHSD2 was co-expressed with MRs in classical mineralocorticoid target tissues, but not in nonepithelial tissue, despite claims to the contrary; in the heart, for example, a report of their co-existence was predicated on cardiac levels of the enzyme <1% of those in the kidney, where it is expressed in only ~5% of the total number of cells. More recently, however, co-localization has been shown to occur in several areas, although the ascription of physiologic roles to such MRs is the objective of current studies. In the amygdala, for example, co-expression is thought to allow a degree of mineralocorticoid selectivity in terms of salt appetite, particularly necessary given the very high reflection coefficient of aldosterone vis-à-vis glucocorticoids at the blood–brain barrier. In the placenta, 11βHSD2 has long been ascribed the role of separating maternal and fetal glucocorticoids; a role in MR protection, however, seems possible given the demonstration that prostaglandin 15 dehydrogenase production in human placenta increases 100-fold in its sensitivity to cortisol (from an IC_{50} of 10^{-8} *M* to an IC_{50} of 10^{-10} *M*) in the presence of carbenoxolone to block 11βHSD2. Finally, an elegant series of studies on the rapid nongenomic effects of aldosterone on the Na^+/H^+ exchanger in human VSMCs has shown that not only are such effects mediated via classical MRs, but also that such MRs are 11βHSD2 protected, in that in the presence of carbenoxolone cortisol at nanomolar doses mimics aldosterone but is without effect in its absence.

The vascular smooth muscle cell thus appears to be a candidate aldosterone target tissue by the same criteria and presumably to the same extent as the renal collecting duct or the distal colon. In addition to the acute studies described above, there are as yet unpublished reports of vasoconstrictor effects of near-physiologic doses of aldosterone on human forearm vasculature and a number of previous studies on isolated vessels or dispersed cells that were often consistent with alternative explanations given the high dosages of aldosterone commonly used. It would now seem incumbent upon the vascular biologists in the field to establish the physiologic actions of aldosterone, genomic and nongenomic, via the MR in VSMCs. Given the effects of elevated aldosterone in restoring plasma sodium and volume, a direct vasoconstrictor action of aldosterone appears to be not inconsistent with an overall action to compensate for fluid and electrolyte loss, at least in the short term pending restoration via altered intake and excretion.

That the VSMC MR may be of high pathophysiologic significance in cardiovascular disease is suggested by a number of recent findings on the vascular inflammatory responses following elevation of mineralocorticoid levels in salt-loaded rats. In such studies, the levels of inflammatory cells and markers (ED-1, osteopontin, monocyte chemoattractant protein-1, interleukin-6, etc.) are increased in and around coronary vessels within a week of administration and are very substantially blocked by co-administration of the novel MR selective antagonist eplerenone. What is important is that such lesions reflect

inappropriate MR activation rather than aldosterone per se: animals receiving high salt, plus carbenoxolone to block 11βHSD2 and allow corticosterone access to and activation of coronary MRs, show inflammatory responses identical to those of mice treated with deoxycorticosterone and salt in parallel. This is of particular potential importance if the majority of VSMC MRs are physiologically occupied by glucocorticoids and are or are not transcriptionally active depending on the redox status of the cell.

V. MR EXPRESSION IN THE ABSENCE OF 11βHSD2 IN NONEPITHELIAL TISSUES

The two best studied nonepithelial tissues in which MRs are expressed (often at high levels, as in the hippocampus) are a range of areas in the brain and in the heart. Such receptors appear normally to be occupied by glucocorticoids in what might be described as a tonic inhibitory fashion; if aldosterone is introduced to such receptors, in many circumstances its effects can be blocked (at comparable doses, reflecting the absence of 11βHSD2) by the physiological glucocorticoid. When rats are infused with aldosterone via the lateral ventricle of the brain at doses totally without effect when infused peripherally, it elevates blood pressure; co-infusion of corticosterone antagonizes the blood pressure rise, with infusion of corticosterone alone having no effect. That this neat study may not be the final word, however, is shown by subsequent experiments from the same laboratory, in which intracerebroventricular (icv) RU28318, a water-soluble MR antagonist, blocked the hypertensive response to 0.9% NaCl to drink normally shown by salt-sensitive rats. Similarly, icv RU28318 lowered blood pressure by 20–30 mm Hg in Wistar rats essentially independent of Na^+ status, again evidence against a simple tonic inhibitory role for MR occupancy by physiologic glucocorticoids in the circumventricular areas of the brain involved in blood pressure control.

In cardiomyocytes, MRs similarly "see" aldosterone and glucocorticoids differently, with corticosterone clearly not mimicking the anabolic effect of aldosterone on neonatal rat cardiomyocytes in culture. Though such studies show a functional difference between mineralocorticoid and glucocorticoid occupancy of MRs in such cells, they do not directly show a tonic inhibitory role for glucocorticoids in such circumstances. In a more recent study, however, such a role has been directly demonstrated, by observing the effects of cardiomyocyte-specific overexpression of 11βHSD2 (to levels of only ~10% of those in a renal principal cell, however) allowing aldosterone inappropriate access to cardiomyocyte MRs. Such mice demonstrate a syndrome of progressive cardiac dilation, cardiomegaly, and heart failure, with functional parameters improved significantly by administration of the selective MR antagonist eplerenone. It is important to emphasize that such mice are maintained on regular chow and drinking water and have no exogenous aldosterone; their cardiac pathology thus presumably represents grossly altered transcription under the influence of normal levels of aldosterone inappropriately occupying MRs. It is also important to note that in such animals the coronary vessels—as opposed to the heart muscle—appear normal, supporting the selectivity of the induced lesion.

Finally, a note of further speculation. If MRs have persisted throughout evolution, to be always essentially occupied by glucocorticoids in unprotected tissues such as the cardiomyocyte, it is possible that such glucocorticoid–MR complexes serve a physiologic function. The effects of redox state on GR–dexamethasone transcriptional activity and its proposed parallel role for MR–glucocorticoid complexes in the kidney were noted earlier. One possible physiologic role for an MR always occupied by glucocorticoid in the heart might thus be as a sensor of redox state, with transcriptional activation dependent not on ligand binding but on the metabolic state of the cell. In a recent study on the positional cloning of the combined hyperlipidemia gene HypLip1, a mutation in the cytoplasmic thioredoxin-binding protein TXNIP showed major alterations in the hepatic citric acid cycle, with sparing of ketone body and triglyceride production. Very high cardiac levels of thioredoxin/TXNIP were observed in both wild-type and mutant mice, consistent with a major role in metabolic regulation of redox state, and thus, a possible role for cardiac MRs in modulation of transcriptional activity in response to redox state.

Glossary

aldosterone The physiological mineralocorticoid (salt-retaining) hormone, produced in the zona glomerulosa of the adrenal cortex and circulating at relatively low plasma levels.

cortisol and corticosterone Physiological glucocorticoid hormones, produced in the zona fasciculata of the adrenal cortex. In most species, cortisol is the predominant glucocorticoid, but in rats and mice, corticosterone is the sole glucocorticoid.

11βhydroxysteroid dehydrogenase type 2 An enzyme that converts steroids bearing a hydroxyl group at carbon 11 (e.g., cortisol, corticosterone) to their 11-keto congeners (cortisone, 11-dehydrocorticosterone).

epithelial and nonepithelial tissues Epithelial tissues demarcate a boundary between the milieu interieur and the milieu exterieur (e.g., gut wall, kidney tubule), across which the transport of ions and water in either direction is possible. Nonepithelial tissues are entirely part of the milieu interieur (e.g., brain, vascular wall).

NAD/NADH Proton acceptor/donor pair; required cosubstrate for 11βhydroxysteroid dehydrogenase type 2.

redox state Ratio of total reducing equivalents (NADH, GSH, etc.) to their oxidized form (NAD, GSSG, etc.).

Mineralocorticoids and Hypertension

DAVID J. MORRIS* AND ANDREW S. BREM†

**The Miriam Hospital • †Rhode Island Hospitals, Brown University Medical School*

Although a renal sodium-retaining factor isolated from extracts of animal adrenal glands had been known since the early 1940s, it was not until 1953 that elaborate sequential paper and column chromatography techniques allowed aldosterone to be isolated from beef adrenals. The mineralocorticoid activity of the hormone was established experimentally and through biological studies, and once the chemical structure of aldosterone was determined, it was shown to originate in the zona glomerulosa cells of the adrenal cortex. Patients with primary adrenal tumors containing glomerulosa cells demonstrated all the findings of excess aldosterone production: suppressed plasma renin levels, excessive sodium retention, potassium wasting, and hypertension.

I. INTRODUCTION

The mineralocorticoid activity of aldosterone has been established physiologically by administering the hormone to adrenalectomized rats and measuring in their urine the excretion ratio of $^{24}Na/^{42}K$. Aldosterone has

been isolated from the urine of individuals known to be in positive sodium balance, including pregnant women and patients with congestive heart failure, cirrhosis of the liver, and nephrotic syndrome. The hormone is secreted by the zona glomerulosa cells of the adrenal cortex. Patients with primary adrenal tumors containing glomerulosa cells produce excess aldosterone, which leads to suppressed plasma renin levels, excessive sodium retention, potassium wasting, and hypertension (Conn's Syndrome).

Sodium intake and the rennin–angiotensin system principally regulate the synthesis of aldosterone, but hormone synthesis can also be stimulated by increases in serum potassium and, to a very limited degree, by adrenocorticotropic hormone (ACTH). Mineralocorticoids play a major role in sodium homeostasis and blood pressure regulation. Although the principal tissue targets for mineralocorticoids are sodium-transporting epithelial cells (e.g., in kidney, parotid gland, sweat ducts), mineralocorticoids also have significant potential actions in nonepithelial target tissues (e.g., vascular system, heart, and brain). Extra-adrenal *in situ* synthesis has been recently described in the vascular tissue. Studying patients with forms of low-renin hypertension has also led to the discovery of other relevant, albeit weaker, mineralocorticoids, including deoxycorticosterone and 18-OH-deoxycorticosterone.

II. PROBABLE MECHANISMS OF ALDOSTERONE ACTION ON BLOOD PRESSURE

A. Renal and Volume-Sensitive Processes

The renal sodium-retaining effects of aldosterone were first described over 50 years ago. In a series of elegant physiological experiments, it was demonstrated that after a latent period of 60 to 90 min, amphibian epithelia exposed to mineralocorticoids generated a progressive increase in mucosal to serosal sodium transport. That aldosterone-dependent rise in sodium flux was preceded by specific receptor binding of the steroid hormone; translocation of the receptor–steroid complex to the nucleus was dependent on *de novo* protein synthesis and consumed energy in the form of adenosine triphosphate (ATP). Further studies conducted on renal distal tubules and other aldosterone-responsive tissues expanded our understanding of mineralocorticoid-induced electrolyte transport. Now it has become clear that mineralocorticoids such as aldosterone can induce the synthesis of components of Na^+,K^+-ATPase and can directly increase the apical (mucosal) membrane conductance to sodium by enhancing the open probability for the sodium channel (ENaC) located within that membrane.

Mineralocorticoid receptors are found in the distal nephron, principally in the cortical collecting tubule. Under physiological conditions, the mineralocorticoid aldosterone affects the reabsorption of approximately 3% of the sodium filtered by the glomerulus. Continuous exposure to aldosterone results in a state of positive sodium balance and can expand the extracellular fluid space sufficiently to produce mild edema and hypertension. The progressive increase in extracellular volume induced by mineralocorticoid eventually reaches a limit, however, and renal tubular "mineralocorticoid escape" occurs. The escape, mediated largely through a decreased reabsorption of sodium in the proximal tubule, allows for sodium balance to be reestablished, but at a new steady state. Even with the activation of the escape process and normalization of the extracellular fluid space, the hypertension most often persists. Thus chronic mineralocorticoid exposure influences blood pressure in non-volume-dependent ways.

B. Vascular Effects of Mineralocorticoids

Over the past decade, it has become increasingly clear that mineralocorticoids can and do exert specific effects on the arterial vascular network, independently of extracellular volume and systemic blood pressure. Perhaps the most intriguing observation has been that vascular smooth muscle cells have the ability to directly synthesize minute quantities of aldosterone and that angiotensin II induces CYP11B2, the enzyme responsible for aldosterone synthesis in vascular tissue. Aldosterone, in turn, augments the vascular effects of angiotensin II by directly up-regulating angiotensin II receptor (AT-1 type) number in vascular smooth muscle cells. Thus, these vascular angiotensin II–aldosterone interactions have significant implications for the entire systemic arterial network affecting vessel compliance (resistance), blood pressure, and cardiac function.

Chronic exposure to both angiotensin II and aldosterone promotes the generation of type I and type III collagen in the heart and aorta, resulting in an increase in interstitial fibrosis that is independent of blood pressure. Angiotensin II, unlike aldosterone, also inhibits collagenase activity, preventing or delaying the breakdown of preformed collagen. The net effect of the interstitial fibrosis induced by both aldosterone and angiotensin II is to decrease vessel

compliance, leading to a "stiffer," less resilient ventricle or artery. The diminished arterial compliance is a contributing factor in the evolution of systolic hypertension.

Aldosterone induces a series of specific ionic transmembrane transport processes in vascular smooth muscle cells, transiently changing the intracellular milieu prior to the sequence of structural remodeling. In experimental models, aldosterone exposure over 7–10 days increases the membrane conductance, allowing enhanced influx of sodium in vascular smooth muscle cells. This influx is mediated by mineralocorticoid receptors in vascular smooth muscle. The steroid- receptor binding can be blocked by spironolactone, and sodium channel activity can be directly inhibited by amiloride. Although the entry of calcium ions is not directly affected, there is a decrease in the expression of the membrane-bound sodium–calcium ion exchanger, which would result in a net increase in cytosolic calcium. Subtle changes in the cytosolic concentrations of both of these ions can "sensitize" vascular beds to contractile stimuli and boost vascular resistance.

Two compensatory mechanisms are activated in vascular smooth muscle in response to chronic mineralocorticoid exposure: the sodium pump activity and expression of (Na^+,K^+-ATPase) and efflux of potassium ions via the calcium-dependent potassium channel. The increase in sodium pump activity strives to restore normal intracellular sodium concentrations and the potassium efflux attempts to relax the smooth muscle cell, dropping vascular resistance. Chronic intracellular potassium depletion appears to be one of the factors linked to the stimulation of collagen formation.

C. Central Nervous System Effects

Mineralocorticoids also exert their effects on blood pressure through actions in the brain. Although mineralocorticoid receptors have been observed in the hippocampus and hypothalamus, their role was difficult to determine until relatively recently. In a series of elegant experiments, Elise Gomez-Sanchez demonstrated that infusion of minute quantities of aldosterone into the ventricles of the brain induces hypertension in animals after 14 days. The hypertension could be blocked by the intraventricular infusion of either a mineralocorticoid receptor antagonist or by amiloride. The observed increase in blood pressure in this model could be enhanced with sodium loading but was not dependent on it. This central form of hypertension appears to be mediated by a generalized increase in sympathetic tone with an accompanying rise in vascular resistance. Thus concentrations of aldosterone, which would produce no visible systemic effect, can produce hypertension when placed directly into the brain.

III. ALDOSTERONE-DEPENDENT CONDITIONS

A. Adrenal Tumors

A full discussion of the clinical syndromes associated with aldosterone excess is beyond the scope of this article. Rather, the focus is to mention the key points on the more common conditions encountered in clinical practice. Primary hyperaldosteronism should be considered as a cause of hypertension in patients who present with hypokalemia and metabolic alkalosis or who develop those findings nearly simultaneously with the onset of diuretic treatment. Although plasma renin and aldosterone levels are dependent on dietary sodium and position (lying versus standing), the plasma renin is maximally suppressed in cases of primary hyperaldosteronism.

An adrenocortical adenoma is among the most common causes of primary hyperaldosteronism. These tumors are generally small, less than 2 cm in size, and hence are often difficult to identify radiographically. Aldosterone-producing adenomas often also generate 18-OH-corticosterone in concentrations exceeding 100 ng/dl. Patients with this type of tumor exhibit an unexpected drop in aldosterone secretion with changes in position. When plasma aldosterone levels are measured in the early morning, after patients remain supine overnight, and then are remeasured after the patient stands upright for 4 h, the values fall paradoxically on the standing sample. Adrenal carcinomas are quite rare but also can secrete aldosterone. These cancers are usually large and are easily seen on routine radiographic studies.

B. Idiopathic Adrenal Hyperplasia

Bilateral nodular adrenal hyperplasia, or idiopathic hyperaldosteronism, is the next most common cause of excess aldosterone secretion. Both adrenal glands are involved, but the degree of involvement may not necessarily be symmetrical. In contrast to adrenal adenomas, plasma renin may be only partially suppressed and there is generally no paradoxical position effect on aldosterone secretion. There is some evidence that adrenal glomerulosa cells have increased sensitivity to the normal promoters of aldosterone secretion, including angiotensin II.

Direct bilateral adrenal vein sampling or adrenal imaging using ^{131}I-labeled iodocholesterol may be required to make the diagnosis.

C. Glucocorticoid-Remediable Hyperaldosteronism

Glucocorticoid-remediable (suppressible) hyperaldosteronism is a rare autosomal dominant inherited condition in which adrenal glomerulosa cells respond inappropriately to ACTH. Affected patients exhibit a chimeric gene crossover between the 11β-hydroxylase (responsible for cortisol synthesis) and the aldosterone synthase. Treatment with exogenous glucocorticoids such as dexamethasone suppresses the secretion of ACTH from the pituitary gland, thereby attenuating the release of aldosterone.

D. Renal Renin-Dependent Hyperaldosteronism

Processes affecting renal arterial blood flow, including renal artery stenosis, are associated with enhanced release of renin from the juxtaglomerular apparatus. The enzyme renin cleaves angiotensin I from angiotensinogen, the precursor produced by the liver and released into the circulation. Converting enzyme found in plasma and in the tissues, including kidney, transforms the decapeptide angiotensin I to the octopeptide angiotensin II. Angiotensin II is a potent stimulus for the adrenal glomerulosa cells to secrete aldosterone. Thus, renal vascular disease is associated with both excessive release of renin, leading to elevated plasma angiotensin II, and increased aldosterone levels. Evaluation of the renal arteries is warranted with secondary hyperaldosteronism and worsening hypertension. A captopril renal scan and/or angiography may be required to establish the diagnosis.

IV. CONDITIONS MIMICKING ALDOSTERONE EXCESS

A. Syndromes of Mineralocorticoid Excess: Altered 11β-Hydroxysteroid Dehydrogenase Activity

The syndrome of apparent mineralocorticoid excess (AME) was first described in children who demonstrated sodium retention, potassium wasting, and hypertension without measurable elevations in either renin or aldosterone. Thus the severe hypertension in these children was initially categorized as pseudohyperaldosteronism. Later, it became clear that this syndrome was associated with mineralocorticoid receptor (MR) activation and that it could be successfully treated with spironolactone. Once the mineralocorticoid receptor was cloned, relative binding studies were performed. Quite unexpectedly, the MR demonstrated equal binding affinities for both aldosterone and cortisol. From these observations came the concept that an alternative regulator of steroid binding must exist over the MR to maintain its specificity. In the past decade, one regulatory modulator of steroid binding, the isoform of the enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD2), was isolated and cloned from mineralocorticoid-responsive tissues. 11β-HSD2 converts active endogenous glucocorticoids to their respective 11-dehydro derivatives and confers aldosterone specificity on the MR. 11β-HSD2 has a low K_m for glucocorticoids, making it sensitive, and is dependent on the cofactor nicotinamide adenine dinucleotide (NAD^+) for its activity. As an enzyme, it appears to function physiologically only in the dehydrogenase mode. The 11-dehydro metabolites of cortisol and corticosterone are not able to directly activate mineralocorticoid receptors and induce a primary biologic effect.

Children with AME have homozygous mutations in the 11β-HSD2 gene, resulting in diminished 11β-HSD2 enzyme activity and failure of the "protective" mechanisms that selectively prevent glucocorticoids from accessing the MR in the distal nephron. This inappropriate stimulation of the MR in the kidney by glucocorticoids results in Na^+ retention, K^+ wasting, and hypertension associated with low plasma aldosterone and renin levels. Importantly, when challenged with exogenous cortisol, these children develop sodium retention and a marked increase in blood pressure, confirming that cortisol functions as a mineralocorticoid in the kidney, controlling both electrolyte transport and blood pressure. Licorice derivatives can mimic the hypertensive profile of AME. Licorice contains glycosides of glycyrrhetinic acid, which is a potent inhibitor of both isoforms of 11β-HSD.

Although increased renal sodium retention was thought to be the principal cause of hypertension in this disease, effects of nonmetabolized glucocorticoids in the vasculature due to diminished 11β-HSD local tissue activity may also be a factor in the development of hypertension in these children. Glucocorticoids and mineralocoticoids are known to potentiate the vasoconstrictive effects of both catecholamines and angiotensin II. It has been shown that glucocorticoids further amplify the contractile

effects of catecholamines and angiotensin II when 11β-HSD enzyme activity is inhibited. In *in vitro* experiments using inhibitors of both vascular 11β-HSD1 and 11β-HSD2 dehydrogenase, including the use of 11β-HSD2 and 11β-HSD1 antisense oligonucleotide probes, prior glucocorticoid exposure enhanced catecholamine-induced vascular contraction. Thus, 11β-HSD activity in the control of sodium retention in the kidney and 11β-HSD activity in vascular tissue are important in the control of blood pressure.

B. Liddle's Syndrome

Dysregulation of the sodium channel within the epithelial cells of the cortical collecting tubule can result in a syndrome that mimics hyperaldosteronism, but plasma renin and aldosterone values are maximally suppressed. Liddle's syndrome, a rare autosomal dominant disorder, results from a defective β-subunit of the epithelial sodium channel present in the cortical collecting duct cell apical membrane. This channel is normally activated by mineralocorticoids, but in this case is activated independently of hormone stimulation, resulting in sodium retention, potassium secretion, metabolic alkalosis, and hypertension.

Monoaminergic and Cholinergic Control of the Anterior Pituitary

EDWARD J. WAGNER

Western University of Health Sciences, California

I. INTRODUCTION

Anterior pituitary hormone secretion is regulated by aminergic and cholinergic transmitters. The degree of neurotransmitter regulation varies among the hormones. For some hormones, information concerning

the regulatory mechanisms, the pharmacology, and/or the physiology for a particular neurotransmitter system is either scarce or replete with contradictions. Contradictory findings may arise from differences among species or experimental methodologies, or from a lack of specific pharmacological tools to study a transmitter system. Despite these problems, it is well established that aminergic and cholinergic transmitters alter adenohypophysial hormone secretion primarily by modulating the excitability of hypothalamic neurosecretory cells that contain releasing or inhibiting hormones that are secreted into the median eminence and carried to the anterior pituitary by the portal circulation. In some cases, these neurotransmitters can serve as the hypothalamic factor and have a direct adenohypophysial effect, or can act by another peripheral mechanism. This article provides a compact, concise review of the aminergic and cholinergic transmitter regulation of adenohypophysial hormone secretion. Five major hormones are discussed: adrenocorticotropic hormone (ACTH), growth hormone (GH), prolactin, thyroid-stimulating hormone (TSH), and the gonadotropins. The neurotransmitters and modulators covered include norepinephrine, dopamine, serotonin, acetylcholine, histamine, and, to a certain extent, epinephrine and melatonin.

II. SYNTHESIS, REUPTAKE, AND METABOLISM OF BIOGENIC AMINES AND ACETYLCHOLINE

The first step in the biosynthesis of catecholamines such as dopamine, norepinephrine, and epinephrine involves hydroxylation of the aromatic amino acid substrate tyrosine by the rate-limiting enzyme tyrosine hydroxylase, which forms 3,4-dihydroxyphenylalanine (DOPA). DOPA is then rapidly decarboxylated by the ubiquitous enzyme L-aromatic amino acid decarboxylase (AADC) to form dopamine. In noradrenergic and adrenergic neurons, dopamine is further hydroxylated at the β-carbon of the phenylethylamine moiety by dopamine β-hydroxylase, thus rendering norepinephrine. Norepinephrine, in turn, is subject to an N-methylation reaction in adrenergic neurons by the enzyme phenylethanolamine-*N*-methyltransferase. Biosynthesis of indoleamines such serotonin and melatonin also involves the initial hydroxylation of the aromatic amino acid tryptophan by tryptophan hydroxylase, resulting in 5-hydroxytryptophan (5-HTP). As with the catecholamines, 5-HTP is then decarboxylated by AADC to form serotonin. In the pineal gland, serotonin is N-acetylated by the enzyme serotonin *N*-acetyltransferase to form *N*-acetylserotonin. This intermediate product is then methylated at the 5-hydroxy position by hydroxyindole-*O*-methyltransferase to yield melatonin. Histamine is formed from a single decarboxylation reaction in which the precursor amino acid histidine is acted on by the enzyme histidine decarboxylase. Likewise, acetylcholine is generated in a single enzymatic step involving two substrates: an acetyl group donated by one substrate (acetyl coenzyme A) is transferred to the other substrate (choline) by the enzyme choline acetyltransferase. All monoamine neurotransmitters and acetylcholine are packaged into synaptic vesicles by vesicular transporters that extrude protons from the vesicular lumen in exchange for the transmitters.

The primary means by which monoamine neurotransmitter action is terminated is by their removal from the synaptic cleft via reuptake into the nerve terminal. This is accomplished through membrane-bound transporters, with each one being responsible for the selective reuptake of a given amine. The reuptake process is dependent on the presence of sodium and chloride ions. Once inside their respective nerve terminals, dopamine, norepinephrine, and serotonin can then be oxidatively deaminated by monoamine oxidase (MAO) to form 3,4-dihydroxyphenylacetic acid (DOPAC), 3,4-dihydroxyphenylethyleneglycol (DOPEG), and 5-hydroxyindoleacetic acid, respectively. DOPAC and DOPEG either can be transported out of the central nervous system, or can be acted on by extraneuronal catechol-*O*-methyltransferase (COMT) to yield homovanillic acid and 3-methoxy-4-hydroxyphenylethyleneglycol (MHPG), respectively. Dopamine and norepinephrine can also be directly O-methylated by COMT to form 3-methoxytyramine and normetanephrine, and then deaminated by MAO, resulting in homovanillic acid and MHPG, respectively. The major metabolites of epinephrine are metanephrine formed by O-methylation by COMT, and vanillyl mandelic acid formed by subsequent oxidative deamination by MAO. Catecholamine metabolites such as DOPAC and MHPG can be subsequently conjugated with a sulfate group by the enzyme phenolsulfotransferase. The metabolism of histamine primarily involves an N-methylation reaction by the enzyme that produces *N-tele*-methylhistamine, histamine methyltransferase. Acetylcholine is rapidly cleaved and its action is thus terminated by acetylcholinesterases present in the synaptic cleft. Melatonin metabolites are formed primarily by hydroxylation at the C-6 position, followed by subsequent sulfation or glucuronidation conjugation reactions.

III. NEUROTRANSMITTER ANATOMICAL PATHWAYS

Noradrenergic perikarya are organized in discrete clusters in various brain stem nuclei, e.g., the nucleus of the solitary tract and the locus coeruleus. Seven major noradrenergic cell groups are classified alphanumerically, A_1 through A_7. These cell groups send diffuse projections throughout the brain and spinal cord, including various regions within the hypothalamus. The A_1, A_2, and A_6 cell groups are the most relevant to the noradrenergic control of anterior pituitary hormone secretion. The cell bodies of dopaminergic neurons are also organized in discrete clusters, and are also classified alphanumerically (A_8–A_{16}). Dopaminergic cell groups, however, are more widely distributed than are noradrenergic cell groups, ranging from the ventral tegmentum of the midbrain to the olfactory bulb of the rostral forebrain. The dopaminergic cell groups that are principally involved in regulating anterior pituitary hormone secretion are located in the hypothalamus; these are the A_{12}, or tuberoinfundibular dopaminergic (TIDA), and the A_{14} cell groups. Like the other catecholamines, the somas of adrenergic neurons are discretely localized into three distinct clusters within the medulla of the brain stem, and are alphanumerically classified as the C_1–C_3 cell groups. Each of these adrenergic cell groups has been reported to play a role in regulating the release of certain anterior pituitary hormones. Serotonergic neurons involved in regulating anterior pituitary hormone secretion have perikarya found primarily in the dorsal and median raphe nuclei located in the brain stem. Like the other monoamine neurotransmitter systems, serotonergic neurons are classified alphanumerically, designated as the B_1–B_9 cell groups. Serotonergic neurons send diffuse rostral projections to the hypothalamus and forebrain, and also project caudally to the spinal cord. Histaminergic cell bodies are discretely localized to the posterior hypothalamus, and these neurons send axonal projections to the forebrain, hypothalamus, and brain stem. The pertinent anatomical interrelationships between these aminergic neuronal groups and the hypothalamic neurosecretory cells containing the releasing and inhibiting hormones are depicted in Fig. 1.

The cholinergic neuronal systems involved in regulating anterior pituitary hormone release are less well defined. The highest density of cholinergic perikarya is found in basal forebrain nuclei, e.g., the nucleus basalis of Meynert, but these neurons project primarily to the hippocampus and cerebral cortex.

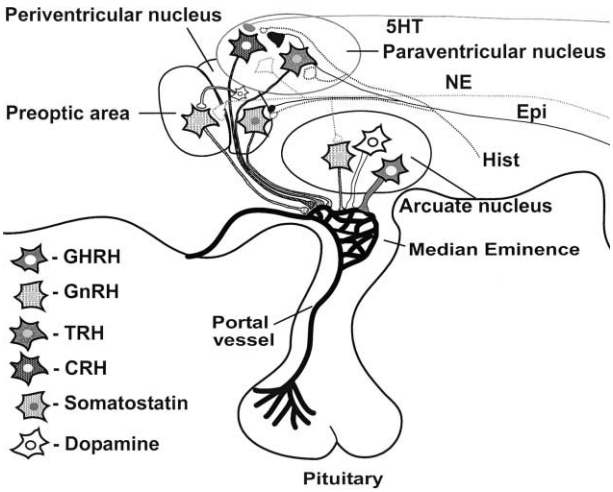

FIGURE 1 Schematic diagram that illustrates the neuroanatomical interrelationships between the ascending aminergic neurons and the hypothalamic neurosecretory cells that contain releasing or inhibiting hormones. 5HT, 5-Hydroxytryptamine (serotonin); Epi, epinephrine; Hist, histamine; NE, norepinephrine.

Cholinergic cell bodies have been observed in the hypothalamic arcuate nucleus and lateral hypothalamus, but the projections of these neurons have yet to be thoroughly characterized. The neuromodulator and hormone melatonin is released from pinealocytes of the pineal gland into the general circulation. It is a lipophilic molecule, and as such it readily enters the brain and the cerebrospinal fluid.

IV. OVERVIEW OF RELEASING AND ANTERIOR PITUITARY HORMONES

The anterior pituitary is interconnected with the brain by way of the hypophysial portal vasculature. The superior hypophysial artery provides the blood supply to the median eminence, a circumventricular organ within the ventral hypothalamus that resides outside the blood–brain barrier. Portal vessels carry substances (e.g., neurotransmitters, peptides, releasing hormones) released from nerve terminals in the median eminence to the anterior pituitary, where they exert their influence over the secretion of specific hormones from specific cell populations.

Parvocellular neurosecretory cells projecting to and terminating in the median eminence originate from several hypothalamic nuclei. Most notable are the hypothalamic preoptic area nuclei, the periventricular nucleus, the paraventricular nucleus, and the arcuate nucleus. Table 1 lists the major hypothalamic

TABLE I Releasing and Inhibiting Hormones Contained in Neuronal Cell Bodies in Hypothalamic Nuclei

Hypothalamic nuclei	Releasing/inhibiting hormone
Preoptic area	GnRH
Periventricular nucleus	Somatostatin
Paraventricular nucleus	CRH, TRH
Arcuate nucleus	Dopamine, GnRH, GHRH

nuclei and the associated neurotransmitter or neuropeptide released from each of these regions.

The neurotransmitters and peptides released from parvocellular neurosecretory cells act on specific cell types in the anterior pituitary to effect changes in the secretion of specific hormones. Table 2 lists the pituitary cell types and the effects on pituitary hormone secretion produced by the various hypothalamic neurotransmitters and peptides.

ACTH is derived from posttranslational modification of proopiomelanocortin, and stimulates the secretion of glucocorticoid hormones (cortisol in humans) from the adrenal cortex in response to many different types of stressful stimuli. GH stimulates postnatal growth by promoting mitosis and protein synthesis. This promotion of growth is ultimately due to the GH-induced stimulation of insulin-like growth factor-I production in, and secretion by, tissues such as the liver and bone. Prolactin, a 199-amino acid polypeptide in its bioactive form, stimulates the synthesis of milk and its subsequent secretion from alveolar epithelial cells of the mammalian female breast. There is also considerable evidence for a regulatory role of prolactin in cellular and humoral immune responses in both physiological and pathophysiological (i.e., autoimmune disease) states. TSH exists as a dimer composed of glycosylated α- and β-subunits (96 and 110 amino acid residues, respectively), and elicits the release of thyroxine and triiodothyronine from the thyroid gland. These hormones play an important role in promoting maturation of the nervous system and in regulating metabolic rate and body temperature. The gonadotropins, follicle stimulating hormone (FSH) and luteinizing hormone (LH), are also both composed of α- and β-subunits. These hormones act on the gonads (testes in the male, ovaries in the female) to stimulate steroid hormone production (i.e., testosterone in the male, estrogen and progesterone in the female), follicle development and ovulation (in the female), and spermatogenesis (in the male). The aminergic and cholinergic regulation of the secretion of these anterior pituitary hormones, which is summarized in Table 3, is the subject of the next five sections.

V. NEUROTRANSMITTER REGULATION OF ACTH SECRETION

Adrenocorticotropin hormone secretion is regulated by norepinephrine, epinephrine, dopamine, serotonin, acetylcholine, and histamine.

1. **Norepinephrine**. Neurons in the A_1 and A_2 noradrenergic cell groups increase corticotropin-releasing hormone (CRH), and thus ACTH release, following the activation of α_1-adrenergic receptors in the parvocellular paraventricular nucleus (PVN) of the hypothalamus. Conversely, norepinephrine can decrease CRH release by activating α_2- and β-adrenergic receptors in the PVN.
2. **Epinephrine**. Medullary adrenergic neurons emanating from the C_1, C_2, and C_3 cell groups increase CRH release by activating α_1- and β-adrenergic receptors in the PVN. In the rat (but not in humans), β_2-adrenergic receptors may also account for some of the stress-induced increase in ACTH secretion caused by circulating epinephrine.
3. **Dopamine**. Dopamine causes a modest stimulation of hypothalamic CRH release via the activation of dopamine D1 receptors.

TABLE 2 Hypothalamic Releasing and Inhibiting Hormones: Specific Effects on the Secretion of Anterior Pituitary Hormones

Releasing/inhibiting hormone	Pituitary cell type affected	Effect
CRH	Corticotroph	↑ ACTH release
GHRH	Somatotroph	↑ GH release
Somatostatin	Somatotroph, thyrotroph	↓ GH, TSH release
Dopamine	Lactotroph, thyrotroph, somatotroph	↓ Prolactin, TSH, GH release
TRH	Thyrotroph, lactotroph	↑ TSH, prolactin release
GnRH	Gonadotroph	↑ FSH, LH release

TABLE 3 Summary of Aminergic and Cholinergic Modulation of Anterior Pituitary Hormone Secretion

Transmitter/modulator (cell body location)	Anterior pituitary hormone[a]				
	ACTH	GH	Prolactin	TSH	Gonadotropins
Norepinephrine (medulla)	↑ (α_1), ↓ (α_2, β)	↓ (α_1)	↓ (α_1), ↑ (?)	↑ (α_2), ↓ (α_1)	↑ (α_1), ↓ (?)
Epinephrine (medulla)	↑ (α_1, β)	↑ (α_2), ↓ (β)	—	—	—
Dopamine (hypothalamus)	↑ (D1)	↑ (?), ↓ (?)	↓ (D2, D3), ↑ (D1)	↓ (D2)	↑ (?), ↓ (?)
Serotonin (raphe nuclei)	↑ ($5HT_{1A,1C,\text{ and/or }2}$)	↑ ($5HT_{1C/2}$)	↑ ($5HT_{1A,2A\text{ and }2C}$)	↑ (?), ↓ (?)	↓ (?), ↑ (?)
Acetylcholine (basal forebrain)	↑ (M,N)	↑ (M)	↓ (N)	↓ (N)	↑ (M), ↓ (?)
Histamine (hypothalamus)	↑ ($H_{1\text{ and }2}$)	↑ ($H_{1\text{ and }2}$), ↓ (H_1)	↑ (H_{1-3})	↓ (?), ↑ (H_2)	↑ ($H_{1\text{ and }2}$)
Melatonin (pineal gland)	—	—	↓ (MEL_{1A})	—	↓ (?)

[a]ACTH, Adrenocorticotropic hormone; GH, growth hormone; TSH, thyroid-stimulating hormone. The receptor subtype mediating a particular effect (when known) is indicated in parentheses. M, Muscarinic receptor; N, nicotinic receptor; D, dopamine; 5HT, 5-hydroxytryptamine; H, histamine; MEL, melatonin.

4. **Serotonin**. This amine increases ACTH secretion in rodents and humans by activating 5-hydroxytryptamine receptors ($5HT_{1A}$, $5HT_{1C}$, and/or $5HT_2$) located on CRH neurons in the PVN. Serotonergic neurons are involved in stress- and hypoglycemia-induced ACTH secretion.
5. **Acetylcholine**. This neurotransmitter increases ACTH secretion by increasing hypothalamic CRH release via the activation of muscarinic and nicotinic receptors.
6. **Histamine**. Histamine increases ACTH secretion in rodents and humans by activating H_1 and H_2 receptors located in the PVN. Histaminergic neurons appear to be involved in stress- and hypoglycemia-induced ACTH release.

VI. NEUROTRANSMITTER REGULATION OF GH SECRETION

Growth hormone secretion is regulated by norepinephrine, epinephrine, dopamine, serotonin, acetylcholine, and histamine.

1. **Norepinephrine**. Norepinephrine decreases GH secretion by increasing the release of somatostatin. This central effect, due to the activation of α_1-adrenergic receptors, has been demonstrated in dogs and rats, but not in humans.
2. **Epinephrine**. Epinephrine elicits an α_2-adrenergic receptor-mediated increase in GH secretion in humans and rodents through a central mechanism involving an increase in growth hormone-releasing hormone (GHRH) release concomitant with a decrease in somatostatin release. On the other hand, central β-adrenergic receptor activation by epinephrine decreases GH release via an increase in somatostatin release. In addition, epinephrine can increase GH directly from the anterior pituitary, but this effect is minor compared to the central effect.
3. **Dopamine**. Dopaminergic agonists have been shown to increase GH release, as well as to decrease hypoglycemia-, levodopa-, and arginine-induced increases in GH release. Because dopamine can increase both GHRH and somatostatin release, it appears that this balance can change under different physiological conditions. Dopamine also decreases GH release via a direct action on the somatotroph. This may be important in regulating differentiation of adenohypophysial cells such as lactotrophs and somatotrophs.
4. **Serotonin**. The literature is replete with contradictory findings, especially with regard to human studies. In general, serotonin and 5HT receptor agonists increase GH release. Also, $5HT_{1C/2}$ receptor antagonists block the α_2-adrenergic receptor agonist-induced increase in GH release. The stimulatory serotonergic effect is thought to be central—due presumably to a decrease in somatostatin release.
5. **Acetylcholine**. This neurotransmitter increases GH release under a variety of physiological conditions, such as the nocturnal increase in GH release and the exercise-induced increase in GH release. This is due primarily to an activation of muscarinic receptors. Cholinergic stimulation of GH release occurs via an inhibition of somatostatin release from the median eminence, and also via a direct effect on the somatotroph.
6. **Histamine**. The activation of H_1 receptors decreases pulsatile and opioid-stimulated GH secretion in rats, whereas in dogs the blockade of H_1 and H_2 receptors decreases the hypoglycemia- and opioid-stimulated increases in GH release, respectively. Similarly, in humans the blockade of

H_1 receptors decreases arginine- and opioid-stimulated GH secretion, and the blockade of H_2 receptors decreases nocturnal-, hypoglycemia-, and levodopa-induced GH secretion. Thus, in dogs and humans histamine facilitates GH secretion under a variety of physiological conditions, whereas in rats it is inhibitory.

VII. NEUROTRANSMITTER REGULATION OF PROLACTIN SECRETION

Prolactin secretion is regulated by norepinephrine, dopamine, serotonin, acetylcholine, histamine, and melatonin.

1. **Norepinephrine**. Norepinephrine exerts a central, α_1-adrenergic receptor-mediated tonic inhibition of prolactin secretion. On the other hand, central noradrenergic pathways may also be involved in the proestrous surge of prolactin, and in the stress-induced increase in prolactin secretion.
2. **Dopamine**. The predominant effect of dopamine released from tuberoinfundibular dopaminergic (TIDA) nerve terminals in the median eminence is a tonic inhibition of prolactin secretion caused by the activation of dopamine D2 receptors on lactotrophs. Centrally, activation of dopamine D2/D3 receptors increases neurochemical estimates of TIDA neuronal activity, resulting in a decrease in prolactin secretion. Conversely, central activation of dopamine D1 receptors decreases TIDA neuronal activity, and thus increases prolactin secretion.
3. **Serotonin**. Exogenous administration of $5HT_{1A}$, $5HT_{2A}$, and $5HT_{2C}$ receptor agonists increases prolactin secretion. In addition, serotonin and its precursor 5-HTP also increase prolactin secretion in both rats and humans. Moreover, central serotonergic pathways emanating from the dorsal raphe nucleus appear to facilitate the prolactin release observed during proestrus in rats and induced by suckling.
4. **Acetylcholine**. Cholinergic agonists decrease basal and suckling-, estrogen-, and opioid-induced prolactin secretion. This may be mediated via an activation of TIDA neurons, due presumably to a central mechanism, although a direct effect on the lactotroph has not been ruled out definitively. These inhibitory effects on prolactin secretion are due primarily to an activation of nicotinic receptors.
5. **Histamine**. Exogenous histamine increases prolactin secretion, and central histaminergic pathways emanating from the posterior hypothalamus appear to play an important facilitory role in the prolactin secretion induced by stress or by suckling. H_1, H_2, and H_3 receptors have all been implicated in the various roles of the amine in promoting prolactin secretion.
6. **Melatonin**. Increasing concentrations of melatonin, such as those that occur during the night or under conditions of decreased day length (i.e., short photoperiod), decrease prolactin secretion due to the interaction of the indoleamine with MEL_{1A} receptors in the pars tuberalis. This interaction is thought to alter the secretion of a seasonal, peptidergic prolactin-releasing factor known as tuberalin.

VIII. NEUROTRANSMITTER REGULATION OF TSH SECRETION

Thyroid-stimulating hormone is regulated by norepinephrine, dopamine, serotonin, acetylcholine, and histamine.

1. **Norepinephrine**. This amine plays a role in activating the hypothalamic–pituitary–thyroid (HPT) axis in response to cold. Norepinephrine can increase TSH release by activating central α_2-adrenergic receptors and can decrease TSH release by activating α_1-adrenergic receptors. There are conflicting reports on the effects of α_1-adrenergic receptor activation in the thyrotroph.
2. **Dopamine**. Dopamine directly inhibits TSH release from the anterior pituitary in both rats and humans. There also appears to be a central component to the dopamine-induced decrease in TSH secretion. Both the central and adenohypophysial effects appear to be mediated by dopamine D2 receptors. Dopamine does not tonically inhibit TSH release under euthyroid conditions, but it may do so under hypothyroid conditions. Dopamine may also be involved in the diurnal variations in TSH secretion.
3. **Serotonin**. There appears to be a dual role of central serotonergic neuronal systems in regulating thyrotropin-releasing hormone (TRH) and thus TSH release. Serotonin may be involved in promoting the characteristic late-morning peak in TSH secretion. However, its involvement in the cold-induced activation of the HPT axis is equivocal. In addition, there is a serotonin-induced decrease in TSH that may be due to a peripheral regulatory mechanism, but a direct action of the amine on the thyrotroph seems

unlikely. The lack of truly specific pharmacological tools has made it difficult to ascribe serotonergic effects on TSH secretion to specific 5HT receptor subtypes.

4. **Acetylcholine**. There is some evidence from rat studies suggesting that central nicotinic receptor activation decreases basal TSH secretion, due possibly to the activation of TIDA or somatostatin neurons.
5. **Histamine**. Histamine increases hypothalamic TRH secretion in rats by activating H_2 receptors, but it also increases hypothalamic somatostatin release. This results in a net decrease in TSH secretion.

IX. NEUROTRANSMITTER REGULATION OF GONADOTROPIN SECRETION

Gonadotropins (follicle-stimulating hormone and luteinizing hormone) are regulated by norepinephrine, dopamine, serotonin, acetylcholine, histamine, and melatonin.

1. **Norepinephrine**. Depending on the species, the gender, the season, and the point in the reproductive cycle, norepinephrine can exert both stimulatory and inhibitory influences on hypothalamic gonadotropin-releasing hormone (GnRH) and thus on FSH and LH secretion. As such, the amine can play an important role in both positive and negative feedback effects of gonadal steroids on the hypothalamic–pituitary gonadal axis. However, the predominant role of norepinephrine is to facilitate the preovulatory GnRH and thus LH surges, as well as the postcastration rise in GnRH and thus LH pulse amplitudes and frequencies. These latter effects arise from the activation of central α_1-adrenergic receptors.
2. **Dopamine**. Dopamine appears to play a facilitory role in the postcastration rise in LH pulse amplitude. Conversely, dopamine released from TIDA nerve terminals in the median eminence appears to decrease LH secretion during the luteal phase of the reproductive cycle in ruminants.
3. **Serotonin**. What little work has been done concerning serotonergic regulation of gonadotropin secretion has yielded very inconclusive results. For example, in the rat, lesioning of serotonergic neurons is reported to reduce plasma levels of LH and to attenuate the preovulatory LH surge. On the other hand, 5HT receptor activation has also been shown to increase LH secretion, depending on the timing of agonist administration in relation to the preovulatory LH surge. Finally, other studies in male rats have shown that 5HT receptor activation is without effect on LH secretion.
4. **Acetylcholine**. This neurotransmitter increases FSH and LH release in rodents by activating muscarinic receptors. However, inhibition of acetylcholinesterase with the organophosphate diisopropylfluorophosphate (DFP) produces a biphasic effect on gonadotropin secretion. Low doses of DFP increase, and higher doses decrease, hormone secretion.
5. **Histamine**. There is some evidence to suggest a stimulatory role for histamine in regulating gonadotropin secretion, most notably in female rodents. H_1 and H_2 receptors appear to be involved. Histamine does not appear to exert a direct adenohypophysial effect, but may indirectly stimulate GnRH release.
6. **Melatonin**. Increases in melatonin concentrations like those observed under nocturnal conditions and those inextricably tied with short photoperiods reduce basal LH release from the rat pars tuberalis *in vitro*. In addition, melatonin decreases LH and FSH release by physiologically antagonizing the stimulatory effects of GnRH on gonadotrophs from neonatal rat pituitary gland. On the other hand, lesioning of the mediobasal hypothalamus of the Syrian hamster blocks the effect of short photoperiods and of melatonin on gonadotropin secretion. This latter finding suggests that, depending on the species, melatonin may also act centrally to effect a decrease in gonadotropin release.

X. SUMMARY

Anterior pituitary hormones are regulated to varying degrees by aminergic and cholinergic neurotransmitters. With the exception of dopamine and perhaps melatonin, these neurotransmitters act upstream to regulate the excitability of hypothalamic neurosecretory cells that contain releasing and inhibiting hormones. Many of these neurotransmitters contribute to physiological and/or pathophysiological (i.e., hypoglycemia) regulatory mechanisms that exist for a particular adenohypophysial hormone. For example, norepinephrine produces a physiologically relevant stimulation of ACTH, TSH, and gonadotropin secretion. Norepinephrine may also inhibit gonadotropin secretion, depending on factors such as species, gender, and stage of development and of the reproductive cycle. Likewise, epinephrine also

provides an important stimulatory signal for ACTH secretion, and increases GH secretion as well. Dopamine is unequivocally the principal prolactin-inhibiting factor, and it appears this amine is also capable of inhibiting both TSH and GH secretion. Serotonin plays an important stimulatory role in regulating ACTH and prolactin secretion, and may also promote GH release. Acetylcholine increases the release of ACTH, GH, and gonadotropins by activating primarily muscarinic receptors, and also inhibits prolactin and TSH secretion by activating nicotinic receptors. It is now becoming readily apparent that histamine provides a stimulatory signal in the control of prolactin and ACTH secretion, and may also stimulate GH secretion and inhibit TSH secretion. Finally, melatonin conveys environmental signals concerning short day length, in part by inhibiting both prolactin and gonadotropin secretion, which may thus provide behavioral cues critical for reproduction in seasonal breeders. Although the physiological relevance of certain transmitters (e.g., dopamine) regulating a given adenohypophysial hormone (e.g., prolactin) is well established, a broader and more cohesive consensus will undoubtedly emerge with further research in this fundamentally important field.

Glossary

adenohypophysis Endocrine subdivision of the pituitary; composed of the pars distalis (i.e., the anterior lobe of the pituitary gland), the pars intermedia (i.e., the intermediate lobe of the pituitary gland), and the pars tuberalis.

anterior pituitary Major lobe of the adenohypophysis; composed of a heterogeneous mixture of cell types, such as corticotrophs, somatotrophs, lactotrophs, thyrotrophs, and gonadotrophs, each of which secretes specific hormones that act on particular end organs to exert biological effects.

hypophysial portal vasculature Circulatory system that connects the median eminence (perfused by the dense capillary network stemming from the superior hypophysial artery) to the anterior pituitary via portal vessels, through which releasing and inhibiting factors are transported.

hypothalamus Heterogeneous region of the brain comprising the ventral diencephalon; serves a diverse array of homeostatic biological functions, including the control of energy balance, reproductive and parental behavior, growth and development, emotional expression, and stress responses, due largely to its regulation of pituitary hormone secretion.

median eminence Highly vascularized region of the mediobasal hypothalamus that resides outside of the blood–brain barrier; contains a high density of neurosecretory terminals and serves as the primary site of release of releasing and inhibiting factors.

neurotransmitter Chemical messenger found in and released from particular nerve cells that possess the protein machinery necessary for its biosynthesis, reuptake and degradation; interacts with a distinct set of plasma membrane-bound proteins called receptors to produce an electrochemical signal associated with cell-to-cell communication.

releasing and inhibiting hormones Polypeptides or small molecule neurotransmitters that are released from the terminals of hypothalamic neurosecretory cells; these hormones are transported from the median eminence via the hypophysial portal vasculature to the anterior pituitary, where they act to stimulate or inhibit the release of specific adenohypophysial hormones.

Motilin

JOHN R. GRIDER, JOHN F. KUEMMERLE, AND KARNUM S. MURTHY

Medical College of Virginia Campus of Virginia Commonwealth University

Motilin, a hormone produced by endocrine cells of the proximal small intestine, is released into the circulation in a cyclic manner. Motilin initiates the contractions of the migrating motor complex in the stomach and upper small intestine during the interdigestive period. Pharmaceutical agents that mimic motilin action are of interest in treating disorders of gastric emptying and colonic motility.

I. INTRODUCTION

The gastrointestinal tract is a rich source of hormones that are diverse in their chemistry, cellular localization, mechanism of action, and physiological function. These hormones, in conjunction with components of the enteric nervous system and the extrinsic autonomic nervous system, are responsible for controlling the processes by which ingested material is digested, absorbed, and distributed to other organs of the body, and for eliminating the unabsorbable waste material. Although a majority of the gut hormones are involved in regulating the postprandial actions initiated in response to ingestion of a meal, one hormone, motilin, has been shown to be particularly important in regulating the activity of the gut during the interdigestive period. This period is characterized by a repetitive increase in motor activity that originates in the proximal gut and moves distally; the moving front of intense contractile activity is termed the migrating motor (or myoelectric) complex (MMC). The MMC appears to be initiated by cyclic increases in the release of motilin that occur during the interdigestive period. It is generally thought that this migrating motor complex performs a housekeeping function, clearing the gut of residual materials and endogenous secretions between meals.

II. STRUCTURE AND SYNTHESIS

Motilin is a 22-amino-acid peptide that was initially isolated from the canine gastrointestinal tract by J. C. Brown and colleagues; it was identified as the agent responsible for the increased gastric motility observed following duodenal alkalinization. The peptide was named motilin because of its ability to increase motor activity, that is, increase motility. Since the original identification and sequencing in the canine, motilin has been identified in several other species, including pigs, cats, rabbits, chickens, and humans. As can be seen from Fig. 1, the sequences of human and porcine motilin are identical and differ from that of canine motilin at positions 7, 8, 12, 13, and 14. Although the sequence in mammals is well conserved, the sequence of motilin in rodents such as rats and guinea pigs differs more widely.The gene encoding motilin has been mapped to the p21.3 region of chromosome 6 in humans and has been shown to contain five exons and four introns spanning about 9 kb. The motilin gene is somewhat unusual in that the active form of motilin is encoded in exons 2 and 3.

Motilin, like other peptide hormones, is synthesized as a larger precursor termed prepromotilin. The sequence of the cDNA encoding the precursor has been identified in a variety of species, including humans, pigs, rabbits, canines, and monkeys, and has been shown to be similar in most species. In each case, the prepromotilin contains a signal peptide of 25 amino acids; the signal peptide is cleaved to yield promotilin, which consists of the 22-amino-acid sequence of active motilin and two lysine residues that are the site of posttranslational processing, followed by a motilin-associated peptide of variable length and amino acid sequence.

Guinea pig:	Phe-Val-Pro-Ile-Phe-Thr-Tyr-Ser-Glu-Leu-Arg-Arg-Thr-Gln-Glu-Arg-Glu-Gln-Asn-Arg-Leu-Arg
Chicken:	Phe-Val-Pro-Phe-Phe-Thr-Gln-Ser-Asp-Ile-Gln-Lys-Met-Gln-Glu-Lys-Glu-Arg-Asn-Lys-Gly-Gln

FIGURE 1 Amino acid sequence of motilin in several species.

The motilin-associated peptide in human is known to be 65 amino acids long; however, its biological action and physiological role have not yet been identified.

III. DISTRIBUTION

The presence of authentic motilin in the gastrointestinal tract has been demonstrated by a variety of techniques, including immunohistochemical methods and measurement of motilin immunoreactivity in tissue extracts. Motilin is located in specialized endocrine cells, termed the Mo, or M, cells, found among the epithelial cells comprising the mucosa, which is the innermost layer of the gastrointestinal tract. The M cell is characterized by cytoplasm containing small (180 nm) solid granules with a homogenous core and a closely applied membrane. These granules are round in human cells and round to irregular in cells from the dog. Motilin has also been reported to be costored with 5-hydroxytryptamine in a subpopulation of mucosal endocrine cells, although this remains a subject of debate. The highest concentrations of motilin are found in the most proximal section of the small intestine, the duodenum and the jejunum; lesser amounts are found in the ileum. Motilin-containing cells have been identified in the proximal intestine of most mammalian species, including humans, monkeys, dogs, cats, and rabbits. Motilin has also been detected in the gastrointestinal tract of a wide range of animals, including rodents (mouse, rat, guinea pig), amphibians (frog, turtle), and birds (chicken, quail). In general, in species in which the motilin prohormone has been isolated and characterized, the signal peptide and the motilin peptide are more closely similar in amino acid sequence (73–100% identity in motilin) than are the various species-specific motilin-associated peptides (23–59% identity). Measurement of mRNA levels leads to the same conclusion, i.e., that motilin is largely a hormone produced in mucosal endocrine cells of the duodenum and jejunum. A single mRNA species of 700 nucleotides has been isolated from the canine duodenum.

Authentic motilin is largely absent from the stomach. Recently, however, a novel peptide that shares a significant sequence homology (about 36% identity) to motilin has been identified in secretory granules of mouse, rat, and, more recently, human gastric antral endocrine cells. This peptide, named motilin-related peptide by Tomasetto *et al.* and ghrelin by Kojima *et al.*, may represent a new member of the motilin family of peptides. To date, preliminary reports indicate that this novel peptide may share similar biological properties with motilin but may produce effects distinct from those of motilin.

Although motilin is found primarily in the proximal gut, there has been a great deal of controversy as to the presence of motilin in nongut tissues. Much of the controversy arises from the use of different antisera with different specificities to search for the presence of the peptide, and the apparent overall much lower concentrations in brain as compared to gut. Nonetheless, motilin or its precursor has variously been reported to be present in the pituitary, in the Purkinje cells of the cerebellum, in the thalamus, and in the hypothalamus of numerous species. Recent studies by the group of T. L. Peeters have shown the presence of the cDNA encoding for the motilin precursor in hypothalamus, hippocampus, and cerebellum of the rhesus monkey. The same group has demonstrated mRNA for motilin in the guinea pig, rabbit, and human brain. Although it is likely that the presence of motilin in nongut tissues will continue to be debated, these studies seem to strongly support the presence of motilin in the central nervous system. The physiological role of motilin in the brain remains to be elucidated.

IV. RELEASE

Perhaps one of the most interesting and distinctive characteristics of motilin is its pattern of release. Unlike levels of other gut hormones, motilin levels are not constant during the interdigestive period, but rather rise and fall in the blood in a regular, cyclic pattern. Peaks in motilin levels occur at intervals of 80 to 100 min. This cyclic pattern of motilin release has been demonstrated in numerous species, including humans and dogs. The peak of motilin release coincides with the end of a brief period of intense contractions in the stomach. This contractile period is phase III of the migrating motor complex, part of a cyclic pattern of contractions that move through the gut during the interdigestive period. As explained in the next section, it is generally accepted that the physiological role of motilin is to initiate this pattern of contractile activity in the stomach and proximal small intestine.

Although the cyclic pattern of motilin release has been well documented since its initial description in the late 1970s, the exact nature of the origin of this pattern remains to be fully elucidated. Many stimuli and inhibitors of motilin release have been identified, but none has adequately been shown to be responsible for controlling the physiologically relevant pattern of release. Studies of the role of the autonomic nervous system have shown that sympathetic inputs to the gut are not involved in the release of motilin. Vagal influences are also controversial because both cooling and electrical stimulation of the vagi can cause the release of motilin. A recent study by Sarr and colleagues demonstrated in the dog that the cyclic pattern of motilin release and the migrating myoelectrical complex were not affected by complete transection of all extrinsic nerves to stomach, small intestine, colon, pancreas, and liver, suggesting that neither afferent not efferent neural components of the central nervous system are responsible for the cyclic pattern of motilin release. Cholinergic mechanisms, however, are clearly important to the regulation of the release of motilin. The muscarinic antagonist, atropine, and the nicotinic antagonist, hexamethonium, can block the cyclical increase in plasma motilin in the dog. The increase in motilin that is elicited by cervical vagal stimulation is also blocked by atropine or hexamethonium. The release of motilin induced by the cholinergic agonist carbachol is, however, blocked by atropine but not by hexamethonium, suggesting a primary role of the muscarinic rather than the nicotinic receptor in mediating the release of motilin. It is likely that the cholinergic neurons involved in the physiological release of motilin are enteric neurons because, as previously indicated, vagotomy does not abolish motilin release.

The release of motilin is influenced by other neuropeptides in the gut. Bombesin has been shown to be a potent stimulator, and somatostatin a potent inhibitor, of motilin release in the dog. Agonists of the opiate receptors stimulate the release of motilin, although a physiological role of endogenous opioid peptides is unlikely because the opioid receptor antagonist, naloxone, has minimal effects on motilin release. 5-Hydroxytryptamine is also likely involved in the human gastrointestinal tract because an antagonist of the type 3 5-hydroxytryptamine receptor inhibits motilin release and the subsequent MMC contractions. Similarly, the same antagonists of the type 3 5-hydroxytryptamine receptor interrupt the MMC in the dog, although the effect may not be mediated through an inhibition of motilin release.

Intralumenal contents in the duodenum greatly influence the release of motilin. It is clear in dogs and humans that ingestion of a meal results in a cessation of the cyclic pattern of motilin release and disruption of the migrating motor complex. The causative agent and mechanism of this meal-induced change in pattern of release of motilin and of the MMC are not known. As stated previously, motilin was first isolated as the endogenous motility-stimulating agent released by the presence of alkaline solution in the canine duodenum. Subsequent studies in dogs and

humans have shown that although pH changes can induce motilin release, their effect on physiological release of motilin is relatively small if the pH is adjusted to between 2 and 8. Biliary and pancreatic secretions have been postulated to be potential intralumenal agents that might influence the release of motilin, but their role in the physiological regulation of motilin release remains controversial. A recent study in humans showed that acute depletion of intraduodenal bile salts with the bile acid binding agent, cholestyramine, resulted in an increase in plasma motilin, suggesting that bile may have an inhibitory or negative feedback effect on motilin release.

Thus, although much is known about endogenous and exogenous agents that stimulate and inhibit the release of motilin from the duodenal mucosa, little is known of the physiological mechanisms responsible for the generation of the distinctive cyclic pattern of release or of the mechanisms responsible for the prompt cessation of this pattern on ingestion of a meal. These remain areas of controversy and intense investigation.

V. PHYSIOLOGICAL ACTION

The physiological function of motilin is induction of gastric contractions that comprise phase III of the migrating motor complex. During the interdigestive period, a very distinct cyclic pattern of increased contractility occurs in the gastrointestinal tract at an interval of about 100 min. This pattern consists of distinct phases. Phase I is a period of quiescence lasting about 60–70 min, phase II is a period of increased but irregular activity lasting 20–30 min, and phase III is a period of intense and regular contractile activity lasting 5–10 min. Phase III is followed by a return to quiescence. This pattern of increased contractility begins in the gastric antrum and lower esophageal sphincter and moves distally through the entire length of the small intestine. The phase III contractile activity can be traced through the gastrointestinal tract and has been shown to take about 2 h to move completely through the gut. Thus, when the phase III activity reaches the distal small intestine, a new phase III is beginning in the stomach. The MMC has been postulated to fulfill a housekeeping role, continually clearing the stomach and intestines of secretions and intralumenal contents during the interdigestive period.

The cyclic pattern of motilin release is very similar to that of the MMC. The cyclic pattern of motilin release also has a period of about 100 min and has a peak that coincides with the end of phase III contractile activity in the stomach. Several lines of evidence support the generally accepted notion that motilin is responsible for induction of phase III contractions in the stomach. First, immunoneutralization of motilin with a specific antiserum in the dog disrupts the phase III contractile activity and prevents initiation of the MMC in the stomach. It should be noted, however, that phase III contractions can still be seen in the distal small intestine in the presence of neutralizing motilin antiserum, indicating a role for motilin in initiation of contraction in the proximal, but not distal, gut. Second, excision of the duodenum in the dog, to remove most of the motilin-secreting cells, impairs the normal MMC in the proximal, but not distal, gut. With time, however, MMC-like activity returns in these animals, suggesting that alternative pathways may fulfill the role of mediating the MMC after removal of the motilin cells. Third, infusion of motilin to reproduce physiological levels induces premature phase III contractile activity in the gastric antrum and duodenum, but not in the distal small intestine. This property of motilin has been demonstrated in humans and many other species. Two aspects of the response to motilin infusion are unusual. First, the intensity of the contractions during phase III is not dependent on the concentration of motilin, although increasing concentrations shorten the latency to initiation of phase III contractile activity. Second, the phase III contractions induced by infusion of motilin abate after a few minutes despite the continued presence of motilin. Thus, the response to exogenous motilin mimics very closely phase III contractile activity in terms of duration as well as contractile characteristics. It also suggests that motilin should be viewed more as the initiator of the physiological processes that produce the MMC, rather than as the mediator of the MMC.

Several other biological actions of motilin have been identified, although their physiological nature is controversial. Motilin has been shown to stimulate pepsinogen secretion in the stomach and generalized enzyme secretion from the pancreas, and contraction of the gallbladder and the lower esophageal sphincter. These effects are all normally associated with phase III of the MMC and have been postulated to be components of a general periodic activation of gut function induced by motilin. It should be noted, however, that the potency of motilin varies widely with respect to these biological effects and that the ability of motilin to induce these actions is also species dependent. Motilin has been shown to increase the emptying rate of liquids but not solids

from the canine stomach, although this effect appears to be less consistent in normal human study participants. There is, however, evidence that motilin increases the rate of gastric emptying in patients with impaired gastric emptying due to diabetic gastroparesis. This effect has been most clearly shown for synthetic motilin-like agents known as motilides and is currently being investigated for potential therapeutic applications (see Section VII).

Finally, although motilin levels are very low or not detectable in the mucosa of the colon, motilin receptors have been identified in this region and colonic muscle had been shown to be very sensitive to exogenous motilin. Thus, motilin and motilides have been shown to be very potent in causing contractions of isolated colonic smooth muscle cells and in enhancing propulsive motility of the colon. Although it is not clear if this is a physiological action of motilin, the potential use of motilides as therapeutic agents to enhance colonic transit is currently an area of intense investigation.

VI. MECHANISM OF ACTION

The action of motilin has been investigated in isolated muscle cells, in muscle strips, and *in vivo*. Depending on the species, motilin has been shown to act directly through an effect on smooth muscle cells and indirectly via activation of enteric neurons. These represent different phenomena. The physiological effect of motilin to cause phase III contractions of the MMC in most species, including humans and dogs, is mediated by an interaction with cholinergic neurons, as evidenced by the ability of muscarinic cholinergic antagonists to block initiation of the MMC. In the dog, 5-hydroxytryptamine neurons have also been implicated as a component of the neural pathway that mediates the physiological action of motilin. Depletion of 5-hydroxytryptamine by treatment with *para*-chlorophenylalanine or blockade of type 3 5-hydroxytryptamine receptors with selective antagonists eliminates the ability of motilin to initiate phase III contractions in the canine stomach. This effect is different in the human stomach, in which 5-hydroxytryptamine is involved in the release of motilin from endocrine cells; in the dog, there is no effect of 5-hydroxytryptamine drugs on motilin levels.

Studies of muscle strips and isolated muscle cells from several species have also identified a direct action of motilin on smooth muscle cells. In smooth muscle cells and muscle strips from human and rabbit stomach, small intestine, and colon, motilin has been shown to cause a direct contraction that is accompanied by an increase in intracellular calcium. The increase in calcium appears to be mediated via influx of extracellular calcium through L-type calcium channels.

Consistent with the pharmacological actions of motilin, specific receptors for motilin have been examined by the classical techniques of radioligand binding and autoradiography. Both techniques have been used in the past to demonstrate the presence of specific motilin receptors within the smooth muscle of the gastrointestinal tract of several species. Motilin receptors were shown to be highest in concentration in the antral muscle and to decrease caudally. Within the wall of the gut, the concentration of motilin receptors was highest in the circular muscle layer. Recent radioligand binding studies by the group of Poitras have confirmed the presence of motilin receptors in the smooth muscle of rabbit colon and human gastric antrum but have also provided evidence for the presence of a distinct motilin receptor type in enteric nerves. Using purified synaptosomal and smooth muscle membranes, it was shown that a variety of motilin agonists and antagonists demonstrate differential binding affinities for motilin binding sites in each membrane preparation, indicative of different receptor subtypes on enteric neurons and smooth muscle cells. These binding studies are supported by functional studies of the rabbit stomach, suggesting that neural receptors mediate the chronotropic effects of motilin whereas smooth muscle receptors mediate the ionotropic effects of motilin. It is interesting to note that, as with other gut neuropeptides, the neural receptors seem to be much more sensitive than the smooth muscle receptors.

The presence of specific motilin binding sites in the rabbit brain has been demonstrated using autoradiographic techniques. It is not clear if the motilin receptors on neurons of the central nervous system are the same as motilin receptors on enteric neurons. The physiological significance of these motilin receptors in the brain remains to be determined.

A human motilin receptor has been identified by screening known sequences of cloned orphan receptors. The original orphan clone, GPR38, has now been shown by Feighner *et al.* to bind both motilin and the motilide erythromycin; thus, the receptor has been renamed motilin-R1A (MTL-R1A). This receptor shares sequence homology (about 50%) with another group of receptors, known as the growth hormone secretagogue receptors, which mediate the action of the related peptide, ghrelin, or

motilin-related peptide (see Section III). The motilin receptor is a member of the class of seven-transmembrane-domain receptors coupled to a heterotrimeric G-protein and appears to activate the phospholipase C signal transduction pathway. The presence of this receptor in the gastrointestinal tract was demonstrated by measurement of specific mRNA levels. Evidence for the presence of this motilin receptor was found in RNA isolated from human esophagus, duodenum, jejunum, ileum, and colon. In the colon, *in situ* hybridization revealed the presence of motilin receptor mRNA in enteric neurons co-expressing either nitric oxide synthase or choline acetyltransferase; in the duodenum, mRNA for the motilin receptor was evident also in smooth muscle cells. This study provides strong support for the presence of a specific motilin receptor in human smooth muscle cells and in enteric neurons. Whether this represents the only receptor or whether there are subtypes of the motilin receptor remains to be determined.

VII. ERYTHROMYCIN AND MOTILIDES

Much of the current interest in motilin stems from a discovery made by Z. Itoh and colleagues in 1984. They observed that a 20-min infusion of the macrolide antibiotic erythromycin, administered to dogs intravenously (iv) at a dose of 30 μg/kg, induced powerful contractions in the stomach and duodenum. These contractions were very similar in duration to those of the phase III contractions of the MMC and moved caudally into the small intestine at the same velocity as the phase III contractions of the MMC. Almost simultaneously, a second study done by G. Zara and co-workers demonstrated that higher doses of erythromycin (7 mg/kg, iv) induced contractile activity throughout the small intestine whereas a lower dose (1 mg/kg, iv) induced a pattern of contractile activity similar to the phase III contractions of the MMC. Zara attributed the effects of erythromycin to an opiate-like effect whereas Itoh correctly recognized the effect as more motilin-like. These initial observations led to a thorough study of the effects of erythromycin and the related macrolide antibiotics. Subsequent studies have confirmed that erythromycin has similar effects to motilin in humans, inducing a phase III contractile pattern that moves through the gut in the same manner as the MMC. The macrolides have been shown to compete with radiolabeled motilin for binding sites in gut smooth muscle, enteric neurons, and brain tissue, and erythromycin has recently been shown to interact with the newly cloned motilin MTL-R1A receptor. The descriptive term "motilide" is thus derived from the words "motilin" and "macrolide," reflecting the fact that erythromycin and related macrolide antibiotics interact with the motilin receptor as potent agonists. These agents have been shown to act via the same mechanisms as motilin, causing direct smooth muscle contractions and activation of cholinergic muscarinic pathways. The motilides show the same species and tissue selectivity as does motilin. In general, their ability to mimic the actions of motilin at subantibiotic doses and their resistance to degradation have made them attractive models for the development of newer compounds with increased motilin-like activity and no antibiotic activity. Numerous new motilides have been synthesized based on the structural characteristics of erythromycin and have been evaluated for potential use as prokinetic agents in stomach and colon. Most interest has focused on their use in patients with decreased gastric emptying as a result of diabetic gastroparesis or functional dyspepsia. The potential for their clinical application is based on a report by Janssens *et al.* showing that gastric emptying in diabetic patients is greatly enhanced by erythromycin. Although the clinical trials of motilides such as ABT-229 and EM574 have been disappointing, the recent removal of cisapride and related prokinetic agents from clinical use may further stimulate development of even newer motilides with enhanced potency.

VIII. SUMMARY

Although the mechanisms that govern the cyclic pattern of release and the exact stimulus for the release of motilin are not known, it is clear that the release of motilin is responsible for initiation of phase III contractions of the migrating motor complex in the stomach and upper small intestine during the interdigestive period in humans, dogs, and many other species. The physiological action of motilin appears to be mediated by specific motilin receptors located on enteric neurons, ultimately leading to activation of muscarinic cholinergic neurons in the gastric antrum. Specific motilin receptors have also been demonstrated on smooth muscle cells of stomach, small intestine, and colon, where their activation results in the influx of calcium and contraction of the smooth muscle cells. The actions of motilin are mimicked by the macrolide antibiotic erythromycin and a group of motilin agonists known as motilides. The motilides are currently being developed as pharmaceutical prokinetic agents to treat patients with impaired gastric emptying and colonic motility.

Glossary

enteric nervous system Ganglionated nerve plexuses contained within the wall of the gastrointestinal tract. Neurons with cell bodies in these plexuses innervate other neurons, muscle cells, and secretory cells of the gastrointestinal tract and can stimulate or inhibit the activity of these other cell types.

migrating motor complex A repetitive pattern of contractile activity that begins in the stomach and moves caudally throughout the small intestine during the interdigestive period. This pattern of activity is also known as the migrating myoelectric complex and the interdigestive housekeeper.

motilide A macrolide antibiotic that acts as a motilin receptor agonist at subantibiotic doses and mimics the physiological and pharmacological effects of motilin.

mucosa Innermost layer of the gastrointestinal tract that is in intimate contact with lumenal contents. This layer is composed of epithelial cells with interspersed enteric endocrine cells.

Multiple G-Protein Coupling Systems

BRIAN HAWES

Schering Plough Research Institute, New Jersey

G-Protein-coupled receptors (GPCRs) are the largest known family of cell surface receptors. GPCRs respond to a myriad of external stimuli. Cellular response to external stimuli is dependent on a wide array of variables. These variables provide the necessary tools to enable particular cells to respond in a specific manner to individual or multiple stimuli. Such stimuli can be physical or chemical in nature. The key

to an integrated response to the multitude of stimuli that are constantly bombarding a cellular system is specificity of response.

I. INTRODUCTION

The first layer of specificity in cellular response is the stimulus, and whether the stimulus is capable of provoking a response. The stimulus and the cell must be within a proximity that allows a response to occur. In addition, the stimulus must be of sufficient magnitude, frequency, or duration to elicit a response. Further, the cell must be capable of recognizing the stimulus and in a state in which a response is possible. Receptors are proteins that convey cellular responsiveness to specific stimuli and initiate the intracellular signaling within the stimulated cell that results in a specific response. Several types of receptors are present on the cell surface, in the intracellular milieu, or on intracellular organelles.

G-Protein-coupled receptors (GPCRs) respond to many stimuli, including light, monoamines, peptides, and chemicals of specific structure. These receptors are composed of seven transmembrane-spanning domains with an extracellular amino terminus and an intracellular carboxyl tail. GPCRs can be grouped into three broad categories: rhodopsin-like, calcitonin related, and metabotropic. The majority of GPCRs that have been identified are rhodopsin-like. These receptors have been the focus of a tremendous research effort over the past two decades.

As the nomenclature implies, GPCRs interact with G-proteins to mediate intracellular signaling. G-Proteins are composed of three subunits, α, β, and γ. In the absence of external stimuli, G-proteins are bound to GPCRs and are inactive. Agonist stimulation of GPCRs results in increased guanosine triphosphate (GTP) exchange for guanosine diphosphate (GDP) on the α-subunit of the associated G-proteins. Binding of GTP to the α-subunit reduces the affinity of the α-subunit to the βγ-heterodimeric subunit. This decrease in affinity allows the G-protein to dissociate into two active entities, the free α-GTP subunit and the free βγ-subunit. Both α-GTP and the βγ-subunit can potentially activate a number of intracellular signaling pathways. Intrinsic GTPase activity of the α-subunit deactivates α-GTP. The α-subunit returns to an inactive GDP-bound state, and reassociates with the βγ-subunit thereby rendering both signaling entities of the G-protein inactive. The multitude of GPCRs, the variety of potential α, β, and γ combinations, and the numerous intracellular signal transduction pathways provide the foundation for conferring specificity of cellular response to external stimuli.

II. G-PROTEIN-COUPLED RECEPTOR DIVERSITY LEADS TO ACTIVATION OF MULTIPLE G-PROTEIN SIGNALING PATHWAYS

As already noted, the first layer of specificity in cellular response is the stimulus. The next layer providing specificity in GPCR-mediated intracellular signaling is the receptor. Hundreds of GPCRs have been identified and characterized. These receptors can be divided and subdivided based on nucleotide and amino acid sequences and ligand interactions. There are many illustrations of ligands that can activate multiple receptors or multiple receptor subtypes. For example, there are several receptors that are activated by adrenaline. These receptors fall into the categories of α- or β-adrenergic receptors. Each of these categories is subdivided into groups, including α1, α2, β1, β2, and β3 receptors. The α receptor types are further delineated to α1a, α1b, α1c, α2a, α2b, and α2c receptor subtypes. These receptor subtypes can be distinguished pharmacologically and functionally and bestow great diversity of cellular response. Similarly, multiple receptor subtypes have been identified for many other ligands, including those for cholinergic, purinergic, opioid, dopaminergic, serotonergic, and many peptide receptors.

Different receptor subtypes can mediate activation of the same G-proteins and regulate similar intracellular signaling pathways. For example M1 and M3 muscarinic receptors couple to G_q to mediate phosphoinositide metabolism. Alternatively, different receptor subtypes may activate distinct G-proteins and regulate independent signaling pathways. The M2 and M4 muscarinic receptor subtypes activate G_i, which inhibits adenylyl cyclase rather than the G_q pathway that is stimulated by M1 and M3. In addition, the pharmacology of a ligand at each receptor subtype may differ. The affinity of a ligand at one receptor subtype can be much higher compared to another receptor subtype. The degree of activation that a ligand can generate in one receptor subtype compared to another can also be variable. Thus, the potency and efficacy of a ligand at one receptor subtype may be quite distinct compared to another receptor subtype. The response of a cell to a particular stimulus is dependent on the receptor subtype that is expressed by the cell. Cells can express

one receptor subtype or multiple receptor subtypes that respond to the same ligand. The cellular response to a particular stimulus is the sum of the responses contributed by each type of activated receptor. A ligand can have a focused response in a cell that expresses one receptor subtype (Fig. 1A), while generating a pleiotropic response in another cell that expresses multiple receptor subtypes (Fig. 1B). Furthermore, the cellular expression ratio of various receptor subtypes can distinguish the response of individual cells to specific stimuli. For example, if a cell expresses a preponderance of receptor subtype R1 (Fig. 2A), the cellular response will be similar to that of cells that express subtype R1 alone (Fig. 1A). In contrast, in cells that express an equal amount of receptor subtypes R1 and R2 (Fig. 2B), the response will be a mixture of R1- and R2-mediated signaling, assuming R1 and R2 have similar affinities and pharmacological properties with a specific ligand. By comparison, a cell expressing primarily receptor subtype R2 will exhibit a response reflecting R2 receptor activation (Fig. 2C). The response may be quite distinct from that elicited by receptor subtype R1 stimulation, even though R1 is expressed to some degree on the cell surface. This provides another layer of specificity in cellular response to external stimuli. The response of an individual cell to a specific ligand is dependent on the receptor subtypes that are expressed and the relative levels of expression of each receptor subtype.

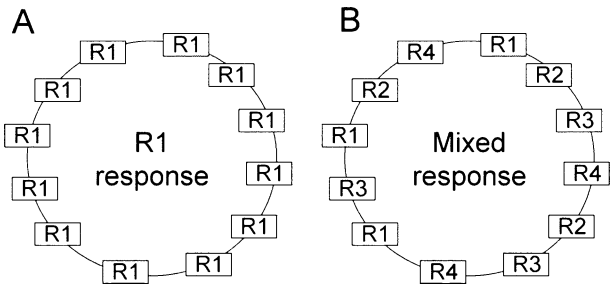

FIGURE 1 (A) Expression of a single receptor (R1), compared to (B) expression of multiple receptors (R1–R4), on a single cell.

III. MULTIPLE G-PROTEINS GENERATE DIVERSE SIGNALING PATTERNS

A. Classes of α and βγ Subunits

In addition to the multitude of external stimuli and the massive diversity in GPCRs, another layer of specificity in cellular response is provided by the numerous combinations of G-proteins potentially expressed within a cell. G-Proteins are categorized by the α-subunit of the heterotrimeric complex. There are four classes of G-protein α-subunits as shown in Table 1. Each class of G-protein α-subunit contains two or more members; 17 α-subunits have been identified. The functions of the subunit classes of α and βγ are shown in Table 1.

1. αs

The $G_{\alpha s}$ class consists of αs-type and αolf. Activation of αs-type G-proteins results in stimulation of adenylyl cyclase and subsequent increases in cAMP production. The αs class of G-proteins also can regulate Ca^{2+} channel activity. Cholera toxin acts on αs G-proteins to inhibit intrinsic GTPase activity. The GTPase activity is the mechanism by which activated G-proteins are inactivated. Thus, cholera toxin enhances the activity of the αs class of G-proteins.

2. αi

In contrast to αs G-proteins, activation of the αi class of G-proteins inhibits adenylyl cyclase, resulting in decreased cAMP production. This class of α-subunits also regulates K^+, Ca^{2+} channels, and cGMP phosphodiesterase. There are several members of the αi class, including αi1, αi2, αi3, αo, αt-1, αt-2, αgust, and αz. With the exception of αz the activity of the αi class of G-proteins is inhibited by pertussis

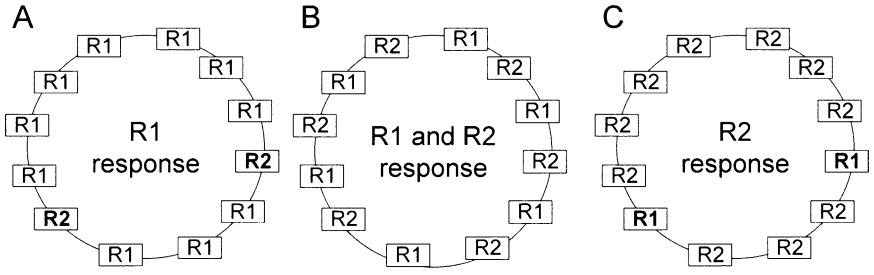

FIGURE 2 Cellular response is dependent on the ratio of receptor expression (see text for discussion).

TABLE 1 G-Protein Classification and Functional Activities

Subunit class	Class members	Effector functionality
αs	αs, αolf	Adenylyl cyclase (stimulation), Ca^{2+} channels
αi	αi1, αi2, αi3, αo, αt1, αt2, αgust, αz	Adenylyl cyclase (inhibition), Ca^{2+} and K^+ channels, cGMP phosphodiesterase
αq	αq, α11, α14, α15, α16	Phospholipase C
α12	α12, α13	Na^+/K^+ exchange
βγ	β1, β2, β,3 β4, β5, γ1, γ2, γ3, γ4,γ5, γ6	Adenylyl cyclase, G-protein receptor kinases, Ca^{2+} and K^+ channels, phospholipases A and C

toxin. Pertussis toxin adenosine diphosphate (ADP)-ribosylates the α-subunit, rendering it unable to associate with receptor.

3. αq

A third class of G-proteins is αq. This class includes αq, α11, α14, α15, and α16. Activation of these G-proteins stimulates phosphoinositide metabolism. The activated α-subunit from this class of G-proteins directly activates phopholipase C, which hydrolyzes phosphatidylinositol 4,5-bisphosphate to form diacylglycerol (DAG) and inositol 1,4,5-trisphosphate ($InsP_3$). Both DAG and $InsP_3$ are intracellular effector molecules.

4. α12

The fourth class of G-proteins is α12. This class consists of α12 and α13. The α12 class of G-proteins regulates Na^+/K^+ exchange. This class of G-proteins is by far the least studied of the four classes and is thus the least well characterized.

5. βγ

The βγ-subunit of G-proteins also is an active signaling entity; βγ mediates numerous intracellular signaling events, including activation of certain subtypes of adenylyl cyclase, phospholipase C, and phospholipase A. The βγ-subunit also activates K^+ channels, and phosphatidylinositol-3-kinase. In addition, βγ binds to G-protein receptor kinases and transports the enzymes to membrane receptor substrates. Like the α-subunit, multiple subtypes of subunits β and γ have been identified. There are five β-subunits (numbered β1–β5) and at least six γ-subunits (numbered γ1–γ6). This theoretically creates 30 different combinations of βγ-subunits. Not all combinations are possible, however. For example, β2 and γ1 do not associate with each other, but β2 and γ2 do form a heterodimer. By comparison, β1 is structurally very similar to β2, but is able to form a dimer with either γ1 or γ2. In addition, some subtypes are expressed only in specific tissues. For example, β1γ1 is expressed only in the retina. Extensive studies to determine which β- and γ-subunits associate with certain α-subunits in particular cell types have not been completed. The multitude of heterotrimeric combinations that can be generated undoubtedly contributes to specificity of cellular response.

B. Models of G-Protein Activation—α

Cellular response to external stimuli is dependent on which G-proteins are activated. In many cases, multiple G-proteins are activated simultaneously. Several models of multiple G-protein activation are possible, as depicted in Fig. 3. In the most simplistic model (Fig. 3A), two separate receptors, R1 and R2, are activated, and each receptor is coupled to a single type of G-protein (G1 and G2). The activated G-proteins then initiate independent intracellular effector pathways (E1 and E2). For instance, a single ligand could activate two receptor subtypes, with one receptor subtype coupled to G_s and the other coupled to G_q. Activation of G_s would lead to increased adenylyl cylcase activity, whereas G_q activation would stimulate phospholipase C.

Alternatively, a single receptor can couple to multiple G-proteins. Indeed, many receptors are capable of coupling to several G-protein subtypes, depending on the cellular conditions. A single receptor coupling to two G-proteins can activate distinct intracellular signaling pathways (Fig. 3B). For example, one receptor could couple to both G_i and G_q, resulting in a decrease in adenylyl cyclase activity and increased phospholipase C activity. It is also possible for the activation of distinct G-proteins to regulate the same effector system (Fig. 3C). For example, if a receptor couples to more than one subtype of $G_{\alpha i}$, both G-proteins mediate inhibition of adenylyl cyclase. G-Proteins from separate classes can also regulate the same effector. Multiple G-proteins may affect downstream signaling pathways in the same manner or may have opposing actions.

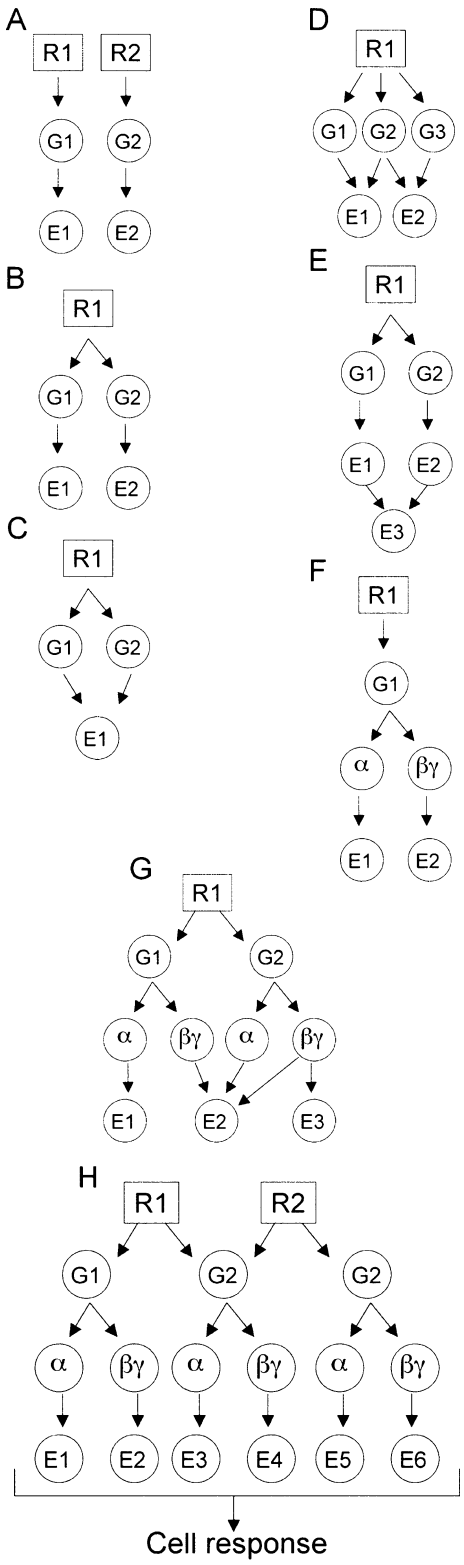

FIGURE 3 Models of multiple G-protein and effector system activation. G1, G2. G-Protein types; R1, R2, receptor types; E1, E2, effector types.

For example, a receptor that couples to both G_i- and G_s-proteins would mediate both positive and negative regulation of adenylyl cyclase activity. In that case, effects on adenylyl cyclase would be dependent on the relative level of G_s versus G_i activation. Parameters that would contribute to this include the expression of G_s and G_i, and the intrinsic ability of the receptor to couple to each G-protein.

Multiple G-protein coupling is not limited to just two G-proteins and two effectors. The model in Fig. 3D depicts a receptor coupling to three G-proteins. Two or more of these G-proteins may regulate the same effector while at the same time also modulating other effectors independently. An example would be a receptor coupling to two G_i subtypes and a G_q-type receptor. The two G_i subtypes decrease adenylyl cyclase activity whereas G_q stimulates phospholipase C. The number of G-proteins to which a receptor is capable of coupling is dependent on which G-proteins are expressed and on receptor/G-protein coupling efficiency.

The effects of activation of distinct G-proteins may also intersect at a point in the intracellular signaling pathway downstream of the initial effector molecule (Fig. 3E). In this model, an individual receptor activates two distinct G-proteins, which, in turn, activate separate second-messenger effector pathways. Through distinct mechanisms, these pathways converge on a downstream effector. The convergent pathways may have synergistic or antagonistic effects. An example of a downstream effector that is regulated by distinct intracellular pathways initiated by activation of multiple G-proteins is mitogen-activated protein kinase (MAP kinase). Many diverse signaling pathways modulate MAP kinase activity, and it is common for a single stimulus to initiate numerous signaling mechanisms that eventually affect MAP kinase activation.

C. Models of G-Protein Activation—α and βγ

As already noted, the α-subunit is not the only active signaling component of G-proteins. The βγ-subunit also interacts with effector systems. This adds a further level of complexity and another layer of specificity in cellular responsiveness. A simple model of α and βγ signaling is shown in Fig. 3F. A single receptor couples to a single G-protein. Following dissociation, two active subunits are formed, α and βγ, which each regulate an effector. For example, following activation of a G_i-coupled receptor, αi inhibits adenylyl cyclase and the βγ-subunit activates an isoform of phospholipase C. A more complicated

model appears if multiple G-proteins are activated following receptor stimulation (Fig. 3G). In this model, a receptor activates multiple G-proteins, which each dissociate into active α and βγ components. Each α and βγ is capable of activating a number of effector systems. Some of these effectors are modulated by more than one α- or βγ-subunit, and the regulation may be synergistic or antagonistic. For example, the αq- and the βγ-subunits of G_i both increase the activity of isoforms of phospholipase C. In contrast, the inhibition of one type of adenylyl cyclase activity may be counteracted by an increase in the activity of another class of adenylate cyclase by βγ-subunits. By comparison, the activity of some effectors may be dependent on only one specific α- or βγ-subunit. As shown in Fig. 3E, the effector systems may converge at another point downstream in the signaling pathway. With α- and βγ-subunits from multiple G-proteins activating a wide array of signaling intermediates, the potential for convergent signaling pathways increases. Likewise, some effector systems remain independent of other signaling pathways.

A model is shown in Fig. 3H demonstrating that the cellular response is a compilation of the activated signaling pathways. External stimuli activate one or more cell surface receptors, which are coupled to one or more G-proteins. The G-proteins each dissociate into α- and βγ-subunits, which activate one or more effector systems. These effector systems can be independent or convergent. The integration of these effector systems results in a dynamic system that can specifically respond to external stimuli.

D. Example of Multiple G-Protein Signaling

An example of a complex intracellular signaling system mediated through multiple G-proteins is melanin-concentrating hormone (MCH)stimulation of MCH receptor-1 (MCH-R1) in Chinese hamster ovary (CHO) cells. Agonist stimulation of MCH-R1 results in activation of G_i, G_o, and G_q. MCH stimulates a decrease in adenylyl cyclase activity, an increase in phosphoinositide metabolism, an increase in intracellular free Ca^{2+}, and an increase in MAP kinase activation. Pertussis toxin completely abolishes the decrease in adenylyl cyclase activity and the increase in MAP kinase, but only partially blocks the increases in intracellular free Ca^{2+} and phosphoinositide metabolism. Thus, the increase in MAP kinase is dependent on G_i and/or G_o activity, whereas changes in intracellular free Ca^{2+} and phosphoinositide metabolism are dependent on G_q and G_i/G_o activity. Looking more closely at MAP kinase activity, G_o-dependent increases in MAP kinase in CHO cells utilize the α-subunit and are dependent on protein kinase C (PKC) activity. G_i-mediated MAP kinase activation in CHO cells utilizes the βγ-subunit and is independent of PKC. Depletion of cellular PKC inhibits MCH-stimulated MAP kinase activation by roughly 50%, indicating that both G_i- and G_o-dependent pathways are employed to mediate MAP kinase activity following MCH-R1 activation. Thus, the βγ-subunit of G_i and αo activate distinct signaling pathways that converge to activate MAP kinase in this system. By comparison, αq, the βγ-subunit of G_i, and/or αo converge at a point higher in the signaling pathway to mediate increases in phosphoinositide metabolism and intracellular free Ca^{2+}.

IV. DIVERSITY IN EFFECTORS

In addition to the subtypes of receptors and G-proteins, subtypes of several downstream signaling effectors have been identified. There are at least nine isoforms of adenylyl cyclase expressed in mammalian systems. These subtypes of adenylyl cyclase vary in tissue expression and interaction with specific G-proteins. Some of these isoforms of adenylyl cyclase are activated by the βγ-subunit, and some are inhibited. The isoforms of adenylyl cyclase that are expressed in a particular cell will have a profound influence on the intracellular signaling characteristics mediated by GPCR activation.

Several isoforms of phospholipase C have also been identified. There are at least 10 phospholipase C (PLC) genes grouped into three families: PLC-β, PLC-γ, and PLC-δ. The αq G-protein subunit activates all PLC-β isozymes, but is more effective at activating PLC-β1 and PLC-β3. By comparison, the βγ-subunit of G_i activates PLC-β2 and PLC-β3. The combination of which PLCs are expressed and which are stimulated by activated G-proteins in a particular cell system contributes to linkage of the signaling pathways to a specific GPCR.

Another major intermediate common in G-protein-dependent signaling pathways is PKC. Similar to adenylyl cyclase and phospholipase C, at least nine isoforms of PKC have been identified. These isoforms are grouped into two broad categories based on structure. One class includes α, β-I, β-II, and γ. These isoforms of PKC all contain a conserved region, C-2. The other class of PKC isoforms includes δ, ϵ, ζ, μ, and θ, which lack the C-2 region. Most of these PKC isoforms are activated by DAG and by increased

intracellular free Ca^{2+}. Because many activated G-protein subtypes stimulate DAG production and/or increase intracellular Ca^{2+}, PKC activity often is involved in GPCR-mediated intracellular signaling pathways. The various PKC isoforms phosphorylate specific proteins. GPCRs are therefore coupled to specific PKC-mediated protein phosphorylation, based on which G-proteins and PKC isoforms are activated. In addition, in some cases, PKC phosphorylates GPCRs and regulates receptor function.

Multiple subtypes of other intracellular signaling intermediates also exist. The wide array of potential signaling intermediates and pathways is too vast to describe in detail. The central theme, however, is that the diversity in intracellular signaling pathways provides the network required to achieve specific cellular response to external stimuli.

V. REGULATORS OF G-PROTEIN-COUPLED RECEPTOR SIGNALING

In addition to the initiation of intracellular signaling pathways, cellular response also involves attenuation of GPCR activity. Several factors act in concert to decrease GPCR function through intracellular signaling pathways of their own. G-Protein-coupled receptor kinases (GRKs) are serine/threonine kinases that phosphorylate agonist-bound or activated GPCRs and initiate receptor internalization. There are seven mammalian GRKs grouped into three classes based on functional similarities. One class has the members GRK1 and GRK7. The second class includes GRK2 and GRK3. The third class consists of GRK4, GRK5, and GRK6. Activation of GRKs by various intracellular signaling mechanisms coupled with the diversity of GRK function provides another layer of specificity in cellular response.

Arrestins comprise another family of proteins that are involved in regulation of GPCR function. At least four arrestins have been identified. The arrestins are grouped into two classes based on sequence homology, function, and tissue distribution. Visual arrestin and cone arrestin (C-arrestin) comprise one class; β-arrestin1 and β-arrestin2 comprise the other class. These proteins are also involved in internalization of GPCRs, and thus regulate receptor function.

Proteins termed "regulators of G-protein signaling" (RGS proteins) are a third major modulator of G-protein-mediated signaling. These are GTPase-activating proteins that act on active G_α subunits to accelerate GTP hydrolysis, thereby decreasing G-protein activity. More than 20 RGS proteins are expressed in mammals. Some RGS proteins selectively modify specific G_α subunits, whereas other RGS proteins act more pervasively. The presence of RGS proteins within a cell can have profound effects on the cellular response to GPCR activation.

Regulation of G-protein-dependent signaling is not limited to the GRKs, arrestins, and RGS proteins. Other cellular agents, both known and unknown, can also regulate intracellular signaling. A cell must incorporate all of the signaling events and all of the regulatory actions to produce an integrated response to external stimuli.

VI. SUMMARY

Many factors contribute to generation of a specific cellular response to external stimuli. Multiple receptors or receptor subtypes can be activated simultaneously by one or more stimuli. Activated receptors then positively couple to one or more G-proteins, creating two potential signaling entities, G_α-GTP and $G_{\beta\gamma}$. There are several types of G-proteins, each varying in functional characteristics. Activation of multiple G-proteins engenders a cascade of signaling events that can be convergent with or independent of each other. Effector molecules that are regulated by G-proteins are also a source of diverse responsiveness. Effector subtypes can vary in responsiveness to specific G-proteins and provoke distinct downstream signaling events. Furthermore, multiple subtypes of proteins that regulate GPCR-mediated signaling (GRK, PKC, RGS proteins, arrestin, etc.) provide another layer of diversity in cell signaling. The receptors, G-proteins, effector molecules, and signaling regulators that are expressed in a particular cell will be determining factors in cellular responsiveness to external stimuli. The overall response will be dependent on the relative amount of expression of each of these factors within a given cell. A specific stimulus in one cell may produce a response that is completely different in another cell, depending on the relative expression levels of receptors, G-proteins, and other signaling intermediates. The integrated signaling systems bestow a cell with specific function.

Glossary

adenylyl cyclase Cellular enzyme that generates increases in intracellular cAMP, leading to activation of protein kinase A, which phosphorylates and regulates a multitude of proteins.

effector Any of a number of enzymes or regulatory molecules within a cell that is stimulated or inhibited

following receptor activation; responsible for transducing a cellular response to external stimuli.

G_α and $G_{\beta\gamma}$ Guanyl nucleotide binding protein subunits α and $\beta\gamma$.

intracellular signaling pathway The series of chemical and physical reactions within a cell following external stimuli that lead to the overall response of the cell.

ligand Agent that activates a receptor, including neurotransmitters, hormones, small molecules, and photons.

phospholipase C Cellular enzyme that is activated by specific G-protein subunits; hydrolyzes phosphatidylinositol 4,5-bisphosphate to diacylglycerol and inositol 1,4,5-trisphosphate, which are second-messenger intracellular signaling molecules.

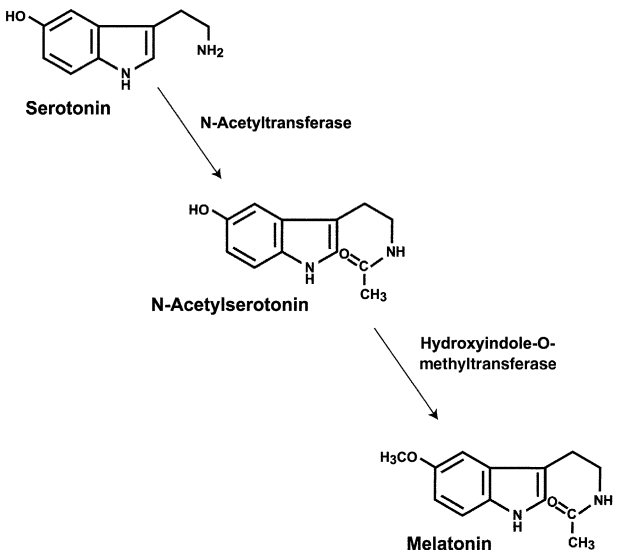

FIGURE 1 Synthesis of melatonin from serotonin.

photoreceptors are involved in entraining the endogenous circadian pacemaker and in regulating melatonin synthesis and secretion.

In mammals, the site of the ECP, or "biological clock," is the SCN of the hypothalamus. The SCN contains about 10,000 neurons and is a paired structure located in the anterobasal hypothalamus, just above the optic chiasm. The SCN receives external photic stimuli from the environment, maintaining entrainment to the 24-h day/night cycle. Photoreceptors in the retina send impulses to the SCN via a specific neural pathway, the retinohypothalamic tract, which is separate from the pathway that mediates vision. Bilateral enucleation probably abolishes all effects of light on circadian rhythms.

Communication between the pineal gland and the SCN is bidirectional. The pineal gland communicates with the SCN via melatonin, which is secreted into the CSF and into the bloodstream. Melatonin binds to specific SCN receptors, which mediate the phase-shifting effects of melatonin on circadian rhythms. The SCN restricts the synthesis and secretion of melatonin to an interval of approximately 12 h.

A polysynaptic neural pathway connects the SCN to the pineal gland (Fig. 2). From the SCN, impulses are transmitted to the paraventricular nucleus (PVN) of the hypothalamus and then to the intermediolateral column of the upper thoracic spinal cord. Preganglionic sympathetic neurons extend from the intermediolateral column to the superior cervical ganglion, adjacent to the internal carotid artery in the neck. Postganglionic sympathetic neurons then innervate the pineal gland. Norepinephrine is the neurotransmitter released from the postganglionic sympathetic neurons terminating on pinealocytes.

Pinealocytes possess both β1- and α1-adrenergic receptors. Norepinephrine stimulates the β1-receptors, leading to activation of *N*-acetyltransferase, the rate-limiting enzyme in melatonin synthesis. This action is potentiated by activation of α1-adrenergic receptors. The nerve endings of the sympathetic neurons terminating in the pineal gland have adrenergic receptors as well. These are α2-adrenergic autoreceptors, and their activation leads to a decrease in melatonin production. Activation of the sympathetic neurons terminating in the pineal gland is tightly controlled by the SCN. Nonspecific sympathetic stimuli, collectively known as the "fight or flight" response, do not activate the pineal gland. This may be partly due to active catecholamine reuptake present in the postganglionic sympathetic neurons innervating the pineal gland.

During the daily dark period, neural impulses from the PVN are transmitted to the pineal gland, where they stimulate melatonin synthesis and secretion. During the day, the SCN sends impulses that decrease the otherwise "on" signal of the PVN. When not inhibited by the SCN, the PVN stimulates

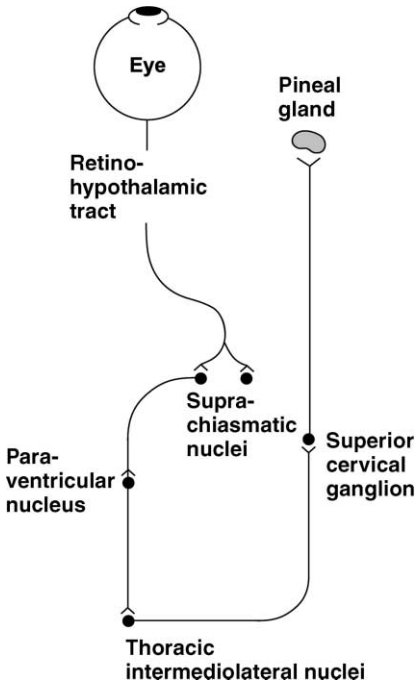

FIGURE 2 Neuroanatomy of the circadian system, depictjing neuroanatomic regulation of mammalian melatonin production.

melatonin production and secretion. As expected, drugs that affect sympathetic activation can alter melatonin secretion. Beta-blocking agents, which interfere with β1-adrenergic stimulation in the pineal gland, cause a reduction of melatonin production. Drugs that stimulate α2-receptors, such as clonidine, will decrease melatonin output, whereas drugs that block these receptors, such as yohimbine, increase melatonin production. Tricyclic antidepressants, which interfere with norepinephrine reuptake, increase melatonin production. Only extreme physical exercise, such as high-altitude marathon races, will lead to increased melatonin production. Drugs that affect melatonin production generally do so consistently throughout the night, so that they affect both the first and the second parts of the profile equally. This is important, because changes in the shape of the melatonin profile can, at least theoretically, lead to phase shifts of the ECP.

Even low levels of light exposure during the dark period can have an acute suppressant effect on melatonin production. This effect can occur only during the dark period, because melatonin secretion is already stopped by the SCN during the daytime (photoperiod). In almost all species studied, including humans, there is no corresponding stimulatory effect of darkness during the day; that is, dark exposure during the daytime does not lead to an acute increase in melatonin production. Thus, melatonin secretion is restricted to about 12 h during the night. The acute suppressant effect of light is critical for endogenous melatonin to augment entrainment of the ECP by the light/dark cycle (Fig. 3).

IV. MELATONIN AS A PHASE MARKER

The phase of the ECP is best assessed by monitoring melatonin levels. Melatonin levels are typically low during the day and generally begin to rise about 14 h after a person's habitual waketime. In normal individuals, the time of the melatonin onset (MO) is very stable from day to day and can be used as a

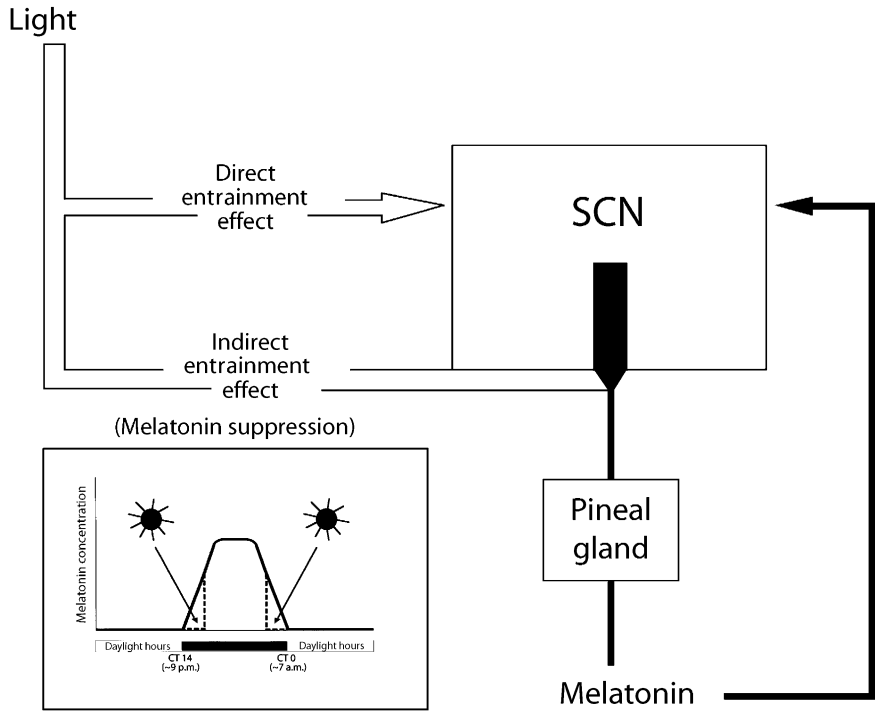

FIGURE 3 Schematic diagram of some of the relationships between nighttime melatonin production by the pineal gland, the light/dark cycle, and an endogenous circadian pacemaker located in the suprachiasmatic nucleus (SCN). Acting on the SCN as described by the melatonin phase response curve (see Fig. 4) at any given time of the day or night, melatonin causes phase shifts opposite to those that light would cause (indicated by the opposing arrows). However, the suppressant effect of light pares the margins of the nighttime melatonin profile (vertical tapered arrow and inset) and reduces endogenous melatonin's stimulation of the melatonin phase response curve at the day/night transitions. This second (indirect) pathway for entrainment by light is particularly significant during shifts of the light/dark cycle. For example, morning light directly advances the endogenous circadian pacemaker and—by suppressing endogenous melatonin production in the morning—removes morning melatonin levels that would otherwise cause a phase delay.

marker to evaluate a person's circadian phase. Researchers often empirically use the time at which plasma melatonin levels reach 10 pg/ml as the MO, although other operational definitions can be used as well. Because sampling for melatonin is usually done in sighted people under conditions of dim light (less than 10–30 lux) to avoid the suppressant effects of light on melatonin secretion, the MO under these conditions is often called the dim light melatonin onset (DLMO). A person whose DLMO is occurring 14 h after waketime (2 h before bedtime) is said to be in normal phase. By frequently sampling overnight melatonin levels, it is also possible to map other points on the melatonin secretion curve. The time when melatonin levels start to fall (when melatonin synthesis stops) is called the synthesis offset (SynOff), and the time when melatonin levels decrease below 10 pg/ml is called the dim light melatonin offset (DLMOff). These phase markers could also be used to monitor a person's circadian rhythms, although the DLMOff may not be as reliable, because it is significantly influenced by the amplitude of melatonin secretion, which can vary markedly among individuals. Also, measuring the DLMOff, and particularly the SynOff, requires waking subjects in the middle of the night, whereas the DLMO can usually be measured prior to sleep onset. In addition to measuring melatonin in plasma, melatonin can also be measured in saliva. Levels in saliva are generally about one-third of those in plasma. Saliva collection is less invasive than blood collection and can easily be done at home.

V. EFFECTS OF MELATONIN ON CIRCADIAN RHYTHMS

Animal studies show that melatonin is able to induce circadian rhythm phase shifts at both behavioral and cellular levels. More than a decade ago, it was demonstrated in human subjects that melatonin administered during the late afternoon or early evening advanced the DLMO, whereas melatonin given in the morning delayed it (Fig. 4). These results allowed for the description of a melatonin phase response curve (PRC), which makes possible accurate predictions of the effect of exogenously administered melatonin based on the time of administration.

The melatonin PRC reveals that there is an approximately 12-h interval during which exogenous melatonin will advance the endogenous pacemaker and a 12-h interval during which melatonin will delay it. Not surprisingly, the melatonin PRC is about 12 h out of phase with the light PRC. This would be expected because melatonin is thought to act as a chemical signal for darkness. The melatonin PRC is most helpful when it is expressed in circadian time (CT; DLMO = CT 14) rather than clock time. This allows the melatonin PRC to be used effectively in people whose circadian rhythms are out of phase with their environment (for example, immediately after a transmeridian flight). The advance zone of the melatonin PRC is generally from CT 6 to CT 18 and the delay zone is from CT 18 to CT 6. This information can be used therapeutically in a number of clinical situations. Figure 5 illustrates the fundamental ways in which bright light and melatonin should be scheduled according to clock times to correct circadian phase disorders.

VI. ABNORMALITIES IN CIRCADIAN RHYTHMS

A. Blindness

The circadian rhythms of blind people are often abnormal. Many blind people have circadian rhythms that are not entrained to the 24-h day/night cycle with a period longer (or rarely shorter) than 24 h; that is, they have "free-running" circadian rhythms. In these blind free-runners, the circadian rhythms governed by the SCN, such as melatonin secretion, core body temperature, and sleep propensity, shift later and later each day. Because of their constantly drifting circadian rhythms, BFRs spend much of their lives "out of phase." When they are out of phase, they often experience adverse effects, including nighttime insomnia and daytime somnolence. Only BFRs who constantly change their sleep and wake hours in accordance with their drifting ECP will have normal sleep. Another subgroup of blind people appears to be entrained but at an abnormal phase: the MO may stably occur at any time of the day or night, and thus they are always out of phase with their environment. These people may have chronic problems with insomnia and daytime somnolence. Still other blind people may have normally and stably phased circadian rhythms. Melatonin can be used successfully to treat circadian rhythm disorders in blind people. It is typically given in the evening or just before bedtime at doses of 0.5 mg (or possibly less). It is not yet known if lower doses of melatonin are needed to maintain entrained rhythms compared to doses needed for correction of abnormal rhythms.

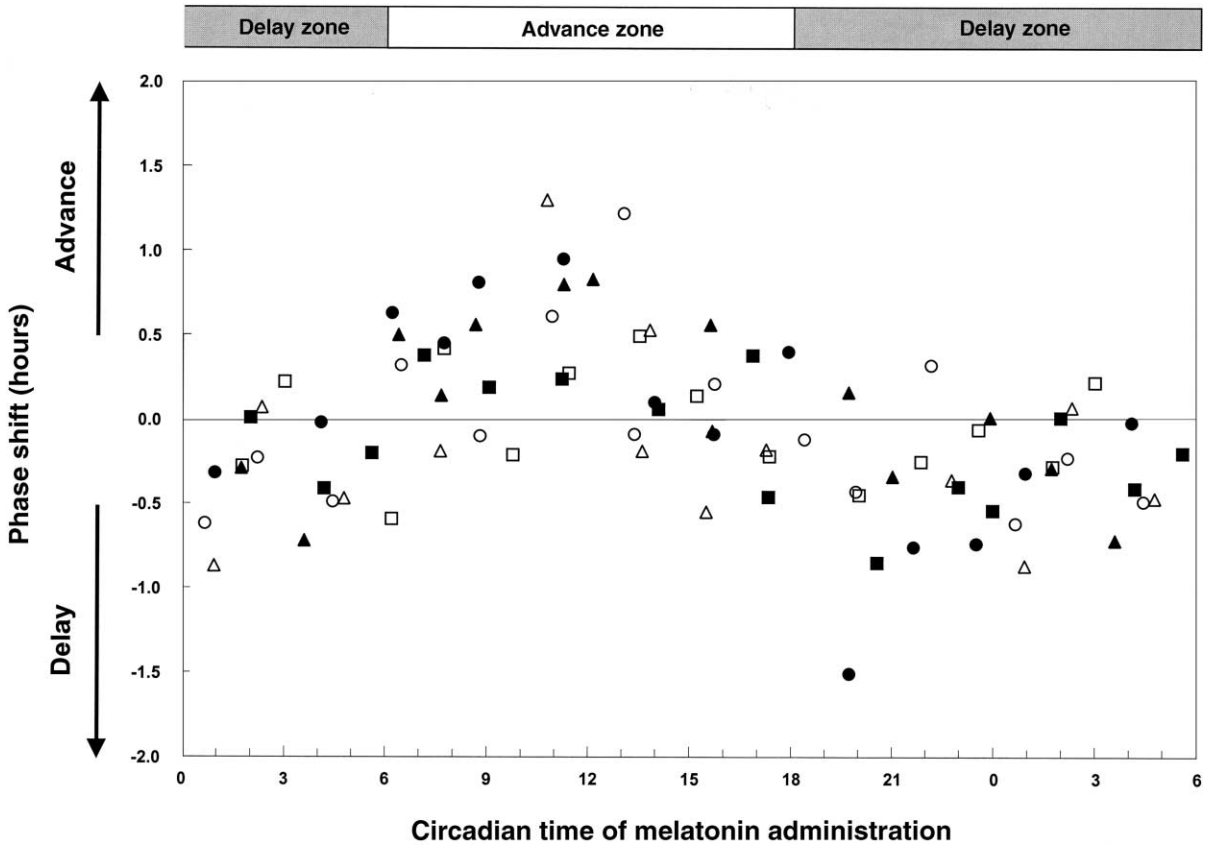

FIGURE 4 Individual phase response curves from six subjects (five females and one male; the single male is represented by the filled circle) given melatonin (0.5 mg) for four consecutive days on 12 occasions. Phase advances and delays are plotted against circadian time (CT) of administration (CT 14 = baseline dim light melatonin onset). Exogenous melatonin causes phase advances when given between CT 6 and CT 18, and it causes phase delays when given between CT 18 and CT 6.

B. Advanced and Delayed Sleep Phase Syndromes

Sighted people can also have endogenous circadian rhythms that are out of phase with their environment and with their desired sleep time. People who suffer from advanced sleep phase syndrome (ASPS) have sleep times that are advanced in relation to normal clock time and in relation to their desired sleep time. These people feel excessively sleepy in the evening, fall asleep early and suffer from early morning awakening. This condition develops more commonly in the elderly. Delayed sleep phase syndrome (DSPS) is just the opposite. People with this syndrome have sleep delayed in relation to clock time and in relation to their desired sleep time. They are unable to fall asleep until late in the night, typically after 1 AM, and they have difficulty awakening in the morning. This condition is more prevalent in the young. Both bright light and melatonin have been effectively used to treat circadian phase disorders in sighted people (see Fig. 5).

C. Jet Lag

People who travel across multiple time zones are usually affected by jet lag, because their endogenous circadian rhythms are out of phase for the first few days in the new time zone. To hasten adaptation to the new time zone, sunlight exposure is scheduled to be obtained at specified times and, perhaps more importantly, to be avoided at specified times, for the first few days after arrival. For example, after traveling six or more time zones to the east, sunlight should be avoided in the morning and obtained in the afternoon for 1–2 days, after which it should be obtained in the morning for a day or two. Low doses of melatonin can be taken in the afternoon for a day

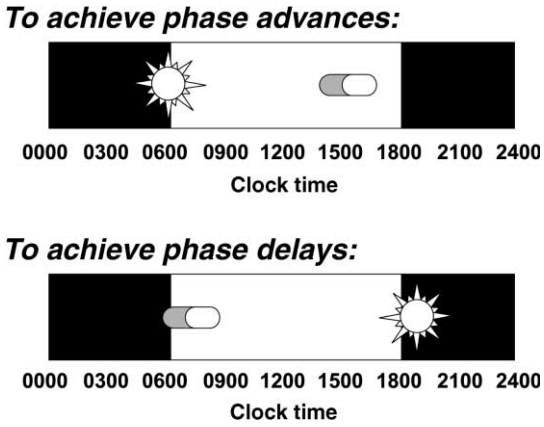

FIGURE 5 Phase-shifting effects of light and exogenous melatonin. In order to cause a phase advance, light should be scheduled in the morning and melatonin should be administered in the afternoon. In order to cause a phase delay, light should be scheduled in the evening and melatonin should be administered in the morning.

or two before travel (see Fig. 5) and also for the first few days after arrival, with the timing of administration then adjusted according to local time.

D. Shift Work

Shift workers can suffer extraordinary physical and psychological consequences from constantly being out of phase. The effects of shift work may be especially difficult as people age. People who permanently work day or evening shifts do not typically have chronobiological problems. The most significant problems are seen in those who do at least part of their work at night. Almost all night shift workers rotate shifts, if only between work days and days off. In a typical week they may work five nights and then try to normalize their schedule to daytime hours on days off in order to maximize time with family and friends. Other shift workers constantly rotate actual work schedules. They may, for example, do a few day shifts, a few evening shifts, and then a few night shifts within a week or so. With these schedule disturbances, they may never fully synchronize with their environment, and consequently they often suffer from insomnia during their desired sleep hours and somnolence while at work. Shift workers can also have impaired productivity and work performance. For all of these reasons and because shift work is so prevalent, this topic has been the subject of intense investigation. Both bright light and melatonin treatments can be used to help the circadian rhythm disturbances of shift workers (see Fig. 5). Avoiding bright light at certain times is also helpful. However, the practical use of these phase-resetting agents in shift workers is complicated by their constantly changing schedules and their individual preferences.

E. Winter Depression

Seasonal affective disorder (SAD) is another condition that appears to stem from disturbed endogenous circadian rhythms. SAD is a condition characterized by recurrent bouts of depression that occur predictably every fall or winter as the days become shorter, with spontaneous improvement every spring or summer as the days lengthen. All patients with SAD have depression, but they also commonly have increased sleep time, hyperphagia (especially carbohydrate craving), weight gain, low energy, low motivation, and social withdrawal.

Bright light exposure is the treatment of choice for SAD. A typical treatment will start with 1–2 h of light treatment (10,000 lux) every morning; morning light is thought to be antidepressant because it causes a corrective phase advance. After patients respond, they can then decrease the duration of light exposure to less than 30 min per day. A subgroup of atypical subjects responds best to bright light exposure in the evening.

Studies into the effects of melatonin on the treatment of SAD have lagged behind studies of light therapy and, so far, very few have been published. However, according to the phase shift hypothesis of SAD, low doses of melatonin in the afternoon and evening should be therapeutic in the typical SAD patient and low doses in the morning should be therapeutic in the atypical SAD patient. In the phase-delayed type of SAD patient, the optimal amount of phase advance seems to be about 1.5 h. Combining light and melatonin may make the most sense for some people, because adding melatonin to light treatment will allow a shorter light treatment duration, which is often desirable. Using melatonin alone without light treatment is another option; however, this is not always feasible, because the doses of melatonin required to cause the necessary phase advance cause somnolence in some SAD patients, who seem to be very sensitive to melatonin's soporific effect. This effect can often be eliminated by using very low doses of melatonin (e.g., 0.075–0.125 mg) given every few hours in the afternoon and evening; however, even these doses will be sedating in some people. It should be emphasized that to achieve the full therapeutic effect of the phase advance caused

by morning light or evening melatonin, it is important that a person not advance their sleep/wake cycle. That is, the ECP needs to be advanced in relation to the sleep/wake cycle.

VII. SAFETY OF MELATONIN

In addition to phase-shifting effects, melatonin can have soporific effects, particularly at high doses. About 30% of people will experience sleepiness as a side effect of melatonin administration. If melatonin is taken incorrectly, it can potentially cause adverse consequences via its effects on sleep and circadian rhythms. For example, someone taking melatonin for jet lag could potentially retard the normalization of circadian rhythms by taking melatonin at the wrong time. Another example would be the development of somnolence when melatonin is taken during the day. Besides predictable consequences such as these, there have been no reports of serious irreversible adverse effects due unequivocally to melatonin. In the United States, where melatonin is easily available without a prescription, millions have used it over the past few years. However, people who choose to take melatonin should do so with the understanding that not much is known about the possible consequences, if any, of its long-term use.

VIII. SUMMARY

Progress has been made during the past 20 years elucidating the physiology of the pineal gland and its primary secretory product, melatonin. Endogenous melatonin in humans probably augments entrainment of the ECP by the light/dark cycle. The production and secretion of melatonin are regulated by the ECP in the SCN of the hypothalamus. Both light exposure and exogenous melatonin can influence the ECP and, consequently, melatonin secretion.

Normally phased endogenous rhythms are thought to be important in maintaining good physical and mental health. Disturbances in the ECP can lead to sleep and mood disorders. Both melatonin and light can be used effectively to treat these. Ongoing work in this area will help refine the current therapeutic approaches and will find improved ways of manipulating body rhythms to help maintain optimum health.

Glossary

advanced sleep phase syndrome A disturbance in which sleep occurs intractably early.

blind free-runners Totally blind individuals whose circadian rhythms drift (usually later) each day.

delayed sleep phase syndrome A disturbance in which sleep occurs intractably late.

dim light melatonin onset The time when melatonin levels rise under dim light conditions; a useful marker for the endogenous circadian pacemaker phase.

endogenous circadian pacemaker Regulates most, if not all, circadian rhythms; located in the suprachiasmic nucleus.

phase response curve A mathematical plot that describes how light and melatonin affect endogenous circadian pacemaker phase.

suprachiasmatic nucleus The collection of neurons in the hypothalamus where the endogenous circadian pacemaker is located.

Melatonin Receptor Signaling

MARGARITA L. DUBOCOVICH AND
MONICA I. MASANA
Northwestern University Feinberg School of Medicine

Melatonin (5-methoxy-*N*-acetyltryptamine), one of the main hormonal outputs of the circadian system, relays photoperiodic information by providing dark timing cues to target tissues. Melatonin receptors receive and transduce the melatonin message to influence daily and seasonal rhythms of physiology and behavior in vertebrates.

I. MELATONIN PHYSIOLOGY

Synthesis and release of the hormone melatonin in the vertebrate retina and pineal gland follow a circadian rhythm that peaks during the dark period of the daily light/dark cycle (the photoperiod) (Fig. 1). In the absence of light cues, the endogenous circadian rhythm of pineal melatonin synthesis and release is driven by circadian pacemaker cells (the "clock") located in the suprachiasmatic nucleus (SCN) of the hypothalamus, which sends the signal to the pineal gland via a multisynaptic pathway through the superior cervical ganglia. In the retina, a local clock mechanism governing melatonin synthesis and release drives the circadian melatonin rhythm. In both the retina and the SCN, the clock is entrained to a 24-h period by environmental changes in the light/dark cycle; the changes in light are sensed by the retina directly and conveyed to the SCN via the retinohypothalamic tract.

Melatonin is synthesized from serotonin through the sequential action of two enzymes: the rate-limiting enzyme arylalkylamine *N*-acetyltransferase (AANAT), which acetylates serotonin to yield *N*-acetylserotonin (NAS), and the enzyme hydroxyindole-*O*-methyltransferase (HIOMT), which transfers a methyl group from *S*-adenosylmethionine to the 5-hydroxy group of *N*-acetylserotonin. The daily fluctuations in AANAT and HIOMT activity are regulated directly by the activation of α- and β-adrenergic receptors in the pineal gland, followed by transcriptional and posttranscriptional mechanisms leading to an increase in activity of the rate-limiting enzyme AANAT, a decrease in serotonin content, and an increase in levels of NAS and melatonin (MLT). Melatonin synthesized in the retinal photoreceptors is secreted locally and is known to inhibit dopamine release. Melatonin and dopamine can act as signals for the dark and light, respectively, mutually inhibiting each other and functioning as major players in dark/light adaptation. Although AANAT and HIOMT have been localized primarily to the pineal and retinal tissues, these enzymes are also present at lower levels in other brain and peripheral tissues. At present, the functional relevance of extrapineal and retinal melatonin is unknown.

II. MELATONIN RECEPTORS

A. Molecular Structure and Pharmacology

The first described biological activity of melatonin can be traced back to 1917 when McCord and Allen discovered that extracts of bovine pineal glands caused blanching of *Rana pipiens* tadpole skin. Aaron Lerner used this bioassay to isolate melatonin from pineal extracts, which led to the elucidation of its chemical structure in 1958. The property of melatonin that allows it to aggregate pigment granules (melanosomes) of amphibian dermal melanophores was used to demonstrate the existence of melatonin receptors and to establish in cultured *Xenopus laevis* melanophores that activation of melatonin receptors inhibited cAMP formation through coupling to a pertussis toxin-sensitive G-protein.

Critical to the discovery of mammalian melatonin receptors was the characterization of the radioligands [^{3}H]melatonin and 2-[^{125}I]iodomelatonin,

Thus, 7S NGF appears to be a storage form of NGF and is apparently restricted to this tissue (and perhaps some other rodent submandibular glands and snake venoms).

As was first determined with the 2.5S preparation, βNGF is composed of two identical polypeptide chains, associated noncovalently, and thus the 7S complex is a symmetrical heterohexamer. Sequence determination of 2.5S NGF, one of the earliest proteins to be so analyzed, indicated that the longest chain contains 118 amino acids ($M_w = 14259$) and each subunit has three intrachain disulfide bonds, which are paired 1–4, 2–5, and 3–6. Their unique conformational arrangement, subsequently determined from X-ray crystallographic studies, is a hallmark of the NGF super family (see later). These studies also showed that the N-terminal octapeptide is not present in approximately 50% of the chains and that somewhat lesser amounts of each subunit are missing the C-terminal arginine residue. βNGF isolated from purified 7S NGF has considerably less of both modifications. The importance of these regions to receptor binding, and hence activity, has been extensively studied. Basically, the N-terminal region including part of the octapeptide sequence is important for interaction with TrkA (one of the two NGF receptors; see later) but the C-terminal arginine does not contribute to interactions with either receptor. The 7S complex is maximally stable at neutral pH and dissociates above or below pH 7 (primarily due to the dissociation of one or the other of the kallikrein subunits). In contrast, the polypeptides making up the β-subunit are very tightly associated and require denaturing conditions to cause chain separation. Thus, the βNGF ligand always functions as a dimer.

As expected for proteins of this type, NGF is synthesized as a larger precursor molecule, and the sequence of this entity, termed prepro-βNGF, has been determined from the cDNA. Due to the use of an alternative initiation codon, two precursors are formed but both yield the same mature protein. The sequence of the human precursor is shown in Fig. 1, with an indication of the alternative initiation site. Similar sequence information is now available for NGF from a variety of other species, including the mouse, cow, chicken, guinea pig, and cobra. The prepro-βNGF gene is located on human chromosome 1 at p22 and on mouse chromosome 3.

Comparison of the βNGF sequence against the limited database available at the time of initial studies of NGF suggested a distant but significant relationship with proinsulin; this was strongly supported by similarities in functional responses of the respective target cells. This correctly presaged that NGF was a part of what has turned out to be a greatly expanded field of hormones and hormone-like substances that primarily function in autocrine and paracrine fashions. However, eventual structural data disproved the NGF-insulin relationship; rather, NGF is a member of another family of homologous factors collectively termed neurotrophins. In mammals there are three other known members: brain-derived neurotrophic factor (BNDF), neurotrophin 3 (NT3), and neurotrophin 4 (NT4). NT4 is sometimes referred to NT4/5 due to some early confusion about the identity of these two neurotrophins. Two additional neurotrophins, NT6 and NT7, have been identified in lower species but do not have mammalian counterparts. Pairwise comparisons of these sequences (within a single species) show about 50% identity (Fig. 2). There is some variability in length that is manifested at both termini and in short insertions in the BNDF and NT4 sequences. However, the half-cystines are conserved, as is the overall structure of each factor (all four native neurotrophins and two artificial heterodimers have been solved by X-ray crystallographic analysis). Although there are distinct residues involved, the receptor-binding regions are also located in similar places (with the exception of the N-terminal region of NGF).

III. STRUCTURE

Although crystals of βNGF were obtained in 1975, the three-dimensional structure was not obtained until 1991. When it was determined, it described a unique and somewhat unexpected fold (Fig. 3). Each subunit has an elongated structure as opposed to a strictly globular one and there are four extended polypeptide segments that form two pairs of twisted antiparallel β-sheets, giving rise to the extensive, highly hydrophobic interface (~ 3000 Å^2) between the two protomers making up the dimer. A "cystine knot" composed of all three intrachain links characterizes one end of this "bundle." Two of these form a circular structure and the third passes through it, providing a quite distinct signature motif. At the opposite end, the β-sheets terminate in three hairpin loops, whereas a fourth, looser loop caps the cystine knot end. The two subunits are oriented in a parallel fashion and a not inaccurate description suggests the overall structure is like a bouquet of flowers.

In addition to the other neurotrophins, which have very similar conformations, there are three other families of hormones/growth factors that share

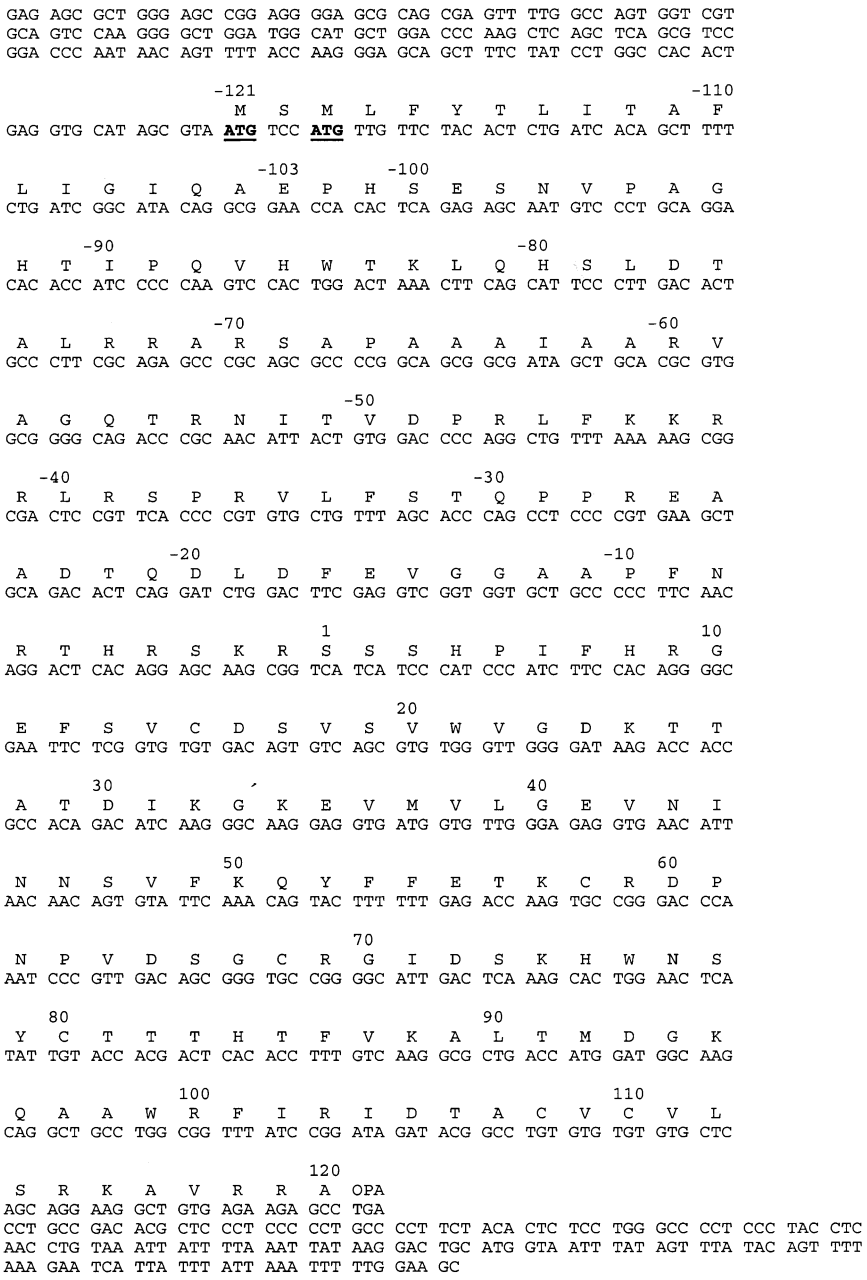

FIGURE 1 The nucleic and amino acid sequences of human prepro-βNGF. The amino acid positions are numbered beginning with the first amino-terminal residue of the mature βNGF molecule. The signal peptide consists of residues −121 to −104 whereas the propeptide is composed of residues −103 to −1. The initiation site is at position −121, with an alternative site at position −119, both of which are indicated by bold text.

the cystine knot/four-strand β-sheet core structure and thus form a superfamily with the neurotrophins. Although each family contains several members, they are represented by platelet-derived growth factor, transforming growth factor-β and chorionic gonadotropin. However, substantial differences, including protomer orientation and the presence of interchain disulfide bonds, distinguish the families. Beyond the conservation of the participating half-cystines, there is no recognizable sequence relatedness between members of the superfamily. This motif has also been found in some other nonhormonal molecules.

The crystal structure of the 7S complex defines the interactions between the kallikrein-like subunits

FIGURE 2 Alignment of the amino acid sequences (single-letter code) of human nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT3), and neurotrophin-4 (NT4). Numbers correspond to positions in the NGF sequence. Residues important for p75 receptor binding are indicated by boldface type and residues of NGF known to interact with the TrkA receptor are shaded. Conserved residues are marked with an asterisk. Dashes represent gaps introduced for alignment purposes. Note that, because of differences in the lengths of the N-termini of the different neurotrophins, homologous positions in different molecules do not have equivalent numbering.

and those of βNGF. The αNGF subunits, which show a "locked zymogen" conformation consistent with their unprocessed state, bind to the core pleated sheets and the γNGF molecules interact mainly with the C-terminal region of the βNGF subunit. This latter interaction includes the C-terminal arginine residue of βNGF, which is bound in the active site of the γNGF. These interfaces are in the range of 2000–2500 $Å^2$. The two γ-subunits also have a major interaction (~2600 $Å^2$) but there is no contact between the α-subunits. The zinc ions occur at the interface (~1600 $Å^2$) of the α/γ-subunits and each contributes two metal ligands. Although α/β and β/γ dimers are stable in solution under certain conditions, α/γ dimers are not. Both kallikreins are monomeric in solution.

IV. BIOSYNTHESIS/EXPRESSION

The signal peptide of human prepro-βNGF is 18 residues in length and the pro sequence contains 103 residues, yielding a full-length zymogen of ~30 kDa. *In vivo* and *in vitro* labeling experiments had initially detected a 22-kDa precursor that could be converted

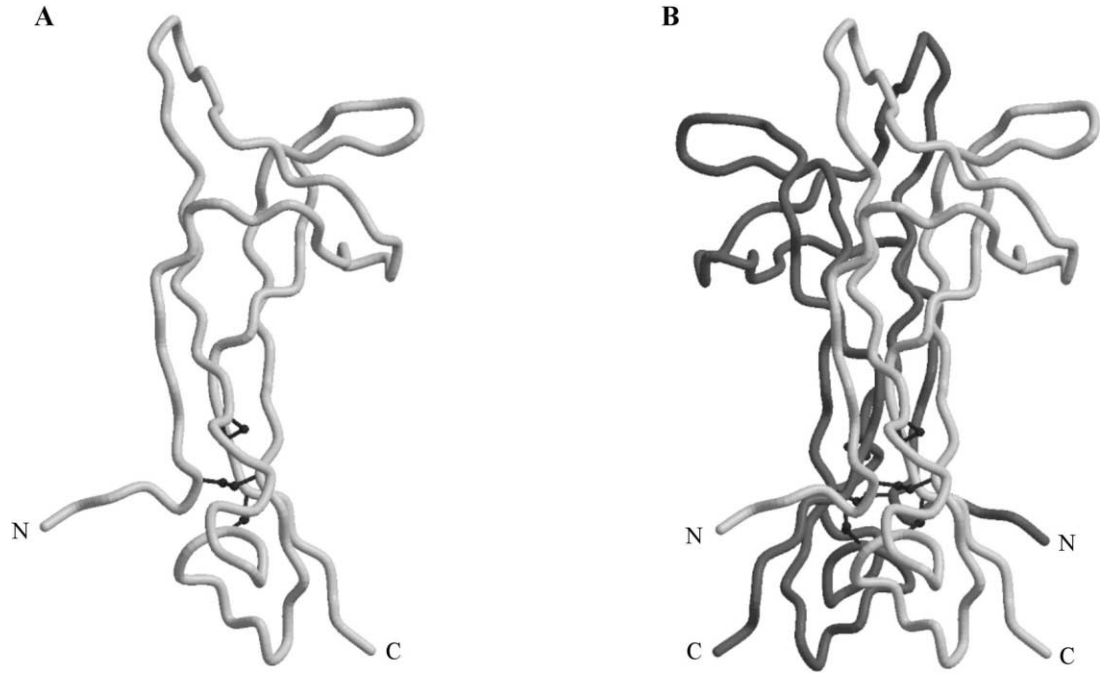

FIGURE 3 Three-dimensional representation of nerve growth factor. (A) The unique tertiary fold for the individual NGF subunit, consisting of the "cystine knot" (indicated by the dark ball-and-stick representation). (B) The NGF dimer with one subunit represented in a darker color for clarity.

by the γ-subunit, among other proteases, to the mature form, and this species was consistent with an intermediate arising from cleavage at a pair of arginine residues. However, the high concentrations required and the lack of specificity argued against γNGF as the pro-βNGF-processing enzyme *in vivo*, and recent studies have identified furin, which is involved in other similar processing events, to be the causative entity. There is also a C-terminal extension, usually of two residues, that is removed in the mouse submandibular protein, probably through the agency of the γ NGF, but this is not apparently the case with the NGF of other species. A possible role for pro-NGF as a preferred ligand for the p75 receptor (see later) has been recently postulated.

NGF is expressed in both glia and neurons in the peripheral and central nervous systems (PNS and CNS), both during development and in the adult, as well as in several nonneuronal tissues. In keeping with the initial identification, NGF is expressed by non-neural target cells of afferent sympathetic and nociceptive sensory neurons and provides support for them via retrograde transport, the basis of the "neurotrophic hypothesis" (see later). The expression of NGF is also up-regulated in some of these tissues in response to injury and inflammation. This is particularly true of Schwann cells, in which, in the adult, it is synthesized only at very low levels, but following injury it is substantially induced by cytokines. In the CNS, the NGF gene is expressed in neurons, the highest levels of mRNA being found in the hippocampus and the cerebral cortex. NGF is also synthesized in astrocytes and microglia and a variety of factors and conditions also affect these levels.

Generally, NGF appears to provide target-derived support for CNS neurons and NGF synthesis by both neurons and support cells is enhanced following injury or other deleterious conditions. However, it should be noted that there have been many identifications of NGF synthesis and expression that are not fully explained. This includes the immune system, in which many types of leukocytes express βNGF, including mast cells, monocytes, T and B lymphocytes, and macrophages. This suggests a major role for NGF in the neural-immune axis, but descriptions of this important physiological system lack detail.

V. RECEPTORS

βNGF interacts with two cell surface receptors: TrkA is a member of the receptor tyrosine kinase (RTK) family and elicits most of the known classical βNGF biological responses; the other receptor, p75NTR, is a pan neurotrophin receptor that binds all of the neurotrophins with similar affinity. The p75NTR induces a largely different set of responses but can also modulate the binding of βNGF to TrkA. TrkA was identified from a chimeric oncogene that contained a portion of tropomyosin fused to the endodomain of an RTK, thus giving rise to the name tropomyosin-related kinase (Trk). The identification of TrkA followed by several years the isolation and characterization of p75NTR and resolved several conflicting reports regarding the signaling entity responsible for the survival and differentiation activities of NGF.

TrkA is a typical single-pass transmembrane RTK. The extracellular part is glycosylated and contains five domains: (1) a cysteine-rich region, (2) three leucine-rich repeats, (3) a second cysteine-rich region, and (4 and 5) two immunoglobulin (Ig)-like domains. NGF binds to the most proximal Ig-domain (domain 5) and a structure of the NGF-domain 5 complex has been determined. Similar structures have also been determined for TrkB and TrkC, the specific receptors for BDNF and NT3. The importance/role of the other domains in TrkA function is less clear. The TrkA-binding site on βNGF has been deduced from several mutagenesis/chemical modification studies and confirmed by the three-dimensional structure. Basically, it is composed of three regions of NGF; the first two have been termed the "specificity patch" and the "conserved patch." The third is less well defined and involves residues in two of the hairpin loops at the end of the molecule opposite the cystine knot. The specificity patch is made up of residues in the N-terminus and the conserved patch is made from residues in the β-sheet core. The residues of TrkA that contact the specificity patch are in a quite hydrophobic pocket that is considerably more hydrophilic in TrkB and absent altogether in TrkC. This interaction is quite consistent with a number of derivatives with various N-terminal modifications that show decreased affinity for TrkA. The conserved patch is made up of several hydrophobic residues and is actually contributed by side chains from both βNGF protomers. There is great deal of similarity in this region in all the neurotrophins and this presumably reflects the commonality of this binding site in all the Trks. The last binding site occurs on the linker segments that connect domain 5 with the transmembrane segment. The βNGF residues involved are less well defined because this interaction has not been observed in the NGF–domain 5 complex.

The p75NTR is also a transmembrane glycoprotein with a single spanning segment. It has a relatively small endodomain containing a "death domain" motif. It also contains a less well-characterized segment of 29 residues, located near the membrane; this segment has been designated "chopper" and can induce cell death when incorporated into other proteins or when expressed in a membrane-bound form. The role of either of these domains in p75NTR activity is unclear. The ectodomain contains four cystine-rich sequences (each containing three disulfide bonds) that are similar to those found in the TNF receptor. As a result, a plausible model has been proposed (there are no crystallographic data). All four appear to be required for NGF binding, with the second being of most importance. The p75NTR binding site appears to be composed of two groups of residues—one contributed by loop 3 (near the cystine knot) and one by a group of basic residues in loops 1 and 4 at the opposite end of the molecule. The former seems to represent a common site found in the other neurotrophins as well. The latter is more specific to NGF.

There is substantial indirect evidence that p75NTR and TrkA can interact and it has been suggested that the high-affinity binding observed for NGF results from such a complex. However, physical evidence for the formation of a p75NTR-TrkA complex, with or without NGF, is lacking. Model building suggests that it would be possible for both receptors to bind NGF simultaneously, which would place the cystine knot end of NGF away from the membrane (given the orientation of NGF in complex with the TrkA domain 5). Association of p75NTR with this complex requires an orientation that is inconsistent with domain 2 of p75NTR providing a major binding site. For that to be achieved, the cystine knot must be located toward the membrane. Because both receptors can function in the absence of the other, it is possible that NGF binds to p75NTR in one orientation with the isolated receptor but in the opposite way in a ternary complex.

VI. CELL SIGNALING

Signaling of all receptors is to some degree cell specific. Most of the information available for NGF signaling is derived from studies with PC12 cells, a rat pheochromocytoma line. These cells differentiate into a phenotype quite similar to that of sympathetic neurons on exposure to NGF (among other agents). Although not strictly neuronal cells, they have been extremely valuable in defining the signaling properties of the NGF receptors. As with other RTKs, the ligand-activated form of TrkA is a dimer. It is stabilized by the phosphorylation of two tyrosine residues in the activation loop and has two additional principal sites for downstream signaling. Tyrosine 490 (Y490), in the endodomain juxtamembrane region, is a docking site for Shc and FRS2, which are scaffolds for assembling signaling complexes, leading to the activation of Ras/ERK1/2 and phosphatidylinositol 3-kinase (PI3K) among other moieties. The former is associated with the differentiative responses whereas the latter is related to survival. Tyrosine 785 (Y785) similarly binds phospholipase C-γ leading to its activation as well. There are additional entities that have also been implicated, such as Src and Abl, but the mechanisms leading to their activation are not well understood.

The p75NTR is activated by NGF to produce ceramide by the activation of sphingomyelinase. The death domain may be responsible for this activity. This receptor also binds and activates tumor necrosis factor receptor-associated factors (TRAFs), leading to the production of nuclear factor κ (NF-κB). Interestingly, TrkA also activates this cytoplasmic transcription factor, but in an Shc-dependent fashion. It has also been suggested that p75NTR may function in a ligand-independent manner to produce cell death based on the overexpression of the intracellular domain. At least some of these effects may be mediated through RhoA and actin cytoskeleton rearrangement.

VII. PHYSIOLOGY

βNGF has a multiplicity of roles in the development and maintenance of the nervous system. It also has less well-defined activities in other tissues. During development, it functions primarily with sympathetic and selected sensory neurons in the PNS and with striatal and cholinergic neurons in the CNS. The PNS activities were the basis for the initial identification by Levi-Montalcini and Hamburger and, indeed, it was the determination that NGF is specifically taken up and retrogradely transported to the perikarya of dependent peripheral neurons the led to the elucidation of the neurotrophic hypothesis. However, NGF, as well as other neurotrophic factors, certainly plays some role in maintaining these neurons before synapses are formed.

The availability of βNGF during development is important in determining the phenotypic rate and numbers of βNGF-responsive sensory neurons in the adult. A combination of βNGF antibody-blocking

experiments and gene knockout experiments in mice has identified two populations of neurons that are reduced by as much as 80% in the absence of βNGF (the dorsal root ganglion and trigeminal ganglion). The antibody-blocking experiments also suggest that a subset of sensory neurons is βNGF dependent during development, including the nociceptive neurons. A role for βNGF in sensory neuron regeneration is also indicated by its neurite proliferation activity and up-regulation. In adult animals, sensory neurons do not require βNGF for their continued survival. Sympathetic neurons show even a greater dependency on βNGF. In gene knockout mice (both TrkA −/− and βNGF −/− mice), more than 90% of the sympathetic neurons disappear in the cervical ganglion. These data are supported by βNGF-blocking antibody experiments in which the same phenotype is observed. Unlike the sensory neurons, βNGF is required for the continued survival of the sympathetic neurons in the cervical ganglion of adult animals. In the CNS, there are similar observations, particularly in the gene knockout animals for the basal forebrain cholinergic neurons. However, it is also clear that the dependency of neurons on trophic stimulation is complex and even transient. Many neurons depend on more than one factor, and these allegiances can change with time.

There is clearly less neuronal dependency on NGF in adult animals, in which activities are more focused on synaptic function, synaptic plasticity, and repair. As a rule, target-derived support becomes less important although it does not completely disappear. However, other activities of NGF may become more important in the adult animal. One of these is a critical role for endogenous βNGF in inflammation and pain suggested by the increased levels of βNGF in damaged or inflamed tissue. Cytokines, such as interleukin-1β (IL-1β), typically involved in tissue damage and inflammatory processes, increase βNGF levels both *in vitro* and *in vivo*. Administration of antibodies that block βNGF prevents the heat and the mechanical hyperalgesia that normally follow tissue inflammation, without affecting the inflammation. The basis for this action includes an up-regulation of peptide neurotransmitters expressed by neurons concerned with the detection of potentially painful stimuli (nociceptors). TrkA −/− animals do not have nociceptive neurons, supporting these observations.

VIII. PATHOLOGY

The neurotrophic hypothesis that envisioned neurons as dependent on target-derived sources of NGF (and other neurotrophic factors) suggested that any disruption in this flow would lead to neuronal death. Thus, a putative link to neural degenerative diseases was readily forged. However, as it became clear that this dependency was reduced, this hypothesis lost attractiveness, particularly in view of the fact that NGF levels were particularly reduced in patients with Alzheimer's disease. However, further studies have suggested that defects in retrograde transport may be more important. Thus, there maybe a connection with NGF and neurodegeneration that can be eventually exploited. NGF has also been documented to be associated with a variety of autoimmune diseases and inflammatory diseases. Increased levels of βNGF in circulating plasma are found in patients suffering from multiple sclerosis, systemic lupus, and arthritis. The nature of the NGF involvement is unknown.

Early attempts to utilize NGF and other neurotrophins therapeutically were not successful, mainly because of a variety of undesirable side effects. There may well be potential therapeutic targets for PNS and CNS disorders for NGF (or small-molecule antagonists or agonists), but these must first deal with the substantial range of activities of this hormone that underlies the negative responses.

IX. SUMMARY

Nerve growth factor has proved to be a scientific "Rosetta Stone" in that it has provided insights into many groundbreaking areas of endocrinology; over many years, initial insights have been ultimately found to have broad applicability to roles of other hormones and growth factors. It is appropriate, therefore, that the humoral substance first discovered gave rise to the term "growth factor" that is so widely used today.

Glossary

cystine knot proteins Superfamily of proteins, including four growth factor families, all of which contain the distinctive motif made up of a circle of two disulfides (and the intervening peptide chains) through which passes a third disulfide bond.

glial cells Nonneuronal support cells of the nervous system. Schwann cells are found in the peripheral nervous system and astrocytes and oligodendrocytes are found in the central nervous system.

neurotrophic factor Any one of several hormonal substances that provide tropic support for neurons by interacting with cell surface receptors and stimulating the metabolic and transcriptional responses required for

maintenance of viability, differentiation, and other activities.

paracrine substances Hormones and growth factors that act in a paracrine fashion are not transported systemically, but rather diffuse from the cell of origin to the target cell. If these are the same type of cell, the mechanism is said to be autocrine. Substances that are transported through the circulation are considered to be endocrine.

prepro structures (zymogens) Precursor forms of proteins that are exported from the cell by removal of the pre sequence (to initiate transfer into the endoplasmic reticulum) and then the pro peptide, to yield the active mature protein. Such structures are common for hormones and hydrolases, for example.

receptor tyrosine kinases A superfamily of plasma-membrane-bound glycoproteins that specifically bind hormones and growth factors, leading to activation of their intracellular tyrosine kinase domains and thus inducing any of several signaling cascades, usually by sequential activation of other kinases.

Neuroactive Steroids

ANDRE H. LAGRANGE* AND MARTIN J. KELLY†

**Vanderbilt Medical Center • †Oregon Health and Sciences University*

Many steroids are produced within the central nervous system, allowing for the possibility of local control of hormone synthesis. Other steroids are produced peripherally but affect neural tissues via the bloodstream. Both centrally and peripherally produced neurosteroids have nongenomic effects; they alter a variety of neuronal functions, including those involving ion channels and ionotropic and G-protein-coupled receptors.

I. INTRODUCTION

Steroid hormones are a broad class of lipophilic, polycyclic chemicals that control a wide variety of physiological functions. Despite the diversity of their actions, these hormones have long been thought to have a common mechanism of action. By regulating gene expression, steroid hormones control physiological processes ranging from immune function to metabolism to reproduction. However, there is mounting evidence that these compounds have important functions that are independent of any genomic effects. One of the earliest indications for a nongenomic mechanism of steroid action was the report

by Hans Seyle that progesterone and ring A reduced metabolites have very rapid, robust anesthetic actions. In particular, the steroid derivative 3α-hydroxy-5α-pregnane-11,20-dione (also known as alphaxalone) is a potent anesthetic that has been used in human surgery. The anesthetic effect is stereospecific in that the closely related isoform betaxalone (3β-hydroxy-5α-pregnane-1,20-dione) has essentially no anesthetic action.

The powerful actions of synthetic steroid derivatives led researchers to explore the possibility that there are endogenously produced steroids that might influence central nervous system (CNS) function. Various steroids and their derivatives have been detected in the brain; due to their lipophilic nature, brain steroid hormone levels are often higher than serum levels. In some rat models, brain levels have been estimated to be as high as 10–100 nM. Levels of some steroid hormones persist in the CNS even several weeks after peripheral production of hormone is halted by gonadectomy and adrenalectomy. Subsequent work has shown that these hormones are synthesized *de novo* within the CNS, and thus the name 'neurosteroids' was adopted. This article reviews some of the neurosteroid effects in different cellular and whole animal physiologic models.

II. STEROID SYNTHESIS

A. Overview of Steroid Synthesis

All steroid hormones are synthesized from cholesterol precursors (Fig. 1). Cytochrome P450scc is a hydroxylase that is responsible for side chain cleavage of cholesterol, which results in the formation of pregnenolone. From pregnenolone, there are two interdependent pathways, one leading to mineralocorticoid/glucocorticoids and another that produces sex steroids. Although progesterone is a sex steroid, it stands at an important crossroad within this pathway and may be converted to other sex steroids, to glucocorticoids, or to 3α,5α-reduced neurosteroids.

The glucocorticoid pathway starts with 3β-hydroxysteroid dehydrogenase/isomerase (3β-HSD), which converts pregnenolone to progesterone. Progesterone can be converted by P450c21 to 11-deoxycortisone, which is then transformed to corticosterone and aldosterone by P450c11. The sex steroid synthetic pathway starts with P450c17, which converts pregnenolone or progesterone to 17-OH complexes. These compounds are then further converted to sex steroids by the same enzyme. The first

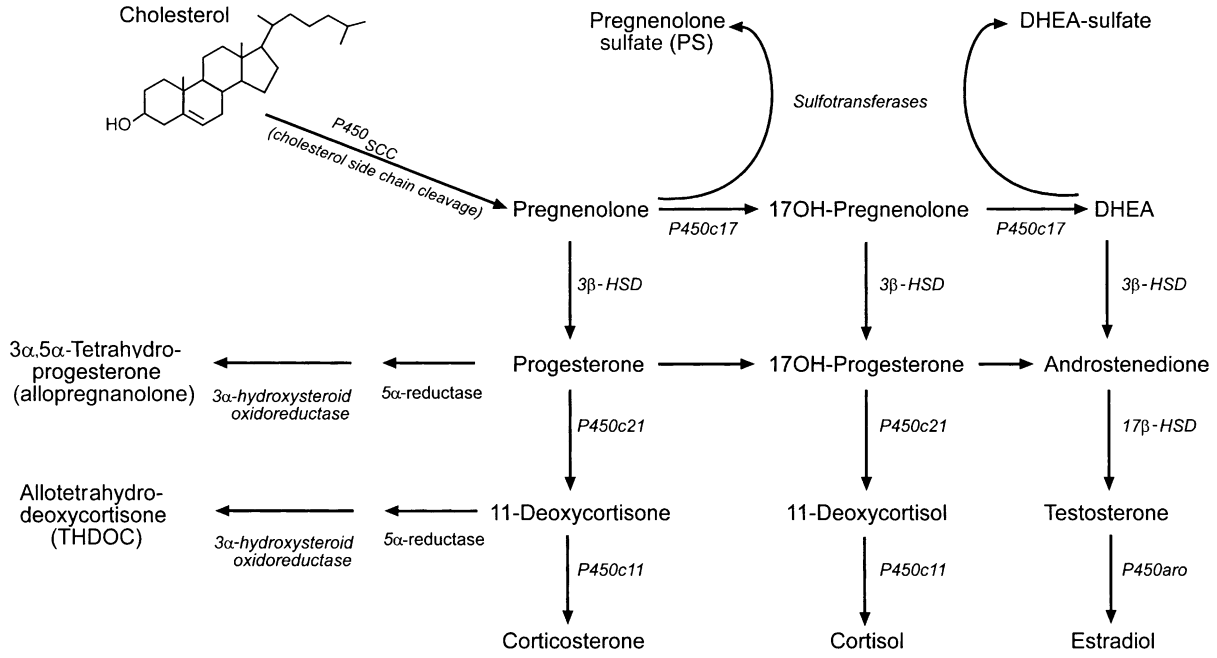

FIGURE 1 Steroid synthetic pathway from the precursor cholesterol. The major enzymes are shown along with the intermediate steroid compounds in the synthetic pathway to the neuroactive steroids [e.g., allopregnanolone, tetrahydrocorticosterone, pregnenolone sulfate, dehydroepiandrosterone sulfate, and 17β-estradiol]. DHEA, Dehydroepiandrostenedione; 3β-HSD, 3β-hydroxysteroid dehydrogenase; see text for discussion of the different P450 enzymes.

sex steroid (other than progesterone) is dehydroepiandrostenedione (DHEA), which may be converted by 17β-hydroxysteroid oxidoreductase to androstenedione and then by 3β-HSD to testosterone, and is subsequently aromatized (P450aro) to 17β-estradiol (E2).

B. Neurosteroids and Neuroactive Steroids

The gonads and adrenal glands produce steroid hormones (Fig. 2). They reach the brain, the spinal cord, and the peripheral nerves via the bloodstream. These hormones, which then have specific, nongenomic affects on neural tissue, are often referred to as "neuroactive steroids," to differentiate them from the neurosteroids, which are synthesized within the nervous system. For example, progesterone that is synthesized in the gonads or in glial cells can act as a neurosteroid or can be converted to other neurosteroids. Although the distinction between neuroactive steroid and neurosteroid may be heuristically useful, it is becoming clear that this is an artificial distinction. Steroids and steroid intermediates, including pregnenolone, progesterone, and DHEA, are made both in the CNS and in peripheral tissues. These lipophilic hormones easily cross the blood–brain barrier and so the physiologic importance of peripherally derived versus CNS-synthesized steroid hormones remains very ambiguous.

Cholesterol can be synthesized *de novo* within the CNS from low-molecular-weight precursors (e.g., mevalonate). The rate-limiting enzyme for steroid hormone synthesis in both the periphery and CNS is P450scc. This enzyme is found in the mitochondria of oligodendrocytes, some astrocytes, and possibly a small number of neurons. Isolated glia are able to produce pregnenolone, which may serve as an intermediate for further steroid synthesis. The next step is the conversion of pregnenolone to progesterone by 3β-HSD. This enzyme is found in both neurons and glia and is widely distributed within the brain, including the cortex, hippocampus, amygdala, and midbrain. As mentioned previously, pregnenolone and progesterone serve as important intermediaries from which glucocorticoids, sex steroids, and 3α,5α-reduced and sulfate derivatives may be formed.

Glucocorticoids can be synthesized from progesterone through the action of P450c21 and P450c11. Although P450c11 enzymatic activity has been demonstrated within the CNS, the same is not true for P450c21. Therefore, it is unclear whether

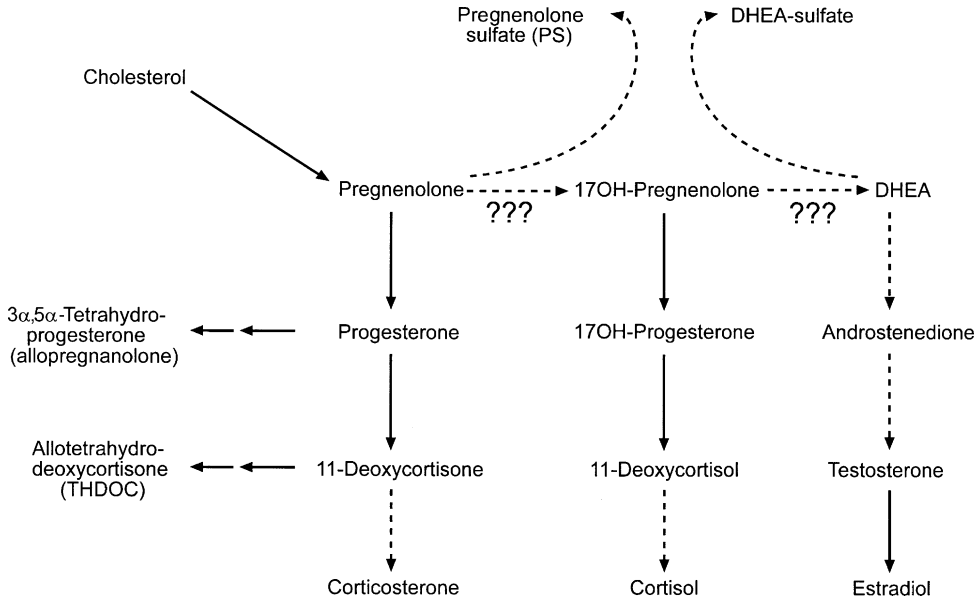

FIGURE 2 *De novo* synthesis of neurosteroids within the CNS. Steps that have been experimentally confirmed are represented by solid lines; steps for which the evidence is incomplete are shown as dashed lines. The enzymes mediating these steps are the same as those in the adrenals/gonads, with the exception of the conversion of progesterone to dehydroepiandrostenedione (DHEA). The P450c17 enzyme that mediates this conversion in the adrenal glands/gonads is not found in the adult CNS. Instead, if *de novo* synthesis of DHEA occurs within the CNS, it is probably mediated by an incompletely characterized Fe^{2+}-dependent enzyme.

there is *de novo* synthesis of glucocorticoids and the important reduced metabolite 3α,5α-tetrahydrodeoxycorticosterone (THDOC) in the CNS.

Within the sex steroid pathway, DHEA is both an early intermediary and a neurosteroid. Within the adult CNS, there is no P450c17 protein or mRNA. Thus, there should be no *de novo* synthesis of sex steroids through the usual pathway. However, DHEA is found to persist in the brain after gonadectomy/adrenalectomy or with inhibition of P450c17 by an antagonist. Recent work suggests there may be an alternative Fe^{2+}-dependent pathway in oligodendroglia and astrocytes for creating this steroid from progesterone. However, the physiological significance of this pathway remains uncertain, because high (10 mM), probably supraphysiologic, levels of Fe^{2+} are necessary to produce significant quantities of DHEA. DHEA may be converted to androstenedione by 3β-HSD, and then to testosterone by 17β-hydroxysteroid oxidoreductase. However, although the enzymatic machinery for conversion of DHEA to testosterone is present, the physiological importance of this step in the CNS is uncertain. Unlike DHEA, the level of testosterone drops rapidly to undetectable levels after adrenalectomy/gonadectomy. Therefore, testosterone in the CNS is probably derived from peripheral sources. However, aromatase (P450aro) is found within the brain and can convert peripherally derived testosterone to 17β-estradiol.

The addition of sulfate moieties causes some very interesting and potentially important changes in the biological activities of neurosteroids. Pregnenolone sulfate (PS) and DHEA-sulfate (DHEA-S) are the most well-studied examples at this time. *De novo* synthesis of sulfated neurosteroids from isolated CNS cells has not yet been specifically demonstrated, and these compounds are known to be taken up from the blood. However, the brain contains the necessary sulfotransferases and sulfohydrolases to interconvert these compounds, and the levels of PS and DHEA-S in the CNS remain constant after adrenalectomy/ovariectomy, despite undetectable serum levels. It is therefore unclear whether sulfated steroids are synthesized *de novo* within the CNS or are derived from peripheral sources, or both.

Finally, the 3α,5α-reduced steroids are among the best characterized neurosteroids. Both 5α-reductase and 3α-reductase (3α-hydroxysteroid reductase) are found in neurons and glia in the pituitary, hypothalamus, medulla, thalamus, and cerebellum. These hormones can convert progesterone to 3α,5α-tetrahydroprogesterone (allopregnanolone) and corticosterone to 3α,5α-tetrahydrodeoxycorticosterone. These two neurosteroids have broad, powerful regulatory effects in several systems.

In summary, there is clear evidence for the *de novo* synthesis of neurosteroids in the CNS. The synthesis of progesterone from low-molecular-weight precursors has been established. The conversion of progesterone to allopregnanolone is well established, but synthesis of sex steroids and glucocorticoids is not as well documented. Progesterone is possibly converted to DHEA within the CNS, but testosterone, which is converted to estrogen, appears to be derived from peripheral sources. It remains completely unclear whether glucocorticoids or sulfated steroid derivatives are centrally or peripherally derived.

III. REGULATION OF SYNTHESIS

The physiological regulation of neurosteroid synthesis remains largely unknown. Nonetheless, some early studies have shown that stress can change the levels of CNS steroid hormones. For example, significant elevations of pregnenolone and allopregnanolone have been observed in the frontal cortex following a swim stress in rats. Perhaps even more interesting is the fact that the stress of adrenalectomy/gonadectomy, although abolishing peripheral synthesis of steroid hormones, actually serves to increase brain tissue concentrations of allopregnanolone, PS, DHEA, and THDOC to physiologically active levels. Little else is known concerning the regulation of steroid synthesis in the nervous system. However, there is clear evidence that the levels of these hormones vary in response to diverse stimuli, and this remains a field wide open for further investigation.

IV. CELLULAR EFFECTS OF NEUROSTEROIDS/NEUROACTIVE STEROIDS

A. $GABA_A$

γ-Aminobutyric acid (GABA), an inhibitory neurotransmitter that is distributed widely throughout the brain, activates two broad classes of GABA receptors, ionotropic $GABA_A$ and G-protein-coupled $GABA_B$ receptors. The G-protein-coupled $GABA_B$ receptors modulate a variety of effectors, including activation of K^+ channels and inhibition of Ca^{2+} channels. $GABA_A$ receptors are composed of five subunits with an intrinsic chloride channel (Fig. 3). A vast majority of inhibitory postsynaptic currents in the brain are due to the activation of this conductance. Currently, there are six α, four β, three γ, one δ, one ε, one π,

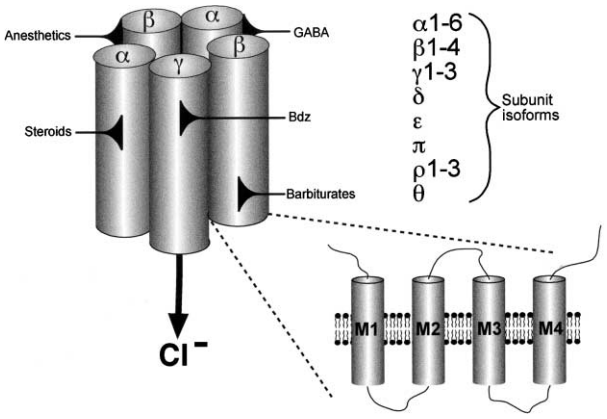

FIGURE 3 γ-Aminobutyric acid type A ($GABA_A$) receptor heteropentameric structure with multiple allosteric modulatory sites. The different subunit isoforms are shown. The inset in the lower right shows the four transmembrane domains of each individual subunit.

three ρ, and one θ known subunit isoforms. Although there are an enormous number of possible subunit arrangements to produce receptors, only a relatively discrete number of actual arrangements have been demonstrated in brain. *In vivo*, these subunits combine to form heteropentamers, likely composed of two α, two β, and either a γ, δ, ϵ, π, or θ subunit. In addition to a GABA binding site, these proteins contain several other distinct allosteric modulatory sites for agents such as benzodiazepines (sedative-hypnotics), barbiturates (sedative-hypnotic/anesthetic), etomidate (general anesthetic), zinc, and furosemide (diuretic). Although the roles of these modulatory sites in normal physiology remain unknown, they are important targets for clinical manipulation. Examples include the use of phenobarbital in the treatment of epilepsy and propofol as a general anesthetic. As previously mentioned, the anesthetic action of the steroid derivative alphaxalone was one of the earliest indications for a neurosteroid effect. A variety of experimental paradigms have shown that, like several other general anesthetics, alphaxalone is an allosteric modulator of $GABA_A$ currents. Alphaxalone increases both the potency and efficacy for the $GABA_A$ receptor agonist, muscimol. Although alphaxalone does not directly activate $GABA_A$ receptors, it increases both the frequency of opening and the mean open time of the $GABA_A$ channels that have been activated by GABA. This modulation is mediated by a novel independent allosteric modulatory site on the $GABA_A$ receptors. Benzodiazepine antagonists do not inhibit the actions of alphaxalone. Instead of competing at benzodiazepine or barbiturate binding sites, the addition of alphaxalone actually increases the binding of these agents.

Further studies have shown that physiologically relevant levels of the endogenously synthesized neurosteroids allopregnanolone and THDOC enhance $GABA_A$ channel activity. A similar effect is seen with the compound 3α-OH progesterone (3α-OHP), thus the 3α-OH group appears to be necessary for biologic action. In contrast, betaxalone, corticosterone, hydroxycortisone, pregnenolone, and the biologically inactive 3β-OHP isomer have no effect in this system. Although this effect is mediated by a unique allosteric modulatory site, the exact binding site on the $GABA_A$ receptor remains unknown. However, there is some information that the subunit composition of $GABA_A$ receptors may be important in mediating the neurosteroid response(s). Oocytes injected with the $\alpha_2\beta_1\gamma_2$ combination have a greater neurosteroid modulation than do those expressing $\alpha_1\beta_1\gamma_2$ subunits. Those oocytes with no α-subunits ($\beta_1\gamma_2$ only) are much less sensitive to neurosteroids. Furthermore, the δ-subunit appears to convey resistance to neurosteroids. This effect of subunit composition is particularly interesting in light of the fact that the $GABA_A$ receptor subunit combinations throughout the brain vary with development and over the reproductive cycle. Furthermore, modulation of $GABA_A$ receptors by allopregnanolone also varies over the reproductive cycle, being most potent at times of high levels of serum estrogens.

In animal studies, allopregnanolone and progesterone enhance the ability of muscimol to impair the righting reflex (the ability to turn over during a fall). Furthermore, inhibition of endogenous allopregnanolone synthesis with a 30-min exposure to a 5α-reductase inhibitor reduces the muscimol sensitivity. This effect was reversed with administration of 5α-dihydroprogesterone, an intermediate compound between 5α-reductase and 3α-reductase. Patch-clamp recording from cortical neurons taken from these animals confirmed that this inhibition of endogenous allopregnanolone synthesis resulted in a smaller muscimol response compared to control. Thus, there is both cellular and behavioral data that neurosteroid modulation of $GABA_A$ responses may be physiologically important.

Interestingly, the sulfated neurosteroids PS and DHEA-S have exactly the opposite effect on $GABA_A$ receptor function. These steroids serve as noncompetitive antagonists that reduce the opening frequency of these channels and increase desensitization to GABA in neurons from multiple preparations,

including primary chick spinal cord and rat hippocampal neurons, and in *Xenopus laevis* oocytes expressing $\alpha_1\beta_2\gamma_{2S}$ $GABA_A$ receptors. The switch from a positive to negative allosteric $GABA_A$ receptor modulator seems to depend on the negative charge, because the inhibitory activity is retained when hemisuccinate is substituted for sulfate at the C-3 position. The interaction between steroid negative and positive modulators is not competitive, indicating that steroid negative and positive modulators act through distinct sites.

B. Glycine Receptors

The glycine receptor is a ligand-gated chloride channel that is highly homologous to the $GABA_A$ receptors, so it is not a surprise that these receptors are modulated by neurosteroids as well. Although there is no effect of allopregnanolone or alphaxalone, the maximum response to glycine is enhanced by PS. The mechanism and physiological significance of this effect remains unexplored.

C. Glutamate Receptors

Glutamate is the most widespread excitatory neurotransmitter within the brain. There are three broad classes of glutamate receptor: *N*-methyl-D-aspartate (NMDA), non-NMDA, and metabotropic receptors. As the name implies, the metabotropic receptor is a G-protein-coupled glutamate receptor, which, among other things, modulates the turnover of intracellular inositol trisphosphate. There are several variations of the non-NMDA receptors, which are activated by various ligands, including kainic acid and 3-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA). All of these receptors have an intrinsic mixed sodium/potassium ion channel. Activation of this receptor/ion channel complex is the basis for many of the excitatory postsynaptic potentials within the brain. The NMDA receptors appear to be much more complicated. The receptors require multiple factors for activation. Opening of the intrinsic sodium/potassium/calcium channel requires binding of both NMDA/glutamate and glycine at two separate sites. There are additional sites for allosteric modulators, such as polyamine peptides. Even after binding of glutamate and glycine, the ion channel pore is blocked by Mg^{2+}. The pore can conduct current only if this magnesium blockade is removed by depolarization of the cell. If non-NMDA and NMDA receptors are simultaneously activated, the non-NMDA receptor-induced depolarization may be sufficient to remove the magnesium block of the NMDA receptors. Activation of NMDA receptors serves to depolarize the postsynaptic cells further. Moreover, some forms of this current are permeable to calcium, which may act as an intracellular messenger, resulting in long-term changes in postsynaptic cell function. The complex interactions among the glutamate receptors appear to play many important physiological functions, ranging from learning to excitotoxicity.

1. NMDA Receptors

Like the $GABA_A$ receptors, there are allosteric modulatory sites on the NMDA receptors. Pregnenolone sulfate acts at the neurosteroid modulatory site to increase the response to glutamate, but does not actually activate the receptor. In contrast, allopregnanolone sulfate (not allopregnanolone) is a negative modulator of NMDA currents. Finally, nanomolar concentrations of estrogen enhance NMDA-mediated excitatory postsynaptic potentials (EPSPs) in hippocampal CA1 pyramidal cells and high doses of this compound are associated with seizure activity in male rats. On the other hand, estrogens attenuate the neuronal damage seen after a variety of insults, including hypoglycemia, hypoxia, and glutamate agonists. It is currently unclear whether these various neurosteroids act by binding the same or different allosteric sites.

2. Non-NMDA Receptors

Estrogen increases the epileptogenicity of systemically administered kainate, more strongly in males than females. Based on *in vitro* intracellular recordings from CA1 pyramidal cells, administration of E2 increased synaptic excitability by enhancing the magnitude, but not the potency, of AMPA and kainate receptor-mediated responses. This effect is stereospecific, rapidly reversible, and does not appear to be due to a direct interaction between 17β-estradiol and the receptor channel. Rather, this effect appears to be mediated by activation of the cAMP/protein kinase A (PKA) pathway (Fig. 4). The actions of E2 are mimicked by PKA activators and blocked by PKA antagonists. The actual estrogen receptor remains unknown but possibly involves a novel binding site. Estrogenic modulation of non-NMDA receptors is seen robustly in a mouse line in which the α isoform of the classical estrogen receptor (ER-α) has been transgenically knocked out. Furthermore, this effect is not blocked by ICI 182,780, which is a potent antagonist at the ER-α and ER-β receptors. These effects may involve a G-protein-coupled receptor in that they are blocked

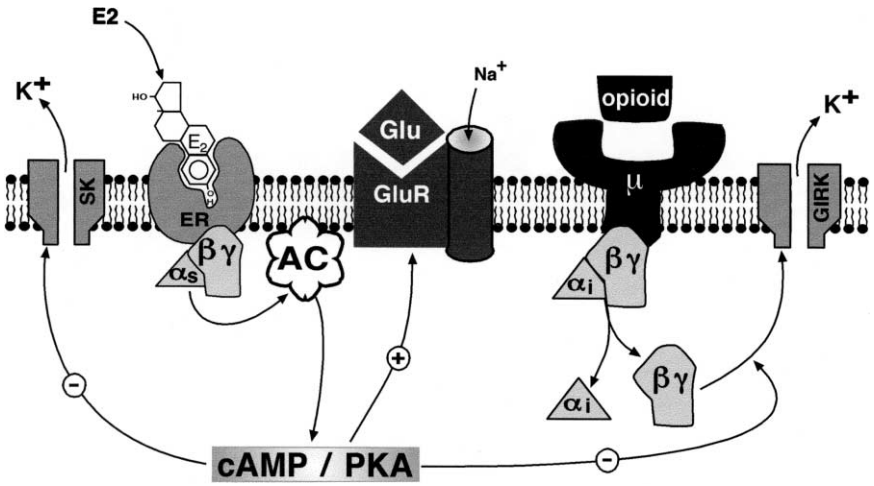

FIGURE 4 Schematic overview of the multiple rapid effects of 17β-estradiol (E2) in CNS neurons. In some cells (e.g., hypothalamic neurons), E2 binds to the estrogen receptor (ER), which stimulates adenylyl cyclase (AC) to produce cyclic adenosine monophosphate (cAMP), possibly via activation of $G_{\alpha s}$. Increased cellular levels of cAMP activate protein kinase A (PKA), which can uncouple μ-opioid (μ) receptors from their effector system (i.e., the inwardly rectifying K^+ channels, or GIRK) through phosphorylation of a protein [e.g., the $G_{\alpha i,o}$ (GIRK) channel]. In other cells (e.g., hippocampal CA1 pyramidal neurons), PKA can phosphorylate Ca^{2+}-dependent K^+ channels (SK), and inhibit their activity (outward K^+ current). Finally, PKA can phosphorylate a glutamate receptor/ionophore to increase its activity (inward cation current) in some neurons (e.g., hippocampal CA1 pyramidal neurons). Although this stylized figure shows the ER in the membrane, the actual subcellular localization of the receptor is not known.

by 5′-*O*-(2-thiodiphosphate) (GDPβS), which is a nonhydrolyzable GDP analogue that competitively inhibits G-protein activation by guanosine triphosphate (GTP), and they are mimicked by the toxin from *Cholerae vibrio* (cholera toxin), which is known to stimulate $G_{\alpha s}$.

D. Calcium Channels

Neurosteroids also modulate N- and L-type calcium channels. Pregnenolone, THDOC, and PS, but not progesterone, all depress the maximal current up to 60%, as well as slow activation and deactivation of these calcium channels in hippocampal CA1 neurons. This effect may be mediated by an extracellular receptor because intracellular dialysis with PS has no effect. Furthermore, neurosteroids may work through action of G-protein-coupled receptors because pretreatment with toxin from *Bordetella pertussis* (pertussis toxin), an inhibitor of $G_{\alpha i,o}$, or intracellular dialysis with GDPβS blocks the effects of PS. The neurosteroid binding site mediating these effects is pharmacologically distinct from the $GABA_A$ modulatory site. Unlike PS actions at $GABA_A$ receptors, both the neurosteroids and their sulfated derivative have similar effects. The replacement of the sulfated group with acetate abolishes the physiological activity of PS, and progesterone has no effect.

In an independent series of experiments, picomolar concentrations of estrogen were shown to inhibit rapidly (within seconds) L-type calcium channels in acutely dissociated striatal neurons. Unlike estrogenic modulation of glutamate receptors, E2 coupled to bovine serum albumin (E2–BSA) readily mimicked the effect of free E2, suggesting an extracellular binding site. As with the other neurosteroids, the effects of estradiol may involve activation of G-proteins. Those cells that were dialyzed with 5′-*O*-(3-thiotriphosphate) (GTP-γ), which is a G-protein-activating GTP analogue that is more resistant to hydrolysis than GTP, had an irreversible suppression of Ca^{2+} channels. Interestingly, a similar inhibition of L-type calcium current by estrogen, but not progesterone, has been demonstrated in vascular smooth muscle.

E. Potassium Channels

Estrogen exerts complex control of neuronal potassium channels. Intracellular recordings in hypothalamic neurons have shown that perfusion of 17β-estradiol hyperpolarizes a subset of hypothalamic neurons in an *in vitro* preparation within seconds and that this effect reversed within minutes of washing out estrogen. Similar actions of E2 were demonstrated in hypothalamic ventromedial nucleus

and amygdala neurons, even in the presence of protein synthesis inhibitors. The E2-mediated hyperpolarization of hypothalamic and amygdala neurons appears to be the result of the opening of an inwardly rectifying K^+ channel. In another set of hypothalamic neurons, the application of E2 causes a rapid depolarization that is due to the closure of a tonically active potassium conductance. It turns out that both the hyperpolarizing effects of E2 in one group of neurons and the depolarizing actions in another group are enhanced by coperfusion with a phosphodiesterase inhibitor. Interestingly, the hyperpolarizing effects of 17β-estradiol are mimicked by 8-bromoguanosine 3′,5′-cyclic monophosphate (8Br-cGMP), a cell-permeable analogue of cGMP, whereas this agent has no effect on that neuron subset that is depolarized by estrogen. Instead, application of 8-bromoadenosine 3′,5′-cyclic monophosphate (8Br-cAMP), a cell permeable analogue of cAMP, or stimulation of endogenous adenylyl cyclase with forskolin mimics the effects of estrogen to depolarize a subset of cells.

F. G-Protein-Coupled Receptors

The discussion thus far has been limited to neurosteroid modulation of ionotropic receptors and ion channels. The effects of many neurotransmitters are also mediated by intracellular G-proteins, which subsequently serve to regulate a variety of intracellular processes. Estrogen is probably the most well-studied neurosteroid modulator of these receptors.

1. μ-Opioid

Activation of μ-opioid receptors hyperpolarizes hypothalamic neurons by opening a G-protein-coupled, inwardly rectifying potassium channel (Fig. 4). Perfusion of E2 *in vitro* results in a fourfold decrease in the potency of μ-opioid agonists to inhibit β-endorphin, but not gonadotropin-releasing hormone (GnRH) neurons. This effect is not mimicked by the inactive isomer 17α-E2, and selective estrogen receptor antagonists block this effect of E2. Estrogenic modulation of hypothalamic μ-opioid potency is mimicked either by stimulation of adenylyl cyclase with forskolin or by direct PKA activation with selective activators. Furthermore, selective PKA antagonists block the effects of E2. The apparent involvement of the cAMP/PKA pathway is highly reminiscent of estrogenic modulation of non-NMDA receptors. Moreover, the potency of the estrogenic effects is similar in both systems (effective concentration $EC_{50} \approx 10$ nM) and is not mimicked by extracellular BSA–E2, implying that there may be a common receptor and/or intracellular mechanism mediating these estrogenic effects.

In hypothalamic neurons, $GABA_B$ and μ-opioid receptors are coupled to the same K^+ channels. Interestingly, E2 also produces a fourfold increase in the EC_{50} of a $GABA_B$ agonist in the same β-endorphin neurons in which it reduces μ-opioid potency, thus implying that E_2 is modulating signaling pathways shared by both receptors.

2. Catecholamines

Voltage-independent, Ca^{2+}-activated K^+ currents underlie the long-lasting afterhyperpolarizations (AHPs) in a number of CNS neurons, including hippocampal, hypothalamic neurosecretory, midbrain dopamine, vagal motor, and cortical pyramidal neurons. These AHPs limit the firing frequency of neurons and are responsible for spike frequency adaptation in regular-firing cortical neurons and phasically bursting neurosecretory neurons. The slow AHP current is mediated by small-conductance, Ca^{2+}-activated K^+ (SK) channels, and three SK channel genes have recently been cloned. In hippocampal CA1 pyramidal neurons, these currents are regulated by monoamine neurotransmitters, which suppress the slow AHP. The effects of norepinephrine, serotonin, and histamine on the slow AHP are mediated via β_1, type 4 5-hydroxytryptamine (5-HT_4), and type 2 histamine (H_2) receptors, respectively. Interestingly, one of the long-term effects of corticosteroid is to increase the slow AHP in CA1 neurons, presumably via a genomic mechanism because protein synthesis inhibitors block these actions of the adrenal steroid. Recently, however, it was found that E2 inhibits the slow AHP current and potentiates the β_1-adrenergic receptor-mediated ($G_{\alpha s}$ coupled) inhibition of slow AHP current in CA1 hippocampal neurons (Fig. 4). Because the slow AHP is involved in spike frequency adaptation, these effects of E2 may be critical in increasing the firing frequency of hippocampal pyramidal neurons that are involved in arousal, attention, and memory.

G. Summary

In summary, recent advances in our understanding of the mechanisms mediating neurosteroid action have helped support the idea that steroids may have a rapid, nongenomic effect to regulate neuronal function (Table 1). Although there are almost certainly multiple pathways, the current understanding allows us to differentiate these into two broad categories.

TABLE 1 Summary of the Effects of Neuroactive Steroids[a]

Effect on	Prog	AlloPreg	THDOC	E_2	PS	DHEAS

$GABA_B$-R	—	—	—	↓ Potency	—	—

[a]Abbreviations: R, receptor; Prog, progesterone; AlloPreg, allopregnanolone (3α, 5α-tetrahydroprogesterone); THDOC, 3α, 5α-tetrahydrodeoxycorticosterone; E2, 17β-estradiol; PS, pregnenolone sulfate; DHEA-S, dihydroepiandrostenedione sulfate; I_{max}, maximum response; potency, potency of agonist binding to receptor; ∅, no measured effect; ±, small or variable effect.

The oldest, most well-established mechanism of action is the modulation of $GABA_A$ and NMDA receptors by progesterone derivatives and sulfated neurosteroids. Although the actual binding site has not yet been identified, these steroids clearly alter neurotransmitter receptors by binding a specific allosteric modulatory site, resulting in well-defined changes in receptor kinetics.

Although the mechanism of estrogenic neuroactive steroid action is less clear, data from multiple systems may be converging on elucidating a single biochemical pathway. Biochemical studies in uterine tissue have shown that estrogen rapidly increases cAMP levels, thereby activating PKA. The ability of estrogen to rapidly uncouple G-protein-coupled receptors, inhibit non-NMDA glutamate receptors, and close potassium channels may all be mediated through cAMP/PKA. It is unknown whether this implies a common mechanism of estrogen action, or simply a single convergent point among multiple complicated pathways. The actual binding site for estrogen remains unknown as well. Several labs have shown a modulation of calcium channels. This may be mediated by a G-protein-coupled membrane estrogen receptor. Whether this is a completely different pathway or another example of the cAMP/PKA family remains undetermined at this point.

V. CLINICAL/PHYSIOLOGICAL RELEVANCE

A. Anesthetic

As previously mentioned, the first hint of neurosteroid existence was the discovery that progesterone and some of its derivatives have potent anesthetic actions. In fact, the drug althesin (mixture of alphaxalone and alphadolone acetate) has been used in human surgery.

B. Regulation of Reproduction

The quintessential role of estrogen in the mammalian CNS is its negative and positive feedback actions on the hypothalamic–pituitary axis to regulate the reproductive cycle. In all mammalian species, the rapid negative feedback actions of estrogen on the hypothalamic GnRH neurons is a critical event for the activation and synchronization of GnRH neurons at the time of ovulation. Synchronous release of GnRH into the portal system produces maximal stimulation of pituitary gonadotrophs to secrete a 'surge' of luteinizing hormone (LH) to cause ovulation. An insight into the mechanism by which estrogen rapidly inhibits GnRH neurons was provided in the 1970s when it was found that E2 could rapidly inhibit hypothalamic neuronal activity. Therefore, the rapid effects of E2 on GnRH neurons may play a role in estrogen's negative feedback on the hypothalamus. In addition, estrogen regulates the reproductive axis through an effect on endogenous opioids. β-Endorphin neurons, originating in the hypothalamic arcuate nucleus, synapse directly on GnRH neurosecretory cells, and these neurons are an integral component of estrogenic negative feedback on the hypothalamic–pituitary axis. The opioid antagonist naloxone blocks the E2 negative feedback and advances the LH surge in women. Activation of μ-opioid receptors mimics E2 negative feedback on GnRH/LH release and has been shown to hyperpolarize directly, and thereby inhibit, GnRH neurons via opening G-protein-activated, inwardly rectifying potassium channels. As previously mentioned, the potency of μ-opioids to hyperpolarize β-endorphin neurons is greatly attenuated by brief application of estrogen (Fig. 4). Because β-endorphin is an endogenous ligand at μ-opioid receptors, these may serve as autoreceptors. By inhibiting β-endorphin

autoinhibition, estrogen may cause increased β-endorphin release. Those cells that are impervious to this estrogenic effect (e.g., GnRH neurons) will remain sensitive to μ-opioids in the presence of increased concentrations of extracellular β-endorphin. Therefore, estrogen may serve to inhibit GnRH release through modulation of μ-opioid transynaptic regulation. The interaction between the direct inhibition and modulation of inhibitory input by estrogen has yet to be explored.

Neurosteroid modulation of reproduction may also be mediated by $GABA_A$ receptors. The activity of 3α-hydroxysteroid oxidoreductase is inversely correlated with E2 concentrations. Ovariectomy increases 3α-hydroxysteroid oxidoreductase activity, and this effect is abolished by subsequent administration of E2 (replacement therapy). Interestingly, allopregnanolone concentrations peak between proestrus and estrus in the rat, and the effects of allopregnanolone on the $GABA_A$ receptor vary over the reproductive cycle, being the most potent during the early follicular phase when the levels of serum estrogens are high. Furthermore, in ovariectomized rats, there is a nearly twofold reduction in the potency of allopregnanolone to modulate $GABA_A$ receptor.

C. Striatal Function/Movement Disorders

Clinically, the basal ganglia (also referred to as the corpus striatum) are important target areas for estrogen's actions outside of the hypothalamus. The basal ganglia are actually composed of several nuclei, including the caudate putamen and globus pallidus. This area is important in the regulation of both movement and motivation. Dopaminergic input from the substantia nigra modulates the function of the basal ganglion and its dysregulation is involved in several diseases, including Parkinson's disease and tardive dyskinesia (TD). TD, a disorder that is characterized by involuntary movements, develops after prolonged exposure to dopamine-antagonist antipsychotic drugs (e.g., haloperidol). This disorder has a 2:1 higher incidence in women versus men. There are some other hyperkinetic movement disorders that are associated with estrogen. Women who are pregnant or receiving estrogen supplementation occasionally develop multifocal rapid movements (chorea gravidarum) that resolve when the pregnancy is over or when the estrogen supplementation is discontinued. In contrast, Parkinson's disease is a hypokinetic movement disorder associated with deficient dopamine. There are reports that there is a worsening of symptoms in women during the premenstrual period, when estrogen levels are falling. There is some preliminary evidence that postmenopausal estrogen replacement therapy is associated with a reduced risk of Parkinson's disease in women and a lower disease severity in women with early Parkinson's disease who are not yet taking 1,3,4-dihydroxyphenylalanine (L-DOPA, precursor for dopamine).

Estrogen has multiple short-term effects in the corpus striatum. It potentiates rotational behavior induced by amphetamine in ovariectomized, 6-hydroxydopamine-lesioned (unilateral) rats. This pronounced behavioral effect is recapitulated at the cellular level. Acute administration of E2 also increases dopamine turnover and amphetamine-induced striatal dopamine release within 30 min as measured by *in vivo* microdialysis. A similar effect has been shown in the nucleus accumbens, a target site of ventral tegmental dopamine neurons. Local injection of E2 (but not 17α-estradiol) rapidly (<2 min) potentiates K^+-stimulated dopamine release as measured by *in vivo* voltammetry.

In addition to modulating dopamine release, E2 affects the postsynaptic response to this neurotransmitter by uncoupling type 2 dopamine (D_2) receptors within the same period. This is consistent with an earlier report that acute E2 treatment reduces the number of caudate neurons that are inhibited by dopamine. Continued exposure to E2 (2 weeks) down-regulates D_2 receptor mRNA and attenuates D_2 inhibition of adenylyl cyclase in striatal neurons. Interestingly, D_2 receptors, like μ-opioid and $GABA_B$ receptors, are $G_{\alpha i,o}$-coupled receptors. In contrast, long-term exposure to E2 potentiates type 1 dopamine receptor (D_1)-stimulated adenylyl cyclase activity. Dopamine D_1 receptors are coupled to $G_{\alpha s}$, suggesting that the nature of estrogen's effects depends on the intracellular biochemical processes being activated. In fact, some of estrogen's actions may be mediated by alterations in G-proteins. Estrogen enhances the pertussis toxin-catalyzed adenosine diphosphate (ADP)-ribosylation of $G_{\alpha i,o}$, which indicates that E2 modifies the G-protein, possibly through protein kinase A phosphorylation. This is analogous to the rapid effects of E2 in the hypothalamus and hippocampus; therefore, this mechanism of 'uncoupling' $G_{\alpha i,o}$-coupled monoamine receptors may be via a common pathway in the CNS and peripheral tissues.

Although the striatum is a prime target for estrogen modulation of motor activity, there is virtually no ER-α receptor mRNA expression and very little ER-β mRNA expression in this dopamine-rich

pathway, suggesting that E2 activates another receptor subtype in this region. Evidence for a membrane receptor for E2 is substantiated by studies showing that membrane-impermeable E2–BSA rapidly stimulates dopamine release from striatal slices. Other studies have shown that femtomolar concentrations of E2 and E2–BSA rapidly inhibit whole-cell L-type calcium currents in medium spiny (GABAergic) caudate putamen neurons.

D. Epilepsy

Given the preponderance of data on neurosteroid modulation of $GABA_A$ and glutamate receptors, it is perhaps no surprise that there is strong evidence that both endogenous and exogenous neurosteroids can affect seizures. Studies in epileptic women have correlated high serum E2 levels with an increased risk of seizures and increased frequency of interictal epileptiform (IED) activity on electroencephalograms (EEGs). Exogenous estrogen administration reduces the latency and increases the severity of kainate-induced seizures in both male and female rats. Inversely, progesterone administration increases the electroshock- or kainate-induced seizure threshold in female rats. In women, high progesterone levels are associated with reduced IEDs. In fact, approximately one-third of epileptic women have a greater than twofold increase in their seizure frequency prior to their menses, when progesterone levels normally drop precipitously (catemenial epilepsy). This is particularly important in epileptic women with inadequate luteal phase syndrome, in which the progesterone levels do not stay sufficiently elevated for the entire luteal phase of the menstrual cycle. This results in irregular menstrual periods, infertility, and a significant increase in seizure frequency before and during menstrual periods. In some studies, it has been shown that administration of progesterone analog reduces seizure frequency by 39% in women with catemenial epilepsy.

At the cellular level, progesterone has a high affinity for intracellular progesterone receptors but has weak actions at $GABA_A$ receptors. However, allopregnanolone is devoid of activity at intracellular progesterone receptors but is a highly effective modulator of $GABA_A$ receptor complexes. There is increasing evidence that the antiseizure effects of progesterone may be mediated by conversion to allopregnanolone. Intravenous or intracerebroventricular administration of allopregnanolone has been shown to suppress seizures in animal models ranging from *in vivo* perforant path stimulation to injection of picrotoxin or bicuculline. Although both progesterone and allopregnanolone inhibit seizures, the effects of progesterone are greatly inhibited if co-administered with 5α-reductase inhibitors. Allopregnanolone may be an endogenous modulator of seizure threshold as well. Although there is no difference in serum allopregnanolone levels in epileptic and nonepileptic women, there is a significant increase in serum allopregnanolone within 15 min of partial-onset seizures.

VI. CONCLUSIONS

The classic model of steroid hormone action is one in which (neuroactive) steroids are produced in the adrenals/gonads and travel through the bloodstream to the brain, where they alter protein synthesis by genomic actions at nuclear receptors. In contrast, neurosteroids, many of which are produced within the CNS, have nongenomic effects (alteration of a variety of neuronal functions, including those involving ion channels and ionotropic and G-protein-coupled receptors), allowing for the possibility of local control of hormone synthesis. Other steroids (e.g., testosterone) are taken up from the blood and may provide a mechanism for coordinating CNS and peripheral (outside the CNS) physiology. Additionally, there is a wide variety of steroid derivatives and they have an equally wide range of specific physiological actions. Given the broad range of neurosteroid action in various cellular physiological systems, it is not surprising that these compounds may be in involved in multiple arenas of CNS neurophysiology. There is good evidence at systemic and cellular levels for a role of neurosteroids in physiological/pathophysiological processes, ranging from reproduction to epilepsy. We have barely scratched the surface in understanding neurosteroid physiology and the prospect of expanding this field is exciting. In addition to increasing our understanding of normal physiology, steroid derivatives may offer important therapeutic options in the future. The broad range of action of neurosteroids may prove to be valuable ammunition in the arsenal of clinicians.

Glossary

dehydroepiandrostenedione Neurosteroid that is synthesized in the central nervous system.

γ-aminobutyric acid The most prominent inhibitory neurotransmitter in the central nervous system.

G-protein-coupled receptor Membrane receptor that activates intracellular G-proteins.

ionotropic receptor Membrane receptor with an intrinsic ion channel.

***N*-methyl D-aspartate** Selective ligand for one class of glutamate receptors.

P450aro Cytochrome P450 (aromatase); enzyme that converts testosterone to estrogen.

P450c11 Cytochrome P450 (11β-hydroxylase); enzyme that converts 11-deoxycorticosterone to corticosterone, 11-deoxycortisol to cortisol, and 18-hydroxycorticosterone to aldosterone.

P450c17 Cytochrome P450 (17α-hydroxylase/C-17,C-20 lyase); enzyme that converts pregnenolone to 17α-hydroxypregnenolone, then to dehydroepiandrosterone.

P450c21 Cytochrome P450 (21-hydroxylase); enzyme that converts progesterone to 11-deoxycorticosterone.

P450scc Cytochrome P450 (cholesterol side chain cleavage); enzyme that converts cholesterol to pregnenolone.

pregnenolone sulfate Neurosteroid that modulates glutamate channel activity.

17β-estradiol Female gonadal steroid that is a neuroactive steroid in the central nervous system.

testosterone Male gonadal steroid that is converted to 17β-estradiol in the central nervous system.

3α,5α-tetrahydrocorticosterone Neurosteroid that modulates $GABA_A$ channel activity.

3α,5α-tetrahydroprogesterone (allopregnanolone) Neurosteroid that modulates $GABA_A$ channel activity.

Neuropeptide Regulators of Juvenile Hormone Production

STEPHEN S. TOBE* AND BARBARA STAY†

*University of Toronto • †University of Iowa

The juvenile hormone of insects is a primary regulator of growth, metamorphosis, and reproduction in most insect species. As a consequence, it is essential that juvenile hormone production be precisely regulated so that it is present only during appropriate periods necessary for the control of these

processes. The presence of juvenile hormone at inappropriate times can result in disruption to metamorphosis and development and, in some cases, to disturbances in female reproduction. For this reason, complex mechanisms that regulate the production of juvenile hormone have evolved and, in many cases, neuropeptides are the primary regulators.

I. INTRODUCTION

In larval insects, the presence of juvenile hormone (JH) directs cells to continue development in a larval direction, whereas its presence in adult females directs specific cells to produce molecules associated with reproduction. In the absence of JH, metamorphosis of larval insects proceeds, either directly to the adult stage, in the hemimetabolous species (e.g., grasshoppers, bugs, cockroaches), or through an intervening pupal stage, in holometabolous species (e.g., beetles, moths and butterflies, flies, bees). The presence or absence of JH therefore determines the direction of development and reproduction in all insects at all stages of the life cycle. It is for this reason that the regulation of production of JH plays a central role in the life cycle of the insect. This article provides an overview of the neuropeptides that are known to regulate JH production in insects.

II. IS JUVENILE HORMONE PRODUCTION REGULATED?

Is there evidence that JH production in insects is in fact regulated? As a central regulator of both development and physiology of the insect, the importance of JH and precisely controlled changes in its production cannot be overestimated. Figure 1 demonstrates that in both larval and adult stages, the production of JH undergoes dramatic and predictable changes. In the larval stages, these changes are associated with the ecdysis or molt, whereas in the adult, these changes are associated with the reproductive cycle and the production of eggs. In both cases, distinct peaks occur, and these are invariably associated with important physiological events,

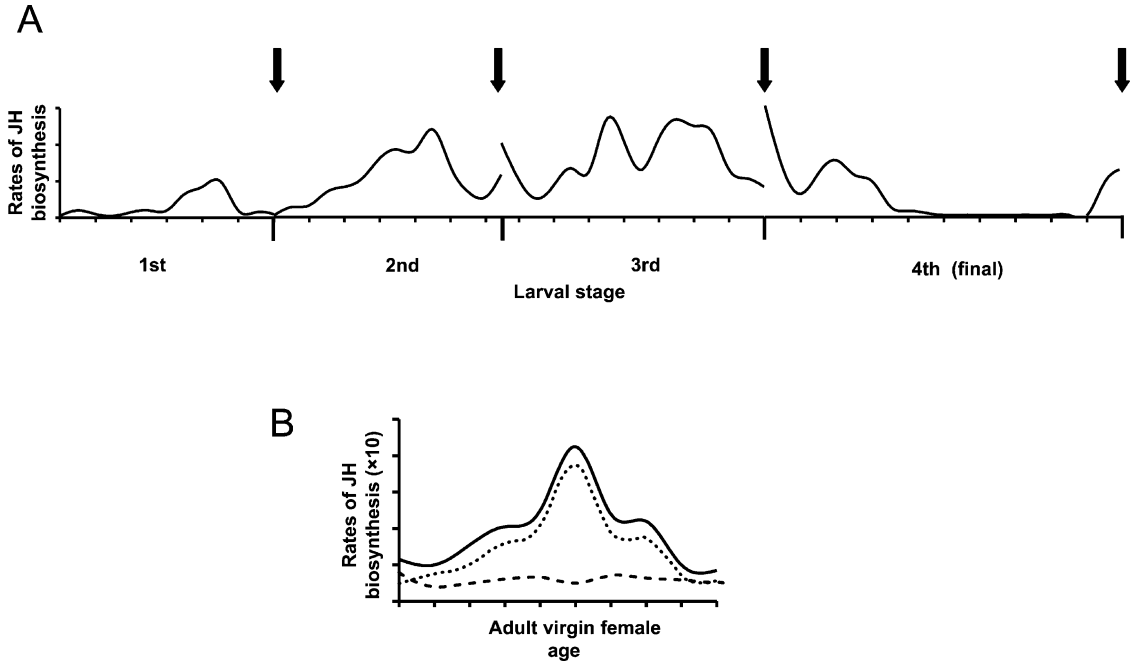

FIGURE 1 Juvenile hormone (JH) biosynthesis as a function of age throughout the larval stage (A) and in the adult virgin female (B) in the cockroach *Diploptera punctata*. Arrows denote the time of molting (A). (B) The results of unilateral cautery of the lateral neurosecretory cell region of the brain of virgin females that do not normally show a cycle of JH biosynthesis. The solid line represents JH biosynthesis by corpora allata on the unoperated side plus the corpora allata from the operated side; the line with long dashes represents JH biosynthesis by the single control unoperated corpus allatum; and the line with short dashes represents JH biosynthesis by the single operated corpus allatum.

including the time of deposition of the next cuticle in larvae and the synthesis of the yolk protein and its uptake by developing oocytes in adult females.

Profiles of JH production have been obtained for only a tiny number of existing insect species but all of these have revealed distinctive and predictable changes in production. In most cases, the periods of maximal production precede the larval molts or are associated with oocyte production in females. Rates of production of JH change dramatically over short periods of time, with changes of 10- to 20-fold being commonplace. In the very few studies that have examined the relationship between JH production and the circulating titer of hormone in the hemolymph, there is a high correlation. Accordingly, JH production mirrors the titer of the hormone.

Assuming that JH production is precisely regulated, how is this process in turn controlled? As with most other endocrine glands, the regulation of hormone production by the corpora allata is effected by neuropeptides and neurohormones. The principal neuropeptide regulators in insects are known as allatotropins (stimulators) and allatostatins (inhibitors) and a range of compounds that show such activity have been isolated. However, it should be noted that most assays for biological activity of these neuropeptides have employed short-term experiments *in vitro*, whereby the compounds in question are incubated with the corpora allata outside of the animal. In very few instances have the neuropeptides been shown to have high activity *in vivo*. Nonetheless, it is now widely believed that neuropeptides were some of the earliest neurotransmitters in the invertebrates and play a major role in the regulation of hormone production in all animals.

III. ALLATOTROPINS

Nomenclature for insect neuropeptides is confusing. Peptides have been named on the basis of the function for which they were originally discovered, which may not be the true function or may be only one of several physiological functions. At present, there are two naming systems, a three-letter prefix, employing the first two letters of the genus and the first letter of the species of the insect in which the peptide was originally discovered, followed by the functional name of the peptide; and a five-letter prefix using the first three letters of the genus and the first two letters of the species (e.g., for *Manduca sexta* allatotropin: Mas-allatotropin or Manse-latotropin).

Neuropeptides known as allatotropins are responsible for the stimulation of JH production. Such stimulation is important to the insect, to raise the titer of JH in the hemolymph at appropriate times during development or reproduction. The allatotropin appears to exert its stimulatory effect directly on the corpus allatum, the site of biosynthesis and release of the JH. To date, a single type of allatotropin, a 13-amino-acid peptide, has been isolated and identified from the hornworm, *M. sexta*. The amino acid sequence of the Manse-allatotropin is Gly-Phe-Lys-Asn-Val-Glu-Met-Met-Thr-Ala-Arg-Gly-Phe-NH_2.

This peptide has been demonstrated to stimulate JH production *in vitro* and structurally related peptides are known to occur in other members of the Lepidoptera, as well as in flies, mosquitoes, locusts, and cockroaches. However, these peptides do not show appreciable allatotropic activity (i.e., the ability to stimulate JH production) in these species, except for the Lepidopteran species. As with many peptides, the allatotropin peptide is not necessarily active at all times of the life cycle and the tissues of the insect show distinct periods of sensitivity. In fact, allatotropin was believed to be active only in adult hornworms, but more recent evidence indicates that it is active at specific times during larval life of some Lepidoptera. In addition, allatotropin exerts effects on tissues other than the corpora allata, including the stimulation of heart/dorsal vessel contraction and inhibition of ion transport across the larval midgut. Such actions are considered pleiotropic and emphasize the multifunctional nature of this peptide as well as of the allatostatins (see below).

Allatotropin is produced by cells in both the brain/central nervous system (CNS) of larvae and adults of *M. sexta* and is prominent in cells of the stomatogastric nervous system (e.g., ganglia and nerves along the foregut) and in the ganglia of the ventral nerve cord. In *Drosophila melanogaster* larvae, immunoreactivity to allatotropin is found in individual cells distributed in the lateral and tritocerebral regions of the brain and in the anterior portion of the ventral ganglion (Fig. 2).

The gene encoding the *Manduca* allatotropin has been cloned and characterized in this species as well as in other Lepidoptera and in *Drosophila*. It is expressed, as predicted from the above discussion, in several tissues, particularly the brain and ventral nerve cord, and at specific times during the life cycle (Fig. 2). The allatotropin peptide can be derived from each of three different precursor proteins and these proteins appear to arise as a result of alternative splicing of the allatotropin gene. The precursors also contain other allatotropin-like peptides that

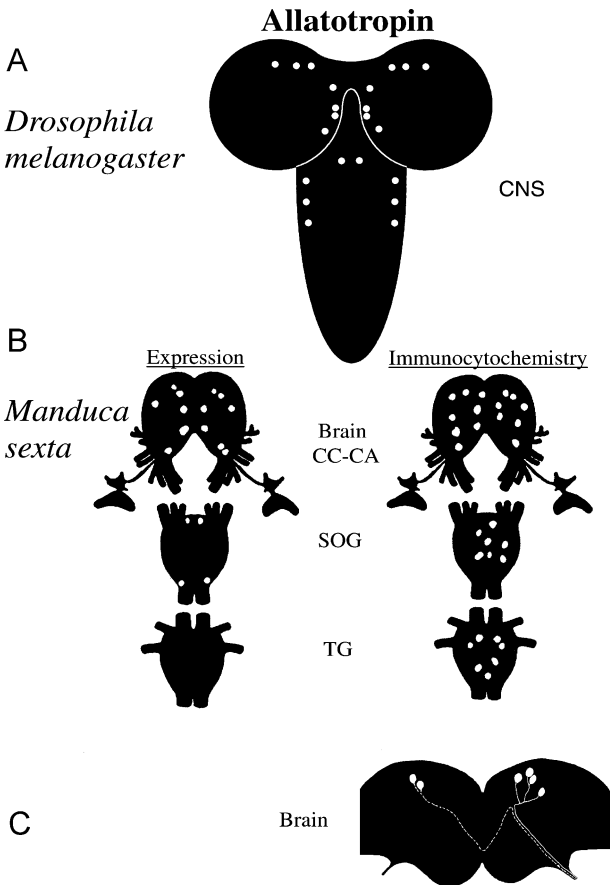

FIGURE 2 Distribution of allatotropin immunoreactivity and expression in larval *Drosophila melanogaster* CNS (A) and in larval (fifth stage) *Manduca sexta* (B). (C) The pathway of cerebral allatotropin-immunoreactive neurons in the larval (fifth stage) *Manduca* brain. (A) *Drosophila* data from P. M. Koladich (2002), Ph.D. thesis, University of Toronto; (B) *Manduca* data from T. R. Bhatt (1998), Ph.D. thesis, University of Nevada, Reno; (C) data from Zitnan *et al.* (1995), modified and redrawn, with permission. show biological activity. Allatotropin is expressed in the brain in larval stages (i.e., mRNA for allatotropin is present), indicating a potential role in the stimulation of JH production, in addition to the midgut function.

Alternative splicing is a common mechanism to increase the capacity and diversity of genes and their protein/peptide products and to regulate gene expression. In addition, the regulation of alternative splicing shows developmental and tissue specificity and may itself be hormonally controlled. It is significant that only a single allatotropin family has been identified to date, and the occurrence of alternative splicing may permit diversity in the function and developmental profile for the peptide.

IV. ALLATOSTATINS

A. Structure and Action

The two mechanisms that potentially regulate JH production involve either stimulation or inhibition of the biosynthetic process for the hormone within the corpora allata. The stimulation of biosynthesis would appear at first glance to represent the simplest means of regulating hormone production—in the presence of stimulatory factors, JH would be produced, presumably in a dose-dependent fashion, and in the absence of such factors, production would cease. An equally viable means of regulation is the inhibition of hormone production. In many species, this appears to be the primary mode of regulation of JH production; that is, corpora allata are normally inhibited or restrained in a dose-dependent fashion, and in the absence of the inhibitory signal, the glands are released and able to produce JH once again. However, in this instance, an increased dose of inhibitory factors would reduce JH production, and in most species studied to date, JH production cannot be completely inhibited by these factors, nor do corpora allata appear to be completely inhibited in the *in vivo* situation. It is likely that the corpora allata produce JH at a basal level, irrespective of the mode of regulation. That is, glands that operate by way of a stimulatory pathway do produce JH even when the allatotropin is not present, albeit at much lower levels than in the presence of the allatotropin (stimulation appears to be in the range of 4- to 10-fold). Conversely, glands that operate by way of an inhibitory pathway produce JH at low levels, even in the presence of the allatostatin. In both instances, such basal rates of JH biosynthesis are important, since they do indicate that the pathway for the production of JH is extant; the presence of the pathway permits a rapid response of the corpora allata to the neuropeptide signals. Glands that are completely inactive (and hence may lack the enzymes of the biosynthetic pathway for JH) may require a longer interval to respond to neuropeptide signals if biosynthesis of the enzymes is required.

The allatostatins or equivalent inhibitory factors have been hypothesized to exist for more than 50 years. Inhibition of the corpora allata and hence of JH production was inferred by studies on the effect of transection of nerves on the volume of the corpora

allata, on production of eggs, or on the nature of the molt in larvae. Similar effects were subsequently obtained following cautery of selected regions of the brain, particularly following destruction of the lateral neurosecretory cells (see Fig. 3). Such operations resulted in the stimulation of JH production (see Fig. 1B) and a stimulation of the physiological processes regulated by JH. Such experiments led workers, including Berta Scharrer, to the conclusion that the corpora allata in cockroaches were normally inhibited by factors from specific neurosecretory cells in the brain.

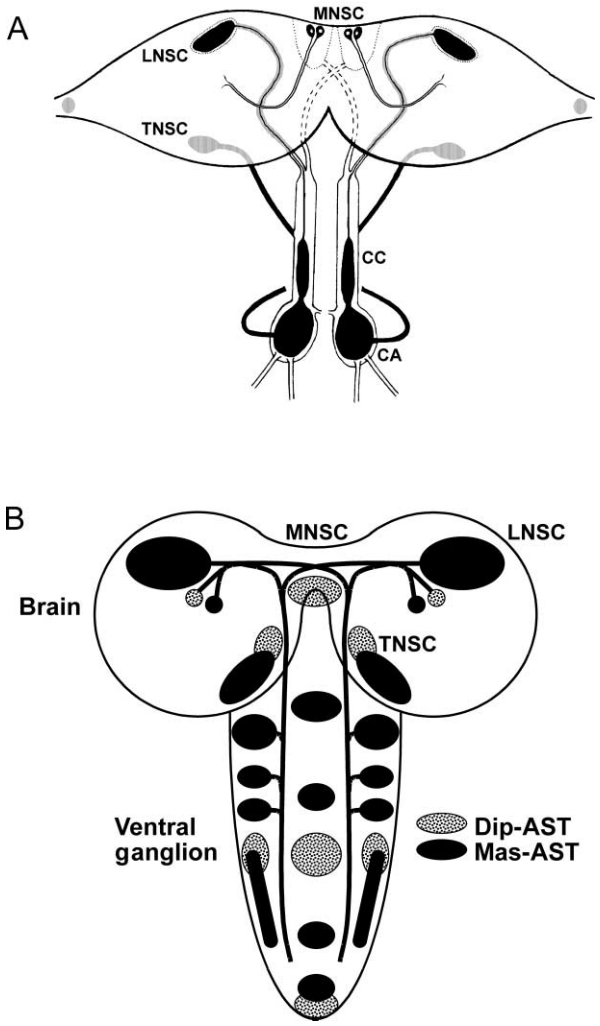

FIGURE 3 Distribution of allatostatin immunoreactivity and expression in the brain and retrocerebral complex of adult female *Diploptera* (A) and CNS of larval *Drosophila* (B), dorsal view. In *Drosophila*, immunoreactivity to both cockroach and *Manduca* allatostatin is shown. In A, lightly shaded regions represent cell groups visible from the ventral perspective. Tobe (1999), Allostatins, *In* "Encyclopedia of Reproduction" (E. Knobil and J.D. Neill, eds). With permission from Elsevier.

The allatostatin neuropeptides can be categorized into three families, based on similarities in their amino acid sequences. The largest, most diverse, and most ubiquitous family is the cockroach allatostatins, or the Phe-Gly-Leu-amide family (FGLa) (see Fig. 4). All of these peptides share this common carboxyl-terminus. The five C-terminal amino acids can be generalized as the consensus sequence Tyr/Phe-Xaa-Phe-Gly-Leu-amide, although some minor substitutions do occur in some species (Fig. 4). To date, over 170 FGLa peptides have been either isolated or predicted on the basis of gene sequences and, although commonly called the cockroach allatostatins, actually occur throughout the insects as well as the crustaceans. Similar sequences or immunoreactivity to FGLa-like compounds has also been found in helminth worms, in mollusks, and in platyhelminths.

Figure 4 shows the 14 allatostatin peptides predicted from the coding region of the allatostatin gene of the American cockroach, *Periplaneta americana*, and the precursor polypeptide structure. Studies on other cockroach species have revealed that this family of peptides is remarkably conserved across the order Dictyoptera, suggesting important and ancient functions for the allatostatins. However, this function may not necessarily be the inhibition of JH production, since these peptides appear to be active only in this respect in cockroaches and closely related species such as crickets. In all other insect orders studies, the FGLa peptides are inactive in terms of JH biosynthesis *in vitro* but are potent myomodulators.

Cockroach allatostatins occur in all other orders that have been studied but at present, the identity of these compounds has been established definitively only in crickets and in selected members of the Lepidoptera and Diptera. It is clear that flies, including *Drosophila*, have different compounds capable of inhibiting JH production, but to date, these have not been sequenced. It will be particularly important to isolate and identify the *D. melanogaster* allatostatins in view of the genetic significance of this species and the availability of the genome sequence.

A second group of allatostatins has been isolated and identified from crickets. These peptides are characterized by tryptophan (W) residues at the N-terminal 2 and 9 positions. The generalized structure of these peptides is shown in Table 1 and this group is

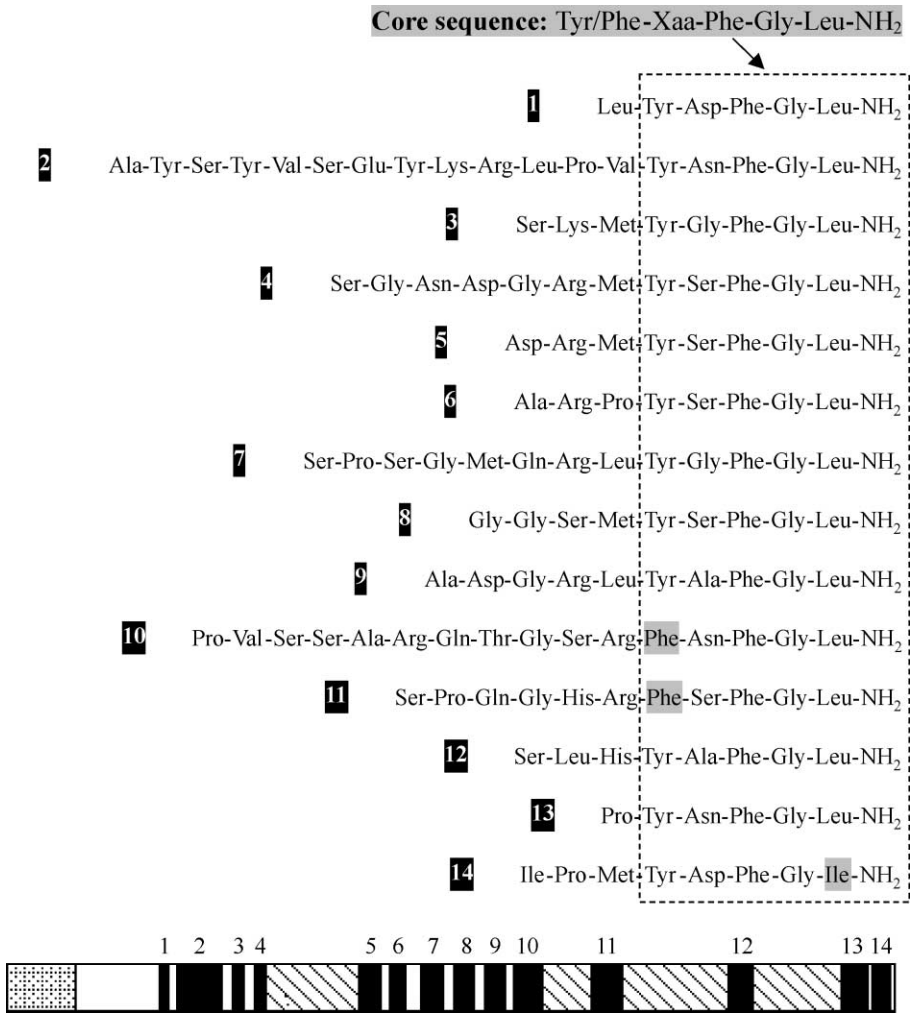

FIGURE 4 Schematic representation (bottom) of the amino acid sequence of the allatostatin precursor polypeptide in the cockroach *Periplaneta americana*. The hydrophobic leader sequence (signal sequence) precedes an untranslated region (clear), which is then followed by the allatostatin peptides. Black boxes represent individual allatostatins, which are numbered according to their position relative to the amino-terminus, and the amino acid sequences of each, corresponding to the numbers, are shown at the top. Acidic regions are indicated as diagonally striped areas. Shaded residues in the peptide sequences represent conservative substitutions.

commonly referred to as the W_2W_9 amide or W_2W_9a family of allatostatins. To date, these peptides are known to occur in crickets and in stick insects, but they are able to inhibit JH production only in crickets and at concentrations that are an order of magnitude greater than those of the FGLa family. The occurrence of these peptides in stick insects has necessitated a change in name of this family because the peptides are of variable length; hence, the designation $W(X)_6Wa$ is more appropriate. The structure of the gene encoding this family of peptides has recently been described in *Drosophila* although the peptides have yet to be isolated in this species.

A third group of peptides capable of inhibiting JH production in Lepidoptera is known as the PISCF family of allatostatins (see Table 1). Currently, only two members have been identified (isolated and sequenced). The *Manduca* peptide is a 15-amino-acid nonamidated, N-terminally blocked peptide originally isolated from *M. sexta* but subsequently found in other Lepidopteran species (Table 1). This peptide is unique, both from the structural perspective, in that it does not occur in any order other than Lepidoptera, and from the functional perspective, since the peptide is capable of inhibiting JH production completely (i.e., 100% inhibition), at least in

Manduca. No other peptide is capable of reversibly inhibiting JH production to this degree. Furthermore, this peptide has no effect on JH production in non-Lepidopteran species and also appears to affect JH production in larvae and adults of selected Lepidoptera differentially.

A peptide very similar to the Manse-allatostatin (Manse-AST) has been identified in the genome of *D. melanogaster*, with a precursor organization similar to that of the *Manduca* precursor. This peptide is identical to Manse-AST, with the exception of a Tyr substituted for a Phe at N-position 4 of the peptide. This peptide does not inhibit JH production in flies but is a very effective modulator of heart muscle contraction, rapidly and reversibly suppressing contractions at specific developmental stages. For this reason, the peptide and associated gene have been named "*flatline*."

B. Distribution of Allatostatins

Studies on the distribution of the allatostatins provide information not only on sites of release but also on potential target organs. Such information can provide insights into the functions of these peptides, which is particularly important for the allatostatins in light of their very large number, their extensive distribution, and the many different functions that they appear to perform (pleiotropism). Most of the information has been obtained from studies on the FGLa and the PISCF families and principally using immunocytochemistry and to a lesser extent *in situ* hybridization. In view of the role of the allatostatins in the inhibition of JH production, cells innervating the corpora allata can be expected to have immunoreactivity to these peptides. Figures 3 and 5 show diagrammatic representations and micrographs of the innervation of the corpora allata by cells in the brain. Innervation arises principally from the lateral neurosecretory cells although medial neurosecretory cells also appear to be important. The neurons arborize extensively within the corpora allata and there are apparent release sites within the glands. In the case of the *Drosophila* larval CNS, both FGLa immunoreactivity and PISCF immunoreactivity are apparent (Fig. 3B). In *Drosophila* as well, the transection of the nerves innervating the corpora allata, as in the cautery experiments with *Diploptera* noted in Fig. 1B, prevent the release of the peptides in the target tissue, thus releasing the corpora allata from the inhibition of the allatostatins. Not all allatostatins are released from the brain by way of axonal tracts to targets outside the brain. Within the brain, axons from the lateral, medial, and tritocerebral groups all arborize extensively and appear to innervate other neurons and thus can be regarded as interneurons.

Figure 5 also demonstrates extensive innervation of the hindgut of the termite by allatostatin-immunoreactive neurons and reveals the very wide distribution of allatostatin immunoreactivity in most insects. A similar distribution can be found in the midgut, foregut, and hindgut of many species, as well as in the reproductive system, in the optic lobes and antennal lobes, and throughout the CNS. Allatostatins are also found in high concentrations in the hemolymph (blood) serum and some hemocytes of cockroaches. Although it is not possible to define the serum source of the peptides, the extensive release sites observed in and on many tissues including the gut and CNS suggest that these tissues are important contributors.

C. Receptors for Allatostatins

The clear action of the FGLa allatostatins as inhibitors of JH production in cockroaches and in crickets demands the presence of appropriate receptors in the target tissues, including the corpora allata. Since there are multiple allatostatins in these organisms, multiple receptors for the peptides may also exist. In addition, the corpora allata show major differences in sensitivity to the allatostatins at selected developmental times, suggesting that receptor occurrence or expression is regulated. In general, in adult females, the glands show a low level of sensitivity at times of high production of JH, whereas in larvae, although a similar relationship exists early in the stadium, at times of minimal JH production, the corpora allata also appear to be insensitive at later times in the stadium.

The other biological actions of the FGLa allatostatins, particularly the ability to modulate myotropic

activity of the midgut and hindgut, also suggest the occurrence of multiple receptors or subtypes for these peptides. These actions are quite distinct from the inhibitory action on the corpora allata and may involve different signaling pathways (see Table 2). To date, two receptor subtypes have been cloned from *Drosophila* and at least one has been cloned from cockroaches. These receptors have been confirmed to be members of the G-protein-coupled superfamily and are structurally related to vertebrate galanin and somatostatin receptors, neither peptide of which is known to occur in insects. These receptors all exhibit seven membrane-spanning domains characteristic of the G-protein-coupled superfamily. The most conserved regions are the transmembrane domains facing the intracellular side of the membrane known to interact with G-proteins, which appear to be effectors both in the vertebrate system and in the insect system. The greatest difference in the receptors is on the extracellular side of the membrane in the ligand-binding region. This suggests that during evolution, the G-protein-binding domains were conserved, whereas the ligand-binding regions have undergone "rapid" change in response to the variety of ligands available.

As noted earlier, the different allatostatins of the FGLa family show different biological activities, with respect to both their ability to inhibit JH

TABLE 2 Rank Order of Effectiveness of Dippu FGLamide Allatostatins

Peptide designation	Length (amino acid residues)	Muscle contraction	JH Production
Dippu-AST1	6	7	13
Dippu-AST2	18	9	1

Dippu-AST10	16	6	4
Dippu-AST11	11	4	7
Dippu-AST12	6	12	9
Dippu-AST13	8	2	12

production and their ability to modulate myotropic activity (Table 2). With the elucidation of at least two receptors in insect systems, it is likely that these differences in biological activities are attributable to differences in the affinity of the receptors for the different allatostatins. The relative distribution of different receptor subtypes probably permits differences in the responses of target tissues.

The core region responsible for biological activity of the allatostatins is the C-terminal pentapeptide (Fig. 4). This sequence, which is conserved throughout the FGLa family of peptides, interacts with the extracellular surface-binding domain of the receptor(s) and shows full biological activity, albeit at high concentrations. This peptide appears to represent the minimal number of amino acid residues necessary for full potency. This suggestion has now been confirmed using expressed receptor in the frog oocyte expression system.

D. Evolution of Allatostatins

The original function of the FGLa allatostatins is clearly unknown, but in view of the ubiquitous nature of the peptides in insects and other invertebrates, it is likely that they performed a myomodulatory function, as they do in modern species. Nonetheless, the remarkable sequence conservation in the cockroaches does suggest that these peptides are ancient and that their co-opting for the purposes of regulation of JH biosynthesis probably occurred before speciation. Thus, the various cockroach allatostatins can be regarded as orthologues.

The large number of extant peptides of the FGLa allatostatin family (at present, over 170 peptides have been isolated or predicted from gene sequences) might also indicate that specific allatostatins have specific functions, at least in cockroaches and related species. It is possible that at least some of the different allatostatins are not replaceable, effecting only narrowly defined functions. There is some suggestion of this in the different rank order of the allatostatins in terms of the ability to inhibit JH biosynthesis versus modulation of myotropic activity in cockroaches, whereby allatostatins that are the most active in terms of one function often show only very low biological activity in the other function (see Table 2). On the other hand, the great profusion of allatostatins suggests that the allatostatins may be replaceable for a particular function, reflecting some flexibility in the receptor-binding domain. The only region in which amino acid differences are not possible for retention of function is in the core region.

It is likely that the additional functions of allatostatins remain to be defined. At present, it is known that the FGLa family of peptides is able to:

(1) inhibit JH biosynthesis in cockroaches and crickets;
(2) modulate muscle contraction, both spontaneous and proctolin-induced;
(3) modulate neuronal activity in crab CNS;
(4) inhibit vitellogenin production in cockroaches; and
(5) modulate digestive enzyme activity in cockroaches.

The same allatostatin can exert several target-specific effects. The redundancy in the FGLa allatostatin function could allow for the proliferation of

the peptides throughout evolution. Immunocytochemistry has putatively identified a very large number of different FGLa peptides in the invertebrates. In insects, in any given species in orders more recently evolved than cockroaches, there is a reduction in the number of members of the allatostatin family (based on gene sequences). For example, this number is reduced from 13 or14 in cockroaches to between 5 and 9 in flies and moths. It is significant, however, that there has been a concurrent loss in functionality of the FGLa peptides since they have no effect on JH production in these orders. At this point, it is impossible to determine whether the loss of inhibitory function (and hence a loss of receptor) preceded the reduction in number of the peptides. It is instructive to observe that in the locust, there has been a reduction in the FGLa family to 10 members and a loss in sensitivity to inhibition of JH production. Accordingly, a loss in biological activity may accompany the loss in the peptides expressed in a given species. In crickets, a family in which allatostatins are effective in the inhibition of JH production, there remain 14 putative peptides in the precursor deduced from cDNA sequences.

The neuropeptide regulators of corpus allatum function are important not only with respect to their modulation of JH production but also in their many other functions and in the insight they may provide into the evolution of neuropeptide families.

Glossary

corpora allata Insect endocrine glands associated with and receiving innervation from the central nervous system; the site of production of juvenile hormone.

juvenile hormone Sesquiterpenoid compound, derived from farnesyl biphosphate, that regulates metamorphosis and reproduction in many insect species.

orthologue Peptides from a pair of genes in related species, derived from a single gene in the last common ancestor, which arose as a result of a speciation event; genes of different species that have a common origin. Orthologue assignments do not involve function.

paralogue When a peptide gene is duplicated giving rise to two copies in the genome, the two genes and their products are considered paralogous; involves a duplication and not a speciation event.

pleiotropism The phenomenon whereby one peptide or peptide family exerts multiple physiological effects on target tissues.

preprohormone The entire polypeptide encoded by an mRNA for a peptide hormone or hormones before processing by prohormone convertase enzymes to remove signal sequences and other nonfunctional regions.

prohormone The polypeptide encoded by an mRNA for a peptide hormone following removal of the signal sequence. Cleavage of the prohormone to individual peptides by prohormone convertases results in the release of the final peptide sequences with biological activity.

Neuropeptides and Control of the Anterior Pituitary

MEGHAN M. TAYLOR AND WILLIS K. SAMSON
Saint Louis University School of Medicine

Neuropeptides are short chains of amino acids that are produced in neurons throughout the body; when released, they bind to specific receptors on target cells, thereby communicating neural information to other neurons or to nonneural tissues (e.g., hormone-secreting cells of the anterior pituitary gland, vascular smooth muscle, and secretory glands). Neuropeptides access the anterior pituitary via a portal vessel system and set into action complex pathways of neuroendocrine control.

I. INTRODUCTION

Peptides are produced in neurons that have axons terminating at the base of the hypothalamus, in a specialized region named the median eminence; these neuropeptides gain access by diffusion to the unique vascular system that links the brain to the anterior pituitary gland. In this manner, neural signals are communicated to the hormone-secreting cells of the gland and, by controlling the release of those hormones, to the entire body. Each type of anterior pituitary hormone-secreting cell is regulated by a balance of stimulatory and inhibitory neuropeptides released from axon terminals in the median eminence, against a background of information (long loop feedback) received from factors secreted into the general circulation by the cells that are the targets of those anterior lobe hormones. Against that background of information from the periphery, it is the relative balance of releasing and release-inhibiting peptides reaching the gland, and the pattern of the exposure to those factors, that determine hormone production and secretion from the anterior pituitary. That balance defines the field of neuroendocrinology.

II. HYPOTHALAMIC COMMUNICATION WITH THE ANTERIOR PITUITARY: LONG AND SHORT PORTAL VESSELS

The adult human pituitary gland weighs, under normal conditions, approximately 0.5 g, except in pregnancy, when the gland may double in size. Located in a protected cradle within the sphenoid bone, the pituitary measures approximately 1.0–1.5 cm in length and width and 0.5 cm in depth (Fig. 1). It is composed of the posterior lobe, which is neural in origin, and the anterior lobe, which is nonneural in origin. The anterior lobe, which contains the hormone-producing and -secreting cells of the gland, arises from the roof of the oral cavity

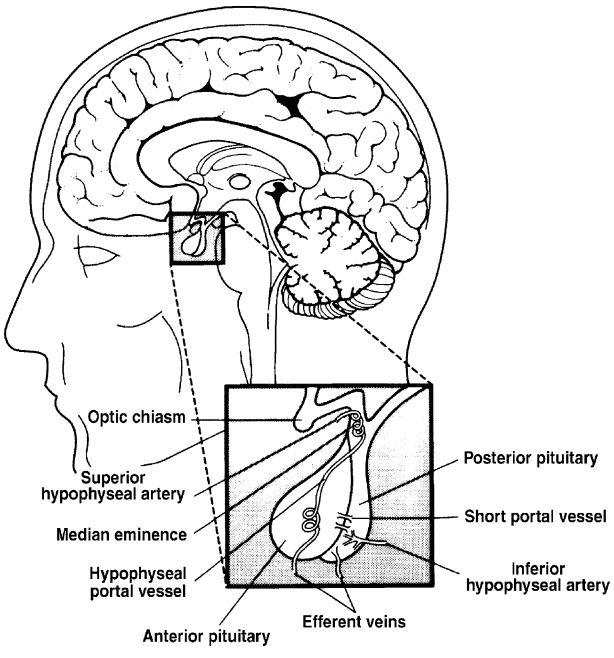

FIGURE 1 Location of the pituitary gland beneath the hypothalamus. The hypothalamo-pituitary portal vessels are idealized for simplicity. Reprinted from "Encyclopedia of Human Biology," Vol. 6 (1991), Academic Press, with permission.

The appetitive drive for energy to sustain physiological well-being and to reproduce successfully at the opportune time are two instinctual urges essential for survival of the species against varied evolutionary pressures. Neuropeptide Y is an important neurochemical signal relaying information regarding these instincts.

I. INTRODUCTION

Since the energy cost of reproduction is high and reproductive function is sensitive to nutritional stress and metabolic demands, scarcity and abundance of energy resources must be perceived and relayed continuously to the neural processes governing reproduction. Recent insight into the diversity and interplay of signals in the hypothalamus, a brain structure involved in homeostatic integration, has elevated neuropeptide Y (NPY) to the top of the list of neurochemical signals that relay information bidirectionally between these instinctual drives (Fig. 1). This article collates our understanding of the neurobiology of NPY produced specifically in the arcuate nucleus (ARC) of the hypothalamus. Participation of NPY in neuroendocrine mechanisms that initiate and sustain the drive for energy intake and expenditure in an orderly manner on the one hand and those that regulate reproduction on the other are described. Subsequently, the ARC NPY links between appetitive and reproductive functions are addressed.

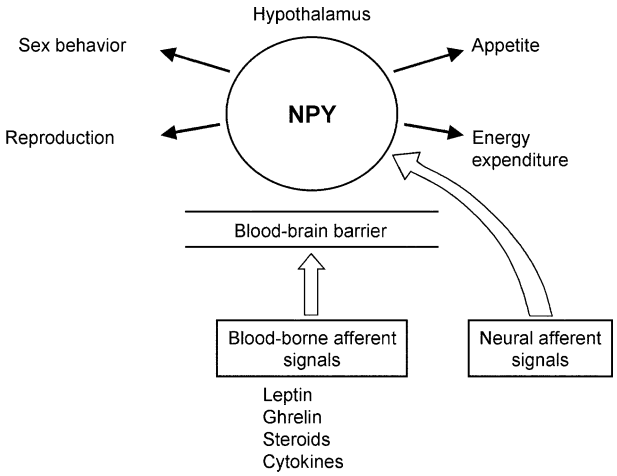

FIGURE 1 Neuropeptide Y (NPY) plays a pivotal role in the hypothalamus in regulating two neuroendocrine functions, reproduction and sex behavior (left) and appetite and energy expenditure to maintain body energy homeostasis (right). In addition to an interconnected circuitry in the hypothalamus (see Figs. 2 and 3), distinct afferent pathways play an important role in regulating NPY release at target sites. Afferent messages from the periphery are relayed by multisynaptic neural pathways through the spinal cord, brainstem, and lateral hypothalamus and then converge onto NPY neurons in the basal hypothalamus. NPY neurons also receive hormonal signals that cross the blood–brain barrier.

II. NEUROANATOMY

NPY was isolated and chemically sequenced from the brain as a 36-amino-acid peptide closely related to members of the pancreatic polypeptide family. Since NPY is produced exclusively in neural tissue and has tyrosine residues at both the amino- and the carboxy-terminals, it was named neuropeptide tyrosine (Y). The NPY localized in various hypothalamic sites is derived from two main sources. The extrahypothalamic source is a cluster of neurons in the brainstem that co-express a few additional messenger molecules, the most prominent of which are the two catecholamines, norepinephrine (NE) and epinephrine. These NPY and catecholamine neurons are synaptically linked with neurons in the hypothalamus that express various neuroendocrine peptides, neuromodulators, and neurotransmitters. Under certain conditions, co-release of these messenger molecules is important in amplifying or restraining the postsynaptic response of hypothalamic target cells. A denser population of NPY-producing neurons distributed along the ARC and a subpopulation located in the dorsomedial hypothalamus (DMH) are the hypothalamic sources of NPY. NPY-producing neurons in the ARC transsynaptically regulate the synthesis and release of several neurohormones—gonadotropin-releasing hormone (GnRH), growth hormone-releasing hormone, somatostatin, corticotropin-releasing hormone, thyrotropin-releasing hormone, vasopressin, oxytocin, and dopamine. In addition, these ARC NPY neurons innervate other hypothalamic nuclei that regulate appetitive and sexual behaviors and thermogenic energy expenditure.

There is regional heterogeneity in the distribution of NPY neurons in the ARC to selectively regulate various neuroendocrine and behavioral functions. A subpopulation of neurons extensively innervate the median eminence (ME), a neurohumoral junction between the hypothalamus and the anterior pituitary gland. Within the ME, NPY neurons terminate in close proximity of nerve endings of neuroendocrine cells to regulate reproduction. NPY release in the ME evokes the efflux of neuroendocrine messengers into the hypophyseal portal veins for transport to target cells in the anterior pituitary gland. NPY itself is also released into the hypophyseal vessels to potentiate the effects of neuroendocrine hormones on pituitary

target cells. ARC NPY neurons that project to the paraventricular nucleus (PVN) secrete NPY in discrete episodes to regulate appetitive behavior. Unlike NPY neurons in the brainstem, the ARC NPY neurons co-express agouti-related peptide (AgrP) and γ-amino butyric acid (GABA); each of these co-transmitters modulates the postsynaptic response of NPY on appetite and reproduction in distinctive ways. Within the ARC itself, NPY neurons are synaptically linked with proopiomelanocortin (POMC)-expressing neurons, an essential component of the neural circuitry involved in the regulation of appetite and reproduction. Since the ARC NPY neurons are strategically positioned inside the weak blood–brain barrier, they receive hormonal afferent messages from peripheral endocrine glands, leptin from adipocytes, ghrelin from stomach, steroids from gonads and adrenal cortex, and cytokines from immune cells (Fig. 1). The ARC NPY neurons also receive messages from ascending neural pathways via the catecholaminergic brainstem neurons and the orexin and melanin-concentrating hormone (MCH)-producing neurons in the lateral hypothalamus (LatH). Thus, the ARC NPY neurons perceive complex afferent messages and propagate command signals for the integration of a spectrum of neuroendocrine and behavioral functions.

Information obtained from investigations across many disciplines to gain insight into the physiology, cellular biology, and molecular biology of this discrete population of ARC NPY neurons in the integration of energy homeostasis and reproduction is summarized below.

III. NEUROPEPTIDE Y AND APPETITE

A. Physiological Orexigen

Among a wide variety of orexigenic neurotransmitters isolated from the hypothalamus, NPY has been found to be the most potent appetite-stimulating signal. Abnormal NPY secretion, as seen in diabetic and genetically altered rodents, produces relentless hyperphagia and increased rate of weight gain, culminating over time in morbid obesity. In laboratory rodents and other mammals, NPY synthesis in the ARC perikarya and storage in nerve terminals in the PVN precede mealtime (Fig. 2). Subsequently, NPY release is triggered by photoperiodically driven neurogenic stimuli from the timing mechanism in the brain. However, in subhuman primates and humans, all these antecedent neurosecretory events are independent of the photoperiodic clock and are entrained to mealtime.

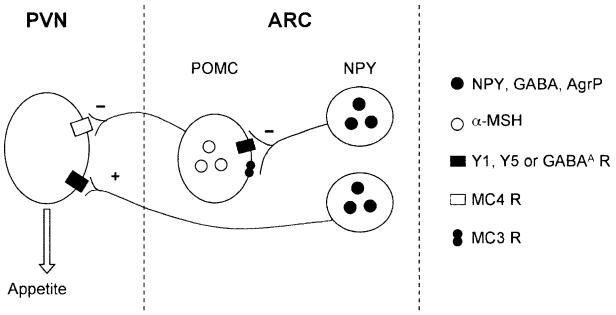

FIGURE 2 A schematic representation of morphological and functional connectivities of neurons that co-express NPY, GABA, and AgrP in the ARC of the hypothalamus (referred to in this and subsequent figures as NPY neurons). These neurotransmitters/neuromodulators are released in the ARC and PVN to evoke appetite. A subpopulation of NPY neurons directly release NPY, AgrP, and GABA in the PVN to stimulate appetite via specific receptors. Another subpopulation of NPY neurons release NPY, AgrP, and GABA in the ARC to transsynaptically curtail the MC4 receptor-mediated restraint on appetite by attenuating the release of α-melanocyte hormone from POMC neurons. This curb on the tonic restraint on appetite is supplemented by AgrP-induced antagonism of MC4 receptors. For details, see text.

NPY release-generating signals evoke the synchronized discharge of high-amplitude episodes at a rapid pace in the PVN. This rhythmic NPY secretion initiates episodic feeding. NPY secretion subsides as animals consume a meal; however, in the absence of readily available food, the episodic NPY discharge persists unabated to sustain the food-seeking drive. This antecedent NPY release is indeed a physiological trigger for appetite as evidenced by findings that prior depletion of the readily releasable NPY stores in the PVN nerve terminals with antisense oligodeoxynucleotides, passive immunoneutralization of the released NPY with NPY antibodies, or blockade of NPY receptors with pharmacologic antagonists suppresses appetite. Although the daily feeding pattern persists in the complete absence of hypothalamic NPY in NPY null mutant mice, these mice do not display increased feeding in response to physiological challenges such as fasting and insulin deficiency, and the hyperphagia and obesity of leptin-deficient ob/ob mice are drastically reduced. Adaptive reorganization during early development within the hypothalamic appetite-regulating network and other hypothalamic orexigenic messengers produced elsewhere in the hypothalamus and co-expressed with NPY in the ARC compensate for NPY deficiency to reinstate the instinctive appetitive drive. Consequently, NPY is a physiologically relevant appetite transducer,

and the altered frequency and amplitude of NPY discharge result in the disintegration of the hypothalamic control on energy homeostasis.

B. Mechanism of Action

The orexigenic effects of NPY are mediated by the coordinated participation of three G-protein-coupled receptors, the Y_1, Y_2, and Y_5 receptors, in the ARC–PVN axis (Fig. 2). Y_1 and Y_5 receptor antagonists partially inhibit feeding, whereas germ-line deletions of any of these three receptors elicit varying degrees of altered feeding patterns and hyperphagia, modified response to varied diets, and obesity that manifests at different ages. Normally, a three-pronged interplay under the direction of NPY in the ARC–PVN axis initiates and extinguishes appetitive behavior. First, an increase in NPY and GABA release from the ARC NPY neurons in the PVN generates information to higher brain centers to evoke feeding. Concurrent release of AgrP from the ARC NPY neurons counteracts the tonic restraint exercised by melanocortin 4 (MC4) receptors and amplifies appetite (Fig. 2). Second, at the same time, increased NPY and GABA release within the ARC itself restrains POMC neurons, causing a decreased release of α-melanocyte-stimulating hormone (α-MSH) to diminish the tonic restraint on feeding. This timed and coordinated sequence of dual neurosecretory events, excitation by NPY and GABA and a curb on the tonic restraint on melanocortin signaling in the ARC–PVN axis, stimulates robust and sustained feeding (Fig. 2). Third, a gradual decrease in the release of NPY, GABA, and AgrP in the PVN, evoked by autofeedback through Y_2 receptors on NPY neurons in the ARC, inhibits feeding. Thus, the timely stimulation and termination of NPY release and co-expressed messengers in the hypothalamic ARC–PVN axis constitute an obligatory neurochemical signaling modality to stimulate and inhibit appetite in correlation with the meal pattern on a daily basis.

C. Regulation of Release by Afferent Signals

A complex interplay among diverse neural and hormonal afferent signals under the direction of the central clock precisely times the release of orexigenic signals from NPY neurons in the ARC–PVN axis. The two major hormonal signals from the periphery, leptin from adipose tissues and ghrelin from stomach, restrain and augment, respectively, the ARC NPY efflux (Fig. 1). Neural afferents to the ARC NPY neurons from the ventromedial hypothalamus (VMH) relay inhibitory information generated by circulating leptin. A loss of this relay due to structural damage in the VMH results in hyperphagia and morbid obesity. Excitatory afferents from the LatH to ARC NPY neurons are relayed independently along the orexin and MCH neural pathways in response to reduced circulating leptin feedback. These neural pathways are strategically located to relay ascending visceral information via the spinal cord and brainstem to ARC NPY neurons for final processing and integration for energy homeostasis.

The most physiologically relevant afferent signals that regulate NPY secretion on a moment to moment basis are transmitted directly by the two functionally opposing afferent hormones, ghrelin and leptin (Fig. 1). Due to widespread action in the PVN, VMH, LatH, and other neighboring sites to produce tonic restraint, leptin is considered a major inhibitory signal. With this new understanding, it is possible to paint a clear picture of the sequential temporal interplay between hormonal afferent signals and hypothalamic effector pathways in governing the daily meal patterning. In anticipation of mealtime, the neural timing device, together with diminished leptin restraint from adipose tissue, stimulates high-frequency and high-amplitude ghrelin pulses from the stomach. This shift from inhibitory to excitatory afferents elicits NPY, GABA, and AgrP secretion from the ARC NPY effector pathway that, as described in the preceding section, propagates expression of hunger and the drive toward an energy source to replenish the depleted energy stores (Fig. 2).

Consumption of a meal reverses this chain of neural and hormonal events. First, there is a steady increase in leptin output, possibly stimulated by a gradual postprandial rise in pancreatic insulin secretion. As the tonic restraint by leptin on ARC NPY effector pathways is reinstated along with a steady decline in excitatory ghrelin generated by ingested food in stomach, appetite subsides. In the case of negative energy balance over long periods, such as that provoked by fasting, malnutrition, scarcity of food, or dieting, leptin secretion is drastically reduced but ghrelin output is markedly augmented. As a result of the concomitant suppression of tonic restraint and elevated stimulatory messages relayed by these functionally opposing hormonal afferents, NPY, GABA, and AgrP are hypersecreted to sustain the appetitive drive. Similarly, the high energy demands of lactation are met by hyperphagia induced by hypersecretion of ARC- and DMH-derived NPY in the PVN.

Afferent hormonal signals from other endocrine systems also employ NPY signaling in the hypothalamus to exert a modulatory effect on energy

homeostasis (Fig. 1). Ovarian estrogens inhibit food intake in rodents by both decreasing NPY release in the PVN and increasing leptin secretion from adipocytes. A reduction of appetite and maintenance of reduced weight, consistently observed in response to estrogen therapy in women, are, therefore, likely a result of modified leptin–ARC NPY transmission. On the other hand, since adrenal glucocorticoids stimulate the production and release of hypothalamic NPY, it most likely contributes to hyperphagia and weight gain in patients on glucocorticoid therapy.

D. Eating Disorders: Anorexia and Obesity

During infection, injury in the central nervous system, and other pathological afflictions, anorexia is the predominant condition that results in the loss of body weight and wasting. Under these pathophysiological conditions, the cytokines interleukin 1 and ciliary neurotropic factor are up-regulated. These cytokines efficiently down-regulate NPYergic signaling to produce anorexia and weight loss (Fig. 1). Indeed, NPY replacement therapy has proven beneficial in rodent models as it can counteract cytokine-induced anorexia and weight loss.

The incidence of obesity has increased to epidemic proportions worldwide. A large body of evidence endorses the view that genetic and environmental factors produce an imbalance in the tightly regulated feedback interplay between the peripheral leptin and ghrelin signals and the effector NPY neural pathways. This derangement promotes positive energy balance and enlarged fat tissue to store excess energy fuel. Basically, insufficient leptin restraint along with a rise in the excitatory ghrelin signal to the NPY network contributes to an environmentally induced increase in adiposity and morbid obesity. Recently, gene therapy to circumvent leptin insufficiency and to reinforce the restraint on NPYergic signaling has proven successful. A single injection into the hypothalamus of a nonpathogenic and nonimmunogenic adeno-associated virus vector encoding leptin reinstates the central tonic restraint and suppresses weight gain and adiposity for long periods in rodents consuming a diet rich in calories. This sustained efficacy of leptin gene therapy to suppress weight gain results from a voluntary reduction in food intake and increased energy expenditure. Both of these neural events, in turn, are elicited by a reduced efflux of orexigenic NPY and an increased efflux of anorexigenic α-MSH in the PVN.

IV. NEUROPEPTIDE Y AND REPRODUCTION

A. Anatomical and Functional Links with GnRH

Research spanning nearly two decades documents a crucial regulatory role of NPY in the hypothalamic control of reproduction. NPY is involved in the regulation of GnRH release, a primary brain peptide responsible for the maintenance of reproduction and sexual behavior in both sexes (Fig. 3). GnRH, produced by a network of neurons extending from the rostral septal–medial preoptic area (MPOA) to the ARC–ME caudally in the hypothalamus, stimulates the release of the pituitary gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH). GnRH is secreted into the hypophyseal portal veins in the ME in a pulsatile manner that represents an optimal mode of communication for pituitary gonadotropins to maintain reproduction in the two sexes (Fig. 3). Two oscillatory patterns of GnRH secretion have been observed in mammals. In general, GnRH is secreted in the form of low-amplitude pulses at more or less regular intervals throughout the 24 h period in males and through various stages of the reproductive cycle in females. These regularly spaced basal GnRH pulses in females are interrupted by an abrupt acceleration in the frequency and amplitude of GnRH discharge, culminating in the preovulatory LH surge release, an event that is essential for induction of ovulation (Fig. 3).

A distinct subpopulation of NPY neurons in the caudal ARC play a critical role in the excitation of pulsatile basal and cyclic GnRH discharge. NPY is also secreted in a pulsatile fashion in the ME with a frequency that coincides with that of GnRH. It acts synergistically with other hypothalamic excitatory signals, such as galanin and NE, to generate the basal GnRH pulses. In addition, NPY is a key excitatory signal for the initiation of the preovulatory secretion of GnRH. The sequential feedback actions of the ovarian steroids estrogen and progesterone on NPY neurons initially activate the synthesis of NPY in ARC perikarya and storage in terminal projections in the ME. This antecedent preparatory event culminates in the clock-driven hypersecretion of NPY, which, by a transsynaptic action on GnRH perikarya and dendrites in the MPOA and nerve terminals in the ME, generates a GnRH surge release into the hypophyseal portal veins (Fig. 3). Along with GnRH, NPY is also discharged into the hypophyseal portal vessels to potentiate the GnRH-induced preovulatory gonadotropin surge. Under certain

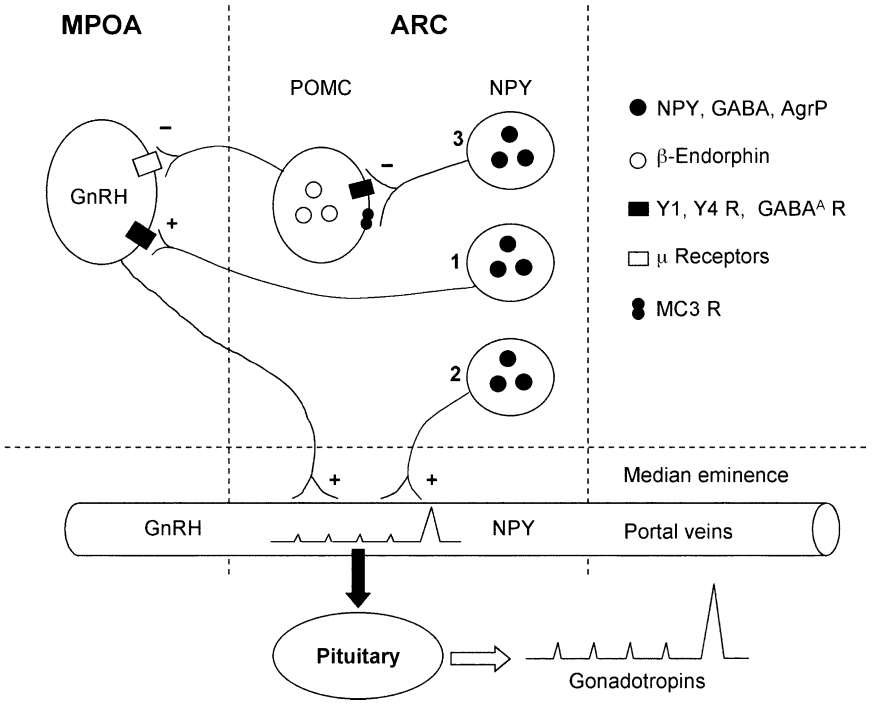

FIGURE 3 A schematic representation of morphological and functional connectivities of NPY-producing neurons in the ARC with the GnRH network in the MPOA and median eminence. NPY acts in three ways to modulate the basal and cyclic release of GnRH into the hypophyseal portal veins for transport to the pituitary gland to stimulate the release of gonadotropins: (1) Pulsatile discharge of NPY in the MPOA and median eminence stimulates GnRH release. (2) NPY is itself released into the hypophyseal portal veins to potentiate GnRH action in releasing pituitary gonadotropins. (3) NPY and GABA act transynaptically to inhibit opioid release from POMC neurons in the ARC. A decrease in tonic opioid restraint on GnRH secretion facilitates NPY-induced stimulation of GnRH and the preovulatory gonadotropin surge.

environmental insults and physiological challenges, disturbances in NPY pulse patterns inhibit both the basal and the cyclical discharge of GnRH, leading to depressed reproduction and infertility. For example, continuous NPY receptor activation produced by either NPY infusion or excessive endogenous NPY secretion, such as that manifested in genetically obese ob/ob mice and in response to fasting or diet restriction, suppresses reproduction. However, these adverse effects on reproduction correct themselves after normalization of NPY episodic signaling. In the complete absence of endogenous NPY, as in NPY null mutant mice, GnRH–LH surges are only partially attenuated because embryonic neuroendocrine reorganization compensates for the loss.

B. Mechanism of Action

Morphological and experimental investigations have delineated distinct neural pathways mediating the excitatory and inhibitory effects of NPY on GnRH secretion (Fig. 3). NPY stimulates GnRH release on its own by acting through Y_1 receptors located on GnRH cell bodies in the MPOA and nerve terminals in the ME. This direct stimulatory action on GnRH is supplemented indirectly by modulation of the release of β-endorphin from POMC neurons by NPY. Normally, these endogenous opioids exert a tonic restraint on GnRH secretion. This restraint is curtailed by a coordinated interaction of NPY and GABA via Y_1 and $GABA^A$ receptors, respectively, on POMC neurons. Thus, an appropriately timed two-pronged action, the synergistic action of NPY with galanin (GAL), another excitatory neuropeptide produced in the hypothalamus, on GnRH neurons concurrent with a NPY–GABA-induced curb on opioid restraint, promotes GnRH secretion (Fig. 3).

On the other hand, experiments involving germline mutations of NPY receptors have identified NPY receptor subtypes that selectively participate in the

inhibition of GnRH secretion by continuous NPY secretion. Under these conditions, overstimulation of Y_1 and Y_4 receptors located on POMC neurons in the ARC augments opioid restraint to turn off GnRH secretion. That these dual effects of NPY on GnRH secretion normally operate is endorsed by observations that a dampening of NPY signaling induced either by cytokine therapy or by germ-line deletion of NPY, Y_1, or Y_4 receptors in infertile ob/ob mice restores gonadotropin secretion and fertility.

V. NEUROPEPTIDE Y AND NUTRITIONAL INFERTILITY

It has long been known that nutrition is one of the most important environmental factors to impact human reproduction. Rapid population growth and environmental degradation in the 20th century have severely diminished food resources worldwide. The chronic shortage of food in conjunction with droughts in underdeveloped nations has impacted fertility. Chronic undernourishment and short-term caloric imbalance retard the onset of puberty and diminish fertility in all mammalian species. Limited caloric intake alone or in concert with the energy demands of strenuous exercise adversely impacts reproductive function. Heavy energy demands during lactation are compensated for by hyperphagia and cessation of reproductive cycles. In several genetic models in rodents and humans, hyperphagia and attendant obesity are concomitant with disturbed reproductive cycles and infertility. Is there a commonality in neurochemical signaling that links the neuroendocrine control of energy homeostasis and reproduction and responds appropriately to challenges of varied nutritional environments?

The information in the preceding sections documents a pivotal role of the hypothalamic NPY pathway in governing the neuroendocrine control of energy homeostasis and reproduction. It is obvious that there is spatial and temporal specificity of NPY involvement in these two neuroendocrine functions. The neuroanatomical substrate engaged by the ARC NPY circuitry in regulating reproduction is the GnRH neuronal network resident in the MPOA–ARC–ME axis (Fig. 3). On the other hand, the NPY ARC–PVN pathway represents a final pathway for the synthesis, storage, and release of NPY and other appetite-regulating peptides (Fig. 2). The neural links with neighboring VMH and LatH regions are also important components of the hypothalamic orexigenic network in the daily management of energy homeostasis. Obviously, the neurochemical link between the circuitries that regulate reproduction and appetitive behavior lies in the commonality of the ARC as the source of NPY and other messenger molecules contacted by NPY neurons, all of which are vulnerable to internal and external environmental challenges of energy supply and hormonal imbalance (Fig. 4).

The intrinsic basal and cyclic patterns of NPY secretion in the MPOA–ARC–ME axis facilitate the secretion of the neurohormone GnRH to sustain reproduction. The rhythmic NPY secretion critical for imparting GnRH pulsatile secretion is modulated by the feedback action of gonadal steroids directly at the level of the ARC NPY subpopulation and the interconnected POMC–GAL pathways. An imbalance of gonadal steroid feedback produced by subnormal or inappropriate patterns of steroid production under nutritional stress disrupts the driving hypothalamic NPY GnRH signals, leading to depressed reproduction. Similarly, deficits in hypothalamic NPY synthesis and release during aging adversely affect GnRH secretion downstream, thereby leading to diminished reproductive and gonadal functions.

Aside from abnormalities in gonadal steroid feedback, deficits in energy fuels are sensed by the NPY network through an imbalance in leptin-ghrelin feedback (Fig. 4). A reduction in leptin feedback relieves the restraint on ARC NPY secretion, which, in concert with heightened stimulation by ghrelin,

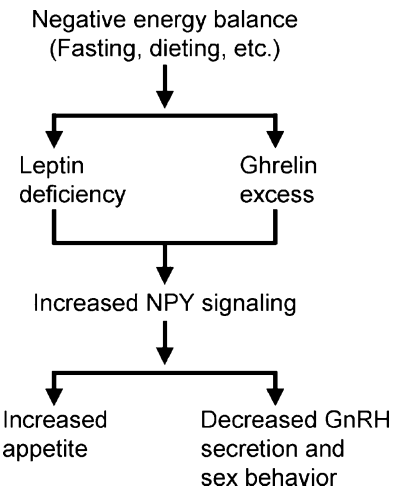

FIGURE 4 Regulatory role of hypothalamic NPY in increasing appetite and concomitantly suppressing reproduction and sex behavior in response to negative energy balance. For details, see text.

up-regulates NPY secretion in both the orexigenic axis of the ARC–PVN and the reproductive MPOA–ARC–ME axis. The overall consequence is robust expression of appetitive behavior to replenish energy fuel through Y_1 and Y_5 receptors at targets both in the ARC and in the PVN. There is concurrent suppression of reproduction and sexual behavior as the inhibitory pathways involving Y_1 and Y_4 receptors on POMC and GnRH neurons and in other sites implicated in regulatory sexual behavior are mobilized. Thus, changes in information flow from the periphery to the NPY network due to severe depletion in energy fuels for short or long periods compromise the intricate communication in the neural network that evokes rhythmic GnRH–gonadotropin secretion. Fortunately, these deleterious effects on reproduction are transient because replenishment of energy fuels reverses these sequelae and reinstates the independent moment to moment control of NPY on energy homeostasis and reproduction. In sum, NPY is an essential messenger molecule in the hypothalamus that serves as a communication bridge between the neuroendocrine processes that regulate reproduction and those that maintain energy homeostasis.

VI. SUMMARY

Information amassed during the past two decades affirms the concept that NPY produced by neurons in the ARC, a discrete subdivision of the hypothalamus, is an obligatory messenger molecule for commanding the two highly regulated innate drives in vertebrates: (1) appetite and the drive toward an energy source and (2) the urge to reproduce. A precise tracking of neural pathways originating in the ARC NPY perikarya has identified two distinct circuitries regulating each of these two hypothalamic regulatory functions. Within these circuitries, ARC NPY neurons, with the aid of intricate interconnections with other neurotransmitter/neuromodulator pathways within the hypothalamus and hormonal and neural afferent information from the periphery, transmit timed signals separately along these two circuitries. Subtle and progressive derangements provoked by environmental, genetic, and hormonal factors propagate molecular events governing the synthesis, release, and signal relay to reciprocally modify NPY transmission along the two circuitries. This commonality of neurochemical signaling has identified vulnerable loci for designing therapies to curb the epidemic of obesity and eating disorders without compromising fertility and, importantly, to alleviate nutritionally based infertility and reproductive disturbances.

Glossary

hypothalamus Area at the base of the brain involved in maintaining body homeostasis and neuroendocrine control of pituitary hormone secretion and appetitive and sex behaviors. Various subdivisions of the hypothalamus, such as the median eminence, arcuate nucleus, ventromedial hypothalamus, lateral hypothalamus, paraventricular nucleus, and medial preoptic area, participate in the regulation of these varied functions.

neurohormones Hormones produced by neurons and released into the hypophyseal portal system in the median eminence of the hypothalamus for transport to the pituitary gland to stimulate or inhibit the release of hormones; for example, gonadotropin-releasing hormone stimulates gonadotropin secretion from pituitary gonadotrophs.

neurotransmitters and neuromodulators Chemicals produced by neurons to transmit messages to other neurons synaptically, for example, neuropeptide Y, γ-aminobutyric acid, agouti-related peptides, norepinephrine, α-melanocyte stimulating hormone, melanin concentrating hormone, and orexins.

orexigen Chemicals produced by cells to stimulate appetite.

pituitary gland An endocrine organ located ventral to the hypothalamus and connected to it neurally and by a specialized vasculature called the hypophyseal portal system.

receptors Proteins in target cells that avidly bind with specific hormones or neurotransmitters/neuromodulators to initiate intracellular signaling responsible for a biological response.

Neurotensin

MICHELE SLOGOFF AND B. MARK EVERS
University of Texas Medical Branch

Neurotensin, a peptide hormone that is produced in the hypothalamus, plays many important roles in regulatory and activation mechanisms in both the central nervous system and the gastrointestinal tract. Cloning of the neurotensin and closely allied genes and their receptors has provided insights into the physiological roles of these molecules, enhancing the potential for development of clinical/therapeutic applications.

I. INTRODUCTION

During the course of work to isolate the peptide substance P from bovine hypothalamus extracts, Carraway and Leeman discovered a new peptide that produced marked vasodilation of exposed cutaneous areas in rats. Sequencing of this novel peptide revealed a 13-amino-acid peptide that was named neurotensin (NT) because it was found in the brain and exhibited hypotensive activity. Subsequently, NT was isolated from the intestine, where it exhibits endocrine and possibly paracrine effects. In the central nervous system (CNS), NT has a neurotransmitter function and is involved in inhibition of dopaminergic pathways. In the gastrointestinal (GI) tract, NT affects GI motility, pancreatic and biliary secretion, and intestinal mucosal growth. Approximately a decade after the identification of NT, neuromedin N, a structurally related hexapeptide, was isolated from porcine hypothalamus. Neuromedin N has a peripheral distribution similar to that of NT and, in fact, has subsequently been found to be tandemly positioned with NT near the carboxy terminus of the precursor protein. A better understanding of the effects of NT in the CNS and the GI tract has been greatly facilitated by the cloning of the NT/neuromedin N (NT/N) gene, the cloning of the high- and low-affinity NT receptors, and the development of NT receptor antagonists. Moreover, the recent development of NT/N null mice by Dobner and colleagues will provide critical information regarding the precise physiologic role of NT in the CNS and GI tract.

The overview provided here primarily focuses on the most recent findings regarding the NT/N gene (structure, expression patterns, and molecular regulation), the NT/N peptide (structure, localization, and secretion), the NT receptors, and the central and peripheral effects of NT. Additional in-depth reviews on this subject are cited in the bibliography at the end of this article.

during embryologic differentiation. Between weeks 4 and 6 of gestation, cells destined to become the anterior lobe have budded off of what will become the roof of the mouth, organized into a spherical shape, and migrated upward toward the developing neural tube. This migration is halted by apposition to the base of the forebrain adjacent to the floor of the third cerebroventricle, which is the ventral aspect of the hypothalamus. At the same time, clusters of hypothalamic neurons are extending their axons downward toward the floor of the third ventricle, some stopping near the midline and others protruding out of the neural tube to lie alongside the developing anterior lobe (the. adenohypophysis), as a collection of axons terminating in what will be the posterior lobe (the neurohypophysis). Hypothalamic cells having axons that comprise the posterior lobe deliver two important neuropeptides to the general circulation, vasopressin and oxytocin. These neurons can be considered endocrine cells, because they release their peptides directly into the general circulation.

The cells that project to the floor of the third ventricle deliver neural products (i.e., peptides and biogenic amines) to a region that is invaded during the fifth and sixth weeks of gestation by mesenchymal elements (precursors of blood vessels), organizing into the vascular link between hypothalamus and the hormone-secreting cells of the anterior lobe. Those mesenchymal elements form the superior hypophyseal artery, a branch of the internal carotid artery, and this artery supplies blood to the hypothalamus and, via the portal vessels, the anterior lobe of the pituitary gland. The superior hypophyseal artery terminates in a series of fenestrated capillaries in the midline of the floor the hypothalamus, giving the tissue its characteristic tufted, vascular appearance. This protrusion on the ventral surface of the hypothalamus is called the median eminence and it is here that neuropeptides and biogenic amines access the portal vessel system for delivery to the anterior lobe. These neural factors are not released directly into the circulation, instead diffusing after release in the parenchyma of the median eminence through the fenestration of the capillary endothelial cells of the portal vessels and then out of those long portal vessels into the sinusoids of the adenohypophysis. Because these peptides are produced in neurons, but are delivered to their target tissue (the cells of the adenohypophysis) not via the general circulation but instead via a specialized circulation (the hypophyseal portal vessels), they are true neuroendocrine substances, as opposed to hormones per se. The superior hypophyseal arteries and thus the long portal vessels provide the majority of the blood flow to the adenohypophysis; the remaining supply comes from superficial, capsular arteries that arise from the inferior hypophyseal artery, which is a major source of flow to the posterior lobe.

Although only a minor component when compared to the contribution of the long portal vessels, a vascular connection between the posterior and the anterior lobes of the pituitary gland has been observed. These short portal vessels, formed from mesenchymal elements that give rise to the inferior hypophyseal artery, are an avenue by which the hormones (vasopressin and oxytocin) released into the general circulation draining the neurohypophysis might gain access to the cells of the adenohypophysis.

III. HORMONE-SECRETING CELLS OF THE ANTERIOR PITUITARY GLAND

There are five major classes of hormone-secreting cells in the anterior pituitary gland. All are encapsulated in a dense collagenous matrix in the gland and are arranged in a sinusoidal fashion adjacent to the thin-walled vascular elements. All five classes exhibit spontaneous (constitutive) secretory activity, but are controlled primarily by tropic factors delivered by the portal vessels (factors originating both in the periphery and in the hypothalamus). In addition, the secretory activity of these endocrine cells can be modulated by locally produced substances acting in a paracrine (after diffusion from neighboring cells) or autocrine (self) fashion. Tropic effects also are exerted by nonendocrine cells of the gland, particularly the folliculostellate cells found among the hormone-secreting cells.

Percentages of cell types in the gland vary with physiologic state, and cell size can similarly vary, dependent on physiologic state. For example, although lactotrophs (prolactin secreting cells) make up approximately 10–15% of the endocrine mass of the tissue under most conditions, during pregnancy and lactation they may contribute as much as 25% of the cell number. Hormone status in general also can affect the size of individual cell types. After menopause, when circulating gonadal steroid levels have fallen and their negative feedback effects are lost, gonadotrophs (cells producing luteinizing and follicle-stimulating hormones) increase in size (volume) by as much as two- to threefold.

In the past, cell types were classified by affinity for basic or acidic dyes; now, using more selective histologic techniques, cell types of the anterior pituitary gland are characterized by their hormone content (Table 1). The endocrine cells of the

TABLE 1 Hormone-Secreting Cells of the Anterior Pituitary Gland

Cell type	Hormone content	Percentage of total cell number
Somatotroph	Growth hormone	50%
Lactotroph	Prolactin	10–25%
Corticotroph	Pro-opiomelanocortins (adrenocorticotropin, lipotropins, endorphins)	15–20%
Thyrotroph	Thyroid-stimulating hormone	<10%
Gonadotroph	Luteinizing hormone (LH) and follicle-stimulating hormone (FSH)	10–15%

adenohypophysis fall into two classes—those that produce and secrete unmodified protein hormones (prolactin, growth hormone, and adrenocorticotropin) and those that produce and secrete glycosylated proteins (thyroid-stimulating hormone, luteinizing hormone, and follicle-stimulating hormone).

IV. REGULATION OF HORMONE SECRETION

Located beneath the thalamus at the ventral surface of the diencephalon forming the walls of the third cerebroventricle, the hypothalamus is small in size (about 4 g in adults) but is a major crossroad for emotional, autonomic, and endocrine circuitry within the brain. Afferents to the hypothalamus provide extero- and enteroceptive information that is then processed into the neural and hormonal signals responsible for maintenance of normal cardiovascular, renal, visceral, and endocrine function, as well as for the expression of appropriate and conditioned behavioral responses to the environment. Neurons in the hypothalamus are organized into dense clusters of cells called nuclei. These nuclei are integrative centers (microprocessors) that assess neuronal, and in some cases humoral, input and send afferent output (nerve fibers) to relay stations (other nuclei in brain) or to the region where the hypophyseal portal vessels form at the ventral surface of the hypothalamus, just at the point where the infundibular stalk penetrates the diaphragma sella. After diffusion into the portal vessels, these tropic substances control production and release of the anterior lobe hormones. Those tropic substances, which can be either small proteins (i.e., neuropeptides) or neurotransmitters such as dopamine or norepinephrine, can act to either inhibit or stimulate the release/production of hormones in the various anterior pituitary cell types.

A. Growth Hormone

Growth hormone (GH), a protein hormone (191 amino acids) produced in somatotrophs of the adenohypophysis, circulates mainly free (i.e., not bound to carrier proteins) in plasma [plasma half-life ($t_{1/2}$) = 20 min; circulating levels are 2–4 ng/ml in adults (4–8 ng/ml in adolescents)]. Growth hormone acts to decrease blood amino acid levels, decrease blood urea nitrogen (positive nitrogen balance), increase DNA, RNA, and protein synthesis, decrease respiratory quotient due to increased fat oxidation, stimulate somatic growth, stimulate growth and calcification of cartilage, and, at high concentration, cause insulin resistance. Growth hormone secretion can be stimulated by exercise, arginine infusion, insulin-induced hypoglycemia, stress, dopamine, and α-adrenergics. Growth hormone is secreted in a pulsatile fashion, with a major daily secretory event occurring at the onset of sleep during Stages III and IV [non-rapid eye movement (REM) sleep]. Growth hormone secretion is inhibited by REM sleep, GH (autofeedback inhibition), insulin-like growth factors (long loop negative feedback), β-adrenergics, and hyperglycemia.

The hypothalamic component of feedback regulation of GH secretion has two major factors (Fig. 2). Growth hormone-releasing hormone (GHRH) is produced in neurons located in the arcuate nucleus and, above that, in the medial aspects of the ventromedial and dorsomedial hypothalamic nuclei. The predominant form of GHRH in humans is a 44-amino-acid peptide that is the final posttranslational product of a prohormone reported to be either 107 or 108 amino acids in length. GHRH is released into the median eminence in a pulsatile fashion, contributing thus to the pulsatile pattern of GH secretion. It acts by binding to a specific somatotroph receptor that is a member of the superfamily of G-protein-coupled, seven-transmembrane domain receptors. Binding results in activation of adenylyl cyclase, the formation of cyclic adenosine monophosphate (cAMP), an elevation in intracellular calcium levels, and both increased GH gene transcription and GH release. Non-cAMP-dependent signaling pathways may also mediate the effects of GHRH on the somatotroph.

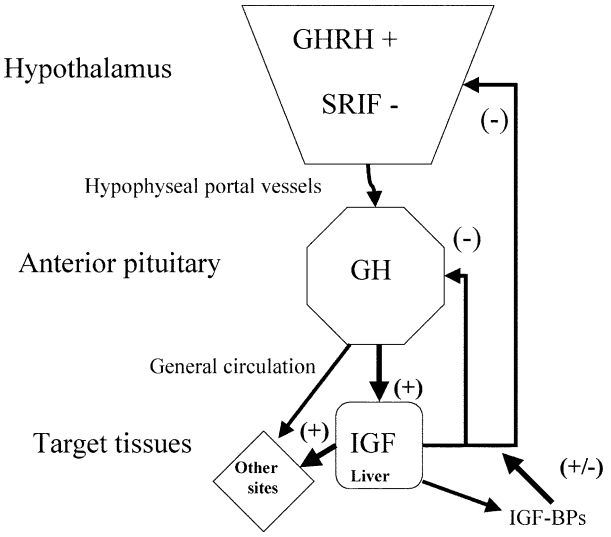

FIGURE 2 Hypothalamic regulation of growth hormone (GH) secretion. The 191-amino-acid hormone has a plasma half-life of 20 min; plasma levels are 2–4 ng/ml in adults and daily surges occur postprandially and at onset of sleep. GHRH, Growth hormone-releasing hormone; SRIF, somatotropin release-inhibiting factor; IGF, insulin-like growth factor; IGF-BPs, IGF-binding proteins.

Growth hormone release also is under inhibitory control, exerted by somatostatin produced in neurons of the anterior hypothalamus, adjacent to the ependymal lining of the third cerebroventricle (the periventricular zone). It, too, is produced by post-translational processing of a larger prohormone form (116 amino acids) and exists in both a 14- and a 28-amino-acid form. Somatostatin, or somatotropin release-inhibiting factor (SRIF), inhibits not only the release of GH, but thyroid-stimulating hormone and prolactin as well. The peptide exerts wide-ranging effects, most inhibitory, in a variety of other tissues. Multiple SRIF receptors have been identified, all being structurally related. In the pituitary gland, SRIF activates inhibitory G-proteins, resulting in decreased cAMP levels and lowered intracellular levels of free calcium. It acts to antagonize the actions of GHRH on adenylyl cyclase and blocks the effects of GHRH downstream of cAMP formation. The action to lower the cytosolic free-calcium levels is thought to be an important mechanism of action, mediated via an effect on voltage-gated calcium channels.

Studies utilizing opioid analogues have revealed the existence of a receptor mechanism, independent of GHRH and SRIF, that controls GH release. The endogenous ligand for that receptor was recently identified to be a novel 28-amino-acid peptide with a unique *n*-octanoyl modification of the serine in position 3 that is necessary for bioactivity. This peptide, called ghrelin, is produced in specialized endocrine cells of the gut, and some production in cells of the hypothalamic arcuate nucleus has also been reported. Thus ghrelin can access the adenohypophysis via the general circulation (from the stomach) or via the hypophyseal portal vessels following release into the median eminence. The ghrelin receptor is a G-protein-coupled, seven-transmembrane-spanning domain protein with homology to the motilin receptor. Binding of ghrelin results in activation of phospholipase C and the formation of inositol 1,4,5-trisphosphate ($InsP_3$). The physiologic relevance of the GHRH-like actions of ghrelin is still being established and the interactions between GHRH, SRIF, and ghrelin merit further scrutiny.

The nonhypothalamic control of GH release from the somatotroph includes, in addition to gut-derived ghrelin, the long loop negative feedback actions of the insulin-like growth factors (IGFs). Although GH can act directly to stimulate growth and metabolism in a variety of tissues, it is clear that its major actions are to stimulate the production and release of protein hormones that are structurally similar to insulin, hence the term IGFs. These peptide growth factors are produced primarily in liver, but also in bone, brain, prostate, and mammary tissues, where they can exert paracrine or true endocrine actions. In addition, the IGFs act in brain to inhibit GHRH release, and stimulate the release of SRIF, thus exerting long loop negative feedback on the hypothalamic regulation of GH secretion. The IGFs also can act directly in the adenohypophysis to antagonize the action of GHRH.

B. Prolactin

Prolactin (PRL) is a protein hormone (198 amino acids.) produced in lactotrophs of the adenohypophysis; it circulates mainly free in plasma [plasma $t_{1/2} = 20–30$ min; plasma levels are 10 ng/ml in nonpregnant/nonlactating females (slightly lower in males and adolescents), slightly higher in lactating females, and 200–300 ng/ml during nursing]. PRL is cleared from the circulation in liver and kidney. The high catabolic clearance rate indicates very high synthetic capability of the lactotroph (45 ml/min/m^2). Pulsatile secretion occurs, with a minor circadian (daily) peak in early morning.

PRL was originally thought to be solely a hormone of reproduction. Indeed, PRL acts to stimulate mammary gland development (ductal and lobuloalveolar growth) and milk production in properly primed breast tissue. Prolactin also has been reported

to organize the neural basis of maternal behaviors. In the adrenal cortex and ovary, PRL stimulates cytochrome P450 side chain cleavage enzyme (P450scc), resulting in the precursor for steroid synthesis. However, PRL has recently been recognized to have a broader spectrum of action, including immune modulation and potential actions on bone mineralization, vascular growth, and sodium homeostasis. Prolactin receptors belong both to a class of cell surface, tyrosine-kinase-linked receptors and to a class of intranuclear receptors (such as those for the steroid hormones). Promitogenic actions of PRL are related to both signaling pathways.

Prolactin secretion is stimulated by stress, hypothermia, tactile stimuli (vaginal or nipple stimulation), gonadal steroids (estrogens), and numerous neuropeptides (Fig. 3). The predominant hypothalamic regulation of PRL release is inhibitory in nature. Dopamine (DA), produced in the tubero-infundibular neurons of the arcuate nucleus, is released in a relatively constant fashion into the median eminence, and therefore PRL secretion is tonically inhibited. Dopamine exerts its inhibitory action on the lactotroph via binding to the D_2 subtype of the family of dopamine receptors. The receptor is another one of the G-protein-coupled, seven-transmembrane-spanning domain region proteins. Once activated by DA, the receptor links to a decrease in cellular levels of cAMP and inositol trisphosphates as well as to a decrease in intracellular calcium levels. The major cue for PRL release is the withdrawal of this inhibitory, dopaminergic tone, although stimulatory effects of some neuropeptides can be expressed even in the presence of physiologic levels of DA.

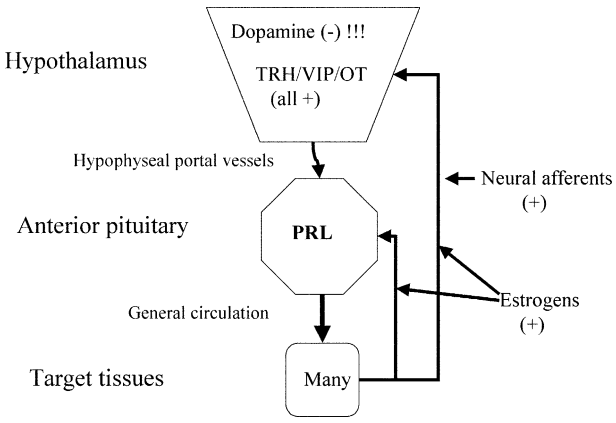

FIGURE 3 Hypothalamic regulation of prolactin (PRL) secretion. The 198-amino-acid hormone has a half-life of 20–30 min; plasma levels are 10 ng/ml, except during pregnancy, laction, and stress. Minor daily surges occur in the morning. TRH, Thyrotropin-releasing hormone; VIP, vasoactive intestinal peptide; OT, oxytocin.

Stimulatory factors controlling PRL release originate in at least three locations. Estrogens of ovarian origin stimulate both PRL gene transcription and hormone release. Estrogens may also stimulate lactotroph proliferation by releasing a locally produced peptide, galanin, which then acts in a paracrine fashion within the gland. Neuropeptides of hypothalamic origin also can stimulate PRL release following delivery in the hypophyseal portal circulation. The most potent of these is the tripeptide, thyrotropin-releasing hormone (TRH), which is also the major regulator of TSH secretion. TRH stimulates PRL release even in the presence of physiologic, inhibitory levels of DA, a fact that separates it from the other peptidergic PRL-releasing factors (PRFs). TRH is the posttranslational product of a much larger prohormone that is produced in cells in the most medial aspects of the hypothalamic paraventricular nuclei. This is the major site of production that leads to peptide being delivered to the median eminence; however, TRH is produced in a variety of other sites. In the lactotroph, TRH binds to G-protein-coupled, seven-transmembrane-spanning domain receptors on the lactotroph, resulting in activation of phosphoinositide hydrolysis by phospholipase C and the subsequent activation of protein kinase C. The resulting elevation in intracellular free calcium levels certainly underlies the PRL secretory event, and perhaps even the elevation in cAMP levels that occurs concomitantly. Additional neuropeptides can stimulate PRL release from cultured pituitary cells and in some select situations *in vivo*. Both vasoactive intestinal polypeptide (VIP), a gut peptide also produced in neurons in the paraventricular nuclei, and oxytocin (OT), a neurophyseal hormone more traditionally considered part of the posterior pituitary system, can access the lactotroph following release into the median eminence and delivery by the portal circulation. Results from animal studies clearly demonstrate that both VIP and OT may be physiologically relevant PRFs, but this has not yet been established firmly in humans. OT may access the lactotroph via a second route, delivery by the short portal vessels connecting the posterior (neural) lobe with the adenohypophysis. In addition, there appears to be at least one additional factor (peptide?) of neural lobe origin that accesses the lactotroph via the short portal vessels, but the identity of this PRF has remained elusive.

C. Adrenocorticotropic Hormone

Adrenocorticotropic hormone (ACTH; adrenocorticotropin) is derived from a large glycoprotein prohormone, pro-opiomelanocortin (POMC), which is produced in corticotrophs. Corticotrophs in the adenohypophysis produce mainly the 91-amino-acid protein β-lipotropic hormone (LPH; lipotropin) and the 39-amino-acid peptide ACTH. ACTH can be further processed to the 13-amino-acid long α-melanocyte-stimulating hormone (MSH), which stimulates pigment deposition in melanocytes. β-LPH can be further processed to β-endorphin (31 amino acids) and γ-LPH. Corticotrophs derived from the fetal intermediate lobe further process γ-LPH to β-MSH and produce γ-MSH from the N-terminal fragment of POMC.

ACTH circulates free in plasma with a half-life of 20 min and is cleared in kidney and liver. Levels under unstressed conditions are low (about 10 pg/ml) and secretion is pulsatile (20-min intervals); peak levels are present between 2:00 and 8:00 AM. ACTH stimulates activation of cytochrome P450 side chain cleavage enzyme, the rate-limiting step in cholesterol metabolism, and cholesterol esterase activities in the adrenal cortex, resulting in increased levels of glucocorticoids, mineralocorticoids, and adrenal androgens. At high levels, ACTH causes increased skin pigmentation because it also binds to the MSH receptor. ACTH acts via a membrane-bound receptor linked to adenylyl cyclase, increasing cAMP formation in hormone-producing cells of the adrenal cortex. The initial increase in cortisol secretion observed following ACTH infusion is due to increased adrenal blood flow and stimulation of conversion of cholesterol to pregnenolone (P450sccc activation). Prolonged actions of ACTH include stimulation of increased synthesis of the rate-limiting enzymes in adrenal steroidogenesis.

Secretion of ACTH is stimulated by stress, hypothermia, inflammatory substances (pyrogens), hypoglycemia, epinephrine (adrenaline), and several neuropeptides (Fig. 4). Cortisol from the adrenal cortex is the major inhibitory agent controlling ACTH production and release.

Neuroendocrine regulation of ACTH release is primarily stimulatory due to the neuropeptide, corticotropin-releasing hormone (CRH). CRH is a 41-amino-acid peptide produced in the parvocellular elements of the hypothalamic paraventricular nuclei. Actylcholine, serotonin, interleukins, and other cytokines all act to stimulate CRH release into the median eminence. At the corticotroph membrane, CRH binds a receptor similar to that for GHRH, resulting in activation, via G-protein coupling, of adenylyl cyclase. CRH also stimulates POMC gene transcription, probably via activation of protein kinase A. Within the hypothalamus, γ-butyric acid (GABA) and cortisol inhibit the activity of the CRH-producing neurons and therefore CRH release. Cortisol also acts directly in the anterior lobe to antagonize the action of CRH, resulting lower secretion and production of POMC-derived peptides. As was the case with PRL, there is credible evidence for the physiologic relevance of the ACTH-releasing actions of vasopressin (AVP) and oxytocin released into the median eminence or delivered via the short portal vessels; however, their role as ACTH secretagogues in humans has not been firmly established.

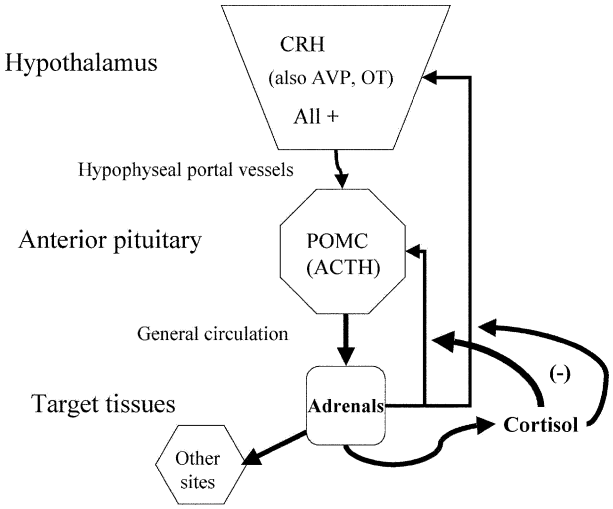

FIGURE 4 Hypothalamic regulation of adrenocorticotropic hormone (ACTH) secretion. The 39-amino-acid hormone has a half-life of 20 min; plasma levels are very low (picograms/milliliter) under nonstressed conditions. Secretion is pulsatile (20 min) and there is a daily surge between 2:00 and 8:00 AM. CRH, Corticotropin-releasing hormone; AVP, vasopressin; OT, oxytocin; POMC, pro-opiomelanocortin.

D. Pituitary Glycoprotein Hormones

The three major pituitary glycoprotein hormones, thyroid-stimulating hormone, luteinizing hormone, and follicle-stimulating hormone, each having a molecular weight of approximately 30,000, are formed from two interconnecting amino acid chains. They all share a common α-chain but their unique β-chains give each hormone an individual, characteristic bioactivity.

1. *Thyroid-Stimulating Hormone*

Thyroid-stimulating hormone (TSH) circulates mainly free in plasma at levels of 1–4 ng/ml under normal conditions. TSH half-life is 50–60 min and it is cleared (degraded) primarily by the kidneys. Secretion is pulsatile, with a circadian rhythm characterized by highest levels between 9:00 PM and 5:00 AM and lowest levels between 4:00 and 7:00 PM. Physiologic surges occur in response to cold exposure (increases), heat (inhibits), starvation (inhibits), and stress (inhibits).

TSH stimulates thyroid hormone production and secretion by several mechanisms. Iodide transport into the thyroid gland is stimulated by TSH. TSH also stimulates thyroglobulin, iodotyrosine, and iodothyronine formation, and thus increases intracellular stores of thyroid hormones. Finally, TSH stimulates thyroglobulin proteolysis, as well as thyroxine (T4) and triiodothyronine (T3) release.

Hypothalamic control of TSH production and secretion (Fig. 5) is primarily exerted by the tripeptide thyrotropin-releasing hormone. Binding of TRH to its receptor (G-protein coupled) on the thyrotroph results not only in rapid secretion of TSH, but also in increased transcription of the β-subunit of TSH. These effects are thought to be signaled by TRH activation of adenylyl cyclase. There is also substantial evidence that TRH controls the final glycosylation (the addition of sugar moieties to the protein backbone of the hormone) of TSH, a step important for the bioactivity of the secreted product. Factors of hypothalamic origin (somatostatin and dopamine) can inhibit TSH secretion by a direct action in the adenohypophysis; however, by far the most significant negative regulation is exerted by T3 and T4 secreted by the thyroid gland (long loop negative feedback). The active agent in pituitary gland is T3, which either reaches the gland via the general circulation or is produced locally by conversion of T4. Triiodothyronine not only inhibits TSH gene transcription, it also down-regulates the TRH receptor.

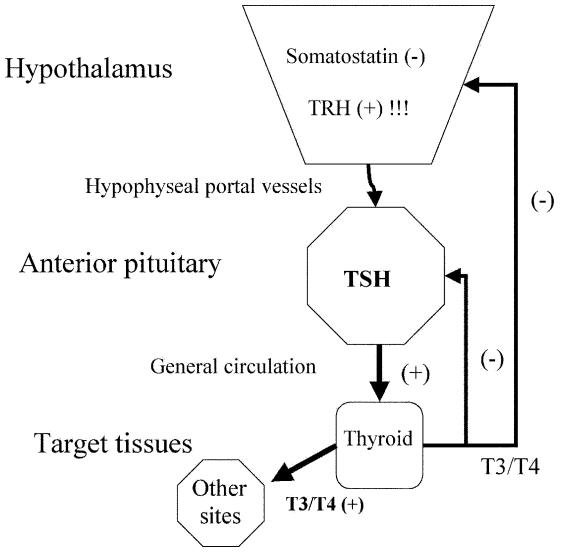

FIGURE 5 Hypothalamic regulation of thyroid-stimulating hormone (TSH) secretion. TSH is a glycoprotein ($M_w = 30{,}000$) with a half-life of 50–60 min; plasma levels are 1–4 ng/ml. Secretion is circadian, with peaks between 9:00 pm and 5:00 AM and a low between 4:00 and 7:00 PM. TRH, Thyrotropin-releasing hormone; T3, triiodothyronine; T4, thyroxine.

2. *Gonadotropins: Luteinizing Hormone and Follicle-Stimulating Hormone*

The 115-amino-acid-long β-subunits of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) confer unique biological activities to each hormone. The β-chain of LH is similar to that of human chorionic gonadotropin (hCG), thus common biologic activities are shared. Plasma levels of LH and FSH are expressed in terms of International Standard preparations (purified human hormones, as opposed to synthetic forms) and thus they are expressed as International Units (IU)/milliliter of plasma. LH and FSH both are secreted in a pulsatile fashion (circhorial in nature, about every 1–2 h) under the influence of gonadotropin-releasing hormone (GnRH), a 10-amino-acid peptide of hypothalamic origin. With the exception of puberty in males, when nocturnal pulses of GnRH entering the hypophyseal portal vessels cause increasing baseline and spike-like discharges of LH, gonadotropin levels remains fairly constant throughout adult life. Females also experience nocturnal gonadotropin pulses that increase in amplitude and frequency during puberty. During the reproductive years, the secretion of gonadotropins in women is circhorial (hourly) and low (basal LH, 0.8–26 mIU/ml; FSH, 1.4–9.6 mIU/ml). Monthly surges occur just prior to ovulation (LH, 25–57 mIU/ml; FSH, 2.3–21 mIU/ml). After menopause, gonadotropins are secreted in a circhorial pattern (LH, 1.3–13 mIU/ml; FSH, 0.9–15 mIU/ml).

In men, gonadotropin levels are low and fairly constant (LH, 1.3–13 mIU/ml; FSH, 0.9–15 mIU/ml). In women, gonadotropin levels fluctuate depending on stage of the menstrual cycle. After menopause, levels rise noticeably due to the absence of normal ovarian negative feed back (LH, 40–104 mIU/ml; FSH, 34–96 mIU/ml).

The plasma half-life of FSH is longer than that of LH (about 1 h for LH and 3 h for FSH) and the metabolic clearance rate for FSH (about 10 ml/min/m^2) is slower than that of LH (about 30 ml/min/m^2). These are at least two of the reasons why the midcycle surge of FSH is broader than that of LH. Both gonadotropins are degraded in the liver and kidneys, and some intact hormone is excreted in the urine. In females, LH acts in the ovary to stimulate follicular growth and rupture at ovulation. LH exerts luteotropic effects, stimulating estrogen and progesterone production. FSH also stimulates follicular growth. FSH further stimulates the conversion of androgens to estrogens by activating the enzyme aromatase in granulosa cells, and synergizes with estrogen to induce formation of LH receptors on those cells. In males, LH acts on Leydig cells to stimulate testosterone production. FSH induces LH receptors on those cells, and acts on Sertoli cells to stimulate spermatogenesis. Both LH and FSH signal through unique receptors that are coupled via G-proteins to adenylyl cyclase.

Neuroendocrine regulation of gonadotropin secretion (Figs. 6 and 7) is exerted primarily by the decapeptide hormone gonadotropin-releasing hormone (also called luteinizing hormone-releasing hormone, LHRH). GnRH binds to its cognate receptor (another G-protein-coupled, seven-transmembrane-spanning domain protein) and activates phosphoinositide hydrolysis (phospholipase C activity).

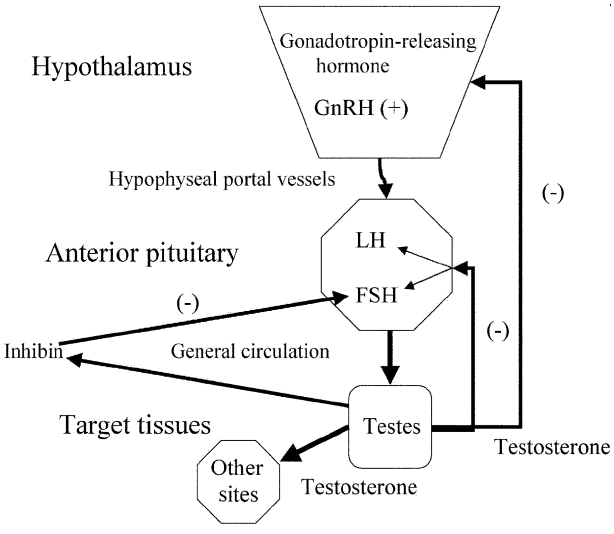

FIGURE 6 Hypothalamic regulation of gonadotropin [luteinizing hormone (LH) and follicle-stimulating hormone (FSH)] secretion in the male. LH half-life, 20–30 min; FSH half-life, 30–40 min; secretion of both hormones is low and constant. GnRH, Gonadotropin-releasing hormone.

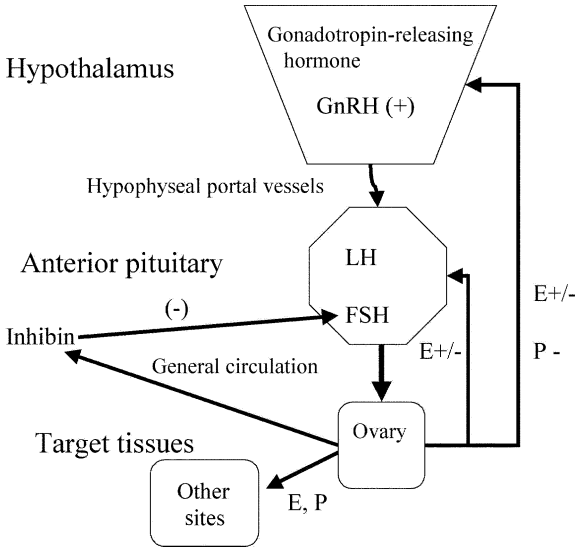

FIGURE 7 Hypothalamic regulation of gonadotropin [luteinizing hormone (LH) and follicle-stimulating hormone (FSH)] secretion in the female. LH half-life, 20–30 min; FSH half-life, 30–40 min; secretion is pulsatile, occurring hourly or monthly. GnRH, Gonadotropin-releasing hormone; E, estrogen; P, progesterone.

The diacylglycerol formed activates protein kinase C and intracellular calcium levels rise, leading to stimulus–secretion coupling and release of LH and FSH. GnRH also stimulates transcription of the GnRH receptor gene and the LH and FSH genes.

Sex steroids exert both positive and negative feedback effects on the hypothalamus and pituitary gland. In females, estrogen at low levels inhibits both LH and FSH secretion, whereas at higher levels the steroid actually stimulates LH β-chain gene transcription and sensitizes the gonadotroph to the actions of GnRH. Progesterone negative feedback is expressed primarily at the level of the GnRH neuron, decreasing pulse frequency of release of the decapeptide into the median eminence. In males, testosterone exerts negative feedback effects in the hypothalamus, similar to those exerted by progesterone in females, and direct inhibitory actions at the pituitary level, similar to those of estrogen in women.

Granulosa cells in the ovary, and Sertoli cells in the testes, also produce a heterodimeric hormone, composed of unique α-and β-subunits, that acts in the gonadotroph to inhibit FSH production and release. The production of this heterodimeric hormone, called inhibin, is in turn stimulated by FSH. It is in all likelihood the loss of inhibin production after menopause that explains the greater rise in plasma FSH levels, compared to LH levels, in the absence of

ovarian feedback. Finally, it appears that a homodimer of the inhibin β-chain is produced in several tissues, including the pituitary gland. This homodimer, called activin, is thought to stimulate FSH production and secretion.

V. SUMMARY

The unique vascular connection between the hypothalamus and pituitary gland established by the experiments of Jacobsen and Harris over 50 years ago is the anatomical basis for the science of neuroendocrinology. Peptidergic releasing and inhibiting factors produced in brain neurons, most localized to the hypothalamus, gain access to their target cells in the anterior lobe of the pituitary gland via this system of portal vessels. The control of peptide release into the median eminence is in turn controlled by neural afferents to the hypothalamus and by blood-borne substances that either cross the blood–brain barrier to act within the hypothalamus or act in the median eminence on the axon terminals containing those peptides, because there is no barrier at this vascularized site. Additional regulation of anterior lobe hormone secretion is determined by direct actions of those circulating hormones (long loop negative and positive feedback) and by intrinsic factors acting in paracrine or autocrine fashion within the adenohypophysis.

Glossary

adenohypophysis The anterior pituitary gland.
autocrine Self-regulation; the release from a cell of a tropic factor that binds to and alters the activity of that same cell.
median eminence Floor of the third cerebroventricle in the hypothalamus; site of the fenestrated endothelium of the capillary loops of the portal vessels.
neuroendocrine Regulation by neural factors reaching the anterior pituitary gland via the portal vessels.
neurohypophyseal Neuronal projections from the supraoptic and paraventricular hypothalamic nuclei to the posterior pituitary gland.
neurohypophysis The posterior pituitary gland.
paracrine Regulation of neighboring cells by a tropic factor that, when released from one cell, diffuses to and acts on another cell.
portal vessels Venous system connecting the capillary loops formed by the superior hypohyseal artery in the median eminence of the hypothalamus with the sinusoids of the anterior pituitary gland.

II. THE NEUROTENSIN/NEUROMEDIN N GENE

A. Structure

The NT/N gene is highly conserved among species. The cDNA encoding the NT/N gene was first cloned from a canine enteric mucosal library by Dobner and colleagues. Using the canine cDNA probe, the rat NT/N gene was then isolated by screening a rat genomic library. The NT/N gene spans approximately 10.2 kb and is divided into four exons and three introns. The NT and neuromedin N domains are tandemly arrayed on exon 4. Subsequent cloning of the human NT/N gene demonstrated an open reading frame encoding a predicted precursor protein of 170 amino acid residues (Fig. 1). At the nucleotide level, the human NT/N precursor is 92, 91, and 81% identical to canine, bovine, and rat NT/N, respectively; the resulting precursor peptide is similarly conserved (Fig. 2).

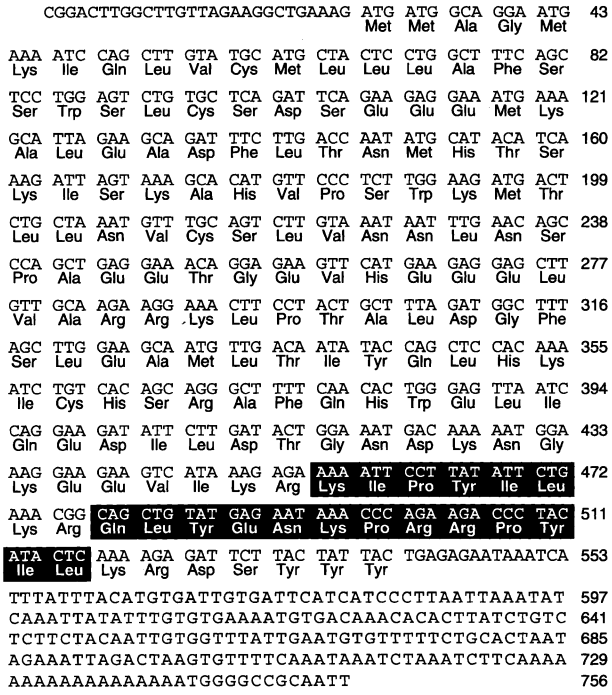

FIGURE 1 Human full-length cDNA clone of NT/N and predicted amino acid sequence of human prepro-NT/N. The neuromedin N and NT coding regions, located in tandem on exon 4, are highlighted in black. Modified from Dong *et al.* (1998), with permission from the *American Journal of Physiology.*

B. Expression

NT/N gene expression in the adult is predominantly localized to the small bowel, with increased expression noted in the ileum. In the adult, NT/N gene expression is not detected in the pancreas, stomach, or colon (Fig. 3). Interestingly, unlike the brush border enzymes (e.g., sucrase-isomaltase), the gradient of NT/N expression is not altered by changing the lumenal contents or the transposition of the intestine to other areas along the longitudinal gut axis. These findings suggest an intrinsic program of NT/N gene expression in the gut that is not affected by positional or nutrient alterations.

During development, expression of NT/N is noted in a well-defined spatial- and temporal-specific pattern. The earliest NT/N expression in fetal rats, identified by sensitive reverse transcriptase and polymerase chain reaction (RT-PCR) analysis, is

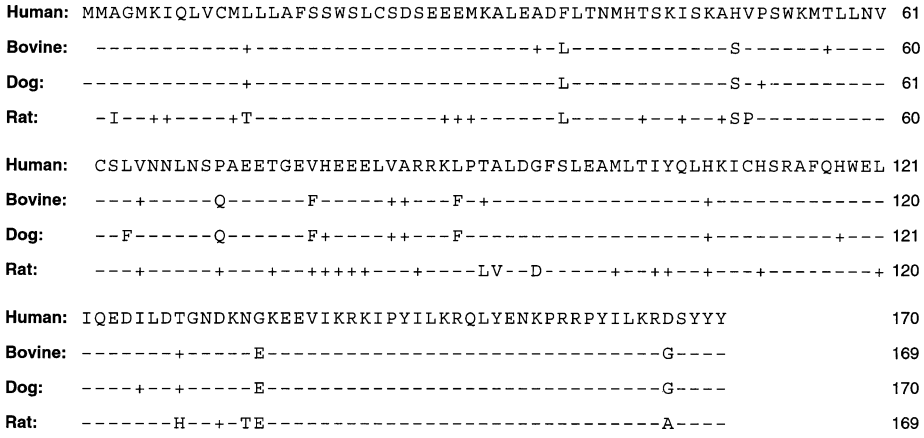

FIGURE 2 Analysis and comparison of the putative amino acid sequence of human NT/N to known sequences of the cow, dog, and rat. −, Identical sequences; +, similar sequences. Modified from Dong *et al.* (1998), with permission from the *American Journal of Physiology.*

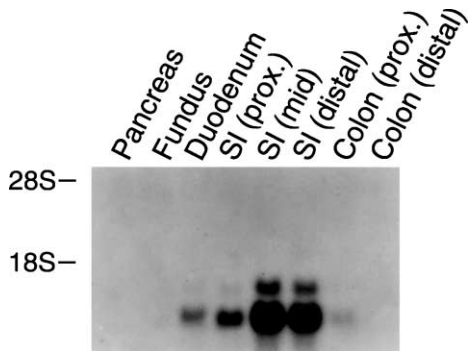

FIGURE 3 Localization of NT/N mRNA in the rat. Rat NT/N cRNA was used to probe 10 μg of polyadenylated RNA. Northern blots are from the pancreas, fundus of the stomach, duodenum, three equal segments of small intestine (SI), and two equal segments of colon. Adapted from Evers *et al.* (1991), with permission from *Surgery.*

noted in the primitive foregut at 12 days of gestation. In early fetal development, expression of the NT/N gene is detected in multiple tissues, including colon, pancreas, liver, and stomach; this expression is transient and disappears by the end of the first week of life. In the intestine, NT/N expression is low in both the jejunum and the ileum of fetal rats; steady-state NT/N mRNA levels rise rapidly after postnatal day 1 to assume the adult topographical distribution of increasing NT/N expression along the jejunoileal axis of the small bowel. By postnatal day 28, the pattern of expression is that of an adult, with no expression detected in the pancreas, liver, and stomach, minimal expression in the jejunum, and the majority of NT/N gene expression in the ileum. Developmental expression of NT/N in humans follows a similar pattern; NT/N expression is found in the fetal colon and liver but is not apparent after 24 weeks of gestation. This widespread distribution of NT/N expression in the developing GI tract suggests the presence in the primitive gut of a shared ancestral stem cell that is capable of multidirectional differentiation.

In addition to the fetal colon expression of NT/N during a gestational stage in which the colon resembles the small bowel, expression of NT/N has been detected in human colon cancers. Approximately 25% of freshly resected colon cancers demonstrate NT/N gene expression, although NT/N expression is not apparent in the adjacent normal mucosa. Furthermore, NT/N gene expression has been detected in human colon cancer cell lines. Similar to the expression of sucrase-isomaltase or carcinoembryonic antigen (CEA), the re-expression of NT/N in certain colorectal cancers further suggests the reversion to a more fetal intestinal pattern. Similarly, NT/N expression has been noted in a variant of hepatocellular cancer (i.e., fibrolamellar cancer) as well as a nonfibrolamellar hepatocellular cancer (Hep3B). Taken together, these findings demonstrate a complex pattern of NT/N expression with well-localized and highly regimented expression in the adult GI tract, a more diffuse expression during fetal development, and re-expression in certain cancers.

C. Molecular Regulation

We have analyzed the molecular factors regulating the constitutive expression of NT/N using the BON endocrine cell line, which was derived from a functioning human carcinoid tumor and established in our laboratory. BON cells, like the terminally differentiated N cells of the small bowel, express high levels of NT/N mRNA, synthesize and secrete NT peptide, and process the NT/N precursor protein in a fashion identical to that of the N cells. Transient transfection assays using the rat NT/N promoter identify the proximal 216 base pairs (bp) of 5′ flanking sequences essential for high-level constitutive NT/N expression. A critical element located in the proximal NT/N promoter binds both activator protein 1 (AP-1) and cAMP-responsive enhancer binding (CREB)/activating transcription factors (ATF) and is critical for NT/N expression in BON cells. Mutation of the cAMP response element (CRE)/AP-1 site almost completely abolishes NT/N expression. This functional "cross talk" between different transcriptional pathways converging on a single binding site within a promoter greatly enhances the combinatorial possibilities of these transcription factors to regulate gene expression. Dobner and colleagues have also shown that elements contained within the proximal 216 bp are important for inducible NT/N gene expression. In contrast to constitutive NT/N expression in BON cells, the elements responsible for NT/N gene induction in the rat pheochromocytoma cell line, PC12, involve the cooperation of multiple elements of the NT/N promoter, including a distal consensus AP-1 site, the proximal CRE/AP-1 site, a near-consensus CRE site, and a near-consensus glucocorticoid response element (GRE) (Fig. 4). Therefore, these results suggest that a different array of regulatory elements is required for the constitutive NT/N expression pattern in the gut, in which NT functions as an endocrine agent, compared with NT/N gene induction in the CNS,

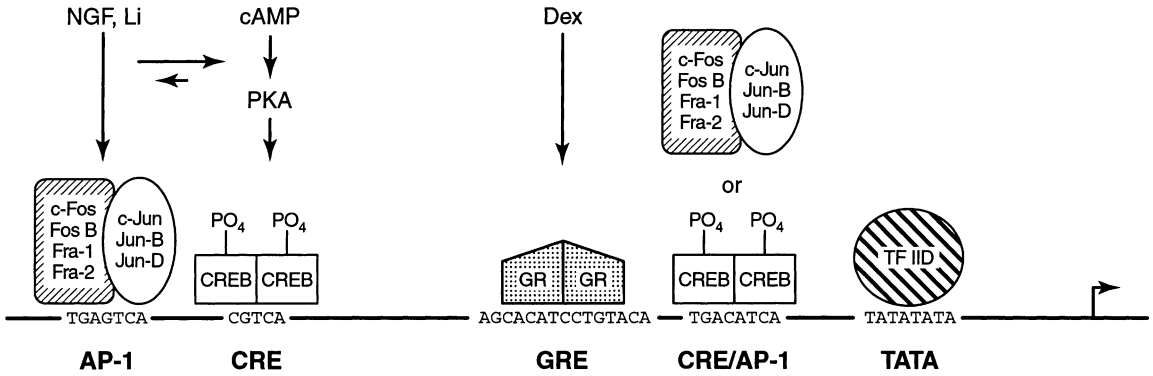

FIGURE 4 Schematic for cooperative regulation of NT/N gene transcription. in which NT serves as a neurotransmitter or neuromodulator.

The signal transduction pathways resulting in subsequent NT/N expression are also under investigation. In particular, the role of the Ras signaling pathway has been examined. Investigators in our group have shown that Ras (both wild type and activated) enhances expression of the NT/N gene in the Caco-2 human colon cancer cell line, most likely acting through the proximal CRE/AP-1 site. Furthermore, overexpression of Src kinase, another signaling protein in the Ras pathway, is associated with an increase in NT/N promoter activity. Mutation of the proximal promoter element inhibits Ras-mediated NT/N induction. Ras and Src can stimulate the binding activity of AP-1 proteins (e.g., c-Jun); therefore, we speculate that Ras, acting through AP-1 proteins, induces NT/N gene expression.

In addition to transcription factor binding, gene methylation regulates expression of various genes. Methylation appears to play a critical role in the expression of a number of genes during both normal development and malignant transformation. Investigators in our laboratory have shown, by complementary approaches, that DNA methylation plays a role in NT/N gene suppression in certain hepatocellular and colon cancer cell lines. Treatment with a demethylating agent, 5-azacytidine, partially activates the suppressed NT/N gene in the HepG2 hepatocellular cancer. Moreover, our group has shown that DNA methylation plays a role in NT/N gene silencing in the human colon cancer KM20 and that NT/N expression in the KM12C cell line is associated with demethylation of CpG sites in the NT/N promoter. These studies suggest that methylation status may be directly related to NT/N re-expression in certain cancers and may account for gene repression during development. In addition, we speculate that gene methylation may play a role, in combination with transcription factors, in providing the strict tissue-specific regulation of NT/N gene expression noted in various tissues.

III. THE NEUROTENSIN/NEUROMEDIN N PEPTIDE

A. Structure

NT is a peptide composed of 13 amino acids. The amino terminus is a pyrrolidone carboxylic acid and resists proteolytic degradation; the inactive degradation product is NT(1–8). The bioactive core, NT(9–13), resides in the carboxy terminus, which is highly conserved among species. The metabolism of NT(1–13) is rapid; therefore, the majority of circulating NT is in the form of the stable NH_2-terminal fragments, primarily NT(1–8) or, less commonly, NT(1–11). The neuromedin N peptide is structurally related to NT, with conservation of the carboxy terminus. Although distribution of neuromedin N is similar to that of NT, the effects of neuromedin N and NT may be different. NT is not lipophilic and thus does not penetrate the blood–brain barrier.

B. Localization

In the GI tract, the NT peptide is localized to enteroendocrine cells (i.e., N cells), predominantly in the small bowel and proximal colon. Similar to the expression pattern of the NT/N gene, N cells are

found in greatest abundance in the distal ileum mucosa. NT immunoreactivity has also been identified in the muscle layers of the gut, mostly in the myenteric plexus. Presumably, in this location, NT functions as a neurotransmitter as it does in the CNS. Within the brain, NT immunoreactivity is primarily located in the substantia nigra, periaqueductal gray matter, amygdala, nucleus accumbens, and some hypothalamic nuclei; lower concentrations are found in the caudate, hippocampus, and globus pallidus.

C. Secretion

The precise signaling mechanisms regulating NT secretion are not entirely known. Fat in the proximal intestine appears to be the most potent stimulus. The initial NT release occurs within 10 min of eating, long before chyme reaches the ileum. Studies have shown that infusion of fat into the jejunum leads to an increase in NT release, whereas infusion of fat into the ileum does not. However, ileal resection abolishes release of NT. Atropine also abolishes this response but truncal vagotomy does not. These findings suggest that NT is released from the ileum via a humoral or neural stimulus from the proximal intestine. Furthermore, the process appears to be cholinergic, but not vagally mediated.

In addition to lipids, *in vitro* experiments using short-term ileal mucosal cell cultures demonstrate that the peptide bombesin directly stimulates NT release that is not abolished by atropine (in contrast to lipid-stimulated release). Catecholamines appear to stimulate NT release via a β-adrenergic receptor. Carbachol stimulates NT release in segments of perfused ileum but has no effect on basal NT release in short-term N cell cultures. In fact, carbachol inhibits β-adrenergic-stimulated NT release; the possible mechanism for these actions has yet to be elucidated. Similarly, substance P stimulates release of NT in neurons and in perfused ileum but not in short-term N cell cultures. Taken together, the data imply that there is more than one pathway affecting NT release (at least one pathway is cholinergically mediated and another is not) and that other mechanisms in the intact organism are required for the activation of release of NT by certain mediators.

IV. NEUROTENSIN RECEPTORS

After secretion, the NT peptide must bind to a receptor in order to produce an effect. Three NT receptors have been identified. The first two receptors, the high-affinity NTS1 and low-affinity nts2, are G-protein-coupled receptors that differ slightly in structure. The recently identified third receptor, nts3, has an altogether different structure compared with NTS1 and nts2.

A. NTS1 Receptor

The high-affinity NTS1 receptor is sensitive to Na^+ ions and guanosine triphosphate (GTP); both substances decrease the affinity of the receptor for NT. This high-affinity receptor is insensitive to levocabastine, an antihistamine-1 that blocks lower affinity binding sites. The NTS1 gene has been sequenced and encodes 424 amino acids (in rats) and 418 amino acids (in humans). The protein has seven transmembrane domains and is considered a G-protein-coupled receptor (Fig. 5). Expression of the NTS1 gene has been identified in the brain and intestine of rats and humans. *In situ* hybridization studies demonstrate high levels of expression in the diagonal band of Broca, medial septal nucleus, nucleus basalis magnocellularis, suprachiasmatic nucleus, supramammillary area, substantia nigra, and ventral segmental area in the brain. In the GI tract, the NTS1 receptor has been identified throughout the small intestine, large intestine, and liver. Following binding with NT, 60–70% of the NTS1 receptor internalizes in a temperature-dependent process; the receptor is not recycled to the cell membrane. After NT binds to this G-protein-coupled receptor, phospholipase C is activated, inducing phosphatidylinositol turnover and mobilization of intracellular calcium. Recent studies have shown that NT binding increases activation of extracellular signal-related kinase (ERK) and c-Jun N-terminal kinase (JNK) (kinases in the Ras pathway). These findings suggest that, like other GI peptides (e.g., cholecystokinin and gastrin), NT activates the Ras pathway via its NTS1 receptor. These observations implicate the Ras pathway in the subsequent downstream effects of NT. Two nonpeptide receptor antagonists synthesized by Gully and colleagues effectively bind NTS1 and prevent many of the actions of NT. SR48692 has been shown to block a number of peripheral and central effects of NT but does not appear to inhibit the hypothermic and analgesic effects of NT. This antagonist binds to a binding site separate from but overlapping that of the NT peptide, thus blocking a portion of the receptor crucial for NT binding. Another antagonist, SR142948A, has been found to have a broader spectrum of activity and also inhibits the

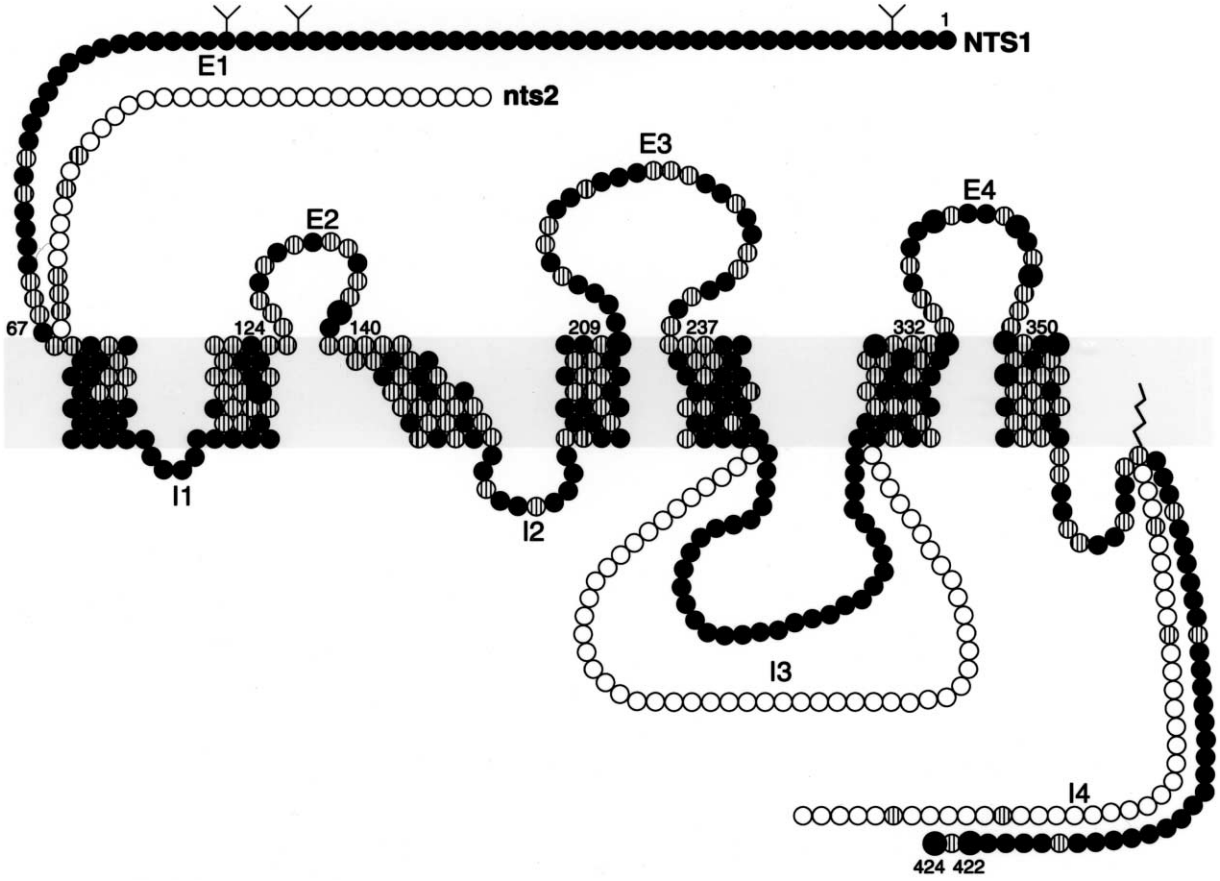

FIGURE 5 Comparison of rat neurotensin receptors NTS1 (•) and nts2. The invariant residues between the NTS1 and nts2 receptors are noted by circles with vertical lines. Regions of the nts2 receptor that vary greatly from NTS1 and are noted by open circles. The N-terminus (1) and C-terminus (424) and the first residues of each extracellular segment of the NTS1 receptor are numbered. Glycosylation sites are highlighted (Y). Residues 422 and 424 are crucial for NTS1 internalization. The third intracellular loop (13) contains a region essential for coupling to phospholipase C. hypothermia and analgesia induced by intracerebroventricular injection of NT.

B. nts2 Receptor

The nts2 receptor is also a G-protein-coupled receptor with seven transmembrane domains. This receptor, in contrast to NTS1, is a low-affinity receptor that can be blocked by levocabastine and is relatively insensitive to Na^+ ions and GTP. The replacement of Asp by Ala or Gly in the second transmembrane domain is believed to be responsible for the decreased affinity of the receptor. This receptor has been localized mostly in the brain. It is specifically expressed in the olfactory system, cerebral and cerebellar cortices, hippocampal formation, and certain hypothalamic nuclei. The nts2 receptor is implicated in NT-induced analgesia. For example, intracerebroventricular injection of antisense oligonucleotides, which specifically block nts2 expression, inhibits NT-induced analgesia. These oligonucleotides have no effect on other receptors. Furthermore, SR48692, which does not block nts2, also does not inhibit NT analgesia.

C. nts3 Receptor

In contrast to the first two receptors, the nts3 receptor is not a G-protein-coupled receptor but has a gp95/sortilin structure (Fig. 6). This receptor has an N-terminal signal peptide, a cleavage site for furin, a long lumenal domain, a single transmembrane domain, and a short cytoplasmic tail; it is stored in vesicles and inserted into the membrane in response to NT. No data are yet available regarding the specific physiologic functions of this newly cloned receptor.

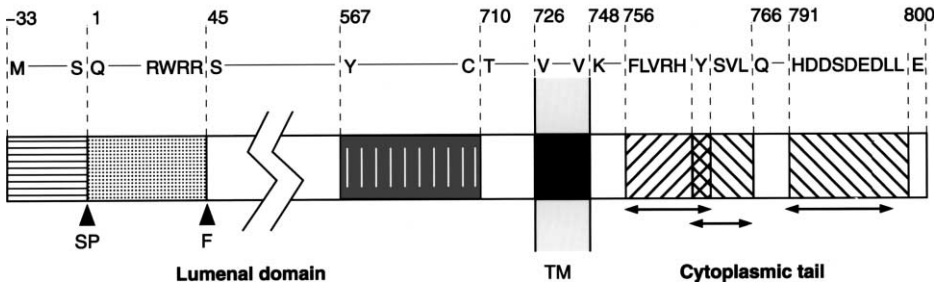

FIGURE 6 The human nts3/gp/sortilin receptor. Numbers indicate the signal peptide (SP) (726–747), the propeptide released by furin (F) cleavage (1–44), the cysteine-rich domain homologous to Vps10p, a yeast receptor for carboxypeptidase Y sorting (567–709), the transmembrane (TM) domain (726–747), and the three internalization/sorting signals in the cytoplasmic tail homologous to the cation-independent mannose 5-phosphate/insulin-like growth factor-II receptor (456–765 and 791–799). Note the partial overlapping between two of these signal sequences. Adapted from Vincent *et al.* (1999), with permission from *Trends Pharmacol. Sci.*

V. EFFECTS OF NEUROTENSIN

NT produces an array of effects in both the CNS and the GI tract. In the CNS, NT functions as a neurotransmitter or a neuromodulator, whereas in the periphery NT can exert its actions via endocrine, paracrine, or neuromodulatory effects.

A. CNS Effects

NT produces significant CNS effects, including hypothermia and a naloxone-insensitive analgesia. NT blocks behaviors associated with activation of dopaminergic pathways, possibly by decreasing the binding efficiency of dopamine to its receptors. Centrally administered NT has been shown to mimic the actions of many antipsychotic drugs. NT, like antipsychotic medications, potentiates the sedation elicited by barbiturates and ethanol, decreases amphetamine-induced locomotor activity, and induces muscle relaxation and hypothermia. Administration of various antipsychotic drugs increases NT concentrations in the caudate nucleus and nucleus accumbens. This effect is preceded by an increase in c-*fos* mRNA levels in the dorsolateral stratum. Typical antipsychotic medications (e.g., haloperidol) induce NT/N expression in the striatum and nucleus accumbens. On the other hand, administration of atypical antipsychotic medications (e.g., clozapine), which are not associated with extrapyramidal side effects (EPSs), results in increased NT/N expression in the nucleus accumbens only. Recent studies using NT/N null mice demonstrate that NT is required for haloperidol-elicited activation of a specific population of striatal neurons; however, the incidence of catalepsy (the model for EPS in mice) was not different in NT/N null mice. These findings indicate that NT mediates the effects of a specific subset of antipsychotic agents but does not contribute to the generation of extrapyramidal side effects.

B. Peripheral Effects

1. Vascular and Hemodynamic Effects

The NT peptide was initially described as a "hypotensive peptide." In reality, the vascular and hemodynamic effects are more complicated than initially described. NT release can lead to either hypotension or hypertension by inducing either histamine release or adrenergic release, respectively. Other hemodynamic effects include decreasing blood flow to adipose tissue and increasing blood flow in the intestine without altering heart rate or blood pressure.

2. Immune Function

Similar to other gut peptides, NT has an effect on immune function. Macrophages demonstrate enhanced phagocytosis in response to NT treatment. Mast cells respond to NT by releasing histamine; the response can be antagonized in rats with diphenhydramine (an antihistamine). In lymphocytes, NT can enhance proliferation, adherence, and chemotaxis. Because the small intestine has a high concentration of immunologically active cells, NT may affect immune function via paracrine effects. In rats, NT has also been shown to be a proinflammatory agent in the colonic inflammation associated with *Clostridium difficile* pseudomembranous colitis. This proinflammatory action is blocked by SR48692.

3. Effects on GI Nutrient Absorption, Motility, and Secretion

Some of the physiologic effects of NT in the GI tract are related to motility. An infusion of NT mimics

the consumption of a fat-rich meal (the most potent stimulator of NT release) in the following ways: NT decreases lower esophageal sphincter pressure, slows gastric emptying and intestinal transit while increasing colonic motility, and inhibits the migrating motor complex (MMC).

In addition to effects on GI motility, NT inhibits gastric acid secretion in a vagally dependent manner. Some debate exists regarding whether concentrations of NT that are present physiologically are sufficient to induce this effect. In contrast to gastric acid secretion, NT stimulates pancreatic bicarbonate and protein secretion in a dose-related fashion and has an additive effect in combination with secretin and/or cholecystokinin. NT potently stimulates biliary secretion of water, bicarbonate, and bile salts. Secretin is more effective than NT in stimulating secretion of bicarbonate and bile salts, but NT is more effective in stimulating secretion of bile water. A recent study demonstrates that NT also enhances jejunal absorption of conjugated bile acids and their return to the liver. Additional effects of NT include a net fluid secretion into the postduodenal small intestine and facilitation of lipid absorption from the proximal intestine.

4. Trophic Effects

NT, given exogenously, has trophic effects on normal tissues as well as on certain cancers. Given in high doses, NT can induce growth of the gastric antrum, small intestine, and pancreas. In rats given an elemental diet, intestinal mucosal atrophy ensues; administration of NT can prevent this atrophy in the jejunum but not in other areas of the small bowel. NT can also augment the adaptive hyperplasia of intestinal mucosa associated with small bowel resection. Other studies demonstrate that NT stimulates mucosal growth in defunctionalized, self-emptying jejunoileal loops or isolated loops of small bowel (Thiry–Vella fistulas). Moreover, NT has been shown to restore gut mucosal integrity in rats and to prevent translocation of indigenous bacteria after radiation-induced mucosal injury.

In addition to its effects on normal tissues, NT has been shown to have a trophic effect on pancreatic and colon cancers that possess NT receptors. NT receptors have also been found in non-GI tumors, such as prostate cancer, in which NT has a similar trophic effect. Recent studies utilizing sensitive RT-PCR procedures have identified NT receptor expression in a majority of pancreatic adenocarcinomas. Although not universally expressed in human colon cancer cell lines, NT receptor expression has been identified in a more metastatic colon cancer cell line (i.e., KM20 cells). *In vitro* and *in vivo* experiments using the human pancreatic cancer line MIA PaCa-2, which possesses high-affinity NT receptors, have demonstrated growth in response to NT. NT treatment of athymic nude mice bearing MIA PaCa-2 xenografts results in increased tumor size, weight, and DNA and protein content. The NT receptor antagonist SR48692 inhibits these trophic effects. NT enhances colon carcinogenesis in rats and stimulates growth of MC-26 (mouse) and LoVo (human) colon cancer cells. These findings suggest a role for NT in the growth of GI cancers with high-affinity NT receptors. Therefore, analogous to current treatment strategies for endocrine-responsive breast and prostate cancers, NT receptor antagonists may play an adjuvant role in the treatment of certain GI and pancreatic cancers.

VI. CONCLUSIONS/FUTURE PERSPECTIVES

Since its initial description almost 30 years ago, much has been learned regarding the regulation and actions of the NT peptide. The cloning of the NT/N gene in multiple species, the identification and cloning of the NT receptor genes, the synthesis of potent NT receptor antagonists, and the development of NT/N knockout mice are recent important developments that have greatly facilitated our understanding of these functions. Collectively, NT has been identified as an important contributory hormone for the maintenance of both gut structure and function. In the GI tract, NT affects intestinal motility, pancreaticobiliary secretion, fat absorption, and growth of normal and neoplastic tissues. In the CNS, an apparent important role for NT appears to be related to the blockade of dopaminergic pathways that have important ramifications in the effects of many psychotropic agents.

Future studies will further extend our current understanding of the effects of NT. Previous studies have identified the NT/N gene as a "model" intestinal gene to further delineate the complex differentiation pathways leading to gut development and maturation, as well as the process of fetal "dedifferentiation" noted in certain colon cancers. Understanding the factors regulating NT/N expression will yield important information on the regulation and attainment of the complete gut phenotype, thus not only providing a better understanding of normal gut development and function, but also providing a model to better understand the cellular events leading to gut neoplasia. The multitude of actions of NT, particularly its trophic and neuroleptic effects, suggest a potential future role for NT as a pharmacologic agent. The fact

that NT is secreted in response to a fatty meal and induces delayed gastric emptying and intestinal motility suggests that NT may play a role in satiety and may be useful in the treatment of obesity. The trophic effects of NT on normal intestinal mucosa suggest that NT may be useful in stimulation of intestinal growth during periods of gut disuse, after small bowel resection, or with administration of chemotherapeutic agents. Furthermore, blocking NT receptors using potent receptor antagonists may be useful as adjuvant therapy in the treatment of certain NT receptor-positive colon and pancreatic cancers. Overall, the analysis of NT in the past has yielded important and clinically relevant information regarding its structure, expression pattern, role in development, secretion, and diversity of actions. It is anticipated that future studies, utilizing sophisticated molecular models and more specific receptor antagonists, will provide additional important information regarding the precise role of this novel peptide in GI and CNS functions, as well as exciting new therapies with diverse clinical implications.

Glossary

Gp95/sortilin receptor Type of receptor that contains only one transmembrane domain.

G-protein-coupled receptor Type of receptor that contains seven transmembrane domains.

N cells Enteroendocrine cells localized to the intestine; produce and secrete neurotensin and neurotensin-related peptides; categorized as "open" cells, in which the apical microvilli are in contact with the intestinal lumen.

neuromedin N Hexapeptide that is encoded on the same gene as neurotensin and has a similar distribution pattern.

neurotensin Tridecapeptide that is found in the brain and gastrointestinal tract.

Neurotrophins

Y.-A. BARDE

Friedrich-Miescher Institute for Biomedical Research, Switzerland

The neurotrophins constitute a small family of structurally related proteins. They are primarily known for their ability to affect key aspects of the biology of vertebrate neurons, including neuronal survival and death, dendrite and axonal elongation, and activity-dependent plasticity. The term "neurotrophin" was introduced subsequent to the finding that the sequence of the protein brain-derived neurotrophic factor was related to that of nerve growth factor. In mammals, two additional genes have been identified and they are designated neurotrophin-3 and neurotrophin-4. All four neurotrophins act through two structurally unrelated receptors designated Trk and p75. Neurotrophins can both prevent program cell death and cause it. In addition, they affect the shape of neurons as well as synaptic transmission.

I. NEUROTROPHIN: BIOCHEMISTRY AND MOLECULAR BIOLOGY

A. Biochemistry

All neurotrophins are small (approximately 120 amino acids), basic (pI 9–10) proteins (Fig. 1). They are strongly similar in primary structure and are found in solution as noncovalently, tightly linked homodimers. They are secretory proteins and their cleavable leader sequence is followed by a pro-sequence of variable length [80 aa for the shortest one, human neurotrophin-4 (NT4)]. Cleavage of the pro-sequence occurs at a consensus sequence of the furin type found in all neurotrophins (R-X-K/R-R) to yield the mature and biologically active neurotrophins. However, recent evidence indicates that pro-neurotrophins may also be secreted and that in comparison with mature neurotrophins they have a higher affinity for the neurotrophin receptor p75 and a lower affinity for the Trk receptors. The functional consequence of this characteristic would be a shift toward the death-promoting activity of neurotrophins.

Each mature monomer comprises six cysteine residues involved in the formation of three disulfide bridges. The crystal structure of the neurotrophin dimers has revealed that the disulfide bridges are all grouped at one end of the molecule in the homodimers in an arrangement similar to that found in the transforming growth factor-β superfamily and in the platelet-derived growth factors.

Nucleotide sequences are available for several mammalian species, and approximately 50% of the amino acids are common to all neurotrophins, including the six cysteine residues. With the exception of NT4, neurotrophins are highly conserved between species. For example, there are no amino acid replacements in the mature sequence of brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT3) in most mammals. Additional neurotrophin sequences have been reported in teleost fishes, but no neurotrophin sequence has been detected in the genome of *Caenorhabditis elegans* and *Drosophila melanogaster*. Similarly, these latter two genomes do not contain sequences corresponding to the neurotrophin receptors p75 or Trks.

B. Molecular Biology

In human, *ngf* (nerve growth factor gene) has been localized to chromosome 1q21–q22.1, *bdnf* has been localized to 11q13, *nt3* has been localized to 12q13, and *nt4* has been localized to 19q13.3. The neurotrophin genes are large (at least 40 kb) and contain several small 5′ exons and a larger 3′ exon that contains most of the translated sequence. The neurotrophin genes encode several transcripts from at least four different transcription start sites. Also, they have short or long 3′-untranslated regions. These genes are transcribed as a major transcript of approximately 1.3 to 1.6 kb and often a larger transcript of approximately 4.3 kb. Their relative abundance depends on the tissue in question. In the brain, neurons are the major cellular site of neurotrophin gene expression and there are considerable differences in the degree of expression between different brain areas and developmental stage. Typically, gene expression is regulated by electrical activity. In particular, increased activity leads to rapid increased transcription of the *ngf* and *bdnf* genes, and decreased activity reduces the expression of *bdnf*. Outside of the central nervous system (CNS),

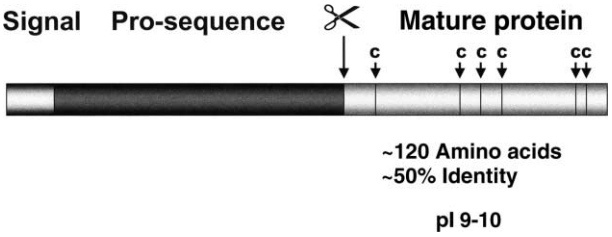

FIGURE 1 Neurotrophins are synthesized as pre-pro proteins. Cleavage occurs following a cluster of basic amino acids. The six cysteine residues indicated in the mature proteins are involved in the formation of three disulfide bridges. Neurotrophins occur in solution as tightly packed homodimers.

numerous cell types express the neurotrophin genes, including Schwann cells, skeletal muscle cells, and smooth muscle cells, as well as cells from heart and lung tissue. Expression has also been detected in cells of the immune system, including lymphocytes.

II. NEUROTROPHIN RECEPTORS

Neurotrophin signaling is quite complex and diverse. There are two different receptor types that bind the neurotrophins, p75, and the Trks (Fig. 2). These receptors can mediate actions as diverse as promoting or preventing the death of neurons. Also, these two receptor types associate in the membrane, and these associations lead to increases in the specificity and affinity of the receptor complex.

A. p75

The neurotrophin receptor p75 was the first member of a large family of receptors, which includes both tumor necrosis factor receptors and CD95, to be molecularly cloned. It was initially designated the nerve growth factor (NGF) receptor. This designation was revisited following the realization that all neurotrophins bind to this receptor and that the Trk receptors also bind neurotrophins (see below). At least two proteins are encoded by *p75*, one of them lacking three of the four cysteine-rich domains that characterize the extracellular domains of all members of the p75 family. Like all other members, p75 has no intrinsic catalytic activity and it transduces signals by associating with, or dissociating from, cytoplasmic partners. There are several protein association motifs in the cytoplasmic domain of p75, one being distantly related to the so-called "death domain" of other members of the family. Also of note is a short sequence of the intracellular domain of p75 that is related to the sequence of mastoparan, a 14-mer peptide derived from wasp venom and capable of directly activating G-proteins. The C-terminus forms a consensus sequence found in several other proteins associating with postsynaptic densities, such as postsynaptic density-95. A number of proteins have been shown to associate with the cytoplasmic domain of p75.

All mature neurotrophins tested bind to p75 with an affinity of approximately 10^{-9} M. Recently, pro-NGF was demonstrated to bind to p75 with a 10-fold higher affinity than mature NGF and to bind to the TrkA receptor with a distinctly lower affinity than mature NGF.

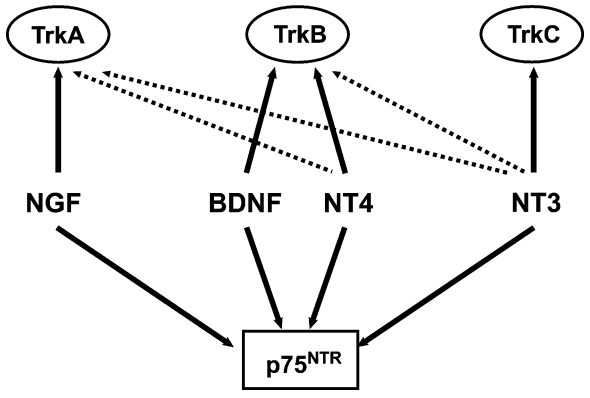

FIGURE 2 Neurotrophins bind two different kinds of receptors. All bind to the receptor p75 with an affinity of at least 10^{-9} M. They also bind to the Trk family of tyrosine kinase receptors. TrkC binds exclusively to NT3, TrkA shows a preference for binding to NGF, and TrkB binds preferentially to BDNF and NT4. NT3 also binds to TrkA and TrkB. All three Trk receptors associate with p75, and this association modulates both the binding specificity and the affinity of the Trk receptors.

B. Trk Receptors

In mammals, three Trk receptors have been identified: TrkA, TrkB, and TrkC. TrkA binds NGF and to a lesser extent NT3, TrkB binds preferentially to BDNF and NT4, though NT3 can also bind to and activate TrkB, especially in the absence of p75 co-expression, and TrkC binds to NT3 exclusively (Fig. 2). As with the neurotrophins, additional Trk receptors have been identified in teleost fishes. Ligand binding leads to receptor-mediated tyrosine phosphorylation. This triggers the activation of pathways leading to some of the best known actions of the neurotrophins, including the prevention of programmed cell death and neuronal differentiation. Three main signaling cascades are activated by the Trk receptors and their substrates: the Ras/Raf/MEK/mitogen-activated protein kinase pathway, phosphatidylinositol 3-kinase, and phospholipase C-γ. At the level of the nerve terminals, the association of neurotrophins with Trk receptors triggers the process of retrograde transport, allowing signals to be transported from the terminals back to the cell body of neurons.

A number of splice variants have been described for the Trk receptors. The most abundant variants are forms of TrkB and TrkC that lack the kinase domain. These truncated TrkB receptors are often expressed in nonneuronal cells in the absence of TrkB.

C. Expression of Neurotrophin Receptors

The expression of both types of neurotrophin receptors is tightly regulated. Typically, only specific subgroups of neurons express one particular Trk receptor. The specificity of the neurotrophins for subgroups of sensory neurons correlates strongly with the selectivity of Trk receptor expression on these neurons. In the peripheral nervous system (PNS), neurotrophins are often expressed in the peripheral targets of those neurons needing neurotrophins for survival in the embryo. In the adult, these target-derived neurotrophins regulate the functional properties of the neurons, including the levels of neurotransmitters and dendritic development. As in the central nervous system, some of the neurotrophin genes are also expressed by neuronal cell bodies, and BDNF in particular is expressed by some sensory neurons and transported in an anterograde manner. It is released by NGF-dependent neurons in the spinal cord, where it affects neurotransmission. p75 is co-expressed with the Trk receptors in many neuronal populations. Its expression profile is highly developmentally regulated. During postnatal development, p75 is down-regulated in most parts of the central nervous system, but it is rapidly induced after nerve lesion or seizure. This receptor is also expressed by many cells, such as neural crest cells, by the time they become postmitotic cells and/or migrate.

III. NEUROTROPHINS AND NEURONAL SURVIVAL

A. Neurotrophins Promote Neuronal Survival

Neurotrophins typically support the survival of embryonic neurons that die in their absence. Thus, antibodies to NGF, like the deletion of the *ngf* or *trkA* gene, lead to the virtually complete destruction of the peripheral sympathetic nervous system as well as to the loss of many neural crest-derived sensory neurons. BDNF, NT3, and NT4 also support the survival of subpopulations of peripheral sensory neurons, including those derived from epidermal placodes, which are not supported by NGF. With the exception of NGF, neurotrophins support the survival of embryonic rat motoneurons *in vitro*, and BDNF prevents their death *in vivo* after axotomy. NGF and to a lesser degree BDNF prevent the loss of cholinergic function seen after axotomy in adult animals. BDNF also supports the survival of dopaminergic neurons dissociated from the rodent mesencephalon as well as of retinal ganglion cells. In the mature nervous system, neurotrophins are involved in the maintenance of neuronal phenotypes; in particular, antibodies to NGF decrease the levels of enzymes synthesizing catecholamines as well as neurotransmitters such as substance P in the peripheral nervous system of adult animals. Neurotrophins also act on some nonneuronal cells, and NT3 in particular contributes to the division and survival of oligodendrocyte precursors. In aged, learning-deficient rats, the intraventricular injection of NGF can reverse the learning deficiencies in simple behavioral tests. Decreased levels of BDNF mRNA have been noted in the hippocampus of patients with Alzheimer's disease.

B. Neurotrophins Cause Programmed Cell Death

Like other receptors belonging to the same family, such as CD95, p75 causes the death of neurons in the developing CNS. This occurs in the developing retina and spinal cord. Also, basal forebrain cholinergic neurons express p75 at high levels, and its complete elimination leads to a long-lasting increase in the number of basal forebrain cholinergic neurons. Cultured oligodendrocytes up-regulate p75 expression and they can be killed by the addition of NGF. NGF is not the only ligand able to activate p75 to cause cell death, and in developing sympathetic ganglia, BDNF also causes cell death through p75.

IV. NEUROTROPHINS AND NEURONAL PLASTICITY

A. Regulation of Process Outgrowth

Beyond their effects on the control of neuronal survival, neurotrophins also have pronounced effects on the size of neurons, on the rate of axonal elongation, and on the growth and branching of dendrites. In adult animals, the administration of NGF causes the length of dendrites of sympathetic neurons to increase. Conversely, antibodies to NGF decrease the length of these dendrites. When such experiments are performed in newborn animals, the increased number of dendrites caused by NGF administration is accompanied by a very large increase in the number of preganglionic axons. In mice carrying a deletion in the pro-apoptotic gene *bax,* the effects of neurotrophins on axonal elongation can be examined in the absence of effects

on survival. In such animals, the lack of neurotrophins or of their corresponding Trk receptors causes a dramatic reduction in the number of peripheral axons. Neurotrophins are required for the elongation of peripheral nerves. Indeed, the acute application of a combination of function-blocking monoclonal antibodies causes a marked reduction in the elongation of both sensory and motor nerves. Also, the neurotrophins are able to attract sensory and sympathetic nerves. Similar mechanisms seem to operate in the CNS, as exemplified by work using live tadpoles and slices of the visual cortex. The effects of neurotrophins appear to be complex and different for apical or basal dendrites. The effects are also specific for each neurotrophin tested and the results indicate that each neurotrophin can act to modulate particular patterns of dendritic arborization. The regulation of cortical dendritic growth by neurotrophins requires endogenous electrical activity.

B. Neurotrophins and Synaptic Transmission

Neurotrophins regulate the number of synapses and the efficacy of synaptic transmission. NGF levels modulate both the strength and the number of presynaptic inputs in sympathetic ganglia. In mice overexpressing BDNF in sympathetic neurons, increased numbers of synapses are observed, whereas in *bdnf* −/− animals, a decreased number of synapses are found. Presynaptic alterations and a decreased number of synapses are observed in the absence of TrkB and TrkC receptors.

Neurotrophins rapidly modulate neurotransmission, both in the PNS and in the CNS. Some of these effects occur very rapidly after the application of the neurotrophins. Within milliseconds, BDNF and NT4 cause depolarization and elicit action potentials in pyramidal cells of the hippocampus or cortex and in Purkinje cells of the cerebellum. This depolarization results from an increased conductance for sodium ions, and it is as rapid as that induced by the neurotransmitter glutamate.

BDNF modulates synaptic transmission in the hippocampus, as reflected by its role in long-term potentiation. This has been demonstrated in animals lacking *bdnf*, as well as by the use of specific monoclonal antibodies.

BDNF is not only stored in neurons, it is also released from internal stores by activity-dependent mechanisms. It is present in presynaptic nerve terminals and also in dendrites, where it co-localizes with the postsynaptic markers.

In the visual cortex, neurotrophins are involved in activity-dependent developmental plasticity. Neurotrophins influence the formation of ocular dominance columns in the visual cortex and promote the maturation of cortical inhibition.

C. Neurotrophins and Behavior

Detailed explorations of the heterozygous *trkB* and of conditional mutants reveal that these animals become increasingly impaired over time with regard to their spatial learning behavior, similar to the phenotype in mice with hippocampal lesions. *Bdnf* +/− animals develop an enhanced aggressiveness and hyperphagia, accompanied by weight gain. BDNF is also necessary for canaries to learn new songs. Interestingly, testosterone treatment increases the levels of BDNF in the high vocal center.

Glossary

brain-derived neurotrophic factor Protein purified from pig brain in the 1980s by monitoring its ability to prevent the death of peripheral sensory neurons.

nerve growth factor (NGF) The first neurotrophin to have been identified in the 1950s. It was purified on the basis of its ability to elicit neurite outgrowth from ganglionic explants. The extraordinary and unexplained abundance of NGF in the adult male mouse submandibular gland was a prerequisite for its early characterization.

neurotrophin-3 Identified on the basis of sequence homologies to the previously sequenced proteins nerve growth factor and brain-derived neurotrophic factor.

neurotrophin-4 First identified in *Xenopus laevis* cDNAs and subsequently detected in rodents and humans. Its sequence is more variable between species than the other three neurotrophins. It was initially designated neurotrophin-4 or neurotrophin-5 but it is likely to be the same protein in different species.

p75 A glycoprotein of 75,000 Da that binds all neurotrophins. It was identified in the mid-1980s by expression cloning.

tropomyosin receptor kinases (Trks) A small group of closely related tyrosine kinase membrane receptors that are activated by neurotrophin binding. Trk was first recognized as an oncogene made up of the kinase domain of Trk fused with a portion of *tropomyosin*. The proto-oncogene was later found to be a nerve growth factor receptor.

Nitric Oxide

DEREK P. G. NORMAN* AND ANTHONY W. NORMAN†
*Harvard University • †University of California, Riverside

Nitric oxide (NO) is one of the body's many hormones. It is unique in that it is the only animal hormone that is a gas. NO, however, is somewhat water soluble and is able to function as a chemical messenger, particularly in cells of the vascular endothelium, immune, and neural systems. Virtually all of the known biological actions of NO on the cardiovascular system are mediated by the activation of a guanylate cyclase, which produces the second messenger cyclic GMP that leads to vasorelaxation (lowered blood pressure).

I. INTRODUCTION

A relatively surprising addition to the family of chemical messengers is nitric oxide (NO). NO is a free radical gas of limited solubility in water. Because NO is noncharged, it can rapidly diffuse across cell membranes and into cells; it has been shown to act as both an intracellular and an intercellular (paracrine) messenger to elicit a wide spectrum of biological responses. A physiological function for NO was first established in the vascular system when the endothelin-derived relaxing factor (EDRF) could be quantitatively explained by the formation of NO. NO is now known to be an integral participant in the signal transduction processes associated with the vascular, immune, and neural systems.

II. CHEMISTRY, BIOSYNTHESIS, AND SECRETION

The formation of NO is an enzyme-mediated reaction (see Fig. 1); the nitrogen donor is the amino acid L-arginine and the oxygen donor is molecular oxygen. The reaction is catalyzed by an NADPH-requiring nitric oxide synthase (NOS). NOS enzymes are structurally related to cytochrome P450 reductase and range in size from 13 to 160 kDa.

NOS exists both as a constitutive enzyme, which is regulated by Ca^{2+} and the calcium-binding protein, calmodulin, and as an inducible enzyme, which is not

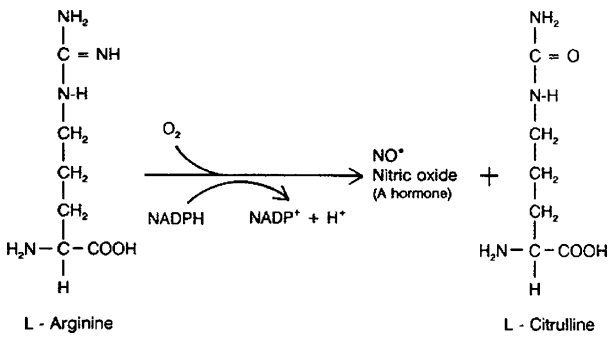

FIGURE 1 Enzymatic reaction catalyzed by nitric oxide synthase (NOS).

regulated by calmodulin. The regulatable forms of NOS are induced by interferon-α (INF-α), tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), and estradiol and are inhibited by glucocorticoids. The inducible forms of NOS are associated with components of the host defense immune system.

There is clear evidence that under some physiological circumstances the classical estrogen receptor, when occupied by its cognate hormone, estradiol, can initiate a signal transduction process that activates NOS. One novel aspect of this activation process is that the estrogen receptor for this biological response is localized not in the nucleus but in caveolae found in the cell's plasma membrane. Caveolae and caveolae-related membrane domains are enriched in molecules that play pivotal roles in intracellular signal transduction. In this setting, the steroid hormone estradiol is not working with its receptor to regulate the traditional response of regulation of gene transcription (over hours to days), but is instead generating a rapid response (over seconds to minutes) via a non-nuclear signal transduction process that results in NOS activation. This system of signal transduction has been particularly documented to occur in vascular endothelial cells where estradiol is known to modulate the local cell biology.

III. BIOLOGICAL ACTIONS OF NO

The wide spectrum of biological actions of NO in the cardiovascular, nervous, and host defense systems is summarized in Table 1. Only the actions of NO in the cardiovascular system are discussed in this article.

TABLE I Biological Actions of Nitric Oxide in the Cardiovascular, Nervous and Host Defense Systems

System	Response
Cardiovascular	
Smooth muscle	Initiate vasorelaxation; control of regional blood flow and blood pressure
Platelets	Limitation of aggregation and adhesion
Nervous	
Peripheral	Neurotransmission (penile erection, gastric emptying)
Host defense	
Macrophages	Defense against bacteria, fungi, protozoans, parasites, and viruses
Leukocytes	
Monocytes	

After the generation of NO in the endothelial cell by the NOS enzyme, the NO diffuses to an adjacent smooth muscle where it acts as an agonist to initiate biological responses (see Fig. 2). Virtually all of the known biological actions of NO on the cardiovascular system are mediated by the activation of a soluble guanylate cyclase. The guanylate cyclase has a heme prosthetic group to which NO binds tightly to this moiety. The resulting activation of the guanylate cyclase results in the production of cGMP, which is then postulated to have actions on protein kinases, nucleotide-sensitive phosphodiesterases,

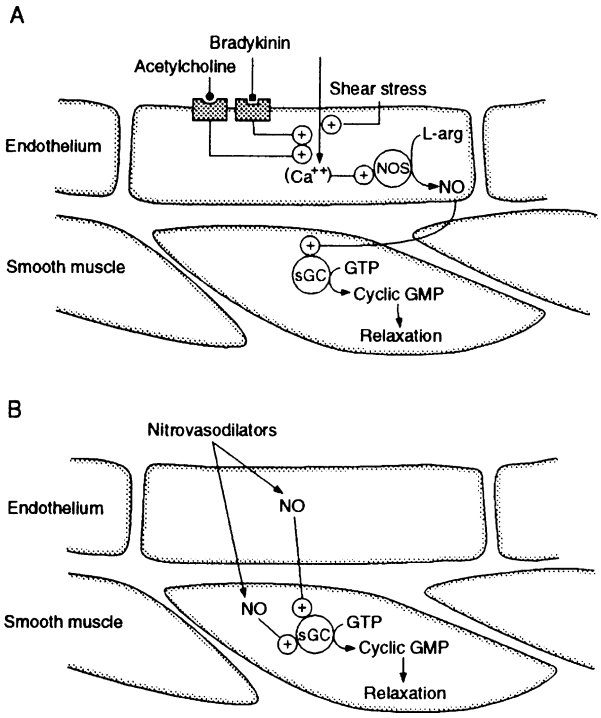

FIGURE 2 Model for the synthesis of NO in endothelial cells and its paracrine actions in smooth muscle cells. In (A), shear stress or receptor activation of vascular endothelium by bradykinin or acetylcholine results in an influx of calcium. The consequent increase in intracellular calcium stimulates the constitutive nitric oxide synthase (NOS). The nitric oxide (NO) formed from L-arginine (L-Arg) by this enzyme diffuses to nearby smooth muscle cells, in which it stimulates the soluble guanylate cyclase (sGC), resulting in enhanced synthesis of cyclic GMP from guanosine triphosphate (GTP). This increase in cyclic GMP in the smooth muscle cells leads to their relaxation. In (B), nitrovasodilators such as sodium nitroprusside and nitroglycerin release NO spontaneously or through an enzymatic reaction. The liberated NO stimulates the soluble guanylate cyclase in the vascular smooth muscle cell, resulting in relaxation. [Adapted from Moncada, C., and Higgs, A. (1993). The L-arginine-nitric oxide pathway, *New Engl. J. Med.* **329**, 2002–2012.]

ion channels, or other unknown cellular proteins that are linked to the generation of the smooth muscle response of vasodilation and also to the inhibition of platelet adhesion and aggregation.

NO is a short-lived agonist in the cellular environment. NO is inactivated either by its chemical linkage to proteins (nitrosylation) or by oxidation to nitrite (NO_2^-) and then nitrate (NO_3^-).

IV. SUMMARY

In the normal physiological state in humans, the distribution, composition, and volume of body fluids are held within relatively narrow limits, despite wide variations in the intake of water and Na^+. Such homeostasis or stability of the internal environment requires a multifactoral collaboration of the hormones and other physiological processes that affect electrolyte and water metabolism. A diverse array of hormones (aldosterone, angiotensin II, rennin, atrial natureatic protein or ANP, NO, endothelin, vasopressin, prostaglandins, and kinins) and signal transduction systems, each responding to different stimuli, is integrated to provide the kidney and cardiovascular system with coherent messages to effect the collective regulation of blood pressure, electrolyte concentration, and water volume.

Glossary

caveolae Sub-domains of the cell's plasma membrane that have a typical flask-like membrane structure where signal transduction molecules may congregate.

endothelium The monolayer of cells lining the inner wall of the vascular system.

estradiol A steroid hormone that belongs to the family of estrogens.

free radical A molecule, usually short-lived and highly reactive, that contains an unpaired electron. All molecules containing an odd number of electrons are free radicals.

nitric oxide A molecule composed of one atom of oxygen and one atom of nitrogen, with the chemical formula NO, which chemically is a free radical. NO is one of the body's many hormones; it is unique in that it is the only animal hormone that is a gas.

basic fibroblast growth factor in human umbilical vein endothelial cells, and expression of granulocyte colony-stimulating factor and granulocyte/macrophage colony-stimulating factor in human endothelial cells. On the other hand, OSM has been reported to down-regulate the expression of cytochrome P450 in human hepatocytes.

IV. BIOLOGICAL ACTIVITIES OF OSM (II)

OSM is secreted from activated T cells and monocytes stimulated by cytokines, T-cell activators, and phorbol 12-myristate 13-acetate (PMA) and plays roles in several inflammatory reactions. OSM increases the secretion of acute-phase proteins (APPs), such as haptoglobin, α1-antichymotrypsin, and fibrinogen, in liver cells at the early phase of inflammation. In the inflammatory process, the remodeling of the extracellular matrix is important for healing the damaged tissue induced by inflammatory responses. Matrix metalloproteinases (MMPs) are involved in extracellular matrix breakdown, and tissue inhibitors of metalloproteinases (TIMPs) inhibit the action of MMPs. Therefore, the balance between TIMPs and MMPs is important for the remodeling of the extracellular matrix. OSM induces TIMP-1 expression and inhibits IL-1β-induced TIMP-3 in cultured human synovial-lining cells. OSM induces the expression of MMP-1 and MMP-3 in astrocytes and of MMP-1 and MMP-9 in fibroblasts. Thus, OSM may be involved in wound healing by modulating the balance between TIMPs and MMPs. It is also known that another family member, IL-6, strongly affects inflammatory reactions. In fact, IL-6-deficient mice exhibit the reduced production of APPs and the delayed repair of the liver injury induced by carbon tetrachloride. Since OSM induces the IL-6 receptor in human hepatoma HepG2 cells and stimulates the production of IL-6 in cultured human endothelial cells, OSM affects inflammation not only directly, but also indirectly through the induction of other members of this family.

V. STRUCTURE OF THE OSM RECEPTOR

It is known that different cytokines exhibit similar biological activities on the same cell type (functional redundancy). The functional redundancy among the cytokines of the IL-6 family is now well explained by their receptor structure. Functional receptors for this family of cytokines consist of multiple subunits including the common signal transducing subunit, gp130 (Fig. 1). The receptor complexes for IL-6 and IL-11 consist of a ligand-specific α receptor subunit and gp130. The binding of each cytokine to its specific α-subunit induces the dimerization of gp130. The LIF receptor consists of the low-affinity LIF-binding protein (LIFRβ) and gp130. LIF binding leads to heterodimerization of LIFRβ and gp130. The CNTF receptor is composed of the CNTF-specific α-subunit, LIFRβ, and gp130. Although OSM is a cytokine that binds with low affinity to gp130 directly, it is not enough to transduce its signals. In human, two types of functional OSM receptor are known: the type I OSM receptor is identical to the high-affinity LIF receptor that consists of gp130 and LIFRβ, and the type II OSM receptor consists of gp130 and the OSM-specific receptor β-subunit (OSMRβ). OSMRβ is expressed in a wide variety of cell types, including endothelial cells, hepatic cells, lung cells, skin cells, and many tumor cell lines. Although LIF and OSM share a number of biological functions in common, it is also known that OSM displays some specific biological properties that are not shared by LIF, e.g., growth inhibition of A375 melanoma cells and up-regulation of α1-proteinase inhibitor in lung-derived epithelial cells. Thus, many overlapping biological responses between hOSM and hLIF are mediated by the shared type I receptor, i.e., the LIF receptor, whereas OSM manifests its specific responses through the type II receptor. However, this is not the case for mOSM. Immediately after the isolation of the mOSM cDNA, it was recognized that there are some differences in biological activity between human and murine OSM. For example, it was shown that a more than 30-fold higher concentration of mOSM is required for the growth inhibition of M1 cells compared with hOSM. Likewise, mOSM is much less potent than hOSM in the inhibition of differentiation of mouse embryonic stem (ES) cells. Molecular cloning of mouse OSMRβ cDNA and reconstitution of the high-affinity functional OSM receptor revealed that mOSM transduces signals only through its specific receptor complex composed of gp130 and OSMRβ, but not through the LIF receptor (Fig. 2). Interestingly, hOSM binds to the mouse LIF receptor and transduces signals; however, it fails to transduce signals through the mouse OSM receptor. Thus, the biological functions of hOSM observed in mouse cells are likely to represent mouse LIF functions.

VI. SIGNAL TRANSDUCTION PATHWAY

Cytokines bind to their receptors on the target cells and then initiate various downstream signaling cascades (Fig. 3). The IL-6 family cytokine receptors

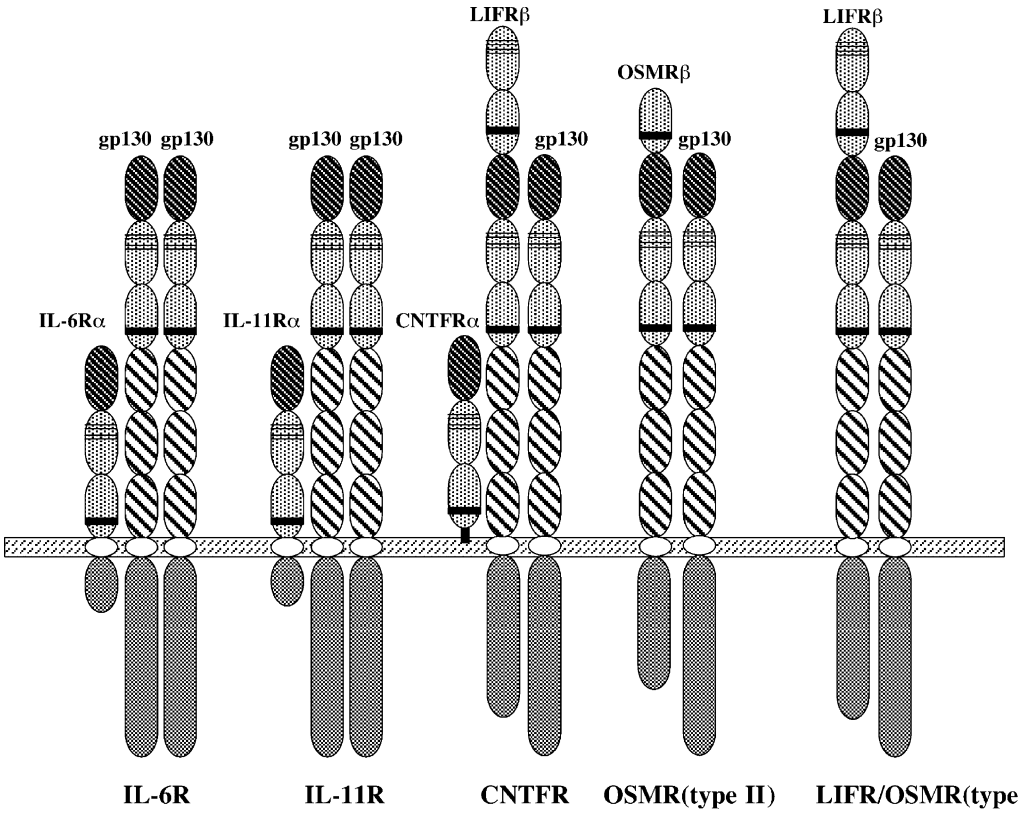

FIGURE 1 Composition of the IL-6 family cytokine receptor complex. IgG-like domains and fibronectin type III-like domains are shown as dark gray and diagonally striped symbols, respectively. The light gray area shows a cytokine-binding module containing the conserved cysteine residues (thin horizontal lines) and WS motifs (thick horizontal lines).

do not possess an intrinsic tyrosine kinase but utilize JAKs/STATs as major mediators of their signals. The first step in receptor activation is the ligand-induced homo- or heterodimerization of signal-transducing receptor subunits. As each signal-transducing receptor subunit binds one JAK (JAK1, JAK2, and Tyk2), dimerization of the subunits leads to the reciprocal phosphorylation and activation of JAKs. The activated JAKs phosphorylate tyrosine residues in the intracellular domain of the receptor, creating docking sites for STATs as well as various signaling molecules with an SRC homology 2 (SH2) domain. These molecules that are recruited to the receptors are then activated by JAKs. Phosphorylated STATs (STAT1, STAT3, and STAT5) then form homo- or heterodimers and translocate to the nucleus, where they are involved in gene regulation. A difference in signal transduction between type I and type II OSM receptors has also been reported. STAT5b is predominantly activated by the OSM-specific type II receptor in the A375 cell line. The IL-6-type cytokines stimulate not only the JAK/STAT signaling pathway but also the Ras/Raf/mitogen-activated protein kinase signaling pathway. It is known that several adapter molecules, such as SHP-2 (SH2 domain-containing protein tyrosine phosphatose 2), Grb2 (growth factor receptor-bound protein 2), and Gab1 (Grb2-associated binder-1), are involved in this pathway. Thus, OSM regulates complex biological responses, such as cell growth, differentiation, and apoptosis, through these signaling pathways.

VII. SUMMARY

OSM is a member of the IL-6 cytokine family. Of all the members of this family, OSM is most closely related to LIF structurally and functionally. In addition, the genes for OSM and LIF are closely linked on the same chromosome. It is also known that the genes for their receptor β-subunits are present in close proximity on mouse chromosome 15. Co-localization of the OSMRβ and LIFRβ genes as well as OSM and LIF genes strongly suggests that they were created by duplication during evolution.

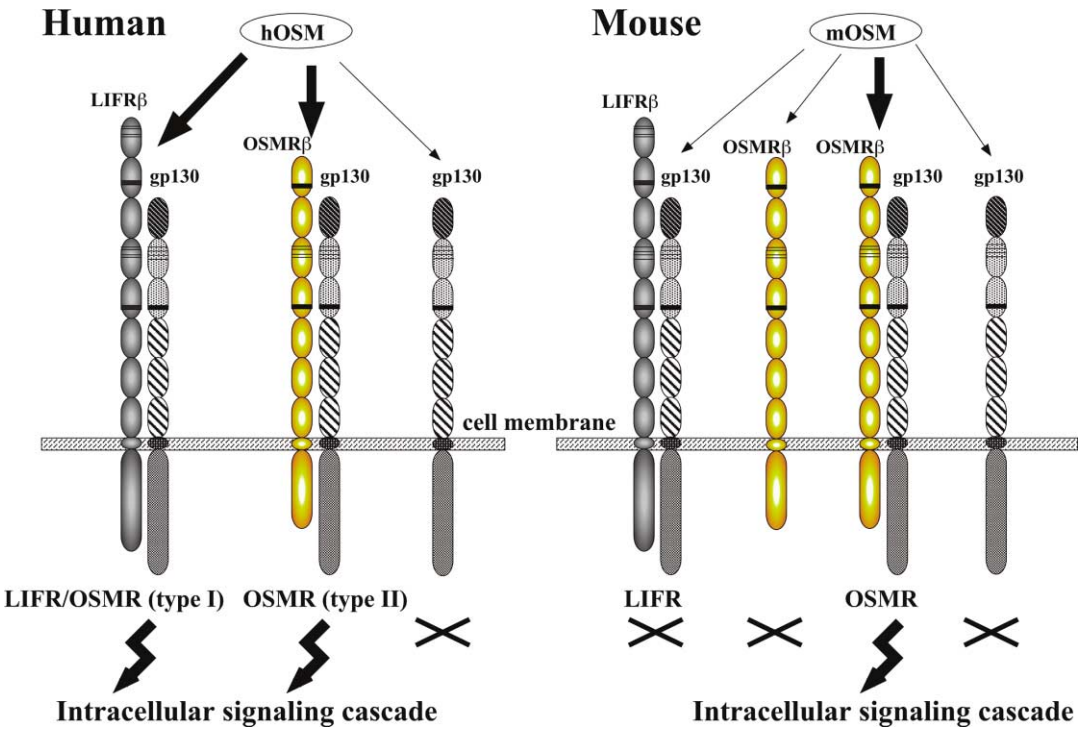

FIGURE 2 Formation of the functional receptor complexes for hOSM and mOSM. Thin arrows show low-affinity binding of OSM to each receptor component and thin arrows indicate high-affinity binding. Broken arrows indicate the relay of the intracellular signaling cascade. X, no signaling.

Since hOSM and hLIF showed various common biological activities, OSM has been thought to be the second LIF. However, hOSM also exhibits unique activities including growth inhibition of A375 melanoma cells, growth stimulation of Kaposi's sarcoma, and induction of TIMP-1 in fibroblasts. Molecular cloning of the hOSM receptor subunit and reconstitution of the functional hOSM receptor indicated that there are two types of functional receptor for hOSM. Although the type I OSM receptor is identical to the high-affinity LIF receptor and shares signaling pathways with LIF, the type II OSM receptor is utilized for OSM-specific signaling. The existence of two functional OSM receptors provides a molecular basis for the biological activities shared in common between LIF and OSM as well as for OSM-specific activities. It should be noted that mOSM uses only the OSM-specific receptor but not the LIF receptor.

Glossary

interleukin-6 A pleiotropic cytokine that acts on a wide variety of cells and exhibits many biological activities, e.g., the induction of B-cell differentiation to antibody-forming plasma cells, differentiation of myeloid leukemic cell lines into macrophages, megakaryocyte maturation, acute-phase protein synthesis in hepatocytes, and development of osteoclasts.

Janus kinases (JAKs) Intracellular tyrosine kinases with molecular masses of 120–140 kDa that bind to cytokine receptors. A typical kinase domain is located at the C-terminus, preceded by a kinase-like domain. Four JAKs (JAK1, JAK2, JAK3, and Tyk2) have been identified.

leukemia inhibitory factor A pleiotropic cytokine that was originally identified as a factor that inhibits leukemic cells and exhibits many biological activities, e.g., induction of monocytic differentiation of the murine leukemic cell line M1, suppression of differentiation of pluripotent embryonic stem cells, and inhibition of adipogenesis.

signal transducers and activators of transcription (STATs) A family of latent cytoplasmic transcription factors with an SH2 domain, members of which are activated by cytokines and translocate to the nucleus to participate in gene expression. Seven mammalian STAT genes (STAT1, 2, 3, 4, 5a, 5b, and 6) have been identified.

tissue inhibitors of metalloproteinases Specific inhibitors of matrix metalloproteinases, a family of enzymes that are responsible for the degradation of collagens, proteoglycans, and glycoproteins of the extracellular matrix.

Mutations affecting the kit ligand (*Kitl*) and *Kit* loci in Steel (*sl*) and white spotting (*w*) mouse models, respectively, cause failures in the proliferation, survival, and migration of the PGCs. Similarly, signaling pathways elicited by members of the transforming growth factor-β (TGF-β) superfamily are necessary for PGC development and have been implicated in PGC migration and in the control of PGC proliferation. Knockout mouse models with mutations in bone morphogenetic protein 4 (*Bmp4*), *Bmp8b*, *Smad1*, or *Smad5* exhibit complete or nearly complete loss of the PGC population. More recently, double-mutant studies generating $Bmp2^{+/-}$, $Bmp4^{+/-}$ double heterozygotes have revealed cooperative functions of these related proteins in PGC development. Thus, multiple TGF-β superfamily ligands (i.e., BMP-2, BMP-4, and BMP-8B) signaling through the intracellular proteins SMAD1 and SMAD5 play key roles in PGC development.

In addition to soluble growth factors and the intracellular signaling proteins that mediate their response pathways, structural proteins that form contacts between cells and from cells to the extracellular matrix are important in PGC development. Knockout mice lacking the gap junction protein connexin 43 demonstrate decreased numbers of PGCs as early as E11.5. In contrast, integrin $\beta1^{-/-}$ chimeras demonstrate that integrin β1 is dispensable for early PGC differentiation but is essential for their migration to the putative gonad.

Germ cell-deficient (*gcd*) and atrichosis (*at*) mutant models exhibit early embryonic loss of PGCs, though the molecular causes underlying these defects are as yet unknown. Identification of the genes disrupted in *gcd* and *at* mutant mice will further elucidate the proteins required for PGC development and function.

II. PRIMORDIAL FOLLICLE ORGANIZATION AND FOLLICULOGENESIS

Single layers of squamous granulosa cells surround oocytes during the perinatal period, and complex bidirectional communications established at this time between oocytes and these somatic cells function during all stages of follicle development and are crucial for female fertility. It is clear that signals from oocytes participate in the assembly of primordial follicles in the newborn ovary as knockout mice that lack factor in the germ line α (FIGα), an oocyte-specific helix loop helix transcription factor, fail to form primordial follicles and lose their oocytes within the first days of life. This suggests that FIGα regulates one or more factors that are critical for either the recruitment of granulosa cells to the oocyte or the adherence of these granulosa cells to the oocyte.

Recruitment of primordial follicles to initiate folliculogenesis is marked morphologically by oocyte and granulosa cell growth, and stages of subsequent follicular development are characterized by granulosa cell proliferation (see Fig. 2). Factors required for the initial recruitment of primordial follicles to form primary (one-layer) follicles are unknown. Oocyte–granulosa cell interaction is crucial to preantral

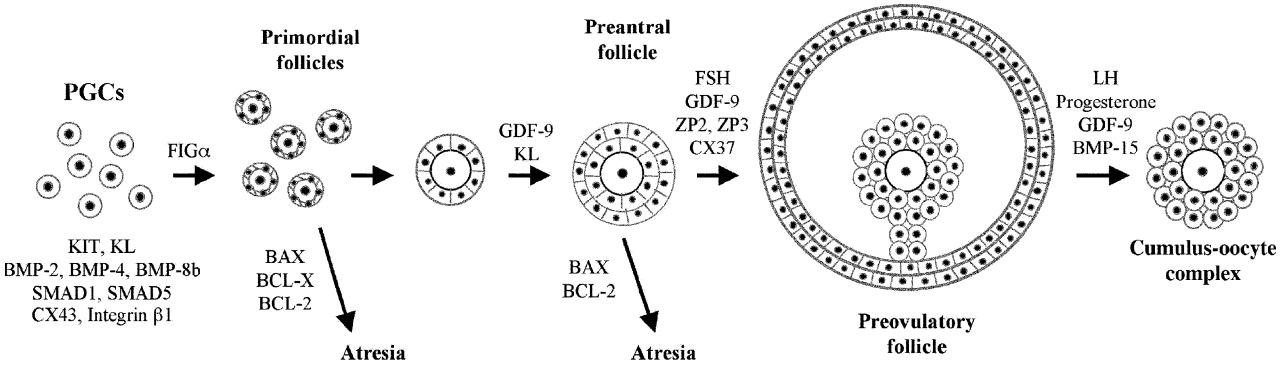

FIGURE 2 Stages of folliculogenesis and its key regulatory proteins. Primordial germ cells proliferate and migrate to the putative gonad during embryonic development and organize granulosa cells to form primordial follicles within a few days after birth in the mouse. Primordial follicles that are not lost to attrition are available to be recruited to the growing pool of follicles, first evidenced by a change in the shape of the granulosa cells from squamous to cuboidal. The mechanisms that regulate the measured recruitment of follicles over a female's reproductive lifespan are as yet unknown. Granulosa cells proliferate during the ensuing stages of folliculogenesis, and large antral preovulatory follicles develop in response to endocrine factors. At ovulation, cumulus–oocyte complexes are released from these dominant follicles, and the remnant cells undergo luteinization. Some of the factors that mediate steps in follicular development as demonstrated by phenotypes of mouse models are shown.

follicle development beyond the primary follicle stage. Growth differentiation factor-9 (GDF-9), a TGF-β superfamily member secreted by oocytes, kit ligand, which is derived from granulosa cells, and kit receptor, expressed on the oocyte surface, are key signaling proteins in these reciprocal interactions. Mice homozygous for a null allele at the *Gdf9* locus or for a hypomorphic *Kitl* allele exhibit female infertility due to blocks in follicular development before the formation of secondary follicles that contain two layers of granulosa cells.

Multilayered follicles become subject to regulation by extraovarian factors, namely, the gonadotropin hormones, and require follicle-stimulating hormone to achieve a crescendo of granulosa cell proliferation and become large antral preovulatory follicles. It is now appreciated that oocyte-derived factors influence granulosa cell proliferation and establish during these later stages of folliculogenesis characteristics unique to the cumulus granulosa cell population (i.e., the granulosa cells closest to the oocyte in the antral follicle as opposed to the mural granulosa cells closest to the follicle wall). For example, GDF-9 has been shown to: (1) stimulate the formation of the cumulus–oocyte complex (COC) by inducing hyaluronan synthase 2 and suppressing urokinase plasminogen activator; (2) promote both the elaboration and the response to prostaglandins in preovulatory granulosa cells, which in turn up-regulate progesterone production during ovulation; and (3) suppress the luteinization of cumulus granulosa cells by inhibiting the production of luteinizing hormone receptor. A related TGF-β superfamily protein, BMP-15, is also expressed in oocytes throughout most stages of follicular development and through ovulation and functions in a cooperative manner with GDF-9 to maintain the integrity of the COC and maximize female fertility in mice. Interestingly, the sheep orthologue of BMP-15, like mouse GDF-9, is crucial for early stages of follicular development and may also affect later events of follicle growth and ovulation. Point mutations occurring in the *BMP15* coding sequence in *Inverdale* ($FecX^{I}$ mutation) and *Hanna* ($FecX^{H}$ mutation) sheep cause defects beyond the primary follicle stage and infertility in homozygote ewes, but enhance ovulation in heterozygotes. Thus, the presence of the mutant BMP-15 in heterozygote sheep may interfere with or promote GDF-9 and/or BMP-15 homodimerizations or heterodimerizations or the interactions of these ligands with their receptors.

In addition to growth factors such as GDF-9 and BMP-15, oocytes produce and extrude structural proteins during follicular development that form their encasing zona pellucida matrix. Knockout mice lacking zona pellucida protein 3 (ZP3) or ZP2 demonstrate defects in early antral and preovulatory follicle development, respectively. Disrupted cumulus–oocyte complex formation and decreased ovulation in response to gonadotropins also contribute to both the infertility of the *Zp3* knockout and the subfertility of the *Zp2* knockout. Interestingly, blastocysts derived from *in vitro* maturation and fertilization of eggs from $Zp2^{-/-}$ and $Zp3^{-/-}$ females are not capable of completing development after transfer to pseudo-pregnant recipients. This suggests that zona matrix proteins are important in mediating granulosa cell signals to oocytes that optimize their later developmental potential. Interestingly, *Zp1* knockout females exhibit a more subtle subfertility phenotype, the first discernible compromise being a premature loss of zona integrity that affects early embryogenesis.

III. CONTROL OF EARLY MEIOSIS AND APOPTOSIS IN OOCYTES

Mitotic divisions during PGC migration give rise to a complement of approximately 26,000 germ cells in the female mouse, and the size of this pool and the rate of its depletion are key determinants of the duration of reproductive potential. In addition to interactions with somatic cells during PGC migration and follicular organization, several factors intrinsic to the germ cells have proved critical to germ cell survival, including proteins involved in the control of early meiosis and apoptosis programs.

Several events of meiosis I precede the dictyate-stage block, which persists until ovulation. Replicated sister chromatids connected by axial elements condense and synapse with their homologous chromosomes by the pachytene stage; the maintenance of dictyate germ cells depends on cross-over exchanges that then occur between homologous chromosomes. Several proteins are known to play key roles between the zygotene and pachytene stages (Fig. 1). Chromosome condensation and the formation of synaptonemal complexes are blocked in knockout mice lacking ATM kinase or the DMC1 recombination protein, and in both of these models, female germ cells degenerate during embryogenesis. Translational control of synaptonemal complex proteins and perhaps other participants in early meiosis is exercised at this stage; knockout mice lacking CPEB or DAZL RNA-binding proteins have defects evident at the pachytene

stage. Mismatch repair proteins encoded by the *Msh4* and *Msh5* loci are also critical for synapsis, and germ cells in these knockout mice have defects in the zygotene/pachytene stage and are lost within a few days postpartum. Similarly, oocytes in *Spo11* knockout mice, which lack an endonuclease that initiates recombination, die in the perinatal ovary. Thus, meiosis prior to the prophase I block requires the cooperative function of many factors and represents a period in oocyte development that is closely "monitored" to prevent the progression of abnormal gametes.

Functional antagonism between BAX and the anti-apoptotic factors BCL-X and BCL-2 regulates programmed cell death in oocytes. After the completion of PGC mitosis, apoptosis is key in controlling the size of the germ cell reserve during perinatal oocyte attrition and postnatally during follicular atresia in response to gonadotropin deprivation and environmental toxins. *Bax* knockout females have a reduction in postnatal loss of primordial and primary follicles, a threefold increase in the number of primordial follicles at sexual maturity, and an extended lifespan of ovarian function. Although late embryonic and perinatal oocyte loss is not measurably inhibited in the single knockouts, BAX is expressed in embryonic PGCs and has been implicated in the loss of PGCs in BCL-X hypomorphic mouse embryos. Like BCL-X, BCL-2 counters early oocyte apoptotic pathways; *Bcl2* knockout mice establish fewer primordial follicles, and many of these follicles are devoid of oocytes owing to germ cell degeneration. Conversely, oocyte expression of a *Bcl2* transgene increases the number of nonatretic maturing follicles, decreases follicular atresia and spontaneous oocyte loss, and suppresses oocyte apoptosis induced by doxorubicin. Thus, both loss-of-function and gain-of-function transgenic models have illustrated important *in vivo* roles for these apoptotic regulators in controlling the size of the finite oocyte pool after the completion of germ cell mitosis in embryogenesis and throughout the lifespan of ovarian function.

IV. ACQUISITION OF MEIOTIC COMPETENCE AND COMPLETION OF OOCYTE MATURATION

In the periovulatory period, oocytes acquire competence to resume meiosis if separated from their surrounding granulosa cells, which normally control the prophase I block release. Coincident with the rise in serum luteinizing hormone (LH) and ovulation, oocytes from preovulatory follicles complete maturation; they undergo germinal vesicle breakdown, complete the reductional meiotic division, extrude the first polar body, and proceed to an arrest in metaphase of meiosis II.

Signals from the cumulus granulosa cells are critical to this progression. Defects in meiotic maturation are evident in oocytes from *Gja4* knockout mice lacking gap junction protein connexin 37, as well as in oocytes from connexin 43 knockout ovaries grafted into recipient mice to allow for follicular development. It is not clear from these models whether the meiotic phenotype reflects specific functions of these pores in discrete stages of oocyte maturation or whether the defects arise because normal intercellular communications within the follicle are never established. It has been speculated that gap junctions serve as a conduit for granulosa cell-to-oocyte movement of cyclic AMP (cAMP) prior to the LH surge, with oocyte cAMP being important in maintaining meiotic arrest. Consistent with this model, the LH surge induces connexin 43 phosphorylation changes, clearance of connexin 43 protein, and down-regulation of the connexin 43 mRNA. Paralleling these changes, decreases in oocyte cAMP levels, dependent on the activity of oocyte phosphodiesterase PDE3, allow for the resumption of meiosis. In addition to inhibiting oocyte maturation via cAMP, cumulus granulosa cells may provide stimulatory signals that promote meiotic progression. It has been hypothesized that granulosa cell-derived Ca^{2+} and a lipophilic sterol (4,4-dimethyl-5α-cholesta-8,14,24-triene-3β-ol; meiosis-activating sterol) function in promoting meiotic resumption in response to the gonadotropin hormones. Investigating how these and other signals are transmitted to the oocyte and coordinate the regulation of meiosis in response to the hormonal environment *in vivo* represents an exciting field of ongoing research (see Fig. 3).

Oocyte factors are also important regulators in directing the completion of meiosis. Female knockouts lacking the endothelial isoform of nitric oxide synthase, expressed on the surface of oocytes, show compromised ovulation, delayed meiotic progression from metaphase I, and subfertility. The mechanism by which nitric oxide interfaces with the cell cycle machinery directing the metaphase I exit is not known, though mouse models have identified some factors relevant to metaphase transitions during mammalian oogenesis. For example, B-type cyclin proteins have been implicated in directing the commitment to complete both metaphase I and metaphase II as regulatory components of the maturation-promoting

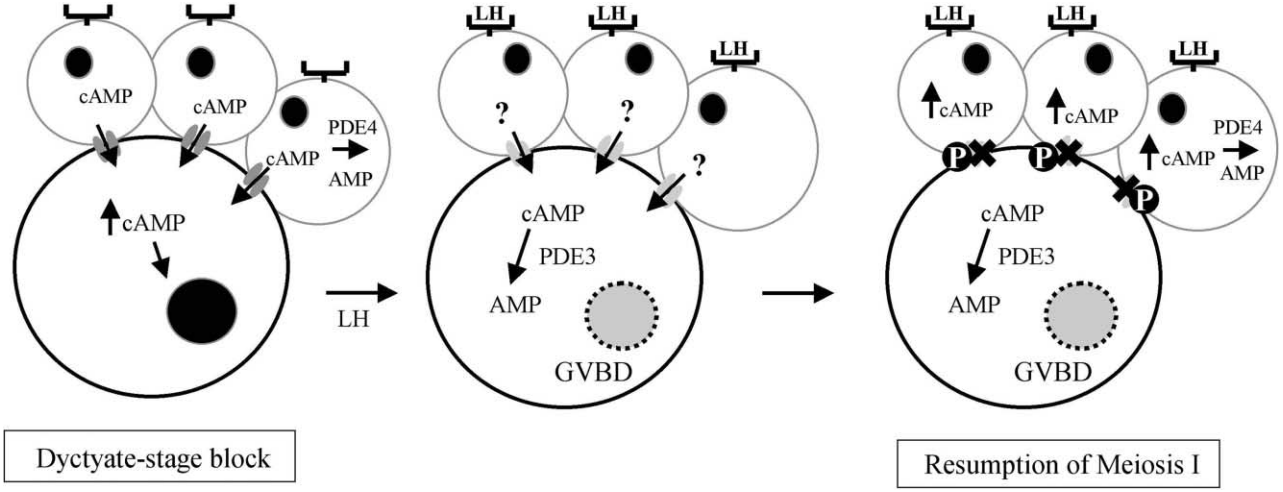

FIGURE 3 A hypothetical model for the resumption of meiosis I. Prior to the preovulatory surge of LH, oocytes are maintained in a prophase I dictyate-stage block, in part by inhibitory signals from the surrounding granulosa cell compartment. It has been proposed that cAMP produced in the granulosa cells is communicated to the oocyte to maintain the dictyate nucleus and prevent germinal vesicle breakdown. The LH surge produces an increase in granulosa cell cAMP, which may affect the phosphorylation, closure, and clearance of gap junction channels by protein kinase cascades. This can be re-created by pharmacologically inhibiting granulosa cell phosphodiesterase (PDE4) activity, which promotes the resumption of meiosis in the absence of LH. It has been postulated that, prior to gap junction closure, a positive effector of meiosis (Ca^{2+} or inositol 1,4,5-trisphosphate) is communicated to the oocyte, where it up-regulates phosphodiesterase enzyme (PDE3) and may mediate other intracellular events that promote oocyte maturation. The gap junction closure effectively isolates the oocyte as a compartment unto itself for the regulation of cAMP metabolism. The subsequent reduction in oocyte cAMP levels is a prerequisite for germinal vesicle breakdown and the release of the dictyate-stage block. Interfering with oocyte PDE3 blocks maturation even in the presence of LH and presumably an intact granulosa cell LHR response. *In vitro* studies have implicated PKA and PKC pathways as downstream mediators of cAMP effects in both the granulosa cells (releasing the meiotic block) and the oocyte (maintaining the meiotic block).

factor complex. B-type cyclin levels increase before each meiotic metaphase, and their ubiquitin-mediated degradation coincides with the metaphase–anaphase transition. Cyclin B1 is expressed in oocytes in this pattern and injection of cyclin B1 antisense mRNA causes defects during the completion of meiosis I and in the onset of metaphase II. Embryonic lethality in cyclin B1 knockout mice has thus far precluded *in vivo* studies of this protein's function in oocytes. Cyclin $B2^{-/-}$ females exhibit a subfertile phenotype, which has not yet been further characterized but may further establish the importance of this cyclin in mouse oogenesis.

The establishment of the block at metaphase II is important biologically to preclude parthenogenic activation of oocytes. This is compromised in *Mos* knockout mice lacking the oocyte-expressed MOS kinase, which is a component of the cytostatic factor complex implicated in maturation-promoting factor stabilization. Female *Mos* knockouts are subfertile and their oocytes have visible abnormalities in chromatin organization after the completion of meiosis I. A naturally occurring defect intrinsic to oocytes in the LTXBO mouse strain also causes a high incidence of parthenogenic activation, which is associated with delayed entry into anaphase I. Oocytes from these mice have elevated protein kinase C activity in late metaphase I, and inhibition of PKC in these oocytes promotes the timely onset of anaphase I and reduces spontaneous activation. These findings suggest that abnormal regulation of protein kinase C in the oocytes of this strain of mice is causal for their defects. Thus, LTXBO mice provide a valuable model for studying the molecular mechanisms underlying the late stages of oocyte meiosis and the onset of embryonic mitosis.

V. FERTILIZATION AND EARLY EMBRYONIC DEVELOPMENT

Fertilization depends upon sperm–egg fusion molecules expressed by the gametes. Integrin $\alpha 6\beta 1$ dimers and an associated tetraspanin protein, CD9, on the surface of oocytes are thought to be important

in interacting with ADAM (a disintegrin and a metallprotease domain) proteins expressed by sperm, facilitating sperm binding and penetration. Corroborating this finding, knockout female mice lacking CD9 have severely compromised fertility owing to defects in the capacity for spermatozoa to bind to CD9 null oocytes.

Mammalian oocytes are normally released from their metaphase II block upon fertilization and this is marked morphologically by the separation of the second polar body. This represents the completion of oocyte maturation and the female gamete may be hereafter referred to as an egg. At least one mismatch repair protein, MLH1, though seemingly dispensable for meiosis I, is critical to the progression through meiosis II. *Mlh1* knockout females are completely sterile. Their oocytes develop, ovulate, and fertilize normally, but postfertilization development is blocked and extrusion of the second polar body is not accomplished. This unique block suggests the presence of a distinct checkpoint in meiosis II governing the completion of oocyte maturation, which involves the detection of aberrant DNA structures and arrests development in gametes with defective heteroduplex repair pathways.

Until sperm DNA decondensation and reorganization of a diploid nucleus are completed, many events of early embryogenesis cannot rely on *de novo* transcription from either parental genome, and factors that are required for embryonic development must be supplied by the oocyte. Disruptions of the maternal genome that cause phenotypes in embryonic development are termed maternal effect mutations and several have been recently characterized in mice using knockout technology. In each case, the gene product is normally accumulated in growing oocytes and persists in the early developing embryo, and the phenotype affects the offspring of homozygote females, regardless of their genotype or gender. Knockout females lacking a PHD-containing protein, ZAR1 (zygote arrest 1), are infertile due to a block in the development of their fertilized eggs to two-cell embryos. Similarly, a maternal effect gene encoding MATER (maternal antigen that embryos require) is necessary for development beyond the 2-cell stage and has been implicated in establishing embryonic genome transcription patterns. A third gene encodes DNMT1o, an oocyte-specific DNA methyltransferase critical for maintaining imprinting patterns established in the embryonic genome and the viability of the developing mouse during the last third of gestation. Transient nuclear localization of the DMTO1o protein during the 8-cell-stage embryo suggests that it normally functions during the fourth S phase and is required for the transmission of methylation patterns to each daughter cell produced in the 16-cell-stage embryo. Presumably, many other oocyte-derived factors mediate the complexities of early embryogenesis—both the dramatic morphological changes that herald early development and the compositional changes in mRNA and protein of reserves of eggs and zygotes around the time of fertilization.

VI. CONCLUDING REMARKS

Our descriptive understanding of mouse oocyte and early embryo development has enabled us to invent transgenic technologies that hold the promise to reveal the molecular aspects of these biological processes. Future knockout models, multiple mutant studies, and the development of temporal and tissue-specific knockouts will allow us to more thoroughly examine the *in vivo* functions of gene products. The conservation of many genes and their functions across species indicates the potential of such studies in our pursuits to understand and affect the biology of female gameotogenesis in humans.

Glossary

folliculogenesis The process by which oocytes and ovarian somatic cells develop to ovulate a fertilizable egg. The first steps in follicle development are directed by intraovarian factors and result in proliferation of granulosa cells surrounding the oocyte and the recruitment of a layer of theca cells. The development of large antral follicles and ovulation depend on the actions of the pituitary gonadotropin hormones, follicle-stimulating hormone and luteinizing hormone. The stages of follicular development are summarized in Fig. 2.

meiosis A specialized cell division program completed during the formation of haploid gametes. In the first stage of meiosis (meiosis I), homologous pairs of replicated chromatids separate into daughter cells, and there is a reduction in both the DNA content and the ploidy. The second stage (meiosis II) involves the separation of paired chromatids. In mammalian female

gametogenesis, the completion of each division results in the extrusion of a polar body so that one haploid egg is produced from the two divisions. There are arrests in meiosis at prophase I and metaphase II; these are released upon ovulation and fertilization, respectively. The stages of meiosis are summarized in Fig. 1.

mitosis Cell division that produces daughter cells with the same DNA content as the parental cell. The process begins after DNA replication and involves four phases as follows: (1) prophase, which is subdivided into stages describing chromosome morphology; (2) metaphase, when condensed chromosomes are aligned; (3) anaphase, when chromatids separate to opposite poles; and (4) telophase, which is followed by nuclear and cytoplasmic division.

transgenic mice Mice with heritable, engineered manipulations of the genome. These mice can have genes introduced for ectopic expression or can have endogenous genes or sequences altered. When the expression of an endogenous gene is completely abrogated, mice homozygous for the null allele are called knockout mice.

Orphan Receptors, New Receptors, and New Hormones

DAVID D. MOORE

Baylor College of Medicine

There are 48 members of the nuclear hormone receptor superfamily in the human genome. Currently, these proteins can be divided into 23 conventional receptors with known ligands and 25 proteins, called orphan receptors, which do not have known ligands.

I. INTRODUCTION

The nuclear hormone receptor superfamily comprises two groups: the conventional receptors, those with known ligands, and the orphan receptors, those that do not have known ligands. The conventional receptors can be further subdivided into the classical receptors for a series of hormones and signaling molecules that were known to have nuclear receptors before any of the genes encoding these proteins were cloned, and the new receptors for more recently identified compounds. The ligands for the former group consist of estrogens, androgens, progestins, glucocorticoids, mineralocorticoids, vitamin D, thyroid hormone, and retinoic acid. Those for the new receptors include fatty acids, prostaglandins, oxysterols, bile acids, and xenobiotics, as well as an increasing number of synthetic ligands. Several of these synthetic ligands have already been found to be valuable therapeutic agents. This article focuses on the discovery of these new ligands, some of which were not expected to have such direct biologic regulatory functions, and their emerging roles in regulating lipid metabolism. The potential functions of several of the current orphans are also outlined.

II. THE FIRST GENERATION OF THE NUCLEAR RECEPTOR SUPERFAMILY: IDENTIFICATION OF CLASSICAL RECEPTORS AND ORPHANS

The cloning and characterization of the cDNA encoding the glucocorticoid receptor (GR) by the laboratories of Keith Yamamoto and Ron Evans in 1984 and 1985 immediately revealed the existence of at least a small family of nuclear receptor proteins, based on the striking similarity of the GR cDNA sequence to that encoding the cellular proto-oncogene c-erbA. The subsequent isolation of clones encoding additional steroid receptors by the laboratories of Bert O'Malley, Pierre Chambon, and others resulted in the identification of the structurally conserved DNA-binding and ligand-binding domains shared by the family members and the initial characterization of the molecular mechanism of action of these receptors. In this mechanism, the DNA-binding domain functions to recognize specific sequences in appropriate target genes. The binding of the hormone to the structurally separate ligand-binding domain results in an allosteric effect that is now known to allow the binding of a series of different co-regulator proteins. Thus, hormone binding results in the recruitment of these co-regulator proteins to the target genes, where they exert their appropriate transcriptional regulatory effects.

However, the isolation of these additional receptors left open the question of what hormone might activate c-erbA. At the time, the main candidates were a small number of signaling molecules known to have nuclear receptors: thyroid hormone (triiodothyronine, T3), all-*trans*-retinoic acid (t-RA), 1,25-dihydroxyvitamin D_3, and dioxin. It did not take long for the laboratories of Ron Evans and Bjorn Vennstrom to identify T3 as the ligand for both c-erbA, which became the thyroid hormone receptor α isoform, TRα, and the closely related TRβ protein. Thus, these proteins were the first to move from the orphan column to the conventional receptor column.

A similar strategy allowed the identification of a protein originally isolated as the target of hepatitis B virus insertions in hepatoma as the retinoic acid receptor α isoform (RARα), which was joined by the RARβ and RARγ isoforms. The last receptors identified in this initial generation were the retinoid X receptors (RXRα, β, and γ), which were initially identified as RAR relatives that were activated by high concentrations of t-RA, but were unable to bind it directly. The identification of the stereoisomer 9-*cis*-retinoic acid (9-*cis*-RA) as a specific agonist ligand for the RXRs was the first example of the use of what was then an orphan receptor to identify a new signaling molecule. Although the physiological significance of 9-*cis*-RA activation of the RXRs remains unclear more than 10 years after their identification, this exciting finding has led to the identification of specific synthetic RXR agonists that have recently received approval as cancer chemotherapeutic agents.

In 1996, estrogen receptor-β (ERβ) was the last of the classical receptors to be identified. This former orphan was found to be an alternative estrogen receptor on the basis of its sequence similarity to the previously identified ERα. The existence of the β isoform was not anticipated based on classical studies of estrogen function.

As these classical receptors were characterized, the list of the orphans that was initiated with estrogen receptor-related receptor-α (ERRα) and ERRβ quickly began to lengthen. The current status of the family, as revealed in the human genome sequence and summarized in Table 1, is 48 total members, 14 of which are receptors for these classical ligands and 8 of which have more recently identified ligands as described below. The remaining 26 are still orphan receptors.

TABLE 1 Nuclear Hormone Receptor Subgroups

Conventional receptors	
Classical	**New**
Steroid ERα, ERβ (3A1, 2), PR (3B3), AR (3B4) GR (3B1), MR (3B2), VDR (1I1)	Fatty acid PPARα, PPARδ, PPARγ (1C1–3)
Thyroid TRα, TRβ (1A1, 2)	Cholesterol/bile acid LXRα (1H3), LXRβ (1H2), FXR (1H4)
Retinoid RARα, RARβ, RARγ (1B1–3) RXRα, RXRβ, RXRγ (2B1)	Xenobiotic PXR (1I2), CAR (1I3)
Orphan receptors	
ERRα, ERRβ, ERRγ (3B1–3)[a] COUP-TFI, II (2F1, 2), ear2 (2F6) HNF-4α (2A1), HNF-4γ (2A2) SF-1, LRH-1, (NR5A1, 2) NGF-IB, Nurr1, Nor1 (4A1–3) RevErbAα, RevErbAβ (1D1, 2) RORα, RORβ, RORγ (1F1–3) TR-2, TR-4, (2C1-2) TLX (2E1), PNR (2E3) GCNF-1 (6A1) SHP, DAX-1 (0B1, 2)	

Note. Conventional and orphan receptors are grouped based on ligand-binding properties. Many of the nuclear properties have a number of different names and/or different isoforms genereated by alternate splicing or promoter utilization, but only a single commonly used name is included here for each. See http://www.ens-lyon.fr/LBMC/laudet/NucRec/nomenclature_table.html for a more comprehensive list and GenBank accession numbers. In a standardized nomenclature for the nuclear receptors, each is referred to as "NR" followed by a three-character code based on evolutionary relatedness. This code is indicated in parantheses for each family member.

[a]Synthetic inverse agonist ligands have been identified.

In retrospect, it was misleading that the examples provided by these classical receptors clearly predicted that the "hormones" for the remaining orphans would share properties similar to those already described. Thus, it was anticipated that these new hormones would combine potent biologic regulatory effects with quite specific and high-affinity binding to their receptors. A major problem with this prediction was the significant discrepancy between the very limited number of remaining compounds with such properties and the much larger number of orphan receptors. The focus on high-affinity ligands stymied progress in this area for several years.

III. THE NEXT GENERATION: LIGANDS AND FUNCTIONS FOR THE NEW RECEPTORS

A. PPARα, PPARγ, and PPARδ

The next generation in the evolution of the understanding of the nuclear hormone receptors began in 1990 with the identification of a series of compounds previously known to increase numbers of peroxisomes in hepatocytes as ligands for a receptor termed the peroxisome proliferator-activated receptor (PPARα) (Table 2). This linkage was consistent with the prediction that a receptor ligand should have a potent biological effect. However, the fact that some of these ligands were active only at very high concentrations did not fit well with assumptions based on the classic hormones. This issue became even more significant when it was proposed that fatty acids were the endogenous ligands for the three PPAR isoforms. Although it is well known that consumption of different fatty acids can have significant effects on metabolism, it was not thought that such effects were due to a specific receptor for such fatty acids. Moreover, simple considerations of equilibrium binding dictate a basic trade-off between binding affinity and specificity that associates low-affinity interactions with decreased specificity. This argues strongly for quite limited specificity for binding of compounds that occupy a receptor at concentrations more than a million times higher than the picomolar

TABLE 2 Some New Ligands for Nuclear Hormone Receptors

Receptor	Endogenous	Synthetic/exogenous
PPARα	Fatty acids, prostaglandins	Fibrates, other peroxisome proliferators
PPARδ	Fatty acids, prostaglandins	Carbaprostacyclin
PPARγ	Fatty acids, prostaglandins	Thiazolidinediones, new-generation anti-diabetic agents
LXR	Oxysterols	T09031
FXR	Bile acids	GW4064, guggulsterone[a]
CAR	Androstanes[b] (bilirubin)[d]	TCPOBOP[c] (phenobarbital)[d]
PXR	Bile acids	Many drugs, catatoxic steroids and steroid antagonists
ERRs	?	DES and 4-hydroxytamoxifen[b]

[a] Antagonist.
[b] Inverse agonists.
[c] Rodent CAR only.
[d] Indirect activator.

levels associated with the effects of T3 and other high-affinity ligands. Thus, even though the concentrations of fatty acids required for PPAR activation may correspond to their endogenous levels, a signaling mechanism based on such poorly binding ligands must incorporate significant compromises in specificity relative to the conventional hormones. Such considerations predict that the PPARs would be unable to distinguish between various fatty acid species or even to exclude the effects of compounds not closely related to these endogenous ligands.

An elegant series of structural studies with the PPARs provided additional focus to these issues and addressed some of the associated concerns. These studies have revealed that the ligand-binding pocket of the PPARs is unusually capacious relative to more conventional receptors with high-affinity ligands. The ability of fatty acids to occupy this large pocket was directly confirmed by an X-ray crystal structure of eicosapentaenoic acid bound to PPARδ. This structure also confirmed the lack of specificity of such binding, since two quite different conformations of this flexible ligand were observed in the crystals.

Importantly, the crystal structures also explained the ability of additional synthetic ligands to bind these receptors with high affinity. A series of fibrate compounds associated with lipid-lowering effects were among the first compounds identified as activators of PPARα and were subsequently shown to be direct ligands. The initial identification of PPARγ as a factor promoting fat cell differentiation led to the identification of a class of compounds known as thiazolidinediones as relatively high-affinity PPARγ ligands, since such compounds were known to promote adipocyte differentiation. As expected, X-ray crystal structures demonstrate that the thiazolidinediones occupy a much larger fraction of the PPARγ ligand-binding pocket and make a good overall fit.

Based on both knockouts (genetically engineered null mice) and pharmacologic approaches, it is now clear that PPARα functions in the liver to stimulate fatty acid oxidation and PPARγ functions in fat cells to promote adipogenesis and expression of fat-specific genes. PPARγ also functions in macrophages to promote the return of cholesterol to the liver via the reverse transport pathway. The function of the third PPAR isoform, usually called PPARδ, is less clear. It is much more broadly expressed than the other two, and intriguing recent pharmacologic results suggest that PPARδ agonists may be therapeutically useful in treatment of the metabolic problems associated with obesity in syndrome X.

B. Liver X Receptor-α, Liver X Receptor-β, and Farnesoid X Receptor

Three former orphans have been identified as receptors for primary metabolites of cholesterol with roles in cholesterol homeostasis. The first of these was liver X receptor (LXRα), which is activated by hydroxylated cholesterol derivatives called oxysterols. In agreement with the fact that these compounds had previously been identified as potential regulators of the expression of proteins involved in cholesterol homeostasis, and also its expression in the liver, LXRα knockout mice showed a profound defect in hepatic cholesterol metabolism. Normal mice are able to manage even relatively high levels of dietary cholesterol. However, the LXRα knockouts are unable to metabolize and eliminate the excess cholesterol, which accumulates in the liver. The closely related LXRβ isoform is also activated by

oxysterols and is expressed in a number of tissues, including the liver, but the phenotype of the LXRα knockout animals demonstrates that LXRβ is unable to fully compensate for the loss of the former isoform. The LXRβ knockout also fails to show the same strong cholesterol accumulation phenotype as the LXRα knockout. However, the double-knockout animals have an even more severe phenotype, indicating some degree of functional overlap.

The phenotype of the LXRα knockout raised the possibility that LXR agonists could be useful in the treatment of hypercholesterolemia. Unfortunately, however, the synthetic agonist T09031 was found to significantly increase triglyceride levels in rodent models. This undesirable side effect is associated with the induction of the transcription factor sterol response element binding protein-1c (SREBP-1c), which promotes fatty acid synthesis.

In addition to their roles in lipid metabolism in the liver, the LXRs also function with PPARγ in the process of reverse cholesterol transport mentioned above. In this pathway, PPARγ activation in macrophages results in induction of LXRα expression, which, in turn, activates target genes responsible for cholesterol efflux, including the ABCA1 active transport pump and apolipoprotein E. Thus, LXR agonists may have beneficial effects in both the liver and the periphery if the triglyceride problem can be circumvented.

Another former orphan that functions in cholesterol homeostasis is farnesoid X receptor (FXR), which is directly activated by bile acids. Bile acids are downstream metabolites of cholesterol. They are produced in large amounts in the liver and are essential for the emulsification and absorption of dietary lipids. Although they are very efficiently reabsorbed in the gut after their release in bile, they represent the primary pathway for elimination of cholesterol from the liver. The potential function of FXR in bile acid and cholesterol homeostasis was supported by results with knockout animals, which show significant defects in these processes, including the inability to appropriately down-regulate bile acid biosynthesis in response to increased bile acid levels.

Like the cholesterol efflux from macrophages, this down-regulation is apparently also a consequence of a nuclear receptor cascade. In this case, activation of FXR by bile acids results in increased expression of an unusual orphan receptor named small heterodimer partner (SHP), which lacks a DNA-binding domain and functions to inhibit transactivation by other nuclear receptors. The orphan receptor liver receptor homologue-1 [LRH-1, also known as fetoprotein transcription factor (FTF)] is particularly sensitive to this repression and its activity is essential for the expression of the rate-limiting enzyme in bile acid biosynthesis, encoded by the *Cyp7A1* gene. Thus, the induction of FXR by bile acids results in decreased *Cyp7A1* expression via a pathway dependent on both SHP and LRH-1.

Like the LXRs, FXR is also a potential target for the modulation of cholesterol levels. Recently, guggulsterone, a natural product found to lower serum low-density lipoprotein levels in humans, was identified as an antagonist ligand for FXR. Treatment with this plant-derived steroid results in decreased accumulation of cholesterol in the liver of wild-type but not FXR knockout mice challenged with a high-cholesterol diet. Thus, it is possible that this or other, more specific FXR antagonists may be useful in the treatment of hypercholesterolemia.

C. Constitutive Androstane Receptor and Pregnane X Receptor

The former orphans constitutive androstane receptor (CAR) and pregnane X receptor (PXR) are each other's closest relatives within the receptor superfamily. Interestingly, they are in the same branch of the evolutionary tree as LXRα, LXRβ, and FXR. The final receptor in this cluster is the vitamin D receptor (VDR). All six of these receptors are expressed to at least some degree in the liver and all are RXR heterodimer partners. They are also all ligand dependent, with CAR and PXR sharing a rather complex overlapping network of xenobiotic agonists/activators and also target genes.

The term xenobiotic refers to all the compounds that organisms encounter that are not normal constituents of the body. This category includes an enormous range of agents present in foods, drugs, and environmental contaminants. It is well known that exposure to particular foreign compounds can increase the capacity of the liver to metabolize both the initial xenobiotic stimulus and other compounds. Both genetic and pharmacologic approaches have demonstrated that CAR and PXR mediate two particularly well-known xenobiotic responses.

In the first step of drug metabolism, called Phase I, a series of cytochrome P450 enzymes with a particularly wide range of substrates catalyzes the hydroxylation of xenobiotic compounds. In Phase II, a variety of other enzymes add a number of other functional groups, often to the site of initial hydroxylation. In general, this results in the inactivation and elimination

of the xenobiotic substrate. Both CAR and PXR induce coordinate responses of Phase I and Phase II enzymes, as well as multidrug resistance transporters and other components of the drug metabolism pathway. Such responses are the basis for a class of clinically significant drug-drug interactions in which the presence of one drug affects the activity or half-life of another. In such interactions, the first drug is a direct activator of CAR or PXR, whereas the second is a substrate for the drug-metabolizing machinery.

The mouse PXR was first described as a receptor for a series of steroids and steroid antagonists that had previously been known to induce a characteristic xenobiotic response centered on the *Cyp3A* gene. A knockout of the mouse PXR gene confirmed its importance in this response, but also helped resolve a complication associated with the fact that the ligand-binding domain of the human PXR (also called SXR) diverges much more from the mouse PXR ligand-binding domain than is common within the superfamily. This divergent sequence had been shown to result in response to different agonist ligands. For example, the human receptor is potently activated by the antibiotic rifampicin, a well-known inducer of *Cyp3A* expression in human patients, but the mouse protein is completely unresponsive. As predicted from the activity of the isolated receptors, a mouse expressing the human PXR/SXR instead of its own PXR gains the ability to induce *Cyp3A* expression in response to rifampicin.

CAR shares a similar, if somewhat more complex, function. The barbiturate drug phenobarbital, used to treat seizures, also induces a characteristic xenobiotic response that centers on *Cyp2B* enzymes. Again, a knockout mouse model was used to demonstrate that this response is mediated by CAR. The pharmacology of this response is complicated somewhat by the fact that phenobarbital is not a ligand for either the mouse or the human CAR. Instead, it induces a specific translocation of the receptor from the cytoplasm of the hepatocyte to the nucleus. Little is known about this process, but it is thought to contribute to the activation of CAR by many other xenobiotics in addition to phenobarbital. Once in the nucleus, this receptor apparently relies on its ligand-independent or constitutive transcriptional activation function to stimulate the expression of appropriate target genes. Such constitutive activity is not a general characteristic of the ligand-dependent nuclear receptors described above. As described below, however, it is a common feature among the remaining orphan receptors.

The constitutive activity of mouse CAR can be further increased by a compound known as TCPOBOP (1,4-bis-[2-(3,5,-dichloropyridyloxy)] benzene), which is both a direct CAR agonist and a potent inducer of *Cyp2B* expression. It can also be blocked by androstanol and androstenol, which are inverse agonist ligands and can inhibit the activation of *Cyp2B* expression by TCPOBOP. As with PXR, the human and mouse CAR ligand-binding domains are divergent and neither of these murine CAR ligands binds the human receptor.

The functions of the two receptors in the xenobiotic responses overlap to a significant degree. For example, CAR is also able to activate *Cyp3A* expression and PXR can activate *Cyp2B*. They also share some activators, such as the antifungal agent clotrimazole, which can activate both human PXR and mouse CAR (but is a weak inverse agonist for human CAR). This overlap of targets and ligands is certainly not complete, however, and the specific and overlapping functions of these two receptors remain to be defined.

One area where they appear to show more specific activities is in their responses to endogenous compounds. Thus, PXR but not CAR has been associated with a protective response to toxic bile acids that is based on their function as both PXR ligands and substrates for *Cyp3A*. CAR, in contrast, functions to activate the clearance of bilirubin, a toxic breakdown product of heme that is specifically metabolized and eliminated by the liver.

IV. FUTURE GENERATIONS: FUNCTIONS OF THE CURRENT ORPHAN RECEPTORS

In general, much less is known about those members of the nuclear receptor superfamily that remain orphans. In some cases, however, key insights into their roles have come from knockouts or other sources. The potential functions of some of the better characterized orphans will be briefly outlined here.

A. ERRα, ERRβ, and ERRγ

The estrogen receptor-related receptors are closely related to the estrogen receptors and were among the first true orphans to be described. Like several of the other orphans, but not the classical receptors, they are evolutionarily ancient with an apparent homologue in *Drosophila*. The recent identification of the synthetic ER ligands diethylstilbestrol and 4-hydroxytamoxifen as inverse agonists strongly suggests that the identification of natural or endogenous ligands

will soon relocate these proteins to the conventional receptor category. Although their overall functions remain uncertain, they also share DNA-binding sites, co-regulators, and target genes with the conventional estrogen receptors ERα and ERβ and may function to modulate estrogen signaling pathways.

B. Steroidogenic Factor 1

In contrast to the isolation of many of the orphans using approaches such as low-stringency hybridization, steroidogenic factor 1 (SF-1) was first identified based on its ability to bind a series of related sites in the promoters of steroid hydroxylases. Also, unlike other orphans that bind DNA as homodimers or heterodimers, SF-1 binds as a monomer to an extended consensus element that includes a single copy of the nuclear receptor-binding hexamer. Like many other orphans, however, SF-1 functions as an apparently constitutive transcriptional activator.

The potential role of SF-1 in the regulation of adrenal steroidogenesis was strongly supported by the observation that the loss of SF-1 function in mice resulted in the absence of adrenals, gonads, and the ventromedial hypothalamus, as well as male-to-female sex reversal of internal and external genitalia. Thus, SF-1 is a key regulator of the development of important endocrine tissues. It is also expressed in these tissues in the adult, where its role remains an interesting question.

C. Hepatic Nuclear Factor 4

Hepatic nuclear factor 4α (HNF-4α) is another orphan originally identified based on its ability to recognize specific sites, in this case in various promoters that are active in the liver. It binds these sites as a homodimer. Additional studies revealed that it is also expressed in the kidney, intestine, and pancreas, particularly the insulin-producing beta cells. A wide variety of target genes have been identified, including genes involved in fatty acid and cholesterol metabolism, glucose metabolism, urea biosynthesis, and liver differentiation. HNF-4α null mouse embryos die at a very early stage of development. The heterozygotes do not show an obvious phenotype. In humans, however, heterozygous loss of HNF-4α results in defective pancreatic beta-cell function and a characteristic syndrome called MODY (mature onset diabetes of the young). HNF-4α is MODY1; heterozygous loss of function of several other nonreceptor transcription factors that function in the beta cell results in a similar phenotype.

HNF-4 is another orphan that functions as an apparently constitutive transcriptional activator. Thus, it was a surprise when the recent X-ray crystal structure of HNF-4γ revealed a fatty acid occupying an unusually small putative ligand-binding pocket. This clearly suggests that the function of this important metabolic regulator could be modulated by appropriate synthetic ligands. However, its location in the structure and other lines of evidence suggest that this fatty acid may play a structural role more analogous to the zinc atoms in the DNA-binding domain than the much more dynamic functions of conventional nuclear receptor ligands. Thus, the potential ligand responsiveness of the HNF-4 isoforms remains to be established.

D. Chicken Ovalbumin Upstream Transcription Factor I and II

These two closely related orphans are the mammalian homologues of an ancient orphan with unusually close relatives in *Drosophila* and a number of other invertebrates. The chicken ovalbumin upstream transcription factors can bind a wide variety of response elements as homodimers. They generally function as transcriptional repressors, but positive effects have been observed in some contexts. Although their activities appear very similar and their patterns of expression overlap significantly, the knockout of either chicken ovalbumin upstream transcription factor I (COUP-TFI) or COUP-TFII is lethal. In the former case, death is perinatal and is caused by multiple defects in development of the central and peripheral nervous system. In the cerebral cortex, for example, layer IV of the cortex is absent, a defect that is apparently secondary to a failure of the appropriate innervation of these neurons and subsequent cell death. In contrast, COUP-TFII null mice die at embryonic day 10 with a variety of heart and vascular defects. Interestingly, some of these defects resemble those observed in mice lacking angiopoeitin 1 or its receptor. The marked decrease in angiopoeitin expression in the knockouts suggests that COUP-TFII is an important upstream regulator of the expression of this important angiogenic factor. Thus, it is possible that modulation of COUP-TFII activity could control angiogenesis in pathologic processes including carcinogenesis.

E. Nur-related Factor 1

Nur-related factor 1 (Nurr1) is one of three related receptors in a group that shows particularly flexible

modes of DNA binding. Thus, nerve growth factor inducible B (NGFI-B) was the first orphan shown to bind with high affinity as a monomer, a property shared by the other two family members and also a subset of other orphans. At least in some cases, however, members of this family can also bind specific DNA sites as homodimers or as heterodimers with each other. In addition, Nurr1 and NGFI-B, but not neuron-derived orphan receptor 1 (Nor1), can bind distinct sites as heterodimers with RXR.

Of these three related orphans, the Nurr1 knockout showed the most dramatic phenotype, a complete loss of mesencephalic dopamine neurons. It is an interesting possibility that this orphan may be involved in disease processes that impact such dopaminergic neurons, such as Parkinson's disease and schizophrenia. Some support for this possibility is provided by the identification of Nurr1 gene mutations in a small number of schizophrenic patients.

F. Reverse ErbAα

Reverse ErbAα (RevErbAα) is an orphan with an unusual genomic location: the coding region for its final exon overlaps with that of the final exon of the variant TRα2 isoform. It has a close relative, RevErbAβ, which is also linked to the TRβ locus but does not share a similar overlap. It is interesting that TRα and RevErbAα are also linked to RARα, whereas TRβ and RevErbAβ are linked to RARβ on a different chromosome, suggesting that a single, ancient duplication generated the two sets of isoforms for the three receptors.

A recent clue to the potential function of RevErbAα was provided by the unexpected demonstration that its expression is very strongly regulated by circadian rhythm. Somewhat less marked circadian variations were observed with RevErbAβ and also ROR isoforms, which can bind similar DNA-response elements. In RevErbAα knockout animals, circadian rhythms are significantly altered, but not absent. RevErbAα and RevErbAβ function as apparently constitutive repressors in co-transfection assays, and results with knockout models show that at least RevErbAα functions *in vivo* to represses the expression of Bmal1, a central component of the molecular circadian clock in mammals. Overall, these results confirm both the role of RevErbAα in the regulation of the circadian clock and the existence of redundant mechanisms in this important and complex pathway.

G. SHP and DAX-1

SHP and dosage-sensitive sex reversal-adrenal hypoplasia congenita critical region on the X chromosome 1 (DAX-1) are unique orphans that lack a nuclear receptor DNA-binding domain. SHP directly interacts with a number of other nuclear receptors and inhibits their ability to activate transcription. As described above, results with SHP knockouts supported a specific role proposed for SHP in an FXR-dependent pathway for negative feedback regulation of bile acid biosynthesis. Interestingly, there are apparently also additional, redundant mechanisms for this process, since SHP null mice do show the expected loss of repression in response to a synthetic FXR agonist, but to a large degree maintain the repressive effect of high levels of dietary bile acids.

In contrast to SHP, which consists solely of a ligand-binding domain, DAX-1 includes an additional N-terminal domain. This domain has been associated with various DNA-binding activities, but the significance of this potential function remains uncertain. Loss of function of the human DAX-1 gene causes an X-linked form of adrenal hypoplasia congenita that is associated with hypogonadotropic hypogonadism. Like SHP, DAX-1 functions as a transcriptional repressor and it is thought that the loss of this repression function accounts for this phenotype. The transcriptional targets of DAX-1 remain unknown but several lines of evidence, including direct interaction and similar patterns of expression, suggest that it modulates SF-1 function.

V. SUMMARY AND PROSPECTS

Two broad themes have emerged from studies of orphan receptors over the past 15 years. Starting with the TRs and RARs and continuing through the recent identification of the ERRs as potential targets of selective estrogen receptor modulators, the first is the identification of new ligands for orphan receptors. This has led to important and in some cases quite unexpected advances in several areas. Perhaps the most notable is the identification of the PPARs, LXRs, and FXR as key regulators of lipid metabolism. These and other receptors will continue to be important targets for the identification of new therapeutic approaches to regulate important metabolic pathways.

The potential therapeutic importance of these receptors highlights the significance of an intriguing question: Will ligands eventually be defined for all of the remaining orphans? This question can be further

divided into whether such ligands will be endogenous ligands with important regulatory functions or synthetic compounds identified by high-throughput functional tests. In the former case, one might predict that many of the current orphans will remain orphans, since there is not a pool of remaining candidate compounds with the expected regulatory functions. Of course, this may be more reflective of a lack of imagination than a lack of such ligands, and it seems very likely that endogenous ligands will be identified for the ERRs and potentially other orphans. Nonetheless, several evolutionary arguments have suggested that the function of the progenitor of the superfamily may not have been ligand regulated and it is quite possible that other processes, such as phosphorylation, control the function of the remaining orphans.

Even if a significant number of the orphans do not have endogenous ligands, it remains an interesting possibility that synthetic ligands could be identified, for example, by efficient high-throughput screening technologies. The isolation of inhibitory peptides capable of binding to estrogen receptor isoforms with high affinity and specificity suggests a different approach to modulate the activity of orphans. With the continuing definition of the functions of the orphans from knockout studies and other studies, the motivation to identify appropriate ligands will be strong.

A second theme is the emergence of a number of important developmental functions of the orphans. Although the conventional receptor knockouts often show relatively limited phenotypes unless they are appropriately challenged, a number of the orphan receptor knockouts result in very early embryonic lethality or other dramatic developmental phenotypes. It is striking that comparisons of the complete human and *Drosophila* genome sequences reveal that the human nuclear receptors with *Drosophila* relatives are not the classical steroid thyroid and retinoid receptors, but the orphans. Though the existence of multiple isoforms of individual receptor types complicates matters, it is also appears that the knockouts of the mammalian receptors with the closest *Drosophila* relatives, such as the COUP-TFs and HNF-4α, show particularly strong embryonic phenotypes.

Whereas a number of such developmental functions have been identified for the conserved orphans, the apparent role of RevErbAα in circadian rhythm clearly suggests that there will be exceptions. It is a simple prediction that the orphans that remain less well characterized have some interesting surprises in store for us.

Osteogenic Proteins of the TGF-β Superfamily

U. RIPAMONTI

Medical Research Council/University of the Witwatersrand, Johannesburg, South Africa

The normal repair and regeneration of bone constitute a complex process that is temporally and spatially regulated by soluble and insoluble signals. The bone morphogenetic proteins or osteogenic proteins, members of the transforming growth factor-β supergene family, are morphogens endowed with the striking prerogative to initiate *de novo* bone formation by induction in heterotopic extraskeletal sites of animal models.

I. INTRODUCTION

The three most important requirements for successful tissue engineering of bone are a suitable extracellular matrix substratum, capable responding cells, and soluble osteoinductive signals, which are members of the transforming growth factor-β (TGF-β) supergene family. The reconstitution of bone morphogenetic proteins/osteogenic proteins (BMPs/OPs) (the soluble signals) with biomimetic matrices (the insoluble substratum) provides a bioassay for *bona fide* initiators of bone differentiation as well as delivery systems for therapeutic local osteogenesis. Contrary to all the results obtained in the rodent bioassay, heterotopic implantation of naturally derived or recombinant human (h) TGF-β isoforms induces vigorous endochondral bone induction in the *rectus abdominis* muscle of the adult primate *Papio ursinus*. The binary applications of doses of recombinant hBMPs/OPs with relatively low doses of hTGF-β1 interact synergistically to rapidly induce massive heterotopic and orthotopic ossicles in the rectus abdominis muscle and calvarial defects, respectively.

The discovery that specific surface and geometric characteristics of sintered porous hydroxypatites can induce bone in heterotopic sites of primates in the absence of exogenously applied BMPs/OPs paves the way for the formulation and therapeutic application of smart porous substrata that lead to the formation of predictable tissue types via intrinsic osteoinductivity. The incorporation of specific biological activities into sintered hydroxypatites defined as geometric induction of bone formation elicits therapeutic osteogenesis in clinical contexts. The intrinsic osteoinductivity of porous substrata in primates indicates that the bone induction cascade is initiated by endogenously produced BMPs/OPs bound to the surface of the smart concavities of the substratum, with induction of bone as a secondary response. The concavities of the substratum are geometric regulators of growth endowed with shape memory, recapitulating events that occur in the normal course of embryonic development and appearing to act as gates that give or withhold permission to grow and differentiate. Extensive studies in animal models, particularly nonhuman primates, have made possible the use of both hOP-1 and hBMP-2 for craniofacial and orthopedic applications in clinical contexts.

II. TRANSFORMING GROWTH FACTOR-β SUPERFAMILY

The initiation of bone formation during embryonic development and postnatal morphogenesis and osteogenesis involves a complex cascade of molecular and morphogenetic processes that ultimately lead to the architectural sculpture of precisely organized multicellular structures. Elucidating the nature and interaction of the signaling molecules that direct the generation of tissue-specific patterns during the initiation of endochondral bone formation is a major challenge of contemporary molecular, cellular, developmental, and tissue engineering biology.

Quantum leaps in these rapidly evolving fields have dramatically advanced our understanding of tissue induction and morphogenesis. First, the putative signaling molecules or morphogens, defined as form-generating substances capable of imparting specific different pathways to responding cells initiating the cascade of pattern formation and the attainment of tissue form and function, have been purified and cloned and their *in vivo* functions have been identified.

Nature relies on common yet limited molecular mechanisms tailored to provide the emergence of specialized tissues and organs. The distilled summary of this research effort is surprisingly simple: first, that tissue regeneration in postnatal life recapitulates events that occur in the normal course of embryonic development and morphogenesis and second, that both embryonic development and tissue regeneration are equally regulated by a select few and highly conserved families of morphogens. In addition, these gene products are members of the TGF-β superfamily, and purification and expression cloning yielded an entirely new family of protein initiators, the BMPs/OPs.

III. BONE MORPHOGENETIC PROTEINS/OSTEOGENIC PROTEINS

The BMP/OP family is indeed an elegant example of nature parsimony in programming multiple specialized functions deploying molecular isoforms with minor variations in amino acid motifs within highly conserved carboxy-terminal regions.

Members of the BMP/OP and TGF-β families are pleiotropic morphogens that have potent and diverse effects on cell proliferation, differentiation, motility, and matrix synthesis. They are powerful regulators of cartilage and bone differentiation in embryonic development and in postnatal life and are soluble mediators of tissue morphogenesis and regeneration. They exert their biological activities through heteromeric serine/threonine kinase complexes of type I and II receptors and are predominantly synthesized as glycosylated homodimers with a carboxy-terminal region containing characteristic cysteine motifs. In addition to bone induction in postnatal life, BMPs/OPs are involved in inductive events that control pattern formation during embryonic morphogenesis and organogenesis in such disparate tissues as the kidney, eye, nervous system, lung, teeth, skin, and heart. These strikingly pleiotropic effects of BMPs/OPs spring from minor amino acid sequence variations in the carboxy-terminal region of the proteins, as well as in the transduction of distinct signaling pathways by individual Smad proteins after transmembrane serine/threonine kinase receptor activation.

The three mammalian TGF-β isoforms share limited homology with members of the BMP/OP family. A striking and discriminatory feature of the BMP/OP proteins is their ability to induce *de novo* cartilage and bone formation by induction when implanted in extraskeletal heterotopic sites of mammals as recapitulation of embryonic development. This ability, originally solely assigned to the BMP/OP family, has been extended to other TGF-β supergene family members including decapentaplegic and 60A gene products expressed early in *Drosophila melanogaster* development, demonstrating evolutionary conservation of related proteins from phylogenetically distant species.

IV. ENDOCHONDRAL BONE INDUCTION BY TGF-β ISOFORMS

In the *bona fide* heterotopic assay for bone induction in rodents, the TGF-β isoforms, either purified from natural sources or expressed by recombinant techniques, do not initiate endochondral bone formation. More strikingly and recently, TGF-β isoforms themselves have shown a marked site- and tissue-specific endochondral osteoinductivity yet remarkably this occurs in primates only. Induction of osteogenic differentiation has also been shown, at least in rodents, by growth and differentiation factor-5 and Hedgehog proteins with an activity synergistically regulated and enhanced by recombinant hBMP-2.

The presence of several related but different molecular forms with osteogenic activity poses important questions about the biological significance of this apparent redundancy, additionally indicating multiple interactions during both embryonic development and bone regeneration in postnatal life. The fact that a single hBMP/OP initiates bone formation by induction does not preclude the requirement and interactions of other morphogens deployed synchronously and synergistically during the cascade of bone formation by induction, which may proceed via the combined action of several BMPs/OPs, resident within the natural milieu of the extracellular matrix of bone. Thus, it is likely that the endogenous mechanisms of bone repair and regeneration in postnatal life necessitate the deployment and concerted action of several of the BMPs/OPs resident within the natural milieu of the extracellular matrix. The presence of multiple molecular forms with bone inductive activity also points to synergistic interactions during endochondral bone formation. Indeed, a potent and accelerated synergistic induction of endochondral bone formation was shown with the binary application of recombinant or native TGF-β1 with hOP-1, in both heterotopic and orthotopic sites of primates (Fig. 1). Whether the biological activity of partially purified BMPs as shown in long-term experiments in the adult primate *P. ursinus* is the result of the sum of a plurality of BMP activities or is a truly synergistic interaction among BMP/OP family members deserves appropriate investigation. It is noteworthy, however, that in the identical orthotopic model, the long-term efficacy of single applications of gamma-irradiated hOP-1 delivered by a xenogeneic bovine collagenous matrix in regenerating large defects of membranous bone of the adult primate was demonstrated (Fig. 2). Ultimately, it will be necessary to gain insights into the potential distinct spatial and temporal patterns of expression of other BMPs/OPs during morphogenesis and regeneration elicited by a single application of hOP-1. *In vivo* studies should now design therapeutic approaches based on information about gene regulation by hOP-1.

The TGF-β isoforms are powerful inducers of endochondral bone when implanted in the *rectus abdominis* muscle of the primate *P. ursinus* at doses of 1, 5, and 25 μg per 100 mg of collagenous matrix as carrier, yielding large corticalized ossicles by day 90 (Fig. 3). Endochondral bone induction initiated by TGF-β isoforms expresses mRNA of bone induction markers including BMP-3 and OP-1. An additional and significant striking result is that the bone inductivity of TGF-β isoforms in the primate is site- and tissue-specific, with rather substantial

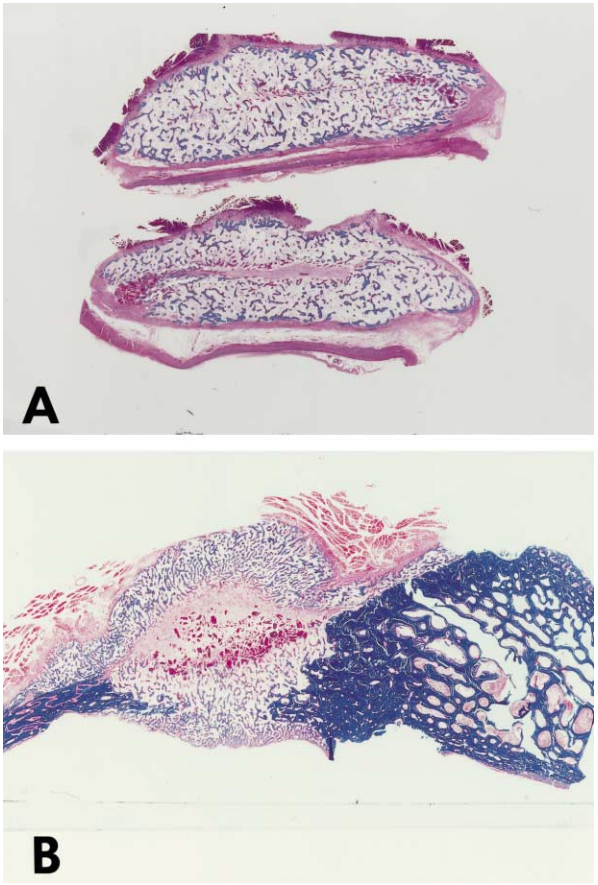

FIGURE 1 Tissue morphogenesis by binary applications of recombinant hOP-1 and TGF-β1. endochondral bone induction in the *rectus abdominis* muscle but absent osteoinductivity in orthotopic sites on day 30 and limited osteogenesis in orthotopic sites on day 90 (Fig. 4).

V. GEOMETRIC INDUCTION OF BONE FORMATION

Importantly, to induce the cascade of endochondral bone differentiation, the soluble signals must be reconstituted with an insoluble signal or substratum that triggers the bone differentiation cascade. Bone regeneration in clinical contexts requires three key components: an osteoinductive signal, an insoluble substratum that delivers the signal and acts as a scaffold for the induction of new bone formation, and host recipient cells that are capable of differentiation into bone cells in response to the osteoinductive signals. All of the components are amenable to manipulation: the signals to be delivered and the nature of the carrier matrix, which additionally can be loaded with the responding cells and tissues. Although molecular biology has made quantum leaps in the mechanistic understanding of cellular and subcellular activities of soluble signals, less knowledge and fewer mechanistic insights have characterized the quest for optimal delivery systems. Such systems would include insoluble substrata that are inorganic and nonimmunogenic, carvable, and amenable to contouring for optimal adaptation to the various shapes of bone defects and initiating optimal osteogenic activity with relatively low doses of recombinant hBMPs/OPs. They would promote rapid vascular invasion, angiogenesis, and mesenchymal invasion when brought into contact with BMPs/OPs previously absorbed onto the carrier and would be capable of remodeling and resorbing once the regenerative processes are well under way. Finally, they would have optimal surface characteristics and geometric configurations, which are of critical importance in the induction of bone

Original magnification: × 3.5.

with and without the exogenous applications of BMPs/OPs. The critical role of the geometry of the carrier substratum in the regulation of bone differentiation has been amply documented using different geometric configurations of collagenous matrix and porous hydroxyapatites, providing evidence that tissue induction and morphogenesis can be greatly altered by the geometry of the carrier.

Since regenerative phenomena recapitulate events that occur in the normal course of embryonic development, the observed multiple patterns of expression of BMPs/OPs in developing tissues and organs may help to devise therapeutic approaches based on recapitulation of embryonic development and ample evidence is accruing regarding the efficacy and safety of two members of the BMP/OP family now available in recombinant form, hOP-1 and hBMP-2, currently the subject of extensive preclinical and clinical research for orthopedic and craniofacial applications.

The finding that heterotopic bone induction in primates is initiated by naturally derived BMPs/OPs and TGF-βs, recombinant hBMPs/OPs and hTGF-βs, and sintered and highly crystalline hydroxyapatites with a specific geometric configuration indicates that heterotopic ossicles develop as a mosaic structure in which members of the TGF-β superfamily singly, synergistically, and synchronously initiate and maintain the developing morphological structures and play different roles at different time points of the morphogenetic cascade.

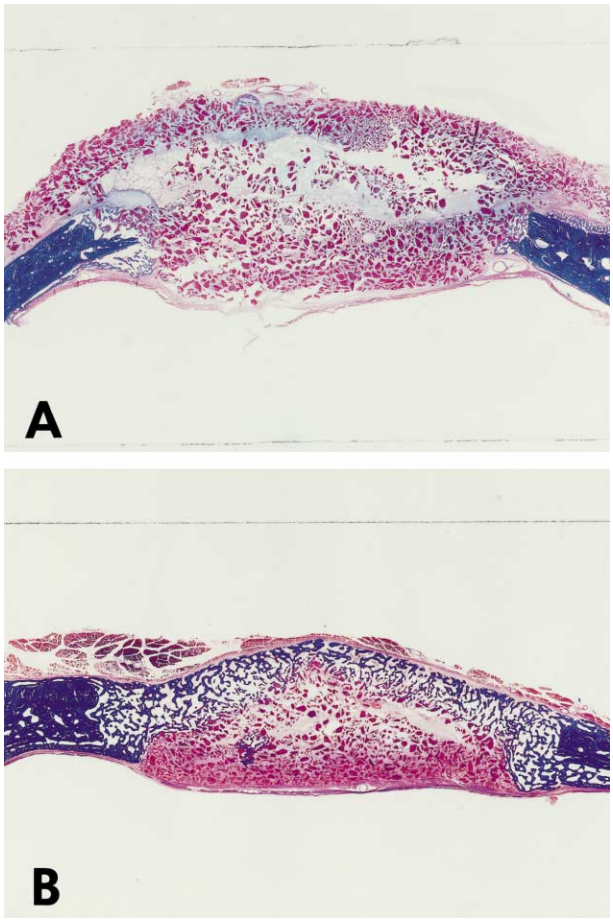

FIGURE 4 Morphology of calvarial regeneration by hTGF-β2 in conjunction with collagenous matrix as carrier. (A) Lack of bone formation on implantation of 100 μg of hTGF-β2 on day 30 with prominent mesenchymal tissue influx and displacement of the collagenous matrix. (B) Limited osteogenesis only pericranially on implantation of 100 μg hTGF-β2. Note the delicate trabeculae of newly formed bone facing scattered remnants of collagenous matrix particles, embedded in a loose but highly vascular connective tissue matrix. Original magnification: × 2.8.

Biomimetic matrices endowed with intrinsic osteoinductive activity, i.e., capable of initiating *de novo* bone formation in heterotopic sites of primates even in the absence of exogenously applied BMPs/OPs, have been developed (Fig. 5). Our findings in nonhuman primates also demonstrate extensive bone formation by hOP-1 adsorbed onto sintered porous hydroxyapatites, indicating that predictable osteogenesis in clinical contexts for the treatment of craniofacial bone defects may be engineered using inorganic, nonimmunogenic, and carvable delivery systems that initiate osteogenesis with relatively low doses of recombinant morphogens, thus mimicking the macro- and microstructures of living bone.

The use of biomimetic matrices capable of initiating bone formation via intrinsic osteoinduction is quickly altering the horizons of therapeutic osteogenesis, leading to a quantum leap in bone tissue engineering. The geometry of the substratum profoundly regulates the expression of the osteogenic phenotype and is defined as geometric induction of bone formation. The intrinsic osteoinductivity regulated by the geometry of the substratum is helping to engineer morphogenetic responses for therapeutic osteogenesis in clinical contexts.

Members of the TGF-β supergene family, BMPs/OPs and TGF-β isoforms endowed with endochondral osteoinductivity in adult primates, are helping to engineer skeletal regeneration and tissue morphogenesis in molecular terms. This prediction is based on a surprisingly simple and fascinating concept: morphogens exploited in embryonic development can be reexploited for the initiation of postnatal morphogenesis and regeneration.

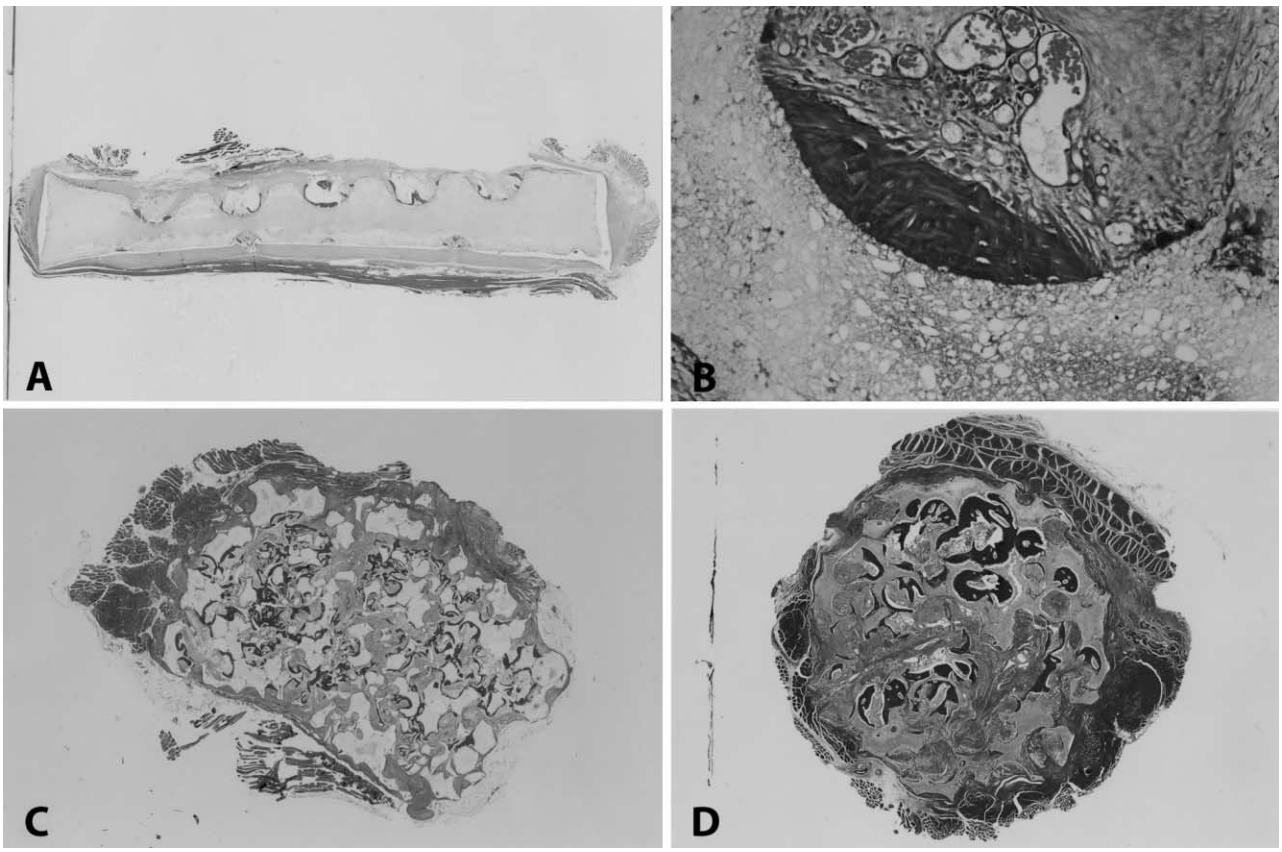

FIGURE 5 Effect of geometry of the substratum on tissue induction and morphogenesis. (A) Monolithic discs of sintered highly crystalline hydroxyapatite with concavities on both planar surfaces were implanted in the *rectus abdominis* muscle of the primate *Papio ursinus* and harvested on day 90 after surgery. Bone forms only within the concavities of the substratum. (B) Note the vascular invasion and angiogenesis close to newly formed and induced bone. (C and D) Low-power photomicrographs of sintered porous hydroxyapatite specimens harvested from the *rectus abdominis* on day 90. Note the intrinsic and spontaneous induction of bone formation within the porous spaces of the hydroxyapatite, essentially initiating in concavities of the substratum. Original magnification: × 8.

Osteoporosis: Hormonal Treatment

NORMAN H. BELL

Medical University of South Carolina

Estrogen, raloxifene, nasal salmon calcitonin, and parathyroid hormone (1–34) are the only hormones or hormonal analogues that have been approved by the Food and Drug Administration (FDA) for the treatment of osteoporosis in the United States.

I. ESTROGEN

It is well established that estrogen deficiency at the time of menopause leads to increases in skeletal remodeling and the rate of bone loss and, in some patients, to osteoporosis and fractures. It is also well established that restoration of estrogen levels via

hormone replacement therapy (HRT) reduces skeletal remodeling and not only prevents bone loss but increases bone mineral density (BMD). Whether estrogen prevents fractures, however, is controversial. Analysis of the Study of Osteoporosis Fracture indicated that current estrogen use was associated with a 61% decrease in the incidence of fractures of the wrist and a 34% decrease in nonvertebral fractures. The incidence of hip fractures was significantly reduced in current users by 61% but only when HRT was begun within 5 years of menopause. In an open, randomized, placebo-controlled study from Finland of women treated with HRT beginning shortly after menopause, the incidence of nonvertebral fractures was significantly reduced by 61%. On the other hand, the incidence of fractures was not reduced by HRT in a prospective, double-blind, placebo-controlled study in postmenopausal women less than 90 years of age.

Earlier epidemiological studies indicated that HRT prevents myocardial infarctions and fatal heart attacks in postmenopausal women. However, the recent prospective, randomized, placebo-controlled Heart and Estrogen/Progestin Replacement Study in postmenopausal women with established heart disease found that the incidence of cardiovascular events was not different in HRT- and placebo-treated groups even though there was an 11% reduction in low-density lipoprotein cholesterol and a 10% increase in high-density lipoprotein cholesterol in the HRT-treated group. Previous to these findings, estrogen was considered to be effective with regard to treatment of coronary artery disease. In view of these findings, the use of HRT for prevention of coronary artery disease is no longer recommended. This recommendation has been confirmed. Recently, the Women's Health Initiative, a prospective, randomized clinical trial with conjugated equine estrogen and medroxyprogesterone acetate in 16,608 postmenopausal women, had to be stopped after 5.2 years because it was found that per 10,000 person years there were 7 more events of cardiovascular disease, 8 more strokes, 8 more pulmonary emboli, 8 more invasive breast cancers, 6 fewer colorectal cancers, and 5 fewer hip fractures in the patients than in the controls. Thus, the risks exceed the benefits from use of combined estrogen and progestin treatment in postmenopausal women.

II. RALOXIFENE

Raloxifene is a member of a group of drugs known as selective estrogen receptor modulators (SERMs) that have a more favorable therapeutic profile than estrogen. Raloxifene is an agonist for bone but, unlike estrogen, is an antagonist for breast and uterine tissue. It is therefore safer than HRT. Raloxifene modestly reduces bone turnover and increases BMD and significantly decreased the incidence of fractures of the spine by 30% (at 30 mg/day) and by 50% (at 60 mg/day) in postmenopausal women. In preliminary studies, it reduced the incidence of breast cancer in postmenopausal women. Raloxifene is undergoing a large clinical trial, Study of Raloxifene and Tamoxifen, for comparison with tamoxifen, the current drug of choice, to determine its efficacy in the prevention of breast cancer. Whether raloxifene prevents coronary heart disease is not known. This question is being addressed in another large clinical trial.

III. SALMON CALCITONIN

In the Prevent Recurrence of Osteoporotic Fractures study, nasal salmon calcitonin at 200 IU daily modestly reduced skeletal remodeling and increased BMD of the spine and significantly reduced the incidence of vertebral fractures by 33% in postmenopausal women. Nasal salmon calcitonin was ineffective in this regard at daily doses of 100 and 400 IU. Nevertheless, the drug is approved for treatment of postmenopausal osteoporosis.

IV. PARATHYROID HORMONE (1–34)

Daily injections of parathyroid hormone (1–34) for less than 2 years significantly increased BMD and reduced the incidence of vertebral fractures by more than 60% and of nonvertebral fractures by more than 50% in postmenopausal women with one or more prevalent fractures. Parathyroid hormone (1–34) given by daily injection is anabolic for the skeleton and does not cause bone resorption.

V. SUMMARY

Estrogen, raloxifene (a SERM), salmon calcitonin, and parathyroid hormone (1–34) are four hormones or hormonal analogues that have been approved for the treatment of osteoporosis. Each was shown to decrease skeletal remodeling and increase BMD by inhibiting bone resorption. Whether estrogen prevents fractures as well as coronary artery disease, however, has not been established. These questions may be answered by results of the Women's Health Initiative. Raloxifene was shown to diminish the incidence of vertebral fractures and has the advantage

of inhibiting the growth of breast and uterine cancer and uterine tissue. It may prove useful for the treatment of breast cancer. Nasal salmon calcitonin at a dose of 200 IU daily was shown to reduce the incidence of vertebral fractures but doses of 100 and 400 IU daily were ineffective. Parathyroid hormone (1–34), an anabolic peptide, diminished the rate of both vertebral and nonvertebral fractures when given by daily injection.

Glossary

osteoporosis A bone disease in which decreased bone mass and alteration in microarchitecture result in increased skeletal fragility and risk of fracture. It occurs in postmenopausal women as a consequence of estrogen deficiency.

parathyroid hormone (1–34) The N-terminal biologically active portion of parathyroid hormone, which is produced by the parathyroid glands and increases bone resorption and tubular reabsorption of calcium by the kidney.

raloxifene A selective estrogen receptor modulator that is an agonist for bone and, unlike estrogen, is an antagonist for uterine and breast tissue.

salmon calcitonin A hormone produced by the parafollicular C cells of the thyroid gland; it inhibits osteoclastic bone resorption and tubular reabsorption of calcium by the kidney. Salmon calcitonin has a different structure than human calcitonin and is more potent.

selective estrogen receptor modulator A drug that has a profile that is similar to or different than that of estrogen with regard to being an agonist or antagonist for skeletal, uterine, breast and other tissues.

III. CLASSIFICATION OF OSTEOPOROSIS

Osteoporosis can be categorized into primary and secondary forms based on the absence or presence of associated medical diseases that predispose to bone loss. Primary osteoporosis is the most common form and is due to age-related loss of bone from the skeleton. Secondary osteoporosis is associated with specific defined clinical disorders that lead to osteoporosis; some of the well-known disorders are given in Table 2.

In 1947, Albright divided osteoporotic patients into postmenopausal and senile groups. He clearly implicated the role of estrogen deficiency in postmenopausal osteoporosis. More recently, based on pathogenic mechanisms, Riggs and Melton used a new terminology: Type I, for postmenopausal osteoporosis, and Type II, for senile osteoporosis. This classification of Riggs and Melton does not include patients with osteoporosis resulting from other diseases and conditions. Appropriately, this latter group of osteoporotics has been classified as Type III. Type I osteoporosis characteristically affects women within 15 to 20 years of menopause, presents principally with vertebral crush fractures and Colle's fractures of distal forearm, and is due mainly to trabecular bone loss as a consequence of estrogen deficiency. Type II (age-related osteoporosis) occurs in both men and women 75 years of age and older and is usually manifested by hip and vertebral fractures. Type II osteoporosis is believed to be mainly due to age-related trabecular and cortical bone loss. Type III osteoporosis, or secondary osteoporosis, occurs in both men and women and is caused by a specific defined clinical disorder or medical treatment. A brief summary of the main features of these three osteoporotic types is shown in Table 3.

TABLE 2 Major Causes of Secondary (Type III) Osteoporosis

Drug use	Corticosteriods
	Anticonvulsants
	Radiotherapy
	Heparin
Gastrointestinal	Malabsorption syndromes
	Primary biliary cirrhosis
Blood diseases	Myeloma
	Thalassemia
	Skeletal metastases
Endocrine	Thyrotoxicosis
	Cushing's syndrome
	Turner's/Klinefelter's syndrome
	Primary hyperparathyroidism
Others	Immobilization
	Transplantation
	Alcoholism
	Chronic renal failure
	Osteogenesis imperfecta

IV. PEAK BONE MASS

Peak bone mass can be defined as the maximum level of bone mass attained in an individual as a result of normal growth. It is usually achieved in the first few years of the second decade of life, the early 20s. It is one of the two principal factors that determine lifelong skeletal health, the other being the bone loss. High peak bone mass provides a larger reserve later in life and offers a protective advantage when bone density declines as a result of aging or other causes. Achievement of peak bone mass is mainly determined by genetics, but nutritional, hormonal, and environmental factors and mechanical loading also influence bone mass.

Data from twin studies suggest that BMD at a number of skeletal sites has a strong genetic component and it is estimated that about 60–80% of peak bone mass is determined genetically. Family studies also provide evidence for a genetic impact on BMD; daughters of women with osteoporosis have a lower BMD than do daughters of women with a normal BMD. Another approach to identify specific genes that influence peak bone mass is to use the candidate gene approach. Using this approach, allelic variation in the vitamin D receptor was first shown to be associated with BMD. The association studies have expanded to other candidate genes known to play a role in normal bone physiology. Common allelic variations in the genes of collagen type Iα1, transforming growth factor-β (TGF-β), interleukin-6 (IL-6), and estrogen receptor have also been found to be associated with BMD in diverse populations. However, results of the association studies have been highly inconsistent. Recently, in a single extended pedigree, Johnson *et al*. reported the linkage of a genetic locus (named HBM, for high bone mass) in the human genome to a phenotype of very high spinal bone density. This HBM phenotype was further demonstrated to be due to a mutation in the low-density lipoprotein receptor-related protein 5 gene (LRP5). However, this mutation was not found in osteoporotic patients. There are probably several other major genes involved in the determination of bone mass.

Calcium is an important nutrient for attaining the peak bone mass. Higher calcium intake during skeletal growth period helps in achieving optimal

TABLE 3 Classification of Osteoporotic Types[a]

Factor	Type I (postmenopausal)	Type II (senile)	Type III (secondary)
Age	55–70	75–90	Any age
Years past menopause	5–15	25–40	Any age
Sex ratio (F:M)	20:1	2:1	1:1
Fracture site	Spine	Hip, spine, pelvis, humerus	Spine, hip, peripheral
Bone loss			
Trabecular	+++	++	+++
Cortical	+	++	+++
Contributing factor			
Menopause	+++	++	++
Age	+	+++	++
Biochemistry

$1,25(OH)_2\ D_3$	↓	↓	⇵
Calcium absorption	↓	↓	↓
1α-Hydroxylase response to parathyroid hormone	↑	↓	?

[a]Adapted from Gallagher (1992) with permission from W.B. Saunders Company.

peak mass. Endocrine reproductive status affects peak bone mass, because early menarche, pregnancy, and the use of oral contraceptive pills are associated with higher bone mass. Sex steroids, estrogen and testosterone, contribute to sexual dimorphism of the skeleton and lead to increased growth velocity at puberty and cessation of linear growth. Increase in bone mass during adolescence results from increases in bone length, bone diameter, cortical bone width, and cancellous bone density. Smoking and alcohol consumption during adolescence and early adult life may have an adverse effect on peak bone mass. Similarly, exercise also modifies bone mass and bone quality through an effect of mechanical loading on the skeleton. Optimum calcium intake and exercise during the early 20s may increase peak bone mass by about 0.5 standard deviations.

V. MODELING AND REMODELING OF BONE

The adult skeleton is a dynamic tissue that remodels throughout life by a coordinated action of osteoblasts, osteoclasts, and osteocytes. It is composed of 80% cortical (compact) bone and 20% cancellous (trabecular) bone. Bone modeling involves both growth and shaping of bones and occurs during the first 20 years of life in humans. The process of bone modeling involves both bone formation and resorption, the former exceeding the latter. Once the initial modeling and growth of bone are completed, bone is then renewed throughout life by a process known as remodeling. A typical remodeling sequence lasts several months. It involves an initial state of activation of bone resorption lasting several days, creating a cavity. Once the resorption cavity has been completed, osteoblasts immediately enter the cavity and fill in the space with new bone. This process lasts several weeks and further consolidation occurs over a period of several months. This process of remodeling represents the way that older bone is replaced and renewed with new bone (Fig. 1). It may be that the initial impetus for remodeling of bone is the presence of microfractures, which occur as a result of strain and stress.

The first event during bone remodeling is osteoclast activation followed by osteoclast formation, resorption, and ultimately apoptosis. The major systemic hormones involved in osteoclast activity are parathyroid hormone (PTH), 1,25-dihydroxyvitamin D_3 [$1,25(OH)_2D_3$], sex steroids, and glucocorticoids. None of these hormones appears to act directly on osteoclasts to stimulate resorption, and, in fact, at the present time only calcitonin has been shown to bind directly to receptors on osteoclasts. These hormones do not directly stimulate the osteoclasts but bring about their effects by causing release of a number of other factors generated by osteoblast-like cells. Local hormones may be more important than systemic hormones for the initiation of bone resorption and for normal bone remodeling. Because remodeling occurs in discrete and distinct packets throughout the skeleton, factors generated locally in the microenvironment of bone govern the cellular events. Some of the local cytokines known to be involved in osteoclast activation are tumor

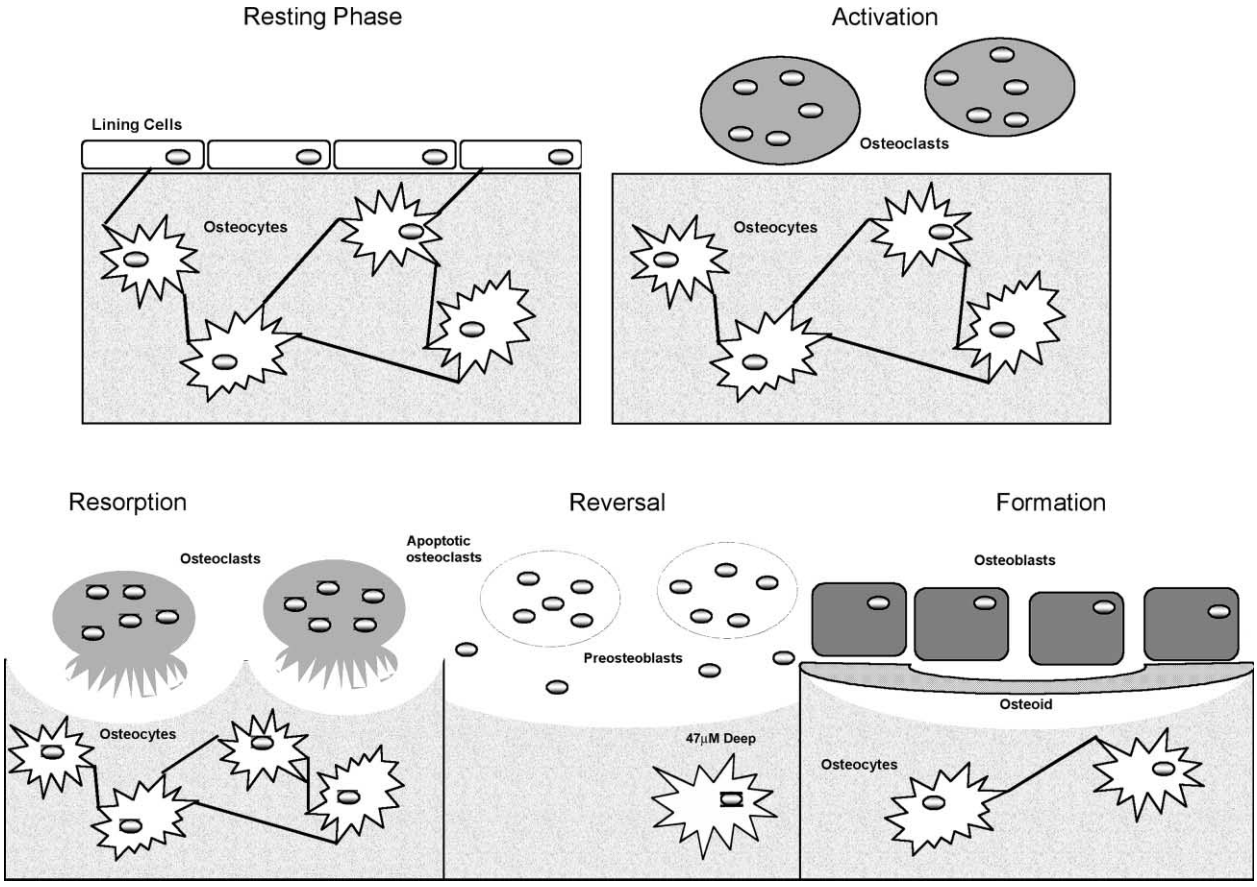

FIGURE 1 Bone remodeling.

necrosis factor (TNF), interleukins (IL-1, IL-6, and IL-18), interferon γ, TGF-β, and colony-stimulating factor (CSF). Some of these factors stimulate osteoclast activity whereas others inhibit the activity. Stimulation of osteoclast activity involves enhancement of proliferation of osteoclast progenitors, differentiation of committed precursors into mature cells, and activation of mature multinucleated cells to resorb bone. Inhibition of osteoclast activity involves blocking proliferation of precursors, inhibiting the differentiation or fusion, and inactivating the mature multinucleated resorbing cells. Current evidence indicates that most factors that stimulate or inhibit osteoclasts act on at least two of these steps. Three new proteins, which are responsible for the interaction between the cells of osteoblastic and osteoclastic lineages and are considered as the final effectors of osteoclast differentiation, have recently been identified. These proteins belong to the family of tumor necrosis factor receptor and have been referred to by different names by different investigators. It has been recommended by a committee that the ligand (osteoblast-derived paracrine factor) be referred to as receptor activator of nuclear factor κB ligand (RANKL), the receptor on the osteoclast as RANK, and the decoy receptor as osteoprotegerin (OPG). The synonyms for RANK ligand include TNF-related activation-induced cytokine (TRANCE), osteoclast differentiation factor (ODF), and osteoprotegerin ligand (OPGL). The interaction of RANKL and RANK stimulates all aspects of osteoclast function. OPG, produced by cells of osteoblast lineage, acts as a decoy receptor for TRANCE, blocking its interaction with RANK and inhibiting osteoclast formation.

The formation phase of the remodeling sequence involves sequential changes in cells in osteoblast lineage, including osteoblast chemotaxis, proliferation, and differentiation. The formation of mineralized bone follows, and once the new bone is formed, osteoblastic activity ceases. The proliferation and differentiation of osteoblast precursors are also controlled by local osteoblast growth factors. The prominent factors include members of the TGF-β superfamily (TGF-β1 and TGF-β2), platelet-derived

growth factor (PDGF), heparin-binding fibroblast growth factor, insulin-like growth factor-I and -II (IGF-I and IGF-II), and bone morphogenetic protein-2 (BMP-2). All of these factors, specifically the TGF-β superfamily members, are important in the coupling that links bone formation to prior bone resorption. The release of local cytokines in the bone remodeling process is another example of autocrine and paracrine control mechanisms.

VI. BONE LOSS

Peak bone mass throughout the skeleton is reached in the late teens, but there is probably a small amount of further consolidation during the next 5 years, which may increase bone density by 3–5%. However, at the radius, a continuous increase is seen in cortical bone mass up to age 40. At the femur and tibia, and to a lesser extent from the trochanter, bone loss starts immediately after peak bone mass has been achieved and proceeds at a rate of 0.5% per year. This loss, however, varies considerably from person to person, starts at different periods of life, and occurs at different rates throughout the skeleton. About 30% of the decrease in BMD of the femoral neck and Ward's triangle in the proximal femur occurs during premenopausal age. At the time of menopause, the bone loss accelerates for a period of 5 to 7 years, and this early postmenopausal phase bone loss is responsible for about one-third of the total lifetime bone loss. Over a 50- to 60-year age span, this steady loss leads to a reduction of about 40% in the bone density of the femoral neck. In contrast, BMD of the spine shows no significant bone loss prior to menopause. At the time of menopause, there is a rapid loss of bone from the vertebral body and about 50% of the lifetime trabecular bone loss occurs within the first 10 years after menopause. Other sites in the body, such as the radius or the humerus, or the total body, also show predominantly menopausal changes in the pattern of bone loss.

Various regions of the skeleton differ in the proportion of cortical and trabecular bone. The variable rates of bone loss that are seen in different regions of the skeleton can be explained by the fact that the trabecular bone has a large surface area for resorption and shows a greater susceptibility to estrogen deficiency at menopause. In cortical bone, resorption occurs primarily at the endosteal surface. In general, the spine is a more hormone-dependent bone than is the femur, while other aging factors are more important in the pathogenesis of bone loss from the proximal femur (neck and trochanter). Thus, up to age 60, 90% of the bone loss in the spine and 40% of bone loss in the femoral neck are due to estrogen deficiency. By the age 85 years, age-related factors cause 75% of femoral neck bone loss and 50% of spine bone loss, whereas estrogen deficiency causes 25% of femoral neck loss and 50% of spine loss.

VII. PATHOGENESIS OF BONE LOSS

Bone loss results as a consequence of an imbalance in the remodeling process whereby the resorption of the bone occurs at a higher rate than the formation, leading to a net decrease in bone density. The age-related bone loss of 0.5% per year occurring before menopause is most likely due to less efficient matrix synthesis by osteoblasts. Immediately following menopause, there is a dramatic increase in bone remodeling process due to estrogen deficiency. The biochemical markers of bone resorption and formation, such as urine cross-links, hydroxyproline, plasma tartrate acid phosphatase, and osteocalcin, are elevated twofold, suggesting an increase in the number of remodeling sites. Usually, bone formation and resorption are coupled efficiently so that bone mass is maintained. However, after menopause, the increase in bone formation is not sufficient to match the increased resorption activity, resulting in a rapid net loss of bone during these years. In bone regions that are primarily trabecular in nature, menopause-induced (estrogen-deficient) bone loss is an important cause of bone loss during the first decade after menopause. Overall, the intensive resorption process after menopause initially leads to thinning of the trabelcula elements, but after several years the trabeculae eventually become completely eroded from continuous resorption, leading to trabecular perforation, loss of continuity of bone structure, and structural damage. During the first phase of trabecular thinning, it is possible to stop resorption and return bone mass to normal, but in the second phase, the antiresorptive agents can only prevent further bone loss.

The mechanism by which estrogen deficiency leads to rapid bone loss is beginning to be clearer. Recent work on the physiology of bone remodeling has further clarified the role of estrogen in maintaining bone health and has provided more evidence for the implication of cytokines in postmenopausal bone loss. Available data suggest that IL-1 and TNF are the main causative agents underlying the bone loss induced by estrogen deficiency, mainly by up-regulating osteoclast formation and activation (Fig. 2). Menopause increases the monocytic production of IL-1 and TNF, which stimulates bone marrow

stromal cells, or their osteoblast progeny, to release factors [IL-6, IL-11, granulocyte/macrophage colony-stimulating factor (GM-CSF), monocyte/macrophage colony-stimulating factor (M-CSF), and RANKL]. These factors in turn stimulate the proliferation of hematopoietic osteoclast precursor cells originating from cells of granulocyte/macrophage colony-forming units (GM-CFUs) and monocyte/macrophage colony-forming units (M-CFUs) lineage. Osteoclast precursors differentiate into mature inactive osteoclasts in response to IL-1 and TNF. Osteoclast activation is rapidly induced by IL-1, TNF, and RANKL.

Following the initial rapid phase of bone loss after menopause, bone loss continues with age at a slower pace. This late phase of bone loss in women is thought predominantly to be due to age-related factors such as secondary hyperparathyroidism, impaired osteoblast function due to changes in local systemic growth factors or cytokines, and, in some elderly patients, nutrition deficiency of vitamin D. In men, the age-related bone loss is believed to be due to the same age-related factors. Recent evidence suggests that estrogen deficiency is also an important contributor to the late phase of bone loss in both women and men.

VIII. PATHOPHYSIOLOGY IN RELATION TO TYPE OF OSTEOPOROSIS

A. Postmenopausal Osteoporosis (Type I)

Type I osteoporosis (Fig. 3) occurs predominantly in women in the mid-60 age group and is presented primarily as crush fractures of the spine and Colle's fractures. It is associated mainly with the bone loss of trabecular rather than cortical bone, which occurs within 5–15 years of menopause. The spine BMD in these patients is usually more than 2 SDs below the

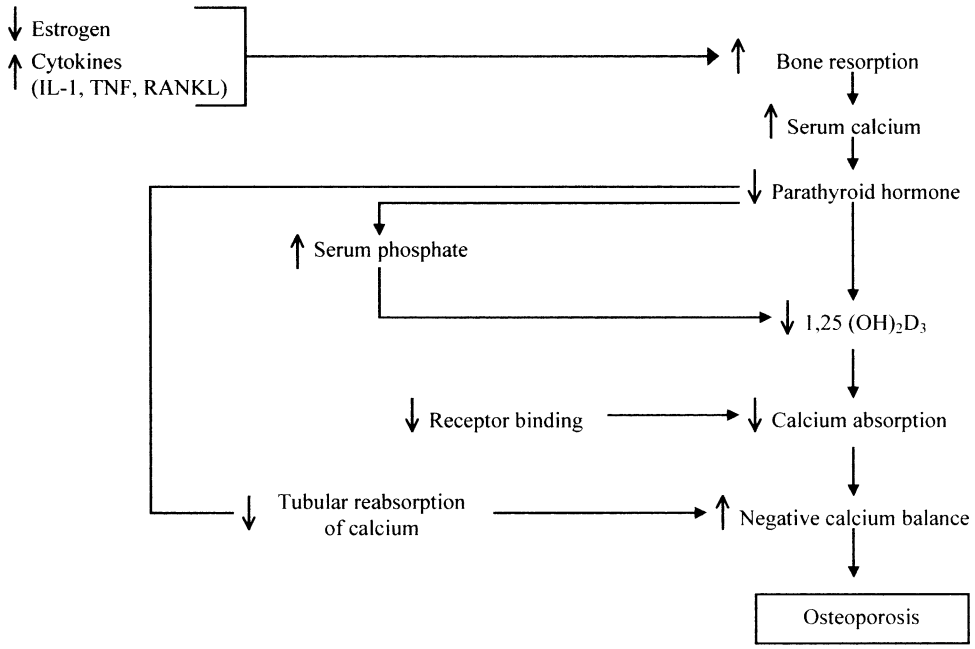

FIGURE 3 Pathogenesis of Type I osteoporosis. IL-1, Interleukin-1; TNF, tumor necrosis factor; RANKL, receptor activator of nuclear factor κB ligand. Adapted from Gallagher (1992) with permission from W.B. Saunders Company.

mean for their age. Histomorphometry of iliac crest biopsies show a reduced bone volume, and about 25% of patients show high bone resorption rates. The rate of bone loss can be anywhere between 1 and 10% per year in the first few years of menopause, and it is likely that women with high rates of bone loss are the ones who develop the fractures due to high-level trabecular bone loss. Another possibility is that these women reach menopause with low peak bone mass, and the menopause-induced bone loss makes them more prone to fractures.

Estrogen deficiency is thought to be the primary factor that underlies Type I osteoporosis. Estrogen deficiency, mediated by changes in cytokines, alleviates bone loss by up-regulating osteoclast formation and activation. The increase in bone resorption is believed to increase serum calcium marginally, which in turn decreases the PTH secretion. The decrease in serum PTH levels down-regulates the production of $1,25(OH)_2\ D_3$ and increases renal calcium excretion. A decrease in circulating $1,25(OH)_2\ D_3$ also results in impaired calcium absorption, which further increases the bone loss.

B. Senile Osteoporosis (Type II)

Type II (senile) osteoporosis (Fig. 4) occurs both in men and in women who are more than 75 years old. In Type II osteoporosis, there is cortical and trabecular bone loss and the patients present with fractures of the hip, pelvis, humerus, and vertebrae.

Age-related physiological changes contribute to the pathogenesis of Type II osteoporosis. Malabsorption of calcium is quite common in the elderly patient, in part due to low circulating levels of $1,25(OH)_2\ D_3$. However, there is evidence for intestinal resistance to endogenous $1,25(OH)_2\ D_3$, which results in secondary hyperparathyroidism. Vitamin D deficiency due to inadequate exposure to sunlight or to low dietary intakes of vitamin D and calcium is also common in elderly people who are housebound, and this can contribute to malabsorption of calcium, secondary hyperparathyroidism, and osteomalacia once serum 25OH D_3 levels fall below 12 ng/ml (30 nmol/liter). The decreased ability of the aging kidney to produce $1,25(OH)_2\ D_3$ is another factor responsible for decreased calcium absorption. The decrease in calcium absorption leads to negative calcium balance, which stimulates parathyroid function, which in turn promotes further bone loss.

Recent evidence, however, suggests that low circulating levels of estrogens in the elderly are also important in the pathogenesis of Type II osteoporosis. It has been demonstrated that in women 65 or older with undetectable serum estradiol concentrations (<5 pg/ml), there is accelerated bone loss and an increased relative risk of 2.5 for subsequent hip or

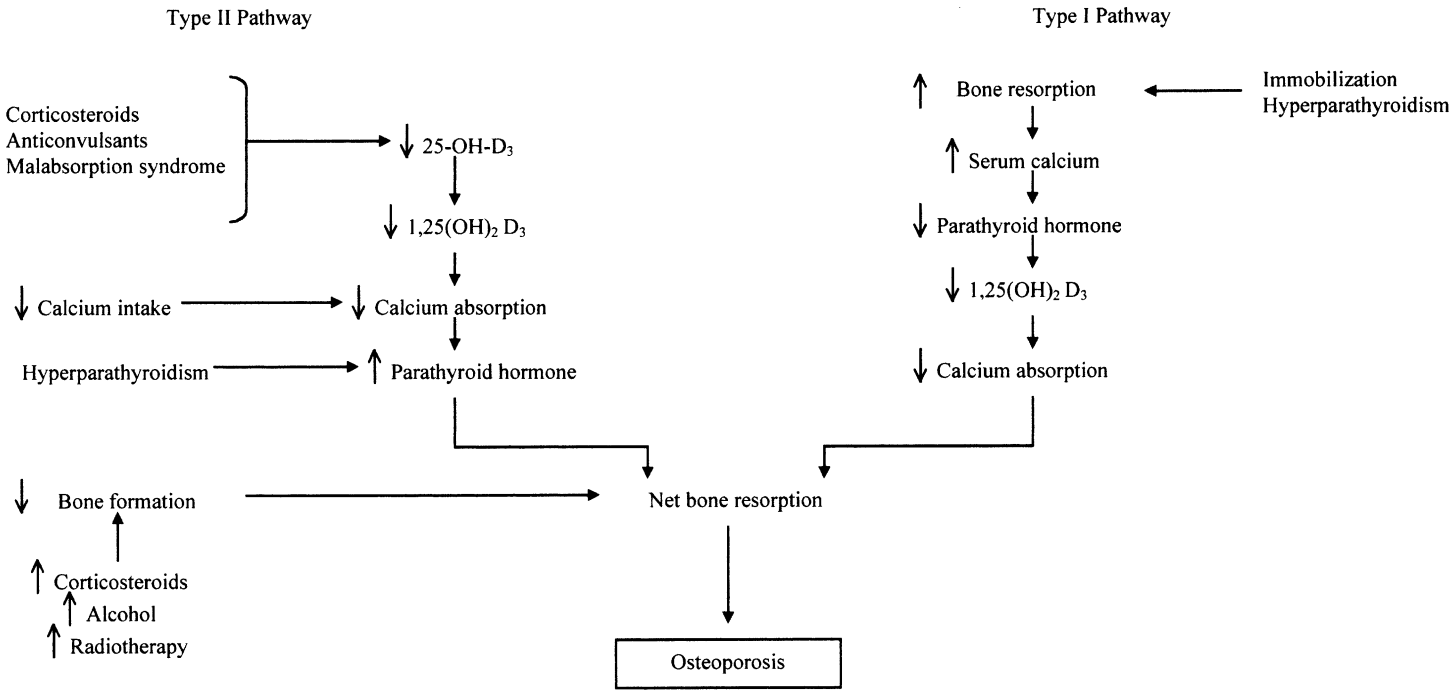

FIGURE 5 Pathogenesis of Type III osteoporosis. Adapted from Gallagher (1992) with permission from W.B. Saunders Company.

vertebral fractures. High serum concentrations of sex hormone-binding globulin, which binds estradiol and decreases its bioavailability, have also been reported to be associated with increased bone loss and increased risk of hip (relative risk of 2.0) and vertebral (relative risk of 2.3) fractures. Further evidence for the role of endogenous estrogens in age-related bone loss is provided by Heshmati *et al.*, who found an increase in bone resorption markers in older postmenopausal women after reducing the already low levels of serum estrogen to near undetectable levels with an aromatase inhibitor, letrozole. Based on this evidence, a unitary model has been proposed, which suggests that estrogen deficiency is the cause for both Type I and Type II osteoporosis. However, this hypothesis needs to be substantiated further.

C. Secondary Osteoporosis (Type III)

Secondary osteoporosis (Fig. 5) is used to describe osteoporosis that can be attributed to specific diseases, surgical procedures, and use of certain drugs. As a result of any of these conditions, Type III patients demonstrate accelerated bone loss, leading to vertebral or hip fracture. Type III osteoporosis can occur equally in men and women and at any age. Vertebral fractures in 20–35% of women and 40–55% men are accounted for by secondary osteoporosis. Some of the common conditions that lead to osteoporosis include hormonal imbalances (Cushing syndrome, thyrotoxicosis, and primary hyperparathyroidism), gastrointestinal disorders (primary biliary cirrhosis and malabsorption syndrome), drug therapy (e.g., corticosteroids, cancer chemotherapy, anticonvulsants, and heparin), neoplasms (multiple myeloma and skeletal metastases), alcoholism, chronic renal failure, immobilization, osteogenesis imperfecta, and transplantation (Table 2). The pathogenesis of the bone loss seen in these conditions could be explained by the mechanisms seen in Type I and Type II osteoporosis. However, in some conditions, the pathogenesis still needs elucidating. In general, patients with secondary causes of osteoporosis present with a hip fracture several years earlier than expected.

IX. THERAPEUTIC CONSIDERATIONS

There are several effective agents for preventing bone loss, and these are grouped together in the category of antiresorptive agents. They include estrogen, selective estrogen receptor modulators (SERMs), bisphosphonates, calcitonin, calcitriol, and, to a lesser degree, calcium supplements that are used as an adjunctive agent. Newer and more potent antiresorptives in the pipeline include osteoprotegerin and RANKL antagonists. However, antiresorptive agents are limited because they only prevent bone loss. For subjects with severe osteoporosis, agents that increase the formation of new bone are needed. Parathyroid hormone is the first of these systemic agents that increase trabecular thickness and continuity of bone. In addition, BMP proteins, which are osteogenic in vivo, are considered to be therapeutic molecules in the treatment of fractures to induce new bone formation at the site of injury. We can expect more anabolic agents to emerge in the next few years as we explore our understanding of the bone remodeling process.

Glossary

hyperparathyroidism Condition defined by excess parathyroid hormone secretion; leads to accelerated bone turnover.

1,25-dihydroxyvitamin D_3 Steroid hormone form of vitamin D; a principal regulator of calcium homeostasis.

osteoblast Cell derived from a pluripotent mesenchymal stem cell; principally involved in bone formation and mineralization of bone.

osteoclast Large multinucleated cell derived from the hematopoietic precursor of monocyte/macrophage cell lineage; involved in resorption of bone.

Ovulation

Ariel Hourvitz* and Eli Y. Adashi†

Tel Aviv University • †University of Utah

Ovulation, a complex process initiated by the surge of LH, constitutes the ultimate step in the maturation of the ovarian follicle and its contained oocyte. Once initiated, a cascade of events transpires that culminates in the disintegration of the follicular wall and the release of a fertilizable oocyte. This complex series of events inevitably involves specific ovarian cell types and diverse signaling pathways. The individual phases of the normal ovarian life cycle are controlled by a highly synchronized and exquisitely timed cascade of gene expression. Appropriate transition from one phase of the ovarian cycle to the next requires the timely expression of a specific gene(s) to ensure the correct continuation of the process.

I. INTRODUCTION

The teleologic underpinning of ovarian function draws on the fundamental need to preserve the species. Accordingly, the very existence of the ovary, and for that matter the very existence of the reproductive axis as a whole, is designed to subserve a single central objective: the generation of a mature, fertilizable ovum.

The ovary is the master gland in this process, the function of which is made possible by the contribution of the various other components of the reproductive axis. This article will emphasize the cycle of follicular growth and development: recruitment, selection and dominance, ovulation, and corpus luteum formation and demise. In addition, the major operational characteristics of ovulation will be reviewed.

II. FOLLICULAR GROWTH AND DEVELOPMENT: RECRUITMENT, SELECTION, AND DOMINANCE

The primordial follicle consists of an oocyte arrested in the diplotene stage of the first meiotic prophase, surrounded by a single layer of granulosa cells. It is first noted by week 16 of intrauterine life, and it is generally accepted that the formation of follicles ends no later than 6 months postpartum. It is quite certain that this stage of follicular development is entirely gonadotropin-independent.

The preantral growth phase is the phase of follicular development in which the primordial follicles (30 μm in diameter) are converted to mature secondary follicles (120 μm in diameter). Initiated during months 5 to 6 of gestation, the process becomes evident when the granulosa cells undergo

proliferation and differentiation combined with theca hypertrophy and the growth and differentiation of the oocyte including the acquisition of the zona pellucida. The resulting mature secondary follicles constitute the pool of preantral follicles from which tonic, likely follicle-stimulating hormone (FSH)-dependent recruitment of follicles takes place.

The term recruitment has been used to indicate that a follicle has entered the so-called growth trajectory, that is, the process wherein the follicle departs from the resting pool to begin a well-characterized pattern of growth and development. Recruitment, although obligatory, does not guarantee ovulation. The recruitment process is a "continuum" process beginning at infancy and stopping when the pool of available oocytes is exhausted. It goes on all times and at all ages, uninterrupted by pregnancy or other periods of non-ovulation. The stimuli for the recruitment of the follicles are unknown but for the process to continue, a specific hormonal environment is needed. The absence of this environment will cause the atresia of most of those follicles. However, the specific hormonal environment present at the beginning of the cycle, mostly the increase in FSH, will enable the formation of a cohort of developing follicles. Following recruitment, the flattened granulosa cells become cuboidal and small gap junctions are formed between the granulosa cells and the oocyte.

The term selection indicates the final winnowing of the maturing follicular cohort (by atresia) down to a size equal to the species-specific ovulatory quota. Accordingly, selection is complete when the number of healthy follicles (i.e., with ovulatory potential) in the cohort equals the ovulatory quota. Like recruitment, selection does not guarantee ovulation. Given its greater temporal proximity to ovulation, however, selection may, with high probability, be expected to be followed by ovulation in a typical cycle.

The leading follicle can be distinguished from other members of the cohort by its sheer size and the high mitotic index of its granulosa cells. Moreover, only the leading follicle at this point in time displays detectable levels of FSH in its follicular fluid. This same follicle also displays significant follicular levels of estradiol. Indeed, it is generally agreed that the capacity to aromatize androgens efficiently is an important determinant of the chosen follicle. Most important, the follicle destined to ovulate displays a granulosa cell mitotic index that is high enough to ensure that smaller, albeit healthy, follicles are unlikely to catch up.

The term dominance refers to the status of the follicle destined to ovulate given its presumed key role in regulating the size of the ovulatory quota. The selected follicle becomes dominant approximately 1 week before ovulation. Consequently, it must maintain its dominance during the week before ovulation. Stated differently, the follicle selected for ovulation is functionally (not merely morphologically) dominant in that it is presumed to inhibit the development of other competing follicles on both ovaries. Inevitably, and for reasons that are not entirely clear, the dominant follicle (i.e., the sole follicle destined to ovulate) continues to thrive in circumstances that it itself has made inhospitable for others. This dominant follicle has produced relatively more estrogen than the other follicles in its cohort. The dominant follicle thus enjoys an orderly sequence of events wherein FSH and estrogen stimulate growth, antrum formation, and the appearance of luteinizing hormone (LH) receptors. The dramatic increase in estrogen production by the dominant follicle, observable during the second half of the follicular phase, is accompanied by falling levels of FSH. As a result, the nondominant follicles fail to thrive. Apparently, the intrafollicular concentrations of gonadotropins and of steroids are central to the self-amplification process.

Experimental findings are consistent with the possibility that the ovary itself may in fact play a zeitgeber role during the menstrual cycle and that this time-keeping function is subserved by the activities of the cyclic structures of the dominant ovary. The 28-day menstrual cycle is thus the result of the intrinsic life span of the cyclic ovarian dominant structures and is not the result of timed changes dictated by the brain or pituitary. The dominant follicle thus determines the length of the follicular phase, with the corpus luteum determining the length of the luteal phase.

These experiments also suggested that the selection of the follicle destined to ovulate had already occurred by day 8 of the cycle. Indeed, it would appear that no other member of the follicular cohort was competent to serve as a surrogate for the follicle to achieve a timely, midcycle ovulation. Thus, it could be suggested that the dominant follicle itself plays a key role in regulating the size of the ovulatory quota by inhibiting the development of any competing follicles in either ovary. A similar function is subserved by the corpus luteum. Thus, the ovulatory follicle, once it is selected during the midfollicular phase, and the corpus luteum are truly dominant ovarian structures. Accordingly, the next round of follicular growth occurs only after the interference by the cyclic structure is removed either artificially, by

experimental intervention, or naturally, after the demise of the corpus luteum. Further insight has been gained from studies wherein progesterone-replaced luteectomized primates were evaluated, revealing progesterone to be the principal luteal hormone responsible for the inhibition of luteal follicular growth. It is critical to note that circulating gonadotropin levels were apparently maintained after follicular or luteal ablation and that follicle recruitment occurred without an attendant increment in circulating gonadotropins. Thus, the inhibition of follicular growth by the cyclic structures of the ovary was not due to a decrement in the circulating levels of gonadotropins. Rather, it appeared to be due to local intraovarian influences. The above notwithstanding, careful re-evaluation of these issues may well be warranted in that careful examination of the data suggests at least a slight, albeit transitory, increase in the circulating levels of FSH after ablation.

Further insight has been derived from experiments revealing that the follicle destined to ovulate attains dominance 5 to 7 days after the demise of the corpus luteum. This conclusion was based on the observation that the levels of estradiol in ovarian venous serum were significantly different between ovaries as early as days 5 to 7 of the cycle. This divergence in estrogen secretion between ovaries provides the earliest hormonal index attesting to the emergence of the dominant follicle.

In the late follicular phase, the intrafollicular concentrations of estradiol are maximal at a time when the circulating estradiol levels surge to a peak. With the ovulatory LH surge, the intrafollicular concentrations of estradiol decrease along with parallel decrements in the intrafollicular concentrations of androstenedione. Concurrently, distinct, progressive increments have been noted for the intrafollicular content of both progesterone and 17α-hydroxyprogesterone, reflecting early granulosa cell luteinization.

III. OVULATION

As midcycle approaches, there is a dramatic rise in estrogen and a subsequent LH surge and to a lesser extent an FSH surge that trigger the dominant follicle to ovulate. The LH surge rapidly acts on granulosa cells of the preovulatory follicles to terminate the follicular growth and at the same time induce those genes required for the ovulatory process. Ovulation is characterized by various processes leading to follicle rupture, oocyte maturation, and formation of the corpus luteum.

For reasons that are not well understood, but possibly because of unique microenvironmental circumstances, one (rarely, more than one) follicle ovulates and gives rise to a corpus luteum during each menstrual cycle. In the human, both LH and hCG have been shown to stimulate the rupture of mature follicles. In hypophysectomized rats, however, highly purified FSH can serve as the ovulatory hormone after follicular maturation has been stimulated by the administration of FSH and LH. Interestingly, inhibitors of prostaglandin synthesis (introduced systemically or locally into the antrum) have been shown to inhibit ovulation in rats and rabbits. Because LH has been shown to stimulate prostaglandin biosynthesis by ovarian follicles, increased prostaglandin synthesis might mediate the ovulatory stimulus of LH.

Mechanically, ovulation consists of rapid follicular enlargement with subsequent protrusion of the follicle from the surface of the ovarian cortex. Ultimately, rupture of the follicle results in the extrusion of an oocyte–cumulus complex. In the human ovary, this sequence may well begin 5 to 6 days before the onset of the preovulatory LH surge. It is the latter event, however, that marks the end of the follicular phase of the cycle and precedes actual rupture by as much as 36 h. Fortuitous endoscopic visualization of the ovary around the time of ovulation has revealed that elevation of a conical stigma on the surface of the protruding follicle precedes rupture. Rupture of this stigma is accompanied by gentle, rather than explosive, expulsion of the oocyte and antral fluid, suggesting that the latter is not under high pressure. Indeed, direct measurements have demonstrated that intrafollicular pressure is low in preovulatory follicles.

Several hypotheses have been advanced to account for the rapid increase in size and rupture of the follicle. For one, consideration was given to changes in the composition of the antral fluid during the period of rapid preovulatory follicular enlargement. In addition to changes in the steroid hormone content, an increase in colloid osmotic pressure has been noted. Although the granulosa cell-derived proteoglycans undoubtedly play a critical role in regulating the colloid osmotic pressure, little concrete information regarding the nature of their involvement is in fact available. Thus, a cause and effect relationship between the altered composition of antral fluid and the enlargement and rupture of the follicle remains to be established. Alternatively, stigma formation and rupture may reflect the effects of hydrolytic enzymes acting locally on protein substrates in the basal lamina.

In keeping with this notion, instillation of protease inhibitors into the antral fluid inhibits ovulation. One such proteolytic enzyme, plasminogen activator, has been localized in increasing concentrations in the walls of rat ovarian follicle just before ovulation. Plasminogen activator, a serine protease, stimulates the conversion of plasminogen (a follicular fluid constituent) to the proteolytically active enzyme plasmin. The latter is known to activate collagenase, presumably an obligatory element in the dissolution of the basal membrane and the perifollicular stroma in the course of ovulation. It is thus generally presumed that plasminogen activator-mediated conversion of plasminogen to plasmin may contribute to the proteolytic digestion of the follicular wall, a prerequisite of follicular rupture. Consideration is also being given to the possibility that plasminogen activator may be involved in gap junction disruption and thereby in the delicate communication between the oocyte and the surrounding cumulus cells. Although the ultimate physiologic significance of plasminogen activator remains a matter of study, there is little doubt as to the ability of somatic ovarian cells to produce this protease in measurable amounts in a manner subject to tight hormonal regulation. The FSH-dependent production of plasminogen activators by granulosa cells is particularly well documented.

IV. CORPUS LUTEUM FORMATION AND DEMISE

After ovulation, the dominant follicle reorganizes to become the corpus luteum. Thus, after rupture of the follicle, capillaries and fibroblasts from the surrounding stroma proliferate and penetrate the basal lamina.

Concurrently, the mural granulosa cells undergo morphologic changes collectively referred to as luteinization. These cells, the surrounding theca interstitial cells, and the invading vasculature intermingle to give rise to a corpus luteum.

Clearly, it is this endocrine gland that is the major source of sex steroid hormones secreted by the ovary during the postovulatory phase of the cycle. An important aspect of this phenomenon is the penetration of the follicle basement membrane by blood vessels, thereby providing the granulosa–luteal cells with circulating levels of low-density lipoprotein (LDL). As stated earlier, LDL cholesterol serves as the substrate for corpus luteum progesterone production.

Normally, the functional life span of the corpus luteum is 14 ± 2 days. Thereafter, the corpus luteum spontaneously regresses, to be replaced (unless pregnancy occurs) at least five cycles later by an avascular scar referred to as the corpus albicans. The mechanisms underlying luteolysis remain unclear. Both estrogens and prostaglandins, however, have been suggested as important factors in the promotion of luteal demise. The above notwithstanding, there is little doubt as to the central role of LH in the maintenance of corpus luteum function. Thus, withdrawal of LH support in various experimental circumstances has virtually invariably resulted in luteal demise.

V. OVARIAN STEROIDOGENESIS

To distinguish steroid hormones secreted by the ovary from those secreted by the adrenal or those produced by peripheral metabolism of precursors, studies have determined and compared the steroid hormone content of ovarian venous effluents and peripheral venous blood. Such studies revealed that the ovaries secrete pregnenolone, progesterone, 17α-hydroxyprogesterone, esterone, dehydroepiandrosterone, androstenedione, testosterone, estrone, and 17β-estradiol. Although such measurements provide significant insight into the steroidogenic pathways under study, they do not identify the specific ovarian cell types involved. In attempts to make these distinctions, steroid hormones have been identified and quantified in medium conditioned by whole (sliced or minced) ovaries, microdissected follicles, or ovarian cell suspensions. It is this combined body of knowledge that underlies our current understanding of adult ovarian steroidogenesis.

Studies using microdissected follicles identified estrone and estradiol as the major products of the follicle. In contrast, progesterone and 17α-hydroxyprocesterone proved to be the major products of the corpus luteum. Studies employing (labeled or unlabeled) C21 and C19 precursors revealed the isolated granulosa cell to be capable of producing mostly progesterone and estrogens along with 17α-hydroxyprogesterone. In contrast, isolated theca cells produced progesterone, 17α-hydroxyprogesterone, and androstenedione.

A. Estrogen Biosynthesis

Granulosa cells are the cellular source of estradiol and progesterone, the two most important ovarian steroids. Although the granulosa cells and their lutein counterparts are capable of producing progesterone independent of other ovarian cell types,

the biosynthesis of estrogens requires cooperation between the granulosa cells and their theca neighbors. The participation of these two cell types and of the two gonadotropins (FSH and LH) in ovarian estrogen biosynthesis underlies the two-cell/two-gonadotropin hypothesis, an integrative process required for ovarian estrogen biosynthesis. According to this view, theca-derived, LH-dependent, aromatizable androgens are acted upon by FSH-inducible granulosa cell aromatase activity. Indeed, in virtually all species ovarian estrone and estradiol derive from the androgen precursors androstenedione and testosterone. A broader view of this concept could and probably should allow its extension to include intercellular exchanges of other steroidogenic substrates. Indeed, recent studies strongly suggest that intercellular exchanges of C21 steroids occur at multiple levels of the steroidogenic cascade.

That follicular estrogen biosynthesis requires both granulosa and theca interstitial cells was first discovered by Falck in 1959 through a series of elegant and now classic experiments. The biochemical basis of this two-cell/two-gonadotropin theory was later provided by Ryan and Petro, whose findings revealed the theca interstitial cells to be the producers of C19 androgens, with the granulosa cells being the primary cellular site of aromatization. Moreover, Ryan *et al.* were able to show that the conversion of acetate to estrogen is substantially enhanced by the co-incubation of granulosa and theca cells. This observation, along with a body of related information, was elegantly summarized by Bjersing in 1967: "C19 precursor steroids are elaborated by theca–interstitial cells and are transferred across the basement membrane of the follicle to the granulosa cells where they are aromatized to estrogens." The above notwithstanding, the two-cell/two-gonadotropin hypothesis has been challenged by *in vivo* studies in the subhuman primate.

In keeping with these conclusions, studies of isolated granulosa cells revealed that FSH, but not LH, stimulates estrogen biosynthesis in a manner contingent on the provision of an exogenous aromatizable androgenic substrate. In contrast, isolated theca cells did not produce significant amounts of estrogens in any experimental circumstances. Indeed, aromatase activity of granulosa cells was estimated to be at least 700 times greater than that of theca cells from large preovulatory follicles. As such, these results are consistent with the hypothesis that granulosa cells are the principal site of estrogen biosynthesis in the dominant preovulatory follicle. These observations suggest that androgen (mainly androstenedione) produced by LH-stimulated theca cells is the main substrate for estrogen biosynthesis by FSH-stimulated granulosa cells. Although estrone may well be the most immediate estrogen produced, it in turn is readily converted to estradiol as a result of the (granulosa cell-based) activity of the steroidogenic enzyme 17β-hydroxysteroid dehydrogenase. The complex aromatization process involves the loss of the angular C19 methyl group and the stereospecific elimination of the 10 and 20 hydrogens of the A ring of the androgen precursor. As such, a total of three hydroxylation reactions are required per mole of estrogen formed.

The hormonal action of both LH and FSH appears to require the intermediacy of the membrane-associated enzyme adenylate cyclase. Indeed, it is generally accepted that gonadotropin-mediated stimulation of adenylate cyclase results in the conversion of intracellular ATP to cyclic AMP. The latter, in turn, is thought to bind to the regulatory subunit of a protein kinase (commonly referred to as A kinase), whereupon the catalytic subunit of the enzyme is activated and dissociated. This in turn phosphorylates key intracellular proteins central to the signal transduction sequence.

B. Progestin Biosynthesis

The granulosa cell, like the theca interstitial cell, is amply endowed to carry out progestin biosynthesis. Central to this process, however, is the availability of abundant supplies of cholesterol, which serves as the starting material for the steroidogenic cascade. Recent studies have shown that cholesterol used for membrane synthesis and steroid hormone production is derived primarily from circulating serum lipoproteins rather than from *de novo* cellular synthesis from acetate. LDL particles are known to bind to specific membrane receptors, with the LDL–receptor complexes entering the cell by receptor-mediated endocytosis. Thereafter, the endocytotic vesicles are known to fuse to lysosomes wherein LDL cholesterol esters are hydrolyzed to yield free cholesterol. The free cholesterol, in turn, is reesterified and stored in the cytoplasm in lipid droplets. Faced with steroidogenic demands, the cholesterol ester is hydrolyzed and the free cholesterol is transported to mitochondria for standard steroidogenic processing.

The importance of LDL cholesterol for ovarian progesterone secretion is demonstrated by the observation that the presence of LDL is required for maximal progesterone secretion by cultured cells.

High-density lipoprotein does not support human ovarian progesterone biosynthesis. Thus, the very availability of LDL to various ovarian compartments could influence steroid hormone production. For example, the relative avascularity of the granulosa cell layer expectedly limits progestin biosynthetic capacity. In keeping with this observation, human follicular fluid contains little or no LDL, thereby limiting the ability of preovulatory granulosa cells to produce progesterone 67. The above notwithstanding, the intrafollicular concentrations of progesterone do rise after the LH surge (before ovulation), suggesting a diminution in the lipoprotein barrier. Moreover, after ovulation occurs, vascularization of the corpus luteum provides the means by which LDL is delivered to the luteinized granulosa cells, thereby allowing progesterone biosynthesis to begin.

Although lipoproteins clearly constitute the most abundant source of cholesterol, endogenously generated cholesterol may also be employed. Cholesterol itself is in turn converted to pregnenolone through the rate-limiting intermediacy of mitochondrial enzyme cholesterol side chain cleavage. The subsequent conversion of pregnenolone to progesterone occurs relatively readily by virtue of the relative abundance of the cytoplasmic enzymes 3β-hydroxysteroid dehydrogenase/Δ5, Δ4-isomerase. Although the human granulosa cell has been reported to contain low levels of 17α-hydroxylase activity and thus has the ability to convert progesterone to 17α-hydroxyprogesterone, the significance of this finding remains uncertain.

C. Androgen Biosynthesis

More recent studies of isolated human theca cells have revealed that the theca layer is the major cellular source of follicular androgen and that LH, rather than FSH, stimulates theca androgen production. In contrast, androgen production by isolated cultured human granulosa cells proved negligible with or without added gonadotropins.

The biosynthesis of C19 androgens is the sole domain of the theca interstitial cell. Accordingly, this cell type is amply endowed with the necessary machinery to generate C21 progestational precursors. More important, however, the theca interstitial cell is amply endowed with 17α-hydroxylase/desmolase (17–20) activity and is capable of converting Δ5 and Δ4 progestational precursors (i.e., pregnenolone and progesterone) to C19 products (dehydroepiandrosterone and androstenedione, respectively). Consequently, the presence of 17α-hydroxylase/desmolase (17–20) activity can be viewed as an exclusive feature of the ovarian theca interstitial cell.

VI. MOLECULAR CHARACTERIZATION OF THE OVULATORY CASCADE

Ovulation, a complex process initiated by the surge of LH, constitutes the ultimate step in the maturation of the ovarian follicle and its enclosed oocyte. Once initiated, a cascade of events transpires, culminating in the disintegration of the follicular wall and the release of a fertilizable oocyte. This complex series of events, inevitably, involves specific ovarian cell types, diverse signaling pathways, and temporally controlled expression of specific genes. To date, a major focus of the research on ovulation has been the analysis of known genes. These studies have led to the establishment of a number of genes as being critical to the murine ovulatory process through the generation of null mutants. Figure 1 depicts those genes

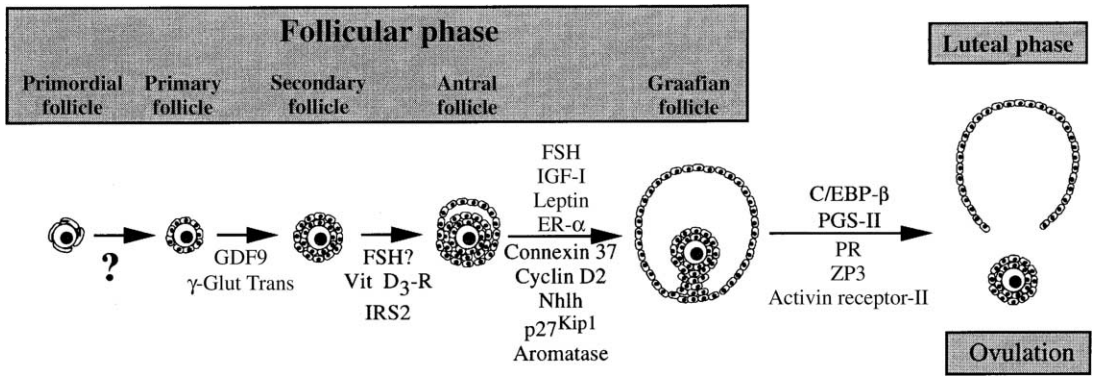

FIGURE 1 Known molecular determinants of folliculogenesis and ovulation. GDF9, growth differentiation factor 9; γ-Glut Trans, γ-glutamyl transferase; Vit D_3-R, vitamin D_3 receptor; ER, estrogen receptor; IRS, insulin receptor substrate; PGS-II, prostaglandin synthase II; PR, progesterone receptor; ZP3, zona pellucida protein 3.

TABLE 1 Gene Mutations Affecting Ovulation and Causing Infertility Due to Ovulation/Fertilization Failure

Disrupted gene	Gene symbol	Ovarian phenotype
Cyclooxygenase type 2	Cox-2 (PGS-2)	Defective ovulatory process; few eggs recovered, none of which were fertilized; the eggs thus recovered proved developmentally abnormal; ovulation failure even when stimulated with gonadotropins
Progesterone receptor	PR	Follicles do not rupture; oocytes become trapped in the ovary
Activin receptor II	ActR-II	Absence of corpora lutea, suggesting ovulatory failure
CCAAT/enhancer-binding protein β	C/EBPβ	Failure to ovulate; absent corpora lutea
Nuclear receptor-interacting protein 1	Nrip 1	Complete failure of oocyte release from mature follicles but luteinization appears normal
Early growth-response protein 1	Egr-1 (Krox-24)	Ovulatory failure due to an inhibition in the expression of the LHβ subunit and LH receptor genes
Ca^{2+}/Calmodulin-dependent protein kinase IV	CaMK-IV	Ovulatory failure with trapped oocytes present in some of the follicles
Cyclin-dependent kinase 4	Cdk4	Abnormal luteinization with disturbed cellularity, trapped oocytes, and a lack of copora lutea; granulosa cells appear normal; increased proestrous and diestrous phases
Cyclin D2	Cd2	Inability of ovarian granulosa cells to proliferate normally in response to FSH; failure to release the oocytes; corpora lutea carrying trapped oocytes
$p27^{Kip1}$	$p27^{Kip1}$	Ovulation is impaired; follicles do not progress to form corpora lutea

identified thus far as obligatory to the ovarian life cycle inclusive of those implicated in ovulation. The genes targeted were mostly those known to be expressed in the ovary and to play a role in follicular growth. Alternatively, a phenotype inclusive of ovulatory failure may be "stumbled upon" in the context of a study of a previously unknown gene or one not previously recognized as being important in ovarian physiology. Tables 1 and 2 display those genes for which the null deletion resulted in ovulation

TABLE 2 Gene Mutations Affecting Ovulation and Causing Reduced Ovulatory Efficiency

Disrupted gene	Gene symbol	Ovarian phenotype
Prostaglandin E2 receptor type 2	EP2	Reduced ovulatory efficiency; cumulus expansion does not occur
Zona pellucida 3	ZP3	Reduced ovulatory efficiency; disorganized cumulus granulosa cells
Colony-stimulating factor-1	CSF-1	Abnormal lengthy estrous cycles; low pregnancy rates; smaller litter sizes
Telomerase RNA	TR	Reduced ovulatory efficiency
Estrogen receptor-β	ER-β	Reduced fertility with altered ovulatory efficiency; increased number of early atretic follicles and sparse presence of corpora lutea, suggestive of arrested folliculogenesis
Nitric oxide synthase	NOS	Reduced fertility with altered ovulatory efficiency; significantly reduced number of ovulated oocytes, longer estrous cycle, and impaired oocyte meiotic maturation
Superoxide dismutase-1	Sod-1	Infertility or reduced fertility with smaller litter size; primary and small antral follicles but few corpora lutea
Urinary trypsin inhibitor	Uti	Severe reduction in fertility; markedly reduced ovulatory efficiency; disorganized corona radiata; large number of retained oocytes
Steroid receptor co-activator-3	Src-3	Decreased ovulation; lower pregnancy rate; small litter size; longer estrous cycling time
c-AMP-specific phosphodiesterase type 4	PDE4D	Reduced number of ovulated oocytes; degeneration of ovulated oocyte; entrapped oocytes

failure (Table 1) or reduced ovulatory efficiency (Table 2) and thus in infertility. Understandably, ovulation failure in the different knockout models is usually associated with additional and often considerable ovarian defects.

In the past few years, the use of advanced molecular biology techniques such as differential display reverse transcription-polymerase chain reaction, subtractive suppression hybridization, DNA array technology, and *in silico* methods has led to the identification of new ovulatory genes. Using these different techniques, researchers were able to identify a multitude of novel ovulatory up-regulated genes. These genes induced by LH include among others, carbonyl reductase, 3α-hydroxysteroid dehydrogenase, regulator of G-protein signaling, tumor necrosis factor-induced gene-6, and early growth regulator-1. The exact role of these genes in the ovulatory process is not clear yet, but their diverse functions and spatial expression in the ovary prove the complexity and global effect of the ovulatory process.

VII. SUMMARY

Recent advances in the human and mouse genome projects, combined with the development of advanced molecular technology such as differential display analysis, subtractive hybridization, and microarray analysis, now provide the opportunity to analyze the expression pattern of thousands of genes. This approach has already led to the identification of new genes that are expressed in the ovary. It will ultimately allow the achievement of a global view of gene expression as it relates to the ovulatory process. Functional studies of these newly discovered genes, based mainly on gene targeting technology, will allow a better understanding of the genetic determinants of the ovulatory cascade and thereby, the endocrine regulation of fertility and its control.

Glossary

dominance The status of the follicle destined to ovulate given its presumed key role in regulating the size of the ovulatory quota.

LH surge Midcycle surge of pituitary luteinization hormone initiating the ovulatory cascade.

luteinization The ovulatory-related process of formation of the corpus luteum from the ovulatory follicle. The corpus luteum comprises luteal and nonluteal cell types. The luteal cells differentiate from the theca and granulosa cells and have the capacity to produce steroids and peptide hormones.

ovulation Release of a fertilizable ovum from the graafian follicle. In its broader sense, the ovulatory response defines the cascade of events following the LH surge and including the resumption of meiosis and oocyte maturation, luteinization, and the rupture of the follicular wall.

ovulatory cascade A highly synchronized and exquisitely timed cascade of specific gene(s) expression to ensure the correct process of ovulation.

recruitment The process wherein the follicle departs from the resting pool to begin a well-characterized pattern of growth and development. Recruitment, although obligatory, does not guarantee ovulation. Stated differently, recruitment is necessary but not sufficient for ovulation to occur.

selection The final winnowing of the maturing follicular cohort by atresia down to a size equal to the species-specific ovulatory quota.

Oxyntomodulin

BO AHRÉN

Lund University, Sweden

Oxyntomodulin is a gut hormone. This article describes the structure and processing of the hormone, the regulation of its expression and secretion, its effects and mechanisms, as well as possible involvement of the hormone in gastrointestinal disorder.

I. INTRODUCTION

Oxyntomodulin, a 37-amino-acid peptide, is processed from proglucagon in the intestinal L-cells and is released after food intake. Although the physiological role of oxyntomodulin remains to be established, it inhibits gastric acid secretion, gastric emptying, and pancreatic exocrine secretion and stimulates insulin secretion.

The intestinal proglucagon-derived peptide oxyntomodulin works mainly by activating receptors that are more specific for other proglucagon-derived peptides, through actions involving phosphoinositide hydrolysis and formation of cyclic AMP. Physiologically, the peptide may be an enterogastrone and/or an incretin factor; oxyntomodulin may be involved in gastrointestinal disorders, although this has not been established.

II. OXYNTOMODULIN BIOCHEMISTRY

A. Expression of Oxyntomodulin

Oxyntomodulin belongs to the enteroglucagons or the glucagon-like substances in the gut. These substances were initially identified in intestinal mucosa in 1948 by Sutherland and de Duve using bioassay techniques, and in the sixties by Unger and collaborators using radioimmunoassay. Later studies revealed that these substances consist of a variety of several different peptides. All are produced in the gut L-cells, which are of the open type of gut endocrine cells that are located preferentially in the mucosal cell lining of the distal portion of the ileum. All enteroglucagons are encoded by the same glucagon gene, which in humans is located on chromosome 2q36–q37. This gene is also expressed in the pancreatic A-cells and in the brain. It encodes a single proglucagon messenger RNA transcript that is translated into a single 158-amino-acid sequence comprising the proglucagon peptide. Proglucagon, which is identical in all cells expressing the proglucagon gene, is processed through intracellular cleavage, yielding several different peptides (Fig. 1). However, the prohormone processing is different in each cell type expressing proglucagon. In the gut L-cells and in the brain, proglucagon is processed to glicentin, glicentin-related polypeptide (GRPP), oxyntomodulin, glucagon-like peptides (GLP-1 and GLP-2), and intervening peptide-2 (IP-2). In contrast, in the pancreatic A-cells, proglucagon processing gives rise to glucagon, GRPP, major proglucagon factor

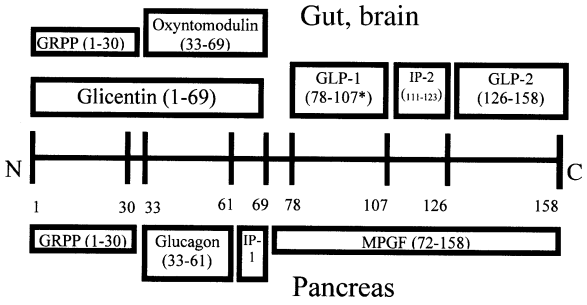

FIGURE 1 Processing of the 158-amino-acid sequence of the proglucagon molecule in the intestinal L-cells and brain (top) versus the pancreatic A-cells (bottom). Numbers denote amino acids. In the gut and brain, proglucagon is processed to glicentin, glicentin-related polypeptide (GRPP), oxyntomodulin, glucagon-like peptide-1 (GLP-1), intervening peptide-2 (IP-2), and GLP-2, whereas in the pancreas, proglucagon is processed to GRPP, glucagon, IP-1 (sequence 64–69), and major proglucagon factor (MPGF). * Indicates oxidation.

(MPGF), and IP-1. The differences in how glucagon is processed in L- and A-cells are explained by tissue-specific differences in expression of the two prohormone convertases (PCs), PC1 and PC2. Thus, oxyntomodulin is formed in cells expressing PC1, as in the L-cells, whereas glucagon is formed in cells expressing PC2, as in the pancreatic A-cells.

B. Formation and Structure of Oxyntomodulin

Formation of oxyntomodulin from proglucagon is a two-step process. First, glicentin is formed through cleavage between amino acids 69 and 70 in the proglucagon sequence. Glicentin is then further processed to form the 30-amino-acid sequence of GRPP and the 37-amino acid sequence of oxyntomodulin through a cleavage of a Lys-Arg dibasic sequence. Oxyntomodulin is equivalent to the C-terminal 37 amino acids of glicentin, corresponding to glicentin(33–69). From a quantitative point of view, approximately 20–40% of the glicentin formed is processed to oxyntomodulin, whereas the majority is released as glicentin. Oxyntomodulin also shows a high degree of structural identity to the other proglucagon-derived peptides, glucagon, GLP-1, and GLP-2 (Fig. 2). In fact, the N-terminal 29-amino-acid sequence of oxyntomodulin, i.e., glicentin(33–61), is identical to pancreatic glucagon. The amino acid sequence of oxyntomodulin is conserved through evolution, as is evident by the identical structure of oxyntomodulin in humans and guinea pigs.

C. Distribution of Oxyntomodulin

Because oxyntomodulin is formed during processing of proglucagon in cells expressing PC1, its cellular distribution is limited to the gut L-cells and certain brain areas. In fact, the rat ileum has a 10-fold higher oxyntomodulin content per gram of tissue, compared to the duodenum, and the content in the colon is approximately double that in the duodenum, which is the same distribution as for L-cells. Studies on oxyntomodulin levels in extracts of various areas of the rat brain show that the most marked expression of oxyntomodulin is in the hypothalamus. Oxyntomodulin is also expressed in the medulla oblongata, although at a 10-fold lower level than in the hypothalamus. In contrast, only trace amounts of oxyntomodulin have been demonstrated in the olfactory bulb, cerebellum, and cortex, and no oxyntomodulin has been detected in the pituitary.

D. Regulation of Expression of Oxyntomodulin

Nutrient ingestion is the primary stimulus for expression of the proglucagon gene in the gut, and therefore for formation of oxyntomodulin. Increased proglucagon gene expression is seen in rats after feeding, whereas fasting is associated with reduced gene expression. Proglucagon gene expression and proglucagon formation are also increased in rats after intestinal injury or intestinal resection. These findings suggest that proglucagon-derived factors are of importance for prandial processes as well as for response to injury.

E. Regulation of Secretion of Oxyntomodulin

After its formation, the mature 37-amino-acid oxyntomodulin is stored in the secretory granules and is secreted extracellularly when L-cells are activated. A rapid secretion of the proglucagon-derived peptides from the L-cells is induced by nutrient ingestion, and both intralumenal carbohydrates and triglycerides have been shown to be of relevance. These nutrients stimulate oxyntomodulin release through activation of L-cells from the gut lumenal side. Nutrient ingestion may, however, stimulate L-cell secretion indirectly through activation of intestinal nerves, as illustrated in rats by a study showing that oxyntomodulin released by intraduodenal administration of oleic acid is inhibited via ganglionic blockade by hexamethonium.

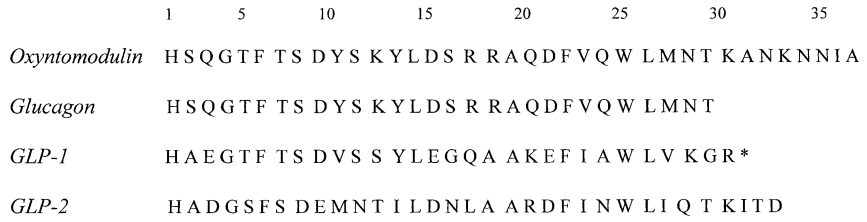

FIGURE 2 Amino acid sequences of oxyntomodulin, glucagon, glucagon-like peptide-1 (GLP-1), and GLP-2. The asterisk indicates amidation.

This is analogous to studies on the potential involvement of nerves in the regulation of GLP-1 secretion, showing that cholinergic nerves and the intestinal neuropeptide gastrin-releasing peptide (GRP) are stimulatory whereas adrenergic nerves are inhibitory.

F. Circulation of Oxyntomodulin

In plasma, circulating fasting levels of oxyntomodulin are approximately 15 pmol/liter in both humans and rats, and these levels are increased approximately twofold following refeeding. The increase in circulating levels is evident within 30 min after meal ingestion. Similarly, a study on the 24-h profile of oxyntomodulin-like immunoreactivity in humans has shown that plasma levels increase after each meal. Pharmacokinetic studies have shown that oxyntomodulin is rapidly eliminated through a two-phase elimination mechanism. In the pig, a rapid first phase has a half-life of 7 min and a slow second phase has a half-life of 20 min. In humans, the plasma half-life of oxyntomodulin has been estimated to 12 min. However, the metabolic pathways responsible for degradation of oxyntomodulin in plasma are not known. The fate of oxyntomodulin differs from the metabolic fates of the two other hormones from the L-cells, GLP-1 and GLP-2, which are both degraded by removal of the two N-terminal amino acids (His-Ala) by the enzyme dipeptidyl peptidase IV, because this enzyme requires for action either alanine or proline in position 2 of the substrate, which is not the case for oxyntomodulin.

G. Effects of Oxyntomodulin

The first described effect of oxyntomodulin was a stimulatory action on the formation of cyclic AMP in the acid-secreting fundic portion of rat stomach, which in fact was the basis for Bataille and collaborators to name the peptide oxyntomodulin. They found that oxyntomodulin was approximately 20 times more potent than glucagon in augmenting cAMP in this system, in contrast to having only 10% of the potency of glucagon in stimulating cAMP formation in membranes from the rat liver. This difference was later reproduced in studies using a preparation of highly enriched rat gastric parietal cells, and it was also shown that oxyntomodulin stimulates acid secretion through a cAMP-dependent mechanism.

However, in several other systems, oxyntomodulin has been shown to inhibit gastric acid secretion. Oxyntomodulin inhibits histamine- and pentagastrin-induced gastric acid secretion in rats *in vivo* without affecting basal gastric acid secretion; in humans, oxyntomodulin inhibits pentagastrin-stimulated gastric acid secretion. This inhibitory action on gastric acid secretion *in vivo* is explained by a stimulatory action of oxyntomodulin on somatostatin secretion from D-cells; somatostatin in turn inhibits gastric acid secretion. Oxyntomodulin has also been shown to stimulate smooth muscle contraction in the stomach, as demonstrated by a reduced mean length of isolated rat gastric smooth muscle cells, and the peptide also inhibits ion and water transport through the rat small intestine. Moreover, oxyntomodulin inhibits pancreatic exocrine secretion in rats, both in terms of the volume of juice as well as the bicarbonate and protein output, which has been shown to be an indirect action through activation of the vagal nerves. In humans, oxyntomodulin also delays gastric emptying, inhibits postprandial duodenal motility and exocrine pancreatic enzyme secretion,and inhibits pentagastrin-stimulated gastric acid secretion. Therefore, at least under *in vivo* conditions, oxyntomodulin seems to act as a general inhibitory agent on proximal gastro-entero-pancreatic postprandial events, suggesting that it is involved in the small intestinal inhibitory control of these functions.

Oxyntomodulin also affects processes of relevance for carbohydrate metabolism. Infusion of oxyntomodulin in rats increases glucose absorption in the jejunum and promotes glucose release from isolated hepatocytes. Furthermore, oxyntomodulin stimulates insulin and somatostatin secretion from the pig pancreas and augments insulin secretion in the presence of glucose in the perfused rat pancreas. Infusion of oxyntomodulin increases plasma insulin and C-peptide concentrations in humans. Thus, oxyntomodulin has the ability to increase glucose levels through actions on the gut and liver, but also to reduce glucose levels through its stimulation of insulin secretion.

III. RECEPTORS FOR OXYNTOMODULIN

In spite of the various effects induced following exogenous administration of oxyntomodulin, no specific oxyntomodulin receptor has been identified or cloned. Instead, oxyntomodulin has been suggested to act through activation of receptors that are more specific for the other proglucagon-derived peptides. For example, oxyntomodulin increases cAMP formation in a cell line transfected with the GLP-1 receptor, and the peptide displaces radiolabeled GLP-1 bound to these cells, although the potency of

oxyntomodulin is lower than that of GLP-1. Similarly, oxyntomodulin stimulates the release of somatostatin from a cell line by activating a GLP-1-selective receptor type and displaces radiolabeled GLP-1 from rat parietal cells. This suggests that oxyntomodulin acts at least partially through the GLP-1 receptors. However, oxyntomodulin has also been shown to bind to pig liver glucagon receptors, although with an affinity of only 2% of that of glucagon, suggesting a low-grade cross-reaction with these receptors. In addition, in isolated smooth muscle cells, oxyntomodulin seems to act through a glicentin/oxyntomodulin receptor type that shows high affinity for glicentin and low affinity for oxyntomodulin. Hence, several different receptor subtypes may transduce actions of oxyntomodulin. In a variety of experimental systems, there has been a general finding that the active site of oxyntomodulin resides in its C-terminal portion, because a C-terminal fragment, oxyntomodulin(19–37), is equipotent with the entire peptide.

IV. SIGNALING PATHWAYS OF OXYNTOMODULIN

Because oxyntomodulin may work through activation of GLP-1 and glucagon receptors, cyclic AMP is a likely second messenger for transducing the effects. This has been confirmed in a few studies of the signaling underlying the effects of oxyntomodulin. It has also been shown, however, that oxyntomodulin may activate other signaling pathways. For example, stimulation by oxyntomodulin of gastric smooth muscle cells is mediated by phosphoinositide hydrolysis, resulting in formation of inositol 1,4,5-trisphosphate ($InsP_3$) and liberation of Ca^{2+} from intracellular stores; this is accompanied by reduced formation of cAMP in a pertussis-toxin-sensitive manner. Oxyntomodulin may therefore activate G-protein-coupled receptors, which are linked to phospholipase C and/or adenylate cyclase.

V. OXYNTOMODULIN PHYSIOLOGY

The physiological role of oxyntomodulin remains to be established. Release of oxyntomodulin after ingestion of a meal suggests that the hormone is involved in regulation of postprandial nutritional or metabolic events. Its main function, to inhibit gastric acid secretion and pancreatic exocrine secretion, suggests that oxyntomodulin is an enterogastrone candidate. Enterogastrones are prandially released gut-derived factors that inhibit proximal events such as gastric acid secretion, gastric emptying, and pancreatic exocrine secretion, perhaps to prevent excessive acid or exocrine pancreatic secretion. Evidence that oxyntomodulin is an enterogastrone factor includes that it is released after ingestion of each meal and that it inhibits gastric acid secretion and pancreatic exocrine secretion when exogenously administered at dose levels that are equivalent to circulating levels under physiological conditions. Furthermore, one study has shown a negative correlation between circulating levels of oxyntomodulin and gastric acid secretion in humans. On the other hand, the potency of oxyntomodulin to inhibit gastric acid secretion, as demonstrated in dogs, is much lower than the potency of other enterogastrone candidates, such as peptide YY, secretin, and cholecystokinin. Therefore, the role of oxyntomodulin as an enterogastrone remains to be established.

Because oxyntomodulin also stimulates insulin secretion, it may also be an incretin factor. Incretin factors are gut hormones released after meal intake and they stimulate insulin secretion. Again, the evidence that oxyntomodulin may be an incretin factor resides in its release after food intake and its ability to stimulate insulin secretion. However, in comparison with the potency of the two main incretin candidates, GLP-1 and gastric inhibitory polypeptide (GIP), the potency of oxyntomodulin is low. Therefore, although oxyntomodulin is a potential incretin, it remains to be established that such an effect is indeed of physiological relevance.

Although oxyntomodulin is expressed in the brain, particularly in the hypothalamus, no studies so far have shown any effects of the peptide in the central nervous system. For example, oxyntomodulin infused for 7 days in rats has no effect on body weight or food intake. So far, there is no evidence of any role of oxyntomodulin in the regulation of the central nervous system.

VI. OXYNTOMODULIN PATHOPHYSIOLOGY

The potential involvement of oxyntomodulin in various gastrointestinal disorders has been the matter of a few studies. One study in subjects with duodenal ulcer has shown that circulating oxyntomodulin levels do not differ from those in controls. Another study has shown that children with celiac disease display high circulating levels of oxyntomodulin and that oxyntomodulin levels correlate to markers of malabsorption. Although this may suggest that oxyntomodulin is involved in the development of malabsorption, a more likely explanation is that the

peptide is involved in an adaptive mechanism. Expression of the proglucagon gene is known to be stimulated by intestinal injury and after intestinal resection, thus oxyntomodulin levels will increase under such conditions. Whether, however, oxyntomodulin has any role in this adaptation, as has been suggested for GLP-2, is not known. Therefore, the role of oxyntomodulin under pathological conditions is far from established.

Glossary

enterogastrones Hormones from the gut that are released after meal ingestion; inhibit gastric acid secretion and gastric emptying.

enteroglucagons Hormones produced in the intestinal glucagon cells (L-cells) through processing of the proglucagon molecule.

glicentin Intermediary 69-amino-acid peptide processed from proglucagon and cleaved to form glicentin-related polypeptide and oxyntomodulin.

glicentin-related polypeptide A peptide that is processed from the N-terminal end of glicentin in the intestinal L-cells.

incretins Hormones from the gut that are released after meal ingestion; stimulate insulin secretion.

oxyntomodulin A 37-amino-acid peptide that is processed from proglucagon in the intestinal L-cells and in the brain, but not in the pancreatic A-cells.

Oxytocin

JOHN A. RUSSELL AND ALISON J. DOUGLAS
University of Edinburgh, United Kingdom

Oxytocin is a nonapeptide (Cys^1-Tyr^2-$Ileu^3$-Gln^4-Asn^5-Cys^6-Pro^7-Leu^8-Gly^9-NH_2) that is produced only in mammals. Synthesis occurs in groups of nerve cells (neurons) and (variably, according to species) in reproductive tissues. Circulating oxytocin is entirely from the posterior pituitary gland. Oxytocin in the brain or cerebrospinal fluid is produced in the brain. Parturition, maternal behavior, and lactation are stimulated by oxytocin release.

I. INTRODUCTION

Oxytocin was one of the first hormones to be discovered. At the beginning of the past century, extracts of the posterior pituitary gland were shown to stimulate the contractile activity of the pregnant uterus. This led to the idea that oxytocin had a role in stimulating uterine contractions in parturition, and its name [Gk.: swift (*oxys*) birth (*tokos*)] derives from this action. It was later discovered that posterior pituitary extract is the most effective stimulant of milk let-down or milk ejection in lactating mammals. The other hormonal activity in the posterior pituitary is due to antidiuretic hormone (vasopressin), although it was not until Du Vigneaud characterized and synthesized the vasopressin and oxytocin peptides in the 1950s (for which work a Nobel Prize was awarded) that it was clear these are distinct molecules.

Oxytocin is a nine-amino-acid peptide, comprising a six-member ring formed by sulfide bridges between the two cysteines, and a short tail (~1 kDa). Vasopressin differs from oxytocin by having Phe at position 3 and Arg at position 8. Oxytocin is essentially a mammalian hormone (among other vertebrates it has been found only in the ratfish), and its close chemical similarity to vasopressin indicates that it arose in evolution first, by a duplication of the vasopressin gene (or its forebear), and then by mutations. It is clear, in particular from studies on mice with targeted disruption of the oxytocin gene, that oxytocin is indispensable for milk transfer during suckling; consequently, oxytocin is to be regarded as the hormone without which mammalian reproduction would not be possible. The oxytocin and vasopressin genes remain in close proximity to each other (in humans, on chromosome 20), and in opposite orientation, so that they are transcribed left to right and vice versa. Like other peptide hormones, the RNA transcribed from the oxytocin gene includes transcripts from several (three) exons separated by introns, and this heterogeneous nuclear RNA is processed to an mRNA that codes for the oxytocin peptide and for a much larger (~10 kDa) protein called oxytocin-neurophysin. This acts as a carrier for oxytocin in the cells in which it is produced, and they are secreted together, but as separate molecules; neurophysin has no known hormonal function, but its measurement in the circulation can be used as an indicator of oxytocin secretion. Among the marsupials, the oxytocin hormone produced is either oxytocin or the similar mesotocin (Ile is substituted for Leu at position 8), or both in some species.

Soon after its synthesis in the laboratory was achieved, industrial production began in the mid-1950s so that oxytocin could be used to promote labor in women, replacing use of the relatively impure posterior pituitary extract that had previously been used. Since its introduction into obstetric practice, millions of human births have been aided by the infusion, usually intravenously, of oxytocin. Also, on delivery of the infant, routine intramuscular injection of oxytocin (together with an ergot) to induce strong uterine contractions is a frontline measure to ensure occlusion of spiral arterioles, which are ruptured when the placenta separates, and thus to prevent postpartum hemorrhage. Conversely, the likely involvement of oxytocin in preterm birth has led to the development of oxytocin receptor antagonists to try to prevent this important cause of neonatal morbidity and mortality.

It became clear in the 1950s that oxytocin is also present in neurons projecting within the brain, where it acts as a neurotransmitter or modulator, with stimulatory roles in neural circuits concerned with affiliative and reproductive behaviors (actions that, together with peripheral effects, have earned oxytocin the title "love hormone"). To date, there is no known naturally occurring oxytocin deficiency state, and no known mutations, although both oxytocin peptide and oxytocin receptor "knockout" mice have been generated.

II. SOURCES OF OXYTOCIN IN THE BODY

A. The Posterior Pituitary Gland

The posterior pituitary gland contains the greatest amount of oxytocin in the body. About three times more oxytocin is stored in the posterior pituitary at

the end of pregnancy than is needed to drive the birth process. However, oxytocin stored in the posterior pituitary is not synthesized there: storage occurs in the many thousands of axon terminals of nerve cells that have their cell bodies in the hypothalamus, where oxytocin is continuously synthesized. These nerve cells are concentrated in two paired groups of neurons, or nuclei, in the hypothalamus: the supraoptic and paraventricular nuclei. The oxytocin nerve cell bodies have the general characteristics of neurons. These include dendritic processes, which, like the cell bodies, have many synapses that mediate inputs from many brain areas, using a wide range of excitatory and inhibitory neurotransmitters. Because the neuronal cell bodies produce relatively large amounts of peptide hormone, to achieve effective concentrations in the systemic circulation, they have abundant mRNA for oxytocin (oxytocin mRNA is the most abundant peptide mRNA species in the hypothalamus) and prominent protein synthetic machinery. This includes the Golgi apparatus, where the oxytocin-neurophysin preprohormone is processed and packaged into membrane-bound vesicles. The cell bodies of the oxytocin neurons are thus larger than other hypothalamic neurons and are visible in histological sections as closely packed "magnocellular" neurons. The similarity between oxytocin and vasopressin has been mentioned already, and this extends to the similarity between the oxytocin neurons and those producing and storing vasopressin. Importantly, magnocellular hypothalamic neurons make either oxytocin or vasopressin, but not both (except for a small percentage of vasopressin neurons that may also express oxytocin when there is a large demand, as in lactation), even though both types of neuron are adjacent to one another in both the supraoptic and the paraventricular nuclei. They can be distinguished from each other with an immunocytochemical technique, using antibodies for oxytocin or vasopressin. These neurons differ in other respects that allow them to respond in the most appropriate ways to the different stimuli that activate them and to generate optimal patterns of hormone secretion (see later). What determines whether a magnocellular neuron develops as an oxytocin or a vasopressin neuron is presently not understood; the intergenomic region that links the oxytocin and vasopressin genes evidently contains important sequences that regulate which gene is expressed.

The vesicles containing oxytocin and neurophysin are actively transported within the axon of each neuron, leaving the cell body and arriving several hours later a few millimeters away in the branching terminals in the posterior pituitary. The stalk of the posterior pituitary gland that connects the gland to the hypothalamus mainly comprises these axons, which are packed with the vesicles containing oxytocin (and its neurophysin). Some of the vesicles containing oxytocin are transported from the cell bodies into the dendrites of the neurons, thus remaining in the brain, in the hypothalamus. The secretion of oxytocin by the nerve terminals in the posterior pituitary gland occurs only when the terminals are depolarized by the arrival of action potentials, conducted along the axons from the cell bodies, at $\sim 1\,\mathrm{m\,s^{-1}}$. These action potentials are generated in the cell bodies of the magnocellular oxytocin neurons in the hypothalamus when they are excited by their synaptic input, or are otherwise depolarized. This mechanism can be simulated by electrical stimulation of the pituitary stalk to study the relationship between the frequency and pattern of action potentials and oxytocin secretion, and the signaling mechanisms in the nerve terminals that couple depolarization to the release of oxytocin.

The key event following arrival of action potentials is the opening of the membrane channels that allow entry of calcium ions; the increase in cytoplasmic calcium ion concentration then triggers the intracellular machinery that moves the oxytocin secretory vesicles to the plasma membrane of the nerve terminal, with which they fuse and release their contents into the extracellular space in the process of exocytosis. The peptide released by this neurosecretory mechanism then passes through the fenestrations in the walls of the adjacent capillaries, to be carried in the systemic circulation to target tissues.

There are two particularly important points about the coupling of the stimulation of the cell bodies of the oxytocin neurons to the secretion of oxytocin from their terminals. The first is that more oxytocin is secreted per action potential if the action potentials are close together (in a "burst"); this is "frequency facilitation" of release. The second is that if all of the oxytocin neurons have a burst of activity at the same time, then the result will be the secretion of a "pulse" of oxytocin into the circulation, achieving a high concentration for a short time. (The importance of this pattern of secretion is explained later.) Once oxytocin is secreted into the circulation it has a half-life of only 2 min or so, being cleared by the tissues on which it acts and by excretion from the kidneys.

B. Oxytocin Within the Brain

Very little, less than 1%, of the circulating oxytocin is able to enter the brain because the blood–brain barrier prevents entry of this peptide, as for most other peptide hormones. However, oxytocin has well-established functions in the central nervous system, the blood–brain barrier effectively allowing the brain and posterior pituitary oxytocin systems to function independently. There are two sources of oxytocin in the brain, the first being the magnocellular neurons of the paraventricular and supraoptic nuclei that secrete oxytocin from their axon terminals in the posterior pituitary, because they also secrete oxytocin from their dendrites, in a way similar to the mechanism operating in the posterior pituitary. Oxytocin from these dendrites has local and probably more distant actions. Second, in the paraventricular nucleus, there are the separate populations of oxytocin neurons that project their axons only centrally, to other brain or spinal cord regions.

C. Peripheral Sources of Oxytocin

The hypothalamic magnocellular neuron-posterior pituitary and the central neuron sources of oxytocin are common to all mammals. There are also peripheral sources of oxytocin that show species or class specificity.

1. Uterus

In pregnancy in humans and in rats, but not in the mouse, cow, or sheep, the oxytocin gene is expressed in the lining of the uterus, placenta, and amnion. Because the adjacent late-pregnant myometrium is a target tissue for oxytocin action, it is possible that oxytocin produced locally acts in this way. However, oxytocin is released not from the side of the cells adjacent to the myometrium, but from the lumenal surface of the uterine epithelium, where there are also oxytocin receptors. It seems unlikely that this source of oxytocin can directly stimulate the myometrium. Instead, this oxytocin is more likely to act by stimulating prostaglandin production by the epithelium or endometrial decidual cells, or in humans by the amnion; in the rat, the amnion lacks the oxytocin receptor.

2. Corpus Luteum

In ruminants (cattle, deer, and sheep), the corpus luteum, formed in the ovary from the follicle after ovulation, produces oxytocin. This acts, together with oxytocin secreted by the neurohypophysis, on the nonpregnant endometrium and stimulates prostaglandin F2α secretion, provided oxytocin receptors are expressed; estrogen stimulates the expression of the oxytocin receptors in the endometrium. This prostaglandin F2α is then carried back to the corpus luteum in a local countercurrent circulation to stimulate further oxytocin secretion and to initiate luteolysis. The consequent decrease in progesterone secretion permits gonadotropin stimulation of ovarian follicular development and hence ovulation. This mechanism thus brings forward a further opportunity for conception if the previous ovulation fails to result in pregnancy. Obviously, if pregnancy is to be established, then this mechanism must be prevented. This is achieved by suppression of endometrial oxytocin receptor expression as a result of action of interferon τ produced by the conceptus. This mechanism is thus the key factor in the maternal recognition of pregnancy in these species.

In some other species (e.g., pigs) there is a low level of oxytocin expression in the granulosa cells, which may play a role in luteinization. Studies in pregnant mice show that here low levels of circulating oxytocin maintain the corpora lutea, preventing progesterone withdrawal and paradoxically delaying parturition. Consequently, parturition in mice requires loss of luteal oxytocin receptors as well as up-regulation of myometrial receptors.

3. Heart

In the rat, oxytocin has a natriuretic action. This is consistent with the stimulation of the secretion of both oxytocin and vasopressin by an increase in osmolarity of extracellular fluid in this species. This is usually a result of sodium ion accumulation following food intake or water deprivation; oxytocin promotes sodium excretion, helping to restore normal osmolarity, acting along with vasopressin, which retains water by its actions on the kidney. While oxytocin may act directly on the renal tubules to cause sodium excretion, it now seems that oxytocin also acts on the atria of the heart to stimulate the secretion of atrial natriuretic peptide, which then acts on the kidney to stimulate sodium excretion. It also seems that oxytocin secretion is stimulated by increased blood volume and is important in mediating the subsequent stimulation of atrial natriuretic peptide secretion, which counteracts the volume expansion. Furthermore, the atria evidently produce oxytocin and, if released with atrial distension, as in blood volume expansion, could act locally to stimulate atrial natriuretic peptide secretion in a paracrine fashion.

4. Immune System

Oxytocin is synthesized in the thymus gland, particularly in epithelial and nurse cells, although it is not secreted. Nonetheless, oxytocin produced by thymic epithelial cells has been proposed to signal to the differentiating T lymphocytes with which the epithelial cells are in intimate contact. This neuropeptide signaling may be important in the development of immune self-tolerance.

III. REGULATION OF OXYTOCIN GENE EXPRESSION

Regulation of the massive increase in expression of the oxytocin gene in bovine ovarian follicle granulosa cells at ovulation, as they luteinize, has been extensively studied. As yet the factors regulating gene expression in this system remain unclear.

The store of oxytocin in the posterior pituitary increases by about 50% to the end of pregnancy. This may result from reduced release rather than from increased oxytocin gene expression, in as much as the amount of oxytocin mRNA in the magnocellular neurons has not been consistently reported to increase. The upstream region of the oxytocin gene has variations on the AGGTCA motif, a consensus sequence for nuclear hormone receptor binding, but it is not clear what transcription factors regulate the gene. In view of its reproductive functions, regulation of the production of oxytocin by sex steroids has been investigated by many researchers, but the effects are weak and not consistent. Gene expression is increased at parturition, as a consequence of excitation of the neurons during birth, involving withdrawal of inhibitory actions of progesterone in the presence of estrogen. Oxytocin neurons lack progesterone receptors, but there is a strong inhibitory action of progesterone through its metabolite allopregnanolone (a neurosteroid), which is an allosteric modifier at the inhibitory γ-aminobutyric acid ($GABA_A$) receptors on the neurons. Withdrawal of progesterone at the end of pregnancy thus facilitates oxytocin neuron excitation. Although estrogen is reputed to have stimulatory actions on oxytocin gene expression, the mechanism is not known. However, inhibitory effects of estrogen on stimulated oxytocin release, and on oxytocin mRNA expression, have also been described. In the rat, oxytocin neurons express estrogen receptor-β (and not estrogen receptor-α, which the neurons express in some species), but any role in mediating estrogen actions on oxytocin expression is not clear. Estrogen may act on estrogen receptors on the cell surface rather than through intracellular receptors.

In the paraventricular nucleus, which contains centrally projecting neurons, oxytocin gene expression in rats is increased by estrogen. Interestingly, this action of estrogen is interfered with by thyroid hormone, raising the issue of the importance of thyroid status in the functioning of oxytocin neurons. In pregnant sheep, oxytocin mRNA expression is increased in these neurons in pregnancy, but sex steroid actions may not be responsible.

In lactation, the store of oxytocin becomes greatly reduced as it is secreted to drive milk ejections. After a week of lactation, there is marked up-regulation of oxytocin mRNA expression in the magnocellular neurons, leading to increased oxytocin synthesis. This increase has been attributed in part to the decline at this time in progesterone secretion, which is increased for several days after the postpartum estrus. Other factors, such as consequences of continual stimulation of the neurons by suckling, are also involved.

IV. CONTROL OF OXYTOCIN SECRETION

Oxytocin neurons are like other neurons in that they have many synaptic boutons contacting their dendrites and cell bodies. These mediate control of the oxytocin neuron discharge activity by other brain regions and by sensory inputs from the body. These synaptic inputs comprise a rich variety of types of chemical transmitters, such that it is difficult to find a neurotransmitter or neuropeptide that does not act on oxytocin neurons. Thus, there are excitatory amino acid, eicosanoid, monoamine, purine, and peptide actions (e.g., glutamate, noradrenaline, prostaglandin, adenosine, and cholecystokinin), and similarly actions of a range of inhibitory transmitters (e.g., GABA, opioid peptides, and the gas nitric oxide). The effects of these transmitters on oxytocin neurons are, as in other neurons, the result of their depolarizing or hyperpolarizing actions. Again, as for other types of neurons, local modulation of the activity of the synaptic boutons by other transmitters is important in determining the intensity of excitatory or inhibitory barrage. Oxytocin has such a presynaptic action, as do nitric oxide and opioid peptides produced by the oxytocin neurons.

For magnocellular oxytocin neurons, the major inputs in terms of function are those mediating afferent stimuli from the birth canal during parturition and from the mammary glands during suckling (Fig. 1). In the rat, there is an important input from

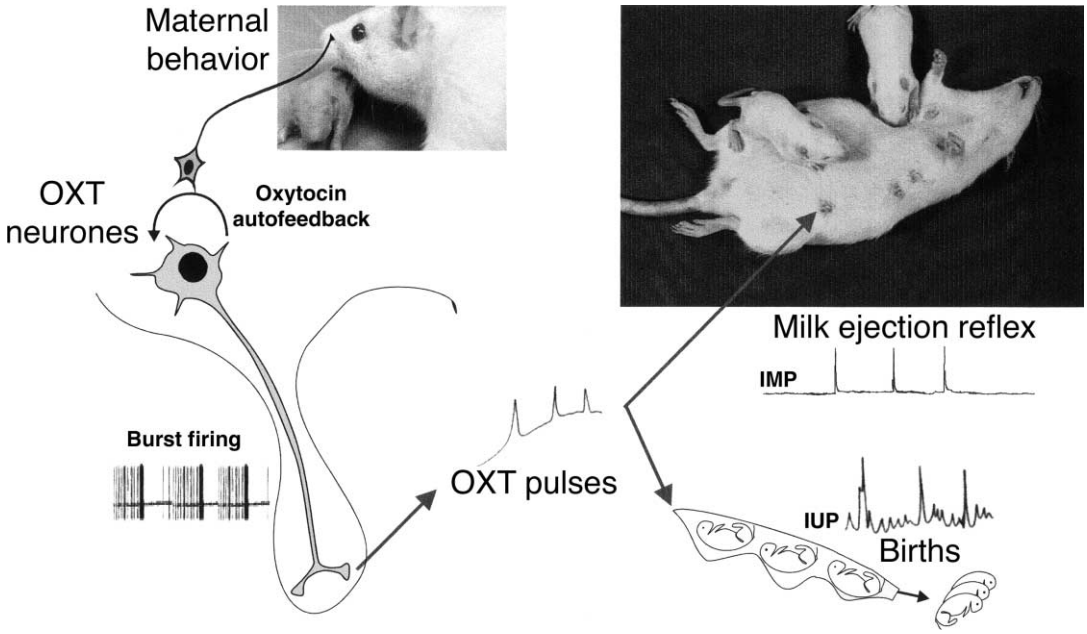

FIGURE 1 Summary of the peripheral and central effects of oxytocin (OXT) in parturition, maternal behavior, and lactation in rats. During the passage of each fetus through the uterine cervix and vagina, afferent nervous impulses from these structures, as they are stretched, are relayed, via the spinal cord and brain pathways, to oxytocin neurons in the hypothalamus. The hypothalamic neurons are excited and send bursts of action potentials to the posterior pituitary, where oxytocin is released into the circulation. Because all of the neurons send bursts at the same time, the result is secretion of a pulse of oxytocin. This stimulates further uterine contractions, increasing intrauterine pressure (IUP) and expelling the fetus. Oxytocin released in the brain at the same time both further excites the oxytocin neurons and evokes maternal behavior. In lactation, the suckling stimulus has similar effects on oxytocin secretion, and now each pulse of oxytocin causes a milk ejection, seen as a sharp increase in intramammary pressure (IMP).

rostral osmosensitive brain structures involved in regulating oxytocin neurones in the context of natriuretic action. Regulation by all of these inputs involves a balance between local GABA and glutamate inputs. These are modulated by actions of oxytocin and nitric oxide released by the dendrites and perikarya of the oxytocin neurons when they are stimulated. Nitric oxide has a local negative feedback effect. In contrast, oxytocin has a local positive feedback effect, provided there is also stimulation by input from the distended birth canal or suckled mammary glands. The neurochemical signature of these inputs is not certain. Noradrenergic neurons projecting from the brain stem, receiving input from the birth canal, are stimulated during parturition, but they are not alone. Similarly, noradrenaline is one of several candidate transmitters mediating excitation of oxytocin neurons by suckling. It seems that there is redundancy in these essential pathways for mammalian reproduction.

In rats, circulating cholecystokinin stimulates oxytocin secretion. As cholecystokinin is secreted by the small intestine during digestion, the consequent secretion of oxytocin helps excrete ingested salt through its natriuretic action. In contrast with the pathways from the birth canal and mammary glands, the pathway for the action of cholecystokinin is clear. It is mediated by vagus nerve afferents and the area postrema and by noradrenergic neurons in the brain stem (nucleus tractus solitarius) that project to oxytocin neurons.

A. Terminal Modulation

The principal determinant of oxytocin release from the posterior pituitary is the frequency of action potentials arriving from the cell bodies in the hypothalamus. However, there is an opportunity for preterminal modulation at this level. First, if the action potentials are clustered, then there is a greater rise in $[Ca^{2+}]$ in the terminals, and hence greater oxytocin release (a mechanism to increase the amount of oxytocin in a pulse). Second, this is a site of inhibition by κ-opioid peptides, which oxytocin neurons also secrete. This mechanism probably

reduces basal secretion and in pregnancy helps to build up a store of oxytocin. At the end of pregnancy, this mechanism is down-regulated, facilitating oxytocin secretion during parturition.

B. Suspending Oxytocin Secretion and Parturition

Several species slow or stop the progress of parturition in adverse environmental conditions. In the rat and pig, this seems to be primarily a result of inhibition of oxytocin secretion by activation of central mu opioid peptide receptors on oxytocin neurons. This central opioid mechanism emerges during pregnancy and may also function to prevent premature oxytocin secretion. In mice, stopping parturition in response to stress does not involve opioids, but instead β-adrenergic mechanisms are used.

V. OXYTOCIN RECEPTOR

The actions of oxytocin on target tissues are determined by the level of expression of receptors, their affinity and stability, and their coupling to postreceptor signaling pathways. Both the expression, i.e., the density of oxytocin receptors, and the affinity of the receptors are regulated by steroids. The oxytocin receptor mediates the contractile effects of oxytocin on the myometrial cells of the uterus and the myoepithelial cells of the mammary gland milk-producing alveoli. In marsupials that produce mesotocin rather than oxytocin, the mesotocin receptor seems identical to the oxytocin receptor in other mammals. In the brain, oxytocin receptors mediate the effects of oxytocin on the release of transmitters from nerve terminals and the postsynaptic actions on the electrical activity of neurons.

Like the neurohypophyseal nonapeptides, the oxytocin and vasopressin receptors are also closely related. However, whereas there are three different vasopressin receptors [V1a, V1b (also called V1 and V3, respectively), and V2], each the product of a different gene, there is only one oxytocin receptor gene. The human oxytocin receptor gene is on chromosome 3 and contains four exons and three introns. The oxytocin receptor is a seven-transmembrane domain, class I G-protein-coupled receptor. The second and third extracellular loops and the transmembrane domains of the receptor show remarkable conservation in their amino acid sequences among species, indicating involvement in oxytocin binding. Site-directed mutagenesis studies in expression systems have identified the amino acid residues in the receptor responsible for selectivity. The eighth amino acid (Leu) in oxytocin interacts with several residues in the first and second extracellular loops and Cys-1 then bonds to a Glu residue in the third extracellular loop. The oxytocin ring is then docked in a pocket formed by the transmembrane domains; the interactions between each residue in the oxytocin molecule and residues in the receptor have been derived from computer modeling. The changed configuration of the receptor leads to binding of G-protein to the intracellular domains. Antagonists and oxytocin probably bind to different domains.

The high-affinity state of the receptor in the myometrium has been known for a long time to require Mg^{2+}, and more recently cholesterol and progesterone have been identified as allosteric modulators. Progesterone has been found to interfere with the binding of oxytocin to its receptor in rat (but not in human) myometrium, reducing its affinity. Clearly, this action could explain some of the inhibitory actions of progesterone on oxytocin stimulation of the uterus and the need for progesterone to be withdrawn in many species (although not in the guinea pig) before parturition can be initiated. Another modulatory influence on oxytocin receptor function is the requirement for a cholesterol content of ~60% in the membranes in which the receptor is embedded for high-affinity binding. The receptor has a binding site for cholesterol as well as for oxytocin and cholesterol stabilizes the receptor in the high-affinity state. *In situ*, oxytocin receptors are localized in cholesterol-rich caveoli at the surface of myometrial cells, and in this location internalization is delayed following oxytocin exposure. The involvement of oxytocin and its receptor in positive feedback mechanisms (e.g., luteolysis, parturition, and milk ejection) implies that oxytocin-induced down-regulation or desensitization would cause these loops to fail; the pulsatile secretion of oxytocin may help prevent this.

One of the striking features of the oxytocin receptor is the very large change that is seen in the number of receptors in the uterus as pregnancy advances. Early in pregnancy the uterus is rather insensitive to oxytocin, but the myometrium becomes exquisitely sensitive just before parturition. This correlates with a dramatic increase in oxytocin receptor expression and an increase in affinity. In the rat, the increase in expression occurs on the last day of pregnancy. Hence, increasing stimulation of uterine contractions by oxytocin near the end of pregnancy need not rely on increased oxytocin

secretion. In contrast, prolonged exposure to oxytocin, as during labor or oxytocin infusion, causes homologous receptor desensitization with marked decreases in receptor binding, and in oxytocin receptor mRNA expression.

Although the expression of the oxytocin receptor in the myometrium is regulated by the sex steroid changes in pregnancy, and, in particular, expression is inhibited by progesterone and up-regulated by estrogen, this does not seem to be by direct actions on the receptor gene. The regulatory elements of the gene lack the palindromic estrogen response element, although there are half-palindromic motifs. The implication is that estrogen acts through other genes, presumably for specific transcription factors, which then regulate the receptor gene. Of particular interest, in view of the proposed role of infection in preterm labor, is the presence of binding sequences for nucleofactor interleukin-6 in the 5′ upstream region. Other regulatory signals may be generated by stretching of the myometrium.

In the brain, even in closely related species there are differences in the distribution of oxytocin receptors. These differences are more striking than changes with reproductive state within a species, except that oxytocin receptor expression in the ventromedial hypothalamic nucleus is exquisitely sensitive to regulation by sex steroids (see later).

A. Postreceptor Signaling

The intracellular signaling mechanisms mediating actions of oxytocin are similar among the various target tissues. The oxytocin receptor in the myometrium is predominantly coupled via G_I and $G_{\alpha q/11}$ proteins to phospholipase C-β. This pathway leads to liberation of Ca^{2+} from intracellular stores, and there is also entry of Ca^{2+} from outside, including via L-type Ca^{2+} channels. The increased intracellular [Ca^{2+}] forms complexes with calmodulin, and this then activates myosin light chain kinase (MLCK); phosphorylated myosin then interacts with actin, and the shortening actomyosin contracts the cell. The jointly contracting myometrial cells, which are united by strong junctions, generate the expulsive force required for fetal expulsion. The automatic activation of intracellular Ca^{2+} sequestering mechanisms, and active expulsion of Ca^{2+} from the cells, lead to relaxation. Relaxants such as adrenaline activate adenylyl cyclase via $G_{\alpha s}$ and hence a protein kinase A (PKA) pathway. PKA phosphorylates and inactivates phospholipase C-β and MLCK. The amount of $G_{\alpha s}$ increases in pregnancy but is decreased at term. In pregnancy, there is a change in the proportions of the types of adenylyl cyclase isoforms, which have different properties, expressed in myometrial cells. These changes may contribute to the shift from uterine relaxation in pregnancy to greater responsiveness to oxytocin at term.

A similar mechanism involving increased intracellular [Ca^{2+}] mediates oxytocin stimulation of mammary gland myoepithelial cell contractions, which cause milk ejection. An additional signaling pathway, studied in the amnion (of humans and rabbits), activates cytosolic phospholipase A_2 and hence releases arachidonic acid for prostaglandin synthesis. Here, the oxytocin receptor couples to G_q; the resulting increase in intracellular [Ca^{2+}] contributes to cytosolic phospholipase A_2 activation, which is phosphorylated by extracellular signal-regulated kinase (ERK). Prostaglandin E2 synthesis is then stimulated. In the endometrium of ruminants, oxytocin stimulates prostaglandin F2α production via mobilization of intracellular Ca^{2+}, which activates a protein kinase C-dependent pathway. As described previously, this mechanism produces a luteolytic signal in the absence of conception. A similar stimulation of prostaglandin F2α production by decidual cells reinforces oxytocin actions on the myometrium in parturition.

The actions of oxytocin on neurons bearing oxytocin receptors involve mechanisms similar to those in other tissues. Hypothalamic magnocellular oxytocin neurons (the source of posterior pituitary oxytocin) are stimulated by oxytocin. Oxytocin induces a rapid and long-lasting increase in intracellular [Ca^{2+}], and most of this is released from intracellular stores. This response has a key role in the driving of oxytocin neuron activity during parturition and lactation.

VI. OXYTOCIN IN PARTURITION

As mentioned already, no naturally occurring oxytocin deficiency state is known. The phenotype of this state is partly known from studies in transgenic mice with deletion or inactivation of the oxytocin peptide gene; and more recently from studies of mice with inactivation of the oxytocin receptor gene. Such mice get pregnant and deliver their young, evidently at the appropriate time. However, their young do not survive for long because they cannot obtain milk. The young are rescued if the mothers are given injections of oxytocin. The conclusions from these studies are that oxytocin, and its receptor are not essential for ovarian function, reproductive

behavior, or parturition. However, they are essential for milk transfer. The conclusion regarding the essential role of oxytocin in milk transfer is clear enough.

It is not appropriate, however, to conclude that oxytocin has no role in, for example, normal parturition. Rather, the performance of parturition in the absence of oxytocin illustrates how other mechanisms, in particular the uterine production of prostaglandins, and possibly vasopressin, can stimulate uterine contractions. This argues for redundancy in the mechanisms that bring about parturition, which might be expected given the crucial importance for the survival of both mother and offspring of the successful completion of this process. If so, then there should be activation of oxytocin secretory mechanisms, and enhanced oxytocin action, at parturition in mice and other species. The large increase in oxytocin receptor expression in the uterus at term and the changes in intracellular signaling mechanisms so that excitatory pathways predominate (see Section V) are strong circumstantial evidence that oxytocin has a role in parturition.

It does seem clear from studies on several species (humans, rats, and guinea pigs) that although parturition can be initiated at term by systemic infusion with oxytocin, the natural initiation of labor is not a result of increased maternal oxytocin secretion. The role of oxytocin in parturition is to promote the strong uterine contractions in the second stage, leading to the passage of the fetus through the dilated uterine cervix and vagina. Oxytocin then stimulates further uterine contractions that cause placental separation and, in polytocous species, the birth of the next fetus. In human deliveries, these further contractions ensure closure of the ruptured spiral arterioles, preventing a potentially fatal postpartum hemorrhage.

The evidence for increased secretion of oxytocin from the maternal posterior pituitary in parturition is manifold. Oxytocin concentration in the circulation increases in the second stage of labor. In marsupials that produce mesotocin, which has actions identical to those of oxytocin, the concentration of mesotocin in the circulation increases at the birth of the fetus. In humans, measurement of oxytocin in the circulation is difficult because the placenta secretes an aminopeptidase that rapidly destroys oxytocin, and secretion is expected to be pulsatile, so occasional blood samples are unlikely to catch a pulse. Nonetheless, increases in circulating oxytocin have been measured in the second stage. Oxytocin antagonist administration is effective in treating preterm labor in humans and delays births in guinea pigs and slows established parturition in rats. The content of oxytocin in the posterior pituitary gland is decreased by $\sim 30\%$ during parturition. Furthermore, oxytocin is released by the dendrites of the magnocellular neurons during parturition, and local oxytocin antagonist disrupts parturition (probably because it interferes with burst firing). Last, magnocellular oxytocin neurons increase their firing rate, express the immediate-early gene product Fos (a sign of activation of the neurons), and increase expression of the oxytocin gene. Most persuasively, in rats, the oxytocin neurons burst-fire as each pup is born and, furthermore, each burst is followed by a pulse of oxytocin that can be measured in the circulation.

So, what stimulates the secretion of oxytocin in parturition? In the 1940s, Ferguson concluded that oxytocin secretion is stimulated by the distension of the birth canal as the fetus is moved through it and stimulates afferent nerve endings. This is a positive feedback mechanism, which, like all such loops, can only end in an explosion—in this case, the birth of the fetus. Subsequent studies have shown that the pathway for this reflex from the birth canal to the oxytocin neurons is via brain stem nucleus tractus solitarius neurons, including noradrenergic neurons, that project directly to the magnocellular oxytocin neurons. There is an increase in noradrenaline release from the terminals of these neurons in the supraoptic nucleus during parturition, and other evidence suggests a role for this input in driving oxytocin neurons.

VII. OXYTOCIN IN LACTATION

Feeding offspring with milk transferred by suckling is a distinctive feature of mammalian reproduction and is new in evolution, contrasting with parturition that has a long evolutionary connection with egg laying. The production of milk requires stimulation of mammary gland development by sex steroids and the subsequent stimulation by prolactin of milk synthesis and secretion by the epithelial cells of the alveoli. The milk is stored in alveoli (e.g., in rats), in sinuses, which are enlargements of the milk ducts beneath the nipple (e.g., in humans), or in a cistern into which the ducts empty, located beneath the nipple (the udder in cattle and sheep). Oxytocin acts on contractile myoepithelial cells around the alveoli, and the combined action of these cells around the thousands of alveoli causes the movement of milk through the ducts. In species with substantial storage

capacity in the sinuses or cistern, this movement comprises milk "let-down." The suckling young then obtain the milk by the milking action as they suck on the nipple and the subjacent storage sites. Milk ejection from the nipple resulting from the action of oxytocin occurs if more milk is let down than can be stored.

It was shown in electrophysiological studies on lactating rats in the early 1970s that a continual suckling stimulus applied to the nipples is converted to intermittent high-frequency action potential discharge of neurons in the supraoptic and paraventricular nuclei. These bursts were found in about half of the neurons recorded and occurred about 7 min apart during suckling. Each burst preceded a sharp increase in intramammary pressure by the time that it takes oxytocin to travel in the circulation from the posterior pituitary to the mammary gland. Later, paired recordings showed that neurons in the supraoptic or paraventricular nuclei burst-fire almost synchronously. Thus, each episode of synchronized bursting leads to the secretion of a pulse of oxytocin, each of which causes a milk ejection and each comprising about 1 pmol (0.5 mU) of oxytocin.

The suckling stimulus applied to the nipples is carried in afferent nerve fibers to the brain stem, and then, via a multisynaptic pathway that is not fully characterized, to the oxytocin neurons. The synapses on oxytocin neurons contain a multitude of neurotransmitter types, but it is not clear which transmitter is of key importance in signaling the suckling stimulus.

VIII. IMPORTANCE OF OXYTOCIN IN THE BRAIN

Oxytocin released within the brain has several actions. There are two broad types of oxytocin action. First, oxytocin has local positive feedback actions on the magnocellular neurons that produce it. In this case, the oxytocin is released from the dendrites of the neurons and it acts back on the oxytocin neurons and their local synaptic inputs to excite the neurons during parturition and suckling. These actions are important in generating the pulsatile pattern of oxytocin secretion at these times. Second, oxytocin is released from the axon terminals of centrally projecting neurons (mainly those with cell bodies in the paraventricular nucleus) at several discrete sites in the brain that are important in organizing reproductive behaviors and associated emotion, or autonomic, outputs.

A. Oxytocin in the Generation of Bursting Activity of Oxytocin Neurons

It is clear that the oxytocin released by dendrites of the oxytocin neurons during the quiet initial period of suckling, before the bursts start, plays an essential role in driving bursts. Oxytocin release in the magnocellular nuclei can be detected by sampling extracellular fluid with a microdialysis probe; bursting is stopped by administration of an oxytocin antagonist into a magnocellular nucleus, and centrally injected oxytocin facilitates bursting.

In addition to actions on the oxytocin neurons, oxytocin also acts presynaptically to suppress excitatory glutamatergic input and to inhibit GABAergic input. These actions may lead to periodic increases in local excitatory input. The synchronization of bursting behavior among the oxytocin neurons, without which a pulse of oxytocin could not be secreted, could also follow periodic activation of a local network. Also involved are morphological changes within the magnocellular nuclei due to retractions of glial processes that bring adjacent neurons into more intimate contact, and to the increased density of GABA and glutamate synapses in lactation. Oxytocin release in the bed nucleus of the stria terminalis (a limbic brain region) contributes to facilitation of the bursting activity of magnocellular oxytocin neurons during suckling, and here estrogen has a positive influence. This is one brain area in which oxytocin receptor expression increases in late pregnancy.

B. Oxytocin and Behavior

Oxytocin in the brain has actions on behavior that are congruent with its peripheral reproductive functions.

1. Maternal Behavior

The first observation, in 1979, was that oxytocin injected into the brain in estrogen-treated virgin rats induced the rapid onset of maternal behavior toward foster pups. Without such oxytocin treatment, virgin rats seem fearful of pups. Conversely, oxytocin antagonist infusion into the medial preoptic area or ventral tegmental area, regions known from other studies to be important in maternal behavior, blocked the initiation of maternal behavior postpartum. Part of the action of oxytocin on maternal behavior involves reducing anxiety.

In sheep, oxytocin is released in the brain in response to vagino-cervical stimulation during birth. Bonding of the ewe with its lamb depends on olfactory memory, and this involves oxytocin action

in the olfactory bulb. The paraventricular nucleus contains the important population of centrally projecting oxytocin neurons that promote maternal behavior. Oxytocin release from terminals in the brain regions where maternal behavior is organized modulates release of other transmitters that in turn elicit maternal behavior. Once this task is performed immediately postpartum, continued action of oxytocin does not seem to be required to maintain maternal behavior. In contrast, transgenic mice with inactivation of the oxytocin gene show normal maternal behavior, but mice are peculiar in that females show maternal behavior without having been pregnant. Thus, mice do not need the drive provided by oxytocin released in the brain during parturition. Indeed, they lack oxytocin receptors in the forebrain area where oxytocin acts in other species to promote maternal behavior.

2. Female Reproductive Behavior

In the rat and hamster, oxytocin from paraventricular nucleus neurons acts in the hypothalamic ventromedial nucleus and medial preoptic area to facilitate female reproductive (lordosis) behavior. The effectiveness of oxytocin depends on estrogen, which induces oxytocin receptors in the ventromedial nucleus, and receptor distribution is expanded by progesterone. This leads to enhanced electrophysiological responses of the neurons to oxytocin. However, estrogen inhibits oxytocin receptor expression in the mouse, and as a corollary the oxytocin knockout female mouse does not show defects in sexual receptivity.

Marked differences in the affiliative behavior of species of voles have been used to uncover roles of brain oxytocin in bonding between sexual partners. Prairie voles are monogamous and live in social groups, but montane voles are not monogamous and live in isolation. Bond formation between a female prairie vole and the male with which she first mates depends on oxytocin released in the brain during mating. In contrast, montane voles do not form bonds after mating, not even if oxytocin is injected into the brain: indeed, they have very low levels of oxytocin receptor expression in brain areas associated with reward, in contrast with prairie voles. These different patterns of receptor expression reflect differences in the upstream region of the gene that confers tissue-specific expression.

A role for oxytocin in the brain in promoting social interaction is supported by finding defects in transgenic mice with inactivation of the oxytocin gene. Unlike normal mice, these transgenic mice fail to learn to recognize conspecifics with which they have become familiar by repeated social exposure. This is attributable to loss of an essential action of oxytocin in the medial amygdala, part of the limbic, emotional, brain.

3. Ingestive Behavior

Consonant with its natriuretic action in the rat, oxytocin acts within the brain to inhibit salt ingestion when this is inappropriate. It is also one of several peptides that act in the brain to reduce food intake; though this may reflect a primary role to inhibit intake of the salt in food. Through projections to the dorsal vagal complex in the brain stem, oxytocin neurons inhibit gastric motility, an appropriate accompaniment to inhibition of intake.

IX. OTHER ACTIONS OF OXYTOCIN/ANTAGONISTS

A. Oxytocin Actions on the Anterior Pituitary

Oxytocin is present in hypothalamo-hypophyseal portal blood at greater concentrations than in peripheral blood. This oxytocin is secreted from magnocellular neuron axon swellings in the median eminence. Oxytocin acts on V1b receptors on corticotrophs [cells secreting adrenocorticotropic hormone (ACTH), which do not have oxytocin receptors] in the anterior pituitary to augment the action of corticotropin-releasing hormone on ACTH secretion in rats; however, in humans, oxytocin is inhibitory.

The main action of oxytocin on the anterior pituitary is to stimulate prolactin secretion in lactation. This is promoted by a large increase in oxytocin receptor expression in lactotrophs (cells secreting prolactin) at the end of pregnancy, but depends on withdrawal of inhibition by dopamine. However, other factors increase prolactin secretion in lactation. Oxytocin can advance the ovulatory luteinizing hormone surge, though the importance of this is not clear.

B. Oxytocin in Males

The importance of oxytocin is primarily in the context of female reproduction. In males, oxytocin secretion is increased by sexual intercourse and stimulates seminiferous tubule contractions, so it may aid the transport of sperm from the testis. Produced by Leydig cells in the testis, oxytocin locally influences steroidogenesis; oxytocin produced in

the prostate affects prostate androgen metabolism. In the brain, oxytocin acts in the paraventricular nucleus to induce penile erection; this probably activates, through a mechanism involving nitric oxide, oxytocin neurons projecting to autonomic outflow neurons in the brain stem and spinal cord. Transgenic male mice without oxytocin show reduced aggressiveness toward intruder males.

C. Oxytocin Receptor Antagonists

Several oxytocin receptor antagonists have been synthesized. Most are peptides based on the nonapeptide prototype. One such peptide, Atosiban, is licensed in Europe for use in the management of imminent preterm birth. Nonpeptide antagonists are not in clinical use. The advantage of targeting the oxytocin receptor for tocolysis (uterine relaxation) over other approaches, such as the use of β_2-adrenergic agonists, is that oxytocin receptors are largely restricted to the pregnant uterus and the mammary gland. Consequently, unwanted actions of selective oxytocin receptor antagonists on other tissues should not be a problem. However, there may be the possibility of actions in the heart, but the main issue is that the antagonists developed so far are also antagonists at V1a receptors. Although this may reinforce tocolytic actions because of the possible involvement of V1a receptors in the stimulation of uterine contractions in parturition, vasopressin stimulation of blood vessel contraction through these receptors will be inhibited. This is a potential problem in the context of defense of blood pressure during hemorrhage. Peptide antagonists are unlikely to enter the brain significantly or to cross the placenta. Atosiban is effective in alleviating the symptoms of dysmenorrhea (pain prior to menstruation), because in this condition vasopressin acting through V1a receptors is responsible for the stimulation of painful uterine contractions.

Glossary

amnion Sac in which the embryo and fetus develop.
axons Thin processes of neurons contacting a target (here, either other neurons or blood vessels in the posterior pituitary); rapidly conduct action potentials (waves of depolarization) from the cell body to the terminals; slowly transport peptide to be secreted from the terminals.
burst Brief, high-frequency cluster of action potentials generated in a neuron; the basis for secretion of a pulse of oxytocin.
corpus luteum Endocrine tissue formed from the ovarian follicle after it ovulates; produces progesterone. Luteolysis is the death of the corpus luteum.
decidua Endometrial lining shed at the end of pregnancy.
dendrites Thick nerve cell processes that receive synapses (contacts) from other nerve cells; also capable of secreting.
endometrium Lining of the human uterus.
hypothalamus Brain region concerned with automatic regulation of many body functions, including controlling secretion of hormones from the pituitary gland.
myoepithelial cells Contractile cells surrounding the milk-secreting glands in the lactating mammary gland.
myometrium Contractile, muscular tissue of the uterus.
natriuresis Stimulated sodium excretion by the kidney.
paraventricular and supraoptic nuclei Areas in the hypothalamus where most of the nerve cells (neurons) in the brain producing oxytocin are located.
posterior pituitary gland Developmentally, a downgrowth from the hypothalamus of the brain. Contains terminals of hypothalamic neurons with stored oxytocin.
preterm birth Emergence of the fetus before it is fully prepared for extrauterine life.

Oxytocin/Vasopressin Receptor Signaling

MELVYN S. SOLOFF AND YOW-JIUN JENG
University of Texas Medical Branch, Galveston

The neurohypophyseal hormones oxytocin and arginine vasopressin are structurally related and signal through a family of G-protein-coupled receptors. The oxytocin receptor is unique and there are three distinct vasopressin receptors: V_1, V_2, and V_3. Oxytocin and vasopressin V_1 and V_3 receptors are coupled to $G_{q/11}$ and $G_{i/o}$ heterotrimeric G-proteins, whereas V_2 vasopressin receptors act through G_s.

I. INTRODUCTION

The signal pathways mediating the actions of oxytocin and arginine vasopressin on specific target cells through their unique receptors are highlighted in this article. Although generalizations have been made, some pathways vary with different cell types or species. Even within the same cell type, there may be differences in signaling at different stages of the cell cycle or during development. Exceptions will be noted whenever possible.

II. OXYTOCIN AND VASOPRESSIN

Oxytocin (OT) and arginine vasopressin (AVP) are produced primarily by the supraoptic and paraventricular nuclei of the hypothalamus; they are transported along axons to cell termini in the posterior pituitary, where they are stored in the form of membrane-bound neurosecretory granules. The two neuropeptides are structurally related to each other and to vasotocin, which occurs in fish, reptiles, amphibians, and birds (Fig. 1). These peptides share a disulfide-linked ring structure of six residues that restricts conformational flexibility, and a flexible three-residue amino-terminal tail. The carboxyl-terminal glycine is amidated in all three peptides. Oxytocin and vasopressin differ only at position 3 of the cyclic peptide portion and position 8 of the C-terminal tripeptide amide region. Duplication of a common ancestral gene likely gave rise to the OT and AVP genes. Both genes reside on the same chromosome and, in humans and mice, are only 12 and 3 kb apart, respectively. Both peptides are synthesized in larger precursor forms and are

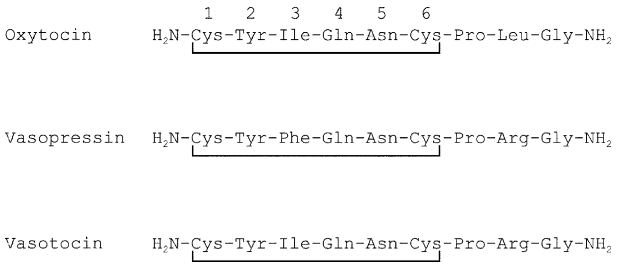

FIGURE 1 Structures of OT, AVP, and vasotocin. In lysine vasopressin, which is found in pigs, a Lys replaces Arg in position 8.

processed to mature hormones in neurosecretory cells. When the nerve cell membrane is depolarized, OT and AVP are released and pass through endothelial cells to enter the circulation. Oxytocin release is caused by vaginal stretch, by suckling, and, in some species, by osmotic stimuli. Higher centers in the brain are also involved. Vasopressin release occurs in response to stimuli that alter the state of fluids in the body, such as increased plasma osmotic pressure and reduced blood volume and/or blood pressure. Oxytocin stimulates mammary myoepithelial cell contraction and is essential for milk ejection in most mammalian species. Oxytocin also elicits contraction of uterine smooth muscle and probably plays a role in labor initiation. Oxytocin targets in the brain elicit responses associated with social, sexual, and maternal behavior. Vasopressin, or antidiuretic hormone (ADH), is a vasoconstrictor, and it also reduces urinary water excretion by increasing the water permeability of the renal collecting duct. Vasopressin is also a costimulator with corticotropin-releasing hormone (CRH) of adrenocorticotropic hormone (ACTH) release from the anterior pituitary.

The similar structures of the neurohypophyseal peptides account for the overlap in agonist activities. Oxytocin has about 1% of the potency of AVP in increasing rat blood pressure or eliciting antidiuresis. Vasopressin has about 15% of the potency of OT in both rat uterus and rabbit mammary gland assays. Generally, these differences are the reflection of reduced affinities for receptor binding sites; but vasopressin has about twice the apparent K_d for OTRs, compared to OT, yet only 15% of the agonist activity. This paradox may be explained by AVP being a partial OT agonist/antagonist that binds to the OTR to a greater extent than is reflected by signal transduction. The selective binding of OT and AVP to their respective receptors is largely determined by the residue at position 8. In vasopressin, a basic residue fills this position; in OT and OT analogues, the residue is neutral and usually aliphatic.

As might be expected from the common ancestry of OT and AVP, the receptors for the neurohypophyseal hormones, which are G-protein-coupled receptors (GPCRs), are more closely related to each other than to any other GPCR family member. The neurohypophyseal hormone receptors comprise a group of four related proteins expressed by separate genes. The OT receptor (OTR) is largely associated with target cells involved in reproductive processes. The V_2 receptor is expressed predominantly in the kidney and accounts for the antidiuretic effects of vasopressin. The V_1 and V_3 receptors can be distinguished by their selectivity for AVP analogues, but the primary difference is in their cellular distribution. Vasopressin V_1 receptors are expressed in vascular smooth muscle and other tissues, whereas V_3 receptors are largely restricted to the central nervous system. The two extremes in the family, the V_2R and OTR, are identical in 40% of their sequences, with the highest similarity in the transmembrane and extracellular domains.

III. OXYTOCIN SIGNALING

OTRs are expressed in the lactating mammary gland, uterine smooth muscle (myometrium), uterine epithelium (endometrium or decidua), and the amnion, among other target sites. There have been extensive studies on neural targets for OT, but less information on signaling mechanisms is available. In general, OTRs are highly regulated. In virtually all species studied, the concentration of OTRs in the myometrium is maximal at the time of parturition, rising several 100-fold in women between the beginning and end of pregnancy. The coupling to G-proteins in the rat myometrium is also up-regulated at the end of pregnancy, as determined by gel filtration analysis of solubilized OTR–G-protein complexes. The concentration of OTRs in the endometrium (or decidua) and amnion is also maximal at the end of gestation. Conversely, OTR concentrations in the mammary gland are maximal during lactation, when the concentration of OT in the blood is elevated; the uterine OTRs are down-regulated at this time, so that only mammary myoepithelial cells are stimulated by OT. Although the AVP receptor subtypes are regulated, the magnitude of change is small compared with OTRs.

A. G-Protein and Effector Coupling to the Oxytocin Receptor

The OTR is functionally coupled to both $G_{q/11}$ and $G_{i/o}$, as demonstrated in several target cell types (Fig. 2). Both classes of G-proteins stimulate phospholipase C-β (PLC-β), which leads to the generation inositol 1,4,5-trisphosphate ($InsP_3$) and 1,2-diacylglycerol (DAG). Inositol trisphosphate triggers Ca^{2+} release from intracellular stores, whereas DAG, acting in conjunction with Ca^{2+}, stimulates protein kinase C (PKC). Activation of mitogen-activated protein (MAP) kinase (MEK) in the MAP kinase cascade occurs downstream of PKC phosphorylation.

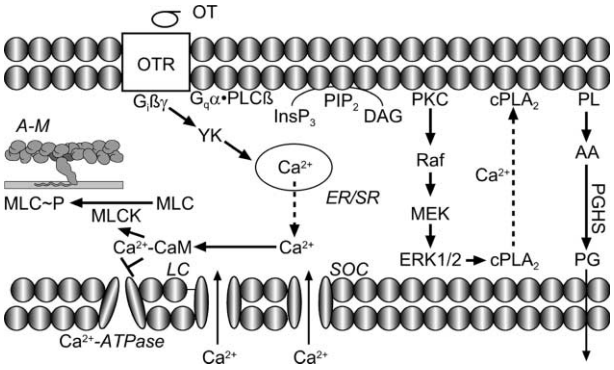

FIGURE 2 Pathways involved in OT signaling result in an increase in myosin light chain (MLC) phosphorylation and contractile activity and/or the stimulation of prostaglandin (PG) synthesis. Both processes are mediated by an increase in $[Ca^{2+}]_i$ from the endoplasmic/sarcoplasmic reticulum (ER/SR) through $G_{q/11}$/phospholipase C (PLC) and $G_{i/o}$/tyrosine kinase activation. The resultant increase in $[Ca^{2+}]_i$ allows the influx of extracellular Ca^{2+} through store-operated channels (SOCs) and L-type voltage regulated channels (LCs). An increase in the binding of Ca^{2+} to calmodulin (CaM) results in inhibition of a sarcolemmal calcium pump (Ca^{2+}-ATPase), resulting in elevated Ca^{2+} levels over a longer time. The Ca^{2+}–CaM complex activates MLC kinase (MLCK) to phosphorylate the myosin light chain 20 of myosin II, which promotes the interaction of actin and myosin (A–M) and the contraction of smooth muscle. The increase in $[Ca^{2+}]_i$ also allows translocation of cytosolic phospholipase A_2 ($cPLA_2$) to internal membranes. Increased protein kinase C (PKC) activity resulting from $G_{q/11}$ activation also leads to successive extracellular signal-related kinase (ERK2/1) and $cPLA_2$ phosphorylations. The activated $cPLA_2$ catalyzes increases in arachidonic acid (AA) levels from membrane phospholipids (PLs) and greater PG synthesis through prostaglandin H synthase (PGHS) activity. OTR, Oxytocin receptor; $InsP_3$, inositol 1,4,5-trisphosphate; PIP_2, phosphatidylinositol 4,5-bisphosphate.

A role for $G_{i/o}$ was initially determined by pertussis toxin (PTX) sensitivity of OT-stimulated signaling pathways (Fig. 2). However, caution is advised in the use of PTX treatment because it elevates intracellular cyclic adenosine monophosphate (cAMP), which inhibits responses to OT that are independent of OTR activation. For example, cAMP-stimulated protein kinase A (PKA) catalyzes the phosphorylation of PLC, resulting in inhibition of OT-stimulated $InsP_3$ production. The inhibition could be reversed by treatment with a selective PKA inhibitor. Thus, at least part of the effects of PTX can be attributed to $G_{i/o}$ that is not coupled to the OTR. Other work, however, has shown that the OTR is associated with $G_{i/o}$; using both coprecipitation with antibody, and assays showing it has been shown that OT stimulation of GTPase activity in intact myometrial membranes is inhibited by PTX. In addition, OT treatment decreases PTX-stimulated ADP-ribosylation of $G_{\alpha i}$ in myometrial membranes. This decrease is consistent with OT activating heterotrimeric G_i by dissociating $G_{\alpha i}$, because ribosylation of the α-subunit occurs only in the heterotrimer. Inhibition of PLC activity by PKA phosphorylation may partially explain the ability of agents that elevate intracellular cAMP to oppose the actions of OT and to maintain uterine smooth muscle in a quiescent state.

Removal of 51 residues from the C-terminus of the rat OTR expressed in stably transfected Chinese hamster ovary (CHO) cells causes the loss of coupling to $G_{q/11}$. PTX-sensitive increases in intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$), however, are unaffected by receptor truncation. Surprisingly, this signaling is independent of PLC activity; the $G_{i/o}$ pathways leading to increased $[Ca^{2+}]_i$ are yet undefined. Activation of $G_{i/o}$ involves the $G_{\beta\gamma}$ subunits, because transient transfection of the cells expressing truncated OTR with the $G_{\beta\gamma}$ sequestrant βARKct blocks OT-stimulated intracellular Ca^{2+} transients. A generic tyrosine kinase inhibitor also inhibits the effects of OT, suggesting that $G_{\beta\gamma}$ subunits transactivate signaling via tyrosine kinase pathways, as has been shown for other GPCRs. Oxytocin signaling in a mutant lacking 39 residues of the C-terminal tail is indistinguishable from that of the wild-type OTR. Therefore, the region between 39 and 51 residues from the carboxyl terminus appears to be critical for coupling of the OTR to $G_{q/11}$.

B. Many Effects of Oxytocin are Mediated by Increased Intracellular Ca^{2+} Concentrations

The initial rise in $[Ca^{2+}]_i$ following OT treatment of isolated myometrial cells is due mainly to the $InsP_3$-mediated release of Ca^{2+} from intracellular stores in the endoplasmic or sarcoplasmic reticulum, but Ca^{2+} influx from extracellular sources also occurs (Fig. 2). Studies have indicated that the increased influx of Ca^{2+} is regulated by store-operated or capacitative channels, following the rise in $[Ca^{2+}]_i$ from intracellular sites. Other studies indicate that extracellular Ca^{2+} influx occurs through L-type voltage channels. The large difference in Ca^{2+} concentration between the outside and inside of cells is maintained in part by the unidirectional export of Ca^{2+} by a high-affinity Ca^{2+} extrusion pump in the cell membrane. This process, involving Ca^{2+},Mg^{2+}-dependent ATPase activity, occurs in a number of cell types. OT inhibits this ATPase in sarcolemmal (plasma) membranes

from the uterine smooth muscle of rabbits, rats, and humans. This process contributes to maintaining elevated $[Ca^{2+}]_i$ in myometrial cells following the increase in Ca^{2+} from intracellular and extracellular sources. The effects of OT are blocked by calmodulin (CaM) inhibition, but the signal pathways require further elaboration.

In uterine smooth muscle cells and mammary myoepithelial cells, which are smooth muscle-like but are derived from ectoderm instead of mesoderm, the rise in $[Ca^{2+}]_i$ leads to Ca^{2+}–CaM stimulation of myosin light chain kinase (MLCK) activity. The phosphorylation of myosin light chain (MLC) 20 allows myosin heads to form cross-bridges with actin filaments, leading to contraction. Yet to be elucidated are the molecular actions of OT on neural targets involved in many behavioral patterns, as well as in memory and learning. It seems likely that OT-stimulated rises in $[Ca^{2+}]_i$ control cellular excitability and modulate firing patterns. These processes almost certainly involve stimulation of gene transcription and protein synthesis.

C. Oxytocin Stimulation of Prostaglandin Synthesis

A second major activity of OT in uterine and other tissues is the stimulation of prostaglandin synthesis. This occurs in endometrial and amnion cells and CHO cells stably transfected with the rat OTR by stimulation of arachidonic acid formation from membrane glycerophospholipids, and the incorporation of arachidonic acid into prostaglandins. OT-induced increases in $[Ca^{2+}]_i$ (described in the preceding paragraph) lead to Ca^{2+} binding to the C-2 domain of cytosolic phospholipase A_2 ($cPLA_2$) and its translocation to the nuclear envelope and endoplasmic reticulum, wherein lie glycerophospholipid substrates for $cPLA_2$-catalyzed arachidonic acid formation. The phospholipase is activated by serine phosphorylation by extracellular signal-regulated protein kinases (ERK1/2), which in turn are activated by OT stimulation of the PKC/MEK pathway. Arachidonic acid is converted to prostaglandins (PGs) through the actions of prostaglandin endoperoxide H synthase (PGHS), also referred to as cyclooxygenase (COX). This bifunctional enzyme catalyzes both the oxidation of arachidonic acid to the prostaglandin endoperoxide, PGG_2, and its subsequent reduction to PGH_2, the precursor for all prostanoids. There are two PGHS isoforms, each expressed by a separate gene. PGHS-1 is constitutively expressed in most cell types, whereas PGHS-2 mRNA is rapidly and transiently induced. Normally, PGHS-2 is undetectable but is induced in the fashion of an immediate-early gene by a variety of agents, including OT, in the endometrium, myometrium, and amnion. Generally, utilization of PGHS-1 is associated with the early phase of prostaglandin synthesis, occurring within several minutes of stimulation, whereas prostaglandin synthesis occurring over several hours coincides with the induction of PGHS-2 expression.

Depending on the cell type and stimulus, PGHS-2 synthesis can be a rate-limiting step with respect to PG synthesis, or it can enhance production of the relatively low levels of PGs synthesized through PGHS-1. The induction of PGHS-2 is necessary for OT-stimulated $PGF_{2\alpha}$ synthesis in bovine uterine endometrium and prostacyclin production by human myometrial cells. In contrast, the levels of PGHS-1 activity in rabbit amnion are constitutively high and the induction of PGHS-2 does not contribute to increased PGE_2 production. The role of PGHS-2 in these cells is presently unknown, as are the pathways involved in OT-induction of PGHS-2 expression. In cultured human myometrial cells, this induction is PTX sensitive, as is activation of the MAP kinase pathway.

D. Down-regulation of Oxytocin Receptors by Endocytosis

Radioligand binding data using intact human myometrial cells have shown that OTR numbers on the cell membrane remain stable for a number of hours after addition of OT. This observation is consistent with physiological observations, because the uterus remains sensitive to OT for a period of time during labor. Human OTRs expressed in human embryonic kidney (HEK) or CHO cell lines, however, are rapidly internalized in response to OT treatment. Internalization is mediated by phosphorylation of two serine clusters in the C-terminal domain of the receptor by PKC, followed by the binding of β-arrestin-2 and uncoupling of the receptor from its G-protein partners. This process results in the termination of OTR signaling. β-Arrestin acts as an adapter protein that links the receptor to components of the endocytic machinery and targets the desensitized receptor to clathrin-coated pits for endocytosis. Like other GPCRs, the internalized OTRs are dephosphorylated in endosomes and recycled back to the cell surface fully resensitized.

It remains to be established whether OTRs in natural target cells, other than myometrial cells, are

rapidly internalized. Apart from internalization, the association of receptors with β-arrestin may be involved in initiating and/or regulating signaling pathways. For example, Src recruitment to the β_2-adrenergic receptor is mediated by β-arrestin, which functions as an adapter protein, binding both c-Src and the agonist-occupied receptor. β-Arrestin also appears to function as a molecular scaffold that organizes and recruits components of the MAPK cascade.

E. Atypical Oxytocin Target Cells

Functional OTRs have been described in several tissues and a variety of cell types not typically considered targets for OT. Generally, the signal pathways involved in OT action have only been examined in a perfunctory manner. In most cases the cell types were not in primary cultures but were established cell lines; therefore, signaling by OT is not necessarily representative of OT action in untransformed cells.

Oxytocin has insulin-like activity in stimulating glucose oxidation and lipogenesis in rat adipocytes. These effects occur independently of insulin action and are mediated by OTRs, which have been characterized by ligand binding. Unlike insulin, the effects of OT on glucose oxidation in fat cells are not mediated by increased glucose transport. Instead, OT stimulates polyphosphoinositide breakdown and elevated $[Ca^{2+}]_i$ in adipocytes. The molar concentration of OT-stimulating glucose oxidation is about five times greater than that of insulin, and the maximal effect is only about 20% that of insulin. Oxytocin is also less effective than insulin in stimulating lipogenesis; therefore, it is not certain whether there is a physiological role for OT in fat cell metabolism.

Oxytocin receptors are expressed in both undifferentiated and differentiated human trabecular bone cells with osteogenic capacity in primary culture. The addition of OT rapidly increases $[Ca^{2+}]_i$ and stimulates prostaglandin synthesis. Oxytocin receptors have been demonstrated in the aorta, vena cava, and pulmonary vein by reverse transcription polymerase chain reaction (RT-PCR) and ligand binding analyses. Because OT is also expressed in these same tissues, these blood vessels appear to contain an intrinsic OT system, which may be involved in the regulation of vascular tone as well as vascular regrowth and remodeling. It is likely that OTRs are confined to the endothelium of these vessels. Occupancy of these receptor sites mobilizes intracellular Ca^{2+} and causes the release of nitric oxide, which is prevented by chelation of extracellular and intracellular Ca^{2+}. Nitric oxide production is associated with vasorelaxation, and presumably OT has a vasodilatory effect on certain blood vessels.

Oxytocin receptors in both atrial and ventricular chambers of the rat heart mediate the OT-stimulated release of atrial natriuretic peptide. This peptide slows the heart and reduces its force of contraction to produce a rapid reduction in circulating blood volume. Oxytocin receptors are found in human breast tumors of epithelial origin, as measured by immunological techniques. There are, however, no clear indications as to whether these receptors are functional. Several breast tumor cell lines have been shown to express OTRs, but the functional role of OT is not clear. Oxytocin receptors have been found in thymocytes, ovarian cells, Leydig cells, and prostate cells, but information regarding signaling pathways in these cell types is still rudimentary.

IV. LACK OF DISEASES ASSOCIATED WITH IMPROPER EXPRESSION OF OXYTOCIN RECEPTORS

No natural mutations in the OTR gene have been described. Oxytocin-null mice fail to lactate, illustrating the importance of OT for survival of the species. There are no changes in the timing of parturition in these mice, but this process is likely dictated by the marked up-regulation of OTRs before labor. It is possible that AVP may replace OT in stimulating uterine contractions when OTRs are up-regulated.

V. DIFFERENTIAL BINDING SITES FOR NEUROHYPOPHYSEAL HORMONE AGONISTS AND ANTAGONISTS

Target size estimation, using radiation inactivation analysis, shows that an OT antagonist binds to a site about half the size of the agonist binding site. These findings suggest that the binding sites for agonists and antagonists are distinct. Indeed, by transfer of domains from the OT receptor into the V_2 vasopressin receptor, chimeric gain-of-function V_2/OT receptors are produced that bind OT agonists with structural requirements distinct from those of antagonists. For agonist binding and selectivity, the first three extracellular receptor domains are the most important. Conversely, the binding site for the OT

antagonist $d(CH_2)_5$ [$Try(Me)^2$,Thr^4,Orn^8,Tyr^9-NH_2]vasotocin is formed by transmembrane helices 1, 2, and 7, with the upper part of helix 7 contributing to binding affinity. Thus, the antagonist displaces OT by interacting with a distinct binding site, yet behaves as a competitive inhibitor.

VI. VASOPRESSIN SIGNALING THROUGH THE V_1 VASOPRESSIN RECEPTOR

The V_1 vasopressin receptor (V_1R) mediates a range of physiological processes, such as contraction of vascular smooth muscle cells and cell proliferation. Vasopressin also stimulates hepatic glycogenolysis in the rat but in no other species, and is one of several agonists that stimulate platelets to aggregate and secrete their granular contents. Platelet activation is partly mediated by $InsP_3$ production.

Occupancy of the V_1R leads to activation of $G_{q/11}$–PLC-β production of $InsP_3$ and the subsequent transient increase in $[Ca^{2+}]_i$ in most of the cell lines studied (Fig. 3). Part of the $[Ca^{2+}]_i$ arises from the influx of extracellular Ca^{2+}. In rat glomerulosa cells, the influx of extracellular Ca^{2+} occurs through L-type channels in a PTX-sensitive manner. Voltage-operated channels, however, do not mediate the influx of Ca^{2+} by vascular smooth muscle cells. Like OT signaling, increases in $[Ca^{2+}]_i$ lead to Ca^{2+}–CaM activation of MLCK and the phosphorylation of MLC. V_1 receptor occupancy also results in the release of arachidonic acid by vascular smooth muscle cells and glomerular mesangial cells via activation of PLA_2. Arachidonic acid release in rat glomerular mesangial cells is PTX sensitive. Thus, V_1 receptors are coupled to both $G_{q/11}$ and $G_{i/o}$ heterotrimeric G proteins, each of which regulates separate pathways.

A. Phospholipase D

A number of studies have implicated phospholipase D (PLD) in AVP action, but the mechanisms have not been thoroughly characterized. Activating PLD converts phosphatidylcholine to choline and phosphatidic acid, which helps regulate specific cellular functions (Fig. 3). Most agonists that activate PLD also induce phosphatidylinositol 4,5-bisphosphate (PIP_2) hydrolysis through the stimulation of PLC. The resulting generation of $InsP_3$ and DAG activates Ca^{2+}-sensitive PKC isoenzymes that stimulate PLD. The activation of PLD, however, is not mediated by PKC in all cell types, and it has been suggested that small GTPases of the Rho and ADP ribosylation factor families also activate PLD. In other cases, βγ- and α-subunits of heterotrimeric G-proteins may stimulate PLD upstream from PKC signaling. Although the regulation of PLD by AVP is still poorly characterized, there is evidence that this pathway may be more relevant that PLC-mediated pathways in mediating smooth muscle contraction. For example,

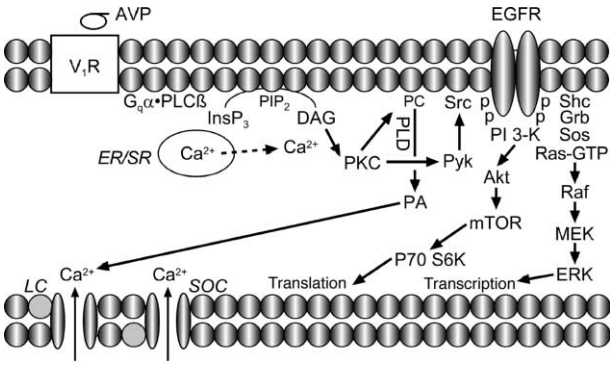

FIGURE 3 Transactivation of the epidermal growth factor receptor by arginine vasopressin (AVP) signaling through the vasopressin V_1 receptor. In addition to signaling by pathways that lead to vascular smooth muscle contraction, as outlined for oxytocin stimulation of myosin light chain phosphorylation in Fig. 2, AVP also stimulates cell proliferation by signaling transcriptional and translational events. These processes are thought to involve transactivation of the epidermal growth factor receptor (EGFR), which serves as a scaffold for signaling proteins. The phosphorylation of a Ca^{2+}-dependent tyrosine kinase, Pyk2, by protein kinase C (PKC) creates a ligand for another nonreceptor tyrosine kinase, Src, which is phosphorylated. Src, thus activated, phosphorylates the EGFR, which has phosphotyrosines that interact with proteins containing SH2 domains. Among them, the regulatory subunit of phosphatidylinositol 3-kinase (PI3K) is activated to catalyze the formation of phosphatidylinositol 3,4,5-trisphosphate, which serves as an attachment site for the Akt plekstrin homology domain. Phosphatidylinositol 3,4,5-trisphosphate also activates phosphoinositide-dependent kinase, which catalyzes the phosphorylation of Ser and Thr residues on Akt, resulting in activation of Akt. Akt stimulates mTOR, which in turn activates p70 S6 kinase and phosphorylation of the S6 protein of the 40S ribosomal subunit that is involved in translational control of 5′-oligopyrimidine tract mRNAs. Phosphorylation of the EGF receptor also creates docking sites for Shc, which serves a scaffolding function in signaling for a variety of receptor tyrosine kinases. Grb2/Sos binds to phosphorylated Shc, activating the Ras/Raf/MAPK pathway. The end product ERK phosphorylates transcription factors, leading to an increase in transcriptional activity of target genes. Protein kinase activation of phospholipase D (PLD) causes the release of phosphatidic acid, which signals the influx of extracellular Ca^{2+} and Ca^{2+}-dependent action potentials, leading to smooth muscle contraction (other abbreviations as in Fig. 2).

in A7r5 vascular smooth muscle cells, 10–500 p*M* AVP stimulates excitation by increasing Ca^{2+} oscillations and Ca^{2+}-dependent action potentials via a PLD-mediated pathway. The PLC pathway is activated only at higher concentrations of hormone.

B. Switching of G-Protein-V_1 Vasopressin Receptor Coupling

The coupling of recombinant V_1Rs to G-proteins has been examined in transfected CHO cells. When expressed at relatively low levels, V_1Rs were coupled solely to G_q. At higher expression levels, however, G_i and G_s were associated with V_1Rs, reflecting the promiscuity in G-protein coupling under contrived conditions. Changes in G-protein coupling, however, also occur naturally during the cell cycle. In proliferating Swiss 3T3 fibroblasts, AVP-induced increases in $[Ca^{2+}]_i$ are mediated by G-proteins of the G_q family. In quiescent cells (G_0/G_1 phase), however, the AVP-induced increase in $[Ca^{2+}]_i$ is partially PTX sensitive, suggesting G_i-protein involvement. The blocking effect of PTX pretreatment in G_0/G_1 cells was mimicked by microinjection of antisense oligonucleotides, suppressing the expression of the $G_{\alpha i3}$ or $G_{\beta\gamma}$ subunits. The significance of both $G_{q/11}$ and G_{i3} coupling is not clear, because both pathways appear to involve activation of phospholipase C-β. Class-switching mechanisms do not appear to be related to any changes in receptor number or type, or to changes in the relative expression of the G-proteins, but may relate to changes in expression level of proteins that are regulators of G-protein signaling (RGS) during the cell cycle.

C. Vasopressin Transactivation of Epidermal Growth Factor Receptors

Kidney mesangial cells, important for maintaining the microcirculation of the glomerulus, contract in response to AVP treatment. Vasopressin is also one of several growth factors that stimulate mesangial cells to proliferate in culture. The growth-promoting effects of AVP are mediated by Ras mitogen-activated protein kinase and the phosphatidylinositol 3-kinase (PI3K) signaling pathways. Treatment with rapamycin, an inhibitor of the p70 S6 kinase activator mTOR, inhibits AVP action downstream from PI3K activation. These activities follow AVP transactivation of the epidermal growth factor (EGF) receptor via tyrosine phosphorylation of the Ca^{2+}/PKC-dependent nonreceptor tyrosine kinase, Pyk2, leading to Pyk2/c-Src interaction and c-Src activation (Fig. 3). Association of c-Src with EGF receptor results in EGF receptor phosphorylation and creation of docking sites for PI3K and Ras. Thus, like other GPCRs, which transactivate EGF receptor through tyrosine phosphorylation of adapter proteins, the V_1R is able to stimulate cell proliferation. Phosphatidylinositol 3-kinase also mediates the growth-promoting effects of AVP on rat fibroblasts.

Vasopressin also stimulates mitogenesis in vascular smooth muscle cells, 3T3 cells, rat hepatocytes, and adrenal glomerulosa cells. All three MAP kinase pathways, ERK1/2, c-Jun N-terminal kinase (JNK), and p38, are phosphorylated after AVP stimulation of vascular smooth muscle cells. JNK or p38 is involved in AVP-stimulated smooth muscle actin transcription.

VII. VASOPRESSIN V_2 RECEPTOR SIGNALING

The V_2R is expressed in the kidney medulla and mediates the antidiuretic effects of AVP, which involve water transport across the epithelium of the renal collecting duct. Occupancy of receptor sites on the basolateral plasma membrane of ductal cells leads to activation of adenylyl cyclase type IV via G_s coupling.

A. Aquaporin-2 Water Channels

Generation of cAMP and activation of PKA cause translocation of intracellular vesicles containing aquaporin-2 (AQP2) water channels to the apical cell surface (Fig. 4). Phosphorylation of AQP2 by PKA occurs on serine residue 256 in the cytoplasmic carboxyl terminus. This step, which is essential for the translocation of AQP2, requires the anchoring of PKA to intracellular vesicles by PKA anchoring proteins. A variety of vesicular-trafficking processes involve localized increases in intracellular Ca^{2+}. In renal cells, an increase in $[Ca^{2+}]_i$ results from the AVP-stimulated rise in intracellular cAMP. This process occurs in the absence of activation of the phosphoinositide signaling pathway and involves ryanodine-sensitive Ca^{2+} stores in the endoplasmic reticulum and the type 1 ryanodine receptor. Calmodulin also plays a role in the AVP-stimulated redistribution of AQP2. Introduction of a synthetic peptide corresponding to the C-terminus of the $G_{\alpha i3}$ subunit into permeabilized cells, derived from rabbit cortical collecting duct and stably transfected with rat

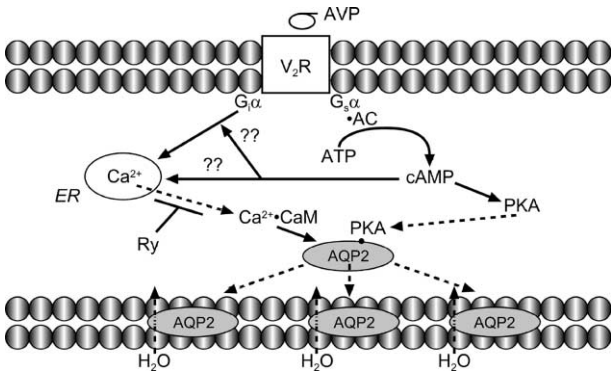

FIGURE 4 Signaling by occupancy of arginine vasopressin (AVP) V_2 receptors (V_2R) involves the generation of cyclic adenosine monophosphate (cAMP), which stimulates the phosphorylation of aquaporin-2 (AQP2) via protein kinase A (PKA) and an increase in Ca^{2+}-calmodulin (CaM). Both events are involved in the targeting of aquaporin-containing intracellular vesicles to the cell surface. Cyclic AMP stimulates Ca^{2+} release from ryanodine-sensitive (Ry) stores in the endoplasmic reticulum (ER) by mechanisms that may involve $G_{\alpha i}$. Translocation events are indicated by broken arrows.

AQP2 cDNA, inhibits cAMP-induced AQP2 translocation. Thus, a member of the G_i family, most likely G_{i3}, is also involved in the cAMP-triggered targeting of AQP2-bearing vesicles to the apical membrane of kidney epithelial cells. The rapid response to AVP involves translocation of AQP2 to the apical cell surface, but longer exposure of cells to AVP (24 h or more) causes an increased abundance of water channels, presumably from increased transcription of the *AQP2* gene.

B. Vasopressin and Urea Transport

Urea transport in the renal medullary loop of Henle and collecting duct is vital for urine concentration and regulation of renal water excretion. Like water channels, there are distinct transporters that regulate the movement of urea across cell membranes. The urea transporter found in portions of the thin descending limb of the loop of Henle is designated as UT-A, to distinguish it from the UT-B transporter expressed in erythrocytes and endothelial cells. AVP increases the expression of the UT-A2 variant of the UT-A gene (UT-A1 is transcribed from a separate promoter). Chronic treatment of rats with AVP almost doubles the level of expression of a Na–K–2Cl cotransporter in the thick ascending limb of the loop of Henle. Increased cAMP levels presumably mediate AVP-stimulated expression of both the UT-A2 and Na–K–2Cl cotransporter, but the signaling mechanisms are not yet characterized.

C. Desensitized Response to Vasopressin

The V_2R recruits β-arrestin to the plasma membrane after AVP occupancy and is internalized in a β-arrestin- and clathrin-dependent manner into endosomes. This process is mediated by the persistent phosphorylation of a specific cluster of serine residues in the carboxyl-terminal tail of the internalized V_2R, which inhibits recycling of receptors to the plasma membrane and causes a prolonged state of receptor desensitization.

D. Vasopressin Mutations and Diabetes Insipidus

Diabetes insipidus is a disease characterized by a severe disturbance of antidiuresis caused by a lack of AVP. Patients produce large amounts of dilute urine and must drink large amounts of fluid to replace what is lost. This disease occurs most often as a result of damage to the hypothalamus from trauma or metastatic disease, or it occurs as a primary idiopathic disorder. In rare instances, the disorder is hereditary and generally is transmitted in an autosomal-dominant manner. In these cases, mutations have been identified in the coding sequence of the preprovasopressin–neurophysin II gene. The AVP precursor protein consists of four regions that are cleaved proteolytically during processing. Starting from the amino terminus, they include a 19-amino-acid signal sequence for targeting to the endoplasmic reticulum; the nonapeptide sequence of vasopressin; neurophysin II (NPII), a 93-residue carrier for AVP that is involved in the proper targeting, packaging, and storage of AVP; and a 39-amino-acid glycopeptide of unknown function. The signal sequence is cleaved by signal peptidases on translocation of the precursor into the lumen of the endoplasmic reticulum. After folding and disulfide bond formation, pro-AVP passes through the Golgi apparatus into secretory granules, where mature AVP is formed by proteolytic cleavage. Mutations identified in different kindred are located in the sequences encoding the NPII portion, the signal peptide, and in one case the AVP sequence. Diabetes insipidus usually develops gradually over a period of months or years after birth. Postmortem examination usually indicates degeneration of the hypothalamic magnocellular neurons in which the AVP precursor is synthesized.

Thus, impaired transport and/or processing of the mutant precursor may result in its intracellular accumulation, eventually leading to degeneration of the vasopressinergic neurons and the gradual manifestation of clinical symptoms.

E. V_2 Vasopressin Receptor Mutations and Nephrogenic Diabetes Insipidus

Patients with nephrogenic diabetes insipidus (NDI) are unable to produce concentrated urine despite normal or elevated plasma levels of AVP. The AVP receptor 2 gene is located on the X chromosome (Xq28), and about 90% of patients with congenital NDI are males with the X-linked recessive form of the disease. Over 155 mutations within the gene have been characterized. Mutations have also been identified in the *AQP2* gene on chromosome region 12q13. When expressed in transfected cells, most NDI mutations result in receptors that are trapped intracellularly and are unable to reach the plasma membrane. AQP2 mutant proteins have also been found to be misrouted and cannot be expressed at the apical surface. A few types of mutant V_2 vasopressin receptors reach the cell surface but are unable to bind AVP or to properly induce cAMP production. One type of mutation results in perpetual down-regulation of V_2R because of constitutive arrestin-mediated internalization.

F. Rescue of Misrouted V_2 Vasopressin Receptors

Modifying the amino acid sequence of the C-terminus of transfected V_2Rs causes an accumulation of these receptors in the endoplasmic reticulum. Considerable functional activity can be regained, however, by coexpression of the mutant with a C-terminal V_2R peptide (130 amino acid residues) spanning the sequence containing the mutations. In many cases, restoration of receptor activity by the coexpressed receptor peptide is accompanied by a significant increase in receptor numbers on the plasma membrane. In other cases, coexpression allows an increased number of AVP binding sites and stimulation of adenylyl cyclase activity without an increase in surface receptor expression. The mechanisms of this rescue phenomenon are unclear. A physical association between the mutant V_2R proteins and the V_2-tail polypeptide has been demonstrated by coimmunoprecipitation, suggesting that functional rescue involves receptor–polypeptide dimerization.

Certain V_2R mutants have been rescued pharmacologically by incubating transfected cells expressing NDI alleles with membrane-permeant receptor antagonists. Of the 15 mutants evaluated, 8 were rescued to the surface and manifested AVP-stimulated cAMP accumulation. A nonpermeant V_2R antagonist was ineffective in receptor rescue, indicating that the effects of the permeant antagonists occur intracellularly, perhaps by inducing a receptor conformation that allows targeting to the cell surface. The expression of partial receptor peptides, by adenovirus-mediated delivery or the use of permeant AVP antagonists that act as pharmacological chaperones, offers an exciting potential treatment modality for NDI.

VIII. DOMAIN SWAPPING OF V_2 VASOPRESSIN AND OXYTOCIN RECEPTORS TO ELUCIDATE LIGAND BINDING AND G-PROTEIN INTERACTIVE DOMAINS

The neurohypophyseal hormone receptor family is ideal for examining the effects of domain swapping, because only the V_2R is coupled to cAMP production. Expression of the V_1/V_2 hybrid receptors in COS-7 cells shows that proteins containing the V_1R sequence in the second intracellular loop activate the phosphatidylinositol pathway with high efficiency. Only hybrid receptors containing the V_2 receptor sequence in the third intracellular loop are capable of efficiently stimulating cAMP production. These findings indicate that specific, single intracellular receptor domains differentiate between G-proteins.

Chimeric vasopressin OT/V_2 receptors have been used to identify receptor regions involved in ligand binding as well as G-protein coupling. A hybrid containing OTR sequences from the N-terminus to the middle of transmembrane region three had high-affinity OT binding sites that were coupled to activation of adenylyl cyclase. In contrast, a hybrid containing OTR sequences extending from transmembrane helix five to the C-terminus preferentially bound AVP but was not coupled to the V_2-selective $G_{\alpha s}$. Thus, OT binding requires the N-terminal third of the OTR. Use of OT/V_2 receptor chimeras and hybrid hormones (e.g. vasotocin) allows for a detailed analysis of the structural motifs involved in binding. The first two extracellular domains of the OTR are involved in binding to the C-terminal tripeptide of OT. The third extracellular domain of the receptor contacts the cyclic part of OT; the fourth and final outer domain does not appear to be involved in ligand binding.

IX. V_3 VASOPRESSIN RECEPTOR SIGNALING

The V_3R (or $V_{1b}R$) was initially described in corticotroph cells of the anterior pituitary, where AVP potentiates the release of ACTH. Subsequent cloning of the receptor showed that it was a third member of the AVP receptor family. Although studies on the AVP pituitary receptor revealed a different pharmacological profile compared to those of the V_1R and the V_2R subtypes, there are no specific AVP analogues that allow V_3R signaling to be completely distinguished from V_1R signaling. Vasopressin V_3R transcripts have been detected throughout the rat brain by reverse transcription polymerase chain reaction and by *in situ* hybridization. These receptors have also been localized immunohistochemically in fiber networks concentrated mainly in the hypothalamus, amygdala, and cerebellum (particularly in those areas with a leaky blood–brain barrier or close to the circumventricular organs). In peripheral tissues, V_3R transcripts are expressed in the kidney, pancreas, and adrenal medulla. Because of the difficulty in discriminating V_3 from V_1 receptor activation, most of what is known about V_3R signaling comes from studies in which the receptor has been stably expressed in CHO cells that do not otherwise express AVP receptors. AVP stimulates PLC activity in V_3R transfected cells. In clones expressing high levels of receptors, a portion of PLC stimulation is PTX sensitive, and AVP stimulates cAMP synthesis. These results suggest that the V_3R has a preferential affinity for $G_{q/11}$ but that at higher concentrations of receptor, it can also interact with $G_{i/o}$ and G_s, presumably by promiscuous interactions.

Vasopressin occupancy of V_3Rs also stimulates arachidonic acid release by a PTX-sensitive process. Activation of MAP kinases by AVP is dependent on activation of PLC and PKC; both the level and duration of activation are a function of the receptor density. Vasopressin stimulates DNA synthesis in clones expressing medium levels of V_3R.

Acknowledgments

Glossary

amnion Tough fibrous membrane that surrounds the fetus; has a simple (usually low-cuboidal with microvilli) epithelium facing inward.

aquaporin-2 Water channel that is expressed in the renal collecting duct; is translocated from intracellular vesicles to the apical membrane in response to an intracellular signaling cascade that is initiated by binding of vasopressin to its receptor.

endometrium Comprises the mucosal and glandular-containing submucosal lining of the uterus.

mesangial cell Contractile cell of the glomerular mesangium, which is a thin membrane that helps support the capillary loops in a renal glomerulus. Vasopressin stimulates contraction of these cells and stimulates their growth in cell culture.

myometrium Uterine smooth muscle.

pertussis toxin *Bordetella pertussis* protein that catalyzes the ADP-ribosylation of G-protein α-subunits of the G_i family; this modification blocks the receptor-G-protein interaction.

ryanodine receptors/calcium release channels Ca^{2+} is released from the endoplasmic and sarcoplasmic reticulum in a wide range of tissues by specialized types of calcium channels, i.e. ryanodine receptors, by the process of Ca^{2+}-induced Ca^{2+} release.

the pancreas, from which mature PST is secreted, whereas CGA is poorly phosphorylated in the ileum, from which there is no processing to PST.

III. PANCREASTATIN SYNTHESIS AND SECRETION

Proteolysis of CGA occurs both inside and outside the cell to yield peptides with biological activity. This function of CGA as a precursor of active peptides was first suggested after the isolation of PST, which turned out to have the sequence of a central part of the CGA molecule. This hypothesis was then supported by the observation of pairs of dibasic residues in the sequence of CGA, which usually represent targets for protease cleavage.

Intact CGA is the major component of secretory granules of the adrenal medulla and hypothalamus. Nevertheless, it is generally accepted that degradation products of CGA do exist in chromaffin cells. In the rat pheochromocytoma cell line PC12, intact CGA is present and is processed only at its N-terminus, although mature PST is rare. Chromaffin cells may be the major source of circulating CGA, and they could therefore be the major indirect source of PST in plasma.

The intracellular processing of PST has been fully described for bovine CGA and partially described for rat CGA. The mechanism involves proteases such as prohormone convertase-2 (PC-2) and carboxypeptidase H.

The extracellular processing of CGA may occur as a result of the activities of proteases co-secreted by the chromaffin granule or may be due to exoproteases localized on the extracellular side of the cell plasma membrane. In addition, fragmentation of bovine CGA by plasma kalikrein has also been shown.

The processing of CGA is tissue- and species-specific. Thus, CGA is more fully processed in the stomach, especially in the endocrine cells of the antrum, and in the endocrine pancreas, of which PST is a major product. PST production is higher in insulinoma cells than in primary human islets. In this tissue, PST expression has been found in the beta-, delta-, and alpha-cell populations. The somatostatin-secreting delta-cell line (QGP-1N) also releases PST.

Enterochromaffin-like (ECL) cells, originating from the gastric antrum, represent the best characterized physiological system of PST secretion. These cells respond to gastrin stimulation by increasing both PST secretion and CGA mRNA levels. In the rat *in vivo*, an increase in gastrin levels, either by infusion or by indirect means, leads to the suppression of acid secretion and an increase in PST levels. Conversely, a decrease in gastrin levels by fasting or antrectomy is followed by a decrease in PST levels. Moreover, gastrin receptor antagonists produce a decrease in PST levels. Finally, patients with gastrinomas have increased plasma PST levels, due to an excess of gastrin secreted by the tumor.

Plasma porcine PST-like immunoreactivity levels have been shown to increase 50% (from 100 to 150 pM) in response to a meal. In perfused porcine pancreas, PST-like immunoreactivity is released in parallel with insulin in response to insulinotropic stimuli.

Elevated PST levels have been found in response to a glucose load in type 2 diabetes, in hypertension, and in pregnant women with gestational diabetes, correlating with plasma catecholamine levels.

IV. BIOLOGICAL EFFECTS OF PANCREASTATIN

Many different biological effects of PST in a variety of tissues have been described. PST may act as an autocrine, paracrine, and/or endocrine peptide in many target cells.

A. Endocrine Secretion

There is accumulated evidence for the ability of PST to modulate endocrine secretion in a variety of systems.

1. The Endocrine Pancreas

The first described effect of PST was the inhibition of glucose-stimulated insulin secretion, and especially first-phase insulin secretion, in isolated rat pancreas. PST also potentiates the inhibition of insulin secretion caused by a physiological decrease in glucose concentration. On the other hand, PST has also been shown to prime glucose-stimulated insulin secretion after a second glucose pulse. PST can also inhibit the stimulatory action of other agents, whether these are physiological (arginine), hormonal (GIP, VIP, CCK, glucagon), or even pharmacological (IBMX, sulfonylurea). The inhibitory effect of PST on insulin release has been confirmed *in vivo* in the rat.

On the other hand, other groups have reported no such effect in dogs and pigs, suggesting different effects depending on the species. In general, PST seems to negatively modulate insulin secretion in an autocrine, paracrine, and endocrine manner. Other effects of PST that relate to endocrine pancreatic

secretion are the stimulation of glucagon release and the inhibition of pancreatic polypeptide secretion.

However, PST has been shown *in vitro* to be able to modulate the formation of insoluble fibers of amyloid polypeptide. Actually, the formation of amyloid fibers seems to be mediated by an inappropriate balance between the amyloid peptide, insulin, C-peptide, and PST.

2. Parathyroid Secretion

PST has an inhibitory effect on parathyroid hormone (PTH) secretion. This effect has been observed in porcine and bovine parathyroid cells on stimulation with low (but physiological) concentrations of either calcium or phorbol ester (a nonphysiological agent). This effect was confirmed by the demonstration that PTH secretion increases if parathyroid cells are incubated with anti-PST antibodies. Moreover, PST inhibits not only PTH secretion but also transcription of the PTH and CGA genes; the stabilities of these mRNAs are also decreased. The mechanism by which PST exerts these effects is not known, however.

The parathyroid gland is very rich in CGA, but complete processing of this protein to PST is very rare, due to the lack of prohormone convertases PC2 and PC1/3. Therefore, it cannot be concluded that PST has an autocrine role in parathyroid secretion. Nevertheless, processed PST is present in calcitonin-producing C cells, and in this way PST may be involved in the regulation of the thyroid–parathyroid axis.

3. Adrenal Medulla Secretion

The inhibition of secretion from the adrenal medulla by CGA-derived peptides (obtained by tryptic proteolysis) suggested that these peptides (including PST) may have some inhibitory action in chromaffin tissue. Consistent with this hypothesis, PST administration in the rat decreases catecholamine levels during surgical stress. It is not yet known whether this is a direct or an indirect effect of PST, however.

4. Atrial Secretion

PST can also regulate endocrine secretion from the heart. Atrial myocardial cells store and secrete atrial natriuretic peptide. Thus, PST has been shown to stimulate atrial cell secretion by 90%. This result suggests that the PST precursor, CGA, which has been identified in atrial secretory granules, may play an autoregulatory role in atrial secretion.

B. Exocrine Secretion

1. Exocrine Pancreatic Secretion

Evidence showing an inhibitory effect of PST on exocrine pancreatic secretion has been accumulating. *In vivo* studies employing physiological stimuli (a meal), CCK-8, and central vagal nerve stimulation have provided convincing data supporting an inhibitory effect of PST on pancreatic exocrine secretion. These effects seem to be mediated by the presynaptic modulation of acetylcholine release from the vagal system. Therefore, PST has been proposed as a new mediator in the islet–acinar axis.

2. Gastric Secretion

Contradictory *in vitro* versus *in vivo* results regarding the effects of PST on gastric secretion have been reported. Thus, PST inhibits gastric secretion in isolated parietal cells, but *in vivo* seems to enhance gastric acid secretion stimulated by different nutrients.

ECL cells from the gastric antrum are an important source of PST. Therefore, PST may play a role in the paracrine regulation of gastric acid secretion.

C. Hepatic Glycogen Metabolism

PST activates glycogenolysis in the rat liver. Thus, PST increases glucose release from the liver, resulting in a hyperglycemic effect. This effect can be observed *in vivo*, without even a modification of glucagon or insulin levels, suggesting a direct effect on liver metabolism. This observation was confirmed by studies in isolated hepatocytes, in which PST had a glycogenolytic effect similar to that of glucagon in potency, but was independent of cyclic AMP production and dependent on calcium. In fact, this glycogenolytic effect correlates with the dose-dependent increase in intracellular free calcium produced by a PST challenge.

In addition to its glycogenolytic effect, PST inhibits insulin-stimulated glycogen synthesis, but unlike glucagon it does not affect the rate of insulin-stimulated glycolysis. In this way, even though the glycogenolytic effect of PST is comparable to that of glucagon, the latter produces higher levels of hyperglycemia. Conversely, PST inhibits glucagon-stimulated insulin release and thus enhances the hyperglycemic effect of glucagon.

D. Metabolic Effects in the Adipocyte

Another target cell for metabolic regulation by PST is the adipocyte. Here, PST has been shown to modulate

glucose, lipid, and protein metabolism in isolated adipocytes. PST also inhibits basal and insulin-stimulated glucose transport, lactate production, glycogen synthesis, and lipogenesis in a dose-dependent manner. It therefore opposes the main metabolic action of insulin in adipose tissue. These effects can be observed at a wide range of insulin concentrations, leading to a shift to the right in the dose–response curve. Maximal effects are obtained at 10 nM PST, with an ED_{50} of 0.1 nM. These counterregulatory effects on insulin action suggest that PST may have a role in insulin resistance. Moreover, PST has a dose-dependent lipolytic effect in isolated adipocytes ($ED_{50} = 0.1$ nM). However, this effect is inhibited by 10 nM insulin. On the other hand, PST has a stimulatory effect on protein synthesis and enhances insulin-stimulated protein synthesis in isolated adipocytes.

E. Insulin Receptor Inhibition

PST signal transduction has been shown to cross-talk with insulin receptor signaling. Thus, PST inhibits insulin receptor tyrosine kinase activity by promoting serine phosphorylation of the insulin receptor β-subunit. Lower tyrosine phosphorylation levels of insulin receptor substrates lead to decreased interactions with the regulatory enzyme phosphatidyl inositol-3 kinase. This is a key enzyme that mediates glucose transport and metabolism in the adipocyte and glycogen synthesis in the hepatocyte. These inhibitory effects of PST on insulin receptor signaling partly mediate the metabolic counterregulatory action of PST and further suggest that PST may have a role in insulin resistance.

Meanwhile, PST stimulates the mitogen-activated protein kinase (MAPK) signaling cascade, potentiating this insulin receptor signaling pathway. In fact, this dual effect on insulin receptor signaling may explain PST's ability to simultaneously inhibit glucose and lipid metabolism and promote protein synthesis in adipocytes.

F. PST Regulation of Cell Growth

PST has been found to have an inhibitory effect on cell growth in a variety of cell lines (pancreatic and hepatic cells). This inhibitory effect of PST has also been observed *in vivo* in islets transplanted into nude mice. Moreover, PST inhibits basal and CCK-stimulated pancreas growth in mice. Consistent with this finding, PST can also inhibit DNA synthesis in rat fetal islets.

Even though PST stimulates MAPK signaling in HTC (hepatoma cells), it has been found that PST inhibits protein and DNA synthesis. The PST-induced inhibition of cell growth observed in HTC hepatoma cells is mediated by nitric oxide (NO) production. If NO production is blocked, PST stimulates cell growth. This stimulatory effect is mediated by activation of the MAPK pathway. In this way, the final effect of PST on hepatocyte growth may depend on NO availability.

G. Effects of PST on Central Nervous System

Peripheral administration of PST has been shown to enhance memory retention in mice. In addition, PST can revert the amnesia produced by the cholinergic antagonist scopolamine. This activity in memory retention seems to be a peripheral rather than a central effect, since intraventricular administration produces only a modest relief. Therefore, these effects may be a consequence of the PST-mediated hyperglycemia previously demonstrated in mice, since hyperglycemia is known to increase memory retention. Moreover, intracranial administration of PST elevates blood glucose and free fatty acids in the rat. This action is opposite to that of insulin, further supporting the counterregulatory effects of PST.

PST may also play a role in the formation of senile plaques in Alzheimer's disease, in which a long 13.5 kDa form of PST seems to be present. The physiological or pathophysiological role of PST in Alzheimer's disease is unknown, however.

H. Immunomodulatory Effect of PST

PST seems to have an immunomodulatory effect. It is able to enhance the mitogenic response of peripheral blood T lymphocytes when they are stimulated by noncognate stimuli (lectins). Therefore, a role for PST as an immunomodulator has been proposed.

V. PUTATIVE PHYSIOLOGICAL ROLE OF PANCREASTATIN

Although the physiological role of PST has yet to be fully established, a multitude of effects have been ascribed, implicating PST in the modulation of secretion and the control of metabolism.

The variety of PST's effects on the modulation of secretion in glands where this peptide is synthesized and processed has led to the hypothesis that PST may have a role as an autocrine and paracrine regulatory peptide of exocrine and endocrine secretion. Nevertheless, further studies to identify the molecular

mechanisms underlying these effects are needed to establish a physiological role in the regulation of secretion.

The metabolic actions of PST have been more thoroughly studied and some of the molecular mechanisms by which PST modulates glucose, lipid, and protein metabolism, with effects that are generally counterregulatory to those of insulin, are already known.

Our current hypothesis is that PST plays a role in the physiology of stress, by regulating the supply of energy to the body (especially the muscle and brain). In fact, PST levels may be increased under stressful conditions, during which CGA is co-secreted with catecholamines. Therefore one would expect that the endocrine actions of PST may actually take place under stressful conditions, when circulating PST levels are high enough to interact with specific receptors in target cells. Consistent with this proposal, specific PST receptors and PST-induced signal transduction have been characterized in liver and adipose tissue, providing a basis for the molecular mechanisms of the metabolic effects of PST.

Moreover, PST can modify the insulin/glucagon ratio by modulating secretion to further increase metabolic anti-insulin effects. In this context, PST could also play a role not only in the physiology of stress, but also in pathophysiological conditions such as insulin-resistant states. In support of this concept, increased levels of PST, which correlate with those of catecholamines, have been found in type 2 diabetes, gestational diabetes, and essential hypertension.

These effects of PST may also be considered complementary to those described for other CGA-derived peptides, which have been found to exert different actions, such as the control of catecholamine secretion, vasodilation, and infection.

In conclusion, PST is a regulatory peptide derived from CGA and, therefore, may be regarded as part of the functional axis controlled by this protein, for which the description of a physiological role has been elusive for so long.

Glossary

chromaffin Tissue of neuroectodermic origin with the specialized function of synthesizing and secreting catecholamines.

chromogranin A A glycoprotein that is very abundant in the secretory granules of chromaffin and other neuroendocrine cells.

insulin resistance A pathophysiological condition in which the action of insulin is impaired, so that a higher insulin concentration is needed to result in the same effect.

pancreastatin A chromogranin A-derived peptide that inhibits secretion and impairs insulin action.

regulatory peptide A peptide that is released in response to a stimulus and that exerts specific biological actions. It may function as an autocrine, paracrine, or endocrine agonist or antagonist.

Pancreastatin Receptor Signaling

VÍCTOR SÁNCHEZ-MARGALET

Virgen Macarena University Hospital, Spain

Pancreastatin (PST) receptor signaling has been thoroughly studied in the rat liver and adipose tissue during the past decade, and it is still an active area of research. PST receptor signaling is a paradigmatic example of the signal transduction of a calcium-mobilizing hormone receptor. Even though the PST receptor has not yet been cloned, the signaling triggered in response to PST has the typical pattern of a seven-transmembrane-spanning receptor coupled to heterotrimeric G-proteins in the plasma membrane to exert the metabolic actions observed in the liver and adipose tissue. This article describes the different signaling pathways that have been shown to be activated in response to PST and the possible molecular mechanisms underlying the modulation of the metabolic action exerted by PST in the liver and adipose tissue, as well as the counterregulatory effects on insulin action.

I. PANCREASTATIN RECEPTOR

One of the hallmarks confirming the endocrine nature of a peptide is the presence of specific receptors in the plasma membrane. Thus, pancreastatin (PST)-binding sites have been characterized in rat liver, adipose, and heart membranes. Binding data obtained using radioiodinated rat PST in rat liver membranes suggested the presence of specific high-affinity receptors for PST. The PST binding fulfills all the criteria for membrane receptors: it is temperature-, time-, and pH-dependent, and it is saturable and reversible. In addition, the binding of the ligand is very sensitive to the PST sequence, further suggesting the specificity of the receptor. Thus, PSTs from species that share a low level of sequence homology with rat PST, such as human or porcine PST, showed a low level of binding affinity in the studies of radioligand displacement. Analysis of binding data under equilibrium conditions showed similar affinity values in rat liver, HTC rat hepatoma, rat adipose, and heart membranes, indicating the presence of a single site with a K_d ranging from 0.2 to 1 nM. This range of K_d values correlates well with the ED_{50} obtained for the effects of PST in hepatocytes and adipocytes and is in accordance with PST levels found in pig and human plasma. In addition, these values are comparable to those obtained for most peptidic hormone receptors. Therefore, the affinity of the putative PST receptor is consistent with a possible physiological and pathophysiological role for this regulatory peptide.

On the other hand, different concentrations of binding sites have been found depending on the target tissue, from 5 fmol/mg of protein in adipose tissue to 34 fmol/mg of protein in heart membranes, with an intermediate B_{max} of 15 fmol/mg of protein in rat liver membranes. These binding data give an estimate of 1000–5000 binding sites per cell.

Active PST receptors have been solubilized and characterized from rat liver membranes. Molecular analysis of the solubilized receptor by covalent cross-linking and further identification on sodium dodecyl sulfate–polyacrylamide gel electrophoresis indicated a single band of 85 kDa. Gel filtration studies of the solubilized receptors confirmed the 80 kDa molecular mass of the PST receptor. In addition, the solubilized receptor is a glycoprotein that can specifically bind to the wheat-germ agglutinin (WGA) lectin.

Taking advantage of the glycoprotein nature of the receptor, a two-step procedure has been employed as a purification strategy. Thus, WGA semipurification followed by affinity purification using a biotinylated PST analogue has led to the purification of PST receptors in homogeneity. The PST receptor can be purified as an 80 kDa monomeric glycoprotein physically associated with a $G_{\alpha q/11}$ protein. The scale-up of the purification process may yield sufficient amounts of receptor proteins to undertake microsequencing in the near future.

II. G-PROTEINS COUPLED TO PANCREASTATIN RECEPTOR

Heterotrimeric (α, β, γ) GTP-binding (G) proteins are one of the most important transducers of the signaling from receptors in the plasma membrane to the interior of the cell, coupling the activation of the receptor with the triggering of different effector systems. The coupling of the PST receptor with GTP-binding proteins has been demonstrated by different approaches in rat liver, adipocyte, and heart membranes.

The first evidence for the coupling of the PST receptor with G-proteins was revealed by the sensitivity of PST binding to the presence of guanine nucleotides, especially nonhydrolyzable analogues. These results were then confirmed with direct evidence of physical and functional coupling. Thus, GTPase activity, GTP-binding studies, and photolabeling, in combination with pertussis toxin (PT) pretreatment and blocking antibodies against different α-subunits, demonstrated the double coupling of the PST receptor, mainly with a G-protein of the $\alpha_{q/11}$ family and to a lesser extent with a G-protein of the $\alpha_{i1,2}$ family (PT sensitive). Moreover, a physical association was demonstrated by binding studies with radiolabeled PST in anti-$G_{\alpha q/11}$ immunoprecipitates. These results were confirmed by the opposite approach. Thus, $G_{\alpha q/11}$ proteins could be observed along with semipurified and purified PST receptor.

In general, a double system of G-proteins seems to be engaged in PST signaling, a pertussis toxin-sensitive G-protein belonging to the $G_{\alpha i1,2}$ family and a pertussis toxin-insensitive G-protein belonging to the $G_{\alpha q/11}$ family (see Fig. 1). The specific G-protein coupled to the PST receptor has been assessed in rat liver membranes, where $G_{\alpha 11}$ rather than $G_{\alpha q}$ seems to functionally couple to the PST receptor. On the other hand, $G_{\alpha 16}$ (another G-protein of the $\alpha_{q/11}$ family) is the G-protein that couples to the PST receptor in the heart. Since $G_{\alpha 16}$ is not present in liver or adipose tissues, but is present in the heart, the coupling of PST receptor with $G_{\alpha q/11}$ in hepatocytes and adipocytes is compatible with the preferential coupling with $G_{\alpha 16}$ rather than $G_{\alpha q/11}$ in heart membranes.

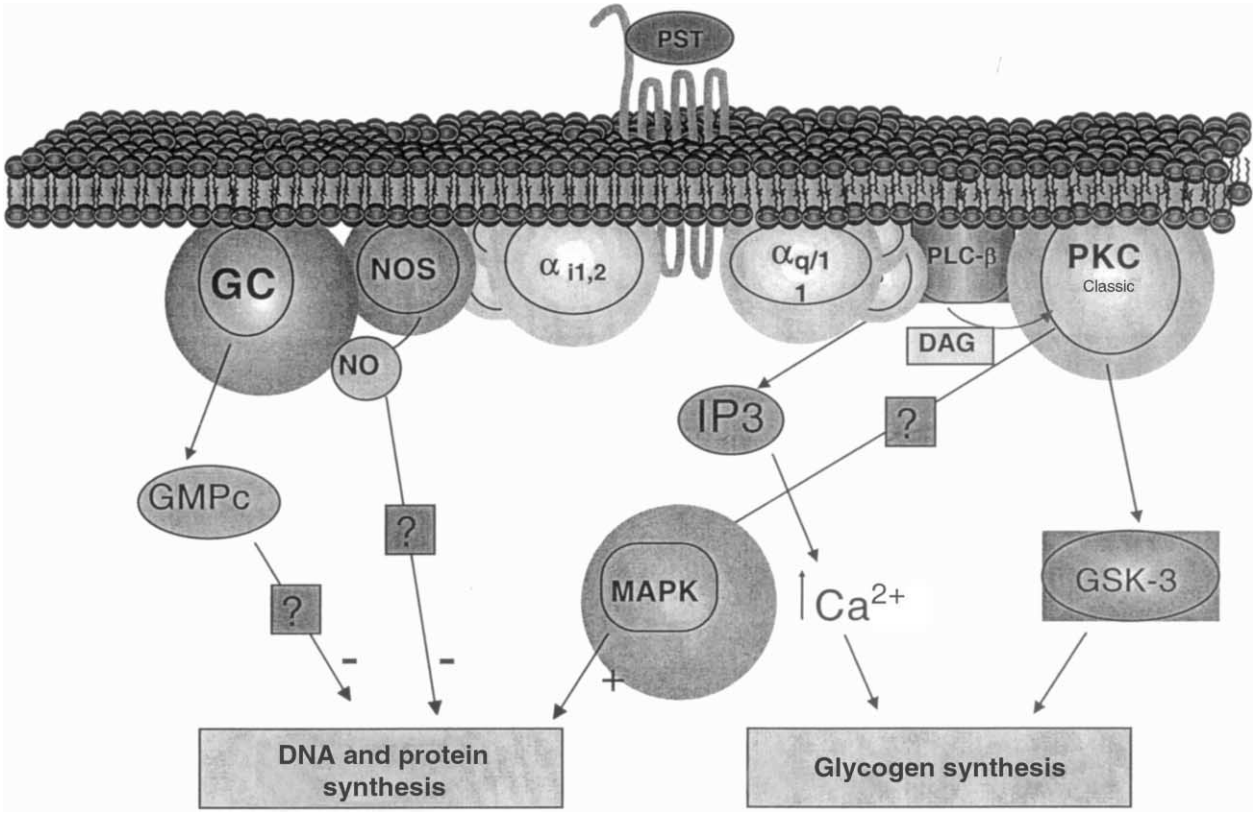

FIGURE 1 Schematic model of pancreastatin receptor signaling.

III. EFFECTORS FOR PANCREASTATIN RECEPTOR SIGNALING

A. Phospholipase C Activity

The polyphosphoinositide-specific phospholipase C (PLC) that is activated by seven-transmembrane receptors by coupling heterotrimeric G-proteins is the membrane-associated PLC-β. PST has been shown to stimulate membrane-associated PLC-β activity in rat liver membranes. Four different PLC-β isoforms (β1–4) have been described, although the expression of PLC-β4 is more limited and cannot be found in hepatic, adipose, or heart tissues. The PLC-β3 isoform seems to be the specific isoform activated by PST receptors in rat liver and adipose membranes, although PLC-β1 is also activated in HTC rat hepatoma cells. The activation of PLC by PST is mediated mainly by $G_{\alpha q/11}$ in liver and adipose membranes, but some activation may be accounted for by βγ released by $\alpha_{i1,2}$ or $\alpha_{q/11}$ activation.

On the other hand, PLC-β2 is the isoform preferentially activated in rat heart membranes by PST, although it can also stimulate some activation of β1 and β3 isoforms. This is not striking when it is taken into account that PST preferentially activates $G_{\alpha 16}$ in heart membranes, and this G_{α} protein preferentially activates PLC-β2, although it can activate β1 and β3 to a lesser extent.

B. Calcium

The role of calcium in PST action has been studied in the hepatocyte. Thus, PST stimulation of isolated hepatocytes induces a rapid increase in intracellular calcium concentration. Consistent with these results, the glycogenolytic effect of PST was found to be cyclic AMP-independent but very dependent on both extracellular and intracellular calcium. In fact, the dose-dependent glycogenolytic effect of PST correlates with the progressive increase in intracellular calcium concentration. Moreover, PST has been found to increase intracellular free calcium concentration by releasing intracellular stores and increasing the influx of extracellular calcium. These effects are mediated by the production of inositol 1,4,5-triphosphate (IP_3) resulting from the activation of PLC-β by $G_{\alpha q/11}$.

C. Protein Kinase C

The activation of PLC-β activity in the plasma membrane by PST stimulation leads to the production of IP_3 as discussed in the previous section, but also produces diacylglycerol (DAG). DAG in addition to calcium is responsible for the activation of protein kinase C (PKC), more precisely, the classical isoforms of PKC. Thus, PST has been found to activate classical isoforms of PKC (α, βI, and βII) by promoting translocation from the cytoplasm to the plasma membrane in HTC hepatoma cells and rat adipocytes. Moreover, the glycogenolytic effect of PST in the hepatocyte and the inhibition of glucose transport in the adipocyte can be prevented by blocking the activation of PKC. Taken together, these results suggest that PKC activity is a very important effector of PST receptor signaling.

D. Mitogen-Activated Protein Kinase

G-protein-coupled receptors are known to signal to the mitogen-activated protein kinase (MAPK) pathway by two different but complementary mechanisms. Thus, the βγ dimer of heterotrimeric G-proteins can activate the Ras–Raf pathway, whereas the $\alpha_{q/11}$ protein connects with MAPK by activating PKC. Therefore, the reported effect of PST-activating MAPK in hepatoma cells and adipocytes can be explained by this dual mechanism. Thus, PST induces the Ser/Thr phosphorylation of MAPK by activation of MAPK kinase. In fact, this pathway mediates the effect of PST-stimulating protein synthesis in rat adipocytes.

E. Glycogen Synthase Kinase-3 Activity

PST stimulation is able to activate glycogen synthase kinase-3 (GSK-3) activity in rat adipocytes. The phosphorylation level of GSK-3 is negatively correlated with the activity. Thus, PST inhibited basal phosphorylation of GSK-3. The PST stimulation of GSK-3 activity seems to be mediated by PKC since it can be prevented by a specific PKC inhibitor. This effect of PST on GSK-3 activity results in the inhibition of both basal and insulin-stimulated glycogen synthesis in rat adipocytes. This effect of PST can also be prevented by using a PKC inhibitor. Therefore, PKC activation by PST mediates the activation of GSK-3, which is one of the final effectors of PST receptor signaling to regulate glucose metabolism.

F. Nitric Oxide and Cyclic GMP

PST was found to increase the production of the second messenger cyclic GMP (cGMP) in rat hepatocytes by a PT-sensitive mechanism, probably involving $G_{\alpha i1,2}$ activation, although this mechanism still

needs experimental confirmation to finally define this signaling pathway. In any case, this effect has been proved to be mediated by nitric oxide (NO) production in hepatoma cells. The production of cGMP may eventually lead to down-regulation of the $G_{\alpha q/11}$–PLC-β signaling by activating protein kinase G (PKG), as observed in other systems for other G-protein-coupled receptors. The role of cGMP/PKG in the counterregulation of PST signaling still needs further investigation, however.

On the other hand, NO and cGMP have been shown to inhibit DNA and protein synthesis in hepatoma cells. Therefore, these effectors seem to mediate the antiproliferative effect of PST in HTC rat hepatoma cells. The antiproliferative effect of the NO–cGMP pathway has been found in other systems. In fact, when NO synthase activity is blocked by pharmacological inhibitors, the effect of PST changes to the stimulation of growth and proliferation, due to the activation of the MAPK pathway. Therefore, the final effect of PST on cellular growth and proliferation may depend on the balance between these two signaling pathways, especially the availability of NO.

IV. CROSSTALK OF PANCREASTATIN RECEPTOR WITH INSULIN RECEPTOR SIGNALING

Crosstalk of the PST receptor with insulin receptor signaling has been studied in hepatoma cells and adipocytes. Similar results have been observed in both systems (Fig. 2).

PST inhibits insulin-mediated autophosphorylation of the insulin receptor β-subunit in a dose-dependent manner. In addition, PST blunts tyrosine phosphorylation of insulin receptor substrate-1 (IRS-1), IRS-2, and p60-70, preventing their association with p85, the regulatory subunit of phosphatidyl inositol 3-kinase (PI3K). This effect results in the inhibition of PI3K activity. Moreover, the insulin activation of the downstream protein kinase B and S6 kinase is also blocked by PST.

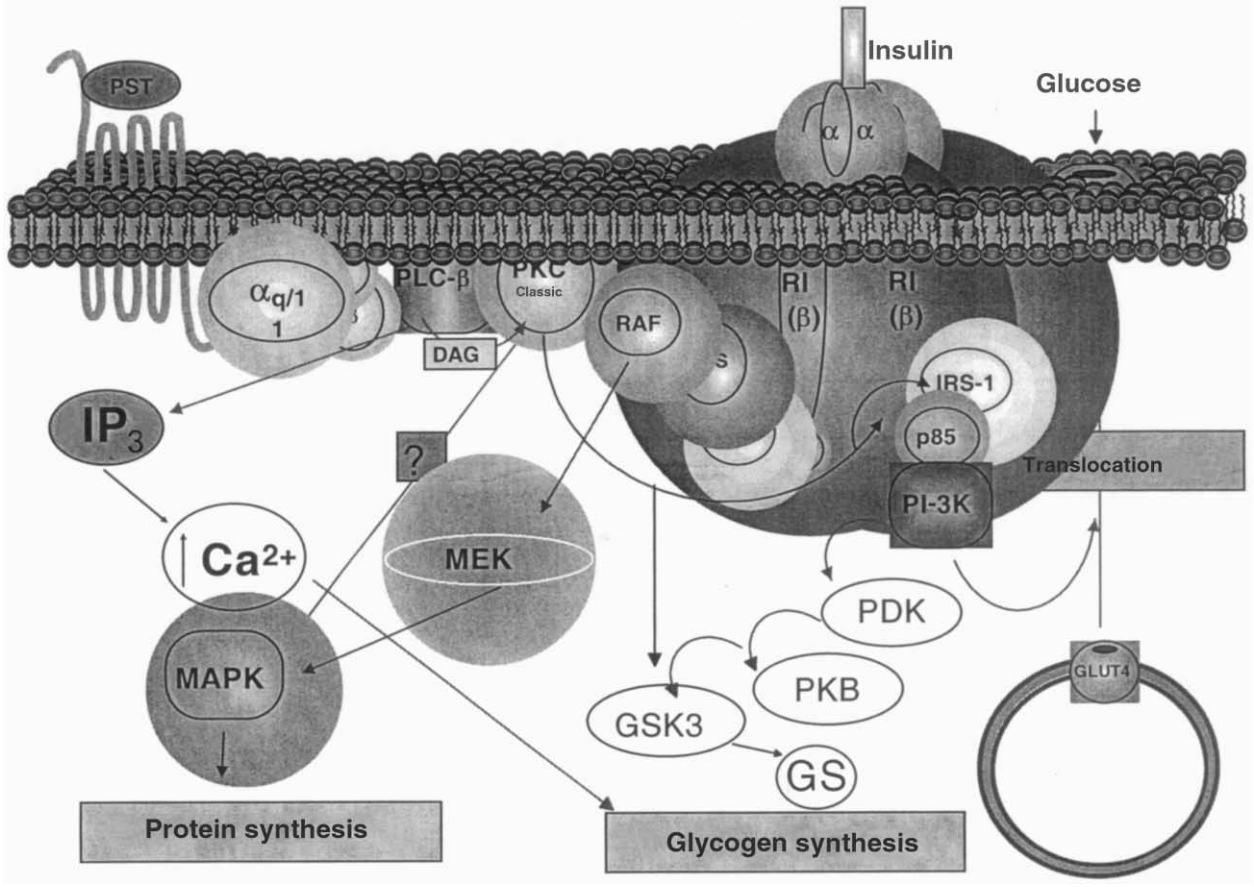

FIGURE 2 Schematic model of the cross talk of pancreastatin with insulin receptor signaling.

These effects of PST in preventing insulin receptor signaling can be fully reversed by blocking protein kinase C activity, strongly suggesting that the PST-induced activation accounts for the crosstalk of both receptors. In fact, PST induces the serine/threonine phosphorylation of insulin receptor β-subunit and IRS-1, which is a well-known mechanism of inhibition of insulin receptor tyrosine kinase activity by counterregulatory hormones. Moreover, the PST-mediated Ser/Thr phosphorylation of the insulin receptor and IRS-1 seems to be caused by the activation of PKC, since this effect can also be prevented by blocking PKC activity. In fact, the PST-mediated activation of PKC has been observed in both the hepatocyte and the adipocyte. PST-inhibited, insulin-stimulated PI3K activity can also be reversed by blocking PKC. In parallel with the signaling results, the PST inhibition of the physiological actions of insulin can also be reversed by preventing PKC activation. Thus, the inhibitory effects of PST on insulin-stimulated glucose transport in adipocytes and glycogen synthesis in hepatocytes are also abrogated by blocking PKC activation.

These findings suggest that PST may exert its anti-insulin effect on the insulin receptor by cross talk with the early signaling events, as a result of PKC-mediated Ser/Thr phosphorylation that inhibits tyrosine phosphorylation in insulin receptor signaling.

V. CONCLUSIONS

Data from PST signaling studies in hepatocytes and adipocytes point to the presence of a specific receptor of high binding affinity and specificity in the plasma membrane. Signal transduction of the PST receptor engages the activation of a double system of G-proteins. On the one hand, a PT-sensitive $G_{\alpha i1,2}$ pathway may mediate the activation of NO and cGMP production, which then may have a role inhibiting the signaling and mediating the inhibitory effect of PST on cell proliferation. On the other hand, a PT-insensitive $G_{\alpha q/11}$ is activated by the PST receptor and certainly mediates the activation of the PLC-β–PKC–MAPK pathway. The activation of classical isoforms of PKC is a central mediator of the metabolic effects of PST and its crosstalk with the insulin receptor, whose signaling and action are subsequently impaired. The balance of both limbs of signal transduction is also important for the final effect of PST on cell growth and proliferation.

Glossary

chromogranin A A glycoprotein that is very abundant in chromaffin and neuroendocrine secretory granules. This protein may function as a prohormone precursor of biologically active peptides.

cyclic GMP Cyclic nucleotide synthesized by guanylate cyclase, an enzyme activated by nitric oxide.

G-protein Heterotrimeric protein (α, β, γ) whose α-subunit has GTPase activity. G-proteins couple seven-trans-membrane-spanning receptors with different effectors.

nitric oxide synthase (NOS) There are three isoforms: inducible, neuronal, and endothelial. The activities of neuronal and endothelial NOS are regulated by extracellular signals and the inducible NOS is regulated at the transcriptional level.

pancreastatin Chromogranin A-derived peptide with autocrine, paracrine, and endocrine effects regulating secretion and metabolism.

phospholipase C Polyphosphoinositide-specific phospholipase, typically producing inositol 1,4,5-triphosphate and diacylglycerol. The phospholipase C β isoform is located in the plasma membrane.

protein kinase C Serine/threonine protein kinase whose activity is dependent on calcium and/or phospholipids.

Pancreatic Polypeptide

RONALD E. CHANCE

Eli Lilly and Company, Indiana

Pancreatic polypeptide is a 36-residue peptide hormone with an amidated carboxyl group at the C-terminus. The hormone was discovered fortuitously in 1968 by scientists at Kansas University during research to purify chicken insulin.

I. INTRODUCTION

Discoverers Joseph Kimmel, Gail Pollock, and Robert Hazelwood named the persistent contaminant avian pancreatic polypeptide (APP; more recently aPP), fully expecting to rename it later once function was established. Because aPP was indistinguishable from glucagon by polyacrylamide disc gel electrophoresis, the peptide was assayed for glucagon bioactivity by William Bromer (Eli Lilly). Even though no hyperglycemic activity was found by the U.S. Pharmacopeia rabbit assay, continued work revealed that aPP was probably a hormone based primarily on a key structural feature. The C-terminal amino acid was amidated (i.e. tyrosinamide). This prompted the author's laboratory at Eli Lilly to further examine some side fractions that the staff had isolated during studies on the characterization of minor components in crystalline insulins (one of these components was already known to be proinsulin). The bovine, human, ovine, and porcine counterparts of aPP were discovered; furthermore, like aPP, all were 36 amino acids in length and all terminated with tyrosinamide.

Antisera against the avian and mammalian pancreatic polypeptides (PPs) along with the respective hormones were widely distributed to investigators by both laboratories in an effort to better understand the physiological role of this newly recognized pancreatic hormone. Immunohistochemistry studies revealed that PP is the product of a fourth type of islet cell, sometimes referred to in earlier literature as the F cell and now known as the PP cell. In mammals, in particular, the PP cell is located on the periphery of the islet; PP-rich islets are often regionally located in the duodenal portion of the pancreas, as shown in Fig. 1. The so-called uncinate process in the canine pancreas is an especially good source of PP cells. Early findings showed that blood levels of PP rose sharply following meals, especially after protein-rich meals. Insulin-induced hypoglycemia was also found to cause a dramatic rise in PP levels. Further investigations revealed that secretion of PP from the pancreas is mediated by vagal, cholinergic mechanisms, and, for this reason, PP responses have sometimes been used in clinical settings to assess vagal function.

Although PP is found primarily in the pancreas, the hormone is often included in discussions on gut hormones. Indeed, an intestinal peptide that is identical to porcine pancreatic polypeptide has been isolated from pig intestinal extracts. Early studies by Tsung-Min Lin (Eli Lilly) showed that bovine pancreatic polypeptide (bPP) administered to dogs did not affect blood glucose like insulin or glucagon but rather was a potent inhibitor of exocrine pancreatic secretion. Similar results in other laboratories led to speculation about using PP to treat pancreatitis. Meanwhile, aPP was studied extensively in chickens by researchers at the University of Kansas

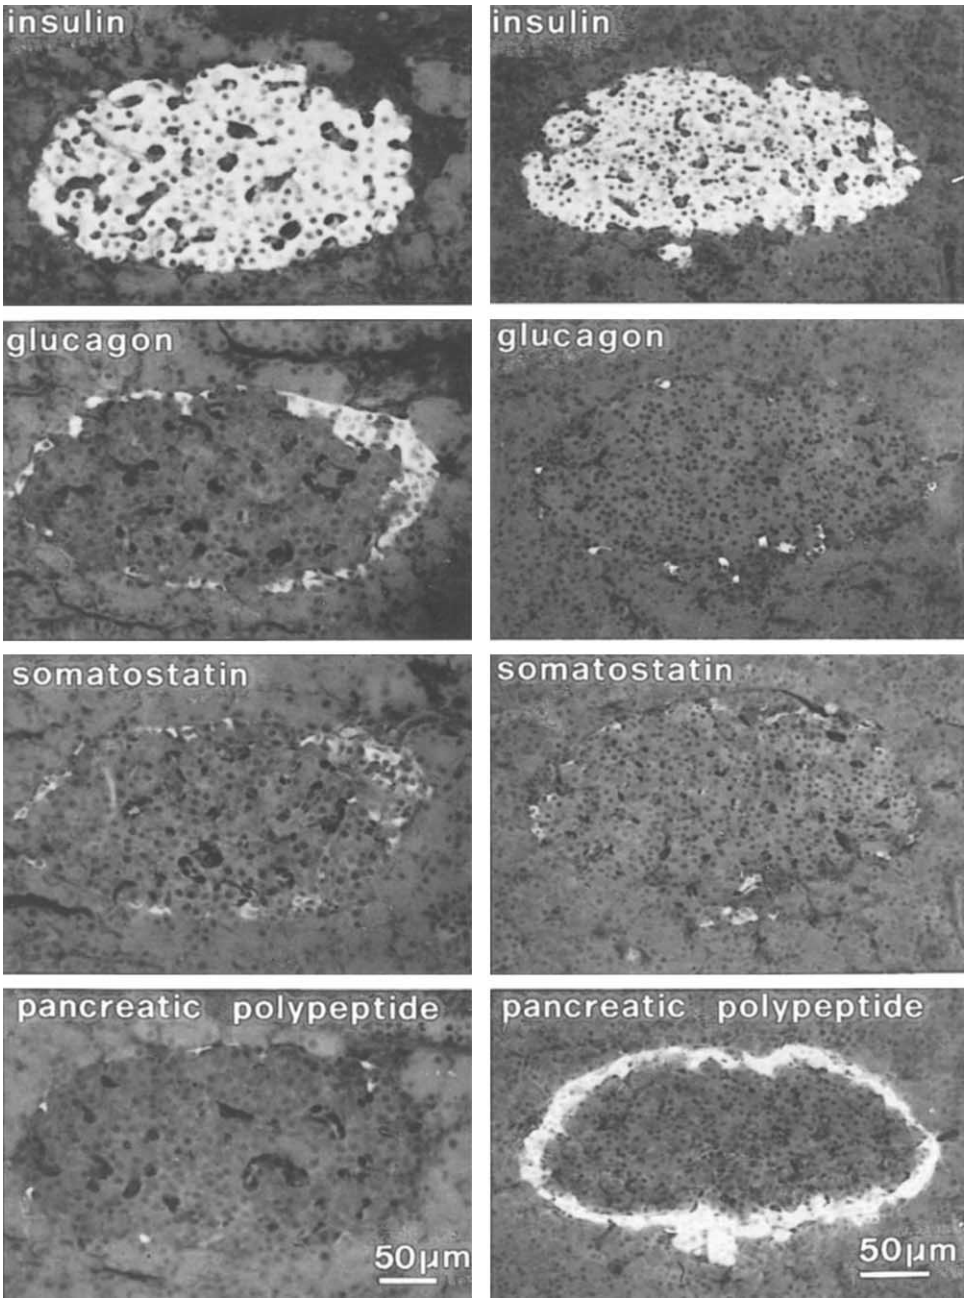

FIGURE 1 Series of four consecutive sections of a rat pancreatic islet stained, respectively, with anti-insulin, anti-glucagon, anti-somatostatin, and anti-pancreatic polypeptide antisera. The pattern shown in the panels on the left-hand side is characteristic of islets situated in the body and tail of the pancreas (the splenic region). The pattern shown in the panels on the right-hand side is characteristic of islets situated in the lower part of the head of the pancreas. The figure is courtesy of Lelio Orci. Reprinted from Hazelwood (1981), with permission.

in collaboration with Robert Hazelwood at the University of Houston. The avian hormone was found to be a powerful gastric stimulant in chickens.

Because PP was a recognized contaminant in therapeutic insulin preparations prior to the advent of highly purified animal insulins, the PP radioimmunoassay was utilized as a quality control assay on post-1980 purified bovine and porcine insulins. Prior to this, persons with diabetes who received the older traditional and nonchromatographed insulins were

sometimes found to have detectable PP antibodies. The assay has also been used in the diagnosis of pancreatic tumors.

II. CHEMISTRY

The primary structures of aPP and several of the mammalian PPs (bovine, human, porcine, ovine, and canine) were reported in the 1970s. This was followed by the discovery and characterization of two peptide hormones that shared considerable homology with the PPs, yet were distinctly different. Using a more elegant and systematic approach to new hormone discovery, Kazuhiko Tatemoto and Viktor Mutt examined intestinal and brain extracts for peptides possessing amidated carboxyl groups and discovered peptide YY (PYY) and neuropeptide Y (NPY) (see comparison of primary structures in Table 1). Based on X-ray crystal studies of aPP, the hairpin-like fold appears applicable to most if not all members of the so-called PP family, which is now referred to as the PP-fold family.

All of the PP-fold peptides are the result of a precursor–product relationship that has been clarified through the use of molecular biology techniques. Whereas the gene for human NPY is on chromosome 7, the genes for PYY and PP are in close proximity on chromosome 17q21.1, and it is thought that gene duplication of the human peptide YY gene (PYY) generated the pancreatic polypeptide gene (gene symbol PPY). The PPY gene product is a 95-residue protein in which hPP is flanked by a 29-residue signal peptide at the N-terminus and a 30-residue C-terminal extension as shown (hPP sequence in boldface type):

Human Prepropancreatic Polypeptide

^{1}MAAARLCLSLLLLSTCVALLLQPLLGAQGly ↓
APLEPVYPGDNATPEQMAQYA
ADLRRYINMLTRPRYGly ↓ Lys ↓ Arg ↓ HKED-TLAFSEWGSPHAAVPArg ↓ ELSPLDL^{95}

Single-letter notation is used for all amino acids except those at the processing sites, which are denoted by 3-letter abbreviations and underlined. Prepropancreatic hPP is matured to hPP through the action of several enzymatic steps. After biosynthesis, the preprohormone is translocated from the endoplasmic reticulum to the *trans*-Golgi network with the removal of the signal peptide by signal peptidase. The prohormone is sorted to a regulated transport site and a proprotein convertase cleaves at the COOH-terminus of the Lys-Arg sequence. Arginine and lysine are removed though the action of carboxypeptidase E. Finally, the remaining Gly becomes a substrate for peptidyl glycine α-amidating monooxygenase, resulting in the carboxyamidation of tyrosine at hPP position 36. An icosapeptide and a heptapeptide result from a trypsin-like cleavage at the single arginine residue in the C-terminal extension peptide.

The primary structures of more than 40 PPs have been reported. A partial list is shown in Table 1. Essentially, all are obvious homologues despite species diversity. X-ray crystal structure studies have been limited to aPP (chicken and turkey have identical sequences), although bPP crystals suitable for X-ray analysis have been grown. A solution

structure of bPP showed a fold remarkably similar to that of aPP. The other PP-family members are considered to fit the so-called PP-fold model, as depicted in Fig. 2. In this model, there is a polyproline type II helix involving residues 2-8, a β-turn, and an α-helical region from residues from ~15 to 32. It is interesting that the prolines at positions 2, 5, and 8 are part of a polyproline-type conformation and interdigitate with the hydrophobic side chains of the helix to form a stable fold.

III. BIOLOGY

The physiologic function(s) of PP is unknown. The hormone does not have readily apparent actions like the other islet hormones. In both birds and mammals, PP seems to mainly involve regulation of various gastrointestinal activities. For instance, aPP is a powerful gastric stimulant in chickens, and bPP has been found to have a wide spectrum of gastrointestinal actions in dogs, the most notable being the relaxation of the gall bladder and the inhibition of pancreatic exocrine secretion. Results from a few small-scale studies conducted in humans are generally in agreement with the results from the research on dogs. In other studies, PP was administered to 11 patients with chronic pancreatitis with a PP deficiency, as shown by lack of response to a test meal. Results indicated some improvement in abnormal glucose metabolism.

A recurring question concerns the role of PP in satiety. Most animal studies have been inconclusive on this matter. When PP was administered to children with the hyperphagia and obesity of the Prader-Willi syndrome (also shown to have a poor PP response to a protein meal), food intake was reduced slightly. In a 2002 review, Katsuura *et al*. cite recent animal studies showing that peripherally administered PP suppresses food intake and gastric emptying, whereas central administration of PP elicits food intake and gastric emptying. Some of the discrepancies in the literature on this subject may be the result of species specificity for PP. Today, virtually any species of PP can be prepared synthetically with relative ease, whereas older studies were conducted mainly with bovine or porcine PP administered to mice and rats (see Table 1 for PP structural differences). Also, recent transgenic technology is useful in addressing such questions. For example, PP transgenic mice that had overproduction of PP exhibited both decreased food intake and decreased gastric emptying.

The reason that central administration of PP stimulates feeding in several different species of experimental animals may be revealed in the future as PP receptors become better understood. Binding sites for PP have been found in several regions of the rat brain, including sites corresponding to brain regions regulating digestion and autonomic function. Binding sites for PP have been also found in the basolateral membranes of canine small intestinal mucosa as well as the ductus choledochus, duodenum, ileum, adrenal gland, and liver in the rat. In chickens, aPP binding was demonstrated in the spleen, liver, pancreas, gastrointestinal tract, and cerebellum.

Structure–activity studies with PP (bPP) using the canine intestinal mucosa model revealed the importance of the C-terminal tyrosinamide at position 36 for full receptor binding. Removal of this residue abolished receptor binding. Similarly, conversion of the native tyrosinamide to tyrosine also abolished receptor binding. When the carboxyl group was converted to a carboxymethyl form, the receptor binding was restored to 60% receptor recognition. Similar studies confirmed this work using a cloned hPP-preferring receptor, now known as the Y4 receptor, a G-protein-coupled receptor. These studies also demonstrated the importance of the N-terminal portion of PP for full receptor binding.

Future research on the PP-fold family of peptides, and on PP in particular, may reveal the true function of PP.

Glossary

neuropeptide Y A 36-residue neuropeptide hormone with considerable homology to pancreatic polypeptide.

pancreatic polypeptide A 36-residue peptide hormone found predominantly in the pancreas.

peptideYY A 36-residue peptide hormone found predominantly in the gut; it shows homology to both neuropeptide Y and pancreatic polypeptide.

PP cell One of four endocrine cell types in pancreatic islets where pancreatic polypeptide is located. Also known as the F cell.

PP-fold Refers to the U-shaped structural fold assumed by members of the pancreatic polypeptide (PP) family (PP, peptide YY, and neuropeptide Y).

Parathyroid Hormone

ROBERT A. NISSENSON

University of California, San Francisco and Veterans' Affairs Medical Center, San Francisco

Parathyroid hormone (PTH) is a polypeptide hormone that serves as a major regulator of plasma calcium. Increased circulating levels of PTH result in a compensating increase in ionized calcium in the blood by mobilizing calcium form the body's enormous calcium reserves in bone, by reducing renal calcium

loss, and by (indirectly) increasing the efficiency of absorption of dietary calcium by the intestine.

I. INTRODUCTION

Parathyroid hormone (PTH) is produced by tiny organs in the region adjacent to the thyroid glands in the neck. Humans generally have four functional parathyroid glands. In evolution, parathyroid glands first appear in terrestrial vertebrates, and their existence is closely linked to the need to maintain adequate levels of ionized calcium in blood. Ionized calcium in the extracellular fluid serves to support a range of essential physiological processes including proper neuromuscular function, exocrine and endocrine secretion, mineralization of bone, and cell growth and differentiation. With the evolution of amphibians, vertebrate life needed to adapt from seawater, which has a very high ambient level of calcium, to land, where calcium must be obtained from dietary sources. A complex endocrine homeostatic system evolved in terrestrial vertebrates in order to ensure maintenance of adequate levels of plasma calcium even under conditions of limited dietary calcium intake. The parathyroid glands play a pivotal role in this homeostatic system, since they are able to detect even small decreases in the level of ionized calcium in the blood and to respond by secreting PTH. This article presents an overview of the current understanding of the biochemistry, physiology, and mechanism of action of PTH as well as a discussion of the clinical diseases associated with abnormalities in this hormonal system.

II. BIOSYNTHESIS, SECRETION, AND CHEMISTRY OF PTH

As mentioned above, the maintenance of adequate levels of plasma ionized calcium (1.0–1.3 m*M*) is required for normal neuromuscular function, bone mineralization, and many other physiological processes. The parathyroid gland secretes PTH in response to very small decrements in ionized calcium in the blood in order to maintain the normocalcemic state. PTH accomplishes this by promoting bone resorption and releasing calcium from the skeletal reservoir, by inducing renal conservation of calcium and excretion of phosphate, and by indirectly enhancing intestinal calcium absorption by increasing the renal production of the active vitamin D metabolite $1,25(OH)_2$ vitamin D. The parathyroid gland functions in essence as a "calciostat," sensing the prevailing ionized calcium level in the blood and adjusting the secretion of PTH accordingly (Fig. 1). The relationship between ionized calcium and PTH secretion is a sigmoidal one, allowing significant changes in PTH secretion in response to very small changes in plasma ionized calcium.

In addition to providing acute regulation of PTH secretion, ionized calcium is a primary factor controlling chronic secretion of the hormone. Thus, sustained hypocalcemia promotes increased expression of the PTH gene and results in parathyroid hyperplasia. A common example of the latter is the marked parathyroid hyperplasia (secondary hyperparathyroidism) that frequently accompanies chronic renal failure. $1,25(OH)_2$ Vitamin D also serves as a negative regulator of PTH gene expression and parathyroid cell hyperplasia. In chronic renal failure, both hypocalcemia and reduced circulating levels of $1,25(OH)_2$ vitamin D presumably contribute to the progression of secondary hyperparathyroidism.

The plasma membrane of parathyroid cells contains high levels of a calcium-sensing receptor (CaR). Unlike intracellular calcium-binding proteins, which have an affinity for free calcium in the nanomolar range (consistent with intracellular levels of free calcium), the CaR binds calcium in the millimolar range. The receptor is a member of the G-protein-coupled receptor superfamily. It contains calcium-binding elements in its extracellular domain and signaling determinants in its cytoplasmic regions.

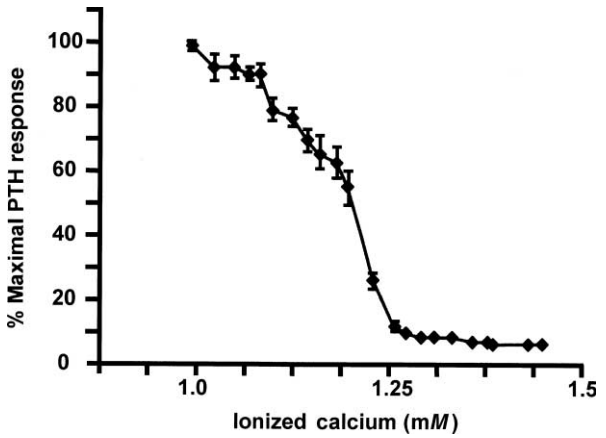

FIGURE 1 Relationship between plasma levels of ionized calcium and the release of PTH(1–84) in normal humans. Variations in plasma ionized calcium were achieved by the infusion of calcium or EDTA. Note the sigmoidal relationship, ensuring significant changes in PTH secretion with small variations in ionized calcium.

Calcium binding to the receptor triggers activation of G-proteins that are able to suppress the synthesis and secretion of PTH. When ionized calcium in the blood falls, there is less signaling by the CaRs on the parathyroid cell and PTH secretion consequently increases. The essential role of the CaR can best be seen in humans bearing loss-of-function mutations in the CaR gene. In the heterozygous state, such mutations result in familial hypocalciuric hypercalcemia, characterized by inappropriately high levels of PTH secretion in the face of hypercalcemia. These individuals are quantitatively resistant to the suppressive effect of calcium on PTH secretion due to the reduced number of parathyroid CaRs. In the homozygous state, patients display a severe increase in PTH secretion with life-threatening hypercalcemia (neonatal severe primary hyperparathyroidism).

The initial translation product of the PTH gene is prepro-PTH. The N-terminal pre-sequence (signal peptide) of the protein facilitates transport across the membrane of endoplasmic reticulum and into the initial biosynthetic pathway where the pre-sequence is proteolytically removed. The amino-terminal pro-sequence is also required for the proper transport of the protein during biosynthesis, and this 6-amino-acid peptide is cleaved in the Golgi by a furin-like peptidase. The resulting product is the mature, 84-amino-acid secretory product of the parathyroid gland, PTH.

Although the biologically active, mature form of PTH is an 84-amino-acid molecule, the major actions of PTH on bone and kidney can be reproduced with synthetic peptides containing as few as the 34 amino acids of the amino-terminus of the protein. The functional importance of the midregion and carboxyl-terminal region of PTH remains unclear. Truncation of merely a single amino acid from the amino-terminus of PTH results in a dramatic loss of biological activity. Thus, the amino-terminus of the peptide appears to have a central role in the ability of PTH to activate its receptor on target cells in kidney and bone. The 1–34 sequence of PTH has been highly conserved throughout the evolution of terrestrial vertebrates, consistent with the important biological function of this region of the molecule. Interestingly, there is a second gene product that shares sequence similarity with the 1–34 region of PTH and is thus able to activate the PTH receptor. The factor is termed PTH-related protein (PTHrP), and its physiological role is to exert local control over the development and function of a number of tissues. For reasons that are unclear, PTHrP is expressed at very high levels by several types of cancers. With some cancers, circulating levels of PTHrP become high enough to cause excessive bone resorption and increased blood calcium due to the actions of circulating PTHrP on PTH receptors.

Early studies demonstrated that PTH circulates in multiple forms that can be distinguished by radioimmunoassays specific for different regions of the PTH molecule. PTH(1–84) is subject to metabolism within the parathyroid gland, resulting in the secretion of PTH fragments as well as the intact molecule. In addition, PTH(1–84) is metabolized in peripheral tissues. Midregion and carboxyl-terminal fragments of PTH have a much longer half-life in the circulation than does PTH(1–84). As a result, midregion and carboxyl-terminal fragments of PTH circulate at much higher concentrations than does intact PTH(1–84). Rapid plasma clearance of PTH is due primarily to hepatic metabolism, with a lesser contribution by the kidneys. Peripheral metabolism generates midregion and carboxyl-terminal fragments of PTH that resemble those secreted by the parathyroid gland. Midregion and carboxyl-terminal PTH fragments are cleared by renal excretion, and thus circulating levels of these fragments are highly dependent on renal function. Extremely high levels of PTH detected with antibodies against the midregion and carboxyl-terminal region of the hormone in many patients with end-stage renal disease thus reflect a combination of secondary hyperparathyroidism and reduced renal clearance of PTH fragments.

Midregion and carboxyl-terminal PTH fragments lack the amino-terminal 1–34 sequence of the hormone required for binding to PTH/PTHrP receptors and producing the classical effects of PTH on kidney and bone. Metabolism of PTH could produce biologically active, amino-terminal fragments of PTH, but there is little evidence for the presence of significant levels of amino-terminal PTH fragments in the circulation or for significant secretion of such fragments by the parathyroid gland. Presumably, both the parathyroid gland and the peripheral organs contain enzymes that degrade amino-terminal fragments of PTH. This ensures that circulating levels of biologically active PTH are derived exclusively from glandular secretion of PTH(1–84). A few studies have demonstrated potential biological effects of midregion or carboxyl-terminal fragments of PTH, and there is also evidence for the existence of membrane receptors for these fragments. However, the biological role of PTH fragments remains unclear.

III. PHYSIOLOGICAL ACTIONS OF PTH IN BONE

The major physiological role of PTH is to mobilize calcium from bone in order to maintain an adequate level of plasma ionized calcium. In times of dietary calcium deficiency, blood levels of calcium fall slightly and this serves to increase the secretion of PTH by the parathyroid gland. PTH acts directly on bone to increase the number and activity of osteoclasts—the cells that promote bone resorption. During osteoclastic bone resorption, calcium-rich hydroxyapatite bone mineral is converted to soluble calcium, which is transported into the general extracellular space to support the level of blood calcium. PTH also increases the efficiency of transport of calcium from bone to blood.

PTH receptors have been localized to bone-forming osteoblasts and their precursors, but it is not clear whether osteoclasts possess PTH receptors. Indeed, PTH is not able to activate isolated osteoclasts *in vitro* unless osteoblast-like cells are also present. These findings suggest that PTH may produce its actions on osteoclasts indirectly, perhaps through direct interaction with cells of the osteoblast lineage. Indeed, PTH induces an increase in the expression of a molecule termed RANK ligand (RANKL) on the surface of osteoblasts (Fig. 2). Osteoclasts and their precursors (myeloid lineage cells) express the receptor for RANKL, a molecule termed RANK. When PTH-stimulated osteoblasts come into contact with osteoclasts or their precursors, RANKL interacts with RANK, resulting in signaling events that produce increased formation and activity of osteoclasts. Osteoblasts also produce an inhibitor of RANKL (termed osteoprotogerin or OPG). PTH inhibits the production of OPG, an effect that also promotes increased osteoclast formation and activity.

Although stimulation of bone resorption is the major physiological response of the skeleton to PTH, pharmacological experiments have shown that PTH is also capable of increasing bone formation. Thus, administration of PTH intermittently to animals or humans results in a marked anabolic response of the skeleton. High levels of PTH are known to produce an increase in the number of osteoblasts, which results in part from the coupling between increased osteoclastic resorption and new bone formation. However, intermittent treatment with low doses of PTH produces a direct positive effect on bone formation that is independent of preceding bone resorption. The cellular basis for this action of PTH is not fully understood but could result from an action of PTH to increase the number and/or functional activity of bone-forming osteoblasts. There is currently great interest in exploiting this action of PTH for the purpose of treating individuals with low-bone-mass diseases such as osteoporosis.

IV. PHYSIOLOGICAL ACTIONS OF PTH IN KIDNEY

PTH produces a series of renal actions that help to ensure that calcium mobilized from bone contributes optimally for the maintenance of plasma ionized calcium levels. The renal actions of PTH include inhibition of renal phosphate reabsorption, stimulation of renal calcium reabsorption, and increased production of $1,25(OH)_2$ vitamin D. The ability of PTH to inhibit renal phosphate reabsorption has been known for many years, providing the basis for

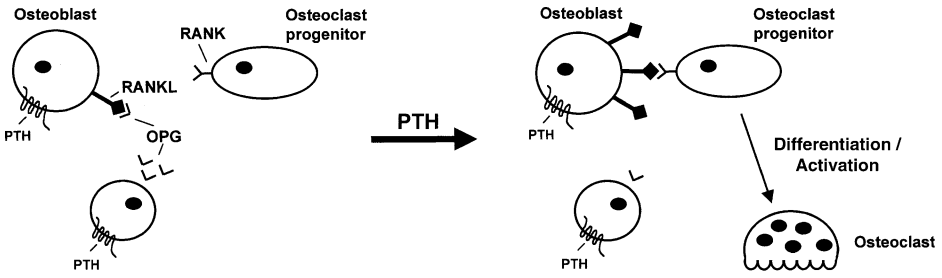

FIGURE 2 Regulation of osteoclast differentiation and activation by PTH. Binding of PTH by receptors on osteoblasts results in increased expression of osteoprotegerin ligand (RANKL) on the cell surface. Activation of PTH receptor can also reduce the secretion of the RANKL inhibitor osteoprotegerin (OPG), which is produced by cells in the bone microenvironment. These effects of PTH promote the action of RANKL on its receptor (RANK) on the surface of osteoclast precursors and mature osteoclasts. RANK signaling, together with the action of macrophage colony-stimulating factor, stimulates the differentiation of osteoclast precursors and promotes the activation of mature osteoclasts.

a clinical test of renal responsiveness to the hormone. Patients with primary hyperparathyroidism display hypophosphatemia and decreased renal tubular reabsorption of phosphate, whereas hypoparathyroid patients are hyperphosphatemic and have increased phosphate reabsorption. Phosphate forms a complex with free calcium in blood. Thus, for a given level of serum calcium, ionized calcium will be reduced as serum phosphate increases. Under conditions of relative hypocalcemia (e.g., during chronic dietary calcium deficiency), PTH secretion is increased, resulting in increased bone resorption. Both calcium and phosphate are released from hydroxyapatite during the process of bone resorption. By promoting renal excretion of phosphate, PTH facilitates a rise in ionized and total plasma calcium. Recently, the molecular basis for PTH-induced inhibition of renal phosphate reabsorption was clarified. PTH inhibits the expression of a specific (type IIa) sodium–phosphate co-transporter in the brush border of proximal renal tubular cells. This results in a reduced V_{max} for phosphate transport and therefore lower efficiency of proximal phosphate reabsorption.

PTH also acts to increase renal calcium reabsorption, thus ensuring that only small amounts of calcium released during PTH-induced bone resorption are lost via renal excretion. The major sites for this effect of PTH are in the distal convoluted tubule and the thick ascending limb of Henle's loop. Recent evidence indicates that distal renal tubular calcium reabsorption is an active process that requires calcium influx through dihydropyridine-sensitive calcium channels located in the apical plasma membrane. Drugs that inhibit these channels are effective in blocking PTH-induced renal calcium reabsorption. Unlike voltage-sensitive calcium channels in excitable tissues, PTH-responsive calcium channels in the distal nephron are activated by membrane hyperpolarization. PTH appears to open calcium channels by inducing hyperpolarization of the apical plasma membrane. Calcium entering the distal renal tubular cell in this manner is transported into the extracellular compartment via a sodium–calcium exchanger present on the basolateral plasma membrane.

PTH promotes intestinal calcium reabsorption indirectly, through an action to increase circulating levels of $1,25(OH)_2$ vitamin D. This vitamin D metabolite acts directly on intestinal epithelial cells to increase the efficiency of calcium (and phosphate) absorption. Primary hyperparathyroidism is commonly associated with increased circulating levels of $1,25(OH)_2$ vitamin D, whereas reduced levels of this metabolite are present in hypoparathyroidism. PTH produces this effect by increasing the rate of production of $1,25(OH)_2$ vitamin D through activation of the 25(OH) vitamin D-1-hydroxylase enzyme located in the proximal renal tubule. Studies *in vivo* as well as in cultured renal cell lines indicate that PTH increases the expression of the 25(OH) vitamin D-1-hydroxylase gene through a transcriptional mechanism.

The actions of PTH to promote increased bone resorption, reduced calcium excretion, and (indirectly) increased intestinal calcium absorption all help to maintain adequate levels of plasma calcium even under conditions of dietary calcium deficiency.

V. MECHANISM OF ACTION OF PTH

PTH action is initiated by the binding of the hormone to a G-protein-coupled receptor on the surface of target cells in kidney and bone (Fig. 3). The major G-protein activated by the PTH receptor is G_s, the G-protein coupled to activation of adenylyl cyclase and production of cyclic AMP. Indeed, shortly after the discovery of the cyclic AMP signaling pathway, it was found that PTH is capable of increasing the levels of cyclic AMP in target cells through activation of the adenylyl cyclase. Cyclic AMP is a second messenger in the cellular action of a wide variety of hormones and other extracellular regulatory molecules. It activates cyclic AMP-dependent protein kinase A (PKA), which in turns phosphorylates and thereby regulates key proteins that participate in physiological responses. Very little is known about the identity of substrates of PKA that are phosphorylated in response to PTH receptor activation. These presumably include transcription factors, ion channels, transporters, and enzymes involved in cellular metabolism.

The important role of the cyclic AMP pathway in mediating PTH action is underscored by the ability of cyclic AMP analogues (or drugs that directly activate adenylyl cyclase such as forskolin) to reproduce many of the biological effects of PTH. For example, cyclic AMP analogues and forskolin are capable of reducing the expression of the renal type IIa sodium–phosphate co-transporter. The also promote an increase in the expression of RANKL in osteoblasts. Furthermore, genetic deficiency in the α-subunit of G_s (as seen in the human disease pseudohypoparathyrodism type Ia) results in renal and skeletal resistance to PTH action.

PTH receptors also couple to the G-protein G_q, which activates phospholipase C, an enzyme that

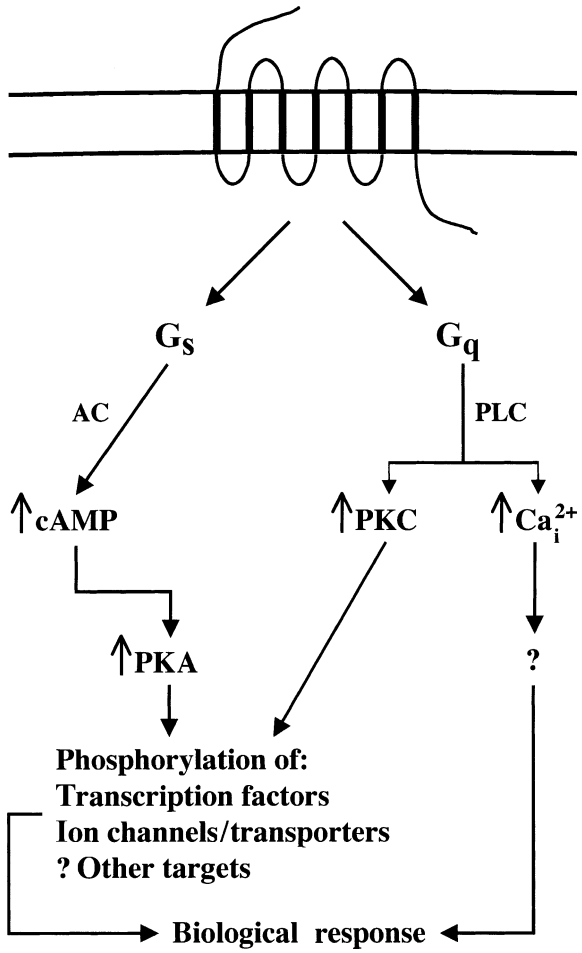

FIGURE 3 Signal transduction by the PTH/PTHrP receptor. PTH and PTHrP bind to determinants in the extracellular domain and in the body of the receptor. This leads to conformational changes in the transmembrane helices and consequent structural changes in the cytoplasmic domain. The latter permit productive interactions between the receptor and the G-proteins G_s and G_q, activating the adenylyl cyclase (AC) and phospholipase C (PLC) signaling pathways, respectively. These pathways are thought to cooperate in determining the cellular response to the receptor activation. Most available evidence supports a primary role of the cyclic AMP/protein kinase A (PKA) pathway in mediating the biological effects of PTH/PTHrP receptor activation, with the PLC pathway playing a modulatory role. PKC, protein kinase C.

hydrolyzes the plasma membrane phospholipid phosphatidylinositol 4,5-bisphosphate to produce diacylglycerol (DAG) and soluble inositol 1,4,5-trisphosphate (IP_3). DAG and IP_3 function as second messengers—the former by activating protein kinase C and the latter by binding to and opening calcium channels on the membrane of the endoplasmic reticulum, thereby increasing cytosolic free calcium. There is currently great interest in understanding how this pathway contributes to the physiological effects of PTH in bone and kidney.

There has been great interest in understanding how the structure of the PTH receptor contributes to ligand binding and signal transduction. The PTH receptor is a member of the large superfamily of G-protein-coupled receptors. All members are intrinsic plasma membrane proteins with seven membrane-spanning segments that line a central cavity. Ligands (PTH and PTHrP) bind to the large N-terminal extracellular domain of the receptor as well as to the extracellular loops. This facilitates the interaction of the ligand with the transmembrane cavity of the receptor, producing a conformational change in the receptor. In the ligand-bound state, the receptor interacts with and activates its cognate G-proteins on the cytoplasmic surface of the plasma membrane. Many features of this activation mechanism are shared by other (so-called class II) G-protein-coupled receptors that are related to the PTH receptor (e.g., receptors for glucagon, calcitonin, and secretin).

As with most G-protein-coupled receptors, signal transduction by the PTH receptor is under strict regulatory control. After an initial burst of signaling, agonist-occupied PTH receptors lose their signaling capacity. This desensitization results from the phosphorylation of the active PTH receptor by a G-protein-coupled receptor kinase. This phosphorylation event promotes the interaction of the receptor with a cytoplasmic protein called arrestin. When arrestin binds to the PTH receptor, interaction with G-proteins is sterically inhibited and thus signaling is prevented. The desensitized PTH receptor is internalized via clathrin-coated pits and is recycled back to the plasma membrane. It is likely that dephosphorylation of the PTH receptor occurs within endocytic vesicles, allowing resensitization of the receptor prior to its reinsertion in the plasma membrane.

VI. DISEASE STATES

The most common diseases of the PTH endocrine system result from excessive production of ligands for the PTH receptor. Primary hyperparathyroidism most commonly results from a benign tumor affecting one of the four parathyroid glands. Occasionally, all four glands are enlarged. Parathyroid cancer can also occur but is extremely rare. Excessive secretion of PTH results in increased bone resorption, increased renal reabsorption of calcium, and increased production of $1,25(OH)_2$ vitamin D (and thus increased

intestinal calcium absorption). These combined actions result in hypercalcemia and (over time) bone loss due to hyperresorption. A similar syndrome occurs in patients with malignant (nonparathyroid) tumors that secrete large amounts of PTHrP. Optimal treatment for these disorders is the removal of the parathyroid tumor or malignancy responsible for producing excessive PTH or PTHrP, respectively. When surgical treatment is not possible, the hypercalcemia can be treated by the administration of drugs that inhibit bone resorption such as bisphosphonate compounds.

Secondary hyperparathyroidism can occur as a result of conditions that produce chronic hypocalcemia such as chronic renal failure. Hypocalcemia has both a direct stimulatory effect on PTH secretion and an indirect effect by promoting the increased proliferation of parathyroid cells. Over time, chronic hypocalcemia produces a massive increase in the size of the parathyroid glands due to hyperplasia. This results in very high circulating levels of PTH and excessive bone resorption, often resulting in bone pain and fragility. Treatment of this disorder is targeted toward restoring the plasma calcium level and thereby removing the stimulus for further proliferation of parathyroid cells. $1,25(OH)_2$ vitamin D is often used therapeutically, since it promotes an increase in intestinal absorption of calcium and thus helps to suppress PTH secretion and parathyroid cell growth.

Although much less common, genetic mutations in components of the PTH receptor signaling pathway are also known to be associated with human diseases. Certain mutations in the PTH receptor are known to result in constitutive (i.e., hormone-independent) receptor signaling. Individuals harboring such a mutation display evidence of PTH receptor hyperfunction, including hypercalcemia and increased bone resorption. They also display premature cartilage differentiation reflecting an exaggeration in the normal physiological action of PTHrP (acting through the PTH receptor) on chondrogenesis. This disorder is known as Jansen's metaphyseal chondrodysplasia. Complete loss of the PTH receptor results in Blomstrand's lethal chondrodysplasia due to the generalized failure in the proper development of endochondral bones. Finally, partial loss of the function of the G-protein (G_s) that couples receptors to adenylyl cyclase results in a disorder known as pseudohypoparathyroidism type Ia. These individuals show partial resistance to a number of hormones that utilize the G_s/adenylyl cyclase signaling pathway. Resistance to PTH action is often particularly severe due to genetic imprinting of the $G_{s\alpha}$ gene in PTH-responsive tissue. These individuals also have a developmental phenotype (Albright's hereditary osteodystrophy) as a consequence of a deficiency in G_s signaling during embryogenesis and early development.

Glossary

adenylyl cyclase The enzyme responsible for converting ATP to the intracellular second messenger cyclic AMP.

bone mineralization The process by which calcium and phosphate are deposited onto the extracellular matrix of bone, resulting in the formation of hydroxyapatite.

G-proteins A family of peripheral membrane proteins that couple membrane receptors to specific effector molecules such as adenylyl cyclase.

hyperplasia Increase in the size of an organ due to excessive proliferation of the constituent cells.

osteoblasts Cells responsible for promoting bone formation by secreting bone matrix proteins and by facilitating bone mineralization.

osteoclasts Multinucleated cells that attach to the mineralized surface of bone and secrete acid and proteases, resulting in the breakdown of bone (bone resorption).

osteoporosis A disorder of bone characterized by decreased bone mass and decreased bone strength.

Parathyroid Hormone-Related Protein (PTHrP)

JOSHUA N. VAN HOUTEN AND JOHN J. WYSOLMERSKI
Yale University School of Medicine

Parathyroid hormone-related protein (PTHrP) is a peptide with the ability to act as a systemic hormone or a local growth factor. It is involved in a wide variety of seemingly disparate functions in development and physiology and it is a key contributor to the pathophysiology of human cancer. In this article, the structures of PTHrP and its gene are characterized and the roles that PTHrP plays in cancer, embryonic development, and reproduction are examined.

I. INTRODUCTION

The isolation of parathyroid hormone-related protein (PTHrP) was the fruit of over 30 years of efforts aimed at understanding the mechanisms underlying the humoral form of hypercalcemia in patients with malignancy. In the 1940s, Fuller Albright predicted that the cause of hypercalcemia in these patients would be a tumor-derived factor related to the calciotropic peptide, parathyroid hormone (PTH). This prediction proved correct when, in the 1980s, PTHrP was isolated concurrently in three laboratories. By the 1990s, the human, mouse, rat, and chicken PTHrP genes had been cloned, and since then the PTHrP gene has also been isolated from a teleost (*Fugu rubripes*) and the sea bream, *Sparus aurata*. Over the past decade, our understanding of the biology of PTHrP has exploded through the study of a variety of transgenic and knockout mouse models. This article will first summarize key aspects of the structure of PTHrP and its gene. Then PTHrP's role in cancer will be discussed. Finally, our new understanding of the biology and comparative physiology of this remarkably versatile protein will be examined.

II. THE PTHrP GENE

As its name suggests, PTHrP is related to parathyroid hormone. The modern versions of these two genes arose from a common ancestor as the result of a tetraploidization event some 200 to 300 million years ago. Several lines of evidence now suggest that, in fact, the PTH gene was derived from an ancestral PTHrP gene, perhaps in response to the new demands of calcium metabolism related to the development of a bony skeleton in fish or to the adaptation of amphibians to a terrestrial environment. Although the two genes have diverged considerably, they share common locations on paired chromosomes, a common genomic organization, and amino-terminal sequence homology, all of which point to their common ancestry. For practical purposes, the last feature is the most important shared trait, for the similar amino-termini of both peptides allows them to bind to and signal through a shared PTH/PTHrP receptor. This unusual arrangement is responsible for the clinical syndrome that led to the discovery of PTHrP (see below).

The human PTHrP gene is located on the short arm of chromosome 12 and is flanked by the genes for lactate dehydrogenase B and the K-ras proto-oncogene. It spans more than 15 kilobases and contains eight exons. It has three different promoters, one that is GC-rich and two that contain typical TATA sequences. There are four noncoding exons at the 5′-end of the gene (Fig. 1) and there is considerable alternative splicing to generate a series of mRNAs with different 5′-ends. In addition, there is alternative splicing at the 3′-end of the gene that gives rise to three distinct classes of transcripts encoding peptides of different lengths [139, 141, or 173 amino acids (aa)]. Thus, there are a variety of different mRNAs for PTHrP that differ in both their 5′- and 3′-ends. However, the physiological significance of these different mRNA species remains obscure. This complexity is a relatively recent event in the evolution of the gene, as the rodent genes are much simpler and contain only one promoter and use only one 3′-terminus. Transcriptional control of the PTHrP gene will not be discussed in this article. Interested readers are referred to recent comprehensive reviews.

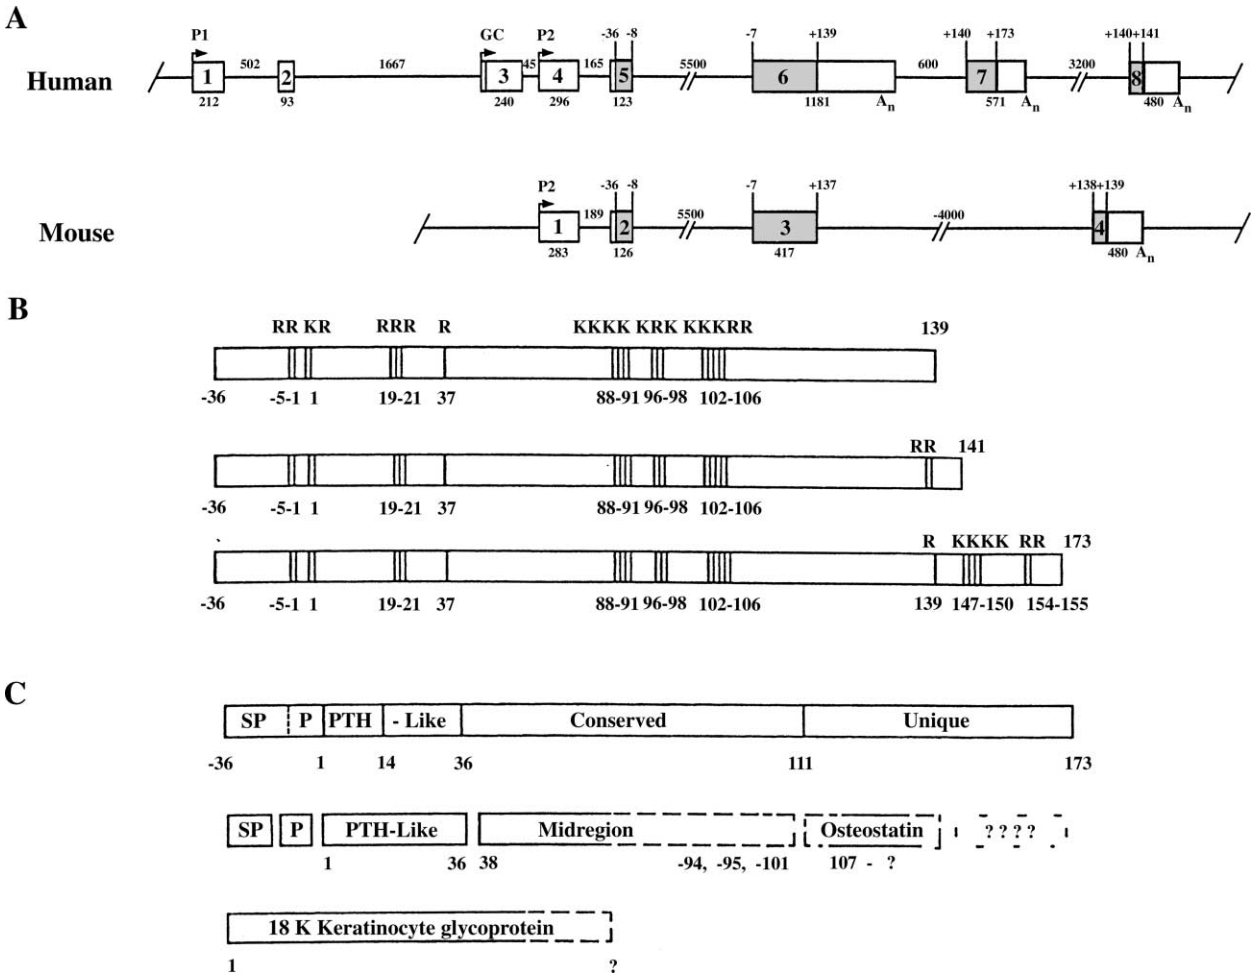

FIGURE 1 Schematic of the human and mouse PTHrP genes. (A) Numbered boxes represent exons, with distances indicated in base pairs. Arrows denote promoters, and amino acid residues are numbered relative to the start of the mature peptide. Polyadenylation sites are marked A_n. Potential multibasic cleavage sites in the three human PTHrP isoforms. (B) Arginine (R) and lysine (K) residues are marked. Functional domains and sequence homologies in PTHrP. (C) Intracellular posttranslational processing removes the signal peptide (SP) and the propeptide (P). The first 36 amino acids constitute the N-terminal PTH-like peptide, reflecting the strong sequence similarity in amino acids 1–13 between PTH and PTHrP. The region between residues 36 and 111 is evolutionarily conserved, whereas the least conserved region of the peptide is the C-terminus (amino acids 111 to 139 or 141). The extreme C-terminus, residues beyond 141, has been found only in humans. Secreted products of PTHrP include the amino-terminal PTH-like fragment (1–36), the glycosylated amino-terminal fragment found in keratinocytes, and midregion peptides. C-terminal species remain ill-defined.

III. PTHrP STRUCTURE AND POSTTRANSLATIONAL PROCESSING

The primary transcript of PTHrP represents a polyprotein analogous to the primary transcript of the proopiomelanocortin gene. Therefore, most cells expressing the PTHrP gene actually secrete several different PTHrP peptides. The primary transcript has a typical prepro sequence encompassing amino acid residues −36 to −1, which confers the ability for secretion from the cell. The mature peptide is very well conserved across species with residues 1–111 being 98% homologous in chickens compared with humans. This area has several stretches of basic amino acids that allow proteolyic cleavage of the primary transcript by prohormone convertases within the Golgi and secretory granules to generate a series of peptides encompassing the amino-terminus, the midregion, and the carboxy-terminus of PTHrP.

The amino-terminus of PTHrP is the portion that is homologous to PTH. Of the first 13 aa of the two proteins, 8 are identical and 3 represent conservative changes. Furthermore, there is considerable similarity in the predicted conformation of the two peptides through residue 34. There are several species containing this amino-terminal region that appear to be secreted by various cells. Most cells produce PTHrP 1–36, which is equipotent with PTH 1–34 at binding and activating the type I PTH/PTHrP receptor (PTH1R). In addition, an "intact" PTHrP molecule that includes at least the first 74 aa circulates in patients with HHM. Finally, keratinocytes have been reported to make a glycosylated amino-terminal version of PTHrP with a molecular weight of 18 kDa.

Various cells have also been shown to produce midregion peptides that begin at Ala-38 and stretch to amino acids 94, 95, or 101. These peptides have been shown to circulate and their secretion appears to be regulated. This portion of PTHrP appears to function to facilitate placental calcium transport from mother to fetus. However, the receptor for this portion of PTHrP has not been identified. The midregion of the molecule also contains nuclear localization sequences (NLSs) and there is a growing body of literature that suggests that nuclear-targeted PTHrP may have effects on cellular proliferation, differentiation, and apoptosis. At this point, it is unclear whether the midregion portions that are secreted versus targeted to the nucleus are the same or represent distinct peptides, as there are potential processing sites between Ala-38 and the NLS between amino acids 87 and 106. Interestingly, in this regard, recent data have suggested that initiation of PTHrP translation may occur downstream of the signal peptide to generate a nonsecreted form of PTHrP. Other evidence suggests that longer peptides containing both the amino-terminal and the NLS sequences may be imported to the nucleus after binding to cell surface PTH1R. Obviously, there is much information concerning this portion of the molecule that remains to be elucidated.

Finally, carboxy-terminal portions of PTHrP also appear to circulate and have been detected in the urine of normal patients and in the serum of patients with renal failure. Peptides encompassing residues 107–111 and 107–139 have been shown to inhibit bone resorption *in vitro* and this portion of the molecule has been dubbed "osteostatin." However, not all groups have demonstrated this effect and the biological significance of carboxy-terminal PTHrP remains undefined.

IV. PTHrP RECEPTORS

As noted previously, the amino-terminal portion of PTHrP can use the type I PTH/PTHrP receptor (PTH1R) for signal transduction. This receptor does not discriminate between PTHrP and PTH, and both peptides are equipotent at binding and activating signaling. The PTH1R is a seven-transmembrane-spanning, G-protein-coupled receptor that signals via the cyclic AMP (cAMP)/protein kinase A and protein kinase C/calcium transient pathways. The ability of PTH and PTHrP to use the same receptor is the reason that patients with cancers that secrete PTHrP into the circulation develop hypercalcemia. Under physiologic conditions, PTHrP is excluded from the circulation and does not interact with PTH1Rs in bone and kidney meant for PTH. PTHrP target tissues appear to have a lower receptor density and rely on high local concentrations of PTHrP for activation of signaling. The exceptions to this rule may be in the setting of tooth eruption and during lactation. In these cases, PTHrP appears to be involved in the physiologic regulation of bone resorption and thus its action mimics that of PTH. These functions may represent the evolutionary pressure that has preserved the ability of both peptides to use the same receptor. With the exception of placental calcium transport, all the currently well-defined biological effects of PTHrP are mediated through the PTH1R. There are undoubtedly other receptors for the non-amino-terminal portions of PTHrP. However, they have not yet been characterized.

V. PTHrP IN CANCER

A. Humoral Hypercalcemia of Malignancy

Humoral hypercalcemia of malignancy (HHM) is a paraneoplastic syndrome defined by elevated calcium levels in patients with malignancy, but no bone metastases. It is the most common metabolic complication of cancer and results from increased bone resorption and decreased calcium excretion by the kidneys. As noted above, PTHrP was isolated from tumors causing this syndrome and several lines of evidence have established that tumor-derived PTHrP is the cause of the perturbations in calcium metabolism in this syndrome. For example, removal of the tumor or administration of neutralizing antibodies against PTHrP have been shown to reverse the syndrome, whereas infusion of PTHrP into rodents or humans reproduces the syndrome. Since PTH and PTHrP share a common receptor, this syndrome is the result of tumor-derived PTHrP acting on the population of PTH1R in bone and kidney normally reserved for the actions of PTH. Therefore, in HHM the physiological autocrine/paracrine signaling molecule, PTHrP, becomes an endocrine hormone and mimics the pathologic effects of PTH as seen in hyperparathyroidism. Although many types of solid tumors and hematologic malignancies are associated with HHM, squamous cell carcinomas and urothelial malignancies are the most frequent cause.

B. Bone Metastasis

In addition to its role in HHM, PTHrP appears to be important in the development of bone metastases in breast cancer. Several studies have found that, in breast cancer patients, PTHrP is expressed more frequently in bone metastases than in metastases to other sites. Initially, it was thought that PTHrP might be involved in targeting cancer cells to bone and, therefore, that PTHrP expression by a primary tumor might predict the occurrence of bone metastases. However, a recent study of transgenic overexpression of PTHrP in a rodent model of breast cancer did not support this idea. Furthermore, in the only large prospective study performed to date, PTHrP expression within the primary breast tumor did not correlate with the presence of bone metastases. However, there is ample experimental evidence demonstrating that manipulation of PTHrP expression within breast cancer cells can alter the development of osteolytic bone lesions. Currently, it is thought that although PTHrP production in the primary tumor may not predict bone metastases, the ability of breast cancer cells to up-regulate PTHrP production in the bone microenvironment is critical. Guise and colleagues have suggested that tumor-derived PTHrP production stimulates bone resorption, which liberates growth factors from the bone matrix that stimulate tumor cell proliferation, further PTHrP production, and increase bone resorption. It appears that bone matrix-derived transforming growth factor-β (TGF-β) is particularly important in up-regulating PTHrP production by breast cancer cells in bone. If this construct proves to be correct, the TGF-β/PTHrP/PTH1R loop may become an attractive therapeutic target for the treatment or prevention of bone metastases in breast cancer.

C. Proliferation

Another proposed role for PTHrP in tumorigenesis is the regulation of proliferation. PTHrP has been reported to have variable effects on the proliferation and/or differentiation of a variety of cultured cell lines. These effects have generally been modest and there is no existing evidence to suggest that PTHrP has a dominant role in regulating the proliferation of cancer cells. However, it was recently found that transgenic overexpression of PTHrP in the mammary gland resulted in a shorter latency to tumor development and a higher overall incidence of mammary tumor development in mice exposed to a chemical carcinogen. Interestingly, recent experiments have also suggested that the intracellular trafficking of PTHrP may determine whether it regulates the growth of breast cancer cells negatively or positively. For example, overexpression of PTHrP in the MCF-7 breast cancer cell line was reported to be mitogenic, whereas adding PTHrP to the extracellular medium inhibited growth. Another group of investigators has reported that neutralization of the endogenous PTHrP produced by MCF-7 cells led to an acceleration of their growth rate in culture. More data, especially from experiments *in vivo*, will be needed to determine whether PTHrP participates in the regulation of breast tumor growth in a meaningful manner.

VI. PTHrP IN EMBRYONIC DEVELOPMENT

PTHrP is expressed early in development in all three embryonic cell lineages as well as the amnion and the trophoblast. In fact, it has been reported that PTHrP and the PTH1R are the earliest hormone/receptor pair to appear, being first detectable at the morula stage. During the later stages of development, the distribution of PTHrP expression is even broader

than in the adult, suggesting its importance as a developmental regulatory molecule. Functionally, in early development, PTHrP appears to participate in the regulation of the differentiation of parietal endoderm from primitive endoderm. During organogenesis, paracrine signaling between PTHrP and the PTH1R appears to be involved in inductive tissue interactions in several organs. The role that PTHrP plays in skeletal development and mammary gland development is discussed below because these systems have been well characterized. However, PTHrP is also necessary for tooth eruption and may be important in the development of the skin, the lung, the heart, and other organs.

A. Skeletal Development

Genetic ablation of PTHrP in mice causes perinatal lethality and short-limbed dwarfism. Upon histological examination, PTHrP null mice exhibit a form of chondrodysplasia in which chondrocytes within the growth plates of endochondral bones differentiate prematurely, leading to early mineralization of endochondral bones and premature loss of linear growth capacity. In contrast, PTHrP overexpression targeted to chondrocytes with a collagen II promoter slows chondrocyte differentiation and inhibits apoptosis of hypertrophic chondrocytes, leading to a delay in the formation of "mature" bone. Thus, the overall effect of PTHrP on endochondral bone formation is to inhibit the program of chondrocyte differentiation and to preserve the proliferative (growth) capacity of the growth plate. These effects are mediated through the PTH1R, since PPR1 null mice phenocopy PTHrP null mice. In humans, Blomstrand's chondrodysplasia, a short-limbed dwarfism similar to that seen in PTHrP and PTH1R null mice, is caused by loss-of-function mutations in the PTH1R gene. Another human disorder, Jansen's metaphyseal chondrodysplasia, results from activating mutations in the PTH1R gene and is similar to the phenotype observed in the collagen II–PTHrP transgenic mice.

The regulation of chondrocyte proliferation and differentiation within the growth plate is complicated and relies on the concerted actions of several families of growth factors and their receptors. It is now known that PTHrP acts together with at least one other of these growth factors, Indian hedgehog (IHH), in a feedback loop to regulate the differentiation of chondrocytes (Fig. 2). PTHrP is expressed in the periarticular region, and the PTH1R is expressed in prehypertrophic chondrocytes. IHH is expressed in the transition zone where proliferating chondrocytes become prehypertrophic chondrocytes. Like PTHrP, IHH activity slows the differentiation of chondrocytes in bone explants from wild-type mice, but not in explants from PTH1R null mice. Therefore, IHH from prehypertrophic chondrocytes is thought to act on the perichondrium (possibly through smoothened, patched, and/or hedgehog-interacting protein), to stimulate PTHrP production in the periarticular region, which, in turn, inhibits further procession of the chondrocytes down the differentiation pathway toward hypertrophy and apoptosis.

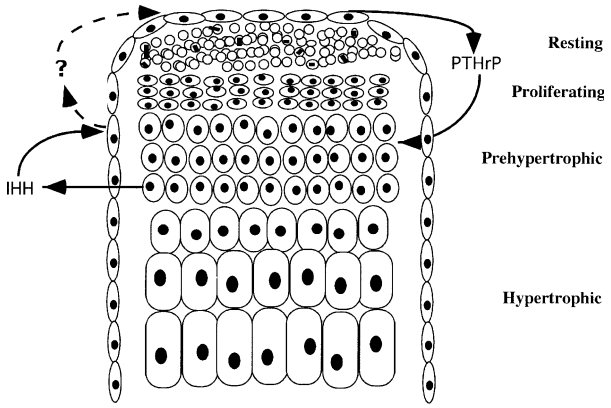

FIGURE 2 Schematic representation of the proposed interactions of PTHrP and Indian hedgehog (IHH) during chondrocyte differentiation in a growth plate. IHH produced by prehypertrophic chondrocytes in the lower zone acts on the adjacent perichondrium to communicate with the PTHrP-producing cells. PTHrP, in turn, acts on PTHR1-expressing prehypertrophic chondrocytes to impair their further differentiation by up-regulating Bcl-2 expression.

B. Mammary Gland Development

PTHrP signaling is necessary for the formation of the mammary gland in mouse and human embryos. PTHrP and PTH1R knockout mice, as well as human fetuses with Blomstrand's chondrodysplasia, lack mammary glands and nipples. The first step in the formation of embryonic mammary glands is the formation of an epithelial bud, which is surrounded by a specialized stroma or mesenchyme. During the development of the mammary buds in mice and humans, PTHrP is produced by epithelial cells within the mammary bud, and the PTH1R is expressed by the surrounding mesenchymal cells. Like many developing organs, the mammary glands rely on a constant conversation between epithelial and mesenchymal cells to coordinate proper morphogenesis.

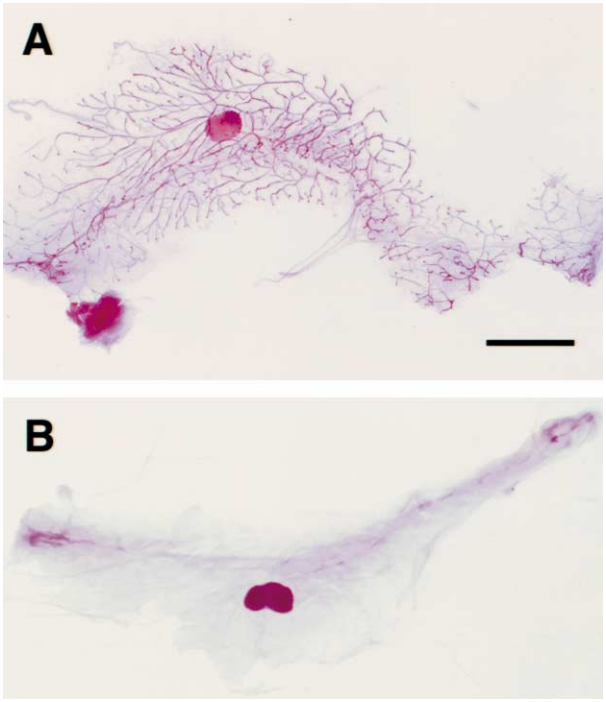

FIGURE 3 Whole-mount analysis of mammary glands from PTHrP null mice rescued from perinatal lethality by targeted expression of PTHrP in chondrocytes (col II-PTHrP/PTHrP null mice) and normal littermates. The normal gland (A) is characterized by a fully branched epithelial duct system surrounding the central lymph node. In contrast, the col II-PTHrP/PTHrP null gland (B) is devoid of epithelial structures; only the lymph node and vasculature are present within the fat pad. These results show that PTHrP is required for the development of mammary epithelium. Scale bar represents 5 mm.

PTHrP participates in this conversation by acting as a message from the mammary epithelial cells that triggers mammary-specific differentiation of the mesenchymal cells. If this message is not received, as in the PTHrP or PTH1R knockout mice, the mesenchyme becomes dermis instead of mammary stroma, the mammary epithelial cells regress, and no further breast development occurs (Fig. 3).

VII. PTHrP IN REPRODUCTION

A. Uterus

In the rat uterus, myometrial PTHrP mRNA levels rise during pregnancy from very low levels in virgin rats to a peak right around the time of birth. Levels then decrease significantly within 4 h after parturition, and by 4 days postpartum, PTHrP mRNA levels have returned to baseline virgin levels. It appears that this profile of expression is related to stretching of the myometrium and not to hormonal changes of pregnancy, as it can be reproduced in virgin rats using mechanical stimuli. However, it has also been reported that uterine PTHrP mRNA expression is also up-regulated by estrogen. Functionally, PTHrP and PTH have been shown to induce uterine smooth muscle relaxation, indicating that this effect is mediated by PPR1 signaling. Therefore, PTHrP expression induced and maintained by some combination of mechanical stretch and estrogen during gestation could serve to prevent premature parturition by inducing uterine relaxation or by antagonizing contractions, allowing the uterus to expand and accommodate the growing fetus. Similar observations in the bladder, stomach, and egg-laying gland of the chicken have suggested that PTHrP might play a more general role in regulating the expansion of hollow, muscular organs.

B. Placenta

There is an uphill gradient of calcium from mother (approximately 9.5 mg/dl) to fetus (approximately 13 mg/dl) that is maintained through the actions of a placental calcium ATPase. Recent data have demonstrated that PTHrP acts to facilitate the placental transport of calcium from mother to fetus. Interestingly, this function of PTHrP appears to be mediated by the midregion portion of the peptide and not by the N-terminal region. In a fetal parathyroidectomized lamb model, midregion PTHrP, but not amino-terminal PTHrP or PTH, was shown to facilitate placental calcium transport. In mice, the maternal–fetal calcium gradient depends upon an intact PTHrP gene, and midregion PTHrP stimulates placental calcium transfer. Thus, there is a considerable body of evidence that now supports a role for midregion PTHrP in regulating placental calcium transport from mother to fetus. However, the nature of the receptor for this portion of PTHrP and the mechanisms by which it stimulates calcium transport remain obscure.

C. Mammary Gland—Lactation

Not long after PTHrP was discovered, several laboratories found it to be expressed in lactating mammary tissue and secreted into milk in large quantities. In fact, milk is the most abundant source of PTHrP in nature. The expression of the PTHrP gene is up-regulated at the beginning of lactation, and PTHrP mRNA is localized to the epithelial cells of the lobuloalveolar units. Expression levels during lactation have been shown to be modulated

by systemic prolactin and local signals initiated by suckling.

Great quantities of calcium are secreted in milk each day and large increases in bone resorption and decreases in bone mass occur during lactation, presumably to mobilize calcium from the maternal skeleton to meet the demands for milk production. Given PTHrP's ability to mimic the actions of PTH on calcium metabolism, it has been suggested that PTHrP might participate in this mobilization of skeletal calcium stores. In order for this to be the case, PTHrP from the breast would need to enter the systemic circulation and act on the maternal skeleton. Although not all studies have concurred, the weight of evidence suggests that circulating PTHrP levels are elevated during lactation. Furthermore, it has been reported that circulating PTHrP levels during lactation correlate with increases in rates of bone turnover and decreases in bone density. Case reports suggest that elevated PTHrP may compensate for the lack of PTH in lactating women with hypoparathyroidism. In addition, studies in rats and cows have correlated the suckling-induced increase in mammary PTHrP with a rise in cAMP and phosphate in urine, possibly indicating systemic effects of PTHrP produced in the mammary gland. However, in the only study that attempted to manipulate PTHrP levels during lactation, passive immunization with anti-PTHrP antibodies did not alter calcium metabolism in lactating mice. Thus, although there is considerable evidence to support an endocrine role for mammary gland-derived PTHrP in lactation, the data are not conclusive. Alternative roles for PTHrP produced by the lactating mammary gland include the regulation of blood flow to the mammary gland or the regulation of gut development or calcium homeostasis in neonates.

VIII. OTHER ACTIONS OF PTHrP

A. Pancreas

PTHrP is expressed in all pancreatic islet cell types and in pancreatic ductular epithelium, but not in adult exocrine cells. Although the PTH1R has not been demonstrated on beta cells, N-terminal PTHrP (or PTH) acts on cultured beta cells to increase intracellular free calcium. This might indicate an alternative PTH/PTHrP receptor. The precise role of PTHrP in the pancreas is not well understood; however, data from transgenic mice expressing PTHrP under control of the rat insulin II promoter (RIP–PTHrP mice) suggest that PTHrP might regulate beta-cell mass. The RIP–PTHrP mice demonstrate islet hyperplasia, due to both an increase in the number of islets and their size. As a result, these mice are hyperinsulinemic and hypoglycemic, conditions that become acutely symptomatic upon fasting. Interestingly, RIP–PTHrP mice are also resistant to the beta-cell-toxic effect of streptozotocin. How these findings relate to the physiologic role of PTHrP in the pancreas is unknown.

B. Cardiovascular System

As mentioned previously, PTHrP may have a general function in the regulation of smooth muscle cell contractility. In tissues such as the uterus, the urinary bladder, and the hen oviduct, PTHrP expression in smooth muscle cells is induced by stretch, with the level of induction proportional to the degree of stretch (or filling). Furthermore, PTHrP acts on smooth muscle cells to cause relaxation. In addition to the organs mentioned above, PTHrP is expressed in the muscularis layer of most vascular beds. In vascular smooth muscle cells, vasoconstrictors, such as angiotensin II, serotonin, endothelin, norepinephrine, bradykinin, and thrombin, induce a potent, but transient, up-regulation of PTHrP expression. As before, mechanical stimulation (stretch) also induces PTHrP expression in vascular smooth muscle cells, but probably through a different pathway than vasoconstrictors. N-terminal PTHrP is a vasorelaxant in many vascular beds, including those of the mammary gland, the placenta, the aorta, the portal vein, the renal artery, and the coronary artery. The ability of PTHrP to relax smooth muscle cells appears to be mediated by a decrease in intracellular free calcium caused by the inhibition of the activity of L-type voltage-sensitive calcium channels (L-VSCC). In addition to its effects on contractility, PTHrP has been reported to modulate vascular smooth muscle cell proliferation. When added exogenously, PTHrP inhibits smooth muscle cell proliferation by inducing the cyclin-dependent kinase inhibitor $p27^{kip1}$. However, when PTHrP is overexpressed in the A10 smooth muscle cell line, proliferation was increased. This occurred only when the cells expressed PTHrP with an intact nuclear localization signal, suggesting that this was an intracrine effect of PTHrP. These effects are identical to the aforementioned studies with MCF-7 cells, again demonstrating that PTHrP can have opposing effects on the same cells, depending on the trafficking of the protein. Finally, exogenous PTHrP also inhibits migration of vascular smooth muscle cells in response to platelet-derived

growth factor. The effects of PTHrP on vascular smooth muscle cell contractility, proliferation, and migration have all generated interest in the potential role of this peptide in atherosclerosis.

In addition to blood vessels, PTHrP has direct effects on the heart. N-terminal PTHrP has been shown to exert positive chronotropic and ionotropic effects in *ex vivo* perfused hearts. It also increases the rate of cardiac myocyte contraction *in vitro*. Although some of the tachycardia caused by systemic infusion of PTHrP is likely related to its ability to cause vasodilation and reduce blood pressure, these experiments also suggest that it may have direct effects on pacemaker function.

C. Skin

The first nonmalignant cell type that was shown to produce PTHrP was the keratinocyte. During development, PTHrP participates in the epithelial–mesenchymal interactions necessary for proper skin appendage formation. In addition, PTHrP may also play a role in the epithelial mesenchymal interactions in the skin of adult animals. Keratinocytes express PTHrP but not the PTH1R, and dermal fibroblasts express the PTH1R but not PTHrP. One likely function of PTHrP in the skin is to regulate the hair growth cycle. Systemic antagonists of the PTH1R have been shown to shorten telogen, lengthen anagen, and inhibit catagen. This suggests that PTHrP may promote the resting or catagen/telogen stage of the hair cycle, thereby causing reduced hair follicle growth. However, somewhat paradoxically, mice expressing no PTHrP in their skin undergo coat thinning over time, rather than the expected increase in hair growth. In addition to any effects on the hair cycle, evidence from mice expressing no PTHrP in their skin and mice overexpressing PTHrP in their skin suggests that PTHrP may also modulate keratinocyte differentiation. It remains unknown whether the effects of PTHrP on keratinocyte differentiation and hair follicle growth result from paracrine signaling to dermal fibroblasts or from autocrine or intracrine pathways. However, current data support the notion that PTHrP participates in the regulation of these processes.

D. Central Nervous System

Both PTHrP and the PTH1R are expressed within the brain. Interestingly, recent studies have demonstrated that other members of the PTH receptor family as well as other potential ligands for these receptors are expressed within the CNS. Therefore, PTH1R signaling is likely to have important yet complex functions in the nervous system. As with vascular smooth muscle cells, PTHrP, acting via this receptor, has been shown to affect the function of L-VSCC in neurons. In response to depolarization-induced L-VSCC calcium influx, PTHrP expression is up-regulated in cerebellar granule cells in culture. In turn, it appears that PTHrP can inhibit calcium entry through L-VSCC. Since calcium entry through these channels can be toxic to neurons (a phenomenon known as excitotoxicity), it has been suggested that PTHrP might participate in a putative neuroprotective short-feedback loop. However, in contrast to its effects on granule cells, PTHrP has been shown to increase L-VSCC activity in PC-12 cells, an effect that leads to an increase in dopamine secretion.

IX. COMPARATIVE BIOLOGY OF PTHrP

A. PTHrP, a Calciotropic Factor in Fish

Fish face a different set of problems than terrestrial mammals in achieving mineral homeostasis. The main challenges to marine fishes are to eliminate excess salts and prevent dehydration. The PTHrP sequence is most similar between fishes and tetrapods at the N-terminus, suggesting that regulation of calcium metabolism could be a conserved function. In support of this hypothesis, PTHrP expression co-localizes with the main sites of active calcium transport in fish (gills, skin, intestine, and opercular epithelium). Furthermore, in sea bream larvae, PTHrP increases the uptake of calcium and decreases total calcium efflux. PTHrP may be a classical endocrine hormone in fish, where it is secreted from the pituitary gland. In elasmobranchs, circulating PTHrP levels correlate positively with potassium and calcium and negatively with sodium, chloride, and urea, suggesting that PTHrP regulates ion transport and/or osmolality.

B. PTHrP in the Avian Oviduct

In the hen, PTHrP is expressed in the immature oviduct of growing animals, but is not highly expressed in the nulliparous adult oviduct. During the egg-laying cycle, expression of PTHrP is greatly up-regulated in the oviduct. The localization of PTHrP mRNA changes with the position of the egg as it descends. When the egg moves through the magnum, PTHrP is expressed most highly in the isthmus, and when the egg moves through the isthmus, PTHrP expression is up-regulated in the shell gland. Finally, when the egg passes out of the shell gland, PTHrP

message is rapidly down-regulated. This sequence of events is strikingly similar to what happens in the mammalian uterus, where PTHrP expression is up-regulated until the time of birth and then declines. One possibility is that PTHrP regulates the passage of the egg through the oviduct by relaxing the smooth muscle "ahead" of the egg so that the contracted muscle "behind" the egg will push it forward. PTHrP can, in fact, relax strips of oviduct smooth muscle *in vitro*. Another possibility is that PTHrP regulates calcium transfer from the hen to the egg for shell formation. Interesting parallels can be raised between a function in egg shell formation and the putative roles of PTHrP in regulating placental calcium transfer and calcium transfer to the milk during lactation. Finally, PTHrP could regulate blood flow to the oviduct through its actions on vascular smooth muscle.

Peptide YY

THOMAS E. ADRIAN
Northwestern University Medical School

Peptide YY, a hormonal peptide produced by endocrine cells in the intestinal mucosa, was first isolated from porcine small intestine using a novel chemical assay to detect peptides with a carboxy-terminal amide group, a structural feature shared by many regulatory peptides. PYY inhibits cholecystokinin- and secretin-stimulated pancreatic secretions, suggesting a hormonal role. In this article, the biological effects of PYY in the gastrointestinal tract are described and the clinical ramifications of these effects are explored.

I. CHEMISTRY AND MOLECULAR BIOLOGY OF PYY

Peptide YY is a straight-chained 36-amino-acid polypeptide that is structurally related to pancreatic polypeptide (PP) and neuropeptide Y (NPY). All three of these biologically active peptides have both C-terminal and N-amino-terminal tyrosine residues, which is the source of the name assigned to PYY (in the single-letter-code peptide nomenclature, Y represents tyrosine). Human PYY differs from porcine peptide at three residues, whereas the sequences of rat, dog, and pig PYY are identical. The amino acid sequences of the human peptide family are shown in Table 1. Truncated forms of human and canine PYY with 34 residues (PYY 3–36) have been isolated from colonic mucosa. The differences in the biological effects of the truncated and full-length forms of PYY relate to the PYY receptor subtypes (see later). Another posttranslational modification of PYY is phosphorylation of the serine residue in position 13 of the peptide. This phosphorylated form retains biological activity but is slightly less potent than the nonphosphorylated form.

The human and rat PYY genes have been cloned and sequenced. In both cases, the gene is composed of four exons and three introns spanning approximately 1.2 kbp. The human gene resides on chromosome 17q21.1 in a cluster with the PP gene. Two mRNA species are derived from the PYY gene by alternative splicing. The PYY precursor is a 98-amino-acid protein residue in which the PYY sequence is preceded by a signal peptide and followed by the cleavage and amidation sequence of Gly-Lys-Arg, which is followed by a cryptic peptide of another 31 amino acids. Thus, the precursor is similar in structure to that of pancreatic polypeptide and neuropeptide Y, and all are derived from a common ancestor by gene duplication. Indeed, the most recent gene duplication event has led to production on the 17q21 chromosome of a second cluster called the PYY2–PPY2 gene cluster, which has been detected in the cow, baboon, and human genomes. Despite the 92% sequence identity of the two gene clusters, a few specific mutations have resulted in significantly altered peptide sequences. These structural alterations have led to acquisition of new functions. The cow PYY2 gene codes for seminal plasmin, which is involved in reproductive function rather than gastrointestinal physiology.

A peptide with strong sequence identity with PYY has been isolated from the skin of the South American arboreal frog, *Phyllomedusa bicolor*. This peptide, called skin peptide tyrosine-tyrosine (SPYY), inhibits melanotropin release from frog neurointermediate lobes in a manner similar to that of NPY.

II. TISSUE DISTRIBUTION AND ONTOGENY

Cells containing PYY are found in the mucosa throughout the small and large bowel in humans. PYY concentrations increase distally through the gut, reaching peak concentration in the rectal mucosa. Similar gut distributions have been reported in the rat, mouse, dog, and monkey, with concentrations in the colon generally 100- to 200-fold higher than in the duodenum. PYY is colocalized with the glucagon gene products in the intestinal L cells. Interestingly, this

TABLE 1 Amino Acid Sequences of Mammalian PYY, NPY, and PP

[a]PYY, Peptide YY; NPY, neuropeptide Y; PP, pancreatic polypeptide.
[b]Rat and canine PYY sequences are identical to the porcine sequence.

colocalization is also seen in the glucagon-producing pancreatic islet alpha cells in mice, rats, guinea pigs, cats, dogs, pigs, and cows. These cells expressing glucagon and PYY are the earliest islet cells identified in the fetus and presumably represent the islet stem cells that have differentiated from the pancreatic endoderm. At this early stage, the products of the glucagon gene represent those expressed in the adult intestine (glicentin and the glucagon-related peptides, rather than glucagon), and because of this difference in posttranslational processing, the metabolic hormone glucagon is not made. In the developing mouse pancreas, PYY is transiently co-expressed with insulin, PP, and somatostatin, when the cell types expressing these peptides first appear. PYY expression may thus serve as a marker for islet differentiation. Production of PYY peaks just before term and ceases in the human pancreas shortly after parturition, although PYY continues to be co-expressed with glucagon in the rodent pancreas. In the mouse pancreas, the immunoreactive PYY is mostly confined to a major subpopulation of alpha cells in the splenic lobe. The PYY-expressing cells are also the earliest endocrine cells to appear in the fetal intestine. Once again, co-expression of PYY with other hormones such as secretin, cholecystokinin, neurotensin, gastrin, and somatostatin is seen when these hormones are first expressed. These findings suggest that PYY plays an important role in endocrine cell differentiation in the gut and the pancreas and support the existence of a common endocrine cell progenitor in these tissues.

Peptide YY is found not only in endocrine cells of the gut but also in nerve fibers in the myenteric plexus in several species, including rats, cats, ferrets, pigs, and dogs. In the rat, these are restricted to the stomach, but in cats, ferrets, and dogs, numerous fibers are also found in the upper small intestine. In the pig, only a few fibers are seen in these myenteric plexus locations and no fibers are seen in human gastrointestinal smooth muscle tissues.

III. PYY SECRETION AND RELEASE MECHANISM

As would be expected with a gastrointestinal hormone, circulating concentrations of PYY in humans change with food ingestion. Circulating concentrations rise in response to food intake and the magnitude of the increase reflects the total caloric load ingested. It should be emphasized that the increase in response to a small meal in healthy subjects is small. Ingested fat and protein, in particular, elicit a PYY response in humans. Similar increases in circulating PYY in response to feeding have been noted in a number of species, including rats, pigs, and dogs. In dogs, fat, rather than proteins and carbohydrates, appears to be responsible for PYY release.

The observed rapid PYY response to feeding led to early speculation that the foregut played a role in release of the peptide. It was seen that intraduodenal oleic acid releases PYY into the circulation even when the flow of chyme is prevented, whereas ileocolectomy abolishes PYY release in response to duodenal oleate. Infusion of the upper intestinal hormone, cholecystokinin (CCK), causes concentration-dependent release of PYY into the circulation. Other studies in the dog have shown that response to a fatty meal as well as to CCK infusion is abolished by a specific CCK-A-type receptor antagonist, underlining the importance of CCK-stimulated PYY release in this species. Concentrations of PYY in cord blood are substantially greater than those in normal fasting adults, and the response to feeding in neonates is massive, suggesting a role for the peptide in early adaptations to extrauterine life. Concentrations in neonatal animals, such as the pig, are also high.

Secretion has also been investigated in isolated intestinal endocrine cells cultured *in vitro*. Sodium oleate concentration dependently stimulates PYY release, as does bombesin, epinephrine, and forskolin, but not carbamyl choline. Studies in isolated perfused rabbit left colon have revealed that bile salts, rather than fatty acids per se, are responsible for release of the peptide following colonic stimulation. In contrast, high concentrations of amino acids are more effective at releasing PYY from the dog colon than is fat, glucose, or protein. Bile salts selectively and potently released PYY from the human colon. Although added oleic acid does not increase the PYY response to deoxycholate, this fatty acid causes a concentration-dependent increase in release of glucagon gene products. Because both peptides appear to be secreted from the same cell type, either there must be a difference in the hormone content of granules within the responding endocrine cells or a subpopulation of enteroglucagon secreting cells must be stimulated. Short-chain fatty acids also release PYY from the rabbit colon, a mechanism that could be highly significant in this species, which largely relies on short-chain fatty acids from colonic fermentation for its caloric intake.

Secretion studies in rats show a different spectrum of PYY release in response to nutrients, compared to the other mammalian species just mentioned.

Intraduodenal isocaloric amounts of glucose and amino acids release as much PYY as does a meal; oleic acid in place of a meal is less effective. This is likely to reflect the high tonicity of these solutions, because hyperosmolar saline also releases PYY but isotonic solutions have little effect. Studies in the vascularly perfused isolated rat colon show relatively weak stimulation of PYY by CCK and secretin, but a marked increase in PYY secretion in response to glucose-dependent insulinotropic peptide (GIP). Similarly, blockade of CCK and bombesin receptors is without effect on PYY release in anesthetized rats. With regard to intralumenal stimulation of PYY release in isolated perfused rat intestine, only supraphysiologic concentrations of glucose and amino acids are able to elicit a response. In contrast, some fibers, including pectin and gum arabic, but not cellulose, stimulate marked PYY secretion. The β-adrenergic agonist isoproteranol, the cholinergic agonist bethanechol, and calcitonin gene-related peptide all increase PYY secretion in this model. The effects of these agents are not affected by tetrodotoxin, suggesting direct effects on the PYY cells rather than mediation through the enteric nervous system.

There is some controversy regarding the extrinsic neural release of PYY. Several groups have shown a PYY response to two peptide transmitters, vasoactive intestinal polypeptide (VIP) and gastrin-releasing peptide (GRP), or to the amphibian analogue to GRP, bombesin. Studies in the pig reveal that electrical stimulation of the vagus supplying the pig distal intestine results in PYY release, whereas splanchnic stimulation has no effect. In keeping with this observation, atropine and hexamethonium significantly inhibit the PYY response to food. In contrast, total extrinsic jejunoileal denervation results in an increased PYY response to intralumenal fat stimulation in the dog. Interestingly, the CCK responses to fat are abolished in this denervation model, indicating that the increased PYY responses to fat are not mediated by CCK. Similarly, the PYY responses to food are enhanced by truncal vagotomy. Taken together, these findings suggest that food-induced PYY release is influenced by both an atropine-blockable postganglionic, parasympathetic pathway and a tonic inhibition, probably through a vagal cholinergic pathway.

A variety of other hormones and growth factors can influence the production and secretion of PYY. Pharmacologic inhibition of gastric acid secretion elevates circulating gastrin levels and concomitantly reduces both transcription and secretion of PYY. This inhibition is prevented by the gastrin receptor antagonist LY365,260. This control mechanism may relate to enterogastrone effects of PYY (see later). Insulin-like growth factor stimulates both expression of PYY mRNA and the peptide as well as its secretion into the circulation. A similar effect on tissue and plasma PYY levels, but not its mRNA content, is seen in transgenic mice overexpressing transforming growth factor-α. Somatostatin has been shown to inhibit PYY release in all species studied. This effect is mediated via type 5 somatostatin receptors in the rat and type 2 somatostatin receptors in humans.

IV. PYY RECEPTORS AND SECOND-MESSENGER SYSTEM

The PYY peptide family shares several different receptor (Y receptor) subtypes. There are currently six recognized members of this family, although only five of these (excluding Y3) have been cloned, i.e., Y1, Y2, Y4, Y5, and y6 (it should be noted that the y6 receptor is a pseudo-receptor in humans and pigs, hence the designation y6). The y6 receptor is absent in the rat but is apparently functional in the rabbit and mouse. All of the Y receptors are members of the G-protein-coupled seven-transmembrane-domain "serpentine" superfamily of receptors, which are coupled to inhibition of adenylate cyclase. The G-proteins involved are members of the G_o and G_i family and the effect of receptor activation is generally pertussis-toxin-sensitive, although exceptions in presynaptic receptors have been reported. This is, however, likely to arise from the inability of pertussis toxin to penetrate and activate the G-proteins rather than from a distinct signaling mechanism.

Structure–affinity and structure–activity studies with peptide analogues, together with studies based on site-directed mutagenesis and antireceptor antibodies, have given insight into the individual characterization of each receptor subtype relative to its interaction with ligand, as well as to its biological function. The characteristics of the different Y receptor subtypes, including binding characteristics and examples of locations, functions, and selective agonists and antagonists are summarized in Table 2. This summary is simplified because there are species differences as well as differences in reported activities from different laboratories. PYY binds to all the active subtypes, although it is less potent than NPY on Y1 receptors and much less potent than PP on Y4 receptors. Y2 receptors strongly bind PYY 3–36, a naturally occurring product of PYY produced in the small intestine.

TABLE 2 Subtypes of Receptors for PYY and Other Family Members

Subtype	Binding characteristics	Example locations	Example functions	Selective agonists	Selective antagonists
Y1	NPY > PYY ≫ PP	Gut, brain, heart, kidney	Vasoconstriction, anxiolysis; antisecretory in intestine	[Pro34]PYY, [Pro34]NYY	BIBP 3226, GR231118[a]
Y2	PYY = NPY ≫ PP strongly binds PYY 3-36-NH_3	Brain, low levels in peripheral tissues	Presynaptic inhibition of neurotransmitter release	PYY 3-36, PYY 13-36	BIIE0246
Y3[b]	NPY ≫ PYY	Nucleus tractus solitarius, colon, and adrenal	Regulation visceral afferents	None available	None available
Y4	PP > PYY = NPY[c]	Small intestine, colon, prostate, and CNS	Inhibition of pancreatic secretion	PP	GR231118
Y5	PYY = NPY = PP	Brain areas involved in food intake	Increased food intake	Ala-31-Aib_{32} NPY and PP/NPY chimera, [Dtrp32]NPY	None available
Y6	Pseudogene in human and pig brain, absent in rat, functional in rabbit and mouse	Small intestine and adrenal (mouse)	Not known	None available	None available

[a]Putative receptor, not yet cloned.
[b]GR31118 has high affinity for Y1 and Y4 receptors; selectivity toward Y5 is not established.
[c]PYY activates the human but not the rat Y4 receptor.

V. BIOLOGICAL EFFECTS OF PYY

With the considerable overlap between the PP-fold peptides for the various receptor subtypes, it is not surprising that the biological effects of the PYY family overlap, particularly the effects of PYY and NPY. This does not mean that all of these biological effects are important physiological functions of the respective peptides. It is necessary to deliver the appropriate concentration of peptide to receptor, which, in the case of PYY, is via the circulation, with, perhaps, some local effects in the intestine. For NPY, the delivery is made to synaptic receptors in the peripheral and central nervous systems.

The broad range of biological effects of PYY includes gastrointestinal effects, such as slowing of gastric emptying and intestinal transit and inhibition of gastric pancreatic and small intestinal secretions. In peripheral tissues, PYY is also a vasoconstrictor and cardiac stimulant. PYY can reach some brain receptors via the circulation. The central effects of PYY include simulation of food intake as well as effects on circadian rhythm, anxiety, and memory. Interestingly, PYY 3-36 has been shown to inhibit food intake and to reduce weight gain through the NPY Y2 receptor. PYY 3-36 is released from the intestine postprandially directly in proportion to the amount of calories consumed. The motor and secretory effects on the gastrointestinal tract are seen at circulating concentrations that are within the range seen after physiological stimuli, and are, therefore, undoubtedly physiologically relevant. The physiological importance of the other biological effects of PYY is uncertain.

VI. PHYSIOLOGICAL EFFECTS OF PYY

A. Motor Effects of PYY in the Gastrointestinal Tract

Early investigations of PYY showed inhibitory effects on jejunal and colonic motility together with intestinal vasoconstriction. Infusion studies in humans revealed marked inhibitory effects on gastric emptying and intestinal transit. It is now clear from the work of several groups that, in humans

and experimental animals, PYY is responsible for the upper gut inhibitory motor effects that are seen in response to ileal infusion of lipids, known as the "ileal brake." Ileal or colonic infusion of lipid lengthens the interval between migrating complexes and also slows gastric emptying through the stimulation of PYY secretion. These motor effects of PYY appear to be mediated through vagovagal pathways.

There are apparently paradoxical effects of PYY in the stomach. Several studies show that PYY inhibits the ileal brake through the dorsal vagal center. However, under some circumstances, PYY can stimulate gastric motility. Y2 agonists inhibit thyrotropin-releasing hormone (TRH)-stimulated motility, mimicking the suppressive effect of PYY, but have no effect on basal acid secretion. In contrast, Y1 agonists stimulate motor function under basal conditions. This difference is probably due to the localization of Y1 and Y2 receptors in the dorsal vagal complex and the rapid conversion of PYY to a Y2 agonist by the ubiquitous dipeptidyl aminopeptidase.

The role of PYY in gallbladder function is controversial. One group has reported marked relaxation and increased filling of the prairie dog gallbladder in response to modest increases in PYY concentrations. In contrast, studies in the dog have revealed no effect of PYY on gallbladder function.

B. Role of PYY in Gastric Secretion

There is a consensus that PYY is a physiological enterogastrone in several species, including dogs and humans. PYY inhibits gastric acid and pepsin secretion stimulated by pentagastrin, cholinergic agonists, vagal activity, and histamine. The point that is somewhat controversial is the site of action. Most evidence points to inhibitory effects on vagal neurons. However, one group has provided evidence in support of a vagally independent mechanism. It is possible that, in view of the high concentrations of gastrin that are seen in newborns, the very high concentrations of PYY in neonates are important for inhibiting gastric acid secretion, i.e., allowing the tropic effects of gastrin to occur in the gastric mucosa without hyperstimulation of acid secretion.

C. Effects of PYY on Pancreatic Secretion

Multiple studies in dogs and rats have demonstrated that PYY inhibits pancreatic secretion stimulated by CCK, secretin, food, and intraduodenal amino acids, or vagal stimulation by infusion of 2-deoxyglucose. In contrast, a single study in humans showed no effect on CCK- and secretin-stimulated pancreatic secretion. Although there is complete agreement with regard to the effect of PYY in dogs and rodents, the site of action appears to be different in these two species. In dogs, the inhibitory effect of PYY on pancreatic secretion is independent of the vagus, and PYY inhibits secretion from the denervated canine pancreas even in the presence of atropine. Results from another study on dogs suggest that PYY acts on the intrapancreatic cholinergic nerves rather than on extrinsic pathways. Other explanations from groups working with dogs are that PYY acts, at least partially, by blocking CCK release and reducing blood flow.

In one rat study, PYY predominantly inhibited neurally stimulated secretion and this inhibition was blocked by coinfusion of a cholinergic agonist. Results from a more recent study lead to the conclusion that the effect of PYY in the rat is predominantly mediated through the CCK pathway at a site proximal to convergence with the neural pathway. Immunoneutralization studies in the rat have confirmed that PYY is a physiologically important regulator of food-stimulated pancreatic secretion.

D. Effects of PYY on Small Intestinal and Colonic Secretion

Early studies using Ussing chambers demonstrated that PYY has antisecretory effects in the small intestine and colon. PYY reduces basal and VIP-stimulated increases in short-circuit current as well as VIP-stimulated increases in cAMP production and chloride secretion. PYY also abolished the secretory responses to cholera toxin and forskolin but not to 8-bromo-cAMP, indicating that the effect is mediated through inhibition of receptor-coupled adenylate cyclase.

In vivo, secretion and absorption occur simultaneously and all regions beyond the duodenum normally show net absorption. When infused at concentrations that mimic the postprandial response, PYY causes a substantial increase in net water and electrolyte absorption in Thiry–Vella fistula dogs. Other studies have revealed that infusion of PYY can augment the increase in net absorption that occurs postprandially, and that immunoneutralization with a monoclonal PYY antibody blocks the meal-induced increase in absorption. Whether the proabsorptive effect acts directly on the enterocyte or is mediated indirectly is not clear. One study has shown that the effects on short-circuit current and chloride secretion are blocked by hexamethonium, suggesting neural mediation, whereas another study has concluded that the effects are independent of neural blockade.

E. Growth and Differentiation-Inducing Effects of PYY in the Gut

Some studies in rats and mice have shown that administration of PYY can increase the weight and DNA content of the duodenum, ileum, and colon. However, other infusion studies in the rat have shown no effect on mucosal weight or crypt cell production rate, a very sensitive indicator of intestinal hyperplasia. In Caco-2 intestinal epithelial cells, PYY induces expression of the brush border enzyme alkaline phosphatase and decreases the specific activity of dipeptidyl dipeptidase. These findings suggest that PYY promotes differentiation of Caco-2 cells to a more colonocyte phenotype.

The effects of PYY on preventing the gut hypoplasia that accompanies total parenteral nutrition (TPN) have been assessed after 7 days of TPN in tumor-bearing rats. PYY was coinfused with clenbuterol, an anabolic β-adrenergic agonist. The combination resulted in significant savings in small intestinal weight and protein content, but had no effect in sparing the colon. Histologic analysis of the ileal tissues suggested that the effects of PYY were mostly mucosal, whereas clenbuterol mainly influenced the muscle. The combination treatment also resulted in a significant saving of protein content in the gastrocnemius muscle, suggesting a reduction in the cachectic response. Studies in breast (MCF7 and ZR-75) and pancreatic cancer (MIA PaCa-2) cells have shown significant growth-inhibitory effects of high concentrations of PYY.

F. Other Effects of PYY on the Gastrointestinal Tract and Metabolism

As already mentioned, PYY has vasoconstrictor effects on several vascular beds and, in particular, it reduces intestinal blood flow. Infusion of PYY in humans is accompanied by a small but significant increase in both systolic and diastolic blood pressure. Indeed, it is quite possible that inhibitory effects on secretion and motor activity may be mediated, at least in part, through effects on the splanchnic vasculature.

PYY increases expression of intestinal fatty acid-binding protein, suggesting that PYY plays a role in the trafficking of free fatty acids in the enterocyte. Similarly, physiologically relevant concentrations of PYY increase production of apolipoprotein AIV in the intestinal mucosa. PYY has also been shown to stimulate mucin secretion in the rat colon. PYY has been shown to inhibit the secretion of several gastrointestinal hormones, including motilin and pancreatic polypeptide in humans and cholecystokinin in rats and dogs. In contrast, PYY has no effect on circulating concentrations of glucagon, gastrin, glucose-dependent insulinotropic peptide, neurotensin, or enteroglucagon. A study in dogs has shown that PYY inhibits the insulinotropic effects of GIP, suggesting a role for the peptide in the negative feedback regulation of insulin secretion. Studies in humans show no effect on basal or glucose-stimulated insulin secretion or on the glucose elimination rate after intravenous glucose. Furthermore, PYY has no significant effect on circulating concentrations of glucose, lactate, glycerol, or free fatty acids. It remains to be seen whether PYY influences the enteroinsular axis in humans.

PYY infused at concentrations similar to those seen after a meal had significant effects on renal function in a group of male subjects. The effects included a decrease in glomerular filtration rate, plasma renin activity, and aldosterone levels. Infusion of PYY at a higher dose, which reproduced plasma levels seen in diarrheal illness, resulted in similar changes in function but also reduced renal plasma flow. These findings suggest that PYY may be an important mediator of the postprandial natriuretic response.

G. Orexigenic Effects of PYY

Lateral ventricular injections of PYY and NPY in hamsters induces a dose-dependent increase in food intake but causes a marked reduction in lordosis duration. In rats, injection of these peptides into the paraventricular nucleus causes a dramatic dose-dependent increase in food intake as well as a small increase in water intake. When the animals are able to select from different macronutrient diets, they overwhelmingly select carbohydrate over diets rich in either fat or protein. A recent study showed that infusion of PYY 3-36-NH_2 at physiological concentrations has marked inhibitory effects on food intake in humans.

VII. PATHOPHYSIOLOGY OF PYY

In endocrinology, a lot can be learned about the physiological role of a hormone by studying syndromes associated with excessive hormonal secretion and lack of hormonal production. This is the case with PYY, which appears to play an adaptive role in several intestinal disorders and after small bowel resection.

A. PYY in Gastrointestinal Diseases

Circulating basal and postprandial PYY concentrations are grossly elevated in patients with celiac sprue and in patients with postinfective tropical malabsorption (tropical sprue). Patients with these disorders have severe malabsorption resulting from small intestinal mucosal atrophy; in celiac patients this is due to sensitivity to the gliadin fraction of wheat flour and in tropical sprue it is caused by an unknown infective agent. In both conditions, PYY levels normalize with successful treatment with a gluten-free diet or antibiotics, respectively. The increased secretion of PYY is entirely appropriate in these conditions, given the inhibitory roles of PYY on gastrointestinal secretion and motility. PYY is presumably released in response to unabsorbed nutrients that reach the PYY-containing cells in the distal ileum and colon. This contrasts with the normal situation in which nutrients are almost totally absorbed in the proximal small bowel. High concentrations will reduce secretions and therefore the intralumenal volume in the gut and will also slow gastric emptying and intestinal transit. All of these physiological changes tend to enhance absorption by increasing the contact time with the small intestinal mucosa and by increasing local nutrient concentrations.

Smaller elevations of PYY are seen in patients with inflammatory bowel diseases (Crohn's disease and ulcerative colitis) and chronic pancreatitis and in patients recovering from a severe, acute, infective diarrhea. These conditions are associated with a degree of malabsorption, although direct effects of intestinal inflammation may also play a role in enhancing secretion of the hormone in inflammatory bowel disease and diarrhea. Once again, the elevation in diarrhea is appropriate, because PYY will slow nutrient transit and enhance intestinal absorption.

PYY concentrations are normal in meal studies performed in patients with other gastrointestinal disorders, including peptic ulcer, diverticular disease, and irritable bowel syndrome.

B. PYY Abnormalities Following Alimentary Surgery

Peptide YY secretion changes in response to a variety of surgical procedures, which, once again, could be considered to be appropriate adaptive changes. First, a proportion of patients who undergo gastric resection will suffer from "dumping" syndrome. In these patients, rapid emptying of hypertonic chyme into the upper small intestine causes water to pass from the vascular space into the intestinal lumen. This results in a shortness of breath, rapid heart rate, pain, bloating, nausea, vomiting, and even diarrhea. Furthermore, rapid absorption of glucose results in an exaggerated insulin response that can cause a reactive hypoglycemia, with symptoms including weakness, cold sweating, confusion, and headache. PYY levels are markedly increased following oral glucose ingestion in patients with dumping syndrome.

The pattern of secretion after massive small bowel resection is similar to that seen in sprue. This is not surprising, because unabsorbed nutrients rapidly reach the distal bowel, triggering release of the peptide YY. Generally, the more small intestine that is resected, the greater the elevation of PYY levels. Similar increases of PYY secretion are seen in dogs and rats after small bowel resection. In dogs and humans, infusion of PYY at concentrations that raise circulating levels to those seen after resection markedly slows intestinal nutrient transit, inhibits gastrointestinal secretions, and enhances net water and electrolyte absorption throughout the small intestine. As previously mentioned, PYY does not seem to be responsible for the ileal resection-induced adaptive mucosal hyperplasia and hypertrophy that are seen in the remaining bowel in continuity. Indeed, it is now clear that glucagon-like peptide-2 (GLP-2), a product of the same cell but not of the PYY gene, is responsible for the adaptive intestinotropic response to bowel resection. Studies on the expression of the GLP-2 and PYY genes have revealed that their respective mRNA contents are already markedly increased within 6 h after enterectomy, even before the animals are fed. Plasma PYY concentrations are also increased within 24 h. One can only speculate on this early endocrine response to small bowel resection. In the absence of food, it is possible that biliopancreatic secretions reaching the distal intestine are responsible. A modest increase in PYY response accompanies orthotopic jejunoileal autotransplantation in the dog. This is nothing like the magnitude of the increase seen after small bowel resection and is likely to be the result of motor changes in the denervated gut.

In contrast to the effect of massive small bowel resection, colonic resection is associated with low PYY levels. Here the postprandial response reflects the postsurgical anatomy. Levels are very low in patients with an ileostomy; this is not surprising because all of the PYY-containing colonic mucosa is out of the intestinal stream. Responses are a little greater in patients with an ileoanal anastomosis, but there is no difference between straight ileoanal anastomosis

and patients who have a J-pouch fecal reservoir. Interestingly, in patients with ileoanal pouches, fecal retention time is related to the plasma PYY response as well as to mouth-to-pouch transit time. This finding suggests that it would be advantageous to maintain PYY responses in patients who have undergone colonic resection. A recent report of a new pouch procedure, the 9-pouch with a recycle segment, reveals that this more physiological approach, with attention to the effects of ileal peristalsis, results in PYY responses that are not different from those of healthy controls and offers a marked improvement in the functional outcome in these patients. The time-course of changes in PYY function has been carefully studied in the dog and rat after colonic resection and ileoanal anastomosis. Both the number of PYY positively stained cells and the PYY content of the ileal J-pouch mucosa are greater than is seen in control ileum and mucosa from straight ileoanal anastomoses. Furthermore, PYY responses increase with time after resection, suggesting that these changes represent an adaptive response that is improving the functional outcome.

PYY levels are modestly increased after total pancreatectomy. This pattern of response is very similar to that in chronic pancreatitis with exocrine deficiency, undoubtedly reflecting the malabsorption.

C. PYY and Tumors of the Intestine

Peptide YY, glucagon gene products, and PP are all common constituents of rectal carcinoid tumors, but PYY is not generally seen in endocrine tumors from other regions of the gut, such as the pancreas. An interesting report of a patient with an ovarian carcinoid revealed that excessive PYY production was associated with severe constipation that resolved after tumor resection. Low concentrations of PYY are seen in colonic cancer tissues and adenomatous polyps, compared with normal mucosa. Extremely low concentrations appear to reflect the malignant potential of these lesions, but this is probably related to the differentiation of the tumors, because concentrations are highest in tubular polyps, lower in villus polyps, and lowest in carcinomas. This is consistent with epithelial dysplasia and incomplete formation of mucosal endocrine cells.

D. PYY in Eating Disorders

A recent report on the measurement of PYY in the cerebrospinal fluid (CSF) in patients with eating disorders showed a dramatic increase in CSF PYY levels in bulimics who had abstained from bingeing for 30 days, compared with controls or their own levels when actively bingeing. No differences were seen in anorexia nervosa patients. It is possible that bulimic behavior corrects a central nervous system abnormality in PYY. Because PYY can profoundly increase food intake, these results are very interesting and worthy of further investigation.

VIII. THERAPEUTIC POTENTIAL

The spectrum of actions of PYY, including slowing of gastrointestinal nutrient transit and inhibition of secretions, make this peptide an ideal candidate for treating a number of different conditions, including acute or chronic diarrheal diseases and patients who have undergone colonic resection. In addition, PYY alleviates experimental pancreatitis, presumably because of its inhibitory effects on pancreatic secretion, so it also has potential for treating this condition.

Problems with the therapeutic use of PYY, however, are that the peptide has a short half-life (about 10 min) in the circulation and is large, making synthesis expensive. It is possible that there will be further development of long-acting analogues of PYY or some of the small-molecule agonists that target the PYY receptors that are responsible for PYY secretory and motor functions. Such compounds would have widespread clinical use. Because of the profound inhibitory effects of PYY on intestinal motor function, it is possible that a PYY antagonist could be useful in the treatment of postoperative ileus.

Glossary

enterogastrone Putative inhibitory hormone from the small intestinal mucosa; inhibits gastric acid secretion.

enteroinsular axis Stimulation of insulin secretion by hormonal signals from the gut; triggered by ingested sugars and amino acids.

ileal brake Inhibitory effects on upper gastrointestinal motor activity; triggered by a distal intestinal hormone that is released in response to intralumenal fat.

ileoanal anastomosis Surgical end-to-end connection between the terminal ileum and distal rectum after total colonic resection.

ileostomy Terminal ileum exteriorized through the abdominal wall; allows intestinal waste to be collected in a bag.

Thiry–Vella fistula Loop of intestine with ends exteriorized through the abdominal wall; allows easy access to intestinal contents. The loop retains its blood and neural supply through intact mesentery.

Ussing chamber Small glass chamber in two halves that sandwich a small piece of bowel or mucosa; used to

study ion fluxes. A voltage clamp across the tissue allows measurement of short-circuit currents.

vagovagal reflex Signal transmitted through afferent vagal fibers to the dorsal vagal complex and then back to an abdominal target through efferent vagal fibers.

Peptidomimetics

MARK T. GOULET AND RALPH T. MOSLEY
Merck & Company, Inc., New Jersey

Many G-protein-coupled receptors can utilize peptides or proteins as their natural ligands for effecting signal transduction. Nonpeptide ligands, or peptidomimetics, that can either reproduce the activity of a peptide agonist or act as an antagonist of that system have been discovered for many of these receptors. Rational peptidomimetic designs rely on structural information derived from the ligand in either the receptor-bound or the solution state. Peptidomimetic ligands can serve as useful tools for the study of receptor signaling pathways and as important pharmacological agents for the treatment of disease.

I. INTRODUCTION

Approximately 60% of known G-protein-coupled receptors (GPCRs) utilize peptides or proteins as their natural ligand for effecting signal transduction. For many of these receptors, non-peptide ligands, or

peptidomimetics, have been discovered that can either reproduce the activity of a peptide agonist or act as an antagonist of that system. Natural products derived from the secondary metabolism of lower organism occasionally function as peptidomimetic ligands for GPCRs, but a majority of peptidomimetic ligands are the outcome of a premeditated design as a means of obtaining biologically active receptor modulators with properties distinct from those of peptides. This effort is driven primarily by research in the pharmaceutical industry, because nonpeptides have demonstrated improvements over peptides with respect to oral bioavailability, metabolic stability, and tissue distribution. Many modern drugs are peptidomimetic ligands for receptors that either cause or ameliorate disease. Along with the discovery of peptidomimetics has come an increased understanding of the principles for their design and the nature of the nonpeptide–protein interaction.

For the purposes of classification, three types of peptidomimetics have been described, based primarily on the nature of their interaction with macromolecules. A type I mimetic incorporates an amide bond surrogate, or "isostere," that is intended to mimic the local topography about an amide bond. Often type I mimetics are designed as atom-for-atom replacements of the amide bond and are utilized predominantly in the construction of enzyme (e.g., protease) inhibitors. Type II mimetics are functionally analogous to a given peptide agonist or antagonist, but their mode of binding to the receptor is distinct from that of the original ligand. Thus, type II mimetics do not necessarily mimic the structure of the parent hormone. The type III mimetics possess the necessary groups, arrayed about a nonpeptide core, to mimic the parent ligand topographically. Often these structures bear no obvious resemblance to the original hormone, but because their mode of binding is predicted to be the same as the parent they have been termed "ideal" peptidomimetics. Representatives of the three types of peptidomimetics are shown in Table 1.

II. "NATURAL" PEPTIDOMIMETICS

Evaluation of the biological activity of natural products, isolated primarily from plants and

TABLE 1 Classification of Peptidomimetics

Type	Structure	Peptide	Receptor
Type I	 Saquinavir	⦚-L N F- P I-⦚ (gag-pol)	HIV protease (enzyme)

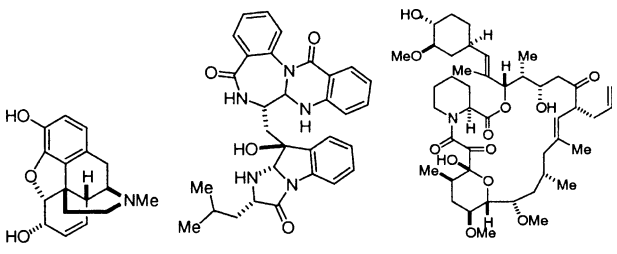

FIGURE 1 Natural product peptidomimetics.

microorganisms, has revealed a number of compounds fitting the description of peptidomimetics. Some representative "natural" peptidomimetics are shown in Fig. 1. Perhaps the most well-known example is the plant-derived alkaloid morphine. Morphine and related structures are agonists of the opioid receptor family and act by mimicking the N-terminal Tyr-Gly-Gly-Phe of the endorphin neuropeptides. Morphine, as well as its synthetic and semisynthetic analogues, has been used extensively for the study of receptor–ligand interactions and subsequent GPCR signaling. Asperlicin is a natural product that acts as an antagonist of the neurotransmitter peptide cholecystokinin (CCK). Although only weakly active as a CCK antagonist ($IC_{50} = 1\ \mu M$), asperlicin has served as the structural basis for the design of potent and subtype-selective CCKA and CCKB receptor antagonists. The macrocyclic bacterial metabolite FK-506 (Tacrolimus) is an interesting peptidomimetic of clinical relevance to the field of immunosuppression. Through studies relating to the pharmacological mechanism of action, it was discovered that the amidopyranose portion of FK-506 functions as a peptidomimetic ligand for the peptidyl-prolyl isomerase FKBP-12. This complex, in turn, binds and inhibits the serine/threonine phosphatase PP2B (calcineurin) to block signal transduction in activated T cells. It is thought that portions of the polyketide-derived backbone act as a peptidomimetic ligand for PP2B during this second binding event.

III. STRATEGIES FOR PEPTIDOMIMETIC DISCOVERY AND DESIGN

A. Privileged Structures

Certain nonpeptide units that exhibit a propensity for binding to GPCRs and other macromolecules have been termed "privileged structures." In general, these are hydrophobic assemblages that often contain aromatic rings and are constructed in a manner so as to maintain a defined shape even in an aqueous environment, thereby avoiding what is known as hydrophobic collapse. Several common privileged structures are depicted in Fig. 2. A successful strategy for discovering peptidomimetics is to identify a privileged structure or derivative thereof that exhibits affinity for the desired receptor, then modify this structure by addition of appropriate groups to optimize potency and selectivity for that receptor. At times, the same privileged structure can be used to produce potent peptidomimetics for a variety of receptor types. For example, the biphenyltetrazole privileged structure is found in the angiotensin II antagonist prodrug losartan and in the Merck growth hormone secretagogue (Fig. 3). Preparation of chemical libraries based on a privileged structure has proved to be a successful method for both generation and optimization of pharmacologically active peptidomimetics.

B. Benign Scaffolds

Privileged structures within a peptidomimetic both bind to the macromolecule and provide a site(s) for additional chemical modification. Another strategy for peptidomimetic design is the use of a rigid template, onto which groups that can interact with a receptor are appended. These "benign scaffolds" are not intended to participate directly in the binding event but rather to connect and display the pharmacophore elements in a manner appropriate for binding. One example of a benign scaffold is the sugar core of the type III peptidomimetic shown in Fig. 1. Another is the thyrotropin-releasing hormone (TRH) agonist RO 24-9975, wherein elements of the three amino acid side chains present in TRH are displayed about a 1,3,5-trisubstituted cyclohexane ring (Fig. 4). Computer algorithms that utilize

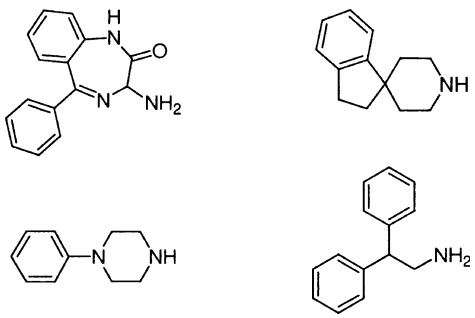

FIGURE 2 Some common privileged structures.

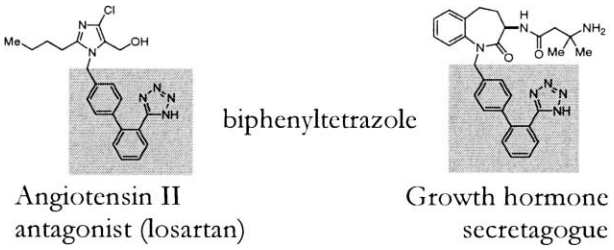

FIGURE 3 An angiotensin II antagonist and growth hormone secretagogue that share a common privileged structure (shaded area).

knowledge of the bound conformation to predict useful benign scaffolds have enhanced the success of this approach to peptidomimetic design.

C. Using Structural Information

The regular nature of α-amino acid amide linkages has facilitated study through biophysical and theoretical methods such that it is possible to predict secondary structure from primary sequence and, in limited cases, to propose reasonable tertiary structures. This amount and type of information also permits the discovery of materials that can mimic large structural motifs, such as entire β-strands and α-helices (which are beyond the scope of further discussion here), as well as smaller structural features, particularly β and γ turns. And, although it can be shown that widely dispersed residues of a peptide hormone make contributive interactions with a receptor for binding and function, it is often the case that small regions of the hormone, comprising three to four amino acids, critical to receptor activation can be identified. This is typically accomplished through amino acid scans (sequential replacement of each residue in the polypeptide strand by an unobtrusive amino acid, typically alanine) and

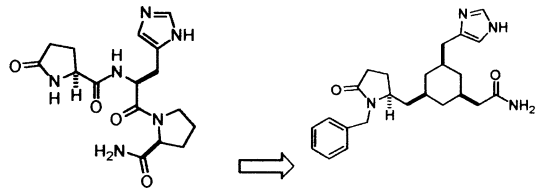

FIGURE 4 Thyrotropin-releasing hormone mimetic derived from a benign, cyclohexane scaffold.

peptide truncation. Oftentimes, these critical residues are found within a turn region of the peptide. Analysis in this manner results in the development of a conceptual pharmacophore and begins the peptidomimetic design process. Having identified the requisite residues for activity, additional analytical and computational tools, such as X-ray crystallography, nuclear magnetic resonance (NMR), and molecular modeling, are often applied to further refine the structural requirements for peptidomimetic design and optimization.

The conformation of the receptor-bound peptide hormone and, by extension, the placement of the peptide side chain moieties would be the most useful information for peptidomimetic design. At present, this information is largely gathered by inference from peptide structure–activity relationships (SARs), receptor mutagenesis, and studies with related peptidomimetics. Alternatively, it might be assumed that the conformation that can be confirmed in the solution phase is relevant, because it is that conformation that is initially "sensed" by the receptor and from which the bound conformation is derived.

The clearest pieces of structural data from solution-state NMR studies include strong nuclear Overhauser effects (NOEs), which typically indicate stable and close proximity (2–2.5 Å) between two protons, small temperature coefficients for amide protons (indicating lack of solvent accessibility and, by extension, involvement in an internal hydrogen bond), up-field chemical shifts of proton resonances (indicating a deshielding environment typically that is found near an aromatic ring system), and coupling constants between vicinal protons (indicating torsion angles between them). These types of information can be used in conjunction with molecular modeling techniques to generate energy-minimized conformations that meet the conditions stipulated by the NMR experiments. The two most prevalent ways to generate conformations are via distance geometry followed by energy minimization or by molecular dynamics (MD) simulations. The NMR-generated data can be used to restrain the calculation, usually the case during MD, or as a postprocessing filter. The resultant peptide conformations can be clustered on the basis of the backbone conformation and energetics to propose the prevalent bioactive conformation.

If NMR information is unavailable, small peptides can be modeled as just described and the resultant low-energy conformers can be examined for any proclivity toward a particular turn type as determined by the $\Phi-\Psi$ angles of the main-chain

TABLE 2 Commonly Mimicked Reverse Turns

Turn structure	Turn type	Φ_{i+1}	Ψ_{i+1}	Φ_{i+2}	Ψ_{i+2}	Amino acid turn inducers
	γ classical	70 to 85	−60 to −70	—		—
	γ inverse	−70 to −85	60 to 70	—		—
	βI	−60	−30	−90	0	*i*: D, N, S, C *i* + 1: P *i* + 2: no P *i* + 3: G
	BI′	60	30	90	0	*i* + 1: G *i* + 2: G
	βII	−60	120	80	0	*i* + 1: P *i* + 2: G, N
	βII′	60	−120	−80	0	*i* + 1: G

atoms. Identification of a turn type can be further advanced by examination of the peptide SAR (e.g., increases in potency by use of amino acids known to induce reverse turns in the suspected loop region). Table 2 contains the typical Φ–Ψ angles for the most common reverse turns, as well as some of the amino acids known to contribute to their stabilization.

D. Design Strategies

With this data, there are now several approaches that can be followed to maintain the shape of the peptide while removing much of the peptide character. Which approach is taken depends on the derived SAR. A constrained amino acid via Cα–Cβ cyclization, Cα or Cβ substitution, or N-side chain cyclization can fix the conformation of the side chain (usually measured as the χ angle: N-Cα–Cβ–Cγ) and sometimes the entire turn region. If maintaining the β-strand motif and main-chain atoms is important, the side chains of residues at the $i + 1$ and $i + 2$ positions in a β-turn can be replaced with a cyclic structure to maintain the β-strand structural motif, a so-called "external scaffold." Finally, if the side chains provide the important contacts, the main chain of these residues can be replaced with some cyclic system, or an "internal scaffold." These different routes of structure stabilization are schematically depicted in Fig. 5.

Choosing to internally cyclize the γ or β reverse turn is equivalent to replacing the hydrogen bond to create a 7-membered or 10-membered ring, respectively. In the latter case, this typically takes the form of a fused bicyclic system. At this point, modeling of the proposed peptidomimetic is typically conducted to ensure that the three-dimensional realization of the design is in agreement with the target. Modeling studies of some turn mimetics have indicated that there can be several conformational families present or that the turn mimetic even fails to meet the desired conformation.

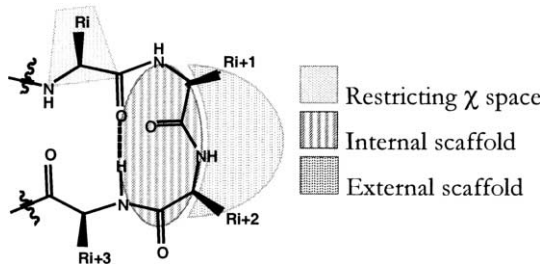

FIGURE 5 Schematic of a β-turn depicting various peptidomimetic approaches.

Several conclusions from work in the peptidomimetic field can be proposed:

1. The more sequentially posited the amino acids to be mimicked, the greater the probability for success.
2. Determining the conformation of both the peptide backbone and side chain, particularly for the critical residues, is important and becomes more so as the critical amino acids become less contiguous in the sequence.
3. Identification of a nonpeptide lead through screening approaches (e.g., binding assays), which can then be further developed as a peptidomimetic, rather than *de novo* design based on peptide sequence, is another frequently used method of discovery.

Ultimately, the goal is to imitate or antagonize the function of the peptide ligand, and mimicking the conformation of the peptide is merely one potential means to that end.

E. Database Search Approaches

Rather than design the scaffold, various searching methods can be used to identify scaffolds to replace the main-chain atoms. One approach is to use three-dimensional substructure searches in which the Cα–Cβ bond vectors of the modeled peptide hormone are used as the probe to identify scaffolds that contain similar bond vectors, such as is done in the program CAVEAT. Or, one might use three-dimensional similarity searches to identify replacements for the main chain directly.

Designing and synthesizing a scaffold or identifying one through a database search still requires that care then be taken to incorporate the relevant side chains into the design process. Rather than take this intermediary step, a number of tools exist that can be used to search for replacements of the requisite amino acid side chains directly, either in the form of three-dimensional substructure or three-dimensional similarity searches. An example of this is discussed in the following case study for the somatostatin peptidomimetics. Finally, database searching technologies exist that allow one to forgo the use of three-dimensional information entirely. Markush queries can be readily constructed for two-dimensional substructure searches to identify molecules that contain the side chain moieties of interest. Topological similarity searches are more problematic in that a peptide probe tends to identify other peptides; the recurrence of the peptide bond creates a "signal" that overwhelms that of the side chains. Even here, methods have been developed that circumvent this to identify peptidomimetics successfully.

F. Case Study: Somatostatin Peptidomimetics

Somatostatin is a neuropeptide known to modulate the secretion of growth hormone, insulin, and glucagon, among others; somatostatin agonist drugs could lead to treatments for diabetes, cancer, and acromegaly. Somatostatin occurs in both a 28- and 14-residue peptide form and binds to five distinct somatostatin receptor (SSTR) subtypes (1-5), which are members of the G-protein-coupled receptor family A (rhodopsin-like). Early SARs showed the importance of Trp-8 and Lys-9 to activity; peptides cyclized via a Cys–Cys disulfide linkage, e.g., the octapeptide Sandostatin, or via regular peptide bonds, e.g., the hexapeptide seglitide (MK-678), are highly potent compounds (Fig. 6). NMR-derived data such as NOEs, vicinal proton coupling constants,

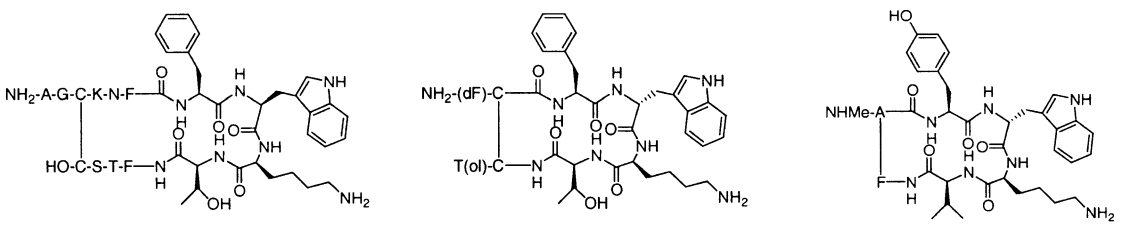

FIGURE 6 Somatostatin and related constrained peptide analogues.

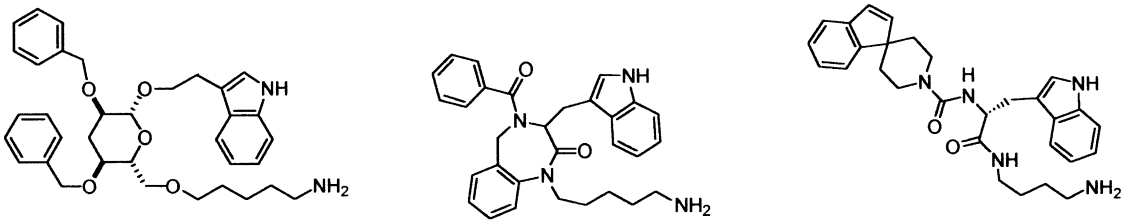

FIGURE 7 Somatostatin peptidomimetics.

and small-temperature coefficients indicate the occurrence of a βII′-turn at the DTrp-8–Lys9 of these peptides. Upfield chemical shifts in the NMR spectrum of methylene protons in the Lys side chain indicate proximity to an aromatic system, presumably the indole of DTrp8. Additionally, it is known that the backbone atoms of the peptide are unnecessary for SSTR activation.

As an alternative to the backbone cyclization strategy just described, several attempts have been made to mimic the side chain positions by supporting their equivalents from a central scaffold, such as a sugar or benzodiazepine core (Fig. 7). Typically, this has resulted in compounds with modest agonist activity. A different approach is to use the three-dimensional structure derived from NMR and SAR results to query a database containing three-dimensional models of molecules and thereby identify new leads without predilection for a particular scaffold or other structural constraint to be used as a synthetic starting point. Using a three-dimensional model of one of the cyclic peptides, the probe can be constructed to replicate the SAR using only side chain atoms for Phe-7–DTrp-8–Lys 9 in which the side chains of DTrp-8 and Lys-9 are near each other. Interestingly, the most potent compounds identified using this search method at Merck Research Laboratories do not contain a central scaffold, but rather mimic the basic amine of the Lys and the aromatics of the Trp and Phe in a linear manner, presumably while maintaining the three-dimensional relationship of the pharmacophoric elements. This is accomplished, in part, by the incorporation of a "privileged structure" unit (Fig. 7).

The Merck database lead was amenable to optimization by both traditional medicinal chemistry and combinatorial chemistry and became the basis for the design and synthesis of analogues with a 10,000-fold increase in binding potency and 1000-fold increase in selectivity for the various receptor subtypes compared to the original lead. The Merck database lead is composed of three units, a diamine to mimic Lys, an amino acid to mimic Trp, and a "privileged structure" amine to mimic Phe. These units are combined in sequence by forming amide and urea bonds between the fragments. In order to facilitate biological screening of what could potentially be a

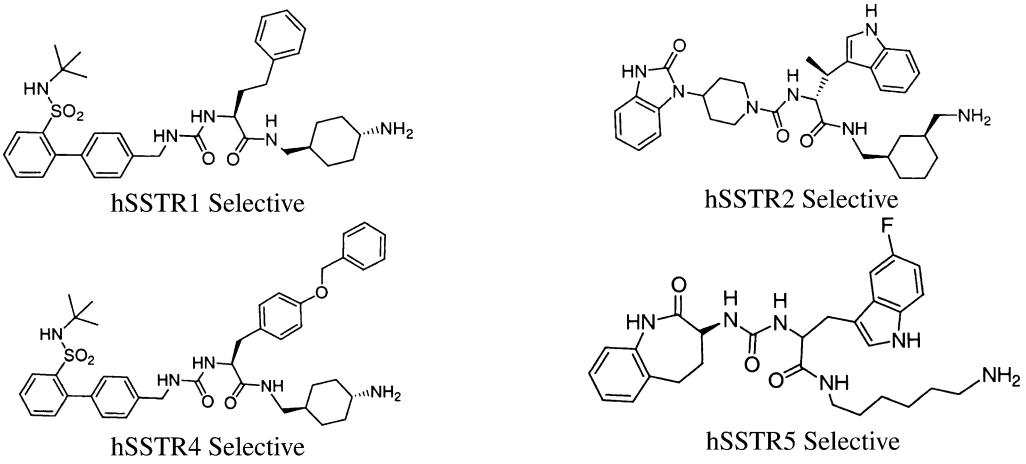

FIGURE 8 Selective somatostatin peptidomimetics from a combinatorial approach.

very large chemical library, it was decided to synthesize mixtures of compounds, which could then be quickly and selectively deconvoluted if a particular mixture showed activity in the assay. The library is synthesized by first coupling the diamine to a resin. A protected amino acid is then added to create the amide bond, the amine protecting group is removed, and the urea link to the terminal amine is formed. The products are then cleaved from the resin. Some of the resin is archived after each addition of a subunit to facilitate later deconvolution and identification of active components. Theoretically, 131,670 compounds were prepared in this library of 79 mixtures, when stereo- and regioisomers for the 20 diamines, 20 amino acids, and 79 amines are taken into account.

The design process for peptidomimetics was used in the selection of the library components. The most important consideration was to ensure that the pharmacophoric elements identified for somatostatin were present in the selected starting materials. Most of the amino acids used contained an aromatic group, as did the final amine fragment. Conformational restraints in the form of rings and branching groups were used in all components to further restrict flexibility, with the "privileged structure" amine biased toward piperidines and piperazines to further mimic the database lead. Biological screening followed by iterative deconvolution of components in the active mixtures led to the identification of compounds that were individually selective as agonists for somatostatin receptor subtypes 1, 2, 4, and 5 (Fig. 8).

IV. SUMMARY

Peptidomimetic ligands can serve as useful tools for the study of receptor signaling pathways and as important pharmacological agents for the treatment of disease. One method for their discovery involves activity screening of natural products and other compound collections. Use of "benign scaffolds" and chemical modification of "privileged structures" are two tactics for further refinement of the potency and selectivity of a peptidomimetic lead structure. Principles for rational design have also been put forth that rely on structural information derived from the ligand in either the receptor-bound or the solution state. Application of computational methods has greatly assisted this design process.

Glossary

chemical library A group of chemical compounds generally related by structure and method of preparation.

isostere A chemical equivalence in which an undesired chemical moiety is replaced by an atom or groups of atoms that retain the desired properties of the moiety being replaced.

Markush query Chemical database search tool in which substituents on the core structure do not need to be precisely enumerated.

peptidomimetic Nonpeptidic compound that, when bound to a receptor, can either imitate or block the action of a peptide ligand at the receptor level.

pharmacophore A conceptualization of features, both steric and electronic, minimally required in a molecule in order to elicit some desired biological response.

privileged structure Fragment or group often used in peptidomimetic design; contains elements of both pharmacophore (typically hydrophobic/aromatic) and scaffold.

topography Representation or "mapping" out of three-dimensional features in two-dimensional space.

Peroxisome Proliferator-Activated Receptors

KAREN L. MACNAUL AND DAVID E. MOLLER
Merck Research Laboratories, New Jersey

Peroxisome proliferator-activated receptors regulate key genes involved in glucose and lipid metabolism. In addition, these receptors are involved in many diverse biological functions, including development of the central nervous system, inflammation, cancer, and fertility. Development of specific, potent ligands for these receptors offers the potential for therapeutic intervention in many debilitating diseases.

I. INTRODUCTION

Peroxisome proliferator-activated receptors (PPARs) are members of a large superfamily of ligand-activated nuclear receptors. Three human isoforms, encoded by separate genes, have been identified in the past decade: PPAR-α [NR1C1], PPAR-δ [NR1C2], and PPAR-γ [NR1C3]. The subtypes share many structural similarities typical of nuclear receptors. Physiologically, PPARs are known to regulate key genes involved in both glucose and lipid metabolism. Synthetic PPAR agonists have been found to be efficacious in decreasing serum glucose, insulin, and lipids. By lowering these parameters in humans, metabolic disorders such as type 2 diabetes and dyslipidemia are improved. With the prevalence of type 2 diabetes and related metabolic disorders such as dyslipidemia and atherosclerosis reaching epidemic proportions in countries consuming a high-fat Western diet, the need for effective, safe therapies is critical.

II. STRUCTURE OF PPARs

PPARs have been identified and cloned from numerous species, including *Xenopus*, rodents, and humans. Like other nuclear receptors, they share characteristic functional domains. The amino-terminal region contains a variable "A/B" domain, which is poorly conserved between the three isoforms and contains a ligand-independent activation function (AF-1) domain. The highly conserved central "C" region contains the DNA-binding domain. This region contains two zinc finger structures that bind to PPAR responsive elements (PPREs) in target genes. Comparing the human isoforms, there is greater than 80% amino acid identity in this region. A flexible hinge region, "D," separates the DNA-binding domain (DBD) from the ligand-binding domain (LBD). The LBD "E" region is also highly conserved, with greater than 60% amino acid identity between human isoforms. The carboxy terminus of the LBD contains a ligand-dependent activation function domain, AF-2 (Fig. 1). The crystal structures of all three PPAR LBDs have been solved, both as apoproteins and co-crystalized with ligands. PPARs are ligand-dependent transcription factors that switch from an inactive form to an active form on binding agonist. The LBDs contain 13 α-helices and a small four-stranded β-sheets (Fig. 2). This structure contains a relatively large hydrophobic ligand-binding pocket in comparison to other nuclear receptors.

As with many nuclear receptors, all three PPAR subtypes are known to heterodimerize with the 9-*cis*-retinoid X receptors (RXRs) (Fig. 3). PPAR:RXR heterodimers are "permissive" in that they can be activated by either PPAR- or RXR-selective agonists. These heterodimers bind to direct repeats (DR-1) of a hexameric nucleotide sequence with the consensus sequence AGGTCA separated by one nucleotide. PPREs are located in the promoter of PPAR target genes. After agonists are bound, the LBD undergoes conformational changes, co-activators are recruited, and transcriptional activation is initiated.

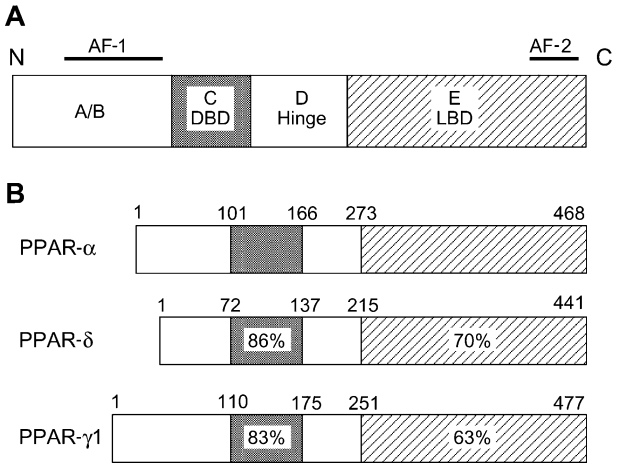

FIGURE 1 Functional domains of the PPARs. (A) The N-terminal A/B domain contains the ligand-independent activation function domain (AF-1). Domain C contains the DNA-binding domain (DBD), connected by hinge region "D" to the "E" region containing the ligand-binding domain (LBD). The C-terminus of the LBD contains a ligand-dependent activation function domain, AF-2. (B) The amino acid identities of DBD and LBD regions of the three human subtypes are compared; the percent identity relative to PPAR-α is indicated within the domains. The numbers above the individual receptors indicate the number of amino acid residues from the N-terminus for the regions.

PPARs can complex with a number of co-activator or corepressor proteins to regulate transcriptional activation or repression, respectively, of PPAR target genes. Binding of co-activators usually occurs at the AF-2 region, which has been located on helix 12 of the LBD. Several PPAR co-activators have been identified to date and can be grouped into three general categories based on their mode of regulation of transcriptional activation. Two prototypes are steroid receptor co-activator-1 (SRC-1) and cyclic adenosine monophosphate response element binding (CREB) protein p300 (CBP/p300); both have histone acetylase activity that is involved in the remodeling of chromatin structure to allow transcription factors access to DNA binding sites. Another class of co-activators that includes members of the vitamin D-interacting protein/thyroid hormone receptor-associated protein (DRIP/TRAP) complex augments basal transcriptional activity by interacting with the basal transcriptional complex. Several additional co-activators, including the PPAR-γ co-activator (PGC-1), receptor-interacting protein-140 (RIP140), and androgen receptor 70-kDa co-activator (ARA70), have been implicated as regulators of PPAR action, although their mechanisms of action are not well understood.

III. PPAR-α AND DISEASE TARGETS

A. Characterization and Ligands

PPAR-α was the first isoform to be identified and cloned from a murine liver cDNA library in 1990. PPAR-α has since been cloned from several other rodent species, *Xenopus*, and humans. The human PPAR-α gene has been mapped to chromosome 22q12–q13. PPAR-α is expressed at highest levels in tissues involved in fatty acid catabolism, such as liver, kidney, heart, skeletal muscle, and cells of the arterial wall. In these tissues, PPAR-α plays a key role in lipid metabolism by regulating genes involved in the β-oxidation of long-chain fatty acids, including acyl-CoA oxidase, enoyl-CoA hydratase/dehydrogenase multifunctional enzyme, keto-acyl-CoA thiolase, CYP4A cytochrome P450 enzymes, and fatty acid binding protein. Fatty acid transport protein (FATP) and fatty acid translocase (FAT, also known as CD36), which are involved in transport of fatty acids across the cell membrane, are up-regulated by

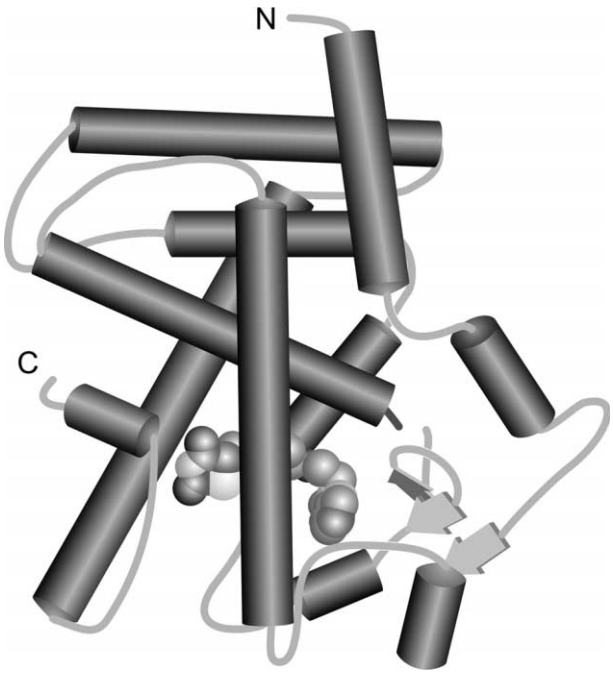

FIGURE 2 Overall structure of the human PPAR-γ ligand-binding domain complexed with rosiglitazone. The α-helices are represented by tubes and the small, four-stranded β-sheet is denoted by arrows. Within the large binding pocket is the thiazolidinedione rosiglitazone, represented by the ball structure, which binds in a U-shaped conformation and occupies only ~40% of the pocket. The AF-2 domain located on the C-terminal α-helix is important for cofactor binding and transcriptional activation.

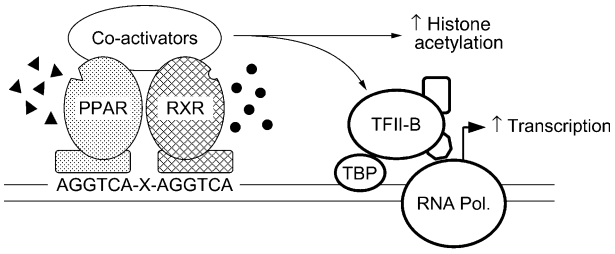

FIGURE 3 The peroxisome proliferator-activated receptor: retinoic acid X receptor (PPAR:RXR) transcriptional complex. PPARs heterodimerize with RXR and bind to specific DNA response elements in the regulatory regions of target genes. PPAR agonists (▲) and RXR agonists (•) bind their respective receptors and undergo conformational changes and recruitment of co-activator proteins. This illustration depicts binding of a co-activator with histone acetylase activity that is involved in remodeling the chromatin structure to allow interaction with basal transcriptional factors (such as TFII-B, TBP, and RNA polymerase).

PPAR-α activation; apoproteins A-I and A-II (apoA-I and apoA-II), the major constituents in high-density lipoproteins, are up-regulated by PPAR-α as well.

Natural ligands for PPAR-α present in human serum are composed of many saturated and unsaturated fatty acids, including palmitic acid, oleic acid, linoleic acid, and arachidonic acid (Fig. 4). These fatty acids bind to PPAR-α with micromolar affinities. However, it is not known if all of these ligands are present in sufficiently high concentrations to be physiologically relevant. Higher affinity naturally occurring PPAR-α activators have been identified, including the lipoxygenase 8(*S*)-hydroxyeicosatetraenoic acid [8(*S*)-HETE] and leukotriene B4 (LTB4). However, these ligands also may not be present at sufficient levels in relevant tissues to be considered key endogenous ligands.

PPAR-α can be activated by a diverse range of synthetic compounds, including industrial plasticizers, pesticides, and the fibrate class of drugs prescribed for hypertriglyceridemia. Among the fibrates are clofibrate, gemfibrozil, and fenofibrate. These compounds are relatively weak agonists (30–50 μ*M*) and require large doses clinically in humans for efficacy in hyperlipidemia. In rodents, PPAR-α agonists cause an increase in the size and number of liver peroxisomes, subcellular organelles containing enzymes involved in long-chain fatty acid oxidation. Peroxisome proliferation in rodents progresses to hepatomegaly and hepatocarcinoma. In humans, however, significant hepatic peroxisome proliferation has not been observed on exposure to PPAR-α activators, as evidenced by the long-term clinical experience with fibrates. Hence, the name "peroxisome proliferator-activated receptors" is a misnomer for this class of human nuclear receptors. It is therefore currently believed that activation of PPAR-α in humans does not warrant concerns for hepatotoxicity. The reason for this species-to-species difference may be because there is 10-fold lower expression of hepatic PPAR-α mRNA in humans, compare to mice. In addition, 30–50% of the PPAR-α expressed in human liver is a truncated splice variant lacking exon 6, which encodes for the ligand-binding domain. This further reduces the amount of functional receptor compared to mice.

B. Dyslipidemia and Atherosclerosis

The increased prevalence of a high-fat Western diet in many societies, coupled with increasingly sedentary lifestyles, has resulted in an increased incidence of metabolic disorders, including type 2 diabetes. Common comorbid conditions are dyslipidemia and progression to atherosclerosis, the leading cause of death among patients with type 2 diabetes. Dyslipidemia, an inappropriate alteration in lipid chemistry, is generally characterized by elevations in serum triglycerides (TGs) and very low-density lipoproteins (VLDLs) and a decrease in high-density lipoproteins (HDLs). PPAR-α activation by fibrates results in the up-regulation of lipoprotein lipase, which enhances

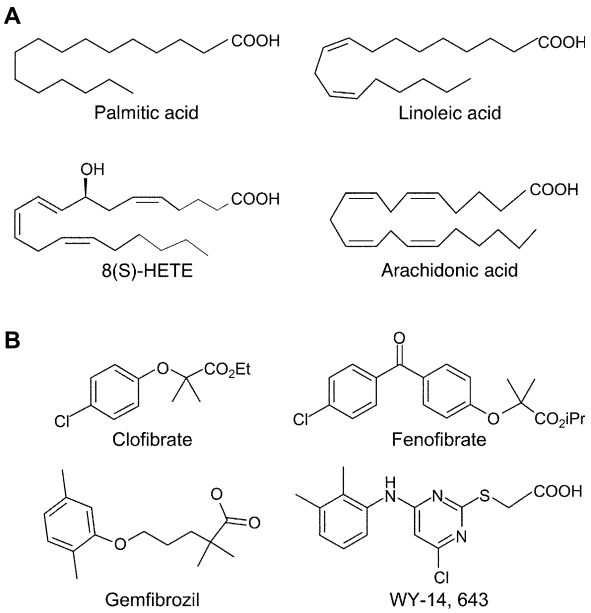

FIGURE 4 The structures of various natural (A) and synthetic (B) PPAR-α ligands. 8(*S*)-HETE, 8(*S*)-Hydroxyeicosatetraenoic acid.

the lipolytic activity of triglyceride-rich VLDL particles, and the suppression of hepatic apoC-III gene expression, which increases VLDL clearance. Fibrates, prescribed since the 1960s, have been investigated in humans in several large clinical trials; they have been found to be efficacious in lowering serum TGs and produce a modest increase in HDL levels. Moreover, fibrates have the proved benefit of reducing the risk of atherosclerosis.

PPAR-α null mice have been generated and exhibit a phenotype of significantly higher levels of total serum cholesterol, HDL cholesterol, and apoA-I mRNA. After 6 months of age, these mice exhibit a phenotype of increased body fat and increased hepatic fatty acids, visualized as lipid vesicles in the parenchyma. Unlike wild-type mice, the PPAR-α null animals do not respond to fibrate challenge with an induction of enzymes responsible for fatty acid oxidation. Neither is there a reduction in serum TGs or total serum cholesterol, further illustrating the role of PPAR-α in lipid homeostasis.

The formation of atherosclerotic lesions involves the recruitment of monocytes and their activation to macrophages, followed by their incorporation into the arterial wall via the vascular cell adhesion molecule 1 (VCAM-1). As the lesion progresses, macrophages become laden with cholesterol esters (foam cells) and a fibrous cap is formed from vascular cells and cell debris. Concurrent with this process is a local inflammatory response involving plasma cytokines such as interleukin-1β (IL-1β), interleukin-6 (IL-6), and tumor necrosis factor α (TNFα), as well as the proinflammatory eicosanoid LTB4. As atherosclerotic plaques mature, they protrude into the arterial lumen, restricting circulation. Rupture of these plaques results in thrombosis, which can cause myocardial infarctions and/or stroke.

PPAR-α is expressed in human monocytes, macrophages, endothelial cells, and vascular smooth muscle cells of atherosclerotic lesions. PPAR-α agonists can improve the outcome of atherosclerosis in a number of ways. One mechanism is the down-regulation VCAM-1 expression in human vascular endothelial cells, thus reducing the formation of lesions. Numerous *in vitro* studies have also shown that PPAR-α activators can inhibit the expression of the inflammatory cytokines IL-6 and IL-1β in a PPAR-α-dependent manner. In addition, arachidonic acid-induced ear-swelling in mice shows that the inflammatory response is prolonged in PPAR-α null mice compared to wild-type mice. However, the most relevant data for humans come from clinical trials in which coronary artery disease (CAD) patients treated with fibrates for several years show reduced prevalence of recurrent myocardial infarction.

IV. PPAR-γ AND DISEASE TARGETS

A. Characterization and Ligands

PPAR-γ, the most extensively studied PPAR isoform, has been cloned from a wide variety of species, including *Xenopus*, mice, hamsters, rhesus monkeys, and humans. The level of amino acid conservation across species is highest (95% identity between murine and human receptors) for this isoform. The human PPAR-γ gene has been mapped to chromosome 3p25. PPAR-γ is expressed at high levels in adipose tissue and is a key regulator of fatty acid metabolism and adipocyte differentiation. Recently, PPAR-γ was found to be expressed in foam cells of atherosclerotic plaques, implying a role for this receptor in cardiovascular disease. The three PPAR-γ mRNA isoforms that have been identified in humans, γ1, γ2, and γ3, differ by alternate promoter usage and splice variants. PPAR-γ1 and PPAR-γ3 encode the same protein whereas PPAR-γ2, a splice variant of PPAR-γ1, has an additional 30 amino-terminal amino acids encoded by one exon. The expression pattern of these three isoforms is regulated in a tissue-specific manner. PPAR-γ1 is expressed in a wide range of tissues, including skeletal muscle, heart, colon, intestines, kidney, pancreas, and spleen. PPAR-γ2 is expressed primarily in adipose tissue, where it is the predominant isoform. PPAR-γ3 expression has been detected only in adipose tissue, macrophages, and colon epithelia. Presently, the functional significance of the two protein isoforms and their differential tissue expression is unclear.

PPAR-γ can be activated at micromolar affinity by a range of natural ligands (Fig. 5), including the fatty acids linoleic acid, arachidonic acid, and eicosapentaenoic acid; the 9- and 13-hydroxyoctadecadienoic acids (9-HODE and 13-HODE) that are generated from the conversion of linoleate by 15-lipoxygenase are micromolar PPAR-γ agonists. Additionally, the prostaglandin (PG) derivatives, most notably 15-deoxy-$\delta^{12,14}$-PGJ2, PGH1, and PGH2, have activation affinities of $<10\ \mu M$ on the PPAR-γ receptor. The affinities of these natural ligands are within the range of levels normally seen in human serum. However, the physiological level, chemical form, or specificity of these ligands in target cells is not known. Recently, the most potent natural ligand for PPAR-γ, the oxidized alkyl phospholipid, hexadecyl azelaoyl phosphatidylcholine (azPC), was identified and

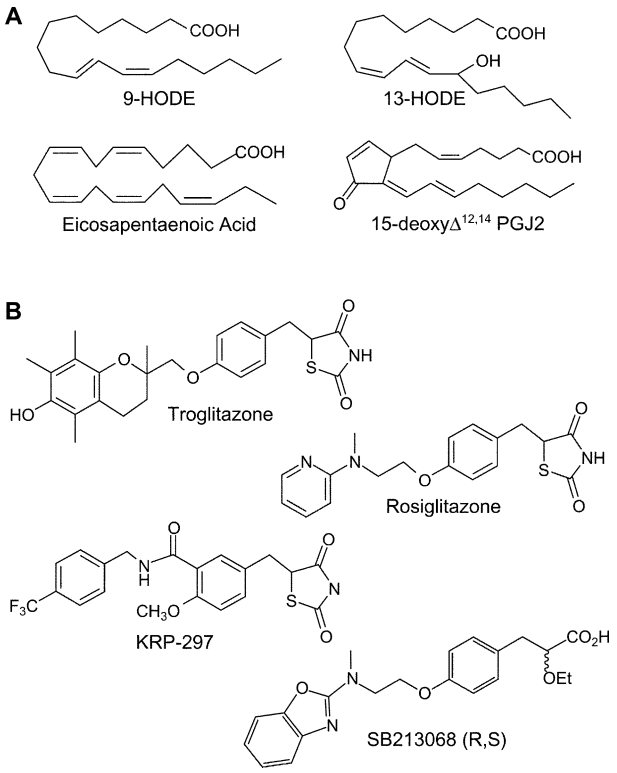

FIGURE 5 The structures of various natural (A) and synthetic (B) PPAR-γ ligands. 9- and 13-HODE, 9- and 13-Hydroxyoctadecadienoic acids; 15-deoxy-$\Delta^{12,14}$-PGJ2, 15-deoxy-$\Delta^{12,14}$-prostaglandin J2.

characterized as a ~40 n*M* activator. Hexadecyl azPC is formed by oxidation of low-density lipoprotein (LDL) phospholipid particles, which are believed to initiate and maintain vascular inflammation during atherogenesis, linking the expression of PPAR-γ in this disease process to a relevant ligand.

Numerous potent synthetic ligands spanning a range of structural classes have been identified as PPAR-γ agonists. The thiazolidinediones (TZDs), also termed "glitazones," were the first class reported. TZDs were identified through empirical compound screening in insulin-resistant, diabetic rodents and have since been developed as insulin-sensitizing agents in humans. Compounds included in this class are troglitazone, pioglitazone, and rosiglitazone, which have affinities ranging from 20 to 100 n*M* for the human and murine receptors. These TZDs are relatively selective for PPAR-γ, but a newer TZD, KRP-297, binds potently to both PPAR-γ and PPAR-α. Recently, another compound class has been identified, the α-alkoxy-β-phenylpropionates, represented by SB 236636 and SB 213068, which are potent PPAR-γ agonists with significant PPAR-α activity. Several nonsteroidal anti-inflammatory drugs (NSAIDs) such as indomethacin and fenoprofen have also been found to activate PPAR-γ and PPAR-α at micromolar concentrations and are able to induce adipocytic differentiation *in vitro*.

B. Type 2 Diabetes

The most extensive use for PPAR-γ agonists is in the treatment of type 2 diabetes in humans. The synthetic TZDs were the first class of compounds shown to have a direct correlation between their *in vitro* potency and their efficacy as insulin sensitizers in diabetic animal models and humans. TZDs increase the sensitivity of target tissues (adipose tissue, liver, and muscle) to the action of insulin. Thus, they improve glucose disposal and inhibit hepatic glucose production, thereby reducing plasma glucose levels. Since 1995, several TZDs have been approved for treatment of patients with type 2 diabetes (troglitazone, rosiglitazone, and pioglitazone), resulting in a major therapeutic advancement in treatment for a metabolic disorder that affects approximately 28 million people worldwide. In March 2000, troglitazone was removed from the market due to idiosyncratic hepatotoxicity, severe enough in some patients to require liver transplants or to cause death. These severe adverse effects have not been seen with rosiglitazone or pioglitazone.

PPAR-γ is expressed at highest levels in adipose tissue, where it has been studied extensively. However, very few PPAR-γ target genes have been identified to explain adequately a mechanism for insulin-sensitizing effects of TZDs. In isolated human adipocytes, rosiglitazone increases expression of p85-α phosphatidylinositol 3-kinase (p85-α PI3K) mRNA, a component of the insulin signaling pathway. Insulin receptor substrate-2 (IRS-2), a key intracellular substrate in the insulin signaling pathway, has also been demonstrated to be increased in cultured adipocytes and human adipose tissue treated with PPAR-γ agonists.

In adipose tissue, PPAR-γ regulates the transcription of several PPAR-responsive genes encoding lipogenic proteins and proteins involved in the differentiation of adipocytes. These genes include the adipocyte fatty acid-binding protein (aP2), phosphoenolpyruvate carboxykinase (PEPCK), lipoprotein lipase (LPL), and the fatty acid transporters FATP and CD36. Currently, it is speculated that altering the expression of fat cell genes may, through a secondary mechanism, result in insulin sensitization of muscle and liver. Confirming this hypothesis, an

insulin-resistant, hyperglycemic transgenic mouse model in which adipose tissue has been ablated fails to show significant glucose lowering when treated with a TZD.

PAR-γ null mice have been generated. However, they demonstrate an embryonic lethal phenotype at approximately day 10 of gestation due to severe defects in placental development and myocardial thinning. Studies performed using PPAR-γ-deficient stem cells to generate chimeric mice have shown that PPAR-γ is required for differentiation of adipose tissue. Surprisingly, PPAR-γ heterozygous mice fed a high-fat diet show decreased fat mass, smaller adipocytes, and improved insulin sensitivity relative to wild-type mice. In humans, three individuals with severe insulin resistance have been found to have two different heterozygous loss-of-function (and dominant-negative) mutations in helix 12 of the PPAR-γ ligand-binding domain (P467L and V290M). These mutations also result in the development of type 2 diabetes at an early age.

C. Atherosclerosis

Monocytes and macrophages are key cell types involved in the immune response. They act by releasing inflammatory cytokines such as IL-1β, IL-6, and TNF α, along with inducible nitric oxide synthase (iNOS), an enzyme responsible for the production of a potent oxidant, nitric oxide (NO). These cell types are also important early mediators in the pathogenesis of atherosclerosis. PPAR-γ has been shown to be significantly up-regulated during the differentiation of monocytes into macrophages, and has been found to be expressed in cholesterol-laden, macrophage-derived foam cells within atherosclerotic lesions. Current evidence shows that PPAR-γ agonists may exert both pro- and anti-atherogenic effects via the expression of macrophage genes involved in atherosclerosis. Treatment of macrophages with TZDs and an RXR agonist *in vitro* increases the expression of the class B scavenger receptors, CD36 and SR-B1, involved in the transport of oxidized LDL (Ox-LDL) cholesterol particles into foam cells. In addition, the Ox-LDL-derived products 9- and 13-HODE are PPAR-γ activators, suggesting a positive feedback loop for a pro-atherogenic effect. On the other hand, TZDs have variably been reported to down-regulate the expression of potentially pro-atherogenic proteins, including matrix metalloproteinase-9 (MMP-9; also named gelatinase B, an enzyme implicated in atherosclerotic plaque destabilization) and scavenger receptor class A (SR-A), along with vascular cell adhesion molecule-1(in vascular cells. Patients treated with troglitazone show a reduction in plasminogen activator inhibitor type 1 (PAI-1), a serine protease inhibitor that promotes thrombosis. These data suggest an anti-atherogenic effect of PPAR-γ agonists. Given that the net effects of PPAR-γ agonist treatment in mouse models of atherosclerosis are to reduce lesion formation, it is hoped that chronic treatment of humans will produce similar effects. However, current clinical data have not yet substantiated this hypothesis.

D. Cancer

PPAR-γ is expressed in a variety of human tumors, including lung carcinoma, breast adenocarcinoma, prostate carcinoma, liposarcoma, renal cell carcinoma, and colorectal carcinomas, in addition to a wide range of human cancer cell lines. PPAR-γ activators have been shown to inhibit the proliferation of fibroblasts *in vitro* during differentiation into normal preadipocytes, leading to the hypothesis that PPAR-γ agonists play a role in inhibiting the growth of adipose tissue-derived carcinoma. This has been demonstrated in metastatic human liposarcoma, a soft tissue malignancy that responds poorly to conventional therapies. Terminal differentiation of this malignant growth cell type has been achieved *in vitro* by treatment with the PPAR-γ activator pioglitazone and an RXRα-specific agonist. In addition, clinical troglitazone treatment of patients suffering from advanced liposarcomas results in inhibition of cell proliferation and terminal differentiation of the solid tumor.

PPAR-γ activators have also been shown to inhibit proliferation of human prostate cells *in vitro*, and patients with advanced prostate cancer treated with troglitazone have a decrease in prostate-specific antigen, a marker for prostate cancer. In human mammary adenocarcinomas, PPAR-γ is also expressed at significant levels and agonists have been reported to inhibit growth and induce terminal differentiation of malignant breast epithelial cells. Although PPAR-γ is expressed in human colonic polyps, primary colon tumors, and colon cancer cell lines, conflicting data as to the benefits vs proneoplastic effects of agonism have been generated from various animal and cellular models of this disease. Further investigation is needed to elucidate the role PPAR-γ may have in cancer and the mechanism by which TZDs exert their antiproliferative effects.

V. PPAR-δ AND DISEASE TARGETS

A. Characterization and Ligands

PPAR-δ, first cloned in 1992 from *Xenopus*, was initially given the name PPAR-β. Subsequently, in various labs it was cloned from humans and mice and was named NUC1 and PPAR-δ, FAAR, or NUC1, respectively. The current accepted nomenclature for all species is now PPAR-δ. The amino acid homology between human and rodent PPAR homologues is 90% in the LBD. The human PPAR-δ gene has been mapped to chromosome 6p21.1–p21.2. PPAR-δ is ubiquitously expressed in adult rat tissues. It has been reported to be expressed in human liver, intestine, kidney, skeletal muscle, brain, abdominal adipose, and skin. Presently, no specific target genes for PPAR-δ have been identified and studies to elucidate its physiological role have just recently begun to emerge.

PPAR-δ binds naturally occurring saturated and unsaturated fatty acids, as well as to their metabolites, including dihomo-γ-linolenic acid, eicosapentaenoic acid, and arachidonic acid, with affinities in the low micromolar range (Fig. 6). Synthetic ligands include L-165041, a compound with 10- to 30-fold selectivity for human PPAR-δ vs PPAR-γ. Recently, GW501516 has been identified as a potent PPAR-δ agonist. This compound is selective for the human, rhesus monkey, and mouse PPAR-δ subtypes vs other nuclear receptors.

B. Dyslipidemia

In *db/db* mice, which serve as a model of type 2 diabetes (increased serum TGs, glucose, and insulin), L-165041 causes a modest increase in HDL at a dose that does not cause TG or glucose lowering. GW501516 has been studied in a population of obese rhesus monkeys with metabolic parameters similar to those in humans with metabolic syndrome (dyslipidemia, insulin resistance, hyperinsulinemia, and hypertension). In this model, GW501516 induces a significant increase in HDL-cholesterol levels along with a reduction in TG. Elevated levels of plasma insulin are also suppressed by GW501516 treatment, whereas serum glucose levels are unaffected. These results suggest that PPAR-δ agonists may prove useful in the treatment of dyslipidemia, but it is important to note that this was a limited study with respect to species and compounds. The role of PPAR-δ in dyslipidemia requires further investigation.

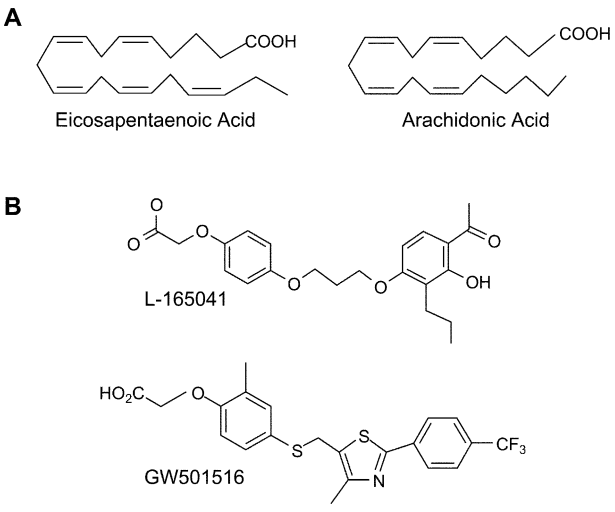

FIGURE 6 The structures of various natural (A) and synthetic (B) PPAR-δ ligands.

C. Fertility

In mice, PPAR-δ is the only PPAR subtype expressed at the site of blastocyst implantation. Expression is induced in the stromal layer surrounding the implanting blastocyst and in the decidual layer following implantation. The same expression pattern is seen for cyclooxygenase 2 (COX-2). COX-2 is the rate-limiting enzyme involved in the synthesis of prostaglandins. Several prostaglandins generated from the COX-2 biosynthetic pathway, such as prostacyclin, are PPAR-δ ligands. COX-2 null mice have defects resulting in reduced implantation and decidualization. Treatment of COX-2 null mice with a natural PPAR-δ agonist, carbaprostacyclin, or the synthetic PPAR-δ agonist L-165041, restores implantation to normal in these animals. When PPAR-δ heterozygous null mice are bred, fewer than expected null offspring are produced, indicating that although PPAR-δ may play a role in implantation and fertility, it is not essential.

D. Cancer

PPAR-δ has been recently identified as a downstream target in a pathway involved in colorectal carcinogenesis. PPAR-δ mRNA expression is up-regulated in many human and rodent colon carcinomas. During the development of colorectal carcinoma, an inactivation mutation in the adenomatous polyposis coli (APC) gene occurs. This mutation causes an increase in β-catenin, a cytoplasmic protein involved in cellular adhesion and development. β-Catenin forms complexes with a protein called T-cell factor 4 (TCF-4), which binds DNA and induces genes

involved in cellular proliferation. β-Catenin/TCF-4 complexes can bind and activate the PPAR-δ promoter and have been shown to up-regulate the expression of PPAR-δ in colon carcinoma cells. A human colorectal cancer cell line, HCT116, in which the PPAR-δ gene is deleted, was established and injected as xenografts into nude mice. In this model, the PPAR-δ null cells result in fewer tumors with slower progression compared to xenografts of wild-type HCT116 cells. Taken together, these data suggest that inhibition of PPAR-δ expression or function by antagonists may result in colon tumor suppression.

E. Central Nervous System

The expression of PPARs during rat embryonic development, assessed by *in situ* hybridization, shows that PPAR-δ is expressed ubiquitously and earlier in development than PPAR-α or PPAR-γ. Interestingly, PPAR-δ is expressed in embryonic tissues at much higher levels compared to the other isoforms, in sharp contrast to expression levels in adult tissues. Peak expression of PPAR-δ occurs at embryonic day 13.5 (E13.5) in tissues of the developing nervous system, suggesting an important role for this subtype in differentiation of cells within the CNS. *In vitro*, PPAR-δ mRNA is expressed in immature murine oligodendrocytes. These are the major lipid-producing cells in the CNS that differentiate into cells with myelin sheets. Treatment of neonatal primary glial cell cultures, which contain immature oligodendrocytes, with the PPAR-δ selective agonist L-165041 results in accelerated differentiation of oligodendrocytes, increased processes, and the formation of membrane sheets. *In vivo*, PPAR-δ null mice have alterations in the extent of myelination in the corpus collosum compared to wild-type controls. This subregion normally expresses high levels of PPAR-δ.

VI. SUMMARY

Data have emerged over the past decade showing the involvement of the three PPAR isoforms as sensors for fatty acids and lipid metabolites in metabolically active tissues. In these tissues, PPARs transcriptionally regulate target genes that play critical roles in lipid metabolism. Therapeutic use of the fibrates in humans has validated the efficacy of PPAR-α agonists in improving hypertriglyceridemia and reducing the risk for atherosclerosis and subsequent myocardial infarctions. Both the TZD and the more recently identified non-TZD PPAR-γ agonists have been shown to improve insulin sensitivity and lower serum glucose in patients with type 2 diabetes, a metabolic disorder of epidemic proportions in westernized cultures. In addition, PPAR-γ agonists have demonstrated provocative effects in animal models, implying that there is great potential for their use in treating or preventing atherosclerosis in humans. The role of PPAR-γ in cancer is just emerging. Further investigation is needed to elucidate the mechanisms of action by which this receptor positively impacts on these disease states. PPAR-δ, the isoform for which only limited data have emerged, may have therapeutic utilities in such diverse disorders as dyslipidemia, fertility, cancer, and demyelinating CNS diseases. Specific, potent ligands are being identified that will allow a deeper understanding of the pleiotropic effects of the PPARs.

Glossary

adipocytes Cells that store energy in the form of triglycerides and release energy as free fatty acids during periods of nutritional deprivation.

atherosclerosis Condition caused by progressive thickening and hardening of the walls of medium-sized and large arteries as a result of extensive fat and cellular deposits on their inner lining, ultimately leading to arterial occlusion.

fatty acid Long-chain aliphatic carboxylic acid found in fats, oils, membrane phospholipids, and glycolipids.

hormone receptor Protein in or on the surface of target cells; functions as a sensor for the hormone by binding the hormone and initiating a cellular response.

ligand Small molecule that binds specifically to a larger one; for example, a hormone is the ligand for its specific protein receptor.

metabolic syndrome Condition defined by insulin resistance, hyperinsulinemia, and dyslipidemia (generally elevated serum triglycerides and decreased high-density lipoprotein cholesterol).

peroxisome Subcellular organelles in the cytoplasm of eukaryotic cells; involved in the β-oxidation of long-chain fatty acids.

type 2 diabetes One of the two major types of diabetes, in which the beta cells of the pancreas produce insulin but the body is unable to use it effectively because the target cells have become resistant to the action of insulin.

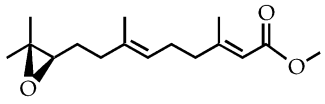
Pheromone Production in Insects

GARY J. BLOMQUIST
University of Nevada

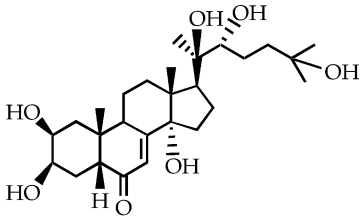
The production of pheromones can be regulated by hormones from the brain, ovary, and corpora allata. In insects, at least three different hormones have been shown to regulate pheromone production: pheromone biosynthesis-activating neuropeptide, juvenile hormone, and ecdysteroids. This article discusses several model insect systems of endocrine regulation of pheromone biosynthesis.

I. INTRODUCTION

The observation that females of certain species have repeated reproductive cycles and that mating occurs only during defined periods of each cycle led to the proposal that pheromone production might be under hormonal control. Studies on a limited number of species demonstrate that pheromone production can be under the regulation of products of the brain, ovary, and corpora allata (CA). At least three distinct hormones have been shown to regulate pheromone production in insects. In many female moths (Lepidoptera), pheromone biosynthesis is regulated by a 33- or 34-amino-acid pheromone biosynthesis-activating neuropeptide (PBAN) (Fig. 1). PBAN alters enzyme activity at one or more steps during or subsequent to fatty acid synthesis during pheromone production. In some species of Coleoptera, Blattodea, and Lepidoptera, juvenile hormone (JH) (Fig. 1) induces pheromone production. In the female housefly, ovarian produced ecdysteroids (Fig. 1) regulate



Juvenile hormone III



20-Hydroxyecdysone

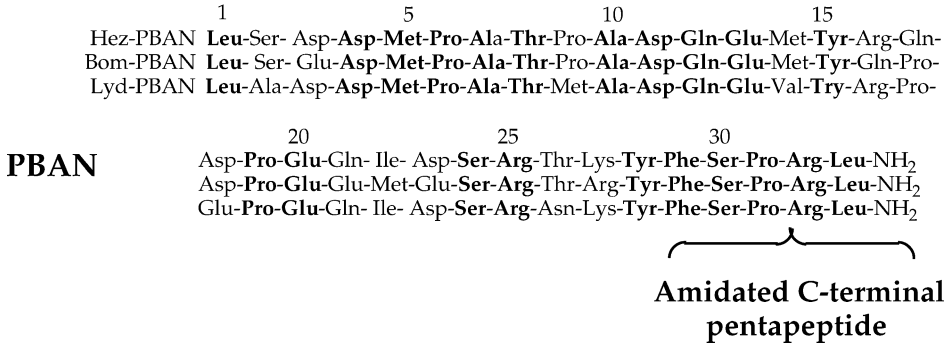


FIGURE 1 Structures of juvenile hormone, 20-hydroxyecdysone, and PBAN.

the chain length of cuticular alkenes so that the pheromone component (*Z*)-9-tricosene (muscalure) becomes a major product. It appears that JH induces key regulatory enzymes, whereas ecdysteroids repress specific enzymes to result in pheromone production. Discussed below is work from a limited number of model insect systems in which endocrine regulation of pheromone production has been most extensively studied. It is not by any means an exhaustive list, and excellent work in other insects has been done. Studies on the endocrine regulation of pheromone production to date have utilized relatively few species, and large gaps in our knowledge are readily apparent.

II. PBAN REGULATION IN LEPIDOPTERA

A pheromone biosynthesis-activating neuropeptide was first purified and sequenced from *Heliothis zea* in 1989 by Ashok Raina and co-workers. PBANs from other lepidopterans, including *Bombyx mori*, *Lymantria dispar*, *Agrotis ipsilon*, and *Helicoverpa assulta*, have subsequently been isolated and identified. All of the PBANs examined to date are 33- or 34-amino-acid peptides that share approximately 80% homology and an amidated C-terminus. The minimum sequence necessary for biological activity is the C-terminal pentapeptide (Phe-Ser-Pro-Arg-Leu-NH_2), although the activity of this pentapeptide is an order of magnitude or so lower than that of the intact peptide.

It is becoming clear that in most moths PBAN is released into the hemolymph and acts directly on the pheromone gland to stimulate pheromone biosynthesis. There is evidence, however, that in some species PBAN undergoes neural transport. Regardless, PBAN is produced in the subesophageal ganglia and transported to the corpora cardiaca (CC). In most species, PBAN is then released from the CC (a neurohemal organ) and transported through the hemolymph to the pheromone gland.

The proposed direct mechanism of PBAN involves the binding of PBAN to a specific pheromone gland receptor (Fig. 2). This triggers second messengers, including Ca^{2+} and cyclic AMP, and may involve phosphatidyl inositol. The steps in pheromone biosynthesis that are regulated by PBAN have been examined, and in some species it appears that PBAN increases acetyl coenzyme A (acetyl CoA) carboxylase activity and in others it may affect the reduction of fatty acyl groups to aldehydes and alcohols or other steps in pheromone biosynthesis.

Although PBAN and PBAN-like peptides have been found in all Lepidoptera examined to date as

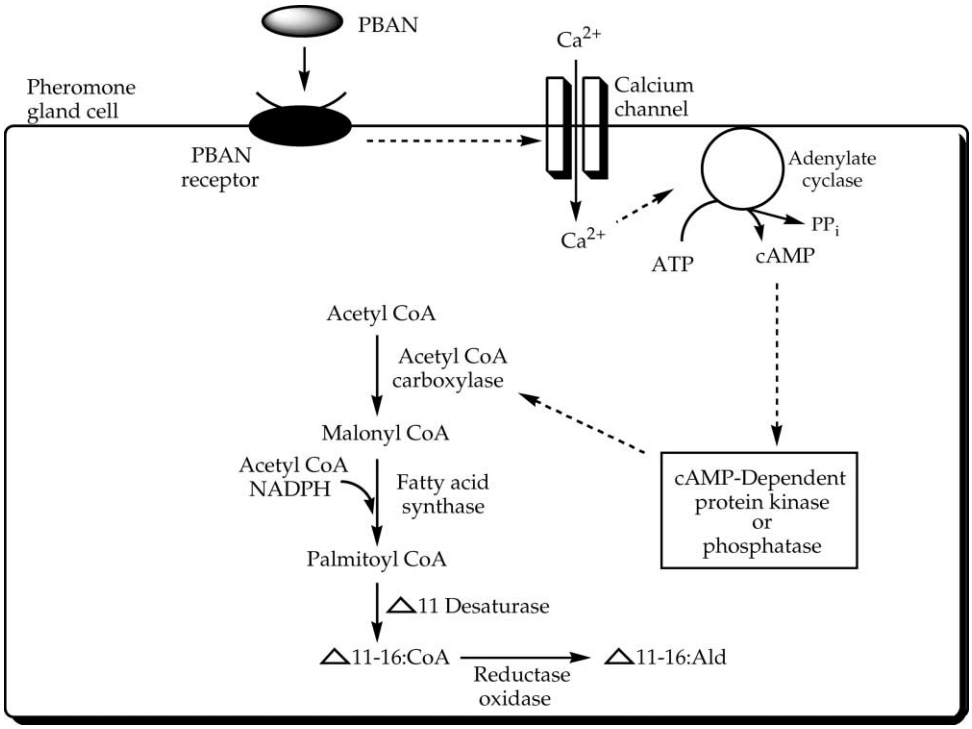

FIGURE 2 Proposed mode of action of PBAN on pheromone production in *Helicoverpa zea*.

well as insects from other orders, in some species they do not appear to regulate pheromone production. For example, in *Trichoplusia ni*, the pheromone gland becomes competent to produce pheromone at adult eclosion and pheromone production continues unregulated for the duration of the life of the female. In some Lepidoptera, JH and ecdysteroids are involved in regulating pheromone production, in some cases apparently regulating PBAN release.

III. JUVENILE HORMONE REGULATION IN COLEOPTERA

Coleoptera (beetles) produce and/or emit pheromones in response to various environmental or physiological factors, with JH often being involved. In many insect species, JH induces vitellogenin production and coordinates other reproductive events, so it is not unexpected that it can also affect pheromone production. A key question for certain species, especially bark beetles, is whether JH stimulates the conversion of host precursors to pheromone or whether it stimulates *de novo* pheromone synthesis. Recent findings, primarily with the pine engraver, *Ips pini*, have demonstrated that JH III can directly induce *de novo* pheromone production.

Perhaps the most complete picture of JH regulation of pheromone production occurs in *I. pini*. Radiotracer studies with male *I. pini* monitoring *in vivo* incorporation of radiolabeled acetate into ipsdienol showed that incorporation increased with increasing topical JH III dose. The *in vivo* incorporation of radiolabeled mevalonolactone into ipsdienol by male *I. pini* was not affected by increasing JH III dose, indicating that the JH regulation of isoprenoid pheromone production occurred at steps between acetyl CoA and mevalonate (Fig. 3). Subsequent studies showed that feeding or topical application of JH III induces the mRNA transcript for 3-hydroxy-3-methylglutaryl CoA reductase (HMG-R) 20- to 30-fold. The emerging picture for this insect is that feeding stimulates JH III production, which in turn induces HMG-R transcript and enzyme activity, resulting in a large increase in pheromone production (Fig. 3). HMG CoA synthase transcript was increased only several fold by JH III, indicating that the main regulatory step is HMG CoA reductase.

Using a mRNA probe to HMG-R, *in situ* hybridization on exposed whole mounts of JH-stimulated male *I. pini* demonstrated that the site of pheromone synthesis is midgut tissue. Furthermore,

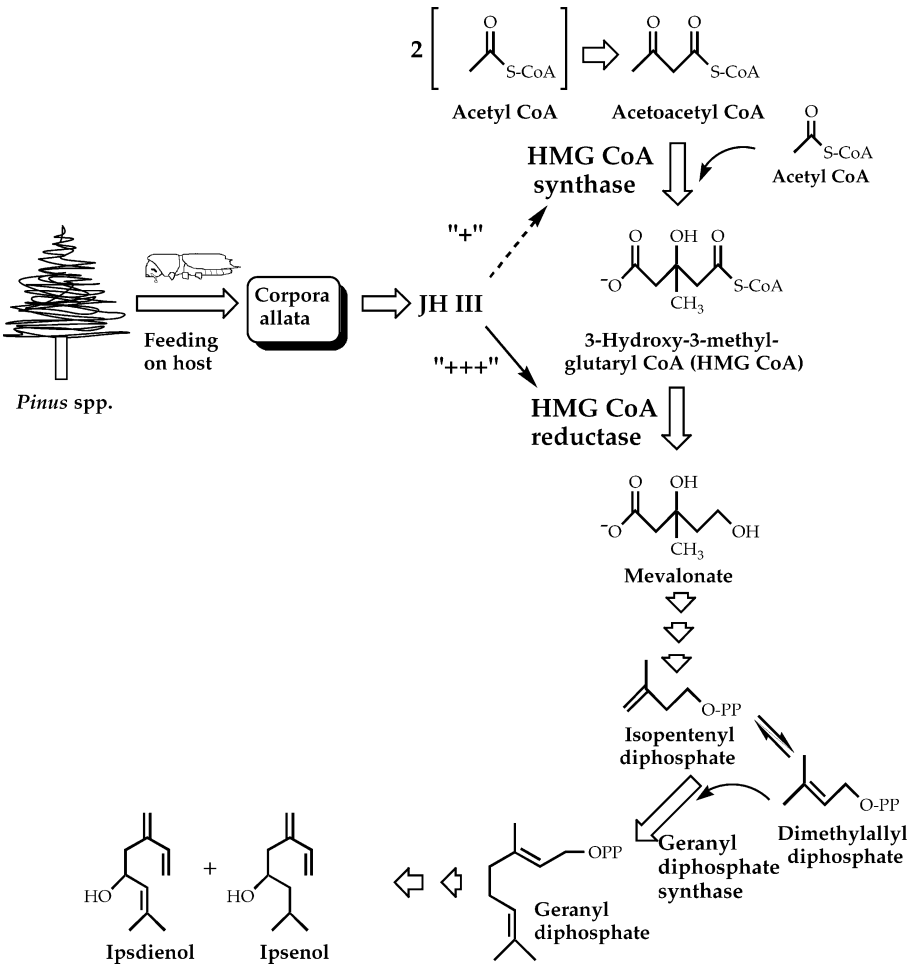

FIGURE 3 Current understanding of the ipsdienol and ipsenol biosynthesis in *I. pini* showing the proposed mode of action of JH III. The major regulatory step induced by JH III is HMG CoA reductase.

isolated midgut tissue incorporated labeled acetate into ipsdienol.

The molecular details of how JH affects transcription and ultimately, coleopteran pheromone biosynthesis, remain to be elucidated. Following release from the CA, lipophilic JH binds to a specific protein (the JH-binding protein) for transport through the aqueous hemolymph and protection from degradative enzymes. Once at the target tissue for pheromone biosynthesis, it would most likely cross the cell membrane and bind to intracellular receptors, although JH has been shown to act at the membrane level in some systems. The isolation and identification of an intracellular receptor for JH remain elusive and controversial. Although it is tempting to extend the intracellular molecular mode of action for steroidal hormones to JH, the diverse physiological phenomena regulated by JH may suggest a more complex interplay involving an ensemble of regulatory proteins or transcription factors with the putative JH receptor. The large induction of HMG-R transcript by JH apparently acting alone (without the involvement of ecdysteroids as occurs during development) makes the *I. pini* system an attractive model for elucidating the mode of action of JH.

IV. JUVENILE HORMONE REGULATION IN BLATTODEA

By far the best studied and most understood example of JH regulation of pheromone production in the Blattodea was done by Schal and collaborators in female German cockroaches, *Blattella germanica*. *In vivo* synthesis of the contact sex pheromone, 3,11-dimethylnonacosan-2-one (3,11-DMN:Ke) and its accumulation on the cuticle are correlated with the

in vitro synthesis of JH III by the CA and oocyte development, suggesting common JH regulation of sex pheromone production as well as other reproductive events. Comparison of the patterns of pheromone and hydrocarbon production in starved, allatectomized, and head-ligated females, as well as in females rescued with hormone replacement therapy, suggests two mechanisms of regulation of sex pheromone production: (1) hormonal, a JH-induced conversion of the hydrocarbon precursor to the oxygenated sex pheromone that is related to the CA cycle and oocyte development, and (2) nonhormonal, a JH-independent process, probably related to feeding, that supplies precursors for hydrocarbon (pheromone) biosynthesis.

Dependence of pheromone synthesis on JH levels in female *B. germanica* is supported by the following findings: (1) the pattern of accumulation of 3,11-DMN:Ke and 3,11-dimethylheptacosan-2-one (minor pheromone component) on the cuticle correlates with the pattern of JH synthesis through two gonotropic cycles; (2) the rates of synthesis of methyl ketones, using labeled propionate, correspond to rates of JH synthesis; and (3) pheromone production declines in allatectomized females or females with experimentally inhibited CA (e.g., starved, protein-deprived, ootheca implanted), whereas juvenile hormone analogue (JHA) treatment restores pheromone production in these females.

Whereas pheromone production is completely suppressed in individuals of other allatectomized cockroach species, allatectomized female *B. germanica* produce a small quantity of pheromone. Because JHAs are also less effective inducers of pheromone production in unfed female *B. germanica*, it was hypothesized that feeding might indirectly influence pheromone production by influencing the availability of pheromone precursor (hydrocarbon), and results from recent studies support this hypothesis.

V. ECDYSTEROID REGULATION IN DIPTERA

In several species of Diptera, ecdysteroids have been shown to regulate the female reproductive process of vitellogenesis. Ecdysteroids also regulate sex pheromone production in the female housefly, *Musca domestica*. Pheromone biosynthesis normally begins approximately 2 days after emergence to adult in female *M. domestica*. However, ovariectomy of newly emerged females prevents pheromone biosynthesis. Pheromone production can be restored in ovariectomized females by implantation of ovaries or injection of 20-hydroxyecdysone (20-HE). These and other studies have led to the conclusion that sex pheromone production in female *M. domestica* is regulated by ecdysteroids.

Male houseflies normally do not produce significant amounts of (*Z*)-9-tricosene or its oxygenated products. However, implantation of ovaries or treatment with 20-HE induces the production of the female sex pheromone. Immature females and males of all ages normally produce cuticular alkenes of 27 carbons or more. Since 20-HE appears to be a product of the mature ovary in adult houseflies, adult males normally are not exposed to 20-HE. Treatment with 20-HE induces pheromone synthesis, indicating that the male has the biosynthetic machinery to produce pheromone.

An in-depth study of the biochemistry of pheromone production in the housefly led to an understanding of the enzyme activity affected by 20-HE. The endocrine-mediated induction of sex pheromone biosynthesis in the housefly involves a change in the fate of tetracosenoyl CoA (*Z*15-24:CoA) from one of elongation to one of reduction to the aldehyde and then decarboxylation to the main sex pheromone component, (*Z*)-9-tricosene (*Z*9-23:Hy) (Fig. 4). The two most likely regulatory points where 20-HE could exert its effect were (1) the fatty acyl CoA elongation step(s) and/or (2) the reductive conversion of fatty acyl CoA to hydrocarbon formation step(s). *In vitro* enzyme assays demonstrate that ecdysone predominantly affects the elongation enzyme(s) rather than the enzymes functioning in the conversion of *Z*15-24:CoA to *Z*9-23:Hy (Fig. 4). It appears that 20-HE exerts its effect primarily if not exclusively by repressing the fatty acyl CoA elongase that converts 24:1-CoA to longer chain fatty acids, resulting in the build up of 24:1-CoA, which is then reduced to the aldehyde and decarboxylated to (*Z*)-9-tricosene (muscalure). A portion of the (*Z*)-9-tricosene is then converted to epoxide and ketone, both of which function in the female sex pheromone (Fig. 4).

As is the case with JH III and coleopteran pheromone biosynthesis, the molecular details of how 20-HE influences the enzymatic reactions in dipteran pheromone biosynthesis remain to be elucidated. By analogy to steroidal hormones in other systems, it is reasonable to hypothesize that gene expression would be regulated for key biosynthetic enzymes, in this case repression of a specific fatty acyl CoA elongase. In general, steroid hormones such as 20-HE are thought to diffuse freely through the cell membrane into the cytoplasm and/or nucleus to bind specific intracellular hormone receptors. A dimerized

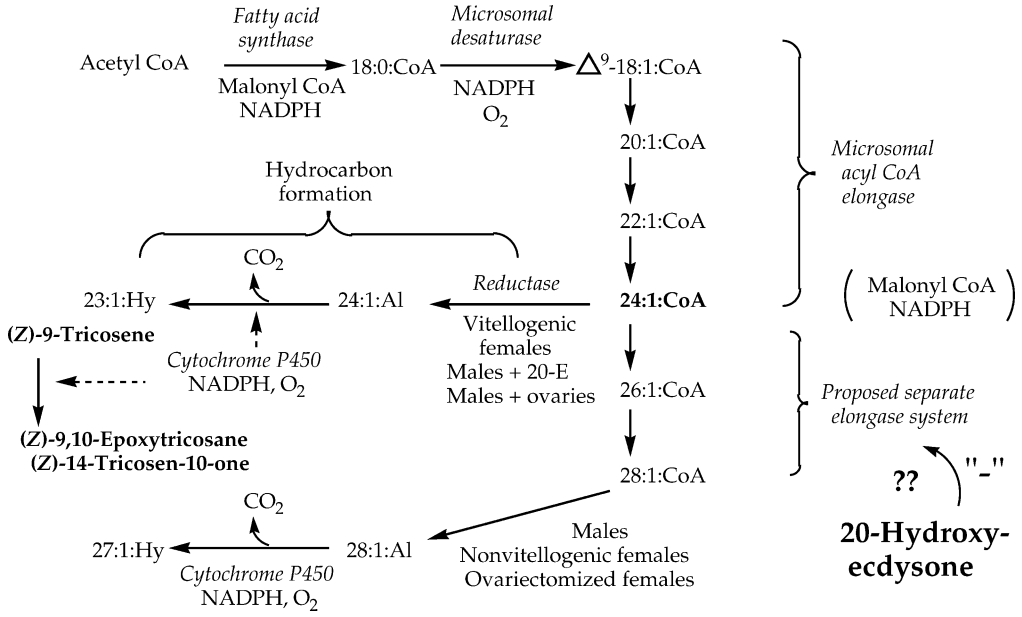

FIGURE 4 Biosynthetic pathway for the housefly pheromone showing the proposed site of action of 20-HE. Reprinted from Tillman *et al.* (1999), with permission from Elsevier Science.

form of the receptor–ligand complex then binds to specific DNA sequences called hormone-responsive elements to affect gene expression. Although the motivation for their study has been insect morphogenesis, ecdysteroid receptors have been isolated from species of Diptera, Lepidoptera, and Coleoptera. These receptors occur in a surprising variety of isoforms and this may have implications for the regulation of pheromone biosynthesis in the Diptera.

VI. CONCLUDING REMARKS

In no model pheromone biosynthetic system are the molecular mechanisms of hormonal regulation completely understood, and studies to address these obvious gaps in our understanding are being pursued in representative species. It is now clear that ecdysone and JH regulate pheromone production by inducing or repressing specific enzymes, but the molecular basis for these changes is not understood. A better understanding of the PBAN receptor and the biochemical steps regulated in pheromone production is needed. In no system are the exact enzymatic steps affected by the pheromone biosynthesis-regulating hormone known with certainty and completeness. Ultimately, just as behavioral chemicals themselves have been extended to pest management, research on pheromone biosynthesis and its hormonal regulation may be directed toward application and ultimately used in insect control.

Glossary

corpora allata Paired ganglia-like bodies often located just posterior to the corpora cardiaca. They synthesize and secrete juvenile hormone.

corpora cardiaca Paired neurohemal organs located behind the brain and often near the corpora allata. They release neurosecretory material from the brain, including pheromone biosynthesis-activating neuropeptide.

ecdysteroids Polyhydroxy steroids that induce molting during development in insects and that are also involved in reproductive processes in some adult insects, including Diptera.

juvenile hormones Sesquiterpenoids with epoxide and methyl ester functional groups produced by the corpora allata. They serve to keep the insect in the immature state during development and to coordinate reproductive events in many adult insects.

pheromone A chemical (or blend of chemicals) that is released by an organism and causes specific behavioral or physiological reaction(s) a in one or more conspecific individuals.

pheromone biosynthesis-activating neuropeptide A 33- or 34-amino-acid peptide produced in the brain that triggers pheromone production in many species of Lepidoptera.

subesophageal ganglion A large nerve center consisting of the fused ganglia of the original mandibular, maxillary, and labial segments, situated in the head, beneath the esophagus.

Phytoestrogens

ALICE L. MURKIES* AND MARK FRYDENBERG†

**Jean Hailes Centre for Women, Australia • †Monash University, Monash Medical Centre, Australia*

Phytoestrogens are plant compounds with binding affinity for the estrogen receptor and consequently have estrogen-like biological activity. Phytoestrogens have physiological effects in humans that vary depending on the phytoestrogens and tissue end-points examined. The most supportive data of the beneficial effects of phytoestrogens in humans are from the effect of soy protein on lipids, lipid profiles, and blood pressure. The active moiety appears to be present in whole foods, which have a greater physiological effect than subfractions or supplements. This article examines the classification and metabolism of phytoestrogens and discusses their biological activities in humans.

I. INTRODUCTION

Historically, estrogenic activity in plants has been referred to in folk medicine. The pomegranate is

associated with fertility, and hops were used by German clergy in the Middle Ages to lower fertility.

In 1923, the Allen Doisy bioassay for estrogens was published, and in 1926, plant extracts were reported to exhibit estrogenic activity. By 1975, several hundred plants were reported to have estrogenic activity on bioassay or to contain estrogenically active compounds. Phytoestrogens gained importance in the 1940s due to infertility in sheep grazing on pastures rich in subterranean clover in Western Australia later known as "clover disease."

Setchell reported measurement of urinary phytoestrogens in nonhuman primates in 1979 and in humans in 1982. Based on epidemiological studies, Adlercreutz has suggested that a diet rich in phytoestrogens as consumed by individuals in Asiatic and Mediterranean nations is associated with reduced risk of the so-called Western diseases such as breast and prostate cancer and cardiovascular disease.

Estrogenic activity has been reported in compounds produced by animals, plants, and microorganisms. Industrially manufactured chemicals, including plastics, household products, food packaging, and pesticides, such as DDT, contain weak estrogen-like compounds and are classified as xenoestrogens. These include organochlorine pesticides, polychlorinated biphenyls (PCBs), phenolic compounds, and phthlate esters. Deleterious effects of xenoestrogens have been hypothesized but not substantiated. Of concern are the long-half-life of these compounds and the persistence in fat tissue for many years. Adverse effects have been documented in wildlife but no direct evidence to show a cause and effect relationship has been reported in humans. The estrogenic potency of industrially derived estrogenic compounds is very limited, but the estrogenic potency of phytoestrogens is significant and the classification, metabolism, and biological effects in men and women and disease states will be the essence of this article.

II. CLASSIFICATION AND METABOLISM

There are three main classes of phytoestrogens found in plants or their seeds. Isoflavones and coumestans, also known as isoflavonoids, are synthesized within the plant itself. One plant can contain more than one category of phytoestrogen. The soybean contains predominantly isoflavones and the soy sprout is a rich source of coumestrol, the major coumestan. Lignans are formed from the action of gut microflora on the lignan precursors found in the plant wall. The resorcyclic acid lactones exhibit estrogenic activity and the active metabolites, zearalenone and zearalenol, are produced by molds that contaminate cereal crops and are better described as mycoestrogens (Fig. 1).

The major isoflavones, genistein and daidzein, exist as inactive glucosides genistin and daidzin. They are also derived from their respective methyl ethers biochanin A and formononetin and after breakdown by intestinal glucosidases are converted to genistein and daidzein. Daidzein can be further metabolized to equol and *O*-desmethylangiolensin (O-DMA).

The estrogenically active lignans enterodiol and enterolactone are derived from secoisolariciresinol and matairesinol plant precursors found in the aleuronic layer of the grain close to the fiber layer. Enterodiol can be oxidized to enterolactone.

In humans, after consumption of plant isoflavones and lignans, complex enzymatic metabolic conversions occur in the gastrointestinal tract by the microflora, resulting in the formation of heterocyclic polyphenols similar in structure to estrogen (Fig. 2). The absorbed phytoestrogen metabolites undergo enterohepatic circulation and may be excreted in the bile, deconjugated by intestinal flora, reabsorbed, reconjugated by the liver, and excreted in the urine.

Phytoestrogen metabolites have been measured predominantly in urine, in trace amounts in feces, and also in semen, bile, saliva, and breast milk. Measurement of urinary phytoestrogen excretion is considered a reliable indication of dietary phytoestrogen intake. Concentrations of metabolites can vary within individuals even in a controlled setting of isoflavone and lignan supplements. This is attributed to the variation in metabolism determined by gastrointestinal flora, antibiotic use, bowel disease, and concomitant dietary intake of fiber, fruit, and vegetables. Similarly, dietary fat, fiber, protein, alcohol, and micronutrients may affect endogenous estrogen metabolism.

Little is known about the metabolism of coumestans in humans.

III. FOOD SOURCES AND SAFETY

The isoflavones that exhibit estrogenic activity occur almost exclusively in legumes and beans, predominantly the soybean, and in derivative products that contain most or all of the bean.

Second-generation soy foods are produced by adding soy to other manufactured foods and thereby reducing the original isoflavone content, for example, soy yogurt and soy noodles. Lignans are widely

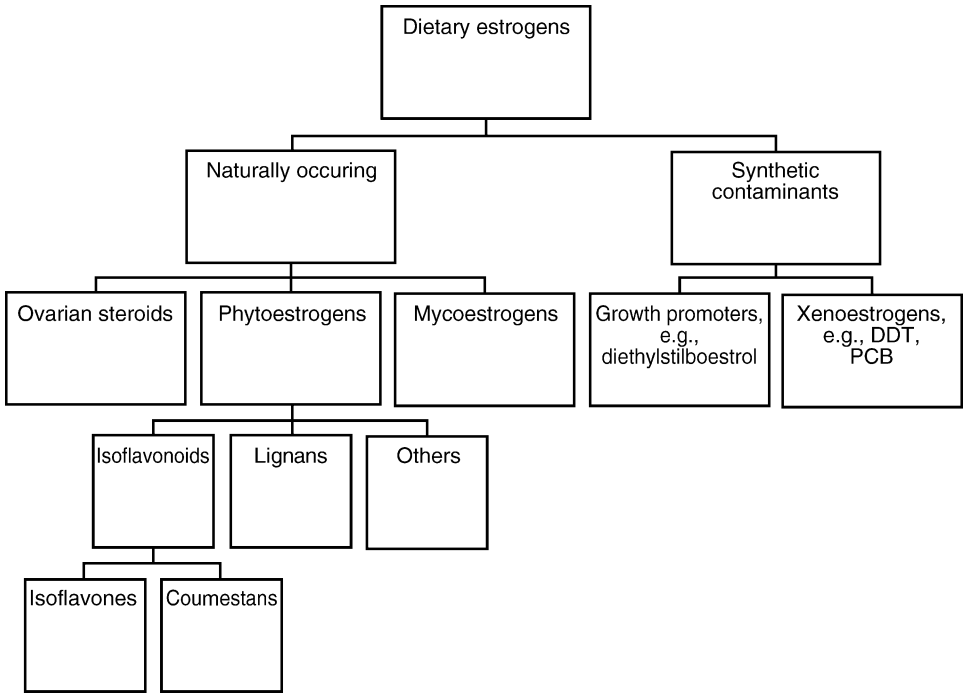

FIGURE 1 Sources and classification of dietary estrogens. Reprinted from Murkies, A.L., Wilcox, G., and Davis, S.R. Clinical review 92: Phytoestrogens. *J. Clin. Endocrinol. Metab.* **83**, 297–303, 1998, with permission. Copyright The Endocrine Society.

distributed in cereals, fruit, vegetables, and seeds, with the highest concentration in flaxseed.

Coumestans occur predominantly with germination, for example, in sprouting beans and fodder crops.

Resorcyclic acid lactone metabolites are produced by *Fusarium* species of mold found growing on crops stored under damp conditions. The compounds are concentrated in the seed hull and are predominantly removed in food processing.

Variation in phytoestrogen content in food can occur due to seasonal variation, genetic differences in plants, infection with fungal diseases, processing, and as part of the plant's defense mechanism.

Promotion of foodstuffs reported to contain a fixed phytoestrogen concentration cannot be substantiated because isoflavone content varies widely between strains in different soybean varieties and between locations of grown soybeans. Soy-enriched breads display a wide range of isoflavone content, from two- to threefold, within and between breads. Due to the natural variation of phytoestrogen concentration, it is probably not prudent for consumption of these foods to be based on isoflavone content alone in the belief that these are constant doses. Products derived from the whole bean such as soy flour, tofu, and soy milk have the highest concentration of isoflavones.

Phytoestrogens are considered beneficial rather than harmful to humans despite evidence from a number of animal species that phytoestrogen consumption can interfere with reproductive development and function. Observations of Asian societies that have consumed a phytoestrogen-rich diet for centuries and appear not to have any deleterious effects have led to a presumption that phytoestrogens may be safe. Consideration of the safety of phytoestrogens introduced into the adult diet is not unreasonable as up to 60% of processed foods may contain soy derivatives.

Macrobiotics and other vegetarians have the highest excretion values of lignans. Asian populations ares estimated to consume 20–150 mg/day of isoflavones, with a mean of 40 mg from tofu and miso. This can be achieved in Western diets with consumption of modest quantities of soy foods. Consumption of isoflavones in the United States has been estimated at <1 mg/day. It has been shown that 50 mg isoflavone consumption is sufficient to have endocrine effects in females and it appears that the dose,

Nutr.* **40**, 569–578, Reproduced with permission by the *American Journal of Clinical Nutrition* © Am. J. Clin. Nutr. American Society for Clinical Nutrition.

duration, and timing of exposure of intake will influence clinical and biological outcomes.

IV. POTENCY AND BIOLOGICAL ACTIVITY

The biological potencies of phytoestrogens vary greatly. The majority of the compounds are nonsteroidal in structure and vastly less potent than synthetic estrogens (10^{-2} to 10^{-5}). The potency determined by human cell culture bioassays varies with species, routes of administration, and tissue end-points used. With estradiol arbitrarily given the value of 100, the relative potencies of estrogenic isoflavonoids are as follows: coumestrol 0.202; genistein 0.084; equol 0.061; daidzein 0.013; and formononetin 0.0006.

More recently, the relative binding affinity of phytoestrogens to estrogen receptor-α (ER-α) and ER-β has been determined with the relative binding affinity of estradiol arbitrarily assigned at 100. Observations are comparable with the human cell culture bioassays, with coumestrol being the most potent. Relative binding affinities to ER-α and ER-β, respectively, are as follows: coumestrol 94 and 185; genistein 5 and 36, with a stronger binding affinity of phytoestrogens to ER-β.

A. Estrogenic Activity, Anti-estrogenic Activity, and Other Biological Properties

Varying physiological effects of individual phytoestrogens highlight the complexity of response of the estrogen receptor. Ligands for ER-α and ER-β can act as estrogen agonists, as antagonists, or as partial or selective agonists/antagonists, depending on the tissue receptors, co-regulators, and the interaction on estrogen-regulated genes. Knowledge of the effects of individual phytoestrogens is limited. Genistein is reported to bind in a manner similar to that observed for 17β-estradiol within the three-dimensional structure of the estrogen receptor-β ligand-binding domain. However, the ER-β–genistein complex induces a distinct orientation in the transactivation helix that is not agonist but partial agonist so that the transcriptional response to certain ligands is attenuated. A diagrammatic representation of the receptor sites for ER-α and ER-β in the human body is seen in Fig. 3.

Adverse estrogenic effects have been observed in animals. Reproductive disturbances observed in sheep in 1946 were attributed to the estrogenic effect of the fodder crop. In some but not all studies, estrogenic effects are seen in laboratory animals, with isoflavones stimulating uterine growth. In contrast, genistein administered with estradiol functions as an anti-estrogen, decreasing uterine estradiol uptake in animal models.

Genistein *in vitro* has been shown to exert both proliferative (estrogenic)and anti-proliferative (anti-estrogenic) effects in human cell lines. In the human ER^+ MCF-7 breast cancer cell line, the effects are biphasic with stimulation at low concentrations of genistein (10^{-5} to 10^{-8} M) and inhibition at higher concentrations (10^{-4} to 10^{-5} M), the latter probably not mediated via the estrogen receptor. At low concentrations, genistein competes with estradiol for binding to the ER with a 50% inhibition concentration of 5×10^{-7} M, and it stimulates the expression of pS2mRNA, a specific marker of ER-mediated estrogen-like activity. Similar stimulatory effects have been shown with daidzein, equol, and enterolactone.

Most studies to date indicate induction of DNA synthesis in tumor cell lines at concentrations close to

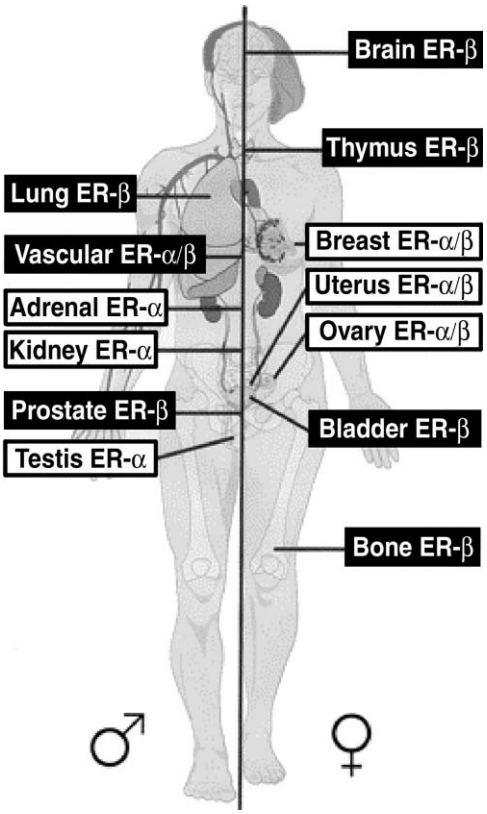

FIGURE 3 Simplified diagram illustrating the anatomical distribution of the newly described estrogen receptor ER-β to sites that are specific targets where classical estrogen replacement is beneficial. Reprinted from Setchell, K.D.R., and Cassidy, A. (1999). Dietary isoflavones: Biological effects and relevance to human health. *J. Nutr.* **129**, S758–S767, with permission from the American Society for Nutritional Sciences.

probable plasma levels in humans, achieved when consuming a high isoflavone intake, and inhibition only at very high concentrations, not achievable by diet.

Isoflavones exhibit anti-carcinogenic activity *in vivo*. Laboratory animals fed soy-fortified diets have less breast tumor proliferation after stimulation with direct and indirect tumor-inducing agents, *N*-methyl-*N*-nitrosurea and dimethylbenz(a)anthracene, respectively.

Anti-proliferative effects are demonstrated *in vitro* and appear to be independent of the estrogen receptor. Genistein and possibly other phytoestrogens interfere with the tyrosine kinase activity of activated growth factor receptors and cytoplasmic tyrosine kinases that are essential for transduction of mitogenic signals and hence inhibit tumor growth. Genistein inhibits epidermal growth factor-receptor (EGF-R) tyrosine autophosphorylation or alternatively exerts inhibitory effects downstream from EGF-R tyrosine autophosphorylation by some other mechanism.

Genistein has been reported to inhibit topoisomerase II, an essential nuclear enzyme involved in DNA replication, and this may result in cell cycle arrest.

Isoflavones exhibit other biological properties *in vitro* and inhibit angiogenesis, cell cycle progression, and aromatase enzyme activity, stimulate sex hormone-binding globulin (SHBG) synthesis, may decrease bioavailable endogenous estrogen, and have antioxidant properties and digitalis-like activity.

V. EFFECTS IN HUMANS

A. Infants

Soy infant formulas contain significantly high levels of daidzein and genistein. Large quantities of phytoestrogens were identified in the plasma and urine in human neonates, raising concerns about possible effects on neuroendocrine developmental processes. This probably arises as neonates have reduced intestinal degradation of the ingested isoflavones and frequent feeds. Cows' milk has been shown to contain isoflavones at low concentrations. A retrospective cohort study examining the association between infant exposure and health in adult life has found that exposure to soy does not appear to lead to different general or reproductive outcomes than cows' milk. This is reassuring about the safety of infant soy formulas.

B. Premenopausal Women

A cyclic pattern of lignan excretion was observed in the menstrual cycle of the vervet monkey and also in humans. Controlled intervention studies with dietary phytoestrogens have shown endocrine-modulating effects with increased cycle length in premenopausal women. Sixty grams of soy protein daily has been reported to increase follicular phase length and to suppress the midcycle follicle-stimulating hormone (FSH) and luteinizing hormone (LH) surges. Thirty-six ounces (1000 ml) of soy milk daily has been reported to decrease serum 17β-estradiol and luteal-phase serum progesterone in young ovulating women. Daily intake of flaxseed at 10 g per day increases luteal-phase length with no difference in follicular phase in normally cycling women. SHBG was not increased in these studies. Supplementation

with 60 g soy/day increases breast epithelium proliferation in premenopausal women.

C. Postmenopausal Women

Epidemiological studies comparing Asian and Western populations have suggested that consuming a phytoestrogen-rich diet may ameliorate the symptoms of estrogen deficiency, such as hot flashes at menopause. However, intervention studies have shown no benefit from phytoestrogens as an alternative to hormone therapy in postmenopausal women.

In 1990, mild estrogenic effects in the vaginal-cell maturation index of postmenopausal women were first reported after supplementation with 45 g soy flour for 6 weeks. Subsequent studies have failed to demonstrate a correlation between vaginal-cell estrogenic response and vasomotor symptoms. Also, a strong placebo effect has been noted. Some studies have reported a reduction in hot flashes upon supplementation with soy versus placebo but the effects have not been dramatic. A controlled trial of wheat versus soy unexpectedly found that wheat-supplemented women showed a significant reduction in hot flashes after 3 months and had low urinary isoflavones. These studies highlight the difficulties in treating hot flashes over time due to their natural resolution. The differences in response could be attributed to varying soy products used, study design, and individual variability in response. Specific dosages and formulations cannot be recommended.

Data on the effect of phytoestrogens on serum estradiol FSH, and LH concentrations are also variable. Isoflavone supplements have no benefit beyond placebo for reduction in hot flashes and no effect on plasma hormones including SHBG and FSH.

Phytoestrogens have no effect on the other symptoms of menopause, such as arthralgia, myalgia, headaches, and anxiety, which comprise part of the Kupperman index.

D. Men

Exposure to compounds with estrogenic activity has been postulated to be responsible for adverse changes in male reproductive health, including declining sperm counts, increase in testicular cancer, and testicular genital malformations although currently there are no definitive studies. Data are limited; however, intervention studies in males fed textured vegetable protein or soy protein isolate report no change in serum testosterone.

VI. PHYTOESTROGENS IN SPECIFIC DISEASES

A. Cardiovascular Disease

Vegetarians and individuals in Asian countries have a reduced risk of cardiovascular disease compared with individuals in Western nations, and Adlercreutz suggested that this may be partly attributable to phytoestrogen consumption. Dietary intake of vegetable protein, particularly soy, is associated with decreased cardiovascular disease risk.

1. Lipid Profiles

Intervention studies with soy-supplemented diets indicate that cardiovascular disease benefits may result from improved lipoprotein profiles. It is not known whether the effects are derived from the soy protein isoflavone or other nonphytoestrogen components of soy such as saponins, from fiber, or from a combination of the two. Limited data suggest that soy subfractions are not as effective at decreasing cardiovascular disease risk factors.

Soy in which substantial portions of the isoflavones and saponins are extracted by alcohol is described as isoflavone deplete (soy $-$) and has been used in primate models and compared with soy protein with isoflavones intact (soy $+$), to help identify the active moiety in soy protein. Studies in primates and humans overall report a beneficial effect in lipid profile of soy $+$ supplementation comparable with studies of estrogen. Since 1977, soy has been reported as a treatment for hypercholesterolemia. A meta-analysis of 38 published controlled clinical trials of soy protein consumption in humans that averaged 47 g/day and serum lipoprotein concentrations found that soy protein consumption was significantly associated with mean reductions in total cholesterol [9.3% ($-$0.6 mmol/liter) decrease, 95% CI 0.35–0.85 mmol/liter], LDL cholesterol [12.9% ($-$0.5 mmol/liter) decrease, 95% CI 0.30–0.82 mmol/liter], and triglycerides [10.5% ($-$0.15 mmol/liter) decrease, 95% CI 0.003–0.29 mmol/liter], with little change in HDL concentration. The degree of cholesterol reduction is similar to that observed with dietary intervention of plant-based foods such as oat bran and garlic. The hypocholesterolemic effect is more profound in men and women with elevated cholesterol, with only marginal benefit for those with a normal baseline lipid profile.

For example, a soybean protein diet in subjects with type II hyperlipoproteinemia may lower cholesterol on average by 20%. Ingestion of 60 g/day of soy protein isolate by normocholesterolemic men resulted

in no change in plasma lipids. Ingestion of 40 g soy supplementation in normocholesterolemic men and women resulted in decreases in triglycerides and an increase in lipoprotein Lp(a) by 15%.

Although results from individual studies are variable and dependent on the original serum cholesterol levels, the Food and Drug Administration approval for labeling of soy foods states "included in the daily diet, they may reduce heart disease."

2. Blood Pressure

Soy supplementation is reported to lower blood pressure in normotensive individuals. In a study of normotensive men and postmenopausal women, 3 months of 40 g daily soy supplementation significantly reduced systolic (2.4 mm Hg lower), diastolic (3.9 mm Hg lower), and mean blood pressure (BP) (4.2 mm Hg lower) compared with the casein-fed placebo group. These changes are greater than reported with dietary intervention alone. Soy supplementation in nonhypercholesterolemic, nonhypertensive, perimenopausal women resulted in a significant decline in diastolic BP (5 mm Hg lower) in the 20 g twice daily soy diet compared with the placebo diet. In contrast, concentrated phytoestrogen supplements did not alter BP in normotensive subjects. This highlights the discrepancy of phytoestrogen doses, the consumption of soy protein in preference to extracts, and the possibility of the hypotensive effect being mediated by nonestrogenic mechanisms.

3. Vascular Compliance and Endothelial Function

ER-β has been shown to be the primary estrogen receptor in the vessel wall and is up-regulated in response to vascular injury. Interest has focused on whether soy has vascular effects similar to those of estrogen. Studies of rhesus monkeys support a reduction in atheromatous plaque with isoflavone-intact soy supplementation and enhanced dilator responses of atherosclerotic coronary arteries to acetylcholine in female monkeys, improving blood vessel dilation and consequent blood flow.

However, a large study of both men and women consuming soy protein reported no beneficial effect on arterial compliance. Two small studies in peri- and postmenopausal women, with no male subjects included, have reported improved systemic arterial compliance of 26% in concentrated phytoestrogen supplements.

Brachial flow-mediated vasodilation (FMD) is a strong predictor of coronary endothelial dysfunction. In the larger previous study, soy supplementation had no effect on FMD in healthy postmenopausal women and unexpectedly reduced FMD in males. In comparison, estrogen administration does not improve FMD in healthy adult males or improve endothelial-dependent vasodilation in the male monkey model.

A small study of postmenopausal women supplemented with an 80 mg phytoestrogen tablet similarly reported no improvement of FMD.

Cross-sectional data from postmenopausal women indicated that women with high genistein intake had a significantly lower body mass index (P-trend = 0.05), waist circumference (P-trend = 0.05), and fasting insulin level (P-trend = 0.07) than those with no daily genistein consumption. Similarly, a population-based cohort of midlife women found that women with a high intake of isoflavones, >40 mg/day, derived from diet were more likely to exercise, were less likely to smoke, had a lower mean body mass index, and observed lifestyle factors that were associated with reduced cardiovascular disease risk.

Dietary soy phytoestrogens may provide cardioprotection via direct lipid effects; however, the response pattern does not follow that of estrogen with respect to BP responses, lipoprotein changes, and vascular function effects and not all effects are beneficial, in particular, elevated lipoprotein Lp(a) and reduced FMD in males. The mechanisms of action are still uncertain. Isoflavones, especially genistein, *in vitro* are reported to have anti-atherogenic properties and inhibit the process of coagulation, a key promoter of plaque formation, by inhibition of growth factors such as platelet-derived growth factor and inhibition of tyrosine kinase activity, an enzyme central to thrombin formation and inflammation in general. Genistein is the most potent antioxidant of the isoflavones in soy protein.

In summary, phytoestrogens have beneficial effects for cardiovascular disease risk via lipid reduction, particularly in hypercholesterolemic men and women, and reduction in blood pressure in normotensive men and women with no overall beneficial effect on arterial compliance or endothelial function in adult males. Individuals that consume phytoestrogens have healthy lifestyle factors that are preventative of cardiovascular disease.

B. Cancer

The incidence of hormone-dependent cancers is lower among vegetarians and in Asia and Eastern Europe than in Western countries. Breast, ovarian, prostate, and colon cancers show a negative correlation with

cereal and phytoestrogen intake when cancer mortality rates and food availability data between countries are compared.

1. Breast Cancer

Some epidemiological studies have suggested an association between high phytoestrogen intake and reduced breast cancer risk. Studies of urinary phytoestrogen excretion in women immediately after diagnosis of breast cancer have shown lower equol, enterolactone, and daidzein excretion in women with breast cancer than in controls, despite similar dietary patterns.

Japanese immigrants to North America have a higher incidence of breast cancer than their counterparts in Japan, with a higher incidence of cancer the younger the age of migration. Such findings support the role of environmental factors in the etiology of breast cancer.

Studies have shown conflicting results. A significant graded inverse association in Japanese women has been reported between risk of breast cancer and consumption of miso (soybean paste soup). A diet high in soy products conferred a low risk of breast cancer in premenopausal women in Singapore, with no effect observed in postmenopausal women. A Chinese study reported no association between soy and breast cancer but did find an inverse correlation between fiber and other nutrient intake and breast cancer rates. Similarly, a progressive reduction in relative risk of breast cancer with each quintile of increasing fiber intake for women has been reported in Australian women. Lower levels of ER-α^+ cells have been shown in normal breast tissue in Japanese women, 9% compared with white Australian women ($>$17% for those over 50 years and 12% for those $<$50 years), and this may contribute to ethnic differences in breast cancer rates.

Isoflavones have been reported to have protective effects in animal models of experimentally induced breast cancer, measured by tumor number, incidence, metastasis, and latency. It may be that prepubertal exposure may confer greater protection by precocious maturation of breast terminal end buds. Breast cancer cell line studies have shown that at low concentrations (equivalent to levels measured in humans consuming a 40 mg isoflavone supplement) genistein stimulates ER^+ cells with no effect on ER^- cells. Consistent with these findings, soy supplementation stimulates breast epithelium proliferation in premenopausal women. Genistein at high concentrations, beyond that achieved by diet, inhibits the growth of ER^+ and ER^- cell lines. Genistein in cell studies has been shown to antagonize the anti-estrogenic effect of tamoxifen, and caution is advised regarding supplements in women with breast cancer.

Phytoestrogens have estrogenic effects on the breast and larger long-term studies are needed before concentrated supplements can be safely recommended.

2. Prostate Cancer

Men in Asia were found to have a higher concentration of isoflavones, equol, and daidzein in plasma and prostatic fluid than their counterparts in Europe. This led to the speculation that phytoestrogens may be protective of prostate cancer. Epidemiological studies have reported an association between consumption of lentils, peas, tomatoes, and dried fruits and decreased prostate cancer in 14,000 Seventh Day Adventist men. A study of Japanese immigrants to North America has shown an increased incidence in prostate cancer, the younger the age at migration, supporting the hypothesis of environmental factors, including diet, having an impact on cancer risk.

In the rodent model, an isoflavone-rich diet reduced the incidence of prostate-related cancer and prolonged the disease-free interval by 27%. The effects were observed only when the rodents were fed soy prior to the exposure of cancer, indicating that early exposure to soy supplementation may protect against prostate cancer in later life.

It is plausible that the effects of genistein are mediated via ER-β, in view of the greater affinity of genistein to ER-β versus ER-α and the high levels of ER-β found in the prostate. In human prostate cancer cell lines, high concentrations of genistein and biochanin A inhibit the growth of androgen-dependent cells. *In vitro* high levels of genistein inhibit 5α-reductase and 17β-hydroxysteroid dehydrogenase in genital skin fibroblasts and prostatic tissue. These two enzymes are involved in androgen and estrogen synthesis. Genistein inhibits the growth of prostatic cells from benign prostatic hypertrophy and prostate cancer cells in histoculture in a dose-dependent manner. In addition, genistein inhibits tyrosine kinase and topoisomerase, which are crucial to cellular proliferation.

Phytoestrogen supplementation with a 160 mg (4×40 mg) isoflavone equivalent, made from red clover, was taken for 7 days prior to surgery for an infiltrating low-grade adenocarcinoma of the prostate in one subject. At surgery, the prostatectomy specimen showed a moderately high-grade adenocarcinoma with patchy microvacuolation and prominent apoptosis typical of a response to prior estrogen

therapy. Decreased serum testosterone, decreased serum prostate-specific antigen, and altered sexual behavior have been demonstrated in men who were administered an herbal remedy containing phytoestrogens used as treatment for prostate cancer. Further intervention studies are currently being conducted.

C. Osteoporosis

Osteoporosis is related to a number of factors including genetics, aging, hormone deficiency, and diet. Epidemiological studies have shown reduced rates of osteoporosis in Asian women compared with Western women and phytoestrogens have been postulated as a protective factor although many other factors could account for these findings. *In vitro* cell culture has shown that phytoestrogens inhibit osteoclasts and may stimulate osteoblasts. *In vivo* animal studies suggest that in high enough doses, dietary soybean prevents bone loss in ovariectomized rats.

ER-β has been identified in bone and its ligand specificity toward phytoestrogens has been reported. Isoflavones appear to have an effect on osteoblasts via the ER, whereas the effects on osteoclast appear to be non-ER-mediated, such as growth factor activity and cytokine activity. There are limited human studies. Postmenopausal women supplemented with casein, soy protein, or soy protein fortified with isoflavores for 6 months demonstrated increased bone mineral content and density in the spine in the soy fortified group alone compared with controls. Forty-five grams of soy-enriched bread improved bone mineral content in postmenopausal women compared with controls. Long-term data on the efficacy and safety of ipriflavone for prevention of postmenopausal bone loss have been conflicting. Ipriflavone (7-isopropoxyisoflavone), a synthetic flavonoid, inhibits osteoclast function and 600 mg/day has been reported to prevent bone loss at the distal radius in postmenopausal women. More recently, a 4-year study of 474 postmenopausal women randomly assigned ipriflavone at 200 mg three times per day or placebo found no difference in bone loss prevention and in biochemical markers of bone metabolism. Long-term studies are needed before the role of phytoestrogens in the prevention of osteoporosis can be supported.

VII. SUMMARY

Cancer research is still in its infancy. The epidemiological and animal data suggest that phytoestrogens may play a beneficial role in breast and prostate cancer. It may be that prepubertal exposure is of importance and ingestion needs to be lifelong. Extrapolations from cell line and animal studies need to be viewed with caution. It is probably naive to attribute many health outcomes to one food, and other lifestyle factors, such as exercise, substance abuse, and the diet as a whole, may be relevant.

In contrast to animal studies in which deleterious effects were observed with consumption of a phytoestrogen diet, in humans few adverse effects are observed. In humans, a genetic tolerance may have evolved in nations with a high-soy-intake diet or the varied human diet may be protective of one food group alone dominating and causing adverse effects. The limited studies to date have confirmed that diet can have significant hormonal effects and these may be of benefit in preventing some of the common diseases. Global nutrition is an increasing problem and further knowledge from scientific studies of plant-based foods is warranted.

Glossary

coumestans A potent subgroup of phytoestrogens found in fodder crops.
daidzein An isoflavone metabolite derived from daidzin by gastrointestinal bacteria.
enterodiol A lignan metabolite derived by gastrointestinal bacteria.
enterolactone A lignan metabolite derived by gastrointestinal bacteria.
genistein An isoflavone metabolite derived by gastrointestinal bacteria from genistin.
isoflavones A subgroup of phytoestrogens derived from legumes, e.g., soybean.
lignans A subgroup of phytoestrogens found in vegetables, fruits, nuts, and seeds.
phytoestrogen A plant compound with binding affinity for the estrogen receptor.

Pilosebaceous Unit (PSU)

DIANNE DEPLEWSKI
University of Chicago

The pilosebaceous unit (PSU) consists of a piliary component and a sebaceous component. Each PSU has the capacity to differentiate into either a terminal hair follicle (in which a large medullated hair becomes the prominent structure) or a sebaceous follicle (in which the sebaceous gland becomes prominent and the hair remains vellus). This article provides an introduction to the role of androgens and other hormones in normal PSU development and in PSU disorders.

I. INTRODUCTION

Androgens play a key role in the development of the pilosebaceous (PSU) in most areas of the body. In androgen-sensitive areas before puberty, the hair is vellus and the sebaceous glands are small. In response to increasing levels of androgens, PSUs become large terminal hair follicles (sexual hairs) in sexual hair areas or they become sebaceous follicles (sebaceous glands) in sebaceous areas. Androgens play a role in PSU disorders, namely, hirsutism, pattern alopecia, and acne vulgaris. However, it is clear that the pathogenesis of these disorders involves more than androgen.

II. POSTNATAL GROWTH AND DEVELOPMENT OF THE PSU

A. Hair Follicle

Hair follicles vary considerably in size and shape depending on their localization in the body. Approximately 5 million hair follicles cover the human body, and this number is established before birth. New follicles are not formed after birth; however, the size of the follicles and hairs can change with time, primarily under the control of androgen. The difference in the apparent density of sexual hair

between men and women is due to a different density of terminal hairs rather than a difference in the number of PSUs. Racial differences also affect various features of hair, such as shape and medullation.

Normal development and cycling of the hair follicle depend on the interaction of the follicular epithelium with the dermal papilla, which consists of specialized fibroblasts located at the base of the hair follicle. Hair grows cyclically by reverting from the anagen (growth) phase, through the catagen (shortening) phase, to the telogen (resting) phase (Fig. 1). The dynamics of the hair growth cycle vary between species, between different body sites in the same species, and between different follicle types at the same body site. It is likely that hair follicles have an intrinsic rhythmic behavior that is modulated by multiple growth factors. The duration of the anagen stage is the major determinant of the length to which a hair grows, and it varies with the location of the hair follicle. For example, scalp hairs are in anagen for a long time (between 2 and 8 years) and produce long hairs, whereas mustache hairs stay in the anagen stage for only 4 months and thus produce short hairs. Other factors influencing hair growth in various areas of the body include the linear growth rate of the hair fiber, as well as the diameter and density of the terminal hairs. During the catagen phase, hair follicles go through a highly controlled process of regression and involution, caused by apoptosis (programmed cell death). This is the shortest phase of the hair growth cycle and lasts from 2 to 3 weeks. During the telogen phase, a club hair develops and is eventually shed from the follicle to make room for new hair growth. This phase lasts for 3 to 4 months. Whereas shaving does not induce hair growth, plucking a resting (telogen) hair causes an advancement in the onset of anagen and thus induces hair regrowth.

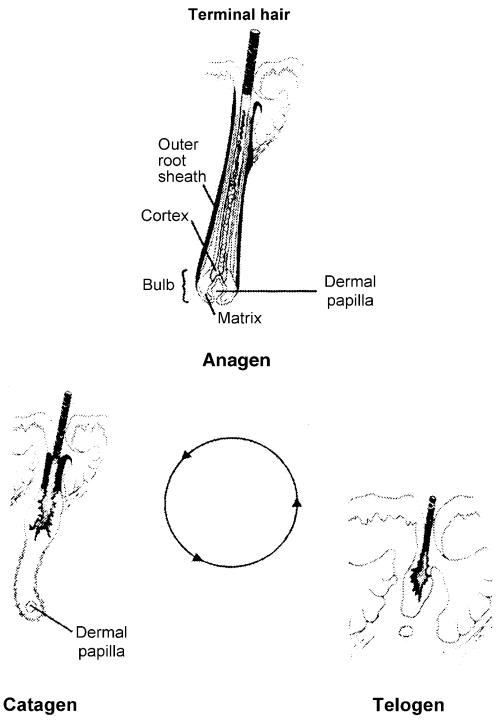

FIGURE 1 The hair growth cycle. Hair follicles progress through repetitive cycles of growth, from anagen (active phase of growth), through catagen (shortening of the hair follicle), to telogen (resting phase of the hair cycle), after which the club hair is shed, and the follicle begins a new hair cycle again. Modified from D. Deplewski and R. L. Rosenfield, Role of hormones in pilosebaceous unit development. *Endocr. Rev.* **21**, 363–392, 2000, with permission. Copyright 2000, The Endocrine Society.

B. Sebaceous Gland

The life cycle of sebaceous cells (sebocytes) begins at the periphery of the gland in the highly mitotic basal layer. As sebaceous cells differentiate, they accumulate increasing amounts of lipid and migrate toward the central duct. Eventually, the most mature sebocytes burst and their lipid is extruded into the ducts of the sebaceous gland as the holocrine secretion sebum. The cells of sebaceous glands turn over more rapidly than those of hairs, as they are normally completely renewed every month.

III. ANDROGEN ACTION IN THE PSU

Before puberty, the androgen-dependent PSU consists of a prepubertal vellus follicle, which consists of a virtually invisible hair and a tiny sebaceous gland component (Fig. 2). Under the influence of androgens produced at adrenarche and then puberty, these PSUs differentiate in a distinctive pattern that depends on their location. In the sexual hair areas, a terminal hair follicle develops and the sebaceous gland develops only moderately. In acne-prone areas, androgen causes the prepubertal vellus follicle to develop into a sebaceous follicle in which the hair remains vellus and the sebaceous gland enlarges tremendously. In the balding-prone area of the scalp, PSUs respond to androgen in yet a different manner in individuals predisposed to pattern alopecia. Terminal hair follicles that previously grew without androgen gradually change with each growth cycle to an intermediate kind of follicle in which the hair component reverts to the vellus state, leaving an adult vellus follicle. Hair follicles are still present and cycling, even in

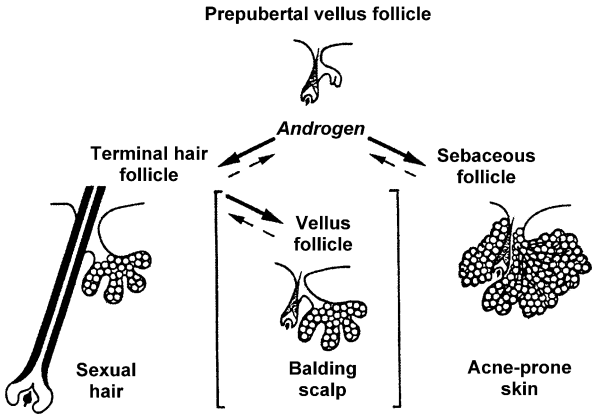

FIGURE 2 Role of androgen in the development of the pilosebaceous unit. Solid lines indicate the effects of androgen; dashed lines indicate the effects of anti-androgens. Hairs are depicted only in the anagen (growing) phase of the growth cycle. In balding scalp (bracketed area) terminal hairs not previously dependent on androgen regress to vellus hairs under the influence of androgen. Reprinted from *Am. J. Med.* **98**, R. L. Rosenfield and D. Deplewski, Role of androgens in the developmental biology of the pilosebaceous unit. pp. 80S–88S. Copyright 1995, with permission from Excerpta Medica Inc.

bald scalp. These phenomena are reversed by anti-androgens: both types of androgen-dependent PSUs revert toward the prepubertal state. The fact that individual PSUs can respond differently to the same circulating hormones illustrates the complexity of the response of the PSU to androgen.

The most direct evidence that androgens are the principal hormones controlling sexual hair growth is that androgens stimulate hair growth in eunuchs and castration reduces hair growth. The latter classic observation illustrates the pliable nature of the PSU response to androgens, i.e., the reversion from terminal to vellus follicles. The sensitivity of PSUs to androgen is determined by their pattern of distribution and generally wanes from pubis to head (Fig. 3). Thus, rising androgen levels recruit an increasing proportion of PSUs in a given area to initiate the growth of terminal hair follicles, each in accordance with its preset genetic sensitivity to androgen. The apparent dose–response curve to androgen is fairly steep, with a mustache typically appearing at plasma testosterone levels just slightly above the upper limits of normal for women and the beard requiring 10-fold higher levels for full growth. There is considerable individual variability. Androgens are thought to control hair growth by influencing the synthesis and release of growth factors from dermal papilla cells that act in a paracrine fashion on the other cells of the hair follicle.

The sensitivity of sebaceous glands to androgens seems to follow a different dose–response curve than the hair follicle, with most sebaceous glands being highly and similarly sensitive to testosterone. Sebum production is at its nadir at approximately 4 years of age and begins to increase between 8 and 11 years of age. Microcomedones (1 mm or less in diameter), which form when desquamated cornified cells of the upper canal of the sebaceous follicle become abnormally adherent and form a plug in the follicular canal, make their appearance in approximately 40% of 8- to 10-year-olds. Thus, sebaceous gland function begins approximately coincident with adrenarche, before true puberty, at levels of androgen below those ordinarily required for the initiation of pubic hair growth (Fig. 4). Seventy-five percent of the normal male amount of sebaceous gland function is achieved at androgen levels normal for women. There is considerable individual variability in the degree of sebum production to a given level of androgen.

It is not yet clear what controls the nature of the response of a PSU to androgen; however, the variability in PSU responsiveness may be related in part to variations in androgen metabolism. Enzymes important in androgen metabolism in skin are shown in Fig. 5. Two forms of 5α-reductase, which are differentially expressed in various tissues, exist. The type 2 isozyme is important for most androgen actions in sexual organs; however, the type 1 isozyme is the major form of 5α-reductase in skin. The activity of 5α-reductase has been found to be higher in

sebaceous glands of the scalp and facial skin (acne-prone skin) than in other skin areas. However, no obvious difference in type 1 isozyme expression has been found between balding and nonbalding areas of adult scalp. In contrast, greater 3β-hydroxysteroid dehydrogenase activity has been found in sebaceous glands from balding scalp than in those from nonbalding scalp. Table 1 depicts the characteristic pattern of androgen metabolism in skin. A summary of the localization of the mediators of androgen signal transduction in the PSU is provided in Table 2.

IV. ROLE OF NONANDROGENIC HORMONES IN THE PSU

In addition to androgen, other hormones including estrogen, growth hormone, insulin-like growth factor-I, insulin, glucocorticoids, prolactin, thyroid hormone, retinoids, and others are well recognized to play roles in PSU growth and development, and these are summarized in Table 3.

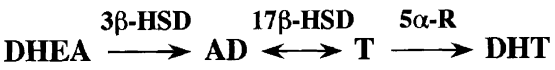

FIGURE 5 Androgen metabolism in skin. The weak androgen dehydroepiandrosterone (DHEA) is metabolized to the more potent androgen dihydrotestosterone (DHT) by specific enzymes as depicted. AD, Androstenedione; T, testosterone; 3β-HSD, 3β-hydroxysteroid dehydrogenase; 17β-HSD, 17β-hydroxysteroid dehydrogenase; 5α-R, 5α-reductase.

V. DISORDERS OF THE PSU: HIRSUTISM, PATTERN ALOPECIA, AND ACNE VULGARIS

A. Hirsutism

Hirsutism is typically defined as excessive male-pattern hair growth in women. This definition distinguishes hirsutism from hypertrichosis, which is the term reserved to describe the androgen-independent growth of body hair that is vellus, prominent in nonsexual areas, and most commonly familial or caused by metabolic disorders (e.g., thyroid disturbances, anorexia nervosa, or porphyria) or medications (e.g., phenytoin, minoxidil, or cyclosporine).

B. Pattern Alopecia

Pattern alopecia is the androgen-dependent thinning of hair that occurs progressively with advancing age in genetically susceptible men and women. However, it can begin as soon as the early teenage years. The process is mainly the result of miniaturization of terminal to vellus hair follicles (Fig. 2). The androgen-dependency of pattern alopecia was initially deduced on the basis of eunuchs not suffering from male pattern hair loss unless they are given replacement testosterone. Pattern alopecia is generally thought to be distinct from the diffuse thinning of scalp hair associated with aging. However, it remains possible that pattern alopecia may partially be due to an accentuation of the normal process of hair loss associated with aging. In men, pattern alopecia typically presents as temporo-occipital pattern (male-pattern) balding. In female-pattern alopecia, the thinning typically begins with involvement of the crown of the scalp (rather than the vertex and bifrontal areas as in men) and may become fairly diffuse. Pattern alopecia can be psychologically devastating in both sexes. The genetic predisposition to pattern alopecia is still poorly understood. However, the pattern of inheritance is considered to be polygenic with variable penetrance. It is likely that the penetrance is greatly determined by the height of the plasma androgen level.

Minoxidil and finasteride are hormonal treatments for pattern alopecia. Minoxidil induces and prolongs the anagen stage and converts vellus follicles to terminal follicles. Finasteride inhibits type 2 5α-reductase, which converts testosterone to DHT.

TABLE 1 Pattern of Androgen Metabolism within Skin Organelles of Axilla and Scalp

	Relative enzyme activity (percentage of total)		
	5α-Reductase (n = 8–10)	17β-HSD (n = 6–16)	3β-HSD (n = 2)
Sebaceous gland	17	21	50
Hair follicle	8	15	
Sweat gland	60	47	40
Dermis	9	6	8
Epidermis	6	11	2
Total	100	100	100

Note. Regional differences in enzyme activity between axilla and scalp may exist. 17β-HSD, 17β-hydroxysteroid dehydrogenase; 3β-HSD, 3β-hydroxysteroid dehydrogenase. Reprinted from D. Deplewski and R. L. Rosenfield, Role of hormones in pilosebaceous unit development, *Endocr. Rev.* **21**, 363–392, 2000, with permission. Copyright 2000, The Endocrine Society.

Finasteride inhibits miniaturization of hairs, converts vellus follicles to terminal follicles, and prolongs the anagen stage in androgen-dependent scalp follicles. Typically, 9 to 12 months of treatment is needed to judge the efficacy of a given treatment on hair growth, because of the long duration of the hair growth cycle. Unfortunately, simply removing androgens does not usually cause a significant conversion of miniaturized vellus follicles to terminal follicles; thus, current treatments for pattern alopecia are less than optimal.

C. Acne Vulgaris

Sebum, the holocrine secretion of sebaceous glands, plays a central role in the pathogenesis of acne vulgaris. Acne occurs at the onset of puberty when plasma androgen levels rise, peaks at midpuberty, and usually resolves by the mid-20s. Virtually all adolescents have at least a few open and closed comedones, which are noninflammatory enlarged sebaceous follicular ducts known as blackheads and whiteheads, respectively. Androgens are an incitant of acne vulgaris since they are necessary for the growth and differentiation of sebaceous glands.

Dehydroepiandrosterone sulfate (DHEAS) plays a role in acne through its conversion to more potent androgens that stimulate sebum production. Plasma DHEAS is likely the most important androgen for the initiation of comedonal acne in early puberty, as it rises first. Excessive DHT formation in skin has also been implicated in the pathogenesis of acne vulgaris, suggesting that the activity of 5α-reductase may also play an important role.

There is more to acne than sebaceous gland growth and sebum production: abnormal sebaceous duct keratinization, bacterial colonization with *Propionibacterium acnes*, and host immune response factors are also important. The pathogenesis of acne is thought by most to commence with plugging of the outlet of the sebaceous gland with desquamated cornified cells of the upper canal of the follicle. The more severe stages of acne are the consequences of obstruction and impaction, with bacterial secondary infection of static sebum occurring in an anaerobic environment. A closed comedone takes 2 months to form from its precursor lesion, the microcomedone. Inflammatory acne, consisting of papules, pustules, nodules, and cysts, is a later phenomenon that develops from comedonal acne.

TABLE 2 Androgen Mechanism of Action in the Pilosebaceous Unit

	Sebaceous gland		Sexual hair	
Parameter	Stroma	Sebocytes	Dermal papilla	Hair epithelium
3β-HSD	?	+++	?	±
17β-HSD	?	+++	Type 3	Type 2
5α-Reductase	?	Type 1	Type 2	Type 1
Androgen receptor	+	++++	++++	±

Note. 3β-HSD, 3β-hydroxysteroid dehydrogenase; 17β-HSD, 17β-hydroxysteroid dehydrogenase. Reprinted from D. Deplewski and R. L. Rosenfield, Role of hormones in pilosebaceous unit development, *Endocr. Rev.* **21**, 363–392, 2000, with permission. Copyright 2000, The Endocrine Society.

TABLE 3 Hormone Action on the Pilosebaceous Unit

Hormone	Action on PSU
Androgen	• Has diverse effects on hair follicles depending on their location in body; for example, sexual hairs grow only in certain areas of the body, whereas hair on the scalp undergo regression from a terminal to a vellus type in genetically susceptible individuals • Induces sebaceous gland development in acne-prone areas
Estrogen	• Prolongs the anagen phase of hair growth • Rapid growth postpartum causes telogen effluvium (loss of a large number of hairs due to simultaneous advancement into telogen) • Directly suppresses sebaceous gland function
Insulin	• Hair growth retarded in diabetes mellitus and accelerated with insulin treatment • Essential for hair follicle growth and sebaceous cell growth *in vitro* • May act as an IGF-I surrogate
Growth hormone	• Augments androgen effects on hair growth and sebocyte differentiation • Important for sebocyte growth and development • GH excess of acromegaly is associated with excess output of sebum from the sebaceous gland (seborrhea) • GH receptor found in hair follicles and sebaceous gland
Insulin-like growth factor	• Prevents hair follicles from entering catagen stage • May mediate some of the androgen effects on PSUs—induces the up-regulation of 5α-reductase by DHT in genital skin fibroblasts • Found in both hair follicles and sebaceous glands
Glucocorticoids	• Hypertrichosis (diffuse excessive hair growth) is present in Cushing's syndrome • Glucocorticoid therapy aggravates acne
Prolactin	• Hyperprolactinemia can cause hirsutism and seborrhea • Receptors localized in dermal papilla and sebaceous glands
Thyroid hormone	• Low or high levels can cause telogen effluvium • Low level cause scalp hair to become dull or brittle • Can stimulate sebum production • Receptors found in PSUs
PPARs	• Likely important in sebaceous gland development
Retinoids	• Important in hair follicle formation and patterning • Prolong anagen stage and decrease telogen stage of hair growth cycle • Trace amounts promote sebocyte growth and differentiation; larger doses cause atrophy of sebaceous glands and a decrease in sebum production
Catecholamines	• May be involved in the aggravation of acne by stress
Vitamin D receptor	• Mutations associated with alopecia in humans
Melanocortin-5 receptor	• Targeted disruption in mice causes a decrease in sebaceous lipid production
Parathyroid hormone	• Inhibits hair growth

Note. DHT, dihydrotestosterone; GH, growth hormone; IGF-I, insulin-like growth factor-I; PPARs, peroxisome proliferator-activated receptors; PSU, pilosebaceous unit.

Topical agents and retinoids play an important role in the treatment of acne, and 2 to 3 months may be needed to see the full effect of treatment on acne. Whereas trace amounts of retinoids promote sebocyte growth and differentiation, larger doses cause atrophy of sebaceous glands and a decrease in sebum secretion in both animals and humans. Retinoids have been postulated to inhibit lipid synthesis in sebocytes either directly, through an inhibition of lipogenic enzymes, or indirectly, by decreased cell proliferation. Retinoids have been used for the treatment of acne vulgaris for a long time although the precise mechanism for their efficacy has not been completely elucidated.

Glossary

acne vulgaris A disorder of the sebaceous gland; characteristic lesions include open (blackhead) and closed (whitehead) comedones, papules, pustules, and nodules.
hirsutism Excessive male-pattern hair growth in women.
pattern alopecia The androgen-dependent thinning of hair that occurs progressively with advancing age in genetically susceptible men and women; the process is mainly the result of miniaturization of terminal to vellus hair follicles.
pilosebaceous unit A skin appendage consisting of a hair follicle, a hair shaft, and a sebaceous gland.
sebaceous gland A small sacculated organ within the dermis; composed of acini, which are attached to a common excretory duct that is continuous with the wall of the piliary canal and, indirectly, with the surface of the epidermis.
terminal hair Thick, long, pigmented hair on scalp and body.
vellus hair Thin, short, usually nonpigmented hair.

Pituitary Adenylate Cyclase-Activating Polypeptide (PACAP) and Its Receptor

JOSEPH R. PISEGNA
VA Greater Los Angeles Healthcare System and UCLA School of Medicine

This article provides an overview of the neuropeptide pituitary adenylate cyclase-activating polypeptide (PACAP) and its receptor, PAC1, which were discovered more than a decade ago. The current understanding of the structure and function of the PACAP hormone and an in-depth understanding of the structure and physiology of the PAC1 receptor are presented. The important roles that the PACAP hormone and receptor play in the regulation of physiological actions in the body are examined. Since the receptor and hormone are localized in both the central nervous system and the periphery, their important effects in both systems are described.

I. INTRODUCTION

Pituitary adenylate cyclase-activating polypeptide (PACAP) is the most recently discovered neuropeptide in the vasoactive intestinal polypeptide (VIP), secretin, and glucagon family of peptide hormones. It was designated PACAP because it stimulated adenylyl cyclase in rat anterior pituitary cells in culture and was a polypeptide of 38 amino acids. Since their discovery, PACAP hormone and its receptor, PAC1, have been identified in numerous tissues by immunohistochemistry and radioimmunoassay. Although the exact role of PACAP in the brain has not been determined, its broad distribution and presence during development suggest that it acts as a neurotransmitter or neuromodulatory peptide. Therefore, PACAP appears to play an important role in the growth and development of the brain. Its role as a neuromodulatory hormone will be discussed in more detail below. PACAP is also present in a number of peripheral tissues, including

the gastrointestinal tract, adrenal gland, and testis. Another important action of PACAP is its ability to stimulate cellular growth and differentiation. PACAP appears to regulate the growth of a number of tumors and may have important actions in cancer biology.

II. PACAP HORMONE

A. Discovery

Arimura and colleagues isolated fractions of ovine hypothalamic extracts that stimulated adenylyl cyclase activity in anterior pituitary cells. The hormone pituitary adenylate cyclase-activating polypeptide was so named for this activity. The hormone PACAP was shown to contain 38 amino acids, and later a 27-amino-acid form was identified. Since both a 27-amino-acid form and a 38-amino-acid form are biologically active, they are designated PACAP-27 and PACAP-38, respectively. There is significant interspecies conservation of the amino acid structure of the PACAP hormone.

B. Structure

The primary sequence of the PACAP hormone is 68% identical to its closest hormone relative, VIP. These hormones belong to a broader category of hormones including PACAP, VIP, secretin, glucagon, and GRF. As demonstrated in Table 1, there is significant homology of these peptides. The peptides most closely related to PACAP are grouped closest to PACAP at the top of Table 1. The three-dimensional structures of the hormones in this family show close similarity. Minor differences in the α-helix conformation may account for receptor specificity of PACAP and VIP.

C. PACAP Hormone Gene

The PACAP hormone gene has been cloned in mice and humans. The human gene is composed of five exons with a structure that is similar to other members of this family of peptides. This close similarity suggests that all of the members of this family of peptides may originate from a similar ancestral gene through duplication.

D. PACAP Hormone Distribution

The greatest concentration of PACAP is detected in the central nervous system of mammals. The site of greatest activity in the rat is the paraventricular and supraoptic nuclei in the hypothalamus. It is thought that the hormone is transported to the pituitary gland, where the hormone has activity in the anterior pituitary. PACAP-38 immunoreactivity is also present in extrahypothalamic sites, such as the substantia nigra, cerebellum, pons, and the paraventricular nuclei of the thalamus. The spinal cord also contains PACAP that is localized mainly in the dorsal root ganglia and dorsal horn. PACAP has been identified in the gastrointestinal enteric neural plexus, where it is an important mediator of gastric acid secretion and intestinal motility. In the adrenal gland, PACAP is present in the adrenal medulla, where it appears to be a potent stimulator of catecholamine release.

III. THE PAC1 RECEPTOR

A. Cloning and Pharmacological Characterization

There are three receptors with high affinity for PACAP hormone that have been identified and cloned. The first of these receptors to be cloned was the classical VIP receptor (VPAC1). Subsequently, a receptor with affinity for only PACAP was cloned, the type I PACAP receptor (PAC1). The last receptor to be cloned in this family was the VIP2 receptor (VPAC1). These receptors can be differentiated pharmacologically based on their relative affinities for the ligands, as shown in Table 2. PAC1 has affinity for only PACAP-38 and PACAP-27, whereas the

TABLE 2 Relative Affinities of the Three PACAP and VIP Receptors for the Ligands PACAP-27, PACAP-38, VIP, and Helodermin

IUPHAR nomenclature	Relative affinities
PAC1	PACAP-27 = PACAP-38 ≫ VIP > Helodermin
VPAC1	PACAP-27 = PACAP-38 = VIP ≫ Helodermin
VPAC2	Helodermin > PACAP-27 = PACAP-38 = VIP

Note. Classification of the receptors in the PACAP superfamily based on relative affinities to the related peptides. Adapted from Harmar *et al*. (1998), with permission.

VPAC receptors have nearly identical affinities for the ligands PACAP and VIP.

Cloning of the rat PAC1 cDNA identified it as a member of the VIP and secretin family of peptide receptors. The receptor cDNA encoded a putative protein of approximately 50 kDa and 495 amino acids. Similar to the VIP and secretin receptors, the PAC1 receptor contained seven hydrophobic domains, conserved cysteines in the extracellular domains, and several N-linked glycosylation sites. Cloning of the PAC1 gene indicated that the receptor could exist as four major splice variants, which were subsequently identified. As shown in Fig. 1, the four potential splice variants differed in the length of the third intracellular domain and were identified by Spengler and colleagues as hip, hop, hip-hop, and null. More importantly, these investigators identified variations in signal transduction coupling to phospholipase C and differences in the tissue distribution of the splice variants. The PAC1 cDNA was also cloned in a number of other species such as rat, mouse, and bovine. Subsequently, all of the human PAC1 receptor cDNA splice variants were cloned. The cloning of human PAC1 revealed a high level of homology with the rat and mouse receptor and a similar gene organization. However, unlike the rat splice variants, differences in signal transduction coupling were not observed in humans. Instead, a higher efficacy for the hop variant, an intermediate coupling for the hip-hop splice variant, and a lower level of coupling for the hip splice variant for coupling to phospholipase C were observed. Similar to the human receptor gene, the rat PAC1 receptor gene has been shown to be large (~50 kb); however, unlike the human gene, which is localized to chromosome 7, the rat gene is localized to chromosome 4.

B. Signal Transduction Characteristics

The PAC1 receptor is coupled to a dual signal transduction pathway. This was first demonstrated in PC12 cells. With the cloning of the PAC1 receptor, the specificity of PACAP-38 and PACAP-27 was shown. A fourth transmembrane splice variant was shown not to couple to either adenylyl cyclase or phospholipase C, yet it does couple to an L-type Ca^{2+} channel. The region of PAC1 shown to be responsible for signal transduction coupling is the COOH-terminus. Two critical amino acids in this region of the receptor, Ser and Arg, were shown by mutagenesis studies to be coupled to signal transduction intermediates.

C. Localization of PAC1 Receptors

The greatest density of receptors occurs in the hypothalamus, for instance, in the supraoptic nucleus, periventricular nucleus, and lateral hypothalamus. Other areas include the olfactory bulb and regions of the thalamus and cerebellum. In the rat brain, the predominant splice variant is the null variant. PAC1 has been detected by immunohistochemistry as well as electron microscopy in the retina, where it appears to be distributed in the inner plexiform layer.

In peripheral tissues, PAC1 receptors have now been identified in a large number of organs. The greatest density has been identified in the adrenal medulla where the predominant receptor splice variant appears to be of the hop type. Similarly, PAC1 receptors are expressed at high levels in the anterior pituitary gland, where, again, the predominant splice

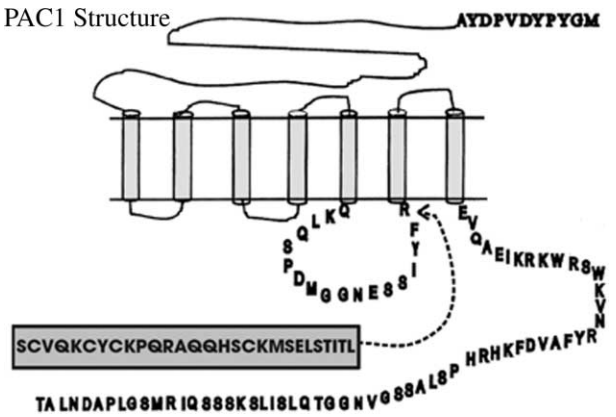

FIGURE 1 Structure of the heptahelical receptor for PACAP, PAC1. The receptor has seven transmembrane domains indicated by the cylinders and a long third intracellular loop. Splice variants are indicated in the shaded rectangle.

variant is the hop type and to a lesser extent the null variant. The human prostate gland also contains PAC1 receptors that are present in conditions such as benign prostatic hyperplasia. PAC1 receptors are also present on germ cells and spermatogonia as well as Sertoli and Leydig cells. The respiratory system contains predominantly VPAC1 receptors with little to no PAC1 receptor expressed, whereas the cardiovascular system contains all three receptor types. The PAC1 and VPAC 1 receptors have been identified in the gastrointestinal tract with the PAC1 receptor expressed on the gastric enterochromaffin-like (ECL) cells and the VPAC1 expressed on the somatostatin-containing D cells and chief cells of the stomach. The liver appears to contain predominantly VPAC1 receptors, although careful studies examining PAC1 receptor expression in this organ have not been performed. The smooth muscles of the gastrointestinal tract contain VPAC1 and PAC1 receptors with the PAC1 receptor well described in the rat taenia coli. Another system that has received much scrutiny recently is the immune system. The PAC1 receptor has been described in macrophages, whereas other PACAP receptor types have been described in a number of tumor cell lines. The cloning of rat PAC1 from the rat pancreatic acinar carcinoma cell line AR42J underscores this observation. PAC1 receptor expression has been described in human lung and breast cancer cell lines. Differences in the expression of splice variants of PAC1 receptors in pituitary tumors have also been shown previously. The rat pheochromocytoma cell line PC12 was one of the classical cell systems in which the signal transduction cascade for PAC1 receptors was reported.

IV. PHYSIOLOGY OF PACAP AND ITS RECEPTOR, PAC1

A. Central Nervous System

PACAP appears to exert a multitude of effects within the CNS. Exogenously administered PACAP increases the activity level as well as amount of vasopressin released. The predominant signal transduction pathway involved in the stimulus and release is the protein kinase A pathway. Intracisternal administration of PACAP has been shown to regulate the release of a number of hormones such as gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), prolactin, somatostatin, and the dopamine analogue DOPAC. PAC1 receptors have been shown to be expressed at relatively high levels within the pineal gland and appear to stimulate melatonin secretion. Intracerebral injection of PACAP increases rapid eye movement sleep in sleep-deprived rats. Another potential action of PACAP is in the control of appetite as suggested by its distribution in key areas of the hypothalamus. In cultured cell systems, PACAP has been shown to activate the c-fos, c-Jun, and mitogen-activated protein kinase signaling system, indicating its role in regulating the proliferation of cells. PACAP has been shown to reduce the cytopathic effects of the human immunodeficiency virus envelope protein gp120 in cultured neuroblasts, again supporting a role for this hormone as a neuroprotective factor. In cerebellar granule cells, PACAP appears to reduce apoptosis.

B. Endocrine Organs

PACAP stimulates gonadotropes, somatotropes, lactotropes, and thyrotropes. Somatotropic cells that release growth hormone are stimulated by PACAP and appear to be additive to the effects of GRF. PACAP activates both adenylyl cyclase and phospholipase C in cultured pituitary cells. PACAP appears to be a major regulator of anterior pituitary function by stimulating the release of growth hormone, LH, follicle-stimulating hormone (FSH), prolactin, and the adrenocorticotropic hormone (ACTH). PACAP may act in a synergistic manner with GnRH to stimulate the release of LH and FSH. In cultured lactotropes, PACAP appears to directly stimulate the release of intracellular Ca^{2+}. Unlike the somatotropes, gonadotropes, and lactotropes, the effect of PACAP on corticotropes appears to be indirect, by stimulating corticotropin-releasing factor, the major stimulus for ACTH release. Similarly, no direct effect of PACAP on the thyrotroic cells of the pituitary has been shown.

The second major endocrine site of physiological activity is in the male and female reproductive tract. PACAP has been localized to the smooth muscles of the female reproductive tract, where it may be involved in muscle relaxation. PACAP has also been localized in the placenta. VPAC2 receptors have also been identified in placental tissue, which is the site of initial cloning of the VPAC2 receptor. The ovary also contains PACAP in the granulosa zone. PACAP appears to stimulate an increase in progesterone production in the preovulatory phase. As described earlier, PACAP and PAC1 receptors have been localized to the male gonadal germ cells. PACAP has been shown to stimulate testosterone release. PACAP has been localized to the epididymis and may be an important trigger for sperm release. A reduction

in PACAP may be an important mechanism in penile erection and thus may have a clinical role in male impotence. The adrenal gland contains the highest concentration of PACAP outside of the CNS. It has been shown that PACAP is the most potent stimulator of catecholamine release from the adrenal gland.

C. Respiratory Organs

The major effect of PACAP in the respiratory tree is bronchodilation, an effect that is mediated primarily through the VPAC1 receptor and the activation of cyclic AMP (cAMP). With the discovery that PACAP and VIP may also activate smooth muscle nitric oxide synthesis, this may represent another important action of these hormones. Given the potent actions of PACAP on bronchodilation in humans, the development of potent agonists may be clinically useful.

D. Gastrointestinal Tract

PACAP-containing enteric nerve fibers have been described in the stomach and co-localized with PAC1 receptors on the surface of enterochromaffin-like cells. In the stomach, PACAP appears to be the major neural pathway involved in gastric acid secretion and may account for the observed nocturnal increase in gastric acid secretion. Through its activity on the VPAC1 receptor expressed on the surface of the D cell, PACAP not only activates gastric acid secretion but also, along with galanin, inhibits acid secretion through the release of somatostatin from the gastric D cell (Fig. 2). Another important effect of PACAP is in the regulation of intestinal motility. The action of PACAP is mainly that of relaxation, being mediated through the VPAC1 receptor, but in rat colon, PACAP appears to stimulate apamin-sensitive K^+ channels. The major colonic peristaltic reflex is mediated through VIP, whereas the descending relaxation phase of intestinal peristalsis appears to be regulated by PACAP through its actions on the VPAC1 receptor. Another novel mechanism that has been discovered is the interplay between the hormones VIP and PACAP in nitric oxide synthesis.

E. Cardiovascular System

As shown in both the respiratory and the digestive systems, the primary effect of PACAP is the relaxation of smooth muscles through the activation of cAMP and protein kinase A. Similarly, in the cardiovascular system, PACAP relaxes the smooth muscle in vessels, resulting in an overall reduction in blood pressure. In whole animal studies, intravenous administration of

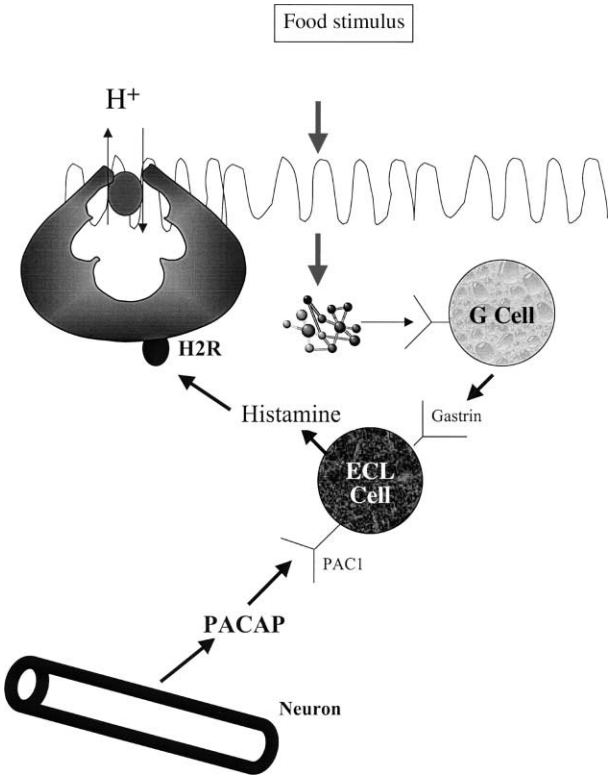

FIGURE 2 Model for the regulation of gastric acid secretion by the hormone PACAP. Released by neurons of the gastrointestinal enteric neural plexus, PACAP binds to the PAC1 receptors of nearby enterochromaffin-like (ECL) cells. PACAP stimulation of ECL cells triggers the release of histamine. Liberated histamine then binds to histamine-2 receptors (H2R) located on the surface of stomach parietal cells, thereby regulating gastric acid secretion.

PACAP results in a biphasic effect with initial vasodilation and a subsequent catecholamine release reflex causing an increase in blood pressure. In cardiac myocytes, PACAP produces a positive inotropic and chronotropic effect and a later reduction in ionotropic effect that appears to be mediated by the resulting vagally released acetylcholine.

F. Immune System

PACAP and VIP have effects on a wide range of immune cells. The role of PACAP in the regulation of cell-mediated immunity has not been thoroughly investigated. In the mouse, PACAP has been shown to activate murine macrophages that would then be able to stimulate T-cell proliferation through specific VPAC1 receptors with a consequent release of interleukin-10 (IL-10) and inhibition of IL-6 and IL-12 production. VIP and PACAP have been shown

TABLE 3 Nomenclature for PACAP and Related VIP Receptors

Receptor type IUPHAR nomenclature	Selective Agonists		Selective antagonists	Fluorescent agonists	Selective antagonist

to inhibit IL-2 transcription in T cells through the reduction of c-Jun. In a recent study, VIP and PACAP were demonstrated to inhibit nuclear factor κB (NF-κB). VIP and PACAP inhibit p65 nuclear translocation and NF-κB DNA binding. In macrophages, VIP and PACAP have been shown to inhibit interferon-γ-induced activation of the Janus kinase 1 (JAK1)/JAK2/signal transactivators and activators of transcription/interferon regulatory signaling cascade.

G. Tumor Biology

The pharmacological characterization of tumor cells expressing PACAP receptors was an integral part of understanding the biology and signal transduction of this hormone and its receptor. Therefore, the majority of the early work on their pharmacology and signal transduction relied on tumor cells such as the rat pancreatic cancer cell line AR-42J, the human neuroblastoma cell line NB-OK1, the human astrocytoma cell line, and the rat pheochromocytoma PC-12 cell line. It has been shown that PACAP stimulates the expression of c-*fos*,c-*myc*, and c-*jun* in a number of tumoral cell lines, indicating that it is a potent stimulator of cell proliferation. In human lung cancer cell lines, PACAP stimulates the growth of tumors injected into nude mice, an effect that can be antagonized by the partial PACAP antagonist PACAP 6–38 (see Table 3). In human tumors, radioligand-binding studies with either ^{125}I-VIP or ^{125}I-acetyl-PACAP-27 show expression of receptor in a large percentage of human tumors including breast, prostate, pancreas, lung, colon, stomach, and liver as well as lymphomas and meningiomas.

V. CONCLUSIONS

PACAP is one of the most recently described neuropeptides. Its biological relevance is only beginning to be understood. Information thus far indicates that both the hormone and the PAC1 receptor are widely distributed in both the CNS and periphery and that this set of biological mediators is relatively important to normal physiology. With the recent study of genetic knockout mice, more information regarding the function of both the hormone and the receptor will be obtained.

Placental Development

MICHAEL T. MCMASTER AND SUSAN J. FISHER
University of California, San Francisco

Survival of the eutherian embryo/fetus depends on the formation of a transient but vital organ, the placenta. Therefore, key events early in placental development play a large role in determining the course and outcome of pregnancy.

I. INTRODUCTION

Placentation, the first test of the embryo's differentiative and organogenetic capacity, accomplishes two critical events: attaching the conceptus to the uterus and bringing the fetal and maternal circulations into close proximity to facilitate effective gas, nutrient, and waste exchange. These functions require that fetal placental cells (trophoblasts) acquire an invasive phenotype. In mammals that form a hemochorial placenta (e.g., humans and mice), fetal trophoblasts come in direct contact with maternal blood. Thus, placentation also entails the unique requirement for close cooperation and direct cellular contact between two immunologically distinct organisms.

During implantation and subsequent placental development, fetal trophoblasts and the uterine cells that they encounter intricately regulate the expression of several classes of molecules. These include adhesion receptors and their ligands, proteinases and their inhibitors, growth factors/cytokines and their receptors, immunomodulators, and transcription factors. This article focuses on the profound changes in trophoblast phenotype that occur during placental development, with emphasis on uterine invasion by cytotrophoblasts (CTBs). Data point to the central importance of the intimate relationship that develops between fetal trophoblasts and the maternal vasculature, as well as to strategies for uncovering the regulatory factors that control the formation of these highly unusual connections.

II. MORPHOLOGICAL ASPECTS OF NORMAL HUMAN PLACENTATION/CYTOTROPHOBLAST INVASION

For many reasons, the human placenta has been difficult to study. With its 9-month life span, developmental processes that take months to years to complete in other organs are compressed into a narrow window of time. Within this short period, additional constraints exist: for example, the requirement that a functioning placenta be in place before substantial fetal growth occurs. As a result, the basic elements of placental development occur during the first half of pregnancy, after which additional growth elaborates on these themes. At term, this organ has reached the end of its life span. As a result of an autocrine program of planned obsolescence, pregnancies that continue beyond this point are endangered by complications that are related to a rapid decline in placental function. Accordingly, the concept that embryonic and fetal development occurs along a smooth continuum during the prenatal period applies only to intraembryonic processes. Differentiation of the extraembryonic lineages is by necessity an explosive event that occurs early in pregnancy. As a result, interpreting any picture of placental development depends entirely on when, during its 9-month life span, that snapshot was taken.

The complex anatomy of the placenta has also made this organ difficult to study. Commonly the placenta is depicted as a simple, pancake-shaped sponge connecting the embryo/fetus to the uterus. This portion of the placenta, which is expelled from the uterus during delivery, is easy to obtain and, consequently, frequently studied. But one of the most interesting parts of the placenta is rarely seen. This portion, which lies buried within the uterine wall, separates from the rest of the placenta during pregnancy termination or delivery. As a result, the only way to obtain this tissue is by uterine biopsy of the site where the placenta attached. Thus, special procedures that are similar to the methods used to obtain any other surgical specimen are required to collect this portion of the placenta.

A full understanding of the placenta can be obtained only by studying both its parts. Figure 1 diagrams these two parts and joins them into a single unit to show how they function, together with modified uterine structures, during human pregnancy. The placenta is made up of individual units termed chorionic villi. Each villus has a connective tissue core that contains fetal blood vessels and numerous macrophages, termed Hofbauer cells. The macrophages often lie adjacent to a thick basement membrane, which underlies a layer of cytotrophoblast stem cells that are the progenitors of all the trophoblast lineages.

The differentiation pathway that cytotrophoblast stem cells take depends on their location. In floating villi, the CTBs fuse to form a multinucleate syncytium, the syncytiotrophoblast, that covers the villus surface. These villi are attached at only one end to the tree-like fetal portion of the placenta. The rest of the villus floats in a stream of maternal blood, which optimizes exchange, across the syncytium, of substances between the mother and the fetus. In anchoring villi, cytotrophoblast stem cells detach from the basement membrane and form a column of nonpolarized mononuclear cells that invade the uterus. As a result, these villi are attached at one end to the fetal portion of the placenta and at the other end to the uterus. This arrangement anchors the villus to the uterine wall. Invasive CTBs rapidly traverse most of the uterine parenchyma (interstitial invasion). They also breach the uterine veins and arteries that they encounter (endovascular invasion). Their interactions with veins are confined to the portions of the vessels that lie near the inner surface of the uterus, but CTBs migrate in a retrograde direction along much of the intrauterine course of the arterioles. Eventually, these fetal cells completely replace the maternal endothelial lining and partially replace the muscular wall of these vessels. This unusual process diverts uterine blood flow to the floating villi.

III. MOLECULAR ASPECTS OF PLACENTATION/CYTOTROPHOBLAST INVASION

Work from the authors' laboratory has focused on molecular aspects of the cytotrophoblast differentiation pathway that leads to uterine invasion. Given the unusual way in which these cells colonize the uterine blood vessels and channel maternal blood to the floating villi, it was hypothesized that they might replicate portions of standard vasculogenesis and/or angiogenesis programs. As a first test of this theory, the cells' expression of adhesion molecules during interstitial and endovascular invasion was examined. The onset of cytotrophoblast differentiation/invasion was found to be characterized by reduced staining for receptors characteristic of polarized cytotrophoblast epithelial stem cells—integrin $\alpha 6\beta 4$ and E-cadherin—and the onset of expression of adhesion

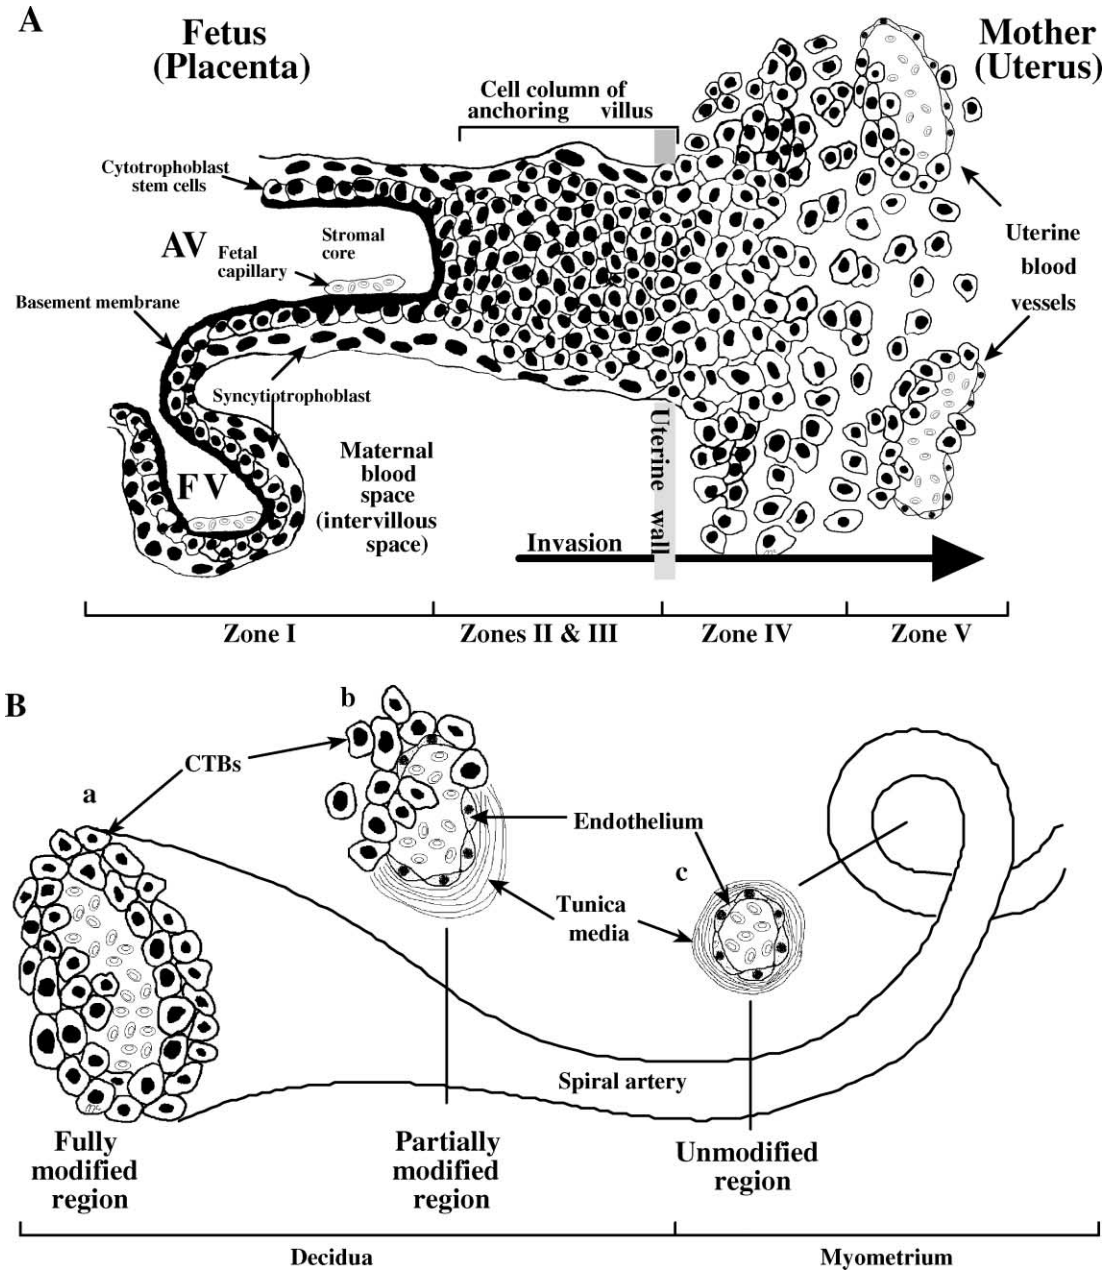

FIGURE 1 (A) Diagram of a longitudinal section of an anchoring chorionic villus (AV) at the fetal–maternal interface at approximately 10 weeks of gestational age. AV functions as a bridge between the fetal and the maternal compartments, whereas floating villi (FV) are suspended in the intervillous space and are bathed by maternal blood. CTBs (cytotrophoblasts) in the AV (Zone I) form cell columns (Zones II and III). CTBs then invade the uterine interstitium (decidua and first third of the myometrium: Zone IV) and maternal vasculature (Zone V), thereby anchoring the fetus to the mother and accessing the maternal circulation. Zone designations mark areas in which CTBs have distinct patterns of adhesion molecule expression. (B) Diagram of a uterine (spiral) artery in which endovascular invasion is in progress (10–18 weeks of gestation). Endometrial and then myometrial segments of spiral arteries are modified progressively. In fully modified regions (a), the vessel diameter is large. CTBs are present in the lumen and occupy the entire surface of the vessel wall. A discrete muscular layer (tunica media) is not evident. (b) Partially modified vessel segments. CTBs and maternal endothelium occupy discrete regions of the vessel wall. In areas of intersection, CTBs appear to lie deep in the endothelium and in contact with the vessel wall. (c) Unmodified vessel segments in the myometrium. Vessel segments in the superficial third of the myometrium will become modified when endovascular invasion reaches its fullest extent (approximately midgestation), whereas deeper segments of the same artery will retain their normal structure. Modified from Zhou *et al*. (1997), with permission.

receptors characteristic of endothelium—VE-cadherin, IgG family members vascular cellular adhesion molecule-1 (VCAM-1) and platelet-endothelial cell adhesion molecule-1 (PECAM-1) and integrins $\alpha V\beta 3$ and $\alpha 1\beta 1$. Accordingly, this phenomenon was termed pseudovasculogenesis. Other investigators showed that additional members of the cadherin family are also up-regulated on invasive CTBs and on decidualizing endometrial stroma. All CTBs in this pathway, regardless of location, stain for Mel-CAM, a melanoma-associated IgG family receptor also expressed on endothelium. Finally, CTBs within the maternal blood vessels turn on the neural cell adhesion molecule (CD56), an adhesion receptor that is also expressed by maternal natural killer cells that home to the pregnant uterus. Thus, as CTBs from anchoring villi invade and remodel the wall of the uterus, these epithelial cells of ectodermal origin acquire an adhesion receptor repertoire characteristic of endothelial cells. It is theorized that this switch permits the heterotypic adhesive interactions that allow fetal and maternal cells to cohabit the uterine vasculature during normal pregnancy.

Changes in the cytotrophoblast adhesion molecule repertoire take place in the context of the cells' equally dramatic modulation of their proteinase and proteinase inhibitor expression. Some aspects of this phenotypic transformation are undoubtedly linked to cytotrophoblast acquisition of an invasive phenotype. For example, expression and activation of matrix metalloproteinase-9 were found to be required for invasion *in vitro*. This observation fits well with recent observations, in other systems, that show that this same proteinase is a key regulator of angiogenesis. It is speculated that CTBs up-regulate the expression of other proteinases/inhibitors in order to present a nonthrombogenic surface to maternal blood. The urokinase-type plasminogen activator and plasminogen activator inhibitor-1, as well as the proteolytically activated thrombin receptor, might function in this manner.

The upstream regulatory factors that control these changes in proteinase and adhesion molecule phenotype include a variety of growth factors. In this regard, vascular endothelial growth factor (VEGF) family members, which are expressed at the maternal–fetal interface, are attractive candidates for regulating pseudovasculogenesis. Other factors, such as hepatocyte growth factor/scatter factor, can promote invasion by interacting with c-Met expressed on invading CTBs.

Finally, invading CTBs up-regulate the expression of other molecules that likely enable them to escape maternal immune rejection. Proteins expressed by trophoblasts that play a role in immunotolerance include human leukocyte antigen G (HLA-G), a unique major histocompatibility class Ib antigen with limited polymorphism, and interleukin-10, a potent immunosuppressive cytokine. HLA-G is expressed by invading CTBs that are in intimate contact with the decidua (which includes abundant maternal immune cells), suggesting a key juxtacrine regulatory role for this molecule. As shown in Fig. 2, HLA-G expression is a very sensitive marker of CTBs that have differentiated toward an invasive phenotype. Interstitial and endovascular CTBs express HLA-G, but syncytiotrophoblast and cytotrophoblast stem cells attached to the villus basement membranes do not. The regulated expression of these molecules by CTBs provides insights into how the placenta, a semiallograft, is able to develop in the context of a fully functional maternal immune system. However, the precise mechanisms whereby the placenta mediates maternal immune tolerance remain poorly understood.

IV. REGULATION OF CYTOTROPHOBLAST ENDOVASCULAR INVASION

How can the knowledge of cytotrophoblast invasion be used to advance the understanding of the regulatory factors that govern placental development? One avenue that is being explored is the extent to which physiological parameters that are known to play important roles in the vasculature operate in the placenta. The first major effort in this direction led to the examination of the role of oxygen tension, one of the major factors at play in the vasculature. In this regard, it is interesting to consider that the placenta is the first organ to function during development. This hierarchy imposes novel requirements on cytotrophoblast growth and differentiation. For example, the critical early stages of placental development occur before the conceptus accesses a supply of maternal blood (≤ 10 weeks of gestation). In accord with this constraint, previous work showed that CTBs proliferate *in vitro* under hypoxic conditions that are comparable to those found during early pregnancy in the uterine lumen and the superficial decidua. As trophoblast invasion of the uterus proceeds, the placental cells encounter increasingly higher oxygen levels, which trigger their exit from the cell cycle and subsequent differentiation.

The discovery that CTBs acquire characteristics of vascular cells during endovascular invasion highlights

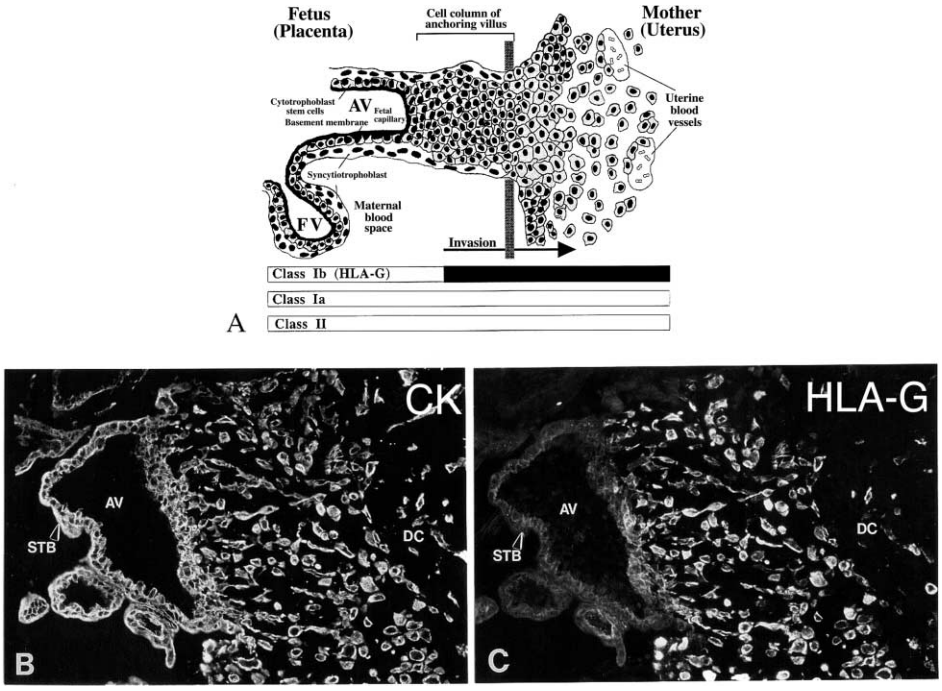

FIGURE 2 Immunostaining of a section of the placental bed shows that HLA-G protein is produced by only invasive CTBs *in vivo*. (A) Summary diagram of the trophoblast populations in anchoring villi and their expression of major histocompatibility class I and II molecules. (B and C) Section of a 14-week placental bed biopsy double-labeled with rat monoclonal antibody 7D3 (anti-cytokeratin) and mouse monoclonal antibody 4H84 (anti-HLA-G). B shows cytokeratin staining, which labels all the trophoblast cells in the section. C shows HLA-G staining detected with fluorescein-conjugated antibodies. The section contains an anchoring villus (AV) with an associated cytotrophoblast cell column and decidua (DC). Note that the invasive CTBs stain strongly for HLA-G, whereas the syncytiotrophoblasts and cytotrophoblast stems cells do not. STB, syncytiotrophoblast.

the potential importance of factors that govern conventional vasculogenesis/angiogenesis in the regulation of placental development. Undoubtedly, this complex differentiation program is controlled by a hierarchy of regulatory factors. At a physiological level, it is already known that oxygen tension, which has profound effects on blood vessels, controls the switch between cytotrophoblast proliferation and differentiation. In these experiments, control anchoring villus explants (6–8 weeks of gestation) were maintained in either a 20 or an 8% O_2 atmosphere, mimicking standard culture conditions and the environment within the uterine interstitium (Fig. 1A, Zone IV), respectively. Other villi were cultured in 2% O_2, mimicking the hypoxic conditions in the fetal compartment near the uterine lumen at this time (Fig. 1A, Zone I; intervillous space). In 20 and 8% O_2, CTBs exit the cell cycle, up-regulate $\alpha1\beta1$, and become highly invasive. In hypoxia, CTBs continue to proliferate, but they fail to express $\alpha1\beta1$ integrin and do not invade. These observations suggest the following model. Before CTBs access the maternal blood supply (e.g., at 10 weeks of gestation), the hypoxic environment near the uterine lumen in which early placental development occurs favors cytotrophoblast proliferation, a phenomenon observed *in situ*. As interstitial invasion proceeds, invasive CTBs encounter a positive oxygen gradient that favors differentiation/invasion. Interestingly, hypoxia *in vitro* mimics some of the effects seen in preeclampsia, suggesting the possible consequences of failed endovascular invasion *in vivo*.

It can be envisioned that oxygen acts through a variety of downstream effectors that include molecular families known to play an important role in vasculogenesis/angiogenesis. In this regard, VEGF family members and their receptors are attractive candidates. There are several reports that CTBs, as well as fetal and maternal macrophages, express VEGF. CTBs also express placental growth factor (PlGF), a unique placental form of VEGF. Unlike VEGF, PlGF is not responsive to hypoxia; furthermore, its homodimers

are not angiogenic and bind VEGF receptor-1 (Flt-1, Fms-like tyrosine kinase-1) but not VEGF receptor-2 (KDR, kinase insert domain-containing receptor). PlGF also forms heterodimers with VEGF that bind both receptors. VEGF up-regulates the expression of $\alpha 1\beta 1$ and $\alpha V\beta 3$ integrins in endothelial cells. These are the same proinvasive integrins that are up-regulated during cytotrophoblast differentiation, tempting speculation that VEGF family factors play analogous roles in invasive CTBs and angiogenic endothelial cells, a hypothesis that was recently proved. CTBs also express Flt-1 and KDR. Other factors and their cognate receptors that regulate vasculogenesis/angiogenesis, including fibroblast growth factors/receptors, TIEs/angiopoietins, and thrombospondins, are also expressed in the placenta.

Given this complexity, it is likely that the regulated balance of pro- and anti-angiogenic mechanisms is critical to coordinating the development of the hybrid vascular structures, composed of CTBs and maternal cells, that control blood flow to the fetus. Placental development actually requires the coordination of three different vasculogenesis/angiogenesis-like programs. First, fetal blood vessels develop in the stroma of floating chorionic villi (see Fig. 1A, fetal capillary). This process probably employs a vasculogenesis/angiogenesis program similar to that taking place within the embryo proper. Second, differentiating/invading CTBs undergo pseudovasculogenesis, the differentiation program that allows them to take on an endothelial adhesion phenotype (Fig. 1A, Zones II–V). Third, endovascular invasion by CTBs occurs without triggering significant angiogenesis in the maternal vessels, which suggests that CTBs also have novel paracrine mechanisms for rendering quiescent the resident uterine vasculature that they remodel (Fig. 1A, Zone V, uterine blood vessels). How are these different processes coordinated within the same microenvironment? The novel requirements of cytotrophoblast endovascular invasion suggest that known regulatory molecules may have novel actions; alternatively, novel regulatory molecules may control the behavior of these unusual cells.

The importance of trophoblast differentiation to embryonic/fetal development is also revealed by the numerous types of genetically engineered mice with placental defects. In the context of normal and abnormal human cytotrophoblast differentiation/invasion, some of the most interesting molecules implicated in knockout mouse experiments include hepatocyte growth factor/scatter factor and its c-Met receptor, VCAM-1 and the integrin $\alpha 4$ subunit, and the hypoxia-inducible transcription factor HIF-1β (ARNT). Although the discovery that these and other molecules, e.g., Mash-2, Ets-2, Wnt2, and interleukin-11 receptor, play important roles in placentation has for the most part been unexpected, the trophoblast phenotypes of genetically engineered mice, which like humans form a hemochorial placenta, will continue to be extremely informative regarding mechanisms of human placental development and cytotrophoblast pseudovasculogenesis.

In summary, recent advances have uncovered the unexpected finding that specialized fetal cells of the human placenta—CTBs—undergo a novel pseudovasculogenesis differentiation program that enables them to masquerade as the endothelial and smooth muscle components of maternal uterine vessels. Discovery of the regulatory mechanisms that govern this unusual transformation will offer fascinating insights into how the placenta forms. Will the results of these studies be applicable to other normal and abnormal processes that require similar sorts of plasticity? One interesting possibility is that tumor cells, which like CTBs are marauders in search of a blood supply, might co-opt portions of the differentiation program described here. Whether lessons learned from placental development could be used to develop additional anti-angiogenesis cancer therapies, analogous to those described by Folkman and co-workers, remains to be investigated.

Glossary

cytotrophoblast stem cells Mononuclear trophoblast precursors to invasive cytotrophoblasts and syncytiotrophoblasts.

decidua Stromal compartment of the endometrium during pregnancy.

invasive cytotrophoblasts Mononuclear trophoblasts that migrate into the uterine interstitium and vasculature.

syncytiotrophoblasts Multinucleate trophoblasts that line the surface of floating villi.

trophoblast Type of epithelial cell that forms the maternal–fetal interface.

Placental Gene Expression

AMRITA KAMAT AND CAROLE R. MENDELSON
University of Texas Southwestern Medical Center

The human placenta is composed of a core of proliferating mononuclear cytotrophoblasts; these trophoblast cells differentiate to form the syncytiotrophoblast layer, which covers the placental villi and has numerous secretory and transport/processing functions. It is this differentiation of cytotrophoblasts to syncytiotrophoblast that generates a cascade of regulatory signals that result in the production of various polypeptide hormones, growth factors, steroid hormones, and steroid-metabolizing enzymes. Cell culture techniques and transgenic technology are used to elucidate molecular events that promote and maintain syncytiotrophoblast differentiation and culminate in expression of different placenta-specific proteins factors.

I. INTRODUCTION

Maintenance of pregnancy and normal growth and development of the fetus are critically dependent on a biomolecular fetal–maternal communication, which is accomplished by the placenta. The placenta is, therefore, a critical organ, not only as the means of exchange of gases, nutrients, and waste products between the fetus and the mother, but also as an important source of hormones, growth factors, and other molecules that maintain uterine quiescence, stimulate fetal growth and development, and contribute to immune privilege. Placental molecules and growth factors include pregnancy-associated hormones (corticotropin-releasing hormone, progesterone, estrogen, and members of the growth hormone/prolactin gene family), enzymes (e.g., aromatase and side chain cleavage enzyme), leptin, interferons, angiogenic growth factors, cell adhesion molecules, and extracellular matrix metalloproteinases. These different molecules play varied but important roles in pregnancy; thus alterations in their expression underlie early pregnancy loss and complications.

In this article, we review work that has elucidated transcriptional regulation of two important human placental molecules, placental lactogen (chorionic somatomammotropin) and the enzyme aromatase, which catalyzes conversion of C_{19} steroids to estrogen.

II. AROMATASE

As normal pregnancy progresses, there is a gradual increase in plasma levels of estrogens and progesterone, which are synthesized primarily by the placenta. Near term in humans, there are extraordinarily high circulating levels of estrogen and progesterone, which decline abruptly with the delivery of the fetus and placenta. Thus, the human placenta, like the placentas of a number of ungulates, including cows, pigs, and horses, is able to synthesize estrogens, a property that is not shared by the placentas of rodent species, such as rats and mice. The physiological significance of the high levels of estrogen production by the human placenta is unclear at this time. However, it is likely that the human placenta has acquired the capacity to synthesize estrogens, in part, to metabolize the high levels of circulating androgens derived from the fetal adrenals, thus preventing their virilizing effects.

The human placenta lacks the enzyme 17α-hydroxylase, thus progesterone cannot be used as a substrate for estrogen biosynthesis. Instead, the high levels of estrogen produced in the human placenta are derived primarily from the C_{19} steroid, 16α-hydroxyandrostenedione, which is secreted by the fetal adrenal. Aromatase P450 is the enzyme responsible for catalyzing the biosynthesis of C_{18} estrogens (17β-estradiol, estrone, and estriol) from C_{19} steroids. Aromatase P450 is expressed exclusively in estrogen-producing cells and is a product of the *CYP19* gene. Homozygous mutations of the single-copy human gene (h*CYP19*) result in virilization of the female fetus *in utero*, conferring subsequent primary amenorrhea.

The h*CYP19* gene spans ~130 kb in the human genome (Fig. 1). It is postulated that expression of h*CYP19* in various estrogen-producing tissues, including the gonads, brain, adipose tissue, and placenta, is driven by tissue-specific promoters that lie upstream of unique first exons, although the aromatase protein synthesized in each of these tissues is identical. Thus, the start site of transcription in placenta (in exon I.1) lies ~100,000 bp upstream of the start site of translation in exon II, whereas the ovary-specific first exon lies immediately upstream of exon II.

Primary cultures of human trophoblast cells transfected with various gene constructs have been used to create functional maps of sequences required for placenta-specific h*CYP19* gene expression. Mononuclear cytotrophoblast cells, which do not express aromatase, are isolated from the midterm placenta. When these cells are placed in culture, they fuse and differentiate to form a multinuclear syncytiotrophoblast. These morphological changes are associated with a marked induction of h*CYP19* gene expression. This primary cell culture system thus provides a physiologically relevant model to study molecular mechanisms in the regulation of h*CYP19* gene expression. Studies using this culture system suggest that 501 bp of exon I.1 5′ flanking DNA is sufficient for trophoblast-specific expression of h*CYP19* gene and that sequences between −501 and −246 bp contain silencer elements that may bind inhibitory transcription factors in nonplacental cells. Findings from deletion mapping analysis, site-directed mutagenesis, and electrophoretic mobility-shift assays also indicate that two overlapping hexameric sequences (AGGTCA, −183 to −191 bp), which may bind members of the nuclear receptor superfamily, and a G/C-rich sequence (−233 bp), which binds Sp1 and other as yet unidentified transcription factors, may contribute to the high levels h*CYP19I.1* promoter activity during syncytiotrophoblast differentiation.

In addition to primary cultures of placental cells, choriocarcinoma cell lines such as BeWo and JEG-3 have been used to study regulation of h*CYP19* gene expression. Using transfected JEG-3 choriocarcinoma cells, it has been observed that the proximal 301 bp upstream of exon I.1 is capable of conferring placental cell-specific h*CYP19* gene expression. Within this region, an element has been identified that is capable of binding a "glial cells missing" motif protein, the expression of which is restricted to the placenta. Other studies using BeWo choriocarcinoma cells have also localized a cell-type specific enhancer element between −242 and −166 bp relative to the transcriptional start site in exon I.1, which may play an important role in sustaining high levels of h*CYP19* expression.

In addition to studies in primary cultures of placental cells and choriocarcinoma cell lines, transgenic mice have been used to map h*CYP19* promoter regions required for appropriate tissue-specific and developmental regulation of gene expression. Initially, it was uncertain whether the mouse would serve as an appropriate model, because its placenta

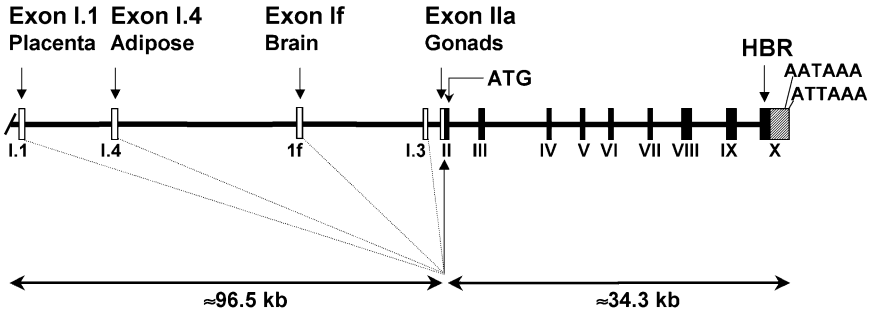

FIGURE 1 Schematic representation of the human *CYP19* gene and its alternative first exons. The protein coding sequences of the human *CYP19* gene, exons II–X (solid bars), and their introns comprise a region of ~34 kb. The heme-binding region (HBR) is in exon X, as are two alternative polyadenylation signals. The untranslated exons IIa, I.3/I.4, If, and I.1 (open bars) encoding the 5′ ends of the aromatase P450 mRNAs in the gonads, adipose, brain, and placenta, respectively, encompass a region of ~100 kb. These tissue-specific first exons are alternatively spliced onto a common site (shown by the septum) just upstream of the ATG codon in exon II. Based on the Celera Human Genome database (hcg 39857 CYP19GA_x2HTBL5L7WT), the human *CYP19* gene lies on chromosome 15, spanning q14–q15. Reproduced from Kamat *et al.* (2002), with permission from Elsevier Science.

does not express the endogenous *cyp19* gene. It was not known if the lack of estrogen synthesis in the mouse placenta was due to an absence of essential gene regulatory elements or of critical transcription factors. However, expression of h*CYP19I.1*$_{-2400}$:*hGH* (human growth hormone) or h*CYP19I.1*$_{-501}$:*hGH* fusion genes in transgenic mice was placenta-specific and developmentally regulated. Thus, just 500 bp of DNA, ~100 kb upstream of the coding region of the human *CYP19* gene, is sufficient to mediate placenta-specific expression in transgenic mice. These results clearly indicate that the transcription factors required to activate the human *CYP19* placenta-specific promoter are conserved between human and mouse genes, but that the mouse lacks the critical cis-acting elements required for expression of its endogenous *cyp19* gene.

To localize h*CYP19I.1*$_{-501}$:*hGH* fusion gene expression within the mouse placenta, *in situ* hybridization was performed using an antisense hGH probe. The main fetal components of the mouse placenta include the trophoblast giant cells, the spongiotrophoblast, and the labyrinthine trophoblast layer. Many of the placental polypeptide hormones and steroidogenic enzymes are expressed in the spongiotrophoblast and the trophoblast giant cells; however, the transgene is not expressed in these cells. On the other hand, the transgene is expressed as early as embryonic day 10.5 (E10.5) specifically in the mouse labyrinthine trophoblast layer (Fig. 2). This trilaminar layer is highly vascularized; its outer cellular layer, which covers two inner layers of syncytial cells, is bathed in maternal blood and thus plays an important role in nutrient and gas exchange. Therefore, the labyrinthine layer of the mouse placenta appears to be analogous to the human syncytiotrophoblast, which expresses aromatase and also is bathed in maternal blood. Thus, studies using trophoblast cells in culture and transgenic mice indicate that the proximal 501 bp flanking the 5′ end of exon I.1 of the h*CYP19* gene is sufficient for placenta-specific expression.

III. HUMAN PLACENTAL LACTOGEN

Placental lactogens (PLs), or chorionic somatomammotropins, play an important role in the regulation of maternal and fetal metabolism and in the growth and development of the fetus. Human *PL* belongs to the growth hormone (*GH*) gene family, which includes the growth hormone gene (*GH-N*) and four growth hormone gene variants (*GH-V*, *PL-A*, *PL-B*, and *PL-L*). This five-gene family cluster shares greater than 90% sequence identity and has evolved by gene duplication. However, although *GH-N* is predominantly expressed in the pituitary somatotrophs, the other four genes are expressed selectively in the syncytiotrophoblast layer of the placenta. In addition to the major transcripts encoding the proteins, multiple alternatively spliced products for *GH-V*, *PL-A*, *PL-B,* and *PL-L* genes have been observed in the placenta.

Although members of the h*GH/PL* gene family share nearly 91–99% sequence identities throughout their coding regions and within a 500-bp 5′ flanking region just proximal to the transcription start sites, studies conducted over the years indicate that the critical trans-acting factors and the cis-acting

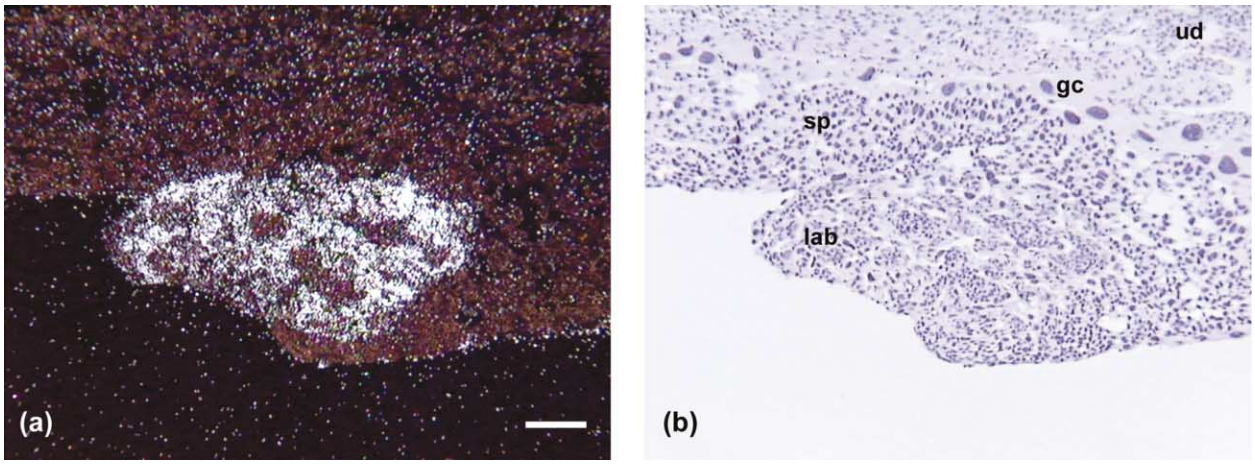

FIGURE 2 Labyrinthine-specific expression of a *CYP19I.1*$_{-501}$:*hGH* fusion gene in transgenic mice. Placental tissue obtained from an E10.5 fetal transgenic mouse carrying the *CYP19I.1*$_{-501}$:*hGH* fusion gene was processed for *in situ* hybridization using a ^{35}S-labeled antisense hGH cRNA probe and then exposed to photographic emulsion for 1–2 weeks. (a) Darkfield and (b) brightfield micrographs reveal trophoblast giant cells (gc), spongiotrophoblast (sp), labyrinthine trophoblast (lab), and the uterine decidua (ud). Reproduced from Kamat, A., Graves, K. H., Smith, M. E., Richardson, J. A., and Mendelson, C. R. (1999), A 500-bp region, approximately 40 kb upstream of the human CYP19 (aromatase) gene, mediates placenta-specific expression in transgenic mice, *Proc. Natl. Acad. Sci. USA* **96**, 4575–4580, with permission from the National Academy of Science, USA.

elements necessary for placenta-specific expression of *PL* are distinct from those that regulate the expression of h*GH* in the pituitary. Work done mainly in choriocarcinoma cell lines indicates that a ubiquitous Sp1 site, two activator protein-2 (AP-2) sites, and a trophoblast-specific initiator element (InrE) located within the 5′ flanking region are important for the regulation of *PL-A* gene expression. The Sp1 site, although found to be necessary, is not sufficient for maximal basal and enhancer-mediated transcription. However, a 70-kDa InrE-binding protein expressed in human choriocarcinoma cell lines BeWo and JEG-3 is observed to be required for maximal enhancer function and cell-specific h*PL* gene expression. Results also suggest that the InrE elements are required for accurate transcription initiation from the PL promoter in these cells. Expression of h*PL* in the placenta is also regulated by PL enhancers, CSEn1, CSEn2, and CSEn5, located downstream, or 3′, of the *PL-A*, *PL-B*, and *PL-L* genes, respectively. These enhancers are composed of multiple enhansons that work cooperatively to mediate maximal enhancer activity. Work done to characterize the enhancer CSEn2 indicates that several DNA–protein interactions occur within this region. Chorionic somatomammotropin gene enhancer factor-1 (CSEF-1), a 30-kDa protein found in BeWo cells, has been suggested to act through CSEn2 to enhance transcription. Transcriptional enhancer factor-1 (TEF-1) also binds to this element with the same affinity as CSEF-1 but reduces activation of the h*PL* promoter by inhibiting preinitiation complex formation. On the other hand, another member of the TEF family, TEF-5, binds to a unique element in CSEn2 and transactivates the enhancer. Further studies to characterize placenta-specific expression of *PL* genes have also indicated that there are mechanisms to suppress h*PL* gene expression in the pituitary. It has been demonstrated that CSEn2 in conjunction with either CSEn1 or CSEn5 forms a composite silencer in pituitary cells. Additionally, two orientation-dependent repressor elements (PSF-A and PSA-B) that exist in the 5′ flanking region of each of the *PL* and *GH-V* genes, but not in that of the pituitary *GH-N* gene, have been reported to bind pituitary nuclear factors that inhibit transactivation of the placental members of the growth hormone family in the pituitary. Thus, these various *in vitro* studies using both cultured placental cells and choriocarcinoma cell lines have indicated that placenta-specific transcriptional control of the h*PL* gene involves both positive and negative regulation.

Studies have also been conducted to ascertain if the critical cis-acting elements, as defined in cell transfection assays, are able to direct appropriate placenta-specific expression in transgenic mice. In initial studies, a 15-kb transgene fragment containing the *PL-A* gene with 5.4 kb of 5′ flanking sequence and

7.2 kb of 3′ flanking sequence was found either not to be expressed or to be expressed at low and variable levels in the mouse placenta. An 87-kb transgene was then created; it contained the majority of the h*GH* gene cluster linked to the entire locus control region, located − 15 to − 32 kb upstream of the hGH cluster, and was used to determine the expression pattern of the human genes as they exist in the native configuration of their family cluster. In the five transgenic mouse lines that were created, all of the h*GH* cluster genes were appropriately expressed, with h*GH-N* being specifically expressed at relatively high levels in the pituitary and the h*PL* genes being expressed specifically in the placenta. In contrast to the human genome, the mouse genome contains a single pituitary-specific *GH* gene and lacks any *GH*-related *PL* genes. Nonetheless, it is apparent that the mouse placenta has the transcription factors necessary to mediate placenta-specific expression of the human *PL*-containing transgene. Further *in situ* studies have indicated that expression of the h*PL-A*-containing transgene is localized to the labyrinth of the mouse placenta, which, as previously mentioned, is functionally analogous to the syncytiotrophoblast.

IV. CONCLUSIONS

Aromatase and the placental lactogens participate in important placental functions in humans. Whereas aromatase is necessary for the conversion of C_{19} steroids to estrogens, and lack of aromatase expression results in virilization of the fetus, the placental lactogens alter maternal carbohydrate and lipid metabolism to provide for fetal nutrient requirements. However, the biological functions of the products of both of these genes are not fully understood, and individuals with mutations in placental genes for *CYP19* or *PL* genes have had normal pregnancies. Studies on regulation of the h*CYP19* or h*PL* gene have thus far indicated that both negative and positive tissue-specific transcription factors are involved in regulation of the placenta-specific gene expression. Additionally, although the mouse placenta does not express aromatase or PLs, the h*CYP19* and h*PL* transgenes are specifically expressed in the labyrinthine layer of the mouse placenta, which is functionally analogous to the syncytiotrophoblast of the human placenta, where these genes are normally expressed. This suggests that specific cells within the labyrinthine layer of mouse placenta express the appropriate transcription factors required to activate the promoters of the h*CYP19* and h*PL* genes. Future studies in placental cells and in transgenic animals will likely contribute to our understanding of the positive and negative regulatory elements involved in tissue-specific regulation of aromatase and PL, and to the role that these two important molecules play in human placenta.

Glossary

enhancers DNA sequences that increase the rate of gene transcription from a distance, irrespective of their orientation relative to the transcription start site in the gene.

enhansons Subunits of enhancers; some enhancers are composed of separate 15- to 20-bp elements that cooperate with one another to enhance transcription. These elements are made up of enhansons, which can be duplicated or interchanged to create new enhancer elements. Unlike enhancers, enhansons are sensitive to changes in spacing.

labyrinthine zone Murine placental complex of trophoblast, mesoderm, and vascular derivatives; functionally analogous to the floating chorionic villi in humans.

spongiotrophoblast Intermediate layer in the murine placenta that, like the trophoblast giant cells, arises from the ectoplacental cone; with the giant cell layer, separates the labyrinthine zone from the maternal decidua.

trans-acting factors Transcription factors (specific proteins) that bind to relatively short DNA sequence motifs, or cis-acting elements, to regulate gene transcription. The cis-acting elements can occur in various locations and at different distances and directions relative to the transcriptional start and stop sites within the gene.

trophoblast cells Progenitor cells, important in the formation of the placenta and responsible for various functions, including nutrition of the differentiating embryo and the growing fetus and secretion of hormones indispensable for the maintenance of pregnancy.

trophoblast giant cells Polyploid mouse trophoblast cells that surround the conceptus and lie in direct contact with the maternal decidua.

Placental Immunology

JOAN S. HUNT AND MARGARET G. PETROFF
University of Kansas Medical Center

Placental immunology may be defined as the study of structural and functional features of the placenta that permit semiallogeneic pregnancy to proceed despite genetic differences between the mother and the fetus. Ordinarily, the presence of "foreign" tissue would stimulate a graft rejection response as is the case in transplantation of organs. In this article, the unique aspects of immune protection at the maternal–fetal interface are presented.

I. INTRODUCTION

In the middle of the past century, immunologists were just beginning to understand the design of the immune system. One general principle emerged; in healthy adults, the immune system is immensely efficient in repelling the invasion of foreign DNA and RNA.

A major enigma is presented by the state of human pregnancy, in which genetically different tissues reside side by side in apparent harmony. In 1953, P. Medawar was the first to offer ideas for mechanisms that could account for the surprising ability of the fetal semiallograft to survive in a potentially hostile environment. His suggestions included (1) anatomic separation of the mother and fetus; (2) antigenic immaturity of the fetus; and (3) tolerance in the mother. Although somewhat different from Medawar's original ideas, all these mechanisms have now been identified. The blood circulations of the mother and fetus are entirely separate, the major fetal cell surface molecules that stimulate graft rejection appear late, and mothers develop multiple tolerogenic mechanisms.

One of the most impressive features of immunological protection, which may be termed "immune privilege," is the wide range of devices used in maternal endometrium and fetal placenta to ensure tolerance. In humans, these may include (1) tight control over the expression of human leukocyte antigen (HLA) expression by cells in human placentas; (2) production of immunosuppressive substances such as prostaglandin E2, progesterone, and T-helper 2 (T_H2)-type cytokines at the maternal–fetal interface; (3) placental cell expression of the apoptosis-inducing cytokines, Fas ligand (CD95 ligand) and tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL) (Apo-2 ligand), as well as proteins that inhibit the complement cascade and those that modulate leukocyte proliferation and cytokine secretion (B7-H1); and (4) restriction of migration of antigen-specific T and B lymphocytes into the decidua. Each of these mechanisms is of great interest and will be discussed briefly in this article.

II. PLACENTAL REGULATION OF HLA

A. HLA Class I Antigens

Both beneficial and potentially detrimental effects are exerted by the functionally unique HLA molecules. These cell surface structures are required for host protection against infectious agents but when they are perceived as foreign by the host, as is likely to happen with paternally derived antigens in human pregnancy, they may stimulate graft rejection.

The major histocompatibility complex (MHC) located on the short arm of chromosome 6 encodes the HLA class I antigens. The proteins comprise three ~100 amino acid "domains" with disulfide bonds looping the domains. HLA class I antigens usually have one transmembrane heavy chain (37 to 45 kDa) associated noncovalently with a light chain (β2-microglobulin, ~12 kDa). HLA class I glycoproteins

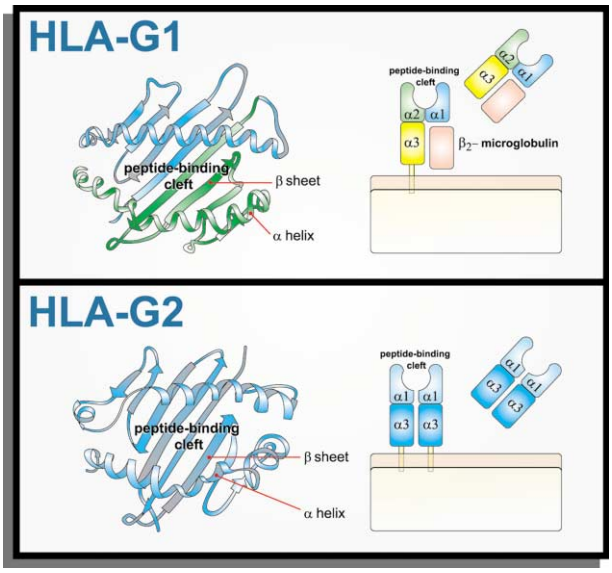

FIGURE 1 Schematic representations of (left) the peptide-binding cleft in HLA-G1 and HLA-G2, as viewed from the top down, and (right) the likely structures of membrane-bound and soluble HLA-G1 and HLA-G2. Note that HLA-G1 is composed of a heavy chain and a light chain (β2-microglobulin), whereas HLA-G2 heavy chains form homodimers and do not bind β2-microglobulin.

carrying foreign peptides within a region called the peptide-binding groove (Fig. 1) are recognized by the T-cell receptor (TCR) on $CD8^+$ precursor cytotoxic T lymphocytes (CTL). The HLA-A, -B, and -C class Ia genes are highly polymorphic and their proteins are co-dominantly expressed on the cell membranes of essentially all eukaryotic cells, the exceptions being germ cells (oocytes, sperm) and placental trophoblast cells. Differences between class I antigens derived from each allele create a major barrier associated with transplantation of donor organs because immune cells recognize nonself alleles as foreign and mount a graft rejection response that includes cytotoxic cells and cytotoxic antibodies.

By contrast, the HLA-E, -F, and -G class Ib genes have few alleles and their proteins are restricted to certain types of cells. Figure 1 shows the probable antigen-binding clefts and stylized isoform structures of soluble HLA-G1 and soluble HLA-G2, two isoforms of HLA-G which are discussed below.

B. HLA Class II (HLA-D) Antigens

The class II antigens have two transmembrane heavy chains, are also highly polymorphic, and also constitute barriers to transplantation. They are expressed primarily on antigen-presenting cells such as macrophages, dendritic cells, and B lymphocytes, but may be expressed on other cells during certain diseases. The class II antigens form homodimers rather than heterodimers. HLA class II (HLA-D) glycoproteins carrying foreign peptides in the homodimeric heavy chain cleft are recognized by TCRs on $CD4^+$ T-helper lymphocytes.

C. HLA on Trophoblast Cells

The surprising success of semiallogeneic pregnancy may be attributed in large part to controlled expression of the HLA molecules in trophoblast cells. These cell surface structures are the main mediators of graft rejection, but HLA is so firmly regulated that there are no known instances of inappropriate expression in fetal tissues as a cause of pregnancy failure where maternal immune cells attack fetal tissues. Trophoblast cells may be subdivided into several subpopulations depending on their stage of differentiation and their anatomic location; regulation of their HLA proteins differs according to need.

D. Trophoblast Subpopulations

Trophoblast cells are derived from the trophectoderm layer of the blastocyst. These cells are not uniform; they differentiate in a stage-specific manner into several subpopulations. The cytotrophoblast is the precursor cell and is driven into one of two pathways of differentiation. In one instance, cytotrophoblast cells coalesce into a multinucleated syncytium. This is an uninterrupted cell layer that, at term, would cover 9 m^2 if spread. The syncytiotrophoblast cell layer modulates bidirectional transport of nutrients and wastes, is responsible for most placental hormone production, and protects the inner cell mass-derived elements (the amnion and chorion membranes, the umbilical cord, and the embryo) from blood-borne maternal immune cells.

A second set of cytotrophoblast cells proliferates and emerges from the floating placental villi to form columns that ultimately contact the maternal decidua (Fig. 2). The extravillous trophoblastic cells invade the spiral arteries and replace the endothelial cells in the vessels. As pregnancy progresses, the extravillous cells cease migrating and regress to form the chorion membrane.

Unlike embryonic cells, trophoblast cells never express normal adult levels or patterns of HLA. As described below, specific HLA class I genes are

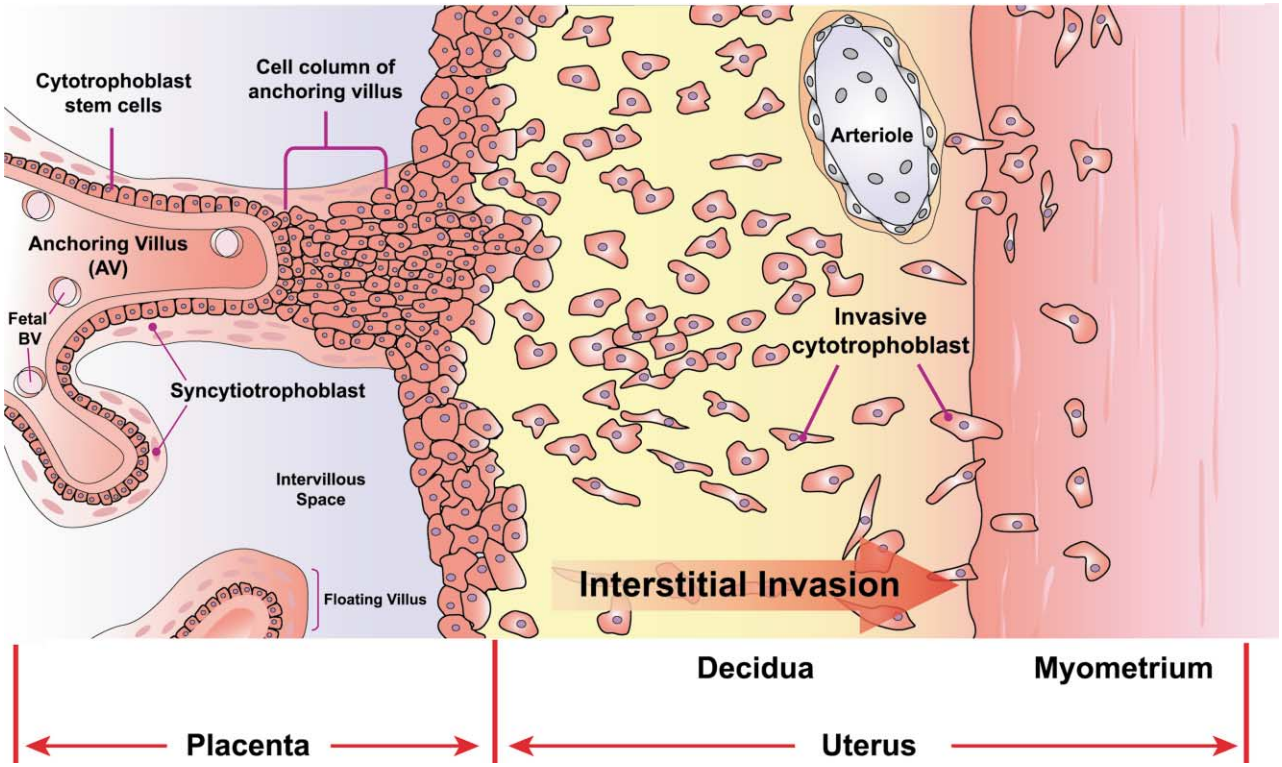

FIGURE 2 A representational drawing of the maternal–fetal interface at the point of contact. Some placental villi form cell columns. Cytotrophoblast cells invade the maternal uterine interstitium and may be found in the myometrium as well as lining maternal spiral arteries. Other villi float in a sea of maternal blood filling the intervillous space.

selected for expression from among the many members of this multigene family, whereas HLA class II genes are essentially unexpressed in trophoblasts. The absence of class II may be due to repressor elements on promoter and other elements in the class II gene sequences. More studies need to be performed to elucidate the nature of the restriction, which is effective even in the presence of class II inducers such as interferon-γ (IFN-γ) and type 1 interferons.

E. HLA Class I in Trophoblasts

The exciting story of how placental expression of the HLA genes and the glycoproteins derived from these genes was revealed has been told frequently. In short, stage of gestation, state of differentiation, and anatomical location dictate expression in this unique cell lineage.

HLA class I message may be present but membrane-bound proteins are difficult to detect in early gestation syncytiotrophoblast and villous cytotrophoblast cells. In late gestation, neither subpopulation contains substantial class I mRNA or membrane-bound HLA class I protein. Although cytotrophoblast cells in early placentas that are proliferating in preparation for column formation are negative for both message and protein, the cytotrophoblast cells distal to the villus in the cytotrophoblastic shell are HLA class I positive. Class I positivity is retained in the chorion membrane cytotrophoblast cells, which are derived from the invasive extravillous cytotrophoblasts.

F. HLA Class I Gene Selection

The ability to select specific members of the HLA class I multigene family for expression is a unique property of trophectoderm-derived cells. Three members of the HLA class I gene family are present in HLA class I positive trophoblasts; one is a class Ia gene, HLA-C, and two are class Ib genes, HLA-E and HLA-G. The highly polymorphic, widely distributed HLA-A and -B antigens are absent.

The function(s) of HLA-C remains unknown. Although the gene is polymorphic and it is clear that

proteins derived from this gene are present on trophoblast cells, whether it has any influence on immune cells or the immunobiology of pregnancy is not known. Unlike other class Ia genes, expression is transient and at a comparatively low level. HLA-E is an interesting molecule; it uses the leader sequences of other class I proteins to gain access to the cell surface. Considerable experimentation has led to the idea that HLA-E interacts with natural killer (NK) cell inhibitory receptors and drives these cells into an anergic condition. The decidua in early and mid stages of pregnancy is packed with NK cells that would attack HLA^- negative cells, so expression of a class I molecule is very important. HLA-G, which was the first HLA to be discovered on trophoblast cells, has been extensively studied. Much has been revealed about this unusual gene, as described in detail below, although the major functions of the spectrum of protein isoforms derived from this gene remain unclear.

To date, nothing is known of how these three genes are selected for expression in trophoblasts from among the members of the HLA class I multigene family. Their appearance appears to be synchronous, suggesting that whatever mechanism constitutes the "ON" signal influences the expression of all three genes.

G. Immunogenetics of HLA-G

HLA-G is a gene exhibiting several unique features. Its cytoplasmic tail is shortened and may or may not transduce signals. Its promoter region contains a large deletion in the enhancer A/IFN consensus region, which results in crippling of IFN-induced transcription, and the γ-activated site has a single nucleotide substitution that prevents activation. As a consequence and unlike other HLA class I genes, HLA-G is only weakly enhanced by exposure to interferons.

Also in contrast to other HLA class I genes, alternative splicing is a feature of the HLA-G message. Mechanisms underlying the production of multiple transcripts from this gene are unknown. Importantly, some transcripts encode cell surface proteins and others encode soluble proteins. The latter is a consequence of a stop codon in intron 4, which precludes translation into the transmembrane region. All the transcripts are readily identified in placentas and trophoblast cell lines. Because the antibodies to HLA-G are poorly characterized regarding binding site and specificity, expression in adult cells and tissues remains uncertain.

H. Functions of HLA-G

Functions clearly attributable to HLA-G are poorly defined at present. Because expression of this gene, which has few allelic variants, is a prominent feature of the maternal–fetal interface, its substitution for HLA-A or -B is widely believed to be critical to the maintenance of semiallogeneic pregnancy. The gene does express a few alleles, identified as *0101, *0103, *0104, and *0106, that might be immunostimulatory in mismatched couples, but it is not yet known whether mothers recognize the products of the different alleles.

Evidence has been presented for the postulate that HLA-G interacts with macrophage immunoglobulin-like transcript 4 (ILT4) receptors and conveys inhibitory signals to this cell lineage just as HLA-E does to NK cells. If this occurs, it could prevent activation of the macrophages in the decidua and subsequent killing of migrating trophoblastic cells. Presumably, these interactions would be cell–cell involvements and would rely on membrane-bound HLA-G on trophoblasts, but this does not preclude the utilization of soluble HLA-G, which is receiving considerable attention. It is important to remember that other suppressive substances such as progesterone and prostaglandins could have similar effects.

Soluble HLA-G is present in placentas and more recently has been demonstrated in the sera of pregnant women. These proteins could have profound effects on maternal immune cells. Evidence from studies employing soluble HLA-G1 partially purified from trophoblastic tumor cells indicates that this substance stimulates the apoptosis of lectin-activated T lymphocytes through the Fas/FasL pathway, a process that has been identified in immune cells exposed to other soluble HLA class I molecules. An immunoregulatory role for soluble HLA-G is indicated in the finding that levels are higher in mothers who have successful pregnancies following assisted reproductive technology as well as in heart transplant recipients who have less rejection. Furthermore, HLA-G transfected into pig islets increases graft acceptance.

Although it is possible that each of the isoforms derived from alternatively spliced messages has a different function, it seems more likely that there is at least some redundancy; pregnancy proceeds in the absence of HLA-G. The placentas of babies with a homozygous deletion that prevents synthesis of HLA-G1 protein contain other HLA-G isoforms; whether these alternative isoforms are the major players in the spectrum of HLA-G proteins or

whether they are simply able to substitute for HLA-G1 remains to be ascertained.

III. INHIBITORY MOLECULES ON TROPHOBLASTS

A. Membrane-Bound Molecules

Since trophoblast subpopulations form the anatomical boundary between maternal blood and tissues and inner cell mass-derived fetal mesenchyme, it is not surprising to find that trophoblast cells display surface-bound proteins that actively participate in defending the fetus from potentially harmful components of the maternal immune system. Toxic entities could include maternal leukocytes as well as cytotoxic antibodies and complement. A number of protective entities on trophoblast membranes have been identified.

1. Tumor Necrosis Factor Superfamily Proteins

Members of the TNF superfamily are emerging as potentially critical mediators of placental immune privilege. Essentially all the ligands may be either membrane-bound or soluble and the same is true of many of the receptors. FasL, which kills activated leukocytes through its receptor, Fas, is expressed discontinuously in villous and extravillous trophoblast cells throughout gestation. Trophoblasts have been shown to mediate apoptosis of leukocytes through the Fas/FasL system *in vitro*. Experiments in mice have shown that the ligand is highly important in protection of the placenta. In FasL-deficient mice, activated maternal leukocytes inappropriately infiltrate the maternal–fetal interface, and viability of the embryos is greatly reduced.

TRAIL is another member of the TNF superfamily that is likely to protect the fetus through expression on trophoblasts. This powerful inducer of apoptosis is incapable of causing death in trophoblasts, most likely because trophoblast cells express high levels of a TRAIL decoy receptor, DcR1. It is generally believed that in a similar fashion, protection against apoptosis by other toxic molecules is effected by receptor blocking. For example, soluble TNF receptor which compete with membrane-bound receptors, are abundant in placentas. FasL, TRAIL, and TNFα are not the only apoptosis-inducing superfamily members in placentas. Messenger RNA encoding other death-inducing ligands in first-trimester placentas include lymphotoxin-β, TNF-like weak inducer of apoptosis (TWEAK), and LIGHT (homologous to lymphotoxin), and term placentas contain these as well as lymphotoxin-α and 4-1B3 ligand (4-1BBL). The distribution of LIGHT protein has now been reported in term placentas, but proteins from most of the other newly identified members have yet to be evaluated systematically.

Importantly, the cytokines that were first identified in the immune system may have other critical functions in placentas such as governing developmental pathways through programmed cell death and perhaps also through effects on gene expression that do not lead to apoptosis. Nearly all the family members that have been examined to date stimulate a protective nuclear factor κB pathway in some cells under specific conditions.

2. Complement Regulatory Proteins

Activation of the complement cascade leads to deposition of complement components on cellular surfaces and formation of lytic pore-forming units termed the membrane attack complexes. The complement system is intended to protect the host against bacteria, parasites, and virus-infected cells. However, damage to host cells can result if they are not protected by a series of complement regulatory proteins, which includes CD59, membrane co-factor protein (MCP, CD46), and decay accelerating factor (DAF, CD55). These complement regulatory proteins are broadly distributed in adult tissues. All three of these membrane-bound proteins are also highly expressed at the apical surface of the syncytiotrophoblast facing the maternal blood space as well by villous (CD59 and MCP) and extravillous (CD59 and DAF) cytotrophoblasts. The presence of these complement regulatory proteins is believed to confer resistance of trophoblasts to antibody-mediated cytotoxicity.

Murine Crry is a transmembrane glycoprotein that functionally resembles DAF and MCP. Crry is absolutely essential to pregnancy in mice. *Crry* $^{-/-}$ embryos fail to survive in normal mothers due to the spontaneous deposition of complement factor C3 in the developing placenta. Furthermore, *Crry* $^{-/-}$ embryos remain viable in mothers lacking C3. Activation of the complement system also leads to fetal loss in a murine model of anti-phospholipid syndrome, suggesting that a similar mechanism may occur in women suffering this disorder.

3. B7 Family Proteins

Members of the B7 family of membrane glycoproteins are ligands that interact with receptors belonging to the CD28 family. Of the six known members of the B7 family, five are highly expressed in

the human placenta. Expression of one of these, B7-H1 (also known as PD-L1), is relatively restricted, occurring mainly in macrophages, trophoblast cells, and cells constituting some organs. Consistent with the need for immunological protection of the allogeneic fetus, the B7-H1 receptor, PD-1, plays a major role in the maintenance of peripheral immunological tolerance. Mice lacking PD-1 develop severe autoimmune disorders that afflict organs whose cells express B7-H1 and its sister ligand, B7-DC (PD-L2). B7-H1 has been shown to inhibit CD3-activated T lymphocytes stimulate allograft survival, and protect tumor cells from T cell-mediated lysis. B7-H1 also alters their cytokine secretion patterns, possibly driving the T cells into the T_H2-type cytokine production profile that is thought to be important to pregnancy. In addition, B7-H1 induces apoptosis in activated, antigen-specific leukocytes, most likely through a receptor distinct from PD-1. The functional significance of placental B7 family members is not yet known, but their distribution within specific cellular elements of the human placenta indicates that this family of molecules plays an important role in the establishment and maintenance of maternal tolerance to the fetus.

B. Soluble Molecules

Pregnancy is known to require adequate levels of progesterone for both implantation and maintenance. Early on, this hormone is synthesized in the corpus luteum of the ovary and subsequently in the placenta. Progesterone has many functions, one of which may be to discourage the proliferation and cytotoxicity of immune cells. As described below, the maternal–fetal interface is characterized by cells supplying the host (mother) with innate immunity rather than lymphocyte-specific acquired immunity. Progesterone may drive the substitution process, which occurs early following implantation. Furthermore, when exposed to high levels of progesterone, innate immune cells such as macrophages are programmed into a suppressive profile characterized by the absence of T_H1-type inflammatory cytokines (TNFα, IFN-γ) and production of T_H2-type anti-inflammatory cytokines [interleukin-10, transforming growth-β (TGF-β)] as well as the negative regulator of immune cells, prostaglandin E2.

Taken together, these elements probably account in large part for the well-described immunosuppressive environment of the pregnant uterus. However, researchers continue to identify additional protectors of the placenta; one recent entry is indolamine oxidase, an inhibitor of tryptophan metabolism.

IV. UTERINE LEUKOCYTE MODIFICATIONS

Among the alterations that occur at the maternal–fetal interface, reassortment of leukocytes is one of the most profound. Although the cycling endometrium has lymphoid aggregates composed of T and B lymphocytes, immature NK cells, and randomly distributed macrophages, the antigen-specific T and B cells nearly disappear with the onset of implantation. Thus, the pregnant uterus is populated almost exclusively by cells supplying innate or natural immunity, the NK cells and macrophages. In the human decidua, the NK cells disappear in the second trimester, whereas the macrophages remain throughout pregnancy, providing a measure of host defense against infection.

It is clear that molecules present on the surfaces of migrating trophoblast cells and soluble products of the placenta target decidual immune cells, and there is evidence as well for reciprocal activity, with decidual leukocytes targeting placental cells. For the former, membrane-bound HLA-G and soluble HLA-G represent an excellent example. Decidual macrophages express inhibitory receptors for HLA-G, the ILT proteins termed ILT2 and ILT4. Although as yet untested in decidual macrophages, in other cells, ligand–ILT receptor interactions transduce inhibitory signals that reduce cellular cytotoxicity. Thus, membrane and soluble HLA-G could have a major impact on how leukocytes in the decidua are programmed for the benefit of pregnancy.

For the latter, experiments in gene-deleted mice strongly suggest that TNFα derived from decidual cells influences placental organization. Further, there is considerable information in mice on the interaction between uterine colony-stimulating factor-1 (CSF-1) and its receptor on trophoblast cells. CSF-1-stimulated trophoblast cells become phagocytic and then act as a component of the innate immune system at the maternal–fetal interface. Collectively, these types of studies have contributed to a better understanding of the unique utilization of immune system molecules to promote successful pregnancy.

V. SUMMARY

More than four decades of research have brought reproductive immunologists to the understanding that the placental bed is a dynamic, ever-changing

network of maternal–fetal interactions facilitated by a wide range of soluble and cell-surface molecules. Figure 3 illustrates some features of the bidirectional communication that facilitates successful pregnancy. Trophoblast cells secrete powerful soluble molecules such as prostaglandins and progesterone, soluble HLA-G, and immunomodulatory cytokines that include interleukins, members of the TNF supergene family, and members of the TGF-β gene family. Leukocytes are sources of both cytokines and prostaglandins. Membrane-bound molecules on trophoblast cells and leukocytes participate significantly in interactions in the decidua and may also modulate the actions of leukocytes circulating in the mother's blood. These include ILT, c-type lectin, and NK cell immunoglobulin-like receptors for HLA molecules, members of the B7 family of modulators, ligand and receptor proteins for the TNF and TGF-β gene families, and the critically protective complement regulatory proteins.

Identification of the many features of the maternal–fetal interface that circumvent the immune system designed for the destruction of cells carrying foreign DNA and/or RNA has provided the critical framework needed to understand pregnancy failures. Although experiments in women cannot be performed, new approaches to pinpointing the central players in the networks are being conducted in gene-modified mice as well as in nonhuman primates. Both rodent and primate experimental animal systems have attractive features and offer hope for demonstrating proofs of principle that will ultimately lead to new clinical therapies for problem pregnancies.

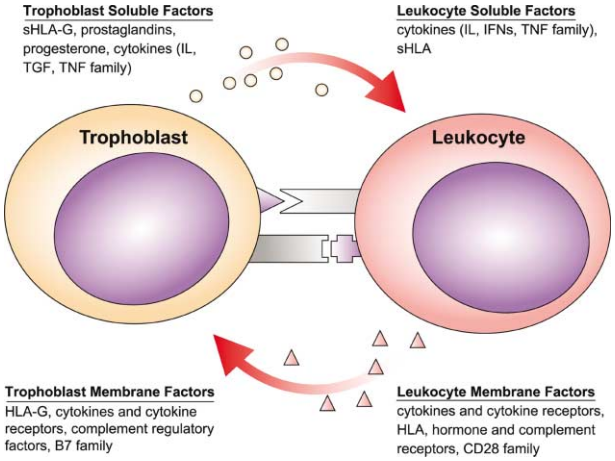

FIGURE 3 Bidirectional interactions between trophoblast cells and leukocytes. Interactions include targeting of soluble molecules supplied by both types of cells as well as direct cell–cell contact and interaction via matching ligands and receptors. IFNs, interferons; IL, interleukins; sHLA-G, soluble HLA-G; TGF, transforming growth factor; TNF, tumor necrosis factor.

Acknowledgments

The authors thank their many students and trainees as well as their colleagues for their contributions to this work, which is supported by research grants from the National Institutes of Health.

Glossary

B7 family molecules Cell surface molecules involved in both stimulation and inhibition of immune cells.

complement The collective term for serum proteins that may cause lysis of cells.

cytokines Molecules of 15 to 30 kDa that mediate cellular interactions. They may be either bound to the cell membrane or soluble and are often subdivided by their usual cell of origin, i.e., T-helper 1 (T_H1, pro-inflammatory) and T_H2 (anti-inflammatory) lymphocytes.

cytotoxic T lymphocyte A type of cell that attacks foreign and infected cells.

human leukocyte antigens Glycoproteins encoded by genes within the major histocompatibility complex on human chromosome 6. They are important self-recognition molecules in host defense but, when foreign, constitute targets for cytotoxic T lymphocytes and antibodies.

leukocytes Bone marrow-derived cells involved in innate and immune host defense.

macrophages Leukocytes that reside in tissues and have innate and immune host defense functions.

major histocompatibility complex Genes that encode the human leukocyte antigen class I and class II proteins.

natural killer cells Non-antigen-specific leukocytes that thickly populate the early to mid gestation pregnant uterus.

Platelet-Derived Growth Factor (PDGF)

CARL-HENRIK HELDIN
Ludwig Institute for Cancer Research, Uppsala, Sweden

Platelet-derived growth factor (PDGF) is of particular importance for the growth, survival, and migration of mesenchymal cell types. It stimulates the differentiation of various cell types of the connective tissue during embryonic development and is important for the formation of blood vessels. In the adult, PDGF regulates the interstitial fluid pressure of the connective tissue and also stimulates the regeneration of connective tissue during wound healing. Overactivity of PDGF is connected with several disorders involving excess cell proliferation, including malignancies, atherosclerosis, and fibrotic conditions.

I. INTRODUCTION

Platelet-derived growth factor (PDGF) constitutes a family of dimeric isoforms, acting on connective tissue cells and certain other cell types. PDGF was originally discovered as a constituent of platelets, which are released into serum in conjunction with blood coagulation. Although the α-granules of platelets are a major storage site for PDGF, PDGF is also produced by many other cell types.

PDGF stimulates the growth of its target cells, but also affects chemotaxis, i.e., directed cell movement, and cell shape through reorganization of the actin filament system. PDGF also affects the differentiation of specific cell types and promotes cell survival. Through these effects, PDGF has important functions in certain organs during embryonic development, as well as in the adult in the stimulation of wound healing and in the maintenance of connective tissue homeostasis.

Overactivity of PDGF has been linked to certain diseases, such as malignancies in which PDGF production may promote tumor growth via autocrine or paracrine stimulation. PDGF is also implicated in other disorders that involve an excess of cell proliferation, e.g., atherosclerosis and fibrotic conditions.

II. PDGF ISOFORMS

The PDGF family contains four different gene products, which are assembled into five different dimeric molecules (Fig. 1). The classical PDGF, purified from human platelets, consists of homo- and heterodimers of structurally related A and B polypeptide chains. More recently, two additional members of the family were discovered, i.e., PDGF C chain and D chain, which appear as homodimeric molecules. The PDGF isoforms are homologous to members of the vascular endothelial growth factor (VEGF) family of angiogenic factors.

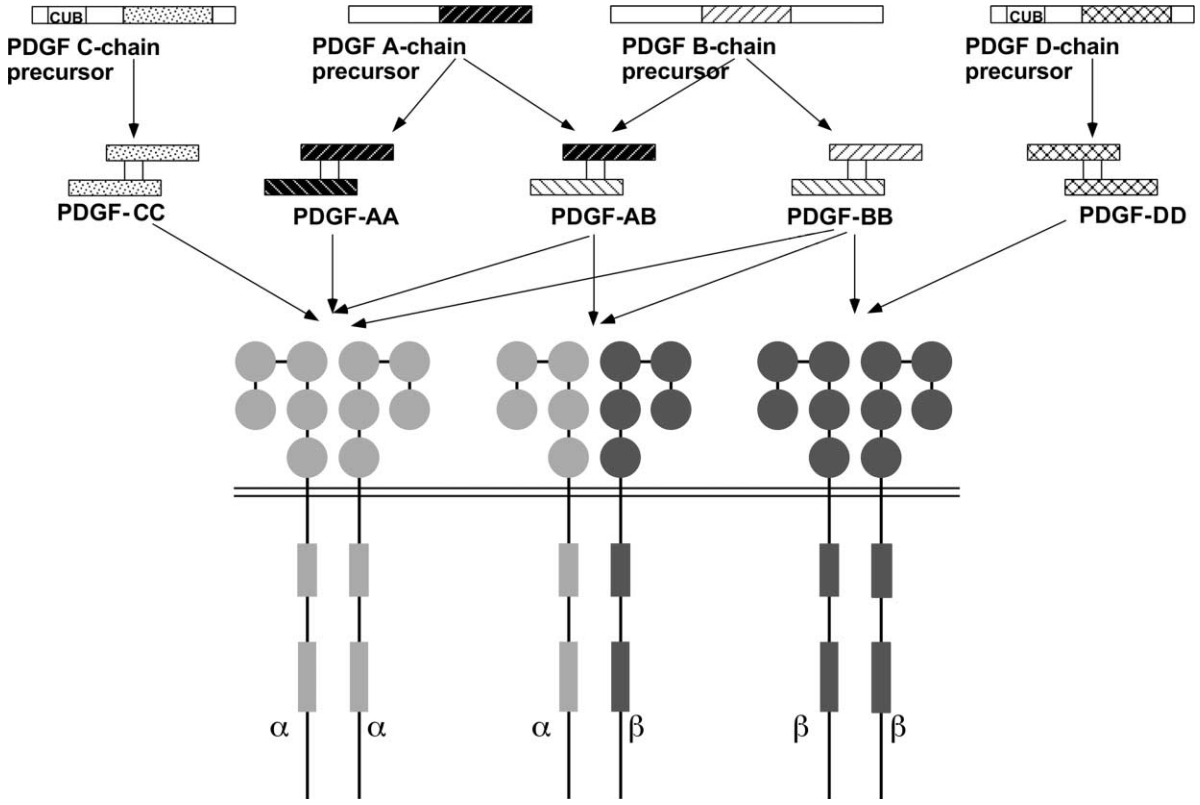

FIGURE 1 Processing and receptor-binding specificities of PDGF isoforms. The A and B chains of PDGF are synthesized as precursors that undergo processing during secretion from the producer cells. The C and D chains are also synthesized as precursors with CUB domains in their N-terminals; these isoforms are processed and activated after secretion from the producer cells. The PDGF isoforms bind to and dimerize α- and β-receptors with different specificities. Each of the receptors has five extracellular Ig-like domains and an intracellular kinase domain that is split into two parts by an intervening sequence.

A. Synthesis of PDGFs

All PDGF isoforms are synthesized as precursor molecules, which undergo processing after synthesis. In the case of the A and B chains, the processing occurs during secretion from the producer cell, resulting in the export of active molecules. In contrast, the C and D chains are secreted as inactive precursors that need to undergo additional cleavage in the extracellular space in order to release the C-terminally located growth factor domain. The cleavages can be performed by plasmin, but the enzymes involved in normal tissues are not known. The N-terminals of the C and D chains contain CUB domains, which are so named because they also are present in complement factor, urchin epidermal growth factor-like protein, and bone morphogenetic protein 1. The CUB domains in PDGF-C and -D keep the growth factor domain inactive.

B. Structure of PDGFs

The crystal structure of PDGF-BB is known; due to sequence conservation, it is likely that the other isoforms are folded similarly. PDGF-BB has a cysteine knot; i.e., one of its internal disulfide bonds passes through the hole formed by two other disulfides and intervening peptide sequences. Cysteine knots, which give a compact structure to the molecules, are also present in the homologous VEGFs, as well as in transforming growth factor-β and nerve growth factor, despite the fact that the latter molecules do not show any sequence similarity to PDGF. In addition to the six cysteine residues involved in the cysteine knot, another two cysteine residues are conserved in the growth factor domain; these residues form interchain disulfide bonds. The C and D chains contain four and two additional cysteine residues, respectively; how they are involved in disulfide bonds is not known.

From the compact cysteine knot of PDGF-BB, two loops (loops I and III) point in one direction and another loop (loop II) points in the other direction. Since the dimer is arranged in an anti-parallel manner, loops I and III from one subunit will be close to loop II of the other subunit; thus, two receptor-binding epitopes occur in the dimeric molecule, each one containing epitopes from loops I and III of one subunit and from loop II of the other subunit.

C. Splice Forms of PDGFs

Certain PDGF isoforms are stored in the extracellular compartment of tissues. The A-chain gene occurs as two splice forms, one with and one without a C-terminal basic sequence, which mediate interactions with components of the extracellular matrix. It is not known whether the splicing of the A-chain gene is regulated, e.g., in response to external signals. A similar basic sequence is also present in the B chain. Whether the CUB domains have effects in addition to keeping the growth factors latent, such as mediating interactions with components of the extracellular matrix and thus providing a mechanism for storage of the PDGF isoforms in the tissues, remains to be elucidated.

Thus, the PDGF family of ligands contains five structurally related members that differ in their processing and other properties. In addition, they differ in their specificity of binding to different receptors, as discussed below.

III. PDGF RECEPTORS

PDGF isoforms exert their cellular effects by binding, with different affinities, to two structurally related protein tyrosine kinase receptors, denoted α- and β-receptors. Each receptor contains five extracellular Ig-like domains and an intracellular kinase domain that is split into two parts by an intervening sequence. The two PDGF receptors form a subfamily among the tyrosine kinase receptors together with the stem cell factor receptor, the colony-stimulating factor 1 receptor, and Flk-1.

A. Receptor Dimerization

Since PDGF isoforms are dimeric and contain two receptor-binding epitopes, they bring together receptors in dimeric complexes on binding. The A and C chains of PDGF bind to α-receptors, the D-chain preferentially to β-receptors, whereas the B chain binds to both α- and β-receptors with high affinity. Therefore, PDGF-AA and -CC cause the formation of αα receptor homodimers, PDGF-DD causes the formation of ββ receptor homodimers, PDGF-AB produces αβ receptor heterodimers as well as αα receptor homodimers, and PDGF-BB produces all three possible combinations of receptor dimers (Fig. 1).

B. Receptor Autophosphorylation

Dimerization is a crucial event in receptor activation, since it brings the intracellular parts of the receptors close to each other so that autophosphorylation *in trans* can occur. The autophosphorylation serves two important functions; i.e., it activates the kinase activity and it creates docking sites for downstream SH2-domain-containing signaling molecules. Activation of the kinase involves autophosphorylation of a tyrosine residue in the activation loop of the kinase, Tyr-849 and Tyr-857 in the α- and β-receptors, respectively. The crystal structures of the PDGF receptor kinases are not known, but solutions of the structures of other kinases have elucidated mechanisms for control of the kinase domain. In the resting state, the activation loop of the kinase is folded over the active site and thereby prevents access to the substrate; phosphorylation causes the activation loop to swing out and thereby allows phosphorylation of the substrates. It is possible that other parts of the receptor, like the juxtamembrane region and the C-terminal tail, also interact with the kinase domain in a negative modulatory manner. Autophosphorylation at tyrosine residues located mainly outside the kinase domain may activate such inhibitory interactions and, in addition, allow binding of downstream signal transduction molecules, initiating a number of signaling pathways. The α- and β-receptors contain at least 9 and 11 such phosphorylation sites that bind, in a specific manner, to different SH2 domain proteins.

C. Docking of SH2 Domain Proteins and Downstream Signaling

Some of the SH2 domain proteins that bind to the PDGF receptors contain intrinsic enzymatic activities, such as the protein tyrosine kinase Src, the protein tyrosine phosphatase SHP-2, phospholipase Cγ, GTPase-activating protein for Ras (RasGAP), and phosphatidylinositol 3′-kinase (PI3-kinase), which consists of a regulatory p85 subunit and a catalytic p110 subunit. Other SH2 domain proteins lack endogenous enzymatic activity and act like adapter molecules, i.e., Shc, Nck, Crk, and Grb2; Grb2 forms

a stable complex with Sos1, a nucleotide exchange molecule for Ras.

Much effort has been put into the elucidation of which signaling pathways result in the various cellular effects of PDGF, i.e., cell proliferation, survival, chemotaxis, and actin reorganization. In general, PI3-kinase has been found to be important for the anti-apoptotic and motility responses of PDGF; Src and Ras, which activate the transcription factor Myc and the extracellular signal-related kinase mitogen-activated protein kinase cascade, respectively, are important for the growth-stimulating effect. However, the results depend on the cell type studied and the experimental conditions used for the studies. The difficulties in finding a clear and universal relationship between individual signaling pathways and specific effects can partly be explained by an extensive cross talk between the components in the various signaling pathways.

Both αα and ββ homodimeric receptor complexes transduce mitogenic signals; however, whereas the ββ homodimer stimulates chemotaxis, the αα homodimer inhibits chemotaxis. The molecular mechanism for the difference between the two homodimeric receptor complexes is not known. Moreover, there is evidence that the αβ heterodimeric complex has unique properties compared to the two homodimers; e.g., it appears to be the complex that causes the most potent mitogenic signal. A possible mechanism for this difference has been elucidated, i.e., the autophosphorylation sites in the PDGF β-receptor differ in a ββ homodimer, compared to an αβ heterodimer. For example, Tyr-771, which binds RasGAP, is phosphorylated efficiently in the ββ homodimer, but not in the αβ heterodimer. Thus, the αβ heterodimer cannot bind RasGAP. Since RasGAP converts active RasGTP to inactive RasGDP, the activation of Ras is therefore more efficient in a heterodimeric receptor than in a ββ homodimeric receptor, which may contribute to its higher mitogenic potency.

D. Internalization of PDGF Receptors

After ligand-induced dimerization, the PDGF receptors are internalized in endosomes. Over time, the pH of the interior of the endosomes becomes acidified, leading to dissociation of the ligand from the receptor. The receptor is then degraded after fusion of the endosomes with lysosomes. An additional degradative route has recently been elucidated, i.e., proteasomal degradation in the cytoplasm, triggered by ubiquitination of the receptor. Alternatively, the receptor is recycled to the plasma membrane after dissociation from the ligand. In the situations that have been studied, the majority of PDGF receptors are degraded after internalization.

IV. FUNCTION OF PDGF *IN VIVO*

PDGF has important functions at specific phases of embryonic development, as well as in wound healing and in control of the homeostasis of the connective tissue compartment in the adult.

A. Embryonic Development

The important function of PDGF during embryogenesis is illustrated by the finding that mice with the A- or B-chain genes or α- or β-receptor genes inactivated die during embryogenesis or perinatally. Data on the phenotypes of mice with the C- or D-chain genes knocked out are not yet available.

A striking effect of knocking out the B-chain or β-receptor genes is that the mesangial cells of the kidney do not develop, causing defective glomeruli with poor filtrating capacity. Moreover, there is a defect in the development of blood vessels in the knockout animals with a dilated aorta. The actual cause of death of the animals is bleeding at the time of birth. The reason for the improper development of the vessels is deficient development of the smooth muscle cells, as well as the inability of the newly formed vessels to attract pericytes.

The major phenotype of animals with the A chain knocked out is emphysema of the lungs, leading to death at approximately 3 weeks of age. The reason for the emphysema is defective distal spreading of alveolar smooth muscle cell progenitors during development.

Since the α-receptor responds to all isoforms containing A, B, and C chains, it is not surprising that knockout of the α-receptor gene gives a more severe phenotype than knockout of the A-chain gene only. The α-receptor knockout animals die during embryogenesis with cranial malformations and deficiency of myotome formation.

Characterization of the expression patterns of PDGF isoforms and their ligands during embryonic development has revealed examples of the expression of a PDGF isoform and the corresponding receptor in the same cell, suggesting autocrine stimulation, as well as in adjacent cell layers, suggesting paracrine stimulation. PDGF receptors are often expressed in mesenchymal cells and PDGF isoforms in adjacent epithelial layers. In this manner, epithelial cells control the development of surrounding mesenchymal

structures through the secretion of PDGF isoforms. Although PDGF is of particular importance for the development of connective tissue cells, PDGF receptors are also expressed in cells of nonmesenchymal origin. For instance, the α-receptor is expressed in the ectodermally derived neural crest and the β-receptor in mammary epithelial cells.

B. Central Nervous System

PDGF isoforms and PDGF receptors are expressed in different types of neurons, as well as in the glial cells of the central nervous system (CNS). The importance of PDGF for glial cell differentiation has been particularly well characterized. The α-receptor is expressed on bipotential oligodendroglial–astroglial cell precursors from the rat optic nerve, spinal cord, and other parts of the CNS. PDGF controls the timing of the differentiation of these cells to astrocytes.

PDGF receptors are also expressed on certain postnatal neurons, and PDGF has been shown to have a neurotropic effect on cultured rat dopaminergic neurons.

C. Vascular System

Capillary endothelial cells have been shown to express PDGF β-receptors, and PDGF has been shown to have an angiogenic effect. However, the angiogenic effect appears to be weaker than that of VEGFs or fibroblast growth factors. PDGF appears not to be important for the initial formation of novel vessels, since no apparent vascular abnormality is observed during early embryogenesis in mice with the genes for PDGF or PDGF receptors inactivated. It appears that PDGF isoforms have more important roles in the development of the smooth muscle layer and recruitment of pericytes to the vessels, which is required at later stages of vasculogenesis to give strength to the vessel wall.

PDGF also affects platelet aggregation. On platelet release and aggregation, induced, e.g., by thrombin or collagen, the released PDGF activates PDGF α-receptors present on the platelets, leading to a decreased platelet aggregation. PDGF, which is present in large amounts in platelets, may thus have an autocrine feedback role in the control of platelet aggregation.

D. Tissue Homeostasis

The interstitial fluid pressure in tissues, which is normally slightly negative, is carefully controlled to allow an exchange of fluid and macromolecules between the extracellular compartment and the vascular system. PDGF exerts an important control on the interstitial fluid pressure, probably because of its ability to stimulate the formation of stress fibers in myofibroblasts of the connective tissue and to promote interactions between these cells and molecules of the extracellular matrix.

E. Wound Healing

PDGF stimulates wound healing through actions on several cell types involved in the healing process. It stimulates chemotaxis of neutrophils and macrophages and both chemotaxis and proliferation of fibroblasts and smooth muscle cells. PDGF also stimulates macrophages to secrete other growth factors that are important for various phases of the healing process. Moreover, PDGF acts on connective tissue cells to stimulate the synthesis of matrix molecules, such as fibronectin, collagen, proteoglycans, and hyaluronic acid. PDGF may also be important during later stages of wound healing; for instance, it stimulates the contraction of collagen gels *in vitro*, suggesting that it may stimulate wound contraction *in vivo*.

Topical application of PDGF to large wounds in patients has been shown to increase their rate of healing. It is likely that PDGF also has a role in normal wound healing since it is present in wound fluid from soft tissue. There are several possible sources of PDGF in healing wounds; it has been shown to be released from platelets, activated macrophages, thrombin-stimulated endothelial cells, smooth muscle cells of damaged vessels, activated fibroblasts, and epidermal keratinocytes.

Whereas PDGF has a significant effect on healing of soft tissue wounds, its effect on fracture healing is less clear; there are reports that application of PDGF increases fracture healing, but other reports indicate that PDGF instead induces a soft tissue repair phenotype and response.

V. PDGF IN DISEASE

There is evidence that PDGF is involved in autocrine as well as paracrine stimulation in malignancies. In addition, PDGF overactivity has been linked to other disorders involving an excess cell proliferation, such as atherosclerosis and fibrotic conditions.

A. Malignancies

The finding that the retroviral oncogene v-*sis* is derived from the PDGF B-chain gene and that transformation by v-*sis* involves autocrine stimulation by

a PDGF-like growth factor prompted investigations of whether overactivity of PDGF also occurs in human malignancies. Work in recent years has revealed several examples in which overactivity of the PDGF pathway drives the proliferation of tumor cells. There are examples of the classical autocrine situation, in which a PDGF receptor carrying cells starts the production of PDGF. For example, the relatively rare skin tumor dermatofibrosarcoma protuberance (DFSP) is associated with a fusion of the collagen 1A1 gene with the PDGF B-chain gene, causing the production of an excess of a collagen–PDGF fusion protein. The fusion protein is processed to a PDGF-like growth factor that stimulates the producer cell in an autocrine fashion. Other types of sarcomas and glioblastomas are also characterized by overexpression of PDGF, although the mechanisms behind the overexpression are not known.

There are also examples of perturbations of the PDGF signaling pathway intracellularly. Thus, in chronic myelomonocytic leukemia, the gene for the Ets-like transcription factor Tel is fused to the part of the PDGF β-receptor gene coding for the kinase domain. The result is the production of a fusion protein consisting of part of Tel and the PDGF β-receptor kinase. Since Tel forms a dimer, the fusion protein dimerizes, thereby causing a constitutive activation of the kinase. Constitutive PDGF β-receptor dimers can also be formed by interaction of the E5 oncoprotein of bovine papilloma virus with the transmembrane part of the receptor.

In addition to driving the proliferation of the tumor cells themselves, PDGF may be involved in paracrine stimulation of normal cells in tumors. Several types of tumor cells synthesize PDGF. In cases where the tumor cells do not express PDGF receptors, no autocrine stimulation will occur. However, the secreted PDGF may affect other cell types in the tumor. Thus, PDGF has been shown to have a weak angiogenic effect and to stimulate stromal cells. The paracrine effects of PDGF may be of importance for the balanced growth of tumors. Moreover, PDGF is important for the elevated interstitial fluid pressure that often characterizes solid tumors and that makes uptake of chemotherapeutic drugs less efficient.

B. Atherosclerosis

Atherosclerosis is characterized by an inflammatory-fibroproliferative response, which includes an increased expression of PDGF. In experimental models, as well as in naturally occurring lesions, increased expression of PDGF and PDGF receptors is seen. PDGF may be released by platelets trapped in thrombi, by activated macrophages, by smooth muscle cells, or by endothelial cells, and it stimulates the migration of smooth muscle cells from the media of the vessel into the intima layer, where the cells also proliferate in response to PDGF. Such intimal thickening at sites of endothelial cell injury occurs at an early phase of the atherosclerotic process.

C. Fibrotic Conditions

As discussed above, PDGF is important for the development of connective tissue compartments in several organs. In the adult, overactivity of PDGF causes fibrosis of the same organs. Thus, several types of pulmonary fibrosis have been shown to involve overexpression of PDGF. Moreover, intratracheal injection of PDGF-BB has been shown to cause transient proliferation of pulmonary mesenchymal and epithelial cells accompanied by collagen deposition. Overactivity of PDGF is also implicated in several types of glomerulonephritides, liver cirrhosis, and myelofibrosis.

D. PDGF Antagonists

The fact that PDGF is involved in several serious disorders makes the development of clinically useful PDGF antagonists highly warranted. Several types of PDGF antagonists have been developed, including antibodies, DNA aptamers and soluble extracellular receptor domains that sequester PDGF, antibodies that bind to and block PDGF receptors, and low-molecular-weight inhibitors of the receptor kinase. Promising results of such antagonists have been obtained in animal models for malignancies, as well as atherosclerosis and fibrotic conditions; their usefulness in the treatment of patients is currently being evaluated.

VI. SUMMARY

In the human genome, there are four genes encoding PDGF isoforms, PDGF-A, -B, -C, and -D. The four dimeric isoforms, PDGF-AA, -BB, -CC, and -DD, bind with different specificities to two related tyrosine kinase receptors, forming αα, αβ, or ββ receptor dimers.

Important aims of future research will be to elucidate the detailed *in vivo* function of the different PDGF isoforms, in particular, the novel isoforms PDGF-CC and PDGF-DD, and their potential involvement in disease. It will also be important to investigate whether additional receptors are involved

in mediating signals from the novel PDGF isoforms. There is preliminary evidence that the different dimeric forms of PDGF α and β receptors transduce different intracellular signals. It will be important to elucidate the *in vivo* significance of such differences.

Acknowledgments

Ingegärd Schiller is thanked for skillful secretarial help.

Glossary

autocrine, paracrine, or endocrine stimulation The process whereby a cell produces a factor(s) that stimulates that cell itself, cells in the immediate environment, or distant cells, respectively.

autophosphorylation A process whereby a kinase phosphorylates itself or kinase-associated receptors in a dimeric complex phosphorylate one another.

chemotaxis Directed cell migration toward a gradient of a chemotactic factor, e.g., a growth factor.

growth factor receptor A transmembrane protein that consists of an extracellular ligand-binding domain and an intracellular effector domain that often is associated with a kinase activity that is activated on ligand binding.

signal transduction pathway A series of molecules activating one another through physical contacts and/or enzymatic modifications, leading to a specific effect, such as cell growth, survival, or migration.

Polycystic Ovary Syndrome

STEPHEN FRANKS
Imperial College London

Polycystic ovary syndrome (PCOS) is a very common, heterogeneous endocrine disorder that is a major cause of infertility, hirsutism, and metabolic disorders. Its most consistent biochemical feature is hypersecretion of ovarian androgens. PCOS is associated with an increased risk of type 2 diabetes in later life.

I. INTRODUCTION

Polycystic ovary syndrome (PCOS) is the most common endocrine disorder in women, accounting for about three-quarters of all cases of anovulatory infertility and about 90% of the causes of hirsutism. Polycystic ovary syndrome is heterogeneous in its presentation and this has resulted in some discussion about how to define PCOS. The classic definition includes the association of anovulatory menses (or estrogen-replete amenorrhea) with clinical and/or

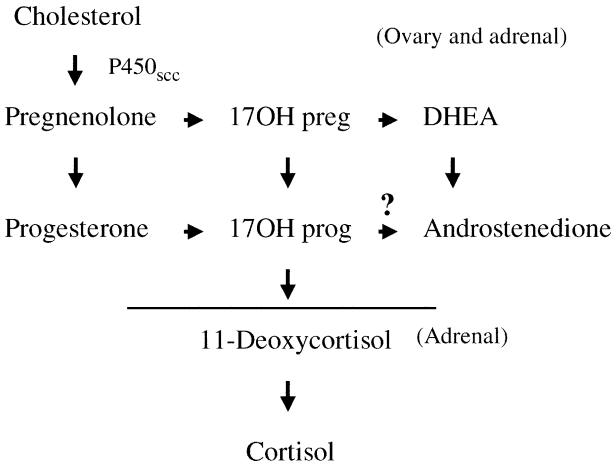

FIGURE 1 The steroidogenic pathway in ovaries and adrenals. Note that cytochrome P450 side chain cleavage enzyme (P450scc) is the key enzyme in the production of pregnenolone, and hence all later stages of steroid production. There is a question concerning the conversion of 17-hydroxyprogesterone (17OH prog) to androstenedione: in the human ovary, it is more likely that androstenedione is derived mainly from conversion of dehydroepiandrosterone (DHEA) by the enzyme 3β-hydroxysteroid dehydrogenase.

biochemical evidence of excess androgen secretion. Using this definition, the estimated prevalence of PCOS is in excess of 5% of the female population of reproductive age. The range of clinical presentation of women with polycystic ovaries—as defined by pelvic ultrasonography—is, however, wide. It includes patients with anovulation who are nonhirsute and those with hirsutism who have regular menstrual cycles. Indeed, polycystic ovaries are found in over 80% of women who would otherwise have been labeled as having "idiopathic hirsutism." The results of ultrasound studies of "normal" populations suggest that polycystic ovaries are present in about 20% of women of reproductive age. The causes of polycystic ovaries (PCOs) and PCOS are not known for certain, but there is strong evidence for a major genetic contribution, as will be discussed in Section IV.

In addition to the reproductive consequences of the syndrome, PCOS is characterized by a metabolic disorder in which hyperinsulinemia and peripheral insulin resistance are the central features. This metabolic dysfunction may play a part in the etiology of anovulation but also has important implications for long-term health. Women with PCOS are two to three times more likely to develop type 2 diabetes mellitus in later life and may also be at increased risk of developing cardiovascular disease.

II. ENDOCRINE ABNORMALITIES IN PCOS

The major endocrine abnormalities in women with PCOS are elevated serum concentrations of androgens and luteinizing hormone (LH) and, particularly in those with the classic definition of PCOS (i.e., including menstrual disturbances), hyperinsulinemia and insulin resistance.

A. Hypersecretion of Androgens

The most common biochemical abnormality in women with polycystic ovaries is hypersecretion of androgens. The ovary appears to be the predominant source of excess androgen production, although many studies have pointed to evidence for an additional adrenal abnormality. Nevertheless, the ovary is clearly the more important contributor to hyperandrogenemia because suppression of LH in women with PCOS leads to a decrease in androgen concentrations to levels that are indistinguishable from those in menopausal or oophorectomized women. Cultured thecal cells from women with polycystic ovaries, regardless of presenting symptoms, produce some 20 times more androstenedione in primary culture than do cells from women with normal ovaries. Increased steroidogenic activity is, however, not confined to androgen production. All stages of the steroidogenic pathway—including progesterone production—appear to be amplified in PCO theca (Figs. 1 and 2). Importantly, these results

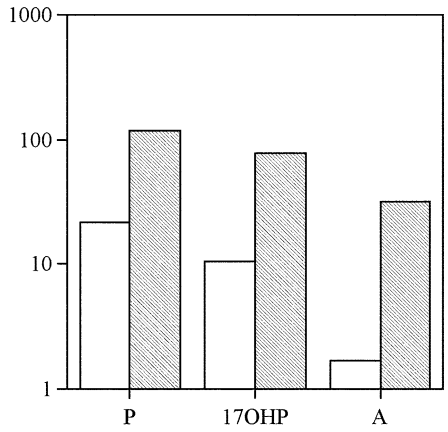

FIGURE 2 Steroid production (in picomoles/1000 cells/48 h) by theca cells from normal (clear bars) and polycystic ovaries (PCO; shaded bars). P, Progesterone; 17OHP, 17-hydroxyprogesterone; A, androstenedione. Note the logarithmic scale. In each case, steroid production by theca cells from polycystic ovaries was significantly greater than that from normal theca (P, $p < 0.01$; 17OHP, $p < 0.01$; A, $p < 0.005$) Redrawn from Gilling-Smith *et al.* (1994).

have recently been confirmed using PCO and normal theca cells that have undergone several passages in culture. This suggests that this biochemical phenotype is an intrinsic feature of the polycystic ovary. Thus, it is unlikely that ovarian hyperandrogenism arises secondary to hypersecretion of LH in PCOS, particularly because this "typical" feature of PCOS occurs in little more than 50% of those with the classic syndrome and in the minority of those with hyperandrogenism and regular cycles.

B. Metabolic Abnormalities in PCOS

In recent years, there has been a great deal of interest in the metabolic associations of PCOS. The classic syndrome is characterized by a distinctive form of insulin resistance. Women with PCOS have higher fasting and glucose-stimulated insulin concentrations and significantly reduced insulin sensitivity compared with weight-matched control subjects (Fig. 3). The cause of this abnormality is unclear, but clinical and laboratory-based studies in PCOS have variously pointed to abnormalities of insulin receptor binding, or, more plausibly, to postreceptor signaling as well as to evidence for a primary abnormality of insulin secretion. It has been demonstrated that weight reduction in obese women with PCOS results in normalization of insulin sensitivity, but "first-phase" insulin secretion in response to an intravenous glucose challenge remains abnormal. These data also illustrate an important principle in understanding the etiology of PCOS, which is that whatever the genetic basis for the syndrome, the phenotype can be influenced by environmental (in this case nutritional) factors.

III. OVARIAN FOLLICULAR ABNORMALITIES IN PCOS

A further phenotypic feature of PCOS is the polycystic ovarian morphology. The polycystic ovary is characterized by the presence of an increased number not only of antral follicles but also of early-growing and preantral follicles. Because these earlier stages of follicular development are thought to be largely independent of gonadotropins, the implication is that local ovarian factors may have a role in genesis of the polycystic ovary. Many growth factors have been shown to have an influence on early folliculogenesis, including those of the transforming growth factor-β superfamily and growth factors signaling through tyrosine kinase coupled receptors such as insulin-like growth factors-I and -II and transforming growth factor α.

Anovulation in PCOS is characterized by arrested development of medium-sized antral follicles. Granulosa cells from these follicles display evidence of premature responsiveness to LH and increased steroidogenesis (indicative of advanced differentiation) compared with similarly sized follicles from normal ovaries. The reason for these

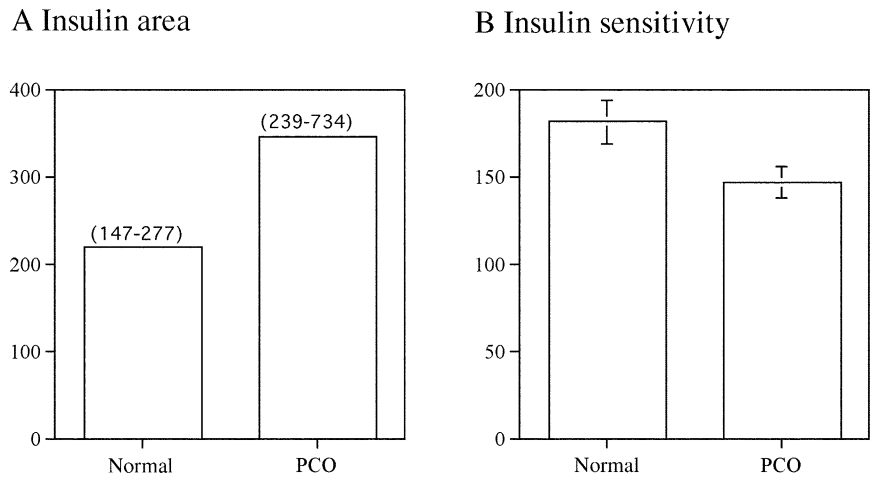

FIGURE 3 (A) Insulin area (median, interquartile range; in milliunits/hour) following a 75-g oral glucose tolerance test dose and (B) insulin sensitivity (in micromoles/minute), measured by the short insulin tolerance test, in 29 women with polycystic ovary (PCO) syndrome and 24 weight-matched control subjects. Insulin area was significantly greater ($p < 0.01$) and insulin sensitivity significantly lower ($p < 0.01$) in women with polycystic ovary syndrome than in controls. Redrawn from Robinson *et al.* (1993).

differences are not yet entirely clear, but because insulin can greatly enhance the response of the granulosa cell to LH, it seems likely that hyperinsulinemia plays an important part in the mechanism of anovulation.

IV. GENETIC STUDIES OF PCOS

The definition of abnormalities in the ovarian steroidogenic pathway, in the secretion and action of insulin, and in ovarian follicular development has paved the way for the use of a candidate gene approach in the identification of genetic susceptibility loci for PCOS.

A. Genes Involved in the Biosynthesis and Metabolism of Androgens

Genes implicated in the pathway of androgen production and metabolism include those encoding the major endocrine regulator, LH, its receptor, and key P450 steroidogenic enzymes such as cholesterol side chain cleavage (P450scc) and 17α-hydroxylase/17,20 lyase (P450c17 α).

1. CYP11a—Coding for P450 Cholesterol Side Chain Cleavage

A polymorphic sequence [a pentanucleotide repeat—$(tttta)_n$] in the 5′ regulatory region of *CYP11a* has been identified, and both case-control association studies and nonparametric linkage analysis have been performed by Gharani and colleagues. Subjects were assigned to two groups according to genotype. The most common genotype, comprising four repeats, occurred with a frequency of 0.59, and was designated 216. Subjects were subdivided according to whether this allele was present (216 +) or absent (216 −). It was found that genotype was associated with serum testosterone concentrations, levels being significantly higher in women with the 216 − genotype (which consists of alleles of six repeats or longer) (Fig. 4). On more detailed analysis, this association held true only in those subjects with clinical evidence of hyperandrogenism. Supportive evidence for the association of PCOS with *CYP11a* comes from two recent European studies, the first of which has reported a relationship between the $(tttta)_n$ polymorphism and androgen levels in 88 hirsute women. This study found that the *CYP11a* genotype, together with endocrine markers, predicts the presence of PCO in hirsute women. Another group, in a case-control study, reported that the *CYP11a* genotype was associated with both PCO and total

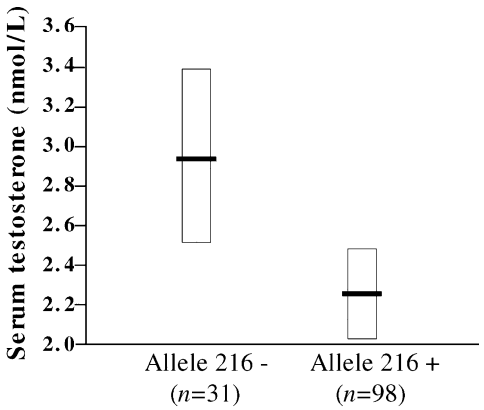

FIGURE 4 Association of *CYP11a* genotype with serum testosterone in a case-control data set of women with and without PCOS. Note significantly higher serum testosterone concentrations ($p = 0.0009$) in association with the 216 − genotype (more than six pentanucleotide repeats). Data shown are mean and 95% confidence intervals Redrawn from Gharani *et al.* (1997).

testosterone concentrations. Further support for this notion has been obtained from mutation screening of the *CYP11a* promoter in a 1.85-kb region 5′ to the start site of translation. Direct sequencing of fragments (amplified by polymerase chain reaction) of DNA samples from affected and unaffected family members has been carried out. Apart from the pentanucleotide repeat polymorphism at position −466 from the start site of transcription (and a previously identified dinucleotide repeat polymorphism at position −1314), no variation from the published sequence is found. Structure–function studies of the promoter region using expression systems need to be performed to explore the putative functional role of this element. An alternative explanation is that this polymorphic marker is in linkage disequilibrium with the disease locus, which may be located outside the promoter region.

Segregation of *CYP11a* has been examined in 20 families. With the aid of a number of polymorphic markers [*D15S153*, *D15S125*, *CYP11a* $(ac)_n$, *D15S169*, and *D15S211*], in the region of *CYP11a*, nonparametric linkage analysis was performed using the GENEHUNTER (multipoint linkage) program. There is evidence for excess allele sharing, i.e., linkage, at the *CYP11a* locus [nonparametric logarithm of the odds (LOD) (NPL) score, 3.03; $p = 0.003$]. In a parallel parametric analysis, assuming the autosomal dominant model for inheritance, evidence of genetic heterogeneity between families is found, with about 60% of families showing linkage at

the *CYP11a* locus. Thus, data from both association and linkage studies suggest that this is a major susceptibility locus for hyperandrogenism in PCOS.

2. CYP17—Coding for 17-Hydroxylase/17,20-Lyase

Because of the reported abnormalities in regulation of 17α-hydroxylase/17,20 lyase in PCOS, initial studies have focused on the role of *CYP17* (coding for P450c17α). Results of a preliminary case-control study suggest that a variant form of *CYP17* is associated with PCOS, but there is no relationship between genotype and serum testosterone levels. Subsequent, larger, case-control studies have also been unable to confirm the putative association. Furthermore, linkage analysis excludes *CYP17* as a major susceptibility gene for PCOS within families.

B. Genes Involved in the Secretion and Action of Insulin

1. The Insulin Gene Variable-Number Tandem Repeat

There is evidence that the insulin gene (*INS*) variable-number tandem repeat (VNTR) is a major susceptibility locus for PCOS. The *INS* VNTR lies in the 5′ regulatory region of the gene; it has been shown to be involved in regulation of insulin gene expression and has been implicated in the etiology of type 2 diabetes. Class III alleles in the VNTR have been found to be associated with anovulatory PCOS in two independent populations and using two different methods of analysis [case-control studies and by the use of affected family-based controls (AFBAC)]. With the aid of a nonparametric linkage analysis program, it has also been established that there is excess allele sharing at the *INS* VNTR locus. The geometric mean of fasting serum insulin concentrations is significantly higher in families in which linkage is demonstrated than in those families without evidence of linkage. This suggests a functional role for the VNTR variant in the expression of hyperinsulinemia/insulin resistance in PCOS. It is also observed, using transmission disequilibrium (TDT) analysis, that there is a "parent of origin" effect in the transmission of alleles of the VNTR to affected subjects. Class III alleles are transmitted significantly more commonly from fathers than from mothers to the affected daughter. Interestingly, this finding has been mirrored recently in an analysis of families with type 2 diabetes for which PCOS is a known risk factor.

C. Genes Involved in Folliculogenesis

1. The Follistatin Gene

As part of a panel of candidate genes related to gonadotropin action, Urbanek and colleagues examined the follistatin locus on chromosome 5 and, somewhat unexpectedly, found the strongest evidence for linkage with PCOS of any of the 37 candidate genes they had chosen. In their affected sibling-pair analysis, 72% of sisters were concordant for the follistatin genotype, and this remained significant after correction for multiple testing. However, recent follow-up data from the same group suggest that this finding is no longer significant when further families are added to the database. This finding nevertheless remains intriguing, and the possibility arises that this and other genes implicated in folliculogenesis may have a causal role in this disorder, which is, after all, characterized by disordered follicle development.

V. CLINICAL MANAGEMENT ISSUES

A. Diagnosis of PCOS

The diagnosis of PCOS is reached primarily on a clinical basis. A patient presenting with irregular menses, oligomenorrhea, or amenorrhea and who has signs of hyperandrogenism is very likely to have PCOS. Even in the absence of hirsutism, PCOS is the most likely cause of these menstrual symptoms (it accounts for about 30% of cases of amenorrhea overall and about 90% of amenorrheic women with normal estrogen levels).

The majority of patients presenting with hirsutism have polycystic ovaries, irrespective of menstrual history. Much rarer but more serious causes of hirsutism and menstrual disturbances include Cushing's disease, acromegaly, hyperprolactinemia, and tumors of the adrenal or ovary. In such cases, however, there are usually other clues, both clinical and biochemical, to the diagnosis, e.g., short history of increasing hirsutism and significantly elevated serum testosterone (>5 nmol/liter). For this reason, serum testosterone should be measured in all hirsute patients as a screening test to exclude more serious causes of hyperandrogenism. Late-onset ("nonclassical") congenital adrenal hyperplasia due to 21-hydroxylase deficiency may be difficult to distinguish clinically from PCOS, but it is debatable whether this makes much practical difference to management of symptoms. Thus, in a typical situation in which the prevalence of nonclassical

21-hydroxylase deficiency is $<5\%$, for example, routine measurement of 17α-hydroxyprogesterone (the biochemical marker of 21-hydroxylase deficiency) is not necessary.

No single test is diagnostic of the syndrome and choice of investigations should be tailored to the clinical presentation. Serum LH levels are typically elevated in PCOS (follicle-stimulating hormone is normal), but up to 50% of women with all other clinical and biochemical features of the syndrome may have normal serum LH. Measurement of LH is therefore of limited diagnostic value; it is quite specific—elevated LH and normal follicle-stimulating hormone (FSH) essentially occur only in PCOS—but it is not very sensitive. Pelvic ultrasonography will define the polycystic ovarian morphology, but accurate assessment of the ovaries by ultrasound is a particular skill, and false negative results are not uncommon. Conversely, the presence of polycystic ovaries does not necessarily mean that the patient has polycystic ovary syndrome. Polycystic ovaries may be found coincidentally in women who have, for example, hypothalamic, estrogen-deficient amenorrhea.

In summary, pelvic ultrasonography and measurements of LH, FSH, and testosterone may be of some diagnostic value when set in the appropriate clinical context. By contrast, routine measurements of adrenal androgens are not indicated and measurement of sex hormone-binding globulin (which is primarily an index of body weight) is not at all helpful. Because of the increased risk of type 2 diabetes, it is recommended that obese women with PCOS should have a fasting glucose measurement at least once a year and, in view of the associated dyslipidemia, there may also be some merit in checking the lipid and lipoprotein profile at the same time.

B. Management

Because the physiological basis of PCOS is unknown, treatment is largely to alleviate symptoms. Patients with anovulation may require induction of ovulation. The antiestrogen, clomiphene, is usually effective, but even this "simple" treatment should be monitored at a specialist center because of the risk of ovarian hyperstimulation and multiple pregnancy. For those not concerned about fertility, menstrual regulation by means of oral contraceptives or cyclical progestagens should be considered. Nonandrogenic progestagens (e.g., medroxyprogesterone acetate, desogestrel, and gestodene) are obviously preferable to norgestrel and norethisterone for women who may anyway have symptoms of androgen excess.

Symptoms of hyperandrogenism can be managed by antiandrogens such as cyproterone acetate. For women with acne and mild or moderate hirsutism, this can usually be given in the form of Dianette (cyproterone acetate, 2 mg, with ethinylestradiol, 35 mg). Cosmetic advice about removal of hair should not be forgotten, even with administration of antiandrogens.

Obese subjects with PCOS require particular attention. It has been clearly demonstrated that calorie restriction in obese women with PCOS improves insulin sensitivity and glucose tolerance. It also leads to resumption of spontaneous ovulatory cycles and normal fertility in many subjects. Significantly, such improvements in glucose–insulin homeostasis and reproductive function can be achieved with weight reduction of as little as 5% of the initial body weight. Insulin-sensitizing drugs may also have a role in reducing the risk of diabetes and improving ovarian function. The thiazolidinediones (TZDs) are a relatively new class of insulin-sensitizing drugs that have been introduced primarily for the control of type 2 diabetes. In a large randomized, multicenter study, troglitazone has been shown to improve insulin sensitivity and menstrual cyclicity in obese women with PCOS. Unfortunately, this drug has been withdrawn because of serious side effects, and although there are newer, apparently safer preparations available, there are concerns about the wisdom of prescribing TZDs in women of reproductive age. Metformin is a well-established medication in management of type 2 diabetes. Its mechanism of action is complex, but its effects include reduction of insulin receptors and insulin levels. Recent studies in women with PCOS have suggested that this may be a safe and effective means of improving the metabolic profile and reproductive function in both lean and obese women with PCOS. Results so far have been encouraging, but by no means conclusive. Randomized controlled trials have been few and have produced conflicting results.

VI. SUMMARY

PCOS is clinically and biochemically heterogeneous. The major endocrine hallmark is hyperandrogenemia and although it is clear that hypersecretion of adrenal androgens may contribute to the hyperandrogenemia of women with polycystic ovary syndrome, the weight of evidence favors the ovary as the major source of excess androgen secretion.

The biochemical basis for the putative disorder of ovarian androgen biosynthesis remains controversial. There is evidence, from both clinical and *in vitro* studies of human ovarian theca cells, of dysregulation of the rate-limiting enzyme in androgen biosynthesis, cytochrome P450c17α, which catalyzes both 17α-hydroxylase and 17,20 lyase activities. Initial data have suggested that alleles of *CYP17*, the gene encoding P450c17α, are associated with PCOS but this has now been excluded as a candidate gene. However, *CYP11a*, which encodes cholesterol side chain cleavage enzyme, does appear to be a major susceptibility locus for hyperandrogenism in women with PCO. Nevertheless, the finding that the expression of other enzymes in the androgen biosynthetic pathway is also up-regulated suggests that this may not be the only focus for genetic abnormalities of steroidogenesis. The precise nature of the interaction of androgens and genetic loci affecting insulin secretion remains unclear.

From the viewpoint of clinical management, the major issues relate to correction of infertility, menstrual disturbance, and hirsutism. The metabolic abnormalities in PCOS have implications both for management of anovulatory infertility and for the increased risk of type 2 diabetes in later life. Dietary measures are very important in overweight subjects, but there is increasing evidence that insulin-sensitizing agents may have an important role to play in management both of anovulation and of metabolic consequences of PCOS.

Glossary

CYP11a Gene encoding the P450 side chain cleavage enzyme.

insulin gene variable-number tandem repeat Sequence in the regulatory region of the insulin gene.

P450 cholesterol side chain cleavage enzyme Key enzyme in ovarian steroidogenesis.

polycystic ovaries Characteristic ovarian multiple antral follicles, increased stroma, and androgen hypersecretion.

polycystic ovary syndrome Clinical and endocrine abnormalities, typically manifested as anovulation and hyperandrogenism; associated with polycystic ovaries.

Pregnancy

See *Decidualization; Implantation; Placental Development*

localized to a specialized region of steroid metabolism and action in the female reproductive tract. Steroid hormones synthesized by the adrenal glands (corticosteroids) and ovaries (progesterone) are natural anti-inflammatory agents that are intimately involved in these serial injury-repair processes. The immunoendocrine interplay between pro-inflammatory cytokines and anti-inflammatory steroids is therefore fundamental to reproduction.

I. INFLAMMATION AND REPRODUCTION

Ovulation, menstruation, implantation, and parturition share cardinal features of an acute inflammatory response: vasodilation, increased vascular permeability, and cellular infiltration. Each process involves a tightly controlled phase of local tissue breakdown and regeneration. During ovulation, the wall of the preovulatory follicle and overlying ovarian surface epithelium are breached to release an oocyte for fertilization. Implantation involves invasion of the uterine wall by the embryonic trophoblast to initiate pregnancy. Menstruation, at the conclusion of each nonconceptual ovarian cycle, entails shedding of spent uterine endometrial and vascular tissues. And if pregnancy occurs, parturition culminates in softening of the uterine cervix to permit delivery of the neonate.

In every case, the inflammatory reaction unfolds as a biochemical cascade involving the sequential production of cytokines, lipid mediators (steroids, prostanoids, and leukotrienes), vasoactive mediators, and matrix-degrading proteolytic enzymes. The central role of cytokines is to control the direction, amplitude, and duration of the inflammatory response, thereby localizing and limiting the site of tissue injury and repair.

II. PRO-INFLAMMATORY CYTOKINES

Cytokines serve classic functions in host responses to injury and infection. They also function in the immunoendocrine system during ovulation, implantation, menstruation, and parturition, as paracrine signals that promote tissue remodeling. Cytokines are commonly classified as pro- or anti-inflammatory, as shown in Table 1.

This classification is undoubtedly overly simplistic, since individual cytokines can have multiple, overlapping, and sometimes opposing functions depending on their concentration, site of action, and the presence of other cytokines and mediators. The best characterized pro-inflammatory cytokines in the female reproductive tract are interleukin-1α (IL-1α), IL-1β, and tumor necrosis factor α (TNFα).

TABLE 1 Common Pro- and Anti-inflammatory Cytokines

Pro-inflammatory	Anti-inflammatory
Interleukin-1 (IL-1)	IL-4
Tumor necrosis factor-α of GR	IL-10
Interferon-γ	IL-13
IL-6	Interferon-α
IL-8	Transforming growth factor-β
IL-12	
IL-18	
Granulocyte/macrophage colony Stimulating factor	

Interleukin-1 and TNFα signal via membrane-associated receptors on target cells to increase the expression of genes with roles in inflammation. The type I IL-1 receptor is a member of the Toll-like receptor (TLR) superfamily involved in signal transduction during inflammation and host defense. The superfamily includes the *Drosophila melanogaster* protein Toll, the IL-18 receptor, and the Toll-like receptors TLR-2 and TLR-4. Ligand binding of the corresponding receptor activates postreceptor signaling networks that in turn activate stress-related transcription factors (SRTFs), such as nuclear factor-κB (NF-κB) and activated protein-1 (AP-1) (Jun/Fos or Jun/Jun dimers), as illustrated for IL-1 in Fig. 1. AP-1 and NF-κB are important in immune and inflammatory responses because they localize the expression of genes encoding chemoattractants, cytokines, cytokine receptors, cell adhesion molecules, and matrix-degrading metalloproteinases (MMPs). They are also molecular targets of anti-inflammatory steroid action. Genes activated by AP-1 and NF-κB include the inducible cyclooxygenase isozyme COX-2, otherwise known as prostaglandin-H synthase-2, which catalyzes the formation of prostanoids essential for ovulation (PGE_2), implantation (PGI_2), and parturition $PGF_{2\alpha}$.

III. ANTI-INFLAMMATORY STEROIDS

The endocrine connection between pro-inflammatory cytokines and steroid hormones is provided by glucocorticoids, which are produced in increased amounts through cytokine action on the adrenal glands as a systemic response to infection. In addition

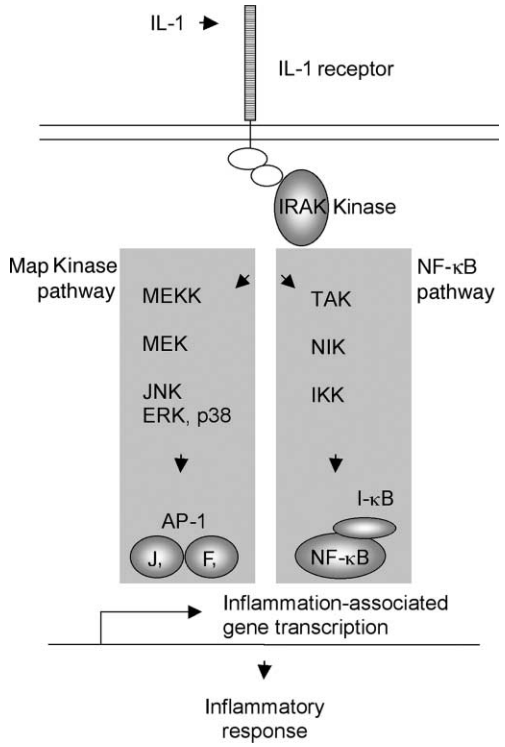

FIGURE 1 Postreceptor mechanisms of inflammatory cytokine action. IL-1, the prototypical inflammatory cytokine, binds to the extracellular domain of the IL-1 receptor, which activates postreceptor signaling via IL-1 receptor-associated kinase (IRAK). IRAK kinases activate at least two major postreceptor signaling pathways, leading to activation of inflammation-associated gene transcription: mitogen-activated protein kinase (MAPK) and nuclear factor κB (NF-κB) pathways. ERK, Extracellular signal-regulated protein kinase; MAPK, p38; MEK, MAPK/ERK kinase; JNK, Jun N-terminal kinase; J, c-Jun; F, c-Fos; AP-1, activated protein-1; TAK, TGF-β-activated kinase; I-κB, inhibitory factor-κB; IKK, I-κB kinase; NIK, NF-κB-inducing kinase.

to classic roles in stress, injury, and nutrition, glucocorticoids exert anti-inflammatory effects via the ligand-activated glucocorticoid receptor (GR) signaling pathway. Mutually negative interactions between the GR and SRTFs underlie the immunosuppressive and anti-inflammatory actions of glucocorticoids.

Progesterone also has immunosuppressive and anti-inflammatory properties that can be explained by transcriptional interference between ligand-activated progesterone receptor (PR) and SRTFs.

A. Glucocorticoid Activation

Reproductive tissues lack expression of key steroidogenic enzymes necessary for glucocorticoid synthesis. However, like most other tissues in the body, they express GR and are potential sites of glucocorticoid action. Glucocorticoids circulate in the blood in a binding equilibrium with corticosteroid-binding globulin, which sets the concentration of steroid available for interaction with the GR in target tissues. Glucocorticoid action is also influenced by metabolism through 11β-hydroxysteroid dehydrogenase (11β-HSD) activity in target tissues, which determines the relative availability of "active" cortisol or "inactive" cortisone for ligand activation of GR signaling (Fig. 2). Two 11β-HSD isoforms are known to exist in human tissues, both of which are microsomal enzymes belonging to the short-chain alcohol dehydrogenase/reductase superfamily. 11β-HSD type 1 is an $NADP^+$-dependent bidirectional enzyme with predominantly 11-oxoreductase activity, which therefore principally converts cortisone to cortisol. 11β-HSD type 2 (11β-HSD2) is an NAD^+-dependent enzyme with strong dehydrogenase activity, which inactivates cortisol to cortisone. Differential expression of 11β-HSD1 and 11β-HSD2 determines glucocorticoid tissue responsiveness. For example, the high level of 11β-HSD2 relative to 11β-HSD1 expressed in kidney promotes cortisol metabolism to cortisone and protects mineralocorticoid receptors from inappropriate occupation by cortisol. On the other hand, in liver, 11β-HSD1 converts cortisone to cortisol, ensuring that GRs are adequately exposed to cortisol.

Cells of tissues from throughout the body, including the reproductive tract, show increased activation of cortisone to cortisol when challenged with pro-inflammatory cytokines *in vitro*, suggesting a critical paracrine link between glucocorticoid activation and pro-inflammatory cytokine action.

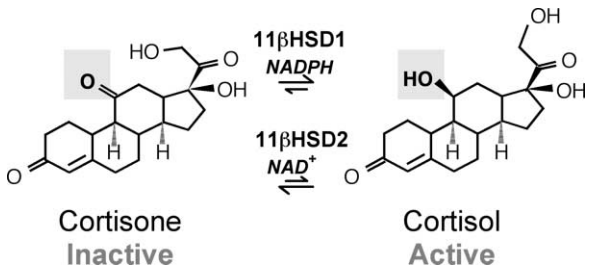

FIGURE 2 Interconversion of cortisone and cortisol catalyzed by 11β-hydroxysteroid dehydrogenases (11β-HSDs). 11β-HSD1 is principally an 11-oxoreductase that reversibly converts "inactive" cortisone to "active" cortisol, which binds and activates glucocorticoid receptors. 11β-HSD2 is a strong 11-dehydrogenase, which inactivates cortisol to cortisone.

IV. CYTOKINE–STEROID INTERPLAY

A. Ovulation

Ovulation in women normally occurs halfway through each menstrual cycle, in response to stimulation of the preovulatory follicle(s) by gonadotropins. The midcycle luteinizing hormone (LH) surge initiates a cascade of biochemical changes in follicular cells and macrophages, leading to dissolution of the follicle wall and shedding of the oocyte. These changes include increased pro-inflammatory cytokine production, progesterone production, activation of COX-2, increased PGE_2 synthesis, histamine release, and increased proteolysis mediated by MMPs. Inhibition of progesterone biosynthesis or pharmacological blockade of the PR prevents ovulation. Mice with null PR mutations are unable to ovulate, demonstrating an absolute need for local progesterone. COX-2 inhibitors also prevent ovulation, and COX-2 and gene knockouts in mice confirm an absolute dependence on COX-2 activation during ovulation. Following follicular rupture, each bout of ovulation-associated damage to the ovary must be rapidly repaired. Inflammation—essential for wound healing—is contained and rapidly resolved. Locally produced progesterone and locally activated cortisol are believed to participate in this compensatory anti-inflammatory process.

Within the preovulatory follicle, a switch in the expression of 11β-HSD isoforms occurs during granulosa cell luteinization. Before induction of ovulation, nonluteinized human granulosa cells express mainly 11β-HSD2 mRNA and little or no 11β-HSD1 mRNA. After exposure to LH or human chorionic gonadotropin, 11β-HSD2 mRNA expression is suppressed and 11β-HSD1 mRNA expression is enhanced. This shift in potential for glucocorticoid metabolism from inactivation to reactivation is reflected in the ability of luteinizing human granulosa cells to undertake predominantly reductive (cortisone → cortisol) metabolism *in vitro* and substantially raised the concentrations of cortisol in follicular fluid. In experiments on cultured rat granulosa cells, treatment with IL-1β mimics the action of LH *in vitro*, up-regulating 11β-HSD1 and down-regulating 11β-HSD2. Treatment of cultured human ovarian epithelial cells with IL-1 also increases the gene expression of 11β-HSD1 and metabolism of cortisone to cortisol *in vitro*. Thus, cytokine-regulated 11β-HSD expression in the follicle wall and on the ovarian surface may determine the local availability of anti-inflammatory cortisol (Fig. 3).

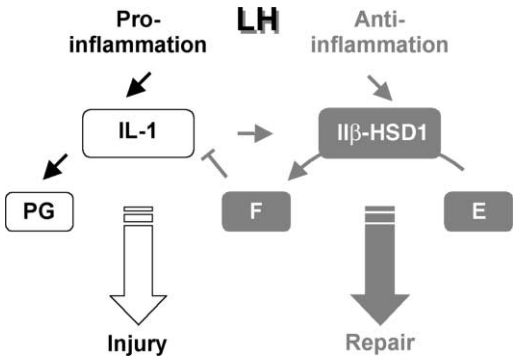

FIGURE 3 Proposed role of 11β-HSD1 in the resolution of LH-induced inflammation at the ovarian surface during ovulation. Ovulation is viewed as a natural injury-repair process. The ovulation-inducing LH surge induces an acute inflammatory response by increasing the local production of inflammatory cytokines (IL-1) and prostaglandins (PG), leading to proteolytic breakdown of the follicle wall and apoptosis of overlying ovarian surface epithelial cells. LH-induced IL-1 simultaneously up-regulates the expression of 11β-HSD1 in granulosa cells and OSE cells, serving to increase the metabolism of "inactive" cortisone (E) into anti-inflammatory cortisol (F). The increased local availability of cortisol is hypothesized to play a role in the resolution of this acute inflammatory event. Reprinted from Yong, P. Y. K., Harlow, C. R., Thong, K. J., Hillier, S. G. (2002). Regulation of 11β-hydroxysteroid dehydrogenase type 1 gene expression in human ovarian surface epithelial cells by interleukin-1. *Human Reproduction* **17** (**9**), 2300–2306. By permission of Oxford University Press.

B. Menstruation

In the absence of pregnancy, progesterone withdrawal due to regression of the corpus luteum causes menstruation, which is associated with up-regulation of inflammatory mediators in the uterus (IL-8, monocyte chemoattractant peptide-1, and COX-2). Hypoxia due to arteriole vasoconstriction is coincident with progesterone withdrawal and in other body systems is a stimulus for IL-8 expression. IL-8 is not only a powerful leukocyte chemotaxin and secretagogue; it has also been shown to have important roles in neovascularization and mitogenesis and thus may be centrally involved in the local inflammatory and vascular events of menstruation.

The uterus expresses PR and the key components of the glucocorticoid response system, and there is evidence from experiments on rats that both activation of glucocorticoid through 11β-HSD enzyme activity and levels of GR are likely to have roles in modulating glucocorticoid action in the uterus. Although 11β-HSDs and GR are expressed in

human endometrium, there are no data on regulation or expression in relation to hormonal status. High concentrations of glucocorticoids inhibit immunologic and inflammatory responses and also inhibit estrogen-stimulated epithelial proliferation. Glucocorticoids can down-regulate uterine estrogen receptors. In the rat, estradiol up-regulates both types of 11β-HSD. Furthermore, 11β-HSD2 mRNA has been localized to the stroma and stratum vasculare of the rat uterus. The physiological significance of the interaction between the GR and the 11β-HSD system in menstruation is as yet unexplored. It remains to be determined whether an altered availability of cortisol to bind to the GR (due to differential expression of 11β-HSD isoforms) is compensated for by activation of the PR by progesterone and vice versa.

C. Implantation

Invasion of the uterine wall by trophoblastic tissue induces a natural inflammatory reaction, which must be contained to allow pregnancy to proceed. Maternal factors secreted into the lumen of the female reproductive tract as well as substances synthesized by the developing embryo itself help to regulate this process. Similar to ovulation, implantation involves increased local production of pro-inflammatory cytokines, dependence on progesterone, up-regulation of COX-2, and increased activity of MMPs that digest collagen as the uterus is penetrated.

During placentation, growth factors and cytokines produced by the placenta and decidual tissues accelerate the production of MMPs by trophoblasts. The release of IL-1β parallels the invasive potential of cytotrophoblasts, being produced in greater amounts by first-trimester cells than term cells. Inflammation-associated IL-1β production and MMP expression are decreased by glucocorticoid treatment *in vitro*. Thus normal trophoblast invasion may be regulated, in part, by the opposing actions of IL-1β and corticosteroids, since both are present in high concentrations at the maternal–fetal interface.

Human placental tissue is a rich source of 11β-HSD activity and a chronic suppressive action of glucocorticoid on cytokine production and nuclear binding of NF-κB and AP-1 proteins in human term placental cytotrophoblasts has been reported. This suggests a potential mechanism through which glucocorticoids may suppress inflammation at maternal–fetal interfaces across gestation.

D. Parturition

Pro-inflammatory cytokines, prostaglandins, anti-inflammatory steroids, and matrix-degrading proteases directly participate in parturition. The pregnant uterus undergoes drastic remodeling during labor and the peripartum period, when the cervix becomes softened, effaced, and dilated to allow expulsion of the neonate. These changes to the cervix can be induced by mechanical trauma (as in "sweeping the membranes") or administration of prostaglandins, anti-progestins, or cytokines, such as IL-1 or IL-8. As in ovulation, menstruation, and implantation, MMPs, up-regulated by pro-inflammatory cytokines and prostaglandins, are instrumental to uterine and cervical tissue remodeling during parturition.

Anti-inflammatory steroids in turn participate in the cytokine- and prostaglandin-mediated mechanisms through which invading cells soften the cervix and initiate the natural onset of birth. Mifepristone, an anti-progestin that ripens the cervix when given during labor, is also a potent anti-glucocorticoid. Combined blockade of PR and GR by this substance presumably impedes ligand-activated anti-inflammatory signaling, thereby promoting the inflammation-associated process of cervical ripening.

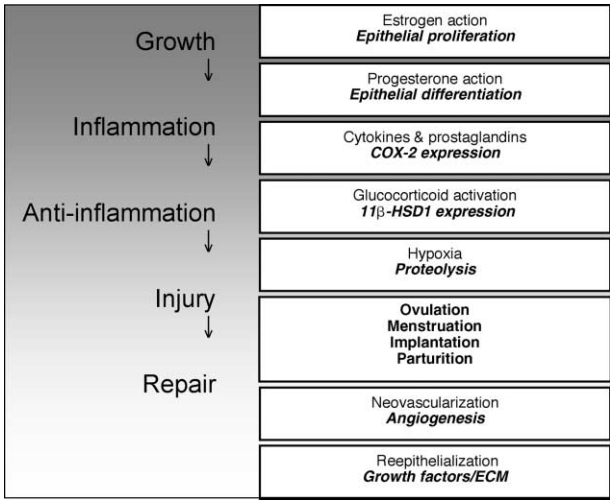

FIGURE 4 Pro- and anti-inflammatory mechanisms common to ovulation, menstruation, implantation, and parturition. All four processes involve locally increased formation of inflammatory cytokines and prostaglandins. Systemic progesterone and glucocorticoids re-activated via local changes in 11β-HSD activity are believed to provide a compensatory anti-inflammatory response. Proteolytic tissue injury is thereby localized, minimized, and promptly healed.

The role of 11β-HSDs in regulating the availability of cortisol to participate in this process remains undetermined but 11β-HSD1 is richly expressed in amniotic membranes, where prostaglandins have been shown to increase the net conversion of cortisone to cortisol *in vitro*.

V. SUMMARY

Locally produced pro-inflammatory cytokines promote inflammation-associated tissue injury and repair during ovulation, menstruation, implantation, and parturition. Each of these critical steps in reproduction depends absolutely on progesterone, which has anti-inflammatory properties. Furthermore, they all occur in regions of the reproductive tract where locally produced pro-inflammatory cytokines and prostaglandins have the potential to alter 11β-HSD enzyme expression, thereby influencing the local availability of cortisol (Fig. 4). Progesterone and cortisol activate anti-inflammatory signaling pathways through binding and activating the PR and GR, respectively. Both types of steroid may serve anti-inflammatory functions in the female reproductive tract, interacting with pro-inflammatory cytokines to localize and contain the natural inflammatory processes on which reproduction depends.

Glossary

corticosteroids Steroid hormones secreted by the adrenal cortex that play crucial roles in nutrition, stress, and tissue responses to injury. In humans, cortisone and its synthetic analogues, such as prednisone and dexamethasone, are used therapeutically to control rheumatism and other inflammatory ailments.

cytokines Polypeptide messenger molecules that mediate cell-to-cell communication through binding to specific receptors on target cells and triggering postreceptor signaling pathways that alter cellular behavior. Cytokines are involved in reproduction, growth and development, injury repair, and the immunoendocrine system. Usually classified as interleukins, interferons, colony-stimulating factors, tumor necrosis factors, or growth factors, their classification is evolving. Interleukins are cytokines produced by leukocytes as part of the immune and inflammatory responses.

inflammation In higher organisms, a defense mechanism that protects the organism from infection and injury by localizing and limiting tissue damage, so that healing can begin. An inflammatory response lasting only a few days is called acute inflammation, whereas a response of longer duration is referred to as chronic inflammation.

prostaglandins Cyclic, unsaturated fatty acids derived from arachidonic acid, a phospholipid that is an integral component of the cell membrane. Inflammatory stimuli induce the rapid release of arachidonic acid, which is converted to prostaglandins, prostacyclin, and thromboxanes by cyclooxygenase (COX) enzyme activity. The inducible form of COX, COX-2, is mainly responsible for the local formation of the prostaglandins necessary for inflammation. Leukotrienes, produced from arachidonic acid due to lipoxygenase enzyme activity, are also important mediators of the inflammatory process, whereas thromboxanes and prostacyclin play roles in blood coagulation.

Prolactin (PRL)

NIRA BEN-JONATHAN
University of Cincinnati

Prolactin (PRL) is a 23 kDa protein hormone that is produced and secreted by pituitary lactotrophs. Pituitary PRL synthesis and release are subjected to tonic inhibition by hypothalamic dopamine and are stimulated by many neuropeptides, steroid hormones, and growth factors. PRL binds to a single-span membrane receptor and exerts its action via several interacting signaling pathways. PRL is a multifunctional hormone that affects reproductive, developmental, osmoregulatory, and behavioral functions. In addition to the pituitary, PRL is produced by many tissues throughout the body and is concentrated from the blood into several cell types and fluid compartments. The heterogeneous nature of the PRL-producing cells together with the expression of PRL receptors by almost every tissue in the body supports the role of PRL as both a hormone and a cytokine and underlies its pleiotropic functions.

I. THE PROLACTIN GENE AND PROTEIN

The prolactin (PRL) gene is present as a single copy on human chromosome 6. PRL shares 40% homology with growth hormone (GH) and placental lactogen (PL), and the three hormones were derived by gene duplication from a common ancestral gene some 400 million years ago. Several proteins with similar structural features, generally named PRL-related or PRL-like proteins, are now included as members of the PRL/GH/PL gene family. The rat PRL gene is 10 kb in size and is composed of five exons. The mature mRNA is approximately 1 kb in length and encodes a 227-residue protein that includes a 28-residue signal peptide that is cleaved on entering the endoplasmic reticulum. A 2 to 2.5 kb sequence at the 5′-flanking region of the rat PRL gene (the proximal promoter) controls tissue-specific and hormone-regulated gene expression (Fig. 1). It is made of two distinct domains, a proximal region and a more distal enhancer, both of which are required for pituitary-specific expression. Eight *cis*-acting elements throughout the proximal promoter bind Pit-1, a homeobox transcription factor. Although Pit-1 is expressed only in the pituitary gland, it is not restricted to lactotrophs and requires interactions with other factors to confer the lactotroph phenotype.

The human PRL gene differs from the rat gene in several respects. It is composed of six, rather than five, exons and is more than 15 kb long. The extra noncoding exon, exon 1a, has a transcriptional start site 5.8 kb upstream of the pituitary start site (Fig. 1). In extrapituitary sites such as decidua, myometrium, and lymphoid cells, exon 1a is spliced to exon 1b, generating an mRNA transcript that is approximately 150 bp larger than the pituitary counterpart in the 5′-untranslated region. A superdistal promoter upstream of exon 1a regulates PRL gene expression in extrapituitary sites and is silenced in the pituitary gland. This region does not contain Pit-1-binding sites and its regulation differs from that of the proximal promoter.

The 23 kDa PRL protein is composed of a single chain of 199 residues. It has three intramolecular disulfide bridges between residues 4 and 11, 58 and 174, and 191 and 199, N- or O-linked glycosylation sites, and three phosphorylation sites. A three-dimensional model of PRL predicts that it is arranged in four anti-parallel α-helices organized in an "up-up-down-down" fashion. This bundle motif is shared with hematopoietic factors such as interferon and many interleukins. The 60 to 100% sequence homology between PRL molecules from different species reflects their phylogenetic relationship. Approximately 30 residues, clustered in four distinct regions, are highly conserved and may be important for binding to the receptor.

spatiotemporally in female reproductive tissues. However, the ratios of the individual isoforms vary in reproductive tissues as a consequence of developmental and hormonal status and during carcinogenesis.

Progesterone receptors have a modular protein structure consisting of distinct functional domains capable of binding steroidal ligand, dimerization of liganded receptors, interaction with hormone-responsive DNA elements, and interaction with co-regulator proteins required for bridging receptors to the transcriptional apparatus. Binding of progestin agonists to the hormone-binding domain induces conformational changes in receptor structure that promote the interaction of co-activator proteins with distinct activation function domains (AFs) located within both the amino- and the carboxy-terminal regions of the receptor. Such co-activators promote chromatin remodeling and bridging with general transcription factors, resulting in the formation of productive transcription initiation complexes at the receptor-responsive promoter. In contrast, binding of receptor antagonist compounds induces receptor conformational changes that render AFs nonpermissive to co-activator binding and instead promote interaction with co-repressor proteins that inhibit the transcriptional activity of the receptor. The ability of progesterone receptors to interact with a variety of co-activator and co-repressor proteins, together with the differing spatiotemporal expression of co-regulators, illustrates a key role of these proteins in mediating different tissue-specific responses of progesterone receptors to steroidal ligand. Importantly, receptors for progesterone can also be activated in the absence of steroidal ligand by phosphorylation pathways that modulate their interactions with co-regulator proteins.

The PR-A and PR-B isoforms differ in that the PR-B protein contains an additional sequence of amino acids at its amino-terminus that is not contained in PR-A. This PR-B-specific domain encodes a third transactivation function region (AF-3) that is absent from PR-A. Recent evidence has demonstrated that the presence of AF-3 allows binding of a subset of co-activators to PR-B that are not efficiently recruited by progestin-bound PR-A. Thus, when expressed individually in cultured cells, PR-A and PR-B display different transactivation properties that are specific to both cell type and target gene promoter context and are associated with the differential ability of PR-A and PR-B to recruit specific co-regulator proteins. Agonist-bound PR-B functions as a strong activator of transcription of several PR-dependent promoters and in a variety of cell types in which PR-A is inactive. Furthermore, when both isoforms are co-expressed in cultured cells, in cell and promoter contexts in which agonist-bound PR-A is inactive, the PR-A can repress the activity of PR-B. This repressor capability of PR-A also extends to other steroid receptors including estrogen receptor-α (ER-α). Finally, the PR-A and PR-B proteins also respond differently to P antagonists. Whereas antagonist-bound PR-A is inactive, antagonist-bound PR-B can be converted to a strongly active transcription factor by modulating intracellular phosphorylation pathways. Although the sequences of the ligand-binding domains of PR-A and PR-B are identical, the ability of different ligands to induce different conformational changes in PR, together with the synergistic activity of the amino- and carboxy-terminal activation domains, predicts that PR-A or PR-B selective transcriptional regulation can be achieved by manipulating ligand interactions with the carboxy-terminal.

III. PHYSIOLOGICAL ROLE OF PRs

Null mutation of the PR gene encoding both isoforms has provided evidence of an essential role of PRs in a variety of female reproductive and nonreproductive activities. Female mice lacking both PRs exhibit impaired sexual behavior, neuroendocrine gonadotropin regulation, anovulation, uterine dysfunction, impaired ductal branching morphogenesis, and lobuloalveolar differentiation of the mammary gland. PRs also play an essential role in the regulation of thymic involution during pregnancy and in the cardiovascular system through regulation of endothelial and vascular smooth muscle cell proliferation and response to vascular injury. Receptors for progesterone have also been identified in the central nervous system and bone, where progesterone has been implicated in both cognitive function and bone maintenance. However, the essential role of PRs in these regions has not yet been confirmed.

The more recent generation of novel mutant mouse strains in which either the PR-A (PRAKO) or the PR-B (PRBKO) isoform is selectively ablated has facilitated physiological analysis of the individual contributions of these proteins to the reproductive activities of progesterone.

IV. PRs AND OVARIAN FUNCTION

Evidence that ovary-derived progesterone may participate in autocrine regulation of ovarian function first emerged with the demonstration that luteinizing hormone (LH), the primary signal for rupture of

preovulatory ovarian follicles leading to ovulation, can stimulate the transient expression of PR mRNA and protein in granulosa cells isolated from preovulatory follicles and that the anti-progestin, RU486, can inhibit ovulation. Definitive proof that PRs are essential mediators of ovulation has been provided by analysis of the ovarian phenotype of the PRKO mouse. Despite exposure to superovulatory levels of gonadotropins, PRKO mice fail to ovulate. Analysis of the histology of these mice has revealed normal development of intraovarian follicles to the tertiary follicular stage. The follicles contain a mature oocyte that is fully functional when isolated and fertilized *in vitro*. However, follicular rupture is effectively eliminated. Despite the ovulatory block, the preovulatory granulosa cells within these follicles can still differentiate into a luteal phenotype and express the luteal marker, P450 side chain cleavage enzyme. Thus, PR is required specifically for LH-dependent follicular rupture leading to ovulation but not for differentiation of granulosa cells to form a corpus luteum (luteinization). Follicular rupture requires induction of a prostaglandin-mediated inflammatory response to LH as well as tissue degradation at the apex of the preovulatory follicle, an event that is mediated by matrix-digesting proteinases. Recent investigations to examine the molecular events associated with ovulation that are mediated by PRs have shown that PRs are induced specifically in the mural granulosa cells of the mature tertiary follicle and are absent from the cumulus granulosa cells that surround the oocyte. Analysis of the expression of potential mediators of ovulation in PRKO mice has demonstrated that LH-induced regulation of COX-2, an enzyme that catalyzes the production of prostaglandins, is unaffected. COX-2 is required for ovulation and is expressed by cumulus granulosa cells. In contrast, the expression of two metalloproteinases, ADAMTS-1 (a desintegrin and metalloproteinase with thrombospondin motifs) and cathepsin-L (a lysosomal cysteine protease), is inhibited in granulosa cells of the mature follicle in PRKO mice. One of these proteases, ADAMTS-1, plays an essential role in ovulation and may represent a critical mediator of the progesterone-induced ovulatory event.

Both the PR-A and the PR-B proteins are induced in preovulatory follicles in response to LH stimulation. Stimulation of immature PRAKO mice with gonadotropins has shown that superovulation is severely impaired in these mice relative to their wild-type counterparts but, in contrast to the findings with PRKO mice, is not completely absent. In contrast, superovulation was unaffected in PRBKO mice expressing only the PR-A protein. Thus, PR-A expression is both necessary and sufficient to mediate the ovulatory response to progesterone.

Histological analysis of the ovaries of PRAKO mice showed numerous mature anovulatory follicles that contained an intact oocyte and were arrested at a stage similar to that previously observed in PRKO mice. Most surprisingly, however, in contrast to PRKO mice, the spatiotemporal regulation of ADAMTS-1 and cathepsin-L by progesterone was unaffected in these mice. Thus, despite its inability to mediate follicular rupture, the PR-B protein is functional in the ovary and capable of regulating a subset of progesterone-responsive target genes.

V. PR ISOFORMS AND UTERINE IMPLANTATION

Female infertility in PRKO mice is also associated with defective uterine implantation and a lack of decidualization of uterine stromal cells in response to progesterone. Consistent with these findings, wild-type embryos failed to implant into the uterus when transferred into uteri of pseudo-pregnant PRKO females. Similarly, mating attempts between superovulated PRAKO females and wild-type males failed to result in successful pregnancies despite the release of small numbers of oocytes from PRAKO females. To determine whether the PRA protein is required for uterine decidualization, ovariectomized PRAKO mice were treated with progesterone and estrogen followed by mechanical stimulation of the left uterine horn of each animal in order to induce decidualization of stromal cells. Decidualization is associated with a marked increase in uterine weight and characteristic histological appearance associated with the differentiation of stromal cells into decidual cells. Both responses were inhibited in PRAKO mice, indicating that expression of the PRA protein in the uterus is required to mediate the decidualization response to progesterone.

The decidualization defect in PRAKO mice was also associated with aberrant regulation of progesterone-responsive target genes associated with implantation. Analysis of the regulation of three genes, calcitonin (CT), histidine decarboxylase (HDC), and amphiregulin (AR), whose expression is increased in the uterine epithelium in response to P in association with uterine receptivity and is abolished in PRKO mice showed that ablation of PR-A resulted in the loss of expression of CT and AR but the regulation of HDC was fully retained. These findings indicated that defective implantation in PRAKO uteri is associated

with the loss of P-regulated expression of a subset of genes associated with uterine epithelial receptivity. Importantly, this differential target gene regulation by PR-B was not due to differences in spatiotemporal expression of PR-B relative to PR-A. The expression of PR-B in PRAKO mice showed the same pattern of intrauterine expression and regulation by estrogen as that observed in wild-type mice. Thus, the uterine defects observed in these mice are due to differences in the transcription factor activity of PR-B rather than to differences in the spatiotemporal expression of the protein relative to PR-A.

VI. OPPOSING FUNCTIONS OF PR-A AND PR-B IN THE REGULATION OF UTERINE EPITHELIAL PROLIFERATION

Estrogen is the primary proliferative stimulus for uterine epithelium and its effects are inhibited by progesterone. Ablation of both the PR-A and the PR-B isoforms in PRKO mice results in marked hyperplasia of the lumenal and glandular epithelial tissue due to the unopposed action of estrogen. Selective ablation of PR-A, however, revealed an unexpected capacity of the PR-B protein to contribute to, rather than inhibit, epithelial cell proliferation. Treatment of PRAKO mice with estrogen alone induced epithelial hyperplasia in a manner similar to that observed in PRKO and wild-type mice. However, the addition of progesterone together with estrogen resulted in a marked increase in proliferation over that observed with estrogen alone, a response that was not observed in PRKO mice. These findings indicate that expression of the PR-B protein alone in the uterus results in a gain of proliferative activity. This acquisition of a proliferative activity of progesterone represents a PR-B-dependent gain of function not previously observed in the uterus, indicating that uterine expression of the PR-A isoform is required to oppose not only estrogen-induced proliferation but also that induced by progesterone acting through the PR-B protein.

The discovery that PR-B can contribute to, rather than inhibit, uterine epithelial cell proliferation is likely to have important clinical implications with regard to hormonal management of uterine endometrial dysplasias. Clearly, the relative expression of PR isoforms under these conditions will be an important determinant with regard to the effectiveness of progestin therapy. The results predict that progestin agonists selective for the PR-A protein should improve the effectiveness of progestin therapy for these conditions.

VII. PRs AND MAMMARY GLAND DEVELOPMENT

Estrogen and progesterone are essential for the maintenance of postnatal developmental plasticity of the mammary gland and both hormones play a key role in mammary tumorigenesis. Null mutation of both PR isoforms in PRKO mice has demonstrated that PRs are specifically required for pregnancy-associated ductal proliferation and lobuloalveolar differentiation of the mammary epithelium. The mammary glands of PRKO mice failed to develop the pregnancy-associated side-branching of the ductal epithelium with attendant lobular alveolar differentiation despite normal postpubertal mammary gland morphogenesis of the virgin mice. Ablation of PR expression in these mice also resulted in a significantly reduced incidence of mammary tumor growth in response to carcinogen challenge. These observations underscore a specific role of PRs (as distinct from ERs) as obligate mediators of the intracellular signaling pathways that are essential for the initiation of murine mammary tumors induced by carcinogens.

The use of PRKO mice in combination with mammary gland transplantation techniques has provided important insights into the mechanisms underlying progesterone-dependent mammary gland morphogenesis. Throughout postpubertal mammary gland development, PRs are expressed exclusively in the epithelium. Consistent with these observations, tissue transplantation approaches using wild-type and PRKO mouse tissue to produce mammary gland recombinants that were devoid of PR in either the stromal or the epithelial compartments have provided strong support for the functional involvement of epithelial, rather than stromal, PRs in mediating mammary gland morphogenic responses to progesterone. The expression of PRs is localized to a scattered subset of epithelial cells throughout the ductal epithelium, the majority of which appear to be segregated from proliferating epithelial cells. The hierarchical organization of these receptors and their segregation from proliferating cells are conserved features in rodent and human mammary tissue. Such an expression pattern predicted that regulation of epithelial cell proliferation by progesterone may occur through a paracrine mechanism whereby PRs residing in nonproliferating cells induce the expression of a proliferative signal that promotes the proliferation of neighboring receptor-negative cells. Although PRKO mammary epithelium cannot undergo side-branching, mixing experiments with PRKO and wild-type epithelial cells demonstrate that the branching and

differentiation defects can be overcome when PRKO cells are placed in close contact with PR^+ cells. Thus, although lacking PR^+ cells, the PRKO mammary epithelium still retains those PR^- cells that are responsive to PR-mediated paracrine signaling. Recent attempts to uncover downstream mediators of the progesterone response have identified the secreted glycoprotein Wnt-4 as a potential PR target that is co-expressed in PR^+ cells, is regulated by P, and is essential for regulating ductal branching via paracrine regulation of proliferation.

Both isoforms of PR are expressed in the mammary gland of the virgin mouse and during pregnancy, although the levels of PR-A protein exceed those of the PR-B isoform by at least a 2:1 ratio in both cases. To examine the selective contributions of each isoform to the morphogenic responses of the mammary epithelium to progesterone, the morphology of mammary glands of ovariectomized wild-type, PRAKO, and PRBKO mice was compared after exposure to estrogen and progesterone. Ablation of PR-A in PRAKO mice did not affect the ability of PR-B to elicit normal progesterone responsiveness in the mammary gland. The morphological changes in ductal side-branching and lobular alveolar development in these glands were similar to those observed in wild-type mice. Thus, the PRB isoform is sufficient to elicit normal proliferation and differentiation of the mammary epithelium in response to progesterone and neither process appears to require functional expression of the A protein. In contrast, more recent analysis of the mammary glands of PRBKO mice under similar conditions has shown markedly reduced ductal side-branching, whereas lobular alveolar differentiation appeared to be unaffected. Thus, PR-B is the primary mediator of the proliferative response to progesterone, but both the PR-A and the PR-B proteins can provide the differentiative signals associated with alveologenesis.

VIII. SUMMARY

Molecular dissection of progesterone signaling mechanisms using *in vitro* systems has demonstrated that the PR-A and PR-B proteins can respond to the same steroid ligand to induce both overlapping and distinct transcriptional responses that are promoter- and cell context-dependent. The use of genetically manipulated mouse models in which one or both of the PR isoforms are ablated has been pivotal in defining the physiological spectrum of progesterone receptor action as well as the contribution of the individual protein isoforms to the plieotropic activities of the hormone. These approaches have provided compelling evidence that the differences in the transactivation properties of the PR isoforms observed *in vitro* are reflected in a differential capacity to regulate the tissue-selective reproductive activities of progesterone.

hormone receptor superfamily, including retinoid and thyroid hormone receptors, can actively silence gene transcription through recruitment of corepressors that recruit proteins with histone deacetylase (HDAC) enzyme activity. HDACs mediate effects opposite to those of HATs by promoting a condensation of nucleosome structure and impairing access of the general transcription machinery to the promoter.

II. STEROID HORMONE RECEPTORS: GENERAL PROPERTIES

Members of the nuclear receptor superfamily share a similar domain organization consisting of a highly conserved DNA-binding domain (DBD) located in the central part of the molecule, a carboxyl-terminal ligand-binding domain (LBD), and an N-terminal domain that is the most variable region among

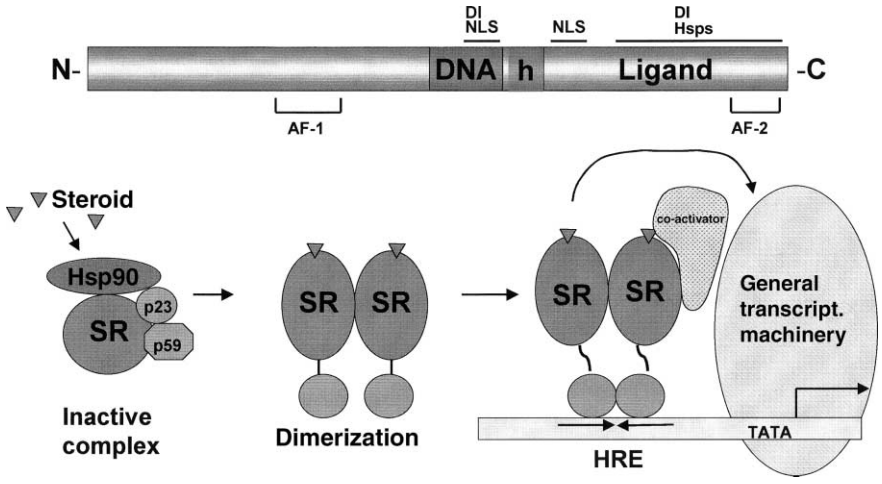

FIGURE 2 General structural organization of steroid receptors as members of the nuclear receptor superfamily of ligand-dependent transcription factors, and activation mechanisms. DI, Dimerization domain; NLS, nuclear localization sequence; h, hinge; Hsps, heat-shock proteins; AF-1, AF-2, transcriptional activation domains; SR, steroid receptor; HRE, hormone response element.

superfamily members (Fig. 2). Three-dimensional atomic structures of isolated DBDs and LBDs have revealed common motifs for these regions. The core DBD contains two asymmetric zinc fingers, each with a zinc ion coordinated by four conserved cysteine residues. An α-helix extends between the two zinc fingers, which makes base-specific contacts in the major groove of HRE DNA. The LBD consists of 10–12 α-helices that fold into a three-layer α-helical sandwich containing a central core positioned between helix bundles on either side. This structure creates a hydrophobic wedge-shaped cavity in which the steroid hormone (ligand) is buried. By comparison, little is known about the structure of the N-terminal domain. Biophysical and biochemical data indicate that the N-terminal domain is in a non-globular extended conformation with little secondary structure. This is the least conserved region among superfamily members with respect to both length and amino acid sequence. The N-terminal domain is functionally important because it is required for full transcriptional activity of steroid hormone receptors and for many cell-specific and target gene-specific responses.

Other functional and structural determinants have been identified within these broader three domains. In addition to binding steroid hormone, the LBD contains determinants for dimerization (DI) in the absence of DNA, for binding of heat-shock proteins (Hsps), and for nuclear localization sequences (NLSs). The DBD contains a second NLS and a dimerization domain that is dependent on DNA binding. DNA-dependent dimerization stabilizes the receptor–DNA complex and facilitates orientation of the receptor dimer with the correct spacing of the HRE. Steroid receptors contain at least two transcription activation function (AF) domains. These are autonomous transferable domains required for the DNA-bound receptor to transmit a transcriptional activation response, and they function as specific binding sites for co-activators. AF-2, located in the LBD, is hormone dependent and becomes activated as a result of the steroid hormone inducing a repositioning of the C-terminal-most α-helix-12 in such a way as to create a specific hydrophobic binding pocket for members of the p160 family of steroid receptor co-activators (SRCs). Little is known about AF-1 in the N-terminus. It can function independently of AF-2 in a constitutive manner or can synergize with AF-2 in a ligand-dependent manner. The co-activators that bind to and mediate the activity of AF-1 are yet not well defined.

III. PROGESTERONE RECEPTOR A AND B ISOFORMS

As a member of the nuclear receptor superfamily, the progesterone receptor (PR) shares the general structural domains, but has several unique features. In most species, PR is expressed as two isoforms, PR-A and PR-B. The exception is rabbits, which express only PR-B. In human tissues, PR-A is a truncated protein lacking the first 164 amino acids from the N-terminal domain; otherwise the two PRs have an identical amino acid sequence throughout the remainder of the protein, including the DBD and LBD (Fig. 3). PR-A and PR-B arise from a single gene by alternate transcription from two promoters. The two forms of PR have similar steroid hormone and DNA-binding activities, but they have distinct transcriptional activities due to differences in the N-terminal region. PR-A and PR-B are capable of forming heterodimers, and in the cell PR can exist in three molecular states of AA, AB, and BB dimers. This ability to produce three molecular forms of PR from a single gene expands the functional range of activities of the receptor without the need for a separate receptor subtype gene. The relative expression of PR-A and PR-B is regulated in a tissue-specific manner and by physiological conditions. The ratio of PR-A to PR-B varies significantly in a regular pattern in the uterus during the menstrual cycle; in some breast tumors, very high PR-A:PR-B ratios have been detected. In normal breast tissue, the ratios are close to 1:1, whereas PR-A appears to be the predominant form of receptor in endometriosis. Thus, a difference in relative expression of PR-A and PR-B is one way for a tissue to regulate response to progesterone. The two promoters responsible for expression of the PR isoforms are estrogen responsive. However, the gene region for these promoters is complex and has potential regulatory sites for multiple other factors, and is not likely to be regulated by estrogen alone.

The transcriptional activities of the two PR isoforms vary, depending on the cell type and the context of the target gene promoter. In general, on classical progesterone response element (PRE) targets, PR-B is a much stronger activator compared to PR-A. However, PR-A can be a strong activator under specific cell and target gene contexts. The stronger activation potential of PR-B is due in part to the existence of a third activation domain (AF-3) within the first N-terminal 164 amino acids that is unique to PR-B (Fig. 3). However, AF-3 is not an autonomous activation domain capable of activating transcription when linked to a heterologous DBD. AF-3 functions

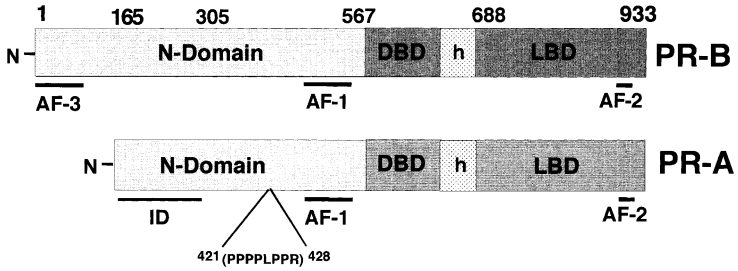

FIGURE 3 Domain organization of human progesterone receptor A and B isoforms (PR-A and PR-B). AF-1, AF-2, AF-3, Transcriptional activation domains; DBD, DNA-binding domain; h, hinge region; LBD, ligand-binding domain; ID, inhibitory domain.

only when linked to the PR DBD, and co-activators that interact with AF-3 have not yet been identified. Thus, AF-3 is thought to facilitate activity of AF-1 and AF-2 through intramolecular domain interactions. In support of this idea, the N- and C-terminal domains of PR (both A and B isoforms) are capable of directly associating with each other in a hormone agonist-dependent manner, but these interactions are more efficient for PR-B than for PR-A.

Under certain cell and target promoter contexts, PR-A is inactive as a transcription factor and can function as a ligand-dependent transdominant repressor of other steroid receptors, including PR-B, estrogen receptor (ER), androgen receptor (AR), glucocorticoid receptor (GR), and mineralocorticoid receptor (MR). PR-A can act in this repressor mode in response to binding either progestin agonists or antagonists. An inhibitory domain (ID) responsible for this transrepressor function has been mapped to the first 140 N-terminal (165–305) amino acids of PR-A (Fig. 3). The ID is functional and transferable to other steroid receptors, such as chicken PR and human ER, which do not exhibit this trans-repressor activity. Truncation of the ID from PR-A increases its transcriptional activity to the level of PR-B. The sequence within the ID is present in both PR isoforms but is active only in the context of PR-B, suggesting that a role of the PR-B-specific N-terminal segment is to suppress the activity of the ID. This is thought to occur through the PR-B N-terminal segment exerting a long-distance effect on the conformation of the PR-A N-terminus.

How PR-A can repress transcriptional activity of other steroid receptors remains unclear. This property does not involve the phenomenon of transcriptional squelching of a common limiting cofactor for PR-B and other steroid receptors. Instead, PR-A and PR-B exhibit a different ability to interact with coregulatory proteins. PR-A interacts more efficiently with the silencing mediator of retinoid/thyroid (SMRT) receptor corepressor than does PR-B, and this difference requires the inhibitory domain of PR-A. Conversely, PR-B interacts more efficiently with members of the SRC family of co-activators than does PR-A. Thus, the A isoform of PR may recruit a distinct coregulatory protein complex to promoters that contains corepressors and is functionally inhibitory to other DNA-bound complexes.

Studies with PR isoform-specific gene knockout mice and transgenic mice that overexpress either PR-A or PR-B have provided evidence that the two forms of PRs have distinct physiological roles *in vivo*. Selective knockout of PR-A in mice has a strong phenotype in the uterus but not in the mammary gland, suggesting that the PR isoforms have tissue-specific roles. Overexpression of PR-A or PR-B results in abnormal mammary gland development, but the phenotypes of the two transgenic mouse lines are not the same.

Transcription factors that harbor both activation and repression domains, or are expressed as truncated forms capable of functioning as dominant transrepressors, have been identified in several different families of transcription factors. Such factors include the Id protein of the MyoD transcription factor family, the jun dimerization proteins (JDP-1 and JDP-2) of the AP-1 (fos/jun) family, and isoforms of the basic-region leucine zipper (bZIP) containing activating transcription factor-2 (ATF-2) and CCAATT/ enhancer-binding protein (C/EBP) transcription factors. These naturally occurring transrepressors have important physiological roles in shutting off activation responses at specific times during development and differentiation or under specific physiological conditions. Among the steroid hormone receptors, PR-A has been suggested to have a similar role that may be particularly relevant

in the uterus, in which progesterone is known to antagonize the growth-stimulatory activity of estrogen.

IV. PHOSPHORYLATION OF PR

As with other steroid hormone receptors, PR in human tissues is phosphorylated on multiple serine/threonine residues in a highly specific and hormone-regulated manner. Specific sites of phosphorylation on the PR *in situ* (PR expressed in mammalian cells) that have been confirmed by peptide sequencing are shown in Fig. 4. Most of the sites are located throughout the N-terminal domain; five are unique to PR-B whereas the others are within the N-terminal domain in common with PR-A and PR-B. The exception is phosphorylation of Ser-676 within the hinge region between the DBD and LBD. The PR phosphorylation sites are classified as basal and hormone dependent. Three hormone-dependent sites (Ser-102, Ser-294, and Ser-345) are unphosphorylated in the absence of ligand and become fully phosphorylated in response to hormone *in situ*. Some of the remaining sites are basally phosphorylated without hormone and increase phosphorylation rapidly within 5–10 min after hormone treatment of cells. The hormone dependence of the other sites has not been determined. Most of the phosphorylation sites reside within Ser-Pro motifs and there are at least three kinases capable of phosphorylating human PR, including the cyclin-dependent kinase CDK-2/cyclin A (Ser-130, Ser-162, Ser-190, Ser-213, Ser-400, and Ser-676), mitogen-activated protein kinase (MAPK; Ser-294), and casein kinase II (Ser-81). The kinases that phosphorylate the hormone-dependent sites at Ser-102 and Ser-345 and basal sites at Thr-430, Ser-554 have not yet been identified. The fact that subsets of sites are substrates for different kinases suggests that these groups of phosphorylation sites have distinct roles in PR structure/function and are regulated by different signaling pathways.

The function of PR phosphorylation has not been well defined. Analysis of various phosphorylation site mutants (serine to alanine substitutions) reveal no effect of phosphorylation on PR–DNA binding or steroid-binding activities. However, up to a 50% decrease in hormone-dependent transcriptional activity is observed with two mutants, Ser to Ala-190 and Ser to Ala-676. Other mutations have little to no effect on transcriptional activity of the PR. The Ser-294 phosphorylation site has been reported to be a signal for hormone-dependent down-regulation of the PR that targets the receptor for degradation by proteasomes. The PR from chicken oviduct (cPR) is also phosphorylated on multiple serine/threonine residues in the N-terminal domain and on a single site in the hinge. Phosphorylation site mutations in the N-terminal domain of cPR result in as much as a 75% reduction in transcriptional activity *in situ*, whereas mutation of the hinge region site reduces the hormone sensitivity of cPR-mediated transcription without altering steroid binding affinity. The magnitude of the effect of these phosphorylation site mutations on PR activity varies and is dependent on cell and target gene promoter context, suggesting that phosphorylation has a role in modulating PR interactions with other proteins for which expression may be cell type or target gene specific. Thus, phosphorylation does not appear to be a regulatory on/off switch but seems to have a more subtle role in

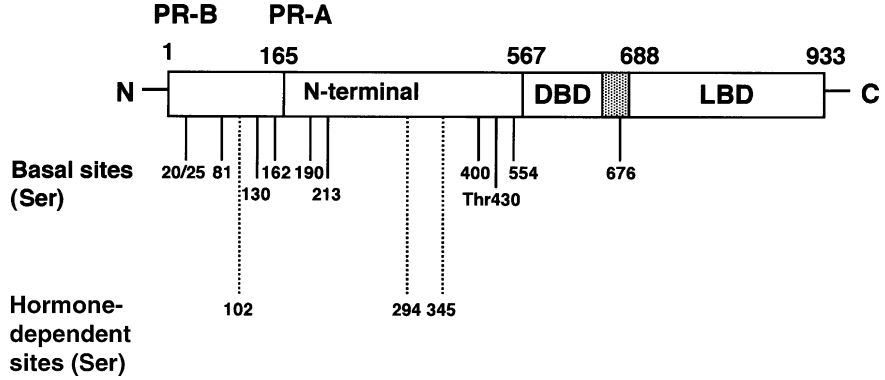

FIGURE 4 Phosphorylation sites of the human progesterone receptor. All sites are on serine residues, with the exception of position 430 (threonine). PR-A, PR-B, Progesterone receptor isoforms A and B; DBD, DNA-binding domain; LBD, ligand-binding domain.

modulating different functional activities of the PR. Additionally, phosphorylation could have a structural role in stabilizing the folded state of the receptor, in particular the N-terminal domain, which is fairly devoid of secondary structure. A physical mapping of the surface structure of the N-terminal domain of the PR by limited proteolysis shows that protease-accessible sites are limited to phosphorylation sites, suggesting that these sites are surface exposed and may stabilize domain interactions or folding within the N-domain.

V. PR CROSSTALK WITH OTHER TRANSCRIPTION FACTORS

Steroid receptors can regulate transcription of genes that lack HREs as a primary response through protein-protein interactions with other DNA-bound transcription factors (Fig. 5). Although this mode of regulation can be either positive or negative, it is more commonly a pathway for negative gene regulation by steroid receptors, and in some cases a mutual repression between steroid receptors and the other transcription factor has been observed. Genes that contain composite response elements consisting of a less than optimal DNA-binding site for the steroid receptor (often a HRE half-site) that overlaps, or is adjacent to, a good binding site for another sequence-specific transcription factor are a variation of this mode of regulation. Regulation of composite elements often involves both receptor–DNA and receptor–protein interactions

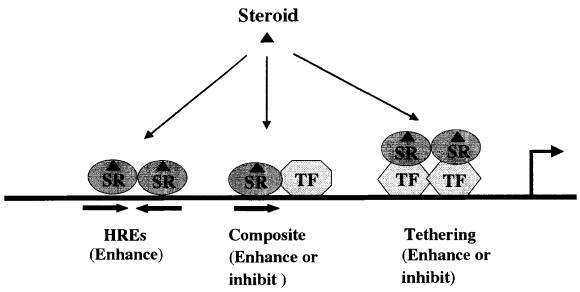

FIGURE 5 Different mechanisms by which steroid receptors activate or inhibit gene transcription as a primary gene regulation response. Left: Direct binding of the steroid receptor (SR) to hormone response elements (HREs) within promoters of steroid-responsive genes. Middle: Composite element consisting of a weak HRE half-site and a neighboring optimal site for another sequence specific transcription factor (TF). Steroid receptors can either enhance or inhibit transactivation mediated by the other transcription factor. Right: Tethering response element. Steroid receptor interacts with another DNA-bound transcription factor through a protein–protein interaction to either enhance or inhibit transactivation.

with other transcription factors. The ability to enhance the activity of other transcription factors arises through recruitment of receptor transcription activation domains; in essence, the receptor acts as a co-activator. Negative regulation can occur via the steroid receptor interfering with activation domains of other transcription factors or competing for DNA-binding sites. Examples of negative PR crosstalk with other transcription factors are repression of nuclear factor κB (NF-κB) activity (through interaction with RelA/p65 subunit), interference with the dioxin arylhydrocarbon receptor (AhR) signaling, inhibition of prolactin-induced Stat5-mediated activation of the β-casein gene, and repression of AP-1 (fos/jun) activity. Not all crosstalk with the PR results in repression; unliganded PR can enhance AP-1 in human endometrial carcinoma cells, although addition of progesterone reverses this enhancement. This positive crosstalk between PR and AP-1 appears to be cell type specific suggesting that other cellular factors are required. Because NF-κB is activated by various cytokines, crosstalk with the PR is thought to be involved in the immunosuppressive effects of progesterone during pregnancy. Progesterone receptor crosstalk with AP-1 and Stat5 is thought to be involved in proliferative and differentiation functions of progesterone, respectively, in the mammary gland and uterus.

VI. PR CROSSTALK WITH CELL SIGNALING PATHWAYS

Steroid receptors as ligand-dependent transcription factors and cell membrane/cytoplasmic signal transduction pathways have traditionally been viewed as completely separate pathways for regulating gene expression in response to external signals. However, it was discovered in the early 1990s that steroid receptors are nuclear targets of certain signal transduction pathways, suggesting a convergence of these two major pathways. Modulation of protein kinases or phosphatases in mammalian cells can either activate steroid receptors in the absence of ligand or potentiate ligand-dependent activity of receptors. Crosstalk with other signal transduction pathways was first reported with cPR and subsequently with human PR and all classes of steroid receptors. Agents that elevate intracellular cAMP (8-bromo-cAMP) to activate protein kinase A (PKA), inhibitors of protein phosphatases 1 and 2A (okadaic acid), and natural peptides that activate membrane receptor-linked signal transduction pathways, including the neurotransmitter dopamine and epidermal growth

factor (EGF), can all activate cPR in the absence of progesterone. Although the human PR is not activated in the absence of ligand, 8-bromo-cAMP, okadaic acid, EGF, and activators of protein kinase C, all stimulate hormone-dependent PR transactivation in different cell lines, including breast cancer cells. Activation of cPR in the absence of progesterone by these agents and potentiation of human PR activity in the presence of ligand are not accompanied by changes in receptor phosphorylation. The lack of effect on direct PR phosphorylation suggests that receptor-interacting co-activators are the targets of phosphorylation by these different protein kinase signaling pathways. As evidence for this idea, SRC-1 becomes phosphorylated on two specific MAPK sites (Ser-1179 and Ser-1185) in response to activation of PKA pathways. This phosphorylation does not facilitate direct SRC-1 interaction with the PR; rather, its role is to modulate functional cooperation between SRC-1 and CREB-binding protein (CBP), which is required for activity of a larger multiprotein SRC co-activator complex (Fig. 6).

A reverse crosstalk was recently discovered between human PR and cell membrane/cytoplasmic signaling pathways. The N-terminal region common to PR-A and PR-B contains a short, contiguous polyproline-rich sequence (amino acids 421–428, written as PPPPPLPR using the single-letter code, where P is proline, L is leucine, and R is arginine) that conforms to a consensus type II motif for binding the Src homology domains (SH3) of cell membrane/cytoplasmic signaling molecules. These polyproline sequences form a left-handed helix conformation that interacts with a binding pocket of SH3 domains. PR interacts *in vitro* and in cells with SH3 domains of various signaling molecules. including c-Src tyrosine kinases. This interaction is stimulated by progestins and is mediated directly by the proline-rich motif in the N-terminus of PR. The consequence of this interaction is a rapid progesterone-dependent stimulation of Src kinase enzyme activity through PR-mediated displacement of an intramolecular SH3 domain interaction that maintains Src kinases in an inactive state. Point mutations in the proline-rich motif that abolish progestin-induced activation of Src do not affect the transcriptional activity of PR. Conversely, point mutations in the DBD or AF-2 that cripple PR as a transcription factor have no effect on the ability of PR to mediate progestin activation of Src kinase. This PR–SH3 domain interaction is of biological consequence. Progestins can rapidly and transiently (10 min) activate the entire Src/ras/MAPK pathway in mammalian cells in a manner that is dependent on the integrity of the proline-rich–SH3 domain interaction motif within the PR. Also, PR–SH3 domain interactions contribute to two known

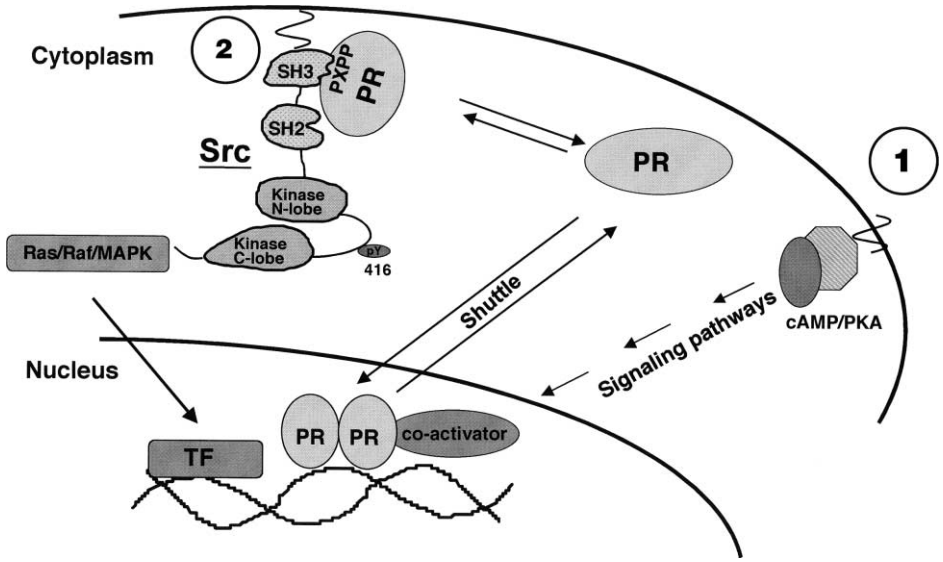

FIGURE 6 Two-way crosstalk between the progesterone receptor (PR) and cell signal transduction pathways. Cell signal transduction pathways can potentiate the transcription activity of nuclear PRs through phosphorylation of receptor-interacting co-activators. (1) Phosphorylation enhances the transcription activity of the receptor–co-activator complex. (2) The PR can modulate other cell-signaling pathways through a direct interaction in the cytoplasm with regulatory SH3 domains of signaling molecules, including Src kinases. This extranuclear function of the PR is rapid (5–10 min) and is not dependent on transcription.

biological responses of progesterone, including inhibition of proliferation of normal breast epithelial cells and induction of meiosis in *Xenopus* oocytes. These data suggest that the PR is a dual-function protein capable of directly interacting with target DNA in the nucleus in its well-established role as a transcription factor, and also interacting with SH3 domains to modulate cytoplasmic signaling pathways (Fig. 6). Although the function of the PR is traditionally thought to take place in the nucleus, it rapidly shuttles between the cytoplasm and nucleus by active nuclear import and export mechanisms. Thus, the PR has the opportunity to encounter signaling molecules in the cytoplasm and to have extranuclear functions.

VII. PROGESTERONE ANTAGONISTS

Several steroid analogues of progesterone that have been developed function as potent PR antagonists. The most important antagonist clinically is RU486 (Mifapristone), which is used as an antifertility agent and in experimental treatment of diseases such as brain meningiomas, endometriosis, uterine fibroids, and breast cancer. The structural features of RU486 that confer antagonist activity are the aromatic ring at the 11β-carbon position and the side chain at the carbon-17 position of the steroid ring structure of progesterone (see Fig. 1). RU486 competes with progesterone for binding to the PR and has a higher affinity for the receptor than does the natural hormone. RU486 binding effectively inactivates the PR by a complex mechanism. The receptor activation steps of dissociation from the sequestering Hsp complex, dimerization, and binding to PREs are not impaired when the PR is occupied by RU486. PR interaction with DNA, however, is nonproductive as a result of RU486 inducing a conformation in the carboxyl-terminal tail of the PR that is distinct from that induced by hormone agonist. This alternate conformation inactivates AF-2 and does not permit interaction with co-activators. However, RU486 is a more potent antagonist than is predicted by a simple inactivation of AF-2 of those PR molecules occupied by RU486. First, PR bound to RU486 is capable of heterodimerization with PR bound to hormone agonist and of inhibiting the activity of the agonist-bound PR *in trans*. Thus, effective inhibition of PR bound to agonist requires less than stoichiometric amounts of RU486. Additionally, the alternate conformation of PR induced by RU486 results in a substantial enhancement of corepressor binding to PR. Thus, in the presence of RU486, PR is capable of actively repressing gene transcription.

As with most steroid antagonists, RU486 is not a pure antagonist and exhibits partial agonist/antagonist activity, dependent on physiological conditions. PR crosstalk with cAMP and protein kinase A signaling pathways results in a dramatic potentiation of the agonist activity of RU486. This antagonist-to-agonist switch appears to be fairly specific to crosstalk with cAMP/PKA signaling pathways. Activation of protein kinase C and growth factor pathways does not cause this functional switch. Only the B receptor responds to cAMP in this manner, suggesting a requirement for both AF-3 and AF-1 together for RU486 to act as an agonist. The mechanism by which the cAMP/PKA pathway potentiates the agonist activity of RU486 involves a decreased association of corepressors (NcoR and SMRT) with PR. However, dissociation of corepressor alone is not sufficient for PR activation. Because AF-2 becomes inactivated by RU486, recruitment of an N-terminal domain co-activator would also be required, but such a co-activator has not yet been identified. Thus, the relative agonist/antagonist activity of RU486 is thought to be a reflection of the balance in the cell between expression and availability of specific N-terminal co-activators and corepressors. This concept is of potential relevance to the clinical use of RU486 and other steroid antagonists and could explain the variable efficacy of steroid antagonists in clinical settings, especially in the treatment of breast cancer.

VIII. SUMMARY

Many biological responses to progesterone are mediated through the PR interacting directly with target DNA, thus acting as a transcription factor, or through the PR interacting with other DNA-bound proteins, thus acting as a transcription cofactor. Transcription activities of PR can be further modulated by variable expression of the A and B isoforms and through crosstalk with other signal transduction pathways. PR-A may also function as a naturally occurring repressor of other members of the steroid hormone group of nuclear receptors. The progesterone receptor also has rapid nontranscription functions through its ability to interact directly with SH3 domains and to activate cytoplasmic signal transduction pathways.

Glossary

DNA-binding domain Region of steroid receptors that makes specific contact with DNA; has a conserved structural motif among members of the nuclear receptor family and can function autonomously.

hormone response elements Specific DNA sequences in the promoter region of steroid-responsive genes; bind and mediate transcriptional responses to steroid receptors.

ligand In the context of the nuclear receptor superfamily, a small lipophilic molecule, in some cases a steroid hormone, that binds to the ligand-binding domain of a receptor.

ligand-binding domain Region of receptor in the C-terminus that binds steroid hormone; has a conserved structural motif and can function autonomously.

progesterone response elements Hormone response elements that are specific for the progesterone receptors.

SH3 domain Src tyrosine kinase homology domain 3; a conserved regulatory region of many signaling molecules that interacts with other proteins.

steroid receptor co-activators Family of proteins of 160,000 molecular weight (p160); interact with transcriptional activation domains of nuclear hormone receptors and act as bridging factors between the DNA-bound receptor and the general transcriptional machinery.

transcriptional activation domain Region of steroid receptors that binds co-activators and mediates transcriptional enhancement activity.

Pro-inflammatory Cytokines and Steroids

STEPHEN G. HILLIER
University of Edinburgh

Pro-inflammatory cytokines produced by somatic cells and activated macrophages are mediators and modulators of ovulation, menstruation, implantation, and parturition. Each of these hormonally regulated processes is

investigations showed that GHR and PRLR must be dimerized to properly transmit signals, which allowed the design of potent PRL and GH antagonists that interfered with the efficient dimerization of these receptors. Until the beginning of the 1990s, however, the downstream mechanisms involved in signal transmission by PRL and GH receptors were only poorly elucidated, and not until the discovery of the Janus tyrosine kinase (JAK) and signal transducers and activators of transcription (STAT) factor families was the JAK/STAT pathway identified as the first major signaling cascade responsible for the effects of PRL and GH. Within the past 6 years, there have been numerous reports describing molecules involved in or interacting with known pathways or even identifying new pathways/molecules.

This article is divided into four sections aimed at elucidating the molecular basis of signaling properties of these receptors: (1) the structure–function relationships of naturally occurring receptor isoforms; (2) the mechanism of ligand-induced receptor activation; (3) the major signaling pathways; and finally (4) the ways in which animal models (knockout, transgenics) can correlate with and highlight molecular studies of PRLR/GHR signaling.

II. PRLR AND GHR ISOFORMS HAVE DIFFERENT SIGNALING CAPABILITIES

PRLR and GHR are single-pass transmembrane receptors with the N-terminal outside the cell (the ligand-binding domain) and the C-terminal inside the cell (the signaling domain). The three structural features conserved among hematopoietic cytokine receptors are found in both the PRLR and the GHR: two pairs of disulfide-linked cysteines in the N-terminal part of the extracellular domain (C12–C22 and C51–C62 in hPRLR), the typical "WS motif" (a double W-S repeat, conservatively mutated into Y-G-E-F-S in the GHR) in the membrane-proximal region of this domain, and finally, the proline-rich region (called Box 1) in the juxtamembrane region of the cytoplasmic domain (Fig. 1). The first two features are required for correct folding and therefore for the functioning of the extracellular domain (including ligand binding and receptor trafficking to the cell surface), whereas Box 1 is required for triggering (all) signaling cascades (see below). These conserved features are thus essential for the PRLR and GHR to elicit their activities.

One of the characteristics of cytokine receptors is that alternative splicing of the primary transcript (a single gene exists for each receptor) leads to the occurrence of multiple protein isoforms, which in most cases are not correlated with pathological states. These isoforms differ mainly in their cytoplasmic tail, which affects their signaling properties. The classical isoform, called the "long" form, contains ~600 amino acids (591 for hPRLR and 620 for hGHR) and is considered to elicit all the actions attributed to the ligand. The "short" forms are truncated at their C-terminal and lack part of, or almost all of, the cytoplasmic tail. In rat, the short PRLR contains 291 amino acids, and in human cells, a 288-residue PRLR isoform has been recently described. All PRLR isoforms identified thus far from natural sources contain Box 1. Regarding the hGHR, two short isoforms containing 277 or 279 residues and lacking Box 1 have been identified. These short GHRs are thus devoid of signaling properties and act as dominant negatives of the full-length receptor by trapping the ligand and/or by forming inactive heterodimers with long receptor isoforms (see below). Intermediate forms have also been described, such as in rat Nb2 lymphoma cells (393 amino acids, due to a deletion in the PRLR gene) or in human cells (376 amino acids, due to alternative splicing). At least for the Nb2 receptor, none of the major signaling properties displayed by the full-length receptor are affected by this deletion. Finally, soluble receptors corresponding to the extracellular domain of membrane receptors have been identified; they originate either from alternative splicing or from limited proteolysis of full-length receptors (Fig. 1). As deduced from cloned cDNAs encoding these binding proteins (BPs), their overall length is 246 amino acids for the hGHBP and 206 for the PRLBP. Soluble receptors are intrinsically devoid of intrinsic signaling activity, although they may be indirectly involved in PRL/GH functions by controlling the levels of ligand available (BPs increase the hormone's half-life).

III. LIGAND-INDUCED RECEPTOR DIMERIZATION: THE FIRST STEP OF SIGNALING

The extracellular domain is the ligand-interacting region of these receptors. The three-dimensional structure of genetically engineered hPRLR and hGHR extracellular domains has been determined by crystallographic analysis (Fig. 2A). Not only are the GHR and PRLR extracellular domains structurally related (they fold in two antiparallel β-sheets),

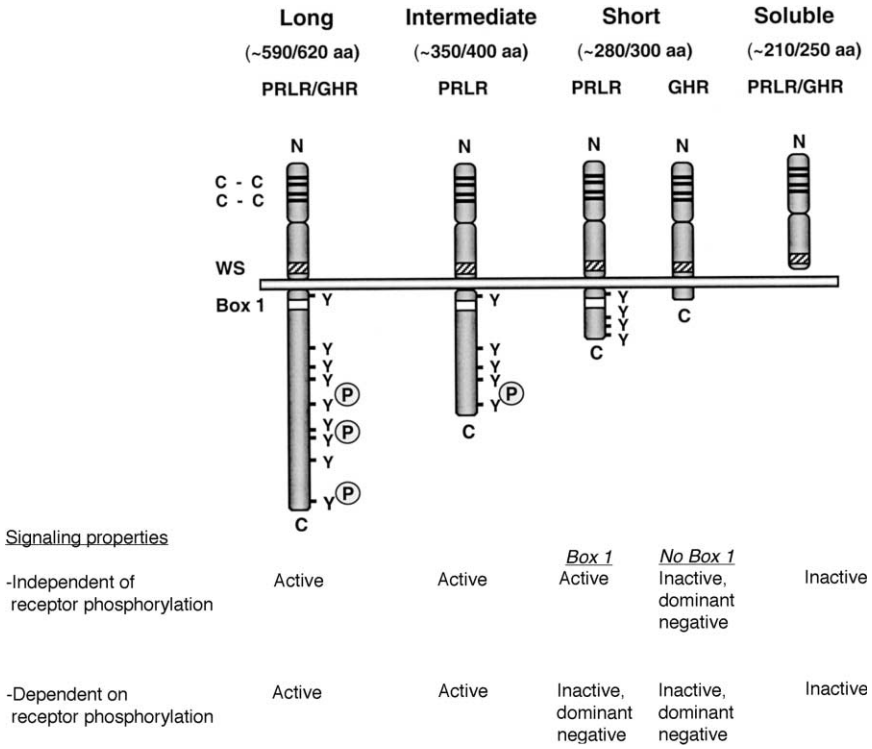

FIGURE 1 Schematic representation of the PRLR and GHR isoforms. The PRLR and GHR exist in various isoforms that differ only in their cytoplasmic tail regions. The four types of receptor isoforms, referred to as long, intermediate, short, or soluble with respect to their overall length, are illustrated. The conserved features among cytokine receptors are indicated: C–C, internal disulfide bonds; WS, for the Trp–Ser repeat, hatched box; and Box 1, for the proline-rich region, white box. "Y" represents tyrosines (number and position of tyrosines are random) of the cytoplasmic domain, some of which are phosphorylated (denoted by "P" in gray circle) by JAK2; short isoforms are not tyrosine-phosphorylated. Signaling properties of each isoform are summarized at the bottom (see text for more details).

their ligands also share a high level of structural similarity since both PRL and GH adopt the antiparallel four-α-helix-bundle fold characteristic of hematopoietic cytokines (Fig. 2B). Thus, it is not surprising that the ligand-induced activation of the PRLR and that of the GHR share very similar mechanisms. PRL and GH interact with two molecules of their receptors via two distinct regions, binding sites 1 and 2 (Fig. 2B). The active hormone–receptor complex is thus a trimer, comprising one molecule of ligand and two (identical) molecules of receptor (homodimer). Thus far, no specific receptor cDNA has been identified for placental lactogen (PL, another member of the PRL/GH hormone family). Interestingly, PRLR/GHR heterodimers have been proposed to constitute such a specific receptor complex, but the physiological relevance of this observation remains to be demonstrated. Since receptor homodimerization is required and is presumably sufficient to trigger downstream signaling cascades, receptor antagonists that interfere with this process have been designed. Impairing binding site 2 of PRL or GH by introducing sterically hindering mutations within this region leads to ligands that are unable to induce functional dimerization of the receptor and, therefore, act as inhibitors of the natural hormones by competing for receptor-binding sites. In many biological contexts, the ability of PRL or GH antagonists to inhibit PRL- or GH-induced signaling cascades has been clearly demonstrated.

IV. MAJOR SIGNALING PATHWAYS

With the exception of constitutively active N-terminal truncated receptors experimentally engineered for research purposes, all actions mediated by the PRLR and GHR result from their interaction with

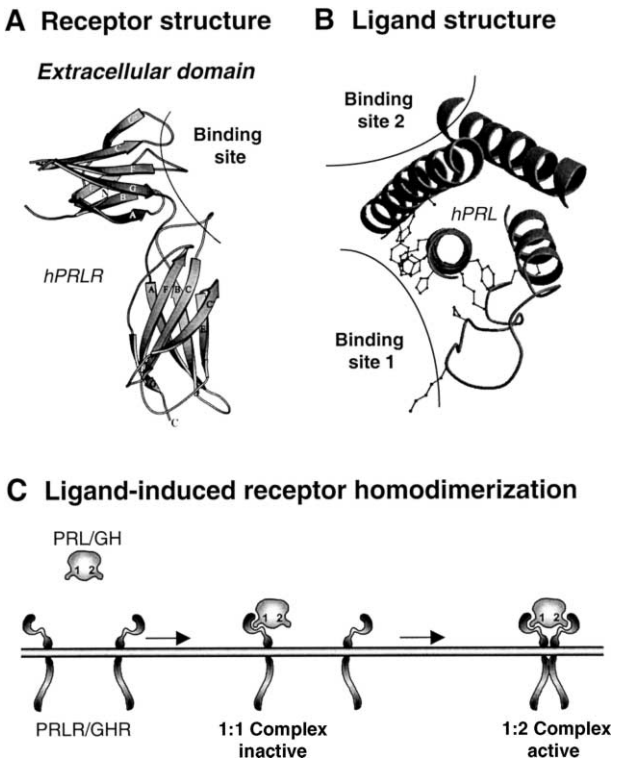

FIGURE 2 Mechanism of receptor activation. PRLR and GHR extracellular domains adopt the seven-β-strand sandwich fold typical of cytokine receptors (A), and hormones adopt the four-α-helix-bundle fold typical of hematopoietic cytokines (B). Regions involved in hormone–receptor interactions are indicated. Following ligand binding, receptors are homodimerized in a sequential manner: the first receptor molecule binds to binding site 1 of its ligand, and then the second receptor molecule binds to binding site 2 to form the active trimeric complex (C).

any of their natural ligands, which leads to receptor dimerization and the activation of cascades in the intracellular space. Thus far, in contrast to the majority of cytokine receptors, there is no evidence that any "accessory" membrane protein is required or that the type of ligand (e.g., hPRL, hPL, or hGH for the hPRLR) affects the nature of signals that are transmitted inside the cell.

A. JAK/STAT Pathway

1. Activation of the JAK/STAT Pathway

The PRLR and GHR are devoid of any intrinsic enzymatic activity. In 1993–1994, JAK2 was identified as the Janus tyrosine kinase associated with these receptors. Although the involvement of JAK1 and JAK3 was also proposed later for both receptors, their role is clearly less relevant. In contrast to the GHR, which recruits JAK2 to the receptor complex on ligand binding, the kinase is constitutively associated with the PRLR; i.e., its recruitment is not induced by ligand binding. For the GHR, SH2-Bβ has been recently identified as a cytoplasmic protein tightly binding to and potentiating the activity of phosphorylated JAK2.

The receptor–JAK2 interaction requires integrity of Box 1, which does not preclude the involvement of additional C-terminal regions of the receptor. Thus, with the exception of short GHR isoforms lacking Box 1 (Fig. 1), all PRL/GH receptor isoforms are able to interact with and activate JAK2 and, therefore, to exhibit some signaling properties. Mutational analysis of Box 1 has assigned a critical role to proline residues in the interaction with JAK2, suggesting an SH3 domain-mediated interaction. However, due to the absence of a typical SH3 domain in the JAK2 sequence, the question of whether the interaction between kinase and the receptors is direct or involves an intermediate protein (adapter) remains unresolved.

JAK2 activation is a prerequisite for triggering many, if not all, downstream signaling cascades (Fig. 3). Accordingly, receptor mutants unable to associate with JAK2, such as engineered Box 1-deleted PRLR or short GHR isoforms (Fig. 1), are unable to trigger tyrosine phosphorylation cascades and downstream activation of target genes. Interestingly, heterodimerization of the short and intermediate PRLR cytoplasmic tails results in complexes that are unable to stimulate JAK2 autophosphorylation, whereas both can associate with and activate the kinase in the context of their respective wild-type receptor. This observation suggests that only "perfect" homodimers can signal properly, which might be important in a physiological context since many tissues express different receptor isoforms, potentially forming heterodimers. Accordingly, short PRL receptors have been assigned a dominant negative role *in vitro* by inhibiting the transcriptional activation of milk protein genes induced by the full-length receptor; the physiological relevance of this observation remains to be demonstrated. Short GHR isoforms have been cloned from patients displaying a novel form of GH insensitivity syndrome, clearly indicating a dominant negative role of this short receptor isoform *in vivo*.

Once it is tyrosine-phosphorylated (i.e., activated), JAK2 phosphorylates the receptor on several tyrosines. No correlation between tyrosines that are preferentially phosphorylated by JAK kinases and their surrounding amino acids has been established

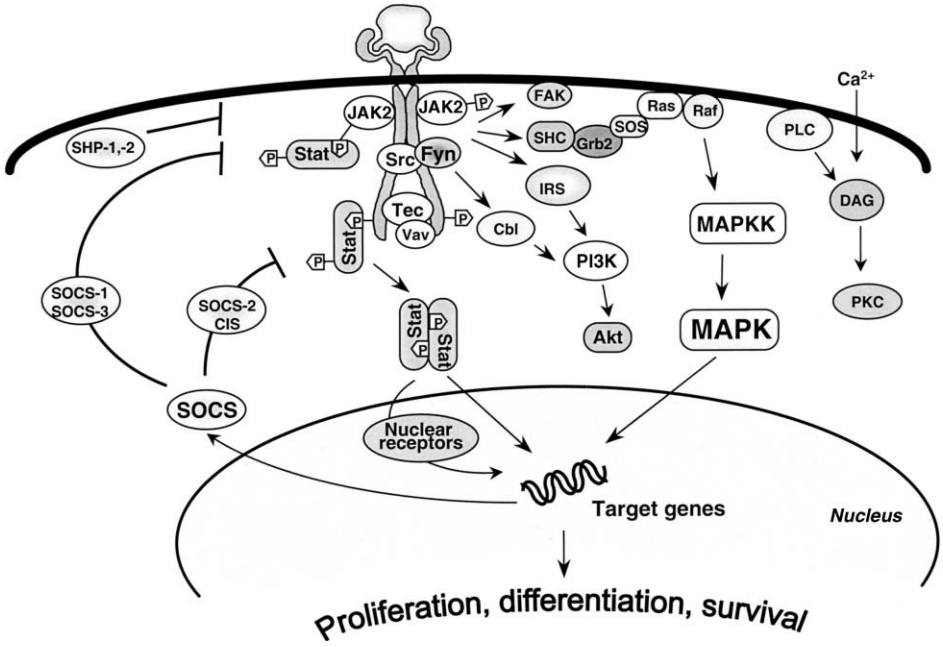

FIGURE 3 Signaling pathways. Major signaling pathways activated by the PRLR and GHR are represented (see text for differences). The JAK/STAT pathway and the MAPK pathway are among the best characterized cascades. In addition to these pathways, several other kinases/adapters have been shown to be involved in PRLR signaling, although their downstream effectors may be less well defined.

(no consensus sequence). Therefore, the reason that the short PRLR isoform does not undergo tyrosine phosphorylation despite its ability to activate JAK2 and the presence of tyrosines in its cytoplasmic domain remains unknown. The phosphotyrosines of receptors, as well as of JAK2, become sites of interaction with signaling molecules containing phosphotyrosine-binding motifs (SH2, PTB). Among these, recruitment of STAT factors to the receptor complex has been extensively studied. Both the PRLR and the GHR activate three of the seven known STATs: Stat1, Stat3, and mainly Stat5 (A and B isoforms). Stat1 and Stat3 bind to phosphotyrosines of the receptors and/or of JAK2; in agreement with these findings, short isoforms containing Box 1 (short PRLR or engineered C-terminal-truncated GHR) activate these STATs although the receptor is not phosphorylated. In contrast, Stat5 interacts only with the phosphotyrosine(s) of full-length and intermediate receptors. Although redundancy between some of these tyrosines has been reported, C-terminal tyrosines play a critical role, at least in the PRLR. Thus, one of the major differences between short and intermediate/long isoforms lies in the ability to activate Stat5-dependent downstream targets, which is directly correlated with the phosphorylation status of the receptor (Fig. 1).

Once recruited to the receptor complex, STATs are phosphorylated by JAK2 on their C-terminal tyrosine, dissociate from the JAK–receptor complex, and translocate as dimers into the nucleus, where they specifically activate transcription by interacting with consensus DNA sequences within the promoters of PRL or GH target genes. The transcriptional specificity exhibited by identical STAT factors activated by distinct cytokines remains poorly understood. The answer may partly reside in the arsenal of other transcription factors that are also activated and can interact with STATs, modulating their transactivation activity (cross talk). Among these are nuclear receptors (estrogen, progesterone, glucocorticoid, etc.), Sp1 (specificity protein 1), CREB-binding protein/p300, peroxisome proliferator-activated receptor α (PPARα), nuclear factor κB, members of the interferon regulator factor (IRF) family, c-jun, MCM5 (mini-chromosome maintenance protein 5), and BRCA1 (breast cancer 1 gene). Different STATs can also interact with one another; e.g., Stat1 and Stat5 have been reported to exert opposing actions on IRF-I gene transcription.

2. Down-regulation of the JAK/STAT Pathway

The recent discovery of a family of proteins down-regulating the activation of the JAK/STAT pathway has greatly helped in understanding how these activated (phosphorylated) proteins return to their steady state after hormone stimulation. These proteins are denoted SOCS (suppressor of cytokine signaling) or CIS (cytokine-inducible SH2 proteins) and down-regulate the JAK/STAT pathway by interfering with either JAK2 enzymatic activity (SOCS-1, -3) or STAT recruitment to the receptor complex by competing for phosphotyrosine binding (SOCS-2, CIS). Importantly, the SOCS/CIS genes are targets of the cytokine-induced JAK/STAT pathway, meaning that they encode proteins functioning as regulators of this pathway in a feedback manner. Internalization and proteasome-dependent degradation of a GHR/JAK2/CIS complex have been proposed to be important steps in the time-dependent CIS inhibition mechanism. However, not all SOCS proteins inhibit receptor signaling; SOCS-2, which binds directly to the PRLR, potentiates receptor signaling.

In addition to SOCS, SH2-containing tyrosine phosphatases (SHP-1 and SHP-2) are important in signaling down-regulation by dephosphorylating JAK and/or receptors. SIRP (signal-regulated protein), a transmembrane protein interacting with JAK2 on GHR stimulation, recruits signaling molecules to the receptor complex, including the phosphatase SHP-2, which leads to JAK2 dephosphorylation; SIRP is thus currently regarded as a negative regulator of GH signaling. The role of phosphatases remains poorly understood, however, since SHP-2 also appears to be necessary for initiating PRLR and GHR signaling.

B. Other Pathways

The JAK/STAT pathway is undoubtedly one of the major cascades triggered by these receptors. However, many other signaling proteins have been shown to be activated by the PRLR and GHR. This section is aimed at providing an overview, albeit certainly not an exhaustive one, of these additional signaling cascades.

1. Mitogen-Activated Protein Kinase

The well-known mitogen-activated protein kinase (MAPK) pathway involves the Shc (Src homology and containing protein)/SOS (Son of Sevenless)/Grb2 (growth factor receptor-bound protein 2)/Ras/Raf/MAPK cascade. This pathway has been demonstrated to be activated by both the PRLR and the GHR, including the short PRLR isoform, in agreement with the observation that the membrane proximal Box 1 region is sufficient to activate the MAPK pathway. Shc directly interacts with the receptor complex and becomes tyrosine-phosphorylated, presumably by JAK2. Whether activation of the MAPK cascade requires kinases other than JAK2, e.g., Src kinases, is yet to be elucidated. Also, indirect activation of the MAPK cascade via JAK2-induced phosphorylation of the EGF receptor and subsequent recruitment of Grb2 by phosphorylated EGF receptor have been reported in the case of GH stimulation. More recently, activation of c-jun N-terminal kinase and p38 by PRL has also been described.

2. Src Kinases

At least two members of the Src tyrosine kinase family, namely, Src and Fyn, are activated by the PRLR and this activation seems to occur independent of JAK2. Fyn has been shown to be constitutively bound to the PRLR. Src tyrosine kinases play an important role in PRLR signaling, especially in PRL-induced cell proliferation. There are as yet no reports demonstrating the involvement of Src kinases in GHR signaling.

3. Insulin Receptor Substrate and Phosphatidyl Inositol 3-Kinase

Insulin receptor substrate members (IRS-1, -2, -3) also interact with phosphorylated receptors and themselves become tyrosine-phosphorylated (by JAK2), which creates docking sites for SH2-containing proteins, including the p85 subunit of phosphatidyl inositol 3-kinase (PI3K). One downstream effector of PI3K has been shown to be the serine/threonine kinase Akt, the stimulation of which is involved in the anti-apoptotic effect of GH.

4. Other Molecules

The above-mentioned pathways do not exhaustively summarize the current knowledge in the field of PRLR/GHR signaling, but rather represent a broad overview. Other tyrosine kinases (ZAP-70, Tec), serine/threonine kinases (protein kinase C), phospholipase Cγ and the downstream pathway modulating intracellular calcium concentration, adapters (Cbl, a substrate of Src kinases), guanine nucleotide exchange factors (Vav, complexed to Tec), proteins of the cytoskeleton (FAK), the 17β-hydroxysteroid dehydrogenase/17-ketosteroid reductase (known as PRAP, for PRLR-associated protein), and proteins linked to the apoptotic pathway (including Bax,

Bcl-2, and Bag-1) have also been identified as molecules that are associated with and/or involved in signaling by the PRLR and/or GHR.

V. HOW ANIMAL MODELS CAN HIGHLIGHT *IN VITRO* SIGNALING STUDIES

The analysis of genetically modified animal models (knockout, transgenic) is extremely informative in evaluating the involvement of a particular signaling protein in the physiological development and function of a given organ. For example, the conditional knockout of Stat3 has clearly demonstrated a dramatic delay in the involution process of the mammary gland after weaning, establishing this STAT as a key factor in signaling the initiation of physiological apoptosis *in vivo* in this organ. However, it may prove difficult to correlate this kind of information with the identification of signals involved in upstream activation of signaling proteins in a normal context [e.g., which cytokine(s) or growth factor(s) regulates Stat3 activation in the mammary gland to control involution]. Examples of knockout models that have clearly highlighted the role of signaling proteins involved in PRLR- and GHR-mediated functions are provided below.

Stat5A and Stat5B are two closely related STAT proteins that, although they are encoded by distinct genes, have been often considered to be redundant in most molecular (*in vitro*) studies involving Stat5 analysis. It is only when Stat5A- and Stat5B-deficient mice were shown to exhibit distinct phenotypes that their nonredundant roles began to be understood. Stat5A-deficient mice display alterations of mammary gland development, including defective proliferation of the lobulo-alveolar ductal epithelium during pregnancy and lactation failure. All these phenotypes are very similar to those observed in PRL or PRLR knockout mice, suggesting that Stat5A, originally designated mammary gland factor, is tightly linked to PRLR-mediated signaling. In contrast, Stat5B-deficient mice exhibit a loss of normal sexually dimorphic growth, a phenotype reminiscent of Laron dwarfism in humans, which suggests that Stat5B is presumably more closely linked to GHR- than PRLR-mediated signaling.

Another very interesting knockout is that of SOCS-2, which leads to a gigantism phenotype very similar to that observed in GH transgenic mice. At 6 weeks of age, SOCS-2-deficient mice are 40% heavier than wild-type mice and their long bones are significantly longer, which is strong evidence that SOCS-2 is a natural negative regulator of GH and/or insulin-like growth factor-I (the main second messenger of GH) signaling.

Finally, a negative regulator of PRL signaling, SOCS-1, has recently been proposed as a factor capable of preventing lactation prior to parturition. In fact, mice deficient for SOCS-1 that were rescued from neonatal death by concomitant deletion of the interferon-γ gene were shown to have accelerated mammary lobulo-alveolar development. Interestingly, when a single allele of the SOCS-1 gene was deleted and these animals were crossed with $PRLR^{+/-}$ mice, the lactational defect normally seen in heterozygous mice was rescued. The functional pathways involved in SOCS-1 inhibition of the mammary gland remain to be identified.

VI. CONCLUSIONS

As for all cytokine receptors, the JAK/STAT pathway appears to play a central role in PRLR/GHR signaling, and receptor isoforms unable to activate JAK2 (naturally occurring or experimentally engineered) have been shown to be devoid of signaling properties. However, the variety and multiplicity of signaling pathways activated by PRL and GH receptors are presumably correlated with the unusually extended range of biological functions displayed by these hormones, whose receptors are widespread in the organism. Interconnection (cross talk) of these cascades now appears to be one of the key components to achieving some degree of specificity using a limited set of signaling molecules (JAKs, STATs, MAPKs, etc.) activated by distinct cytokines, hormones, and growth factors. Understanding how these activated protein pathways are organized in space as well as in time is a major challenge for future signaling studies.

Glossary

binding protein In many species, prolactin- and growth hormone-binding proteins are generated and result either from alternative splicing of transcripts encoding full-length receptors or from limited proteolysis of membrane-bound receptors. Soluble binding proteins bind circulating ligands and prolong their half-life. They are devoid of intrinsic signaling properties, but may interfere with membrane-receptor signaling by forming inactive heterodimers (one soluble receptor and one membrane-bound receptor).

cytokine receptor A family of single-pass transmembrane receptors identified in the late 1980s based on sequence comparison of receptors for prolactin, growth hormone, erythropoietin, interleukin-2 (IL-2), and IL-6. Additional members of the class I hematopoietic cytokine receptor superfamily include receptors for leptin, thrombopoietin, and many cytokines regulating the immune system, such as most interleukins. The main conserved features of class I cytokine receptors are two pairs of cysteines and a Trp-Ser repeat (WS motif) in the extracellular domain and a proline-rich region (called Box 1) in the intracellular domain, which is essential for signaling properties. Cytokine receptors are devoid of intrinsic enzymatic activity and signal through associated kinases, the most classical of which are Janus tyrosine kinases (which bind to the Box 1 region of the receptors). Receptors for prolactin and growth hormone are very similar with respect to overall structure and signaling properties.

growth hormone (GH) A polypeptide hormone (191 amino acids in humans) that adopts the α-helix-bundle fold typical of hematopoietic cytokines. GH is secreted mainly by the pituitary gland, although it is also produced by other cell types, such as lymphoid cells. Its actions are related mainly to growth (soft tissues, long bones, etc.) and metabolism. It belongs to a family of hormones that includes prolactin and placental lactogens, as well as other placental factors.

homodimerization Cytokine receptors are activated by clustering of two or more receptor subunits, identical or not. Prolactin and growth hormone receptors are both activated by ligand-induced homodimerization of two identical receptor chains. In fact, a single molecule of ligand (prolactin or growth hormone) contains two binding sites (binding sites 1 and 2), each interacting with one receptor molecule. Based on this homodimerization model for receptor activation, hormone antagonists have been designed by impairing binding site 2 in prolactin or growth hormone, leading to ligands that are able to bind the receptor via their site 1 but unable to induce efficient receptor dimerization.

Janus kinase/signal transducers and activators of transcription (JAK/STAT) The most typical signaling pathway activated by cytokine receptors. This pathway involves a family of four tyrosine kinases designated "Janus" or "JAK" kinases (members are JAK1, JAK2, JAK3, and Tyk2). JAK2 is the main JAK involved in growth hormone and prolactin receptor signaling. Substrates of JAK tyrosine kinases include cytokine receptors and STAT factors. The eight members of the STAT protein family must interact with tyrosine-phosphorylated cytokine receptor complexes to be activated by tyrosine phosphorylation (by JAKs); they then migrate into the nucleus and transactivate cytokine target genes. With respect to growth hormone and prolactin signaling, Stat5 and, to a lesser extent, Stat1 and Stat3 are activated.

mitogen-activated protein kinase (MAPK) pathway One of the major pathways activated by membrane receptors. It involves a cascade of serine/threonine and dual-specificity (Tyr/Ser/Thr) kinases, leading to the activation of several target genes. The MAPK pathway has been historically linked to cell proliferation, but recent data have shown that it is involved in many cell responses and crosstalk with other pathways, including the Janus kinase/signal transducers and activators of transcription pathway. Activation of the MAPK cascade by prolactin and growth hormone receptors involves Box 1 but not the phosphotyrosines of the receptor.

prolactin (PRL) A polypeptide hormone (199 amino acids in humans) that adopts a four-α-helix-bundle fold typical of hematopoietic cytokines. PRL is secreted mainly by the pituitary gland, although it is also produced by other cell types and tissues, such as mammary gland, endometrium, lymphoid cells, and prostate. Its actions are essentially related to reproduction and lactation, but its involvement in an extremely wide spectrum of biological responses has been reported (osmoregulation, immunoregulation, behavior, growth, metabolism, etc.). Prolactin belongs to a family of hormones that includes growth hormone and placental lactogens as well as other placental factors.

receptor isoform Prolactin and growth hormone receptors are encoded by single genes. However, alternative splicing of primary transcripts leads to the existence of many receptor isoforms, which differ in the length of their cytoplasmic domains and are thus referred to as short, intermediate, or long receptors. Short isoforms have a truncated C-terminal tail and are not tyrosine-phosphorylated, which correlates with their inability to exhibit all signaling properties of long (full-length) or intermediate isoforms. In some instances, short isoforms have been suggested to act as dominant negative receptors, presumably because heterodimerization of short and long/intermediate receptors achieves inactive complexes.

suppressor of cytokine signaling (SOCS) A recently identified family of proteins that play an important role in regulating the Janus kinase/signal transducers and activators of transcription (JAK/STAT) pathway. They are currently viewed as negative regulators of this pathway, either by interfering with Janus kinase activity or by competing with STATs for binding to phosphorylated tyrosines of the receptor complex. Since SOCS genes are themselves targets of the JAK/STAT pathway triggered by activated cytokine receptors, they function by negative feedback regulation.

tyrosine phosphorylation Many stages of signaling cascades triggered by cytokine receptors involve tyrosine phosphorylation of various proteins. With respect to the receptor complex, several tyrosine residues within the cytoplasmic domains of prolactin and growth hormone receptors, or on Janus kinase 2 (JAK2) itself, are phosphorylated (by JAK2) and serve as docking sites

for downstream effectors containing phosphotyrosine-binding domains (e.g., SH2 domains); candidates are signal transducers and activators of transcription proteins, suppressor of cytokine signaling proteins, phosphatases, or adapters (e.g., Grb2). The short receptor isoforms are not tyrosine-phosphorylated, which prevents some of these interactions from occurring.

Protein Kinases

ALAIN ENJALBERT AND
CAROLINE LE PECHON-VALLEE

ICNE, Institut Jean-Roche, Université de la Méditerranée, Marseille, France

Protein kinases are enzymes that catalyze the phosphorylation of proteins. Phosphorylation is an important intracellular signal-generating protein modification used in signal transduction. Protein kinases phosphorylate many proteins and are involved in major cellular processes such as differentiation, proliferation, and cell death.

I. INTRODUCTION

The great importance of the protein kinases within the cell can be understood through review of their function and major physiological roles. This article focuses on the mechanisms that ensure the specificity and tight regulation of protein kinases and their involvement in pathology and disease.

II. DEFINITION OF PROTEIN KINASES

A. The Enzymatic Reaction Catalyzed by Protein Kinases

Protein kinases, members of the family of phosphotransferases, catalyze the transfer of the γ-phosphate of adenosine triphosphate (ATP) to a hydroxyl residue of a protein substrate (see Fig. 1). This covalent

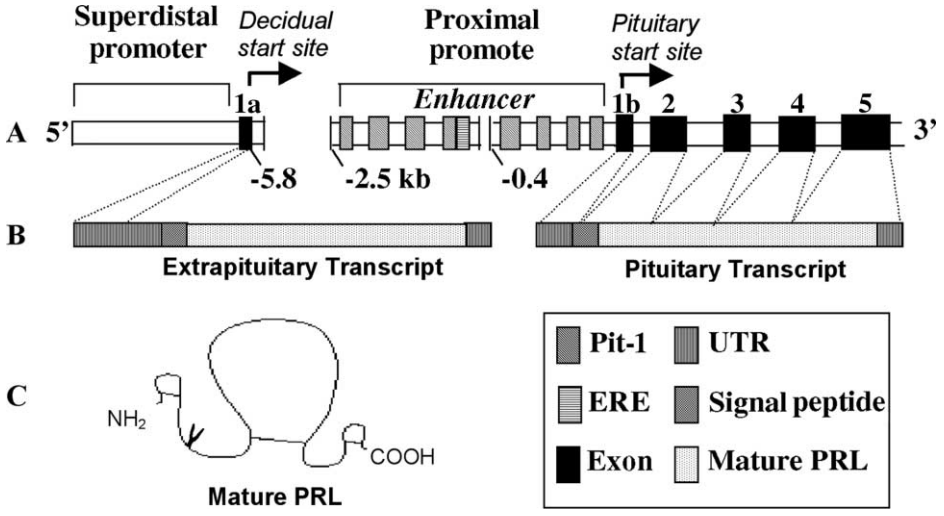

FIGURE 1 Diagram of the human PRL gene (A), extrapituitary and pituitary transcripts (B), and the mature protein (C). Note the use of exon 1a as the transcription start site for extrapituitary PRL and the longer 5′-untranslated region (UTR). The site of N-glycosylation (Y, Asn^{31}) is also shown. ERE, estrogen-response element.

Variants of PRL are formed by transcriptional or translational mechanisms and increase the biological specificity as well as the diversity of PRL. Most variants are generated by posttranslational modifications and differ in size or functional groups. Larger variants are formed by dimerization or aggregation and smaller variants are formed by proteolysis, both at the sites of synthesis and at some target tissues. Some variants retain PRL-like activities and others have unique properties or no known functions. Two variants, a 22 kDa isoform and a 16 kDa isoform, are of interest. The 22 kDa form, PRL_{1-173}, may be important in female reproduction and is generated by kallikrein, a trypsin-like serine protease. The 16 kDa PRL possesses anti-angiogenic activity and is generated by cathepsin D, an acid protease. The angiostatic activity of 16 kDa PRL may occur via a unique receptor since it has low binding affinity to the classical PRL receptor.

Human PRL is N-glycosylated on Asp^{31}, adding 2–3 kDa to its molecular mass. Glycosylated PRL is detected in the pituitary and in several body fluids, ranging from 15 to 20% of total PRL in both the pituitary and the plasma to over 50% in the amniotic fluid and milk. The carbohydrate moieties vary among species and tissues and their heterogeneity accounts for differences in bioactivity, immunoreactivity, receptor binding, and metabolic clearance rate of PRL. Although glycosylation often decreases the bioactivity of PRL, unique physiological functions of glycosylated PRL have not been yet identified. PRL can also be mono- or diphosphorylated on serine and/or threonine residues, a modification that results in charge variability. The ratio of phosphorylated/nonphosphorylated forms is altered during various physiological states and could be involved in determining the balance between the mitogenic and the anti-mitogenic effects of PRL.

II. PITUITARY AND EXTRAPITUITARY PRL

PRL is the secretory product of the lactotrophs, acidophilic-staining cells of the pituitary. Lactotrophs are the last anterior pituitary cells to differentiate during fetal development and are preceded by GH- and dual GH/PRL-producing cells, the somatolactotrophs. Pit-1 is required for the development of somatotrophs, lactotrophs, and thyrotrophs and its inactivation results in the virtual absence of these cell types. The factors that induce terminal differentiation of lactotrophs are unknown, but several growth factors, including nerve growth factor, epidermal growth factor (EGF), and basic fibroblast growth factor, have been implicated in this process.

Lactotrophs constitute 20–30% of total anterior pituitary cells and are heterogeneous in terms of morphology, basal hormone release, electrical activity, and responsiveness to secretagogues. The dual-secreting cells can be interconverted to somatotrophs or lactotrophs, depending on the nature of the stimulus. This process facilitates the rapid recruitment of PRL-producing cells while bypassing

metabolically costly cell division. Unlike most pituitary cells, lactotrophs retain a robust proliferative capacity during adulthood and their number increases during pregnancy and lactation. This proliferative potential also accounts for the higher incidence of lactotroph tumors (prolactinomas) compared to other types of pituitary tumors. Some rat strains are especially sensitive to induction of prolactinomas by estrogens, but a similar role for estrogens in the etiology of human prolactinomas has not been demonstrated.

Although PRL was initially regarded as an exclusive pituitary hormone, many nonpituitary tissues were later found to contain immunoreactive PRL. The widespread distribution of tissues capable of PRL synthesis as well as those that contain PRL is illustrated in Fig. 2. The most established extrapituitary sites that produce PRL are the decidua, immune system, brain, and myometrium, with emerging evidence for PRL synthesis by the skin and exocrine glands, including mammary glands, sweat glands, and lacrimal glands. PRL is produced by a wide variety of cells of different embryonic origins, morphology, and physiological functions. Some, e.g., lymphocytes and epithelia, are less differentiated and have a high proliferative capacity, whereas others, e.g., neurons, are postmitotic and terminally differentiated. Immunoreactive PRL is also present in tissues that do not produce PRL but are capable of taking up and concentrating PRL from the blood.

Another remarkable feature of PRL is its presence in most body fluid compartments. Although all hormones are present in serum and most are excreted into urine, PRL is also found in cerebrospinal fluid (CSF) and the amniotic fluid and is secreted into milk, tears, and follicular fluid. Whereas PRL in the amniotic fluid originates from a local source (decidua), that in milk and CSF is derived from both locally produced and circulating PRL. Significant cellular resources must be spent in transporting PRL into these compartments and yet little is currently known about the functions subserved by PRL in these sites.

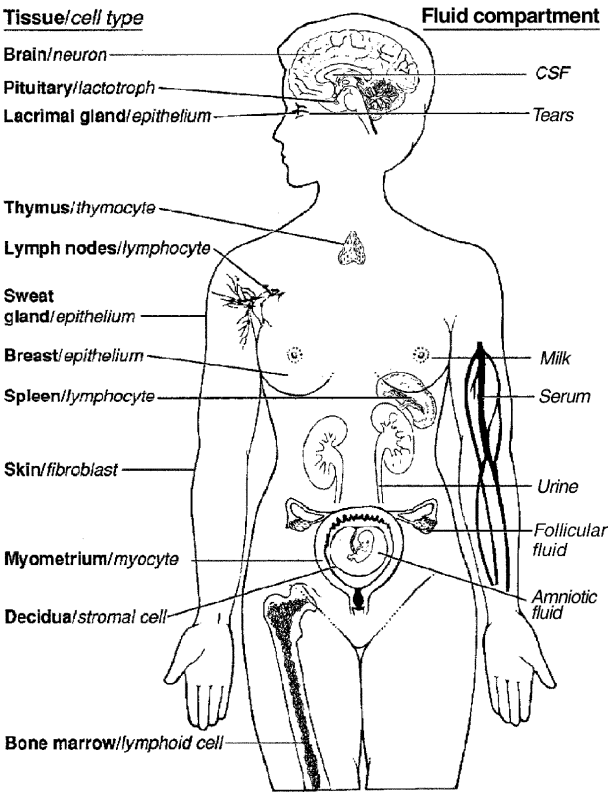

FIGURE 2 Distribution of PRL throughout the human body. Tissues and cells that produce PRL are shown on the left and fluid compartments that contain PRL are shown on the right. Note the heterogeneity of PRL-producing cells (italics) in terms of embryonic origin, morphology, and function.

III. REGULATION OF PRL SYNTHESIS AND RELEASE

Consistent with its function as an adaptive rather than an indispensable hormone, the profile of PRL release varies greatly under many physiological conditions and is dissimilar among species. In humans, serum PRL progressively rises throughout gestation in both the maternal and the fetal circulation and is episodically released in response to suckling during lactation. Adult women have higher serum PRL levels than men but do not exhibit marked changes in the secretory profile of PRL throughout the menstrual cycle. This is in contrast to rodents, in which a clear preovulatory surge of PRL is evident. Stress conditions, including anesthesia, surgery, electric shock, strenuous exercise, and insulin-induced hypoglycemia, also stimulate PRL release in both men and women. PRL is also secreted in an episodic fashion throughout the day with some evidence for sleep-related increases in its circulating levels.

The synthesis and release of PRL by the pituitary lactotrophs are subjected to multiple regulators that can be classified into four broad categories: endocrine, paracrine, juxtacrine, and autocrine (Fig. 3). Endocrine agents originate from the hypothalamus and gonads and reach the lactotrophs via a humoral

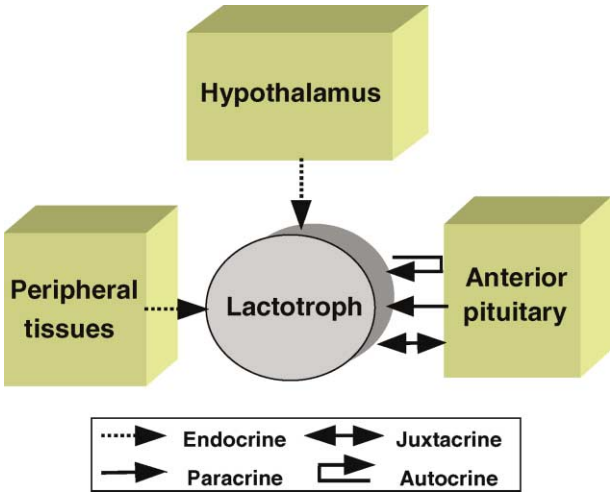

FIGURE 3 Diagram of the four types of regulation of pituitary lactotrophs.

route. Paracrine factors are produced by other pituitary cell types and reach the lactotrophs by diffusion. Juxtacrine interactions emanate from the extracellular matrix and cells adjacent to the lactotrophs. Autocrine agents are synthesized by the lactotrophs themselves. Consequently, the overall secretory activity of the lactotrophs reflects a balance between local and distant releasing and inhibiting factors. In nonhuman species, there is also evidence for PRL-regulating factors that originate from the posterior pituitary.

The pituitary lactotroph is unique in its capacity for constitutive synthesis and secretion of PRL. Unlike pituitary tropic hormones such as luteinizing hormone or adrenocorticotropin hormone, whereby the hypothalamus provides a positive stimulus and peripheral target glands supply negative feedback inhibition, PRL does not have a singular target organ. Hence, its main regulation is provided in the form of tonic inhibition by dopamine, the physiological PRL release-inhibiting factor. Acting via a type 2 dopamine receptor, dopamine exerts multiple actions on the lactotrophs, including suppression of intracellular calcium and cyclic AMP levels, inhibition of PRL gene expression and release, and suppression of cell proliferation. Interruption of dopaminergic input to the lactotrophs caused by physiological inhibition of dopamine release, damage to the pituitary stalk, or dopamine receptor antagonists results in hyperprolactinemia. PRL itself, acting via a short-loop negative feedback mechanism, is the primary regulator of the dopaminergic system. Despite intensive searching, a singular releasing factor for PRL has not been identified, but several neuropeptides, including thyrotropin-releasing hormone (TRH) and vasoactive intestinal peptide (VIP), are capable of stimulating PRL release under some physiological conditions. In contrast to the pituitary, little is known about the regulation of PRL production/release in extrapituitary sites except that they do not respond to dopamine, neuropeptides, or estrogens but appear to be regulated by local autocrine/paracrine factors.

Pituitary PRL gene expression is affected by many hormones, neurotransmitters, and growth factors. Compounds that bind to G-protein-linked receptors, e.g., TRH, VIP, and dopamine, activate protein kinase A, protein kinase C, and/or calcium/calmodulin-dependent pathways. These are mediated via a variety of transcription factors that bind to consensus sequences within the PRL promoter. Estrogens, on the other hand, freely diffuse into the nucleus, where they bind to either estrogen receptor-α or -β. The activated receptor dimerizes and acts as a transcription factor and binds to a unique DNA sequence called the estrogen-response element that is located in the enhancer region next to a Pit-1-binding site (see Fig. 1). Among the growth factors, insulin and EGF stimulate the PRL gene, whereas transforming growth factor-β suppresses the PRL gene. Many of the growth factors bind to transmembrane receptors with intrinsic tyrosine kinase activity and exert pleiotropic actions such as stimulation of PRL gene transcription, increases in hormone storage, and alterations of lactotroph morphology. Again, details about the control of PRL gene expression in extrapituitary sites are largely unknown.

IV. PRL RECEPTORS AND SIGNAL TRANSDUCTION

PRL exerts its actions by binding to specific, high-affinity plasma membrane receptors. The gene encoding the human PRL receptor is located on chromosome 5 and contains at least 10 exons encompassing over 100 kb. The PRL receptor belongs to the cytokine/GH/PRL receptor superfamily that is characterized by a single-pass transmembrane stretch that divides the receptor into an extracellular ligand-binding domain and an intracellular domain. The extracellular domain contains two disulfide bonds and a WS motif (Trp-Ser-X-Trp-Ser) that is required for correct folding of the receptor and may participate in the formation of a ligand-binding pocket. The cytoplasmic domain has a

proline-rich motif (Box 1) near the plasma membrane that couples to intracellular signaling molecules. Another motif (Box 2′) is less conserved.

Humans express primarily one "long" form of the receptor, whereas rats have three: long, intermediate, and short. An intermediate isoform that is uniquely expressed by the rat Nb2 lymphocyte cell line renders these cells dependent on PRL for growth and survival. Given this property, proliferation of Nb2 cells in response to PRL is widely used as a sensitive bioassay for PRL. An intermediate receptor isoform with a deleted segment within the intracellular domain, differentially spliced short receptors, and a soluble receptor form that contains only the extracellular domain have been detected in human tissues, but their exact functions remain to be determined. The PRL receptor is expressed by most tissues, with the highest level of expression in the liver and mammary gland. The PRL receptor concentrations fluctuate under many physiological conditions, especially in response to changes in circulating PRL and steroid hormones. Both PRL and its receptor are also internalized within several cell types but neither the exact intracellular localization nor the function of the internalized receptor or PRL is well understood.

Binding of PRL to its receptor induces sequential receptor dimerization. Two binding sites on the PRL molecule, site 1, comprising helices 1 and 4, and site 2, comprising helices 1 and 3, are required for the induction of receptor homodimerization and formation of an active trimeric complex. The receptor is devoid of intrinsic tyrosine kinase activity, utilizing instead the Janus kinase (JAK)2–signal transducers and activators of transcription (STAT) pathway as its main signaling cascade (Fig. 4). JAK2 (Janus kinase 2), which is constitutively associated with Box 1 on the PRL receptor, is rapidly phosphorylated on receptor dimerization. In turn, the activated JAK2 induces phosphorylation of the receptor, other associated kinases, and Stat proteins. Of the seven known Stat proteins, Stat1, Stat3, and Stat5 are activated by PRL. As revealed by studies with knockout mice, Stat5a and Stat 5b are especially important for mammary gland development and function. The activated (phosphorylated) Stat proteins dimerize and are rapidly translocated into the nucleus, where they bind to specific sequences on target genes. The Ras/Raf/mitogen-activated protein kinase cascade and fyn, a member of the Src kinase family that phosphorylates phosphatidyl inositol 3-kinase, are also activated by PRL in a cell-specific manner but appear to be of lesser importance in mediating PRL action than the JAK2–STAT pathway. Notably, all the above-mentioned pathways have been characterized under acute conditions, whereas the mechanism mediating the long-term effects of PRL are not well understood. In addition, human GH and placental lactogens bind to the PRL receptor with high affinity and mimic some of the actions of PRL.

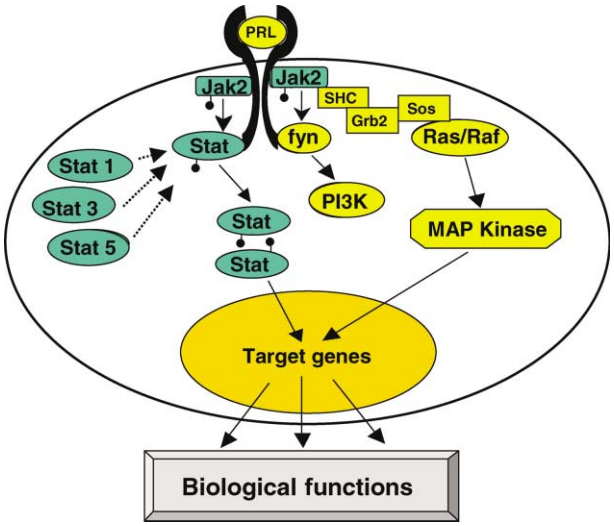

FIGURE 4 Schematic presentation of the PRL receptor and the intracellular signaling pathways that mediate PRL actions.

V. BIOLOGICAL FUNCTIONS

PRL is one of the most versatile hormones, with more than 100 functions ascribed to it, far exceeding the number of all known actions of other pituitary hormones combined. These functions are broadly associated with reproduction, growth and development, osmoregulation, metabolism, immunoregulation, brain function, and behavior. Several caveats should be considered, however, when evaluating these functions. First, although both males and females produce PRL and express the PRL receptor, PRL functions have been most extensively studied in females. Second, some PRL effects in lower vertebrates may have been lost during evolution and are recapitulated in higher animals only during certain developmental stages. Third, PRL often exerts species-specific actions among mammals (e.g., luteotropic activity in rodents only), complicating the interpretation of studies with transgenic animals. Fourth, fetal exposure to very high PRL levels via the blood and the amniotic fluid is unique to humans and

cannot be carefully examined due to lack of suitable animal models. Fifth, the uneven activity of various PRL isoforms in some functional assays leads to incomplete assessment of the spectrum of actions of PRL. Finally, the ability of related hormones, i.e., GH and placental lactogens, to bind to the PRL receptor and mimic some of the actions of PRL can lead to erroneous interpretations of experimental manipulations.

The effects of PRL on reproduction encompass multiple systems and tissues that differ in their importance in a species-specific manner. The principal target for PRL is the mammary gland. Together with several other hormones, PRL promotes growth and differentiation of the mammary epithelium and is essential for the initiation and maintenance of lactation by increasing the synthesis of all major milk components: the milk proteins α-lactalbumin and casein, lactose, and lipids. In some species, however, continuous lactogenesis is supported by GH rather than by PRL. In rodents, PRL has both luteotropic and luteolytic actions on the ovary and supports progesterone production. Therefore, in these species PRL plays a major role in modulating the reproductive cycle and is crucial for pregnancy and lactation. PRL has well-established mitogenic, secretory, and morphogenic effects on the prostate, but its actions on the testes are not well defined. Under normal conditions, PRL has permissive effects on human reproduction. However, overproduction of PRL (hyperprolactinemia) is one of the major causes of neuroendocrine-related anovulation and infertility in women and impotence in men. The inhibitory effects of excess PRL on these reproductive processes occur at both central (hypothalamic–pituitary) and peripheral (gonadal) sites. Recent evidence indicates that PRL may also play a role as a mitogen/anti-apoptotic factor in breast and prostatic cancer.

PRL plays a major role in regulating water and electrolyte balance in fish and amphibians, with lesser osmoregulatory actions in birds and mammals. Whereas the control of development and body growth is normally ascribed to GH, there are some functional overlaps between GH and PRL, especially in lower vertebrates. Both the metabolic and the immunoregulatory actions of PRL have been matters of controversy. PRL stimulates the proliferation of the pancreatic islets and increases insulin secretion primarily during pregnancy. In the immune system, PRL induces the proliferation and differentiation of functional activity of various lymphoid cells, but transgenic animals lacking PRL or its receptor have little if any immune disturbances. Within the brain, PRL affects the production and release of several hypothalamic releasing/inhibiting hormones, e.g., dopamine and gonadotropin-releasing hormone, and has significant effects on maternal behavior.

Glossary

extrapituitary prolactin sites Several nonpituitary tissues, e.g., decidua, myometrium, brain, and breast, that are capable of *de novo* synthesis of prolactin (PRL). The regulation of PRL synthesis and release from extrapituitary sites differs markedly from that in the pituitary.

Janus kinase (JAK)/signal transducers and activators of transcription (STAT) pathway Intracellular signaling cascade that mediates the action of many cytokines and some growth factors. JAK2 and STAT5 constitute the main pathway that is rapidly activated by prolactin.

lactotrophs A class of anterior pituitary cells that produce prolactin. They constitute over one-third of all pituitary hormone-secreting cells. Lactotrophs are heterogeneous in structure and function and are normally subjected to inhibition by dopamine.

posttranslational modifications Changes in the structure of a protein hormone that include glycosylation, phosphorylation, and cleavage. These modifications affect hormone binding to the receptor or clearance from the circulation and thus alter its biological properties.

prolactin promoter A DNA sequence that is used to regulate the transcription of the prolactin gene. The pituitary proximal promoter is located immediately 5′ upstream of the transcription initiation site, whereas the extrapituitary superdistal promoter is located 5.8 kb further upstream.

prolactinomas Nonmalignant tumors of the anterior pituitary that are composed of lactotrophs and result in hyperprolactinemia or abnormally high serum prolactin levels. They usually develop from a single cell (monoclonal) but their etiology is unclear.

Prolactin and Growth Hormone Receptors

VINCENT GOFFIN AND PAUL A. KELLY
Faculty of Medicine Necker, Paris

The prolactin receptor (PRLR) and growth hormone receptor (GHR) are among the class I hematopoietic cytokine receptors. PRLR is expressed is almost all tissues and cell types, although the mammary gland and gonads are the major targets for prolactin (PRL). In primates, both PRL and growth hormone (GH) can activate the PRLR. The GHR bears a strong resemblance to the PRLR but is involved only with the actions of GH, which promotes the growth of several tissue types and has a variety of metabolic functions. Although the Janus kinase/signal transducers and activators of transcription pathway plays a central role in PRLR/GHR signaling, a number of other signaling pathways are also activated by PRLR and GHR < likely relating to the wide spectrum of biological functions carried out by these hormones.

I. INTRODUCTION

It was not until the early 1970s that prolactin (PRL) and growth hormone (GH) were revealed to be two distinct hormones in humans (h). The reason is that in primates, but not in lower species, both PRL and GH are able to activate the PRL receptor (PRLR). The actions mediated by the PRLR (also referred to as the lactogen receptor) are historically linked, but certainly not restricted to milk production and control of reproductive functions; mammary gland and gonads are thus major PRL targets, although the nearly ubiquitous expression of the PRLR renders almost all tissue and cell types potential targets of lactogenic hormones. The GH receptor (GHR) closely resembles the PRLR, but mediates only GH actions (PRL does not bind to the GHR in any species). As suggested by its name, GH exerts growth-promoting activity on several tissues (e.g., soft tissues and long bones) and shows a wide range of metabolic functions.

These two receptors were cloned at almost the same time (in the late 1980s) and are among the five membrane receptors whose sequence analysis led to the identification of a new receptor family, the class I hematopoietic cytokine receptors, which includes receptors for cytokines (e.g., interleukins), erythropoietin, and leptin. Within 5 years after the receptor cDNAs were cloned, biochemical and structural

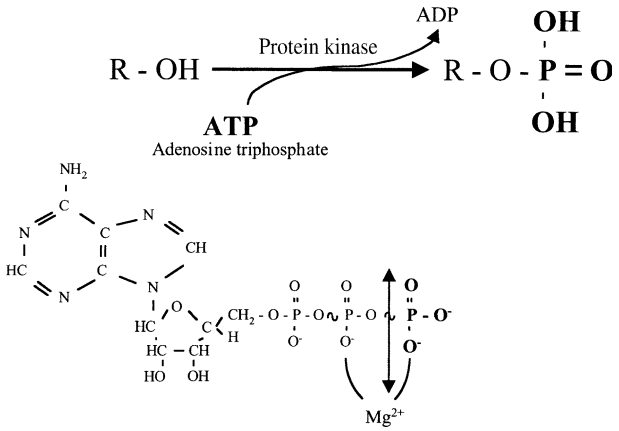

FIGURE 1 The biochemical reaction catalyzed by the protein kinases, showing the structure of ATP and the γ-phosphate that is transferred to the substrate hydroxyl group.

reaction takes place on the alcoholic aliphatic side chain of serine and threonine residues in the case of serine/threonine kinases. It can also take place on the phenolic group of tyrosine residues with protein–tyrosine kinases and on both serine/threonine and tyrosine residues in the case of dual-specificity kinases (see Fig. 2).

Histidyl kinases transfer the phosphate group onto an aspartate residue in their targets. The phosphate group comes from a histidyl residue that has been previously autophosphorylated within the kinase. These protein kinases have been discovered as a two-component histidine–aspartate phosphorelay in prokaryotes and plants. They are quite distinct from the conventional serine/threonine or tyrosine kinases.

The reverse reaction, or dephosphorylation, catalyzed by protein phosphatases, determines the ratio of phosphorylated and unphosphorylated forms. A vast number of protein phosphatases (PPs) exist, including serine/threonine phosphatases, such as the PP1s, PP2A, and PP2B, and a magnesium-dependent protein phosphatase, PP2C (also called PPM) for. The serine/threonine phosphatases are essentially cytosolic or nuclear. They localize within the cell through their binding to subcellular structures such as the endoplasmic reticulum and the cytoskeleton. Another class of phosphatases is the protein tyrosine phosphatases (PTPs). Some of the PTPs have membrane-spanning domains. They dephosphorylate tyrosine residues but some of them dephosphorylate both tyrosine and serine/threonine residues and are dual-specificity phosphatases. Some protein phosphatases have a very narrow specificity for their substrate, whereas others dephosphorylate a large number of proteins.

B. The Protein Kinase Superfamily

Protein kinases are part of a huge superfamily. There exist many kinases and isoforms. According to the human genome, there should be more protein kinases than those discovered to date and some of the new kinases should be quite different from the ones already known. Phosphorylation is a primary means of signal transduction. Signal transduction is based on two main principles. First is the posttranslational modification of pre-existing proteins, such as phosphorylation. But isoprenylation, lipidation, methylation, glycosylation, or partial proteolysis also occurs. Second is production of new proteins or second messengers. Nevertheless, phosphorylation is the most common protein modification used in signal transmission, maybe because it is reversible and because protein kinases use a ubiquitous cofactor, ATP.

III. STRUCTURE, CLASSIFICATION, AND SUBSTRATE RECOGNITION

A. Structure

Protein kinase A (PKA), a cyclic adenosine 3′,5′-monophosphate (cAMP)-dependent protein kinase,

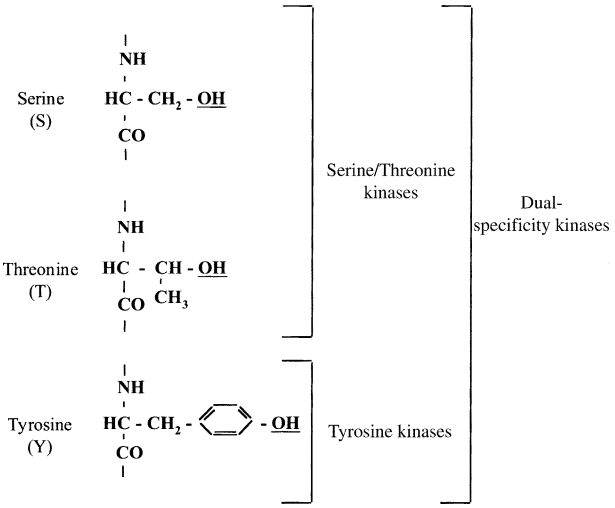

FIGURE 2 Phospho-acceptor amino acids. Protein kinases transfer a phosphate group onto the hydroxyl residue of an amino acid according to the specificity of the kinase. Serine/threonine kinases use either serine or threonine amino acids, tyrosine kinases use tyrosine, and dual-specificity kinases use serine, threonine, and tyrosine residues.

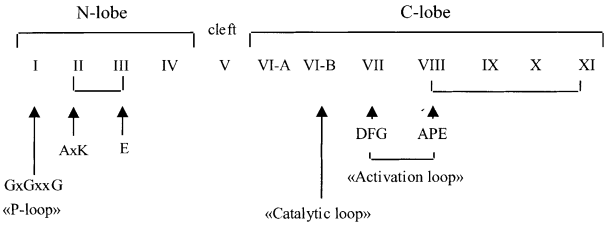

FIGURE 3 Subdomains of the catalytic domain of protein kinase A, showing some of the major residues involved in the structure or catalytic activity of the kinase (see text for discussion).

was one of the first kinases studied and its structure is well known. In the absence of cAMP, PKA enzymes are tetramers composed of two regulatory (R) subunits and two catalytic (C) subunits. Two classes of R subunits, RI and RII, and several isoforms for each class have been identified. The catalytic domain of the PKAs can be divided into 12 subdomains according to the localization of highly conserved regions (see Fig. 3).

The structure of the kinase domain of the PKAs has long served as a model. It folds into a bilobal structure separated by a deep cleft. The smallest N-lobe consists of subdomains I–IV. It is almost a single β-sheet and is involved in proper ATP orientation and binding. The cleft consists of subdomain V and interferes in substrate recognition and catalytic activity promotion. The C-lobe consists of subdomainsVI-A, VI-B, and VII–XI and is almost entirely composed of α-helices. Structure and regulatory processes are unique to each kinase but almost every subdomain contains positions in which structurally similar residues are conserved throughout the entire protein kinase superfamily (Fig. 3).

The most important domains for the structure and the function of the protein kinases are subdomains I, II, VI-B, VII, and VIII. Subdomain I (amino acids 43–64; numbering is derived from the PKA sequence) contains the phosphate-anchoring loop, or the P-loop, which is a glycine-rich β-ribbon ATP-binding consensus sequence. This sequence is GxGxxG, in which G represents glycine (in the single-letter amino acid code) and x denotes positions where any residues would be tolerated. Subdomain II (amino acids 65–83) contains the AxK motif, in which the lysine (K) at position 72 is necessary for maximum activity because it is engaged in a salt bridge with the glutamine (E) in position 91 in subdomain III.

Subdomain VI-B (amino acids 161–177) contains the catalytic loop and is directly involved in catalysis. It is a sequence with at least three conserved residues: an aspartate, a leucine, and an asparagine (DLN). The aspartate residue (D166 in PKA) within the sequence is known as the "catalytic base" because it removes the proton from the hydroxyl group of the phospho-acceptor, producing an anionic oxygen that is involved in the nucleophilic attack of the γ-phosphate of the ATP. In serine/threonine kinases, a lysine (K) is also present (determining a DLKxxN motif) and is thought to be important to neutralize the negative charge of the γ-phosphate and to stabilize the intermediate state during the chemical reaction. In the case of tyrosine kinases, the lysine is replaced by an arginine (R) residue in a DLRAAN (A, alanine) sequence in the case of nonreceptor tyrosine kinases and in a DLAARN sequence in the case of receptor tyrosine kinases. Such conserved features, which characterize subgroups of protein kinases, exist also in other subdomains.

Subdomain VII (amino acids 178–193), also called the "metal-binding loop," referring to the metal ions bound to ATP, contains a DFG triplet (F, phenylalanine). The mutation of the aspartate (D) in this triplet results in an inactive kinase. Subdomain VIII (amino acids 194–210) contains another very important motif for the kinase activity: the APE motif (P, proline). The glutamate (E) is engaged with an arginine residue from subdomain XI in an interaction that contributes to the stability of the C-lobe. The region lying between the DFG and the APE motifs is the activation loop. It is a highly variable sequence but it always contains one or several residues for which phosphorylation induces the conformational rearrangement necessary for kinase activation.

B. Classification

From catalytic domain alignment, Hanks and Quinn, in 1991, provided a general classification of protein kinases. This classification, which is still used, delineates five kinase family groups: (1) AGC, (2) CaMK, (3) GMCC, (4) PTK, and (5) OPK.

1. *AGC group*. This group is so called because it includes protein kinases A, G, and C. The PKA and the PKG families include protein kinases activated by cyclic nucleotides cAMP and cGMP, respectively. The protein kinase C family includes several isoforms, distributed in three subclasses according to their allosteric regulators. The cPKCs (α, βι, βιι, and γ) are the conventional PKCs regulated by calcium, diacylglycerol (DAG), and

phosphatidylserines. The nPKCs (δ, ϵ, η, and θ) are the novel, or nonclassical, calcium-independent PKCs. The aPKCs (ζ and ι/λ) are the atypical calcium- and DAG-independent PKCs. The AGC group also includes the G-protein receptor kinases (GRKs), which phosphorylate G-protein-coupled receptors. These kinases, such as the β-adrenergic receptor kinase (βARK) and the rhodopsin kinase (RK), are involved in desensitization and scaffold construction on the activated receptors (see below).

2. *CaMK group*. The second group of the Hanks and Quinn classification corresponds to the kinases regulated by calcium/calmodulin (CaM). CaMKs are involved in many cellular processes in response to changes of the intracellular calcium concentration. Within the cells, calcium is generally captured by high-affinity calcium-binding proteins such as calmodulin or troponin, which is found in muscles. In the CaMK family of protein kinases (CaM group I, CaM group II, and CaM "other"), the most well-known calcium/CaM-regulated kinases are the CaMKI, CaMKII, and CaMKIV. CaMKI and CaMKIV are closely related and distinct from CaMKII. CaMKII is also called the multiprotein kinase, because it actually comprises a family of closely related enzymes that phosphorylate numerous substrates. Each CaMKII is made of several catalytic subunits. Autophosphorylation may lead to calmodulin trapping, making the kinase calcium independent until it is dephosphorylated by protein phosphorylases or is phosphorylated on additional residues. In the absence of autophosphorylation, the binding of Ca^{2+}/CaM is necessary to promote the transition from an inactive state to a nonactivated state of the CaMK, which has to be phosphorylated to be fully activated.
3. *GMCC group*. The GMCC group is so called because it includes, among others, glycogen synthase kinases (GSKs); mitogen-activated protein kinases (MAPKs), which include the extracellular signal-regulated kinases; cyclin-dependent kinases (Cdks), which are involved in cell cycle progress; and the carboxy-terminal domain (CTD) kinases, which phosphorylate the long carboxy-terminal domain on the largest subunit of RNA polymerase II.
4. *PTK group*. The fourth group is composed of the conventional protein tyrosine kinases (PTKs). It includes nonmembrane (such as Src, Csk, and Fak families) and membrane-spanning protein tyrosine kinases (such as the large growth factor receptor families).
5. *OPK group*. The last group includes various "other protein kinases," i.e., the Raf family from the extracellular signal-related kinase (ERK) cascade and the MAPK/ERK kinase (MEK) family. It includes also other MEK kinases that are intermediates of the c-Jun N-terminal kinase/stress-activated protein kinase (JNK/SAPK) and p38MAPK pathways.

Beyond the distinction based on the catalytic domain amino acid sequence proposed by Hanks and Quinn, protein kinases can be distinguished by the nature of the residues they prefer to phosphorylate or by their subcellular localization. This would lead us either to consider AGC, CaMK, and GMCC kinases plus the other serine/threonine kinases from the OPK group as a unique serine/-threonine kinase family, or to view the superfamily of protein kinases as two groups: the cytosolic group and the membrane-spanning protein kinase group. The cytosolic kinase group would include serine/-threonine kinases (such as PKAs and PKCs) and tyrosine kinases (such as Src). On the other hand, the group of membrane-spanning protein kinases would include some serine/threonine protein kinases (such as the transforming growth factor-β receptor) and the large group of tyrosine kinase receptors. In addition to membrane or cytosolic localization, subcellular targeting is also important and is different from one kinase to another.

Compartmentalization of protein kinases plays a crucial role in their activity and is frequently determined by specific anchoring proteins. Several of these have already been identified. Several A-kinase-anchoring proteins (AKAPs) target the PKAs to subcellular loci (plasma membrane and mitochondrial surface). AKAPs are characterized by their ability to bind RI or RII regulatory subunits of the PKAs. This binding has two consequences. First, it is supposed to change the catalytic activity of the PKAs. Second, it specifically brings the PKAs into close contact with upstream effectors or downstream substrates via protein–protein or protein–lipid interactions mediated by the AKAPs. In addition, AKAPs can bind several PKAs at once and protein phosphatases as well. Such is the case of AKAP79, which anchors PKA, PKC, and PP2B on the plasma membrane. This mechanism may be useful for the fine and coordinated regulation of signal transduction. Several proteins also regulate PKC anchoring and translocation to particulate fractions, including

myristoylated alanine-rich protein kinase C (MAPCK) substrate proteins and the receptors for activated C kinase (RACK) proteins.

C. Substrate Recognition

Protein kinases use proteins as substrates. The phosphorylated residue is identified by the kinase thanks to specificity determinants surrounding it in the substrate sequence. In the case of the PKAs, which are basotropic kinases, the consensus sequence is R-(R/K)-x-S/T-B (where B stands for a hydrophobic residue). Such a small sequence cannot determine by the high specificity needed to select a substrate within the cell. This suggests that additional mechanisms exist, such as the targeting of the substrate and/or the kinase, the accessibility of the substrates, and the existence of a "docking site" on the substrate surface. A docking site corresponds to a larger sequence of amino acids seated astride the phosphorylated residue and an acute three-dimensional folding of the substrate that allows high-affinity interaction with the catalytic core of the kinase and increases the catalytic efficiency. For the moment, only a few docking sites are known. Some kinases are very specific for a protein substrate whereas others phosphorylate a large number of substrates.

IV. REGULATION OF PROTEIN KINASE ACTIVITY

Frequently, the presence of a sequence homologous to the substrate recognition motif in the sequence of the protein kinase forces a refolding of the kinase, which prevents substrate and ATP binding. In the PKA inactive conformation, interaction between regulatory and catalytic subunits is responsible for the autoinhibition of the kinase. In the case of the PKCs, a pseudo-substrate site, located inside the N-terminal conserved "C1" domain of the kinase, interacts with the C-terminal conserved "C4" domain, and the kinase bends back into a closed, inactive conformation. As for the CaMKs, extension of the regulatory domain of the enzyme across the catalytic core leads to multiple inhibitory interactions. In the case of the cytoplasmic tyrosine kinase Src, access to the active site is blocked because of Src homology domain 2 (SH2) and Src homology domain 3 (SH3) intramolecular interactions. Src recruitment via its SH2 domain and dephosphorylation remove the inhibitory constraint from the kinase. In the tyrosine kinase receptor inactive state, the activation loop obtrudes the substrate and the ATP binding site and leads also to autoinhibition. Thus, almost every protein kinase needs an ultimate rearrangement to achieve the activated state. Several events induce separately or concomitantly this reorganization.

A. Second-Messenger-Mediated Activation

PKA is a prime example of protein kinases regulated by a second messenger. The specific binding of two cAMP molecules onto each PKA regulatory subunit leads to the release of the two catalytic subunits and to the relief of the autoinhibition process. Many of the kinases of the AGC group are activated following production of second messengers. For instance, calcium and diacylglycerol participate in the activation of some PKCs. Others kinases are regulated by the local calcium concentration within the cells. Such is the case of the CaMKs. Indeed, the binding of Ca^{2+}/CaM on the CaMKs releases the constraint of the autoinhibitory domain.

B. Ligand-Mediated Activation of Receptor Protein Kinases

The signal transduction initiated by the ligand binding to tyrosine kinase receptors starts with homo- or heterodimerization. The dimerization results in a conformational change and an auto- or interphosphorylation of several tyrosine residues on the cytoplasmic tail of the transmembrane receptor. Current research suggests that tyrosine kinase receptors can also undergo intracellular transactivation. An example of this is the extracellular growth factor (EGF) receptor transactivation downstream of the G-protein-coupled receptors, but some researchers think that this implies a pseudo-ligand binding. This underlines the importance of the ligand-mediated release of the autoinhibition of protein kinase receptors.

C. Regulation by Phosphorylation

Because protein kinases are proteins, they can be used as a substrate and can then be phosphorylated and activated by other protein kinases. Thus, protein kinase activation in series can take place within cells, as illustrated by activation of the ERK MAPK cascade (Fig. 4). The mitogen-activated protein kinase superfamily includes the extracellular signal-regulated kinases, the c-Jun N-terminal kinases/stress-activated protein kinases, and the p38MAPKs. The MAPKs are

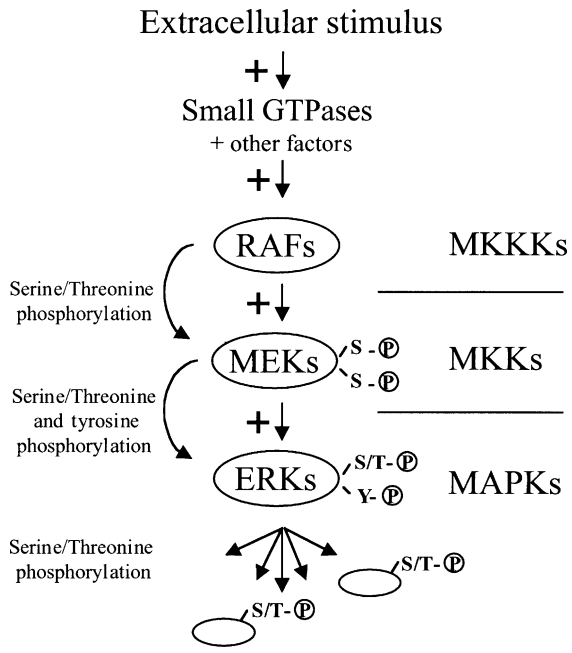

FIGURE 4 The extracellular-regulated kinase cascade is a prime example of phosphorylations occurring in series within the cell. This cascade is initiated by Raf protein activation (MKKKs). Activated Rafs then phosphorylate MEK proteins (MKKs) on serine (S) residues. MEKs, in turn, phosphorylate extracellular signal-related kinase (ERK) proteins or mitogen-activated protein kinases (MAPKs) on serine/threonine (S/T) and tyrosine (Y) residues. This cascade ends with the phosphorylation on serine/threonine of many substrates by the ERKs.

activated at the very last step of a three-kinase cascade. MAPKs are phosphorylated and activated by the MAP/ERK kinases, or MEKs, also called MAPK kinases (or MKKs), as indicated Fig. 4. The MEKs are phosphorylated and activated by the MEK kinases, also called MAPK kinase kinases (or MKKKs). When considering the ERK MAPK cascade, which ends with the activation of ERK1 or ERK2, MEK kinases are Raf proteins; MEKs are either MEK1 or MEK2. Raf proteins phosphorylate MEKs on serine residues. MEKs, which are dual-specificity kinases, phosphorylate ERKs on serine/threonine and tyrosine residues, and ERKs phosphorylate a large number of substrates on serine and threonine residues.

D. Multifactorial Activation

Raf-1 is one of the MEK kinases. Raf-1 regulation is complex and may illustrate what should be the integrated regulation of most protein kinases. Raf-1 is activated downstream of the small GTPase Ras, but Ras is not sufficient to activate Raf-1. Raf-1 activation requires protein–protein interactions, binding to phospholipids, and phosphorylations on serine, threonine, and tyrosine residues, as well as appropriate relocalization within the cell. Several protein kinases have been reported to phosphorylate Raf-1, including Src, PKCs, p21PAK, and Akt. The subcellular localization of Raf-1 is dictated by its binding to Ras but also to several other proteins (such as heat-shock protein 90, p50, and 14-3-3 proteins). According to the combination of these regulations, Raf-1 may exhibit graded activity states.

An additional degree of complexity is achieved because of the multiplicity of isoenzymes acting at each level of the MAPK cascade. Ras and Rap-1 are able to promote Raf protein activation. The Raf protein family includes Raf-1, B-Raf, and A-Raf. The fact that several isoenzymes can act at the same step in the cascade could suggest a redundancy, but it is now agreed that it instead involves a precise regulation that results from the great specificity of regulation and function of each isoenzyme.

V. TRANSDUCTION MECHANISMS

As already mentioned, protein kinases can act on the enzymatic activity of other protein kinases, initiating cascades of protein kinases within the cell, as illustrated with the MAPK pathway. In addition, protein kinases can activate or inhibit other enzymes that are not protein kinases. For instance, in hepatocytes (Fig. 5), PKA not only phosphorylates a protein kinase (the phosphorylase kinase) but also phosphorylates and inactivates glycogen synthase I (an enzyme that catalyzes glycogen synthesis).

Protein kinases also phosphorylate nonenzymatic proteins. For instance, ionic channel opening can be regulated by phosphorylation. In addition, cytoskeletal components or adhesion molecules are phosphorylated by protein kinases. Phosphorylation of some proteins blocks their proteolysis, but more generally serine/threonine phosphorylation promotes ubiquitinylation and subsequent degradation of the protein by the proteasome. Phosphorylation of G-protein-coupled receptors by PKAs, PKCs, or the highly specialized G-protein receptor kinases is the first step in G-protein receptor desensitization. Indeed, the receptor phosphorylation induces arrestin binding, G-protein uncoupling, and the receptor internalization. In addition, it is now believed that it may also initiate cross talk with other pathways and even with G-protein-independent pathways.

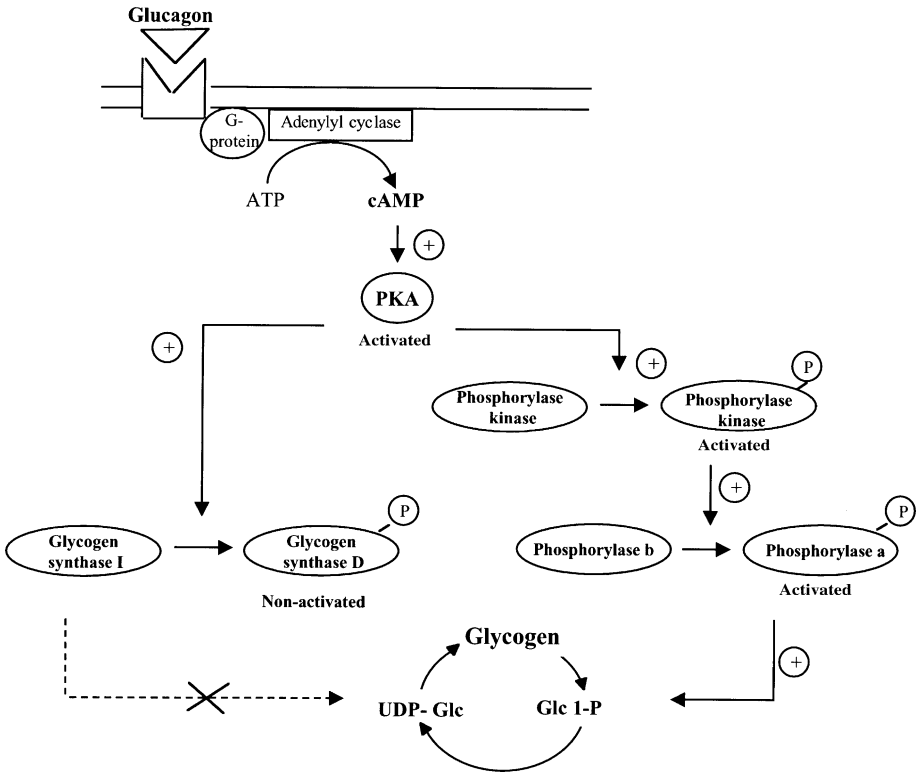

FIGURE 5 The protein kinase cascade regulating glycogen metabolism. In hyperglycemia, glucagon induces protein kinase A (PKA) activation in hepatocytes. PKA activation induces both the inhibition of the glycogen synthase I (a nonkinase enzyme) and the activation of the phosphorylase kinase (a protein kinase). Note that the multiplicity of substrates of PKA renders possible this concomitant effect and prevents a futile cycle from taking place in this metabolic pathway. UDP, Uridine diphosphate; Glc, glucose.

Phosphorylation can affect the activity of transcription factors by modulating their transcriptional activity, but also by regulating their nuclear translocation to the vicinity of DNA. In fact, bidirectional trafficking across the nuclear envelope is tightly regulated for many proteins. The nuclear localization sequence (NLS) targets proteins to the nucleus, whereas the nuclear export sequence (NES) targets proteins to the cytoplasm. The presence of the NLS is not sufficient, however, and a phosphorylation regulatory module for nuclear import (PrNLS), which includes sites in addition to the NLS, has been specified and suggests a significant role of phosphorylation in either promoting or preventing the nuclear localization.

Protein kinases are also involved in the construction of multiprotein scaffolds. Most often they are built on tyrosine kinase receptors through high-affinity phosphotyrosine docking sites. Less frequently, they are built on integrins and on G-protein-coupled receptors. Some investigators think that these scaffolds are crucial in channeling the signal to the right pathway in the intracellular network of signaling cascades and in determining the quantity of proteins to enter signal transduction by delineating a microenvironment. On the contrary, other workers consider that scaffolds generate a high degree of diversity, because the scaffolds increase considerably the number of outputs by multiplying the number of protein–protein interactions. Most agree that the scaffolds promote cross talk between the linear transduction pathways by recruiting proteins from parallel cascades. Cross talk may be the key for a selective, specific, and efficient signaling. The more signal transduction is studied, the more it is seen to proceed through combinatorial interactions of a limited repertoire of proteins and to depend on a few kinds of protein modifications, such as phosphorylation. Thus, the multiplicity of cross talk between canonical pathways is probably necessary to transmit diverse and specific signals.

VI. MAJOR PHYSIOLOGICAL ROLES OF PROTEIN KINASES

In view of the multitude of substrates they phosphorylate and of the variety of transduction mechanisms they use, it is clear that protein kinases participate in many cellular functions. They are at least involved in shaping cell and adhesion regulation, in cellular metabolism, endocytosis, exocytosis, and cellular growth and differentiation. In particular, protein kinases are implied in the cell cycle and in regulation of apoptosis.

Specific cyclin-dependent kinases complexes regulate transitions between two subsequent phases of the cell cycle. The Cdks are serine/threonine kinases. The Cdk association with cyclins, of which the level of expression is regulated during the cycle, is the major means of regulation of Cdk activity, but phosphorylation also modulates activity. Thus, at least, two phosphorylations steps interfere in the cell cycle regulation. The upstream phosphorylation of the Cdks is followed by the serine/threonine phosphorylation of substrates by the activated Cdks.

Apoptosis is a physiologically and genetically programmed cell death that proceeds both through posttranslational modification of pre-existing factors and through regulation of a specific gene expression level. Thus, every intracellular signaling pathway involving phosphorylation can either inhibit or promote apoptosis at a distance. In addition, some proteins of the apoptotic program are also directly regulated by phosphorylation. Such is the case of caspase 9, for which proteolytic activity is reduced when it is phosphorylated. The unphosphorylated caspase 9 cleaves and activates caspase 3, which is one of the terminal caspases. These caspases are responsible for the cleavage of specific cellular proteins and for the DNA fragmentation seen in the cells committed to apoptosis.

Phosphorylation also takes part in almost every single step of the intracellular signaling pathway, from the membrane to the nucleus. This can be exemplified with the platelet-derived growth factor (PDGF) receptor. The phosphorylation of tyrosine residues on the cytoplasmic tail of such a tyrosine kinase receptor and the binding of PTB- or SH2-domain-containing proteins have already been discussed. Among these proteins, Grb2 is constitutively bound to Sos. Sos is an exchange factor that promotes small GTPase activation. Once the GTPases are activated, the MAPK cascades can continue. Finally, ERKs phosphorylate pre-existing transcription factors (such as Elk-1, CREB, and ATF2), which very quickly stimulate transcription of the so-called early gene products of the Fos/Jun family. Later, Fos and Jun transcription factors, associated in an activator protein 1 (AP-1) complex, the composition of which depends on the previous step, induce transcription of specific target genes.

VII. PROTEIN KINASES IN HUMAN PATHOLOGIES

Because phosphorylation and dephosphorylation play an essential role in almost every regulatable cellular process, any abnormality in protein kinase activity is likely to be a feature in human pathology. For example, current research on diabetes and neurodegenerative and cardiovascular diseases suggests the potential for beneficial spin-offs from the study of protein kinase defects. In particular, the role of tyrosine kinases in cancer is well established. Cancers are characterized by unregulated cell growth, differentiation, and apoptosis, processes in which protein kinases are largely involved. Alteration of protein kinase activity, including tyrosine kinase, can be the result of several mechanisms. First is an abnormal protein kinase expression because of mutation, deletion, or chromosomal translocation. For instance, the activating mutations of Ras proteins, which are upstream protooncogene activators of the MAP/ERK cascade, are encountered in 30% of human neoplasms, including 90% of pancreatic adenomas and 30% of colon adenocarcinomas. In chronic myeloid leukemia (CML), the t(9,22) reciprocal translocation, which causes the Philadelphia chromosome, juxtaposes the sequences of the breakpoint cluster region (BCR) and the c-ABL tyrosine kinase. The resulting fusion protein exhibits an elevated tyrosine kinase activity compared to the normal c-ABL. Second, an overexpression of a normal protein kinase and/or of its endogenous activator is sufficient to induce an adverse autocrine loop. Such is the case in some lung cancers in which a sustained stimulation of the EGF-proliferating pathway has been reported. In addition, a positive correlation between an increased tumor neovascularization, an increased risk of tumor invasion, and a decreased survival is well established. Growth factors such as fibroblast growth factors (FGFs), platelet-derived growth factor β (PDGFβ), and vascular endothelial growth factor (VEGF) are stimulators of angiogenesis. This suggests that the tyrosine kinase pathways that they initiate may be involved in the further growth and invasion or in the switch from a dormant to an active state of the malignant cells.

Nevertheless, the use of protein kinase inhibitors as therapeutic agents is an unfulfilled goal. Most of the protein kinase inhibitors that have been developed are ATP-competitive inhibitors, but because all protein kinases use this nucleotide as a cofactor, it is difficult to get specificity. Adverse toxic effects may result from the inhibition of all of the intracellular phosphorylations and may limit any use of protein kinase inhibitors. It is necessary to target tumoral tissue and to preserve the normal protein kinase activity elsewhere. In addition, cross talk between transduction pathways is likely to render impossible or vain the inhibition of a unique kinase.

A few protein kinase inhibitors and angiosuppressive agents are being used in clinical trials, administered alone or in combination with other anticancer drugs. One example is the c-ABL-specific tyrosine kinase inhibitor, STI571, which is currently being tested for chronic myeloid leukemia. Another is the SU101 PDGF receptor inhibitor, which has already shown promising results in hormonorefractory prostate cancer clinical trials. Moreover, much effort has been made to develop farnesyltransferase inhibitors to prevent Ras protein binding to cell membranes and to block transduction of mitogenic signals.

Considering the crucial role of protein kinases in all major cellular processes, a better knowledge of protein kinase function is essential for a better understanding of cell physiology and pathology. There has been an enormous increase in literature on protein kinases since 1968, when E. G. Krebs first discovered the glycogen phosphorylase kinase and PKA. Ongoing research on protein kinases continues to be a promising field of study. Most efforts likely will continue to focus on discovery of new protein kinases and on gaining insight into the molecular mechanisms of regulation of the protein kinases already known. However, the importance of signal transduction compartmentalization in protein kinase function and the role of protein kinases in establishing cross talk between pathways are already under investigation.

Glossary

enzyme A protein that specifically catalyzes a chemical reaction in order to accelerate the reaction speed.

phosphorylation Binding of a phosphate group onto a molecule.

phosphotransferase An enzyme that catalyzes the transfer of a phosphate group from one molecule to another.

signal transduction A set of events taking place in a cell in response to extracellular stimuli, including input reception, intracellular transmission of the information from the membrane to the nucleus, and integration of concomitant signals, resulting in production of a suitable biological response.

substrate The molecule transformed by the enzyme.

II. METHODS TO STUDY PROTEIN–PROTEIN INTERACTIONS

A. Functional Complementation Assays

One of the techniques used for the study of protein–protein interactions has been functional complementation. For this, mutant receptors that are nonfunctional or partially functional are generated either by site-directed mutagenesis or by exchanging individual domains between two distinct types of receptors (chimeras). If co-expression of these receptors results in increased functional activity as compared to individual receptors, it is taken as a measure of physical association between receptors. Functional complementation studies have documented the association between receptors of the same family as well as between receptors of distantly related families. Such functional complementation studies have been useful in predicting the domains involved in the interaction and have led to modeling studies examining the mechanisms of receptor–receptor interaction.

B. Biochemical Techniques

In order to facilitate physical isolation of the interacting receptor–receptor complexes, differential epitope tagging and immunoisolation have been used. Typically, epitope tags (short peptide sequences from proteins that are not commonly expressed in eukaryotic tissues) are expressed at the N- or C-termini of GPCRs. cDNAs harboring distinct epitopes are co-expressed in heterologous cells. Selective immunoprecipitation of the epitope-tagged complex is achieved using antisera to one of the epitopes. The immunoprecipitate is subjected to size fractionation and the second receptor in the complex is visualized using antisera to the epitope on the second receptor. Depending on the conditions of solubilization and immunoprecipitation, there is a possibility that artifactual aggregation of proteins occurs (due to the inherent hydrophobic nature of GPCRs). This can be overcome by using stringent buffers for solubilization and immunoprecipitation. For example, the presence of a disulfide capping agent (such as iodoacetamide) in the buffers used in the receptor complex isolation process reduces chances of spurious formation of disulfide bonds. Treatment of cells with cross-linking agents followed by extraction with a combination of detergents with diverse physical properties is also helpful to disrupt nonspecific aggregation. An important control for these studies is to mix cells individually expressing receptors that are epitope tagged with distinct epitopes and to subject the mixture to solubilization and immunoprecipitation procedures identical to procedures using cells co-expressing these receptors. In the majority of cases, receptor–receptor interaction is seen only on co-expression of the two receptors. Another control is to co-express GPCRs that are known not to interact. Therefore, when the appropriate controls are used, immunoprecipitation is a valid technique for detecting GPCR dimers.

C. Biophysical Techniques

Proximity-based energy transfer assays have been used to study receptor–receptor interactions in living cells. The bioluminescence resonance energy transfer (BRET) technique measures the transfer of energy between a luminescent donor (luciferase) and a fluorescent acceptor [a mutant form of green fluorescent protein (GFP)]. The catalytic degradation of the substrate coelenterazine, by luciferase, leads to the release of bioluminescent energy that can excite mutant GFP; the resulting fluorescence emission is taken as a measure of physical proximity between the two proteins. Because the Forster energy transfer occurs only when the distance between the donor and acceptor is less than 100 Å, this method is ideally suited to examine receptor–receptor interactions. For this, fusion proteins of GPCRs are generated by genetically fusing luciferase or the mutant GFP to their N- or C-termini.

If a BRET signal is detected on co-expression of these fusion proteins in heterologous cells in the absence of agonist treatment, it is taken as a measure of constitutive dimers in intact cells. The selectivity of the BRET signal is measured by expressing GPCR fusion proteins of different families. BRET signals can detect interactions that occur within the cells as well as on the cell surface. Agonist treatment can cause an increase in the number of receptors in the clathrin-coated pits and this can cause an increase in the BRET signal as a result of increased clustering of receptors. Conditions that block receptor clustering (such as 0.4 *M* sucrose treatment or a dominant-negative mutant of dynamin that is known to block agonist-mediated internalization of GPCRs) have been used to examine receptor–receptor interactions at the cell surface.

Fluorescence resonance energy transfer (FRET) measures the Forster resonance energy transfer between two fluorophores that emit fluorescence at nonoverlapping wavelengths. The efficiency of FRET depends on the overlap in the spectrum of the two fluorophores, their relative orientation, and

the distance between them. Typically, fusion proteins of GPCRs (which are fused to two different forms of green fluorescent proteins) are used as donor and acceptor. An external light source is used to excite the donor and the light emitted by the donor excites the acceptor. This method has been used to demonstrate agonist-mediated changes in the level or conformation of receptor–receptor association. A related method, photobleaching FRET, has also been used for examining changes in interactions of receptors on agonist exposure. In this method, antisera conjugated to two different fluorophores (such as fluorescein and rhodamine) are used to bind the receptor. The decrease in the fluorescence intensity of the donor (fluorescein) as a result of photobleaching during prolonged exposure to excitation light is reduced by the acceptor (rhodamine). Because the close proximity of the acceptor slows down the photobleaching process, association between receptors leads to an increase in the photobleaching time constant. Photobleaching FRET is a useful technique to examine the interaction between receptors at the cell surface and has been used to measure changes in interaction mediated by the agonist with a variety of combinations of GPCRs of the rhodopsin family.

BRET and FRET can also be used to measure the strength of interactions between two receptors. For this, increasing amounts of the untagged receptor are co-expressed with a fixed amount of the luciferase-tagged and mutant GFP-tagged GPCR. The concentration of the competitor that decreases the signal by 50% is used to compare the strength of interactions.

III. ROLE FOR RECEPTOR–RECEPTOR INTERACTIONS IN RECEPTOR ACTIVITY

Receptor–receptor interactions have varied effects on the activities of GPCRs. It appears that receptors that are closely related (i.e., members of the same subfamily) as well as distantly related (i.e., members of distinct subfamilies) interact with each other, and this interaction differentially modulates their function (a few examples are shown in Table 1). In some cases, receptor interactions are required for surface expression and generation of functional receptors. In other cases, interactions between two functional receptors lead to the generation of receptors with novel binding properties. Some of these receptors are refractory to selective ligands; activation of both receptors is required for efficient ligand binding and signaling. In some cases receptor–receptor association leads to alterations in the agonist affinity as well as the efficacy and in others only the agonist efficacy is altered. Receptors that couple to distinct G-proteins are able to interact with each other, and this interaction has been shown to differentially affect the signal transduction pathway and/or level of signaling. Receptor–receptor interactions can increase or decrease the level of receptor desensitization due to alterations in agonist-mediated endocytosis of the receptor. Finally, a role for receptor–receptor interaction in the development of pathology has been documented in the case of angiotensin–bradykinin receptor interactions.

TABLE 1 Regulation of GPCR Function by Heteromeric Interactions

Receptor	Modulation of function
Members of the same subfamily	
$GABA_BR_{1a}$–$GABA_BR_2$	Surface expression and signaling
κ–δ opioid	Signaling and trafficking
μ–δ opioid	Signaling
$SSTR_1$–$SSTR_5$ (somatostatin)	Signaling and trafficking
$SSTR_2$–$SSTR_3$ (somatostatin)	Signaling and trafficking

δ opioid–β_2-adrenergic	Trafficking
κ opioid–β_2-adrenergic	Trafficking
Members of different families[a]	
A_1 (adenosine)–$mGluR_1$ (glutamate)	Signaling

[a]Families A and C.

IV. FACTORS THAT MODULATE RECEPTOR–RECEPTOR INTERACTIONS

There is a growing body of evidence to support the proposal that GPCRs interact with each other in the absence of agonist. In a large number of cases, receptor–receptor interactions appear to occur in the biosynthetic compartments (i.e., in the endoplasmic reticulum) and to be required for efficient maturation of receptors. However, in some cases, receptors appear to exist as noninteracting units that undergo increased association mediated by the agonist, as evidenced by biochemical and biophysical studies.

In a subset of cases, GPCRs have been shown to interact with other proteins (such as growth factor receptors, ion channels, receptor activity-modifying proteins, and other intracellular signaling molecules), and these interactions result in efficient surface expression, change in the cellular localization, and/or alteration in their functional activity.

V. DOMAINS OF RECEPTOR–RECEPTOR INTERACTIONS

An examination of the possible sites for receptor–receptor interactions has implicated the involvement of extracellular, transmembrane, and/or C-terminal regions in GPCR association. The evidence accumulated thus far points to transmembrane domain-mediated contacts that lead to receptor–receptor interactions. Hydrophobic interactions within the transmembrane domain are thought to provide the proper receptor conformation to facilitate additional interactions at other domains. Hydrophobic interaction via the coiled-coil domain in the C-tail has also been documented in the case of metabotropic γ-aminobutyric acid receptor. Although in the majority of the cases the interactions are mainly hydrophobic in nature, in some cases covalent interactions do occur. Crystallographic studies of the extracellular domain of metabotropic glutamate receptors have identified cysteine residues involved in the covalent homomeric interactions.

VI. SUMMARY

In conclusion, the study of GPCR interactions is a nascent field and studies thus far support the notion that receptor–receptor associations lead to changes in receptor function by modulating their ligand affinity, signaling, and trafficking properties. These interactions could be useful to modulate receptor activation following the corelease of selective endogenous ligands *in vivo*. Alternatively, these interactions could lead to the generation of a hitherto uncharacterized receptor for a unique endogenous ligand. The number of endogenous peptide ligands far exceeds the number of cloned GPCRs. These endogenous peptides could bind and activate interacting receptors that exhibit novel pharmacology; this could explain GPCR subtypes in some cases. Direct physical interactions between GPCRs have enormous ramifications for our understanding of how their actions are regulated. Furthermore, these findings provide a new strategy for the development of novel therapies.

Glossary

BRET/FRET Measures of the bioluminescence/fluorescence energy transfer from the light emitted by catalytic degradation of the substrate coelenterazine, by Renilla luciferase, to the energy acceptor green fluorescent protein. FRET is similar to BRET with the exception that the energy donor molecule, generally a mutant form of green fluorescent protein (cyan fluorescent protein) is excited by an external light source and the emitted energy is used to excite an acceptor, another mutant of green fluorescent protein (yellow or red fluorescent proteins).

differential immunoprecipitation Technique for isolation and visualization of interacting proteins using distinct antisera to individual proteins.

dimers/oligomers Two monomers/multiple monomers in association; a given G-protein-coupled receptor can exist as monomer, homo- or heterodimer, or homo- or heterooligomer.

functional complementation Technique in which co-expression of two receptors that are nonfunctional or partially functional leads to improved functional activity.

G-protein-coupled receptor Heptahelical or serpentine seven-transmembrane-domain receptor.

G-protein-coupled receptor families Three major receptor families: Family A is characterized by a relatively short N-terminal extracellular region, conserved residues in transmembrane helices, and a palmitoylated cysteine in the carboxy-terminal tail. Family B is characterized by the presence of a large N-terminal extracellular domain that contains several well-conserved cysteine residues. Family C is characterized by a very long N-terminal extracellular domain that is sufficient for ligand binding.

homomers/heteromers Physical association between identical proteins leads to homomers and association between nonidentical proteins leads to heteromers.

Retinoid Receptors

PETER ORDENTLICH AND RICHARD A. HEYMAN
X-Ceptor Therapeutics, Inc., California

Retinoids are metabolic and synthetic derivatives of vitamin A that have been shown to play an essential role in regulating multiple processes including development, vision, growth, and physiological homeostasis.

I. INTRODUCTION

The majority of these effects are mediated through direct binding to a group of receptors that belong to the nuclear hormone receptor superfamily of proteins. These retinoid receptors fall into two families, retinoic acid receptors (RARs) and retinoid X receptors (RXRs). There are three receptors in each group, RARα, RARβ, RARγ, and RXRα, RXRβ, RXRγ, respectively. The retinoid receptors function as transcriptional regulators in the presence or absence of ligand, through the recruitment of multisubunit regulatory protein complexes to promoter sites. Other factors that influence the action of retinoids include the enzymes and proteins that are required to transport and metabolize retinoids. This article will provide an overview of the RAR and RXR receptors with regard to their structure, mechanism of action, biological activities, and role in disease states.

II. RECEPTOR IDENTIFICATION

Two independent groups identified the first retinoid receptor, RARα, in 1987 using similar approaches. In one case, low-stringency hybridization screening of a cDNA library, with a consensus oligonucleotide sequence based on a highly conserved region of the DNA-binding domain, resulted in successful cloning of a novel sequence with homology to other nuclear hormone receptors. The other group designed a similar screening strategy based upon the finding that in a human hepatocellular carcinoma, the hepatitis B virus genome inserted upstream of a sequence that showed strong homology to other nuclear hormone receptors. Subsequently, it was shown that this receptor, RARα, could bind and be activated by retinoic acid.

Based on sequence homology in the DNA-binding domain, RARβ and RARγ were later identified and also shown to bind and be activated by retinoic acid (Fig. 1). The three RARs are highly conserved in both

cell (of B) at time t as a concentration time average over a time delay $[l_1, l_2]$ is represented as

$$\oint_{t-l_1}^{t-l_2} Y(r)dr = \frac{1}{l_2 - l_1} \int_{t-l_1}^{t-l_2} Y(r)dr,$$

where $Y(r)$ is either a hormone concentration or its rate of change at time r. The effect of a feedback/feed-forward signal for a peptide is different from that for a steroid. If hormone A is a steroid, its molecules are able to diffuse through the target cell membrane, whereas if hormone A is a peptide, its molecules do not penetrate but rather attach to receptors on the target cell membrane. Either way, a cascade of biochemical reactions results.

These feedback interactions can be modeled via monotonic logistic dose–response functions

$$H(x_1) = \frac{C}{1 + \exp[-(A + B_1 x_1)]} + D,$$

of one input,

$$H(x_1, x_2) = \frac{C}{1 + \exp[-(A + B_1 x_1 + B_2 x_2)]} + D,$$

of two inputs,

or where the coefficients themselves are described by logistic functions

$$H(x_1, x_2) = \frac{C(x_2)}{1 + \exp[-(A + B_1 x_1 + B_2 x_2)]} + D.$$

If $B_i > 0$, the feedback is positive (i.e., feed-forward effect); if $B_i < 0$, the feedback is negative. For each hormone, its resulting nonbasal rate of synthesis $S(\cdot)$ will depend on time-delayed feedback from the system through some nonlinear dose–response function $H(\cdot)$, plus noise $\xi(\cdot)$. The $H(\cdot)$ function serves the role of an average rate (a "conditional expectation") for all the cells in the endocrine gland; the actual realized rate of synthesis $S(\cdot)$ varies about $H(\cdot)$. Response adaptation and desentization can then be formulated as allowable variation in the parameters of the interfaces.

Whereas dose–response relationships in the above three axes have been largely defined for individual nodes acting in isolation (e.g., GnRH's stimulation of LH secretion, LH's receptor-mediated stimulation of testosterone and estrogen secretion), the implicitly dynamic nature of this network arises from the time-lagged nonlinear feedback and feed-forward interactions among all three interconnected loci.

II. THE HPT (GnRH–LH–Te) MODEL, AS REPRESENTATIVE OF RECEPTOR-MEDIATED SYSTEMS

Secretion of a hormone is usually viewed as occurring in two fractions. There is an approximately constant basal secretion as well as nonbasal secretion, the latter being highly variable and fluctuating. For steroid hormones (e.g., Te), nonbasal secretion occurs as a continuous release. For peptide hormones (e.g., GnRH and LH), there is variable mass accumulation within the endocrine gland, which is released in a pulsatile manner. In either case, upon release from a gland, hormones within the capillary bloodstream are immediately subjected to at least two primary dispersive forces: physical diffusion within the plasma space and advective effects of blood flow within the tubular capallaries. The process of irreversible (metabolic) removal of the hormone molecules can take place in the systemic circulation, since blood is delivered to metabolizing tissues, such as the liver, kidneys, and bone marrow macrophages.

Suppose that the systemic circulation can be described topologically as a circle (S^1) of length L. Let $X(x,t)$ be the concentration and $Z(x,t)$ be the rate of secretion at time $0 \le t \le T$ and at location $x \in S^1$. Also, let α_i be the elimination rate constant and D_i and A_i the diffusion and advection constants. It is assumed that the concentration dynamics, with initial conditions $X_i(x,0) = X_i^0(x)$, are described by

$$\frac{\partial X_i(x,t)}{\partial t} = D_i \frac{\partial^2 X_i(x,t)}{\partial t^2} + A_i \frac{\partial X_i(x,t)}{\partial x} - \alpha_i X_i(x,t) + Z_i(x,t)$$

where G denotes GnRH, L denotes LH, and Te denotes testosterone.

The difficulty with that implementation is that blood sampling is ordinarily performed at a single site x_* and for practical reasons probably always will be. Hence, a representation of the above equation applicable to the sampling at a single location (x_*) is needed. The following approximation can be justified (for a given hormone), where the dependency on $x = x_*$ is left implicit; e.g., $X_G(x_*, t)$ and $Z_G(x_*, t)$ are represented as $X_G(t)$ and $Z_G(t)$, respectively, $i = G, L, Te$,

$$X_i(t) \approx X_i(0)(a_i^{(1)} e^{-\alpha_i^{(1)} t} + a_i^{(2)} e^{-\alpha_i^{(2)} t}) + \int_0^t (a_i^{(1)} e^{-\alpha_i^{(1)}(t-s)} + a_i^{(2)} e^{-\alpha_i^{(2)}(t-r)}) Z_i(s) ds,$$

where $\alpha_i^{(1)}$ can be interpreted as a fast half-life of elimination (primarily diffusion and advection) and $\alpha_i^{(2)}$ as a slow half-life of elimination (irreversible clearance). The $a_i^{(1)}$ and $a_i^{(2)}$ are fractional amounts of secretion, with $a_i^{(1)}$ estimated as 0.63 for LH and 0.76 for Te. The variations among individuals and within a given individual appear to be quite stable, with 0.63 and 0.76 being reasonable representative values. At present, these values have not yet been determined for GnRH.

In order to apply the above model for concentration ($X_i(\cdot)$), models for the rates of secretion for GnRH, L, and Te are formulated in the following sections.

A. GnRH Pulse Generator

The pulsatile nature of GnRH and LH secretion was first discovered in the rhesus monkey and then later in human and other species. There are on the order of 800–1200 GnRH-secreting neurons, each connected to its own individual network of glial cells; the resulting random pulsatile structure is partly modulated by feedback inhibition via testosterone receptors, as well as by a synchronization of network firing frequencies. It is assumed that GnRH signaling dictates the pulse times for LH after a finite time delay τ_L, reflecting hypothalamo–pituitary portal blood transit, and a poststimulus refractory interval, r_L, when further GnRH inputs are ignored. Thus, there will be two corresponding sets of pulse times $T_G^0, T_G^1, T_G^2, \ldots$ and $T_L^0, T_L^1, T_L^2, \ldots$, where

$$T_L^k = Min_j\{T_G^j | T_G^j \geq T_L^{k-1} + r_L\} + \tau_L,$$

$$\text{with } T_G^0 = T_L^0 = 0.$$

Here the pulse times are viewed as a point process, with $N_i(\cdot)$, $i = G$, L being the associated counting processes (i.e., the number of pulses up to that time). The GnRH pulse times are then assumed to be given by a rate parameter process $\lambda(\cdot)$ (number of pulses/day), modulated by feedback:

$$\lambda(t) = H_{1,2}\left[\oint_{(t-l_{1,2})}^{(t-l_{1,1})} X_{Te}(r)dr, \oint_{(t-l_{2,2})}^{(t-l_{2,1})} X_G(r)dr\right]$$

and a parameter γ, which controls the regularity of interpulse interval lengths. The conditional probability densities for T_G^k given T_G^{k-1} are

$$p\left[s|T_G^{k-1}, \lambda(\cdot)\right] = \gamma \times \lambda(s)\left(\int_{T_G^{k-1}}^{s} \lambda(r)dr\right)^{\gamma-1} \times \exp -\left[\int_{T_G^{k-1}}^{s} \lambda(r)dr\right]^{\gamma}.$$

B. Synthesis

A pulsatile rate of secretion means that release is not continuous, but rather at certain times (the pulse times), the rate of secretion rapidly increases, followed by a less rapid decrease; this combined increase and decrease in the rate of secretion will be called a pulse. A pulse at time t, having started at pulse time T^j, is represented by a function $M^j \times \psi(t-T^j)$, where the pulse shape $\psi(\cdot)$ represents the instantaneous rate of secretion per unit mass per distributional volume and M^j is the total mass available for release.

The mathematical effect of cascading target-tissue reactions to a GnRH signal input is (approximately) the multiplication of the initial feedback/feed-forward signal by a linear combination of exponential functions, denoted by $\Gamma_G(\cdot)$, which allows ongoing glandular responses after the signal is withdrawn. Accordingly, synthesis (S), accumulation (C), and fractional mass remaining for later secretion (Ψ) are given as

$$\psi_i(s) = \frac{\beta_i^{(3)}}{\Gamma(\beta_i^{(1)})(\beta_i^{(2)})^{(\beta_i^{(1)}\beta_i^{(3)})}} s^{(\beta_i^{(1)}\beta_i^{(3)})-1} \times e^{-(s/\beta_i^{(2)})^{\beta_i^{(3)}}}$$

(normalized rates of secretion for $i = \mathrm{G}, \mathrm{L}$) (a 3-parameter gamma function)

$$\Psi_i(T_i^{j-1}, T_i^j) = \oint_{T_i^{j-1}}^{T_i^j} \psi_i(s - T_i^j)ds$$

(fraction of $(j-1)-$st mass remaining at time $T_i^j, i = G, L$)

$$S_L(t) = H_{5,6}\left[\oint_{T_L^{N_L(t)}-l_{5,2}}^{T_L^{N_L(t)}-l_{5,1}} X_G(s)ds \times \Gamma_G\left(t - T_L^{N_L(t)}\right), \oint_{t-l_{6,2}}^{t-l_{6,1}} X_{Te}(s)ds + \xi_L(t)\right]$$

(LH synthesis) (expected LH synthesis rate + allowable variation (ξ))

$$S_G(t) = H_3\left(\int_{t-l_{3,2}}^{t-l_{3,1}} X_{Te}(s)ds\right) + \xi_G(t)$$

(GnRH synthesis)

$$A_L^j = \int_{T_L^{j-1}}^{T_L^j} \xi_L(t)dt \text{ and}$$

$$A_G^j = \int_{T_G^{j-1}}^{T_G^j} \xi_G(t)dt$$

(allowable variation in LH and GnRH mass accumulation)

$$C_L^j = \int_{T_L^{j-1}}^{T_L^j} H_{5,6}\left(\int_{T_L^{N_L(t)}-l_{5,2}}^{T_L^{N_L(t)}-l_{5,1}} X_G(s)ds \times \Gamma_G(t - T_L^{N_L(t)}), \int_{t-l_{6,2}}^{t-l_{6,1}} X_{Te}(s)ds\right) dt + A_L^j$$

(the storage of newly synthesized LH granules)

$$\approx [\eta_L^{(0)} + \eta_L^{(1)} \times (T_L^j - T_L^{j-1})] + A_L^j$$

$$C_G^j = \int_{T_G^{j-1}}^{T_G^j} H_3\left(\int_{t-l_{3,2}}^{t-l_{3,1}} X_{Te}(s)ds\right)dt + A_G^j$$

$$\approx [\eta_G^{(0)} + \eta_G^{(1)} \times (T_G^j - T_G^{j-1})] + A_G^j$$

$$M_i^j = \Psi_i(T_i^{j-1}, T_i^j)\, M_i^{j-1} + C_i^j$$

(the j-th pulse mass, for $i = L, G$)

$$\approx \Psi_i(T_i^{j-1}, T_i^j)\, M_i^{j-1} + [\eta_i^{(0)} + \eta_i^{(1)} \times (T_i^j - T_i^{j-1})] + A_i^j$$

$$F_L(t) = \int_{t-l_{4,2}}^{t-l_{4,1}} X_L(s)\, ds$$

(LH feed-forward signal on Te synthesis)

$$S_{Te}(t) = H_4(F_L(t)) = H_4\left(\int_{t-l_{4,2}}^{t-l_{4,1}} X_L(s)ds\right)$$

C. Secretion

Based upon the above constructions, the corresponding interactively controlled rates of secretion for L, G, and Te are given as

$$Z_L(t) = \beta_L + \sum_{j:T_L^j \le t} [(\eta_L^{(0)} + \eta_L^{(1)} \times (T_L^j - T_L^{j-1}) + A_L^j]\psi_L\,(t - T_L^j)$$

$$Z_G(t) = \beta_G + \sum_{j:T_L^j \le t} [(\eta_G^{(0)} + \eta_G^{(1)} \times (T_G^j - T_G^{j-1}) + A_G^j]\psi_G\,(t - T_G^j)$$

$$Z_{Te}(t) = S_{Te}(t) = \eta_0 + \frac{\eta_1 + A_{Te}^j}{1 + e^{-(\eta_2 + \eta_3 \times F_L(t))}},$$

$$T_L^{j-1} < t \le T_L^j$$

(A_{Te}^j's, allowable random variations in upper asymptote (efficacy))

Hence, the basic secretory model for LH and GnRH consists of two components: basal (β) and pulsatile (non-basal) secretion. The amount of mass that accumulates is assumed to be proportional to the previous interpulse interval, plus an allowable random variation (the A_L^j's and A_G^j's). If there were mass accumulation at a rate that randomly varied about a steady-state rate, then the result would be precisely this. Testosterone, also has two components (basal and non-basal), except that the non-basal secretion is assumed to be released continuously, without storage. Moreover, the non-basal component is assumed to be described by a logistic interface function of an LH feed-forward signal, a time-delayed averaging of LH concentration. Again, as in the modeling of the LH and GnRH secretion, flexibility in the structure needs to be allowed. Here, there is allowable pulse-by-pulse variation in the upper asymptote (i.e., efficacy) of the dose-response function, reflecting potential desensitization or adaptation. These models for GnRH, LH, and testosterone secretion reflect the essence of the title: receptor-mediated interlinkages.

D. Concentrations

Incorporating the above secretion rates, the resulting concentration processes are then (approximately) given as: i = G, L, Te.

$$X_i(t) = X_i(0)\left[a_i^{(1)}e^{-\alpha_i^{(1)}t} + a_i^{(2)}e^{-\alpha_i^{(2)}t}\right] + \int_0^t \left[a_i^{(1)}e^{-\alpha_i^{(1)}(t-s)} + a_i^{(2)}e^{-\alpha_i^{(2)}(t-s)}\right]Z_i(s)ds.$$

What one then observes is a discrete-time sampling of these processes, plus joint uncertainty due to blood withdrawal, sample processing, and hormone measurement errors, $\epsilon_i(k)$, $k = 1, \ldots, n$,

$$Y_i(t_k) = X_i(t_k) + \epsilon_i(k), \quad k = 1, \ldots, n, \quad i = G, L, Te.$$

Using the statistical methods developed, which implement the above models, statistical fits can be obtained for the GnRH, LH, and testosterone

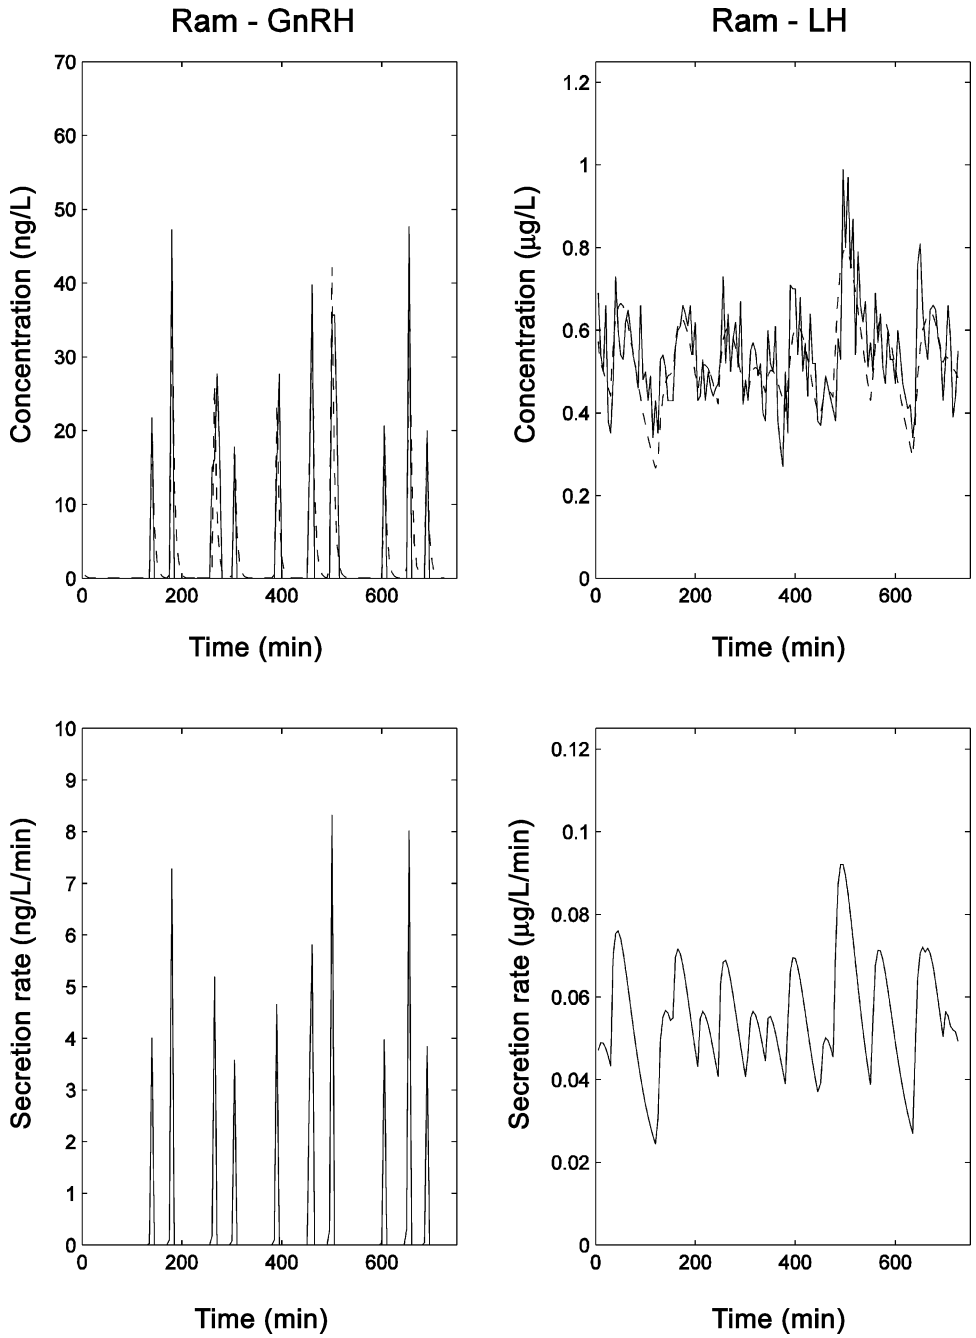

FIGURE 2 GnRH, LH and Te concentrations were obtained in a conscious ram, every 5 min for 12 hours. (Top) GnRH (left) and LH (right) concentrations (continuous line) and their model fits (dashed). (Bottom) Estimated GnRH (left) and LH (right) secretion rates.

concentrations, as well as the estimation of their unobserved secretion rates. The next section presents two applications of the methodology.

E. Applications

For exposition of the above model, data obtained from a ram and a stallion is used. In each, all three of the hormones (GnRH, LH, and Te) were measured. In the ram, blood was sampled every 5 minutes for 12 hours. In the stallion, the sampling was over 6 hours, with GnRH and LH sampled every 5 minutes at the pituitary, and Te and LH sampled every 15 minutes at a jugular. The results are presented in Figs. 2 and 3 for the ram and in Figs. 4 and 5 for the horse. Figure 2 (top) displays the GnRH and LH

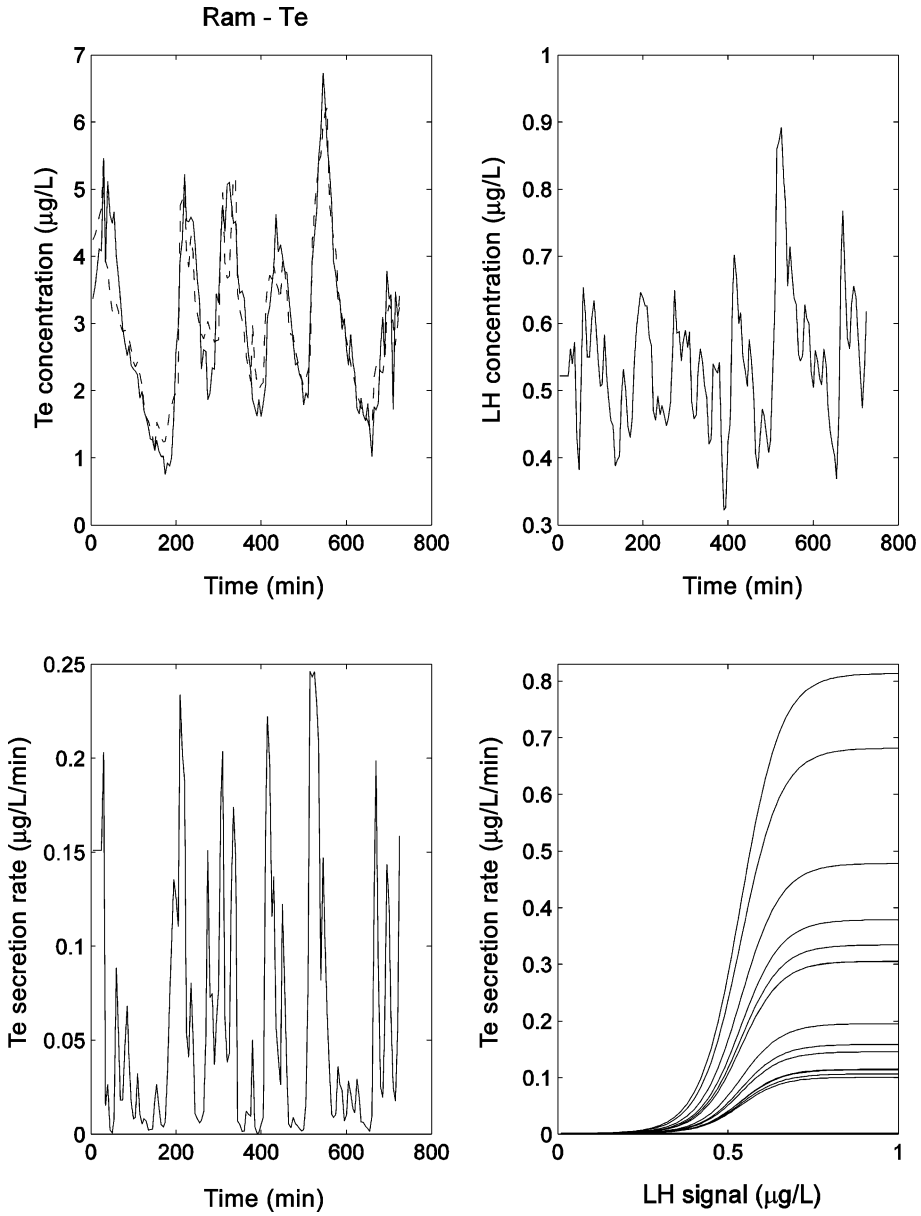

FIGURE 3 (Top left) Te concentration (continuous line) and the model fit (dashed), and (right) the LH feed-forward signal on Te. (Bottom left) The estimated Te secretion right, and (right) the dose-response function, with the allowable, random, pulse-by-pulse responsitivity (efficacy) shifts.

concentrations (continuous line) and their respective model fits (dashed line). The bottom half of Fig. 2 shows the corresponding estimated secretion rates for GnRH and LH. Figure 3, top left, shows the observed Te concentrations (continuous line) and the model fit (dashed line) and the LH feed-forward signal is shown in the top right. The bottom left of Fig. 3 shows the estimated Te secretion rate and in the bottom right is the dose-response function, with the allowable, random, pulse-by-pulse responsitivity (efficacy) shifts. Figures 4 and 5 contain the same plots for the horse, with the addition of LH being observed at both the pituitary and the jugular.

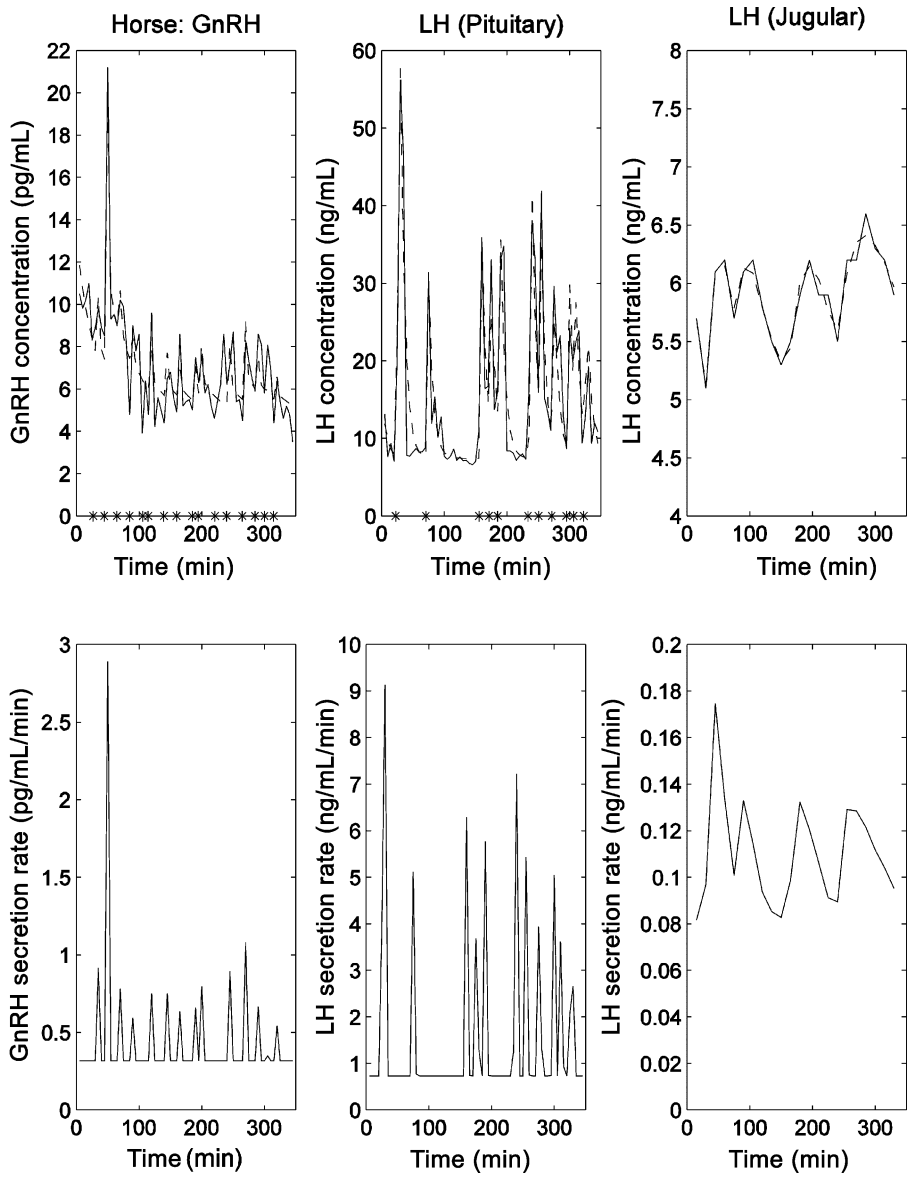

FIGURE 4 GnRH and LH concentration time series monitored every 5 min in pituitary blood, and Te and LH were monitored every 15 min in jugular blood, for 6 hours in an awake stallion. Figures 4 and 5 include the same information format as in Figs. 2 and 3 (with an additional panel for jugular LH). (Top) GnRH (left) and LH (right) concentrations (continuous line) and their model fits (dashed). (Bottom) Estimated GnRH (left) and LH (right) secretion rates.

Glossary

dose–response interface function A function (e.g., a logistic function) whose response output is an instantaneous rate of hormone synthesis, mass accumulation, or release.

fast and slow elimination Secreted molecules undergo combined diffusion and transport in the bloodstream at very rapid rates (short half-life component, $\alpha^{(1)}$) and are removed more slowly but irreversibly (long half-life component, $\alpha^{(2)}$).

feedback and/or feed-forward signal A signal at time t, constructed as a time-delayed, time-averaging of a hormone concentration (or its rate of change) that

serves as an input (driver) to the dose–response interface function.

pulse generator A process, possibly modulated by feedback, that governs the resulting, variable-pulse time-release pattern for a pulsatile secreting gland.

receptor-mediated system A physiological system (e.g., a hormonal axis) whose linkages are interconnected via receptor mechanisms (interface functions).

Receptor–Receptor Interactions

LAKSHMI A. DEVI
Mount Sinai School of Medicine

The function of every cell in the body is regulated by plasma membrane receptors. The dimerization of receptors has been an extensively studied phenomenon. Receptor–receptor associations lead to changes in receptor function by modulating receptor ligand affinity, signaling properties, and trafficking properties. These interactions could be useful to modulate receptor activation and may provide strategies for therapeutic applications.

I. INTRODUCTION

The vast majority of plasma membrane receptors belong to the superfamily of G-protein-coupled receptors (GPCRs), which at current estimates account for ~1% of the genes present in a mammalian genome. Models describing the interaction of GPCRs with their G-protein targets have been based on the assumption that the receptors exist as monomers and couple to G-proteins in a 1:1 ratio. These classical models of receptor/G-protein coupling may be oversimplified, because a number of studies have reported the presence of dimeric and oligomeric arrays in the case of a number of GPCRs. Direct protein–protein interaction (GPCR oligomerization) has not been previously recognized despite a significant amount of indirect evidence derived from cross-linking experiments, target size analysis, and hydrodynamic studies. The availability of GPCR complementary DNAs (cDNAs) now allows direct examination of receptor–receptor association by biochemical and biophysical techniques.

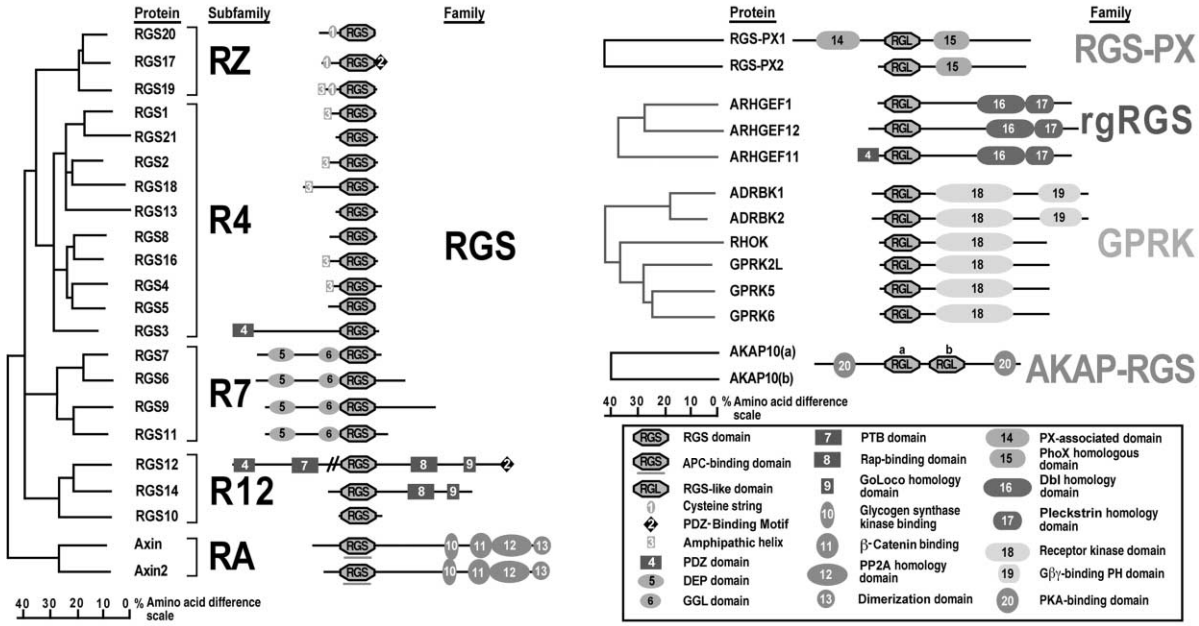

FIGURE 1 The superfamily of RGS proteins. Amino acid identity comparisons within the RGS domain defined five families of RGS and RGS-like proteins: *RGS*, *RGS-PX*, *rgRGS*, *GPRK*, and *AKAP-RGS*. The RGS family is further subdivided into five subfamilies: *RZ*, *R4*, *R7*, *R12*, and *RA*. Human RGS domains contain between 127 and 130 amino acids. Branch junctions approximate the values calculated by DNAStar for sequence identity for each pair of sequences calculated as 100% minus the sum of the horizontal distance to and from the common branch point. Protein domains flanking the RGS domain are identified in the figure, and functions are summarized in Table 2. Common aliases for *RGS* genes are indicated in Table 1.

similarity within the RGS domain (Fig. 1). RGS proteins in the RZ, R4, R7, and R12 subfamilies all display GAP activity (Table 1). By contrast, the RA subfamily proteins lack GAP activity; they are scaffold proteins that help assemble components of the wnt signaling pathway during development and cancerous growth.

The structure of the RGS domain was solved by both X-ray crystallography and nuclear magnetic resonance. Interestingly, even though the entire RGS4 protein was crystallized (complexed with a $G_{\alpha i}$ subunit), only the RGS domain of RGS4 was resolved, whereas the N- and C-terminal residues were disordered. The correspondence of the ordered structure to the evolutionarily conserved RGS domain, which conveys GAP activity, indicates that the RGS domain is a discrete unit of folding and function. The RGS domain is a globular structure composed of two four-helical bundles. Residues within three loops on one surface are important for GAP activity and substrate specificity (Fig. 2). This surface has been termed the "A" or active site. However, RGS proteins do not have residues that directly contribute to catalysis, but rather appear to stabilize the transition state of GTP hydrolysis on the G_{α} subunit. RGS proteins with amino acid substitutions, deletions, or insertions within this region (from experimental mutagenesis or found naturally, as in the RA subfamily) lack GAP activity. A potential regulatory or "B" site occurs within an acidic domain in helices 4 and 5; in axin, this region binds a peptide fragment of adenomatous polyposis coli (APC), and R4 family RGS proteins are thought to alternatively bind phosphatidylinositol 3,4,5-triphosphate (PIP_3) and Ca^{2+}/calmodulin to regulate GAP activity. Other regions of RGS proteins bind additional proteins and lipids (Table 2). Interestingly, the most highly conserved residues within the RGS domain face inward and maintain structure. Several outward-facing residues are conserved within subfamilies and, together with flanking domains, may interact with other proteins or lipids in the signaling complexes that convey specific regulatory functions.

B. Superfamily of RGS Domain Proteins

Sequence homology between families of RGS-like proteins is low and difficult to detect. The different

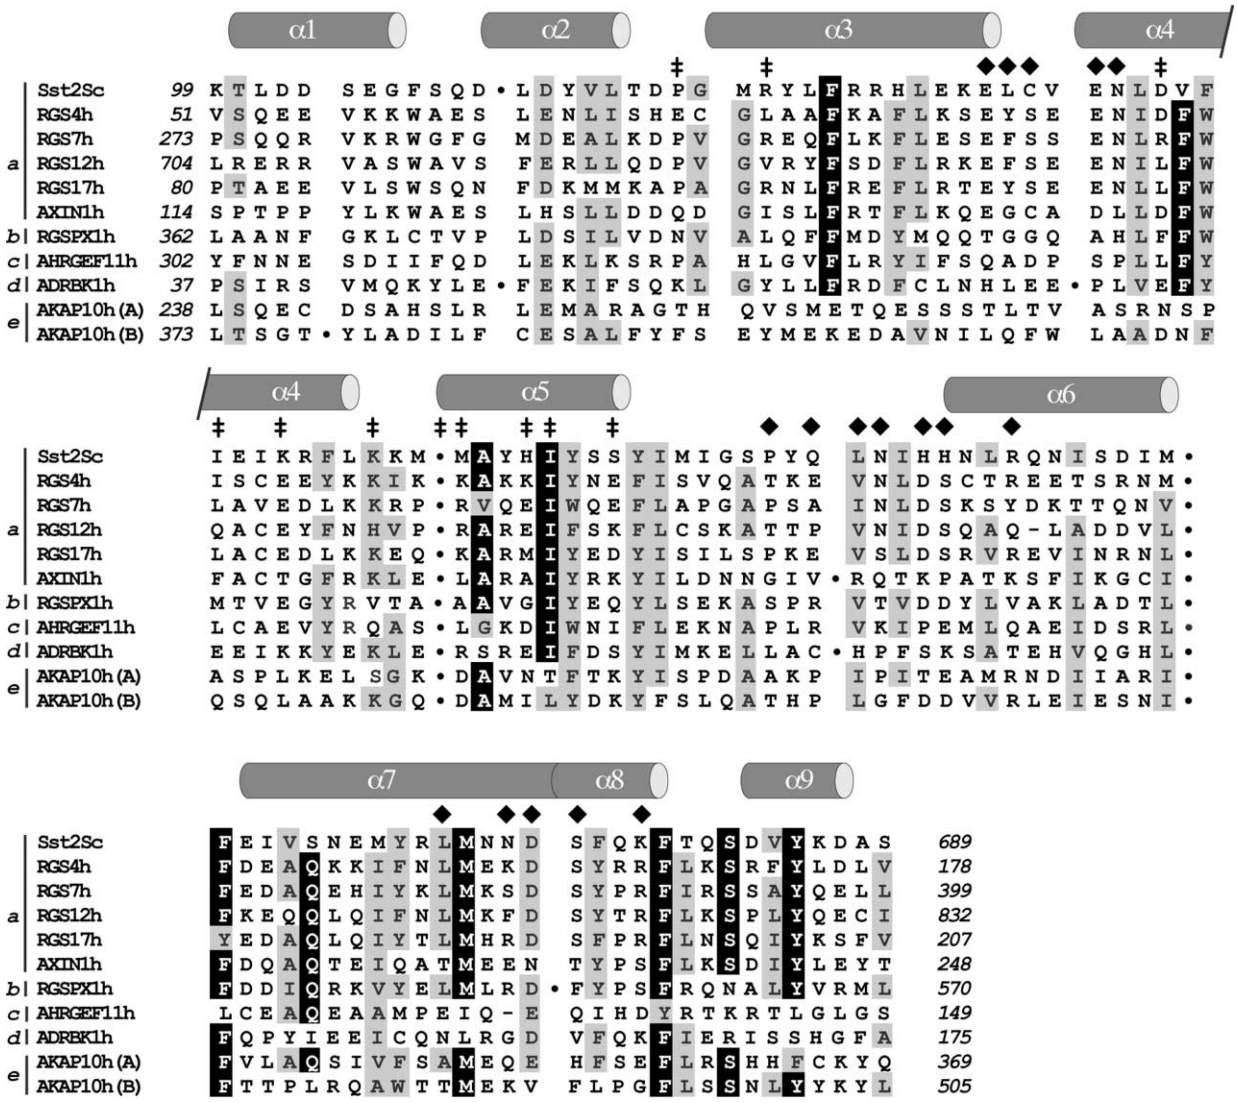

FIGURE 2 Primary structure alignment of RGS superfamily proteins. Amino acid sequence alignment of the RGS domains from a representative member of each RGS subfamily, *R4*, *R7*, *R12*, *RZ*, and *RA*, and the yeast RGS protein Sst2 (*a*) and the four families of RGS-like domains (*b*, *RGS-PX*; *c*, *rgRGS*; *d*, *GPRK*; *e*, *AKAP-RGS*). The features noted in the RGS domain include the position of the α-helices in RGS4, AXIN, and ARHGEF11 (rods), G_α contact residues in RGS4 (diamonds), residues in AXIN that bind APC (double dagger), highly conserved, inward-facing amino acid identities (black), and amino acids of similar chemical function (gray). Dots signify amino acid insertions that were omitted from the alignment, spaces show where other proteins in the RGS superfamily have amino acid insertions, and dashes signify that an amino acid is not present in that RSG subfamily at that position within the alignment.

families are so divergent that only a few inward-facing residues important for structural integrity are conserved (Fig. 2). On the other hand, the crystal structures of RGS and rgRGS proteins are very similar, with the conserved residues identically placed within the RGS domain structure, supporting the notion that these RGS-like proteins are evolutionarily related. Presumably, members of the RGS-PX, GPRK, and AKAP-RGS families also have similar structures, but this is yet to be determined. As a cautionary note, the first protein demonstrated to have G_α-GAP activity, the effector protein phospholipase C-β (PLC-β), is structurally unrelated to the RGS proteins. Thus, G_α-GAP activity has evolved independently at least twice.

Within the superfamily of RGS domain proteins, GAP activity is observed in some but not necessarily all of the proteins of the RGS, rgRGS, RGS-PX, and

GRPK families and not in either RGL domain of AKAP10 (Table 1). Interestingly, the different RGS-like GAPs accelerate GTP hydrolysis on distinct types of G_α subunits. This substrate selectivity may help provide specificity in the regulation of G-protein signaling pathways.

Mammals, flies, and roundworms express four classes of G_α subunits, termed G_i, G_q, G_{12}, and G_s. The four classes are defined on the basis of similarity in sequence, gene structure, and regulation of effector proteins. The G_q class activates phospholipase C-β, and thus regulates the production of the second messengers inositol 1,4,5-triphosphate (IP_3), diacylglycerol (DAG), and oscillations in the concentration of intracellular Ca^{2+}. The G_i class regulates diverse effectors, including the inhibition of adenylyl cyclase, activation of cyclic GMP (cGMP) phosphodiesterase, potassium channel opening, and activation of phospholipase C-β. The G_{12} class activates a guanine nucleotide exchange factor on the small GTP-binding

		20	PKA-binding domain	Binds PKA regulatory subunit

protein Rho (RhoGEF). G_α subunits of the G_s class activate the effector protein adenylyl cyclase, which stimulates the production of the second messenger cyclic AMP (cAMP). The activity of these four classes of G-proteins is opposed by the GAP activity of proteins in the RGS superfamily. G_q and G_i proteins are substrates for proteins in the RGS family, G_{12} proteins are regulated by rgRGS proteins, and G_s proteins are substrates for RGS-PX proteins (Table 1). An aspect of signaling specificity is that RGS proteins in the RGS, rgRGS, and RGS-PX families have no GAP activity on the G-protein substrates of the other two RGS families. G_q proteins are exceptional because GTP hydrolysis on these α-subunits can be accelerated by RGS and GPRK proteins within the RGS superfamily and the unrelated effector protein PLC-β.

At least two other families of proteins that contain RGS-like domains are expressed in metazoans (Table 2). AKAP10 contains two RGS-like domains; although the function of this protein is not known, it is tempting to speculate that it regulates protein kinase A (PKA) activity in response to G_s-stimulated cAMP production. GPRK is the fifth family of RGS-like proteins, including at least two proteins, ADRBK1 and ADRBK2, that have weak G_q-GAP activity. It is not known whether ADRBK1 and ADRBK2 interact with RGS G_q-GAPs to regulate G_q signaling complexes or whether GAP activity by GPRKs, RGS-PX, and/or RGS may influence receptor desensitization and

internalization. Several of the GPRK genes have been deleted in mice, leading to a wide range of defects including light-dependent retinal degeneration, embryonic cardiomyocyte hypoplasia, and increased sensitivity and/or lack of desensitization to physiologically relevant doses of pharmacological agents.

C. Multidomain RGS Proteins

Proteins in the RGS superfamily are defined by their RGS domains, but each has additional flanking domains with distinct functions. These modules mediate protein or lipid interactions that are unique to individual families and even subfamilies of RGS proteins (Fig. 1). A brief description of protein domains specific to different RGS protein families and their functions is presented in Tables 2 and 3. These groupings suggest that the functional domains contribute to subfamily-specific catalytic activities, subcellular localization, and/or regulation (summarized in Fig. 3). For example, the kinase domain in GPRK family proteins phosphorylates activated heptahelical receptors, leading to their internalization and down-regulation. A different family of RGS-like proteins, the rgRGS proteins, are distinguished by a dbl homology domain that binds and activates its effector protein Rho, thereby regulating cell shape changes and motility. The RGS-PX proteins have a PX domain, which is usually found in proteins called nexins, involved in vesicular trafficking within cells. Genetic and biochemical evidence from vertebrates and invertebrates indicates that RGS, GPRK, and rgRGS proteins regulate G_q, G_i, and G_{12} signaling via G-protein-coupled receptors but it is unclear whether the G_s-GAPs of the RGS-PX family regulate hormonal signaling or vesicular transport.

Some RGS proteins serve as scaffolds that bring proteins into proximity to allow specific interactions. For example, the RA protein axin is a scaffold protein that negatively regulates the wnt signaling pathway. The RGS domain of axin has no GAP activity but binds another scaffold protein on the wnt pathway, APC. Flanking the axin RGS domain are additional domains that bind the serine/threonine kinase GSK, its phosphorylation target β-catenin, and its negative regulator, protein phosphatase 2A. Axin and APC together assemble a signaling complex that regulates the stability and activity of the transcription factor β-catenin, thereby influencing development and tumor progression.

Scaffolding functions can also serve to bring the RGS domain into a particular receptor complex where it can act on the G_α subunit and serve to

TABLE 3 RGS Deficiencies in Eukaryotes

Species	RGS family	Gene	Phenotype of genetic deficiency
Saccharomyces cerevisiae	RY[a]	*Sst2*	Supersensitive to pheromone, delayed recovery from cell cycle arrest
		Rgs2	Enhanced glucose response
Schizosaccharomyces pombe		*Rgs1*	Increased sensitivity to mating factor, mating defects
A. nidulans		*FlbA*	No conidiophore formation or asexual reproduction
Caenorhabditis elegans	R7	*Egl-10*	Hypokinesis and delayed egg-laying
		Eat-16	Hyperkinesis and precocious egg-laying
	RC[b]	*Rgs1*	Rgs1;Rgs2 double-mutant delayed recovery from fasting
		Rgs2	
Drosophila melanogaster	R12	*Loco*	Impaired glial cell function and dorsal–ventral axis formation
	rgRGS	*DRhoGEF*	Gastrulation defects
Mus musculus	R7	*RGS9*	Delayed recovery to light in photoreceptor cells
	R4	*RGS2*	Reduced male aggression, T-cell defects, hypertension
	RA	*axin*	Duplication of anterior structures during embryogenesis
	GPRK	*GRPK2*	Embryonic lethality from cardiomyocyte hypoplasia
		GRPK3	Reduced olfactory desensitization, increased muscarinic-evoked airway response

[a] RY is an RGS subfamily found in fungi.
[b] RC is an RGS subfamily found only in *C. elegans*.

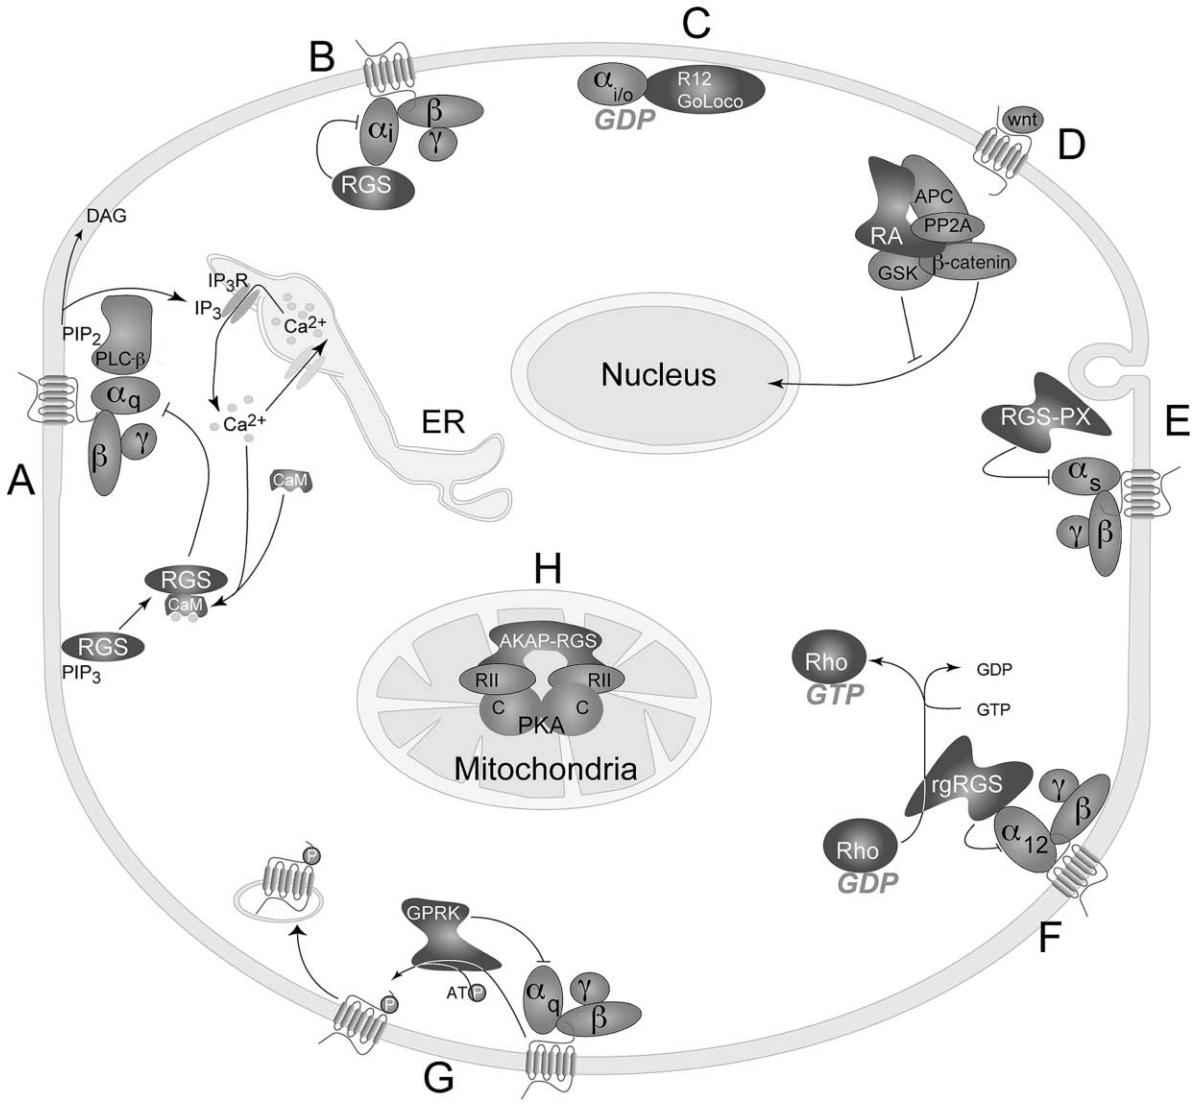

FIGURE 3 Actions of RGS superfamily proteins in cellular signaling complexes. (A) G_q class G-proteins activate PLC-β to produce DAG and IP_3. IP_3 causes the release of the second messenger Ca^{2+} from intracellular stores. Ca^{2+}/calmodulin (CaM) displaces PIP_3 on RGS proteins of the R4 subfamily, which acts as a GAP on the G_α subunit. (B) G_i class G-proteins are negatively regulated by RGS proteins of the R4, R7, R12, and RZ subfamilies. (C) The GoLoco domain of R12 RGS proteins interacts with $G_{\alpha i/o}$-GDP. (D) RA RGS proteins function as structural components of the wnt signaling pathway, bringing β-catenin into proximity of its negative regulator, GSK kinase, which phosphorylates β-catenin, marking it for proteosome-mediated degradation. (E) RGS-PX proteins function as GAPs for $G_{\alpha s}$ and also bind to vesicles. (F) rgRGS serve as GAPs for G_{12} class G-proteins and as guanine nucleotide exchange factors for small Rho G-proteins. (G) GPRKs can serve as GAPs for G_q class G-proteins and also phosphorylate activated receptors, promoting their internalization and down-regulation. (H) AKAP10 contains two RGS-like domains of unknown function and two domains that bind the regulatory subunit of PKA, and it is highly enriched in mitochondria.

distinguish hormonal signals sent through different receptors that couple to the same G-protein. For example, in pancreatic acinar cells, RGS4 has been shown to preferentially inhibit signaling through m3-muscarinic receptors, relative to cholecystokinin receptors, despite the fact that they both couple to $G_{\alpha q}$. RGS4 contains an N-terminal domain shared by some other R4 subfamily members that is responsible for this receptor selectivity. This allows the cell to regulate signaling specificity through a combination of receptor-dependent activation by agonists and attenuation by RGS proteins.

III. GAP ACTIVITY REGULATES SIGNALING

A. G-Proteins Transduce Extracellular Signals to Regulate Intracellular Responses

All higher eukaryotes, including yeast, *Dictyostelium discoides*, plants, and animals, utilize G-protein signaling to mediate intracellular responses to extracellular stimuli. G-protein signaling systems have several components, each encoded by distinct multigene families. Extracellular signals received by heptahelical receptors are coupled by heterotrimeric G-proteins to the regulation of effector proteins that generate intracellular second messengers. Following agonist stimulation, cells must recover to maintain homeostasis. RGS proteins can rapidly attenuate G-protein signaling through feedback regulatory mechanisms. Thus, G-proteins act as signal transducers under the positive and negative regulation of receptors and RGS proteins, respectively. Activation and inactivation may occur within a G-protein signaling complex, composed of perhaps six distinct proteins, which acts like a molecular machine to convey extracellular signals and coordinate intracellular responses. All of the molecular components of G-protein signaling cascades, from ligands to effector proteins, are required to relay information from the outside of the cell to the inside.

B. Regulation of GTP Binding and Hydrolysis

The essential regulatory feature of G-protein signaling is the cycle of GTP binding and hydrolysis on the G_α subunit. Many of the proteins that interact with the G_α subunit regulate its transit through this cycle. Signaling is initiated on receptor binding of extracellular agonists, such as nucleotides or small peptides, or the activation of a prebound chromophore by light. RGS proteins may help assemble a signaling complex that brings receptor, G-protein, and effector protein into proximity to stimulate rapid activation on ligand binding. The GAP activity of RGS proteins accelerates GTP hydrolysis and thereby can rapidly terminate signaling. The balance of activation by hormone binding and inactivation by RGS GAP activity controls the signaling flux through G-proteins.

The heterotrimeric $G_{\alpha\beta\gamma}$ protein complex is required for the receptor to stimulate intracellular signaling (Fig. 4). G_α is the largest subunit in the complex, ranging from 41 to 45 kDa, and binds the guanine nucleotide. $G_{\beta\gamma}$ forms a stable heterodimer of 35 and 7 kDa subunits, respectively. In the inactive state, G_α binds GDP to assume a conformation with high affinity for $G_{\beta\gamma}$. G_α-GDP$\beta\gamma$ can interact with the intracellular loops and tail of the receptor. Agonist binding to receptor on the outside of the cell conveys conformational changes to the intracellular surfaces of the receptor that catalyze the dissociation of GDP from the G_α subunit. In the open state, the G_α subunit will bind GDP or GTP with equal affinity but the cytosolic concentration of GTP is 100-fold higher that GDP, which promotes GTP binding and progression of the activity cycle. GTP binding induces a conformational change in the switch regions of the G_α protein. The switch regions bind at least three different proteins ($G_{\beta\gamma}$, effector proteins, and RGS proteins) at different times during the cycle of GTP binding and hydrolysis. Conformational changes in the switch regions favor dissociation of the previous binding partner and association of the next partner in the cycle. GTP binding to the G_α subunit weakens its interaction with $G_{\beta\gamma}$ and receptor but induces a conformational change that favors interaction with effector proteins. Both G_α-GTP and $G_{\beta\gamma}$ can regulate independent effector proteins. Thus, information is transduced from extracellular ligand binding to effector proteins that regulate the production of intracellular second messengers, such as cAMP and Ca^{2+}. G_α remains active until GTP is hydrolyzed. Conformational changes in G_α-GDP drive the dissociation of the effector protein, thus terminating signaling and favoring reassociation of $G_{\beta\gamma}$. The cycle of GTP binding and hydrolysis can be repeated in the presence of persistent agonist.

RGS proteins are important regulators of G-protein activity because they are GAPs for G_α subunits, thereby inactivating or attenuating signaling. GAP activity is conveyed by the RGS domain. The RGS domain from several different RGS proteins can stimulate GTP hydrolysis up to 2000-fold above the basal activity of the G_α subunit, with all of the catalytic residues being supplied by the G_α subunit. Additionally, recent studies have shown that some RGS proteins also serve as scaffolds to help assemble active receptor complexes that are tightly coupled to effector proteins. Thus, RGS proteins regulate the kinetics of the G-protein activity cycle, and some apparently can accelerate both the activation and the inactivation of signaling. Current models of G-protein signaling suggest that signaling initiates within a multiprotein complex including receptor, G-protein, effector, RGS protein, and perhaps membrane lipids and other proteins (Figs. 3 and 4).

The duration and intensity of G-protein signaling can be modulated by posttranslational modifications of the receptors and RGS proteins that regulate the cycle of GTP binding and hydrolysis. Signaling is

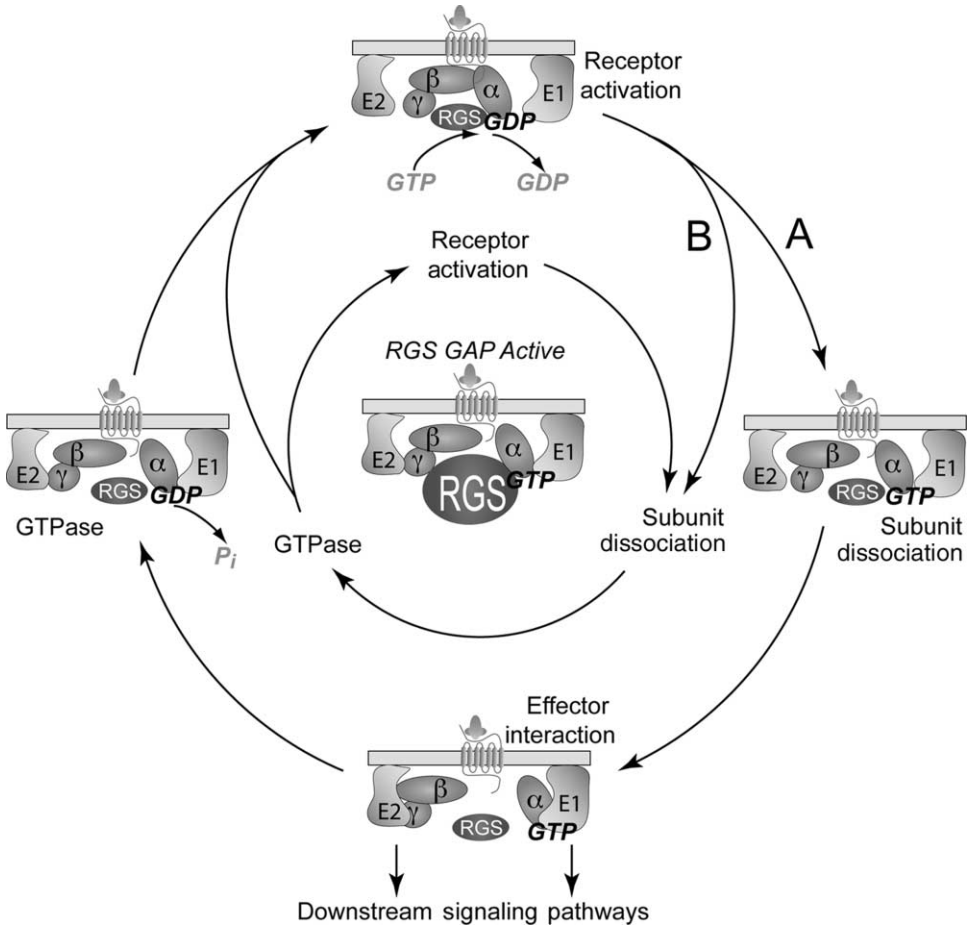

FIGURE 4 Action of RGS within the cycle of guanine nucleotide binding and hydrolysis in heterotrimeric G-protein signaling complexes. In the presence of hormone agonist, receptor activation causes the exchange of GDP for GTP on the α-subunit. In the presence of low or rising second-messenger levels, RGS is inactive, promoting pathway A, where subunit dissociation is followed by effector interaction, and the activation of downstream signaling pathways, causing an increase in second messenger levels. Intrinsic GTPase activity of G_α cleaves the terminal phosphate from GTP, and the cycle is poised for another round in the continued presence of hormone agonist. When second-messenger levels are high, pathway B is promoted, where receptor activation is followed by subunit dissociation, and the GAP activity of RGS accelerates GTP hydrolysis before effector interaction can take place. In the continued presence of hormone agonist, multiple cycles of pathway B can uncouple hormone binding from effector protein activation, thereby terminating signaling. Repeating switches between pathways A and B can initiate oscillations in the production of second messengers, as observed in Ca^{2+} oscillations evoked by G_q-coupled agonists.

activated by agonist (Fig. 4, pathway A) and can be terminated when agonist is depleted or overwhelmed by antagonist. Signaling can also be terminated by constitutively active RGS GAP activity, despite agonist stimulation of the G-protein. Thus, RGS proteins can uncouple effector protein activation even in the presence of persistent agonist (Fig. 4, pathway B). If RGS GAP activity is transiently activated and inactivated in response to the rise and fall of intracellular second messengers, then second-messenger production and downstream signaling can oscillate. RGS proteins have been proposed to play an important role in generating Ca^{2+} oscillations in response to G_q-coupled agonists and thus regulate diverse biological processes such as the release of peptides from neuroendocrine cells and the proliferation and growth of cardiomyocytes during development and progression to heart disease.

C. Effectors as GAPs

At least three G-protein-coupled effectors have GAP activity or stimulate an associated GAP. Although this accelerates the rate of return to the basal state, effector

activation, and thereby signaling, is maintained by persistent agonist stimulation. However, signaling can rapidly terminate on agonist dissociation from the receptor. Thus, effector GAP activity allows a rapid response to both activating and inhibitory inputs.

The rgRGS proteins are both GAPs and effector proteins for G_{12} class α-subunits. These proteins mediate cell shape changes during development and cell migration. Cell shape changes are regulated by the small GTPase Rho, which controls the assembly of actin stress fibers. Rho can be activated by a variety of guanine nucleotide exchange factors (GEFs). rgRGS proteins are RhoGEFs that are uniquely responsive to activation of G_{12} class α-subunits. The rgRGS proteins have an RGS-like domain that binds and accelerates GTP hydrolysis on G_{12} class α-subunits and a dbl-homology domain with RhoGEF activity. This signaling pathway, which couples heterotrimeric G-proteins to the small GTPase Rho, is conserved in vertebrates and invertebrates.

A second example of an effector with GAP activity was discovered in vertebrate photoreceptor cells. In this case, the G-protein transducin interacts with separate GAP and effector proteins, RGS9 and the γ-subunit of cGMP phosphodiesterase (PDE), respectively. RGS9 GAP activity on transducin is intrinsically weak but is augmented by both PDEγ and a recently discovered protein termed R9AP. Thus, a multiprotein complex of G-protein, RGS effector, and ancillary proteins serves the signaling requirements of vertebrate photoreceptor cells.

The regulation of G_q class proteins is a third variation on this theme of multiprotein signaling complexes. As mentioned previously, like rgRGS, PLC-β is both a G_α-GAP and an effector protein, but its sequence and structure are unrelated to those of RGS proteins. In addition to PLC-β, several RGS proteins also have G_q-GAP activity and appear to regulate PLC-β activity within a signaling complex composed of receptor, G-protein, RGS, and PLC-β. Currently under debate is why G_q signaling is regulated by both PLC-β and RGS GAPs. One proposal is that GAP activity of PLC-β is constitutive, and this drives a rapid cycle of GTP binding and hydrolysis in the presence of persistent agonist. This is sufficient to maintain G_α and $G_{\beta\gamma}$ in proximity to the active receptor, acting like a kinetic scaffold to prevent G-protein dissociation from the receptor complex. Despite G_q-GAP activity, PLC-β still generates second messengers in the presence of persistent agonist, but only while the RGS GAP is inactive. By contrast, the GAP activity of many RGS proteins appears to be regulated by the rise and fall of second messengers inside the cell. Thus, GAP activity drives a repeating cycle of GTP binding and hydrolysis; PLC-β generates second messengers, whereas RGS proteins act as feedback inhibitors to uncouple G-protein activation from effector protein activation (Fig. 3). The combined action of these two GAPs may initiate pulses, or oscillations, of second messenger, as observed in many cell types during the initiation of Ca^{2+} signaling by G_q-coupled agonists.

IV. SUMMARY

GTP binding and hydrolysis on G-proteins drive cycles of protein–protein interactions that mediate signaling inside cells in response to extracellular signals. Heterotrimeric G-protein α- and/or βγ-subunits can independently regulate effector proteins, and thus, a single stimulus can generate a bifurcating signal. G-protein signaling via both G_α and $G_{\beta\gamma}$ is subject to feedback regulation through their attendant RGS proteins. The five families of RGS proteins in the RGS superfamily bind, and often accelerate GTP hydrolysis, to distinct types of G-proteins via interactions through their RGS domains. In addition to their catalytic properties, several RGS proteins function like scaffolds to organize multiprotein complexes that rapidly initiate and terminate signaling (summarized in Fig. 3). Each subfamily of RGS protein has protein domains, in addition to the RGS domain, that bind proteins and/or lipids that convey distinct regulatory properties. Thus, regulatory specificity is achieved by the combination of G-protein substrate specificity, cellular targeting, and accessory protein interactions with RGS proteins. Regulation of G-protein signaling by RGS proteins is found in fungi, *Dictyostelium*, and metazoan organisms at all stages of their life cycles and is fundamental to intercellular communication in higher eukaryotic organisms.

Glossary

effector protein G_α and $G_{\beta\gamma}$ bind and regulate proteins that either increase or decrease the intracellular concentration of small molecules, termed second messengers, that stimulate cellular responses to extracellular hormones.

G-protein Proteins that are composed of three subunits; the α-subunit binds GTP and has GTPase activity, the β- and γ-subunits form stable heterodimers, and both G_α and $G_{\beta\gamma}$ can independently activate effector proteins in response to hormone stimulation.

G-protein-coupled receptors Heptahelical transmembrane proteins that bind hormones, chromophores, or other extracellular ligands to promote G-protein signaling inside the cell.

GTPase accelerating proteins (GAPs) Proteins that accelerate the hydrolysis of GTP on distinct types of G-protein α-subunits. GAPs occur in four of the five families of RGS-like proteins and the effector protein phospholipase C-β.

regulators of G-protein signaling proteins GTPase accelerating proteins for the α-subunit of heterotrimeric G-proteins.

second messenger Small molecules, such as cyclic AMP, inositol 1,4,5-triphosphate, diacylglycerol, or Ca^{2+}, that alter the activity of target enzymes and ion channels to influence cellular responses to extracellular hormones, neurotransmitters, and other stimuli.

Salicylic Acid

D'Maris Amick Dempsey and Daniel F. Klessig

Boyce Thompson Institute for Plant Research, New York

Salicylic acid, a phenolic compound synthesized by plants, plays an important role in signaling mechanisms that regulate plant defenses against pathogens. Plant genetic studies show that salicylic acid regulates components of its own signaling pathway and is involved in cross talk with other pathways involved in mediating disease resistance and thermogenesis.

I. INTRODUCTION

Salicylic acid (SA) and its derivatives, collectively known as salicylates, are just some of the many phenolic compounds synthesized by plants.

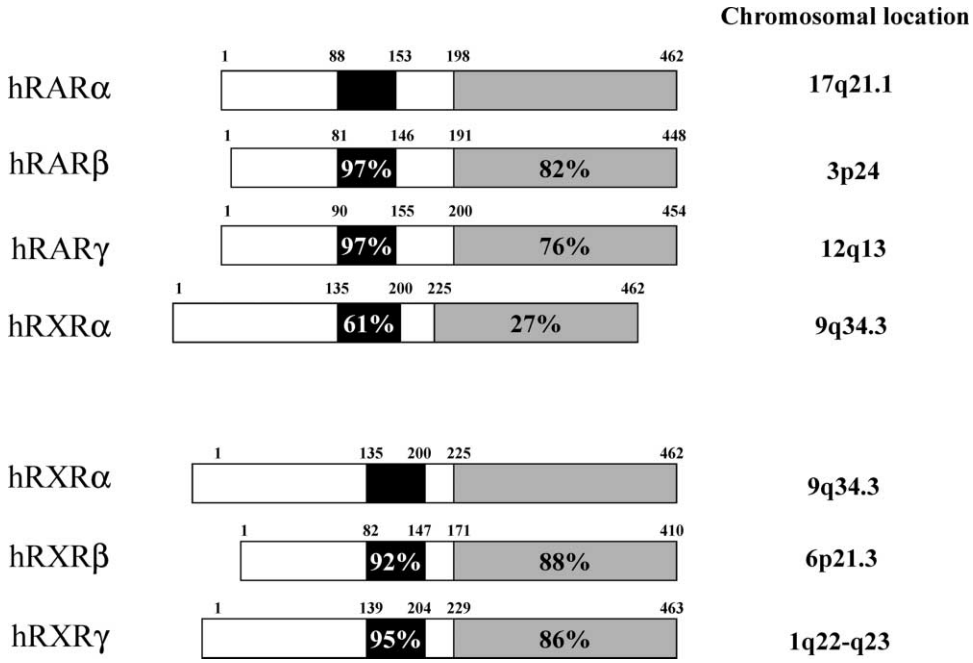

FIGURE 1 Retinoid receptors and homologies A schematic representation of the members of the retinoid receptor family. The diagram provides the amino acid boundaries of the DNA-binding domains (black) and ligand-binding domains (gray) for the receptors. Included also is the amino acid homology of the ligand-binding domains within each class, i.e., RAR and RXR, and also the homology between RXRα and RARα. The DNA-binding domains are generally conserved (greater than 60%) among all the retinoid receptors, whereas the ligand-binding domains are conserved (greater than 75%) within each receptor family, but not between the RAR and RXR (less than 30%) groups. The chromosomal location of each receptor that has been identified in humans is shown as reference.

the DNA-binding domain (97%) and the ligand-binding domain (~75% or greater). The RARs exhibit a broad tissue distribution with the specific isoforms having both overlapping and distinct patterns of tissue and developmental expression. RARα expression is ubiquitous, whereas RARβ is more restricted to neural tissues, heart, lung, and spleen. RARγ is the primary isoform expressed in the skin. In addition to the α, β, and γ subtypes of RAR, differential promoter usage and alternative splicing generate multiple isoforms of each subtype to significantly increase the complexity of retinoid responses. Evolutionarily, the RAR receptors are well conserved and the finding of a retinoid-responsive RAR receptor in ascidians (sea squirts) suggests that retinoid receptor signaling existed early in vertebrate development as long as 500 million years ago.

In an attempt to identify other members of the retinoid receptor family, further screening of cDNA libraries resulted in the isolation of an RARα-related receptor, retinoid X receptor (RXRα). The other isoforms of RXR, β and γ, were subsequently isolated (see Fig. 1 for homologies and chromosomal locations). As with the RARs, multiple splice forms and transcripts expressed from different promoters add to the multiplicity of RXR isoforms. It is possible that the alternative splicing of retinoid receptor promoters and intron–exon boundaries may result in differential tissue expression, transactivation capabilities, and ligand responsiveness of the individual splice forms. RXRα is highly expressed in liver, kidney, lung, muscle, and spleen. RXRβ is generally found in most tissues and RXRγ is expressed predominantly in muscle and brain. Importantly, RXRs have been shown to be critical heterodimer partners for numerous other nuclear hormone receptors, as discussed in detail below. RXR is also well conserved throughout evolution and is considered one of the parental nuclear hormone receptors from which many of the others have evolved. Functional RXRs have been isolated from organisms as primitive as jellyfish, which indicates that they have existed for 600 million or more years. Unlike RAR, a homologue of RXR called ultraspiracle exists in the fruit fly, *Drosophila melanogaster*, although this receptor does not bind 9-*cis*-retinoic acid (9-*cis*-RA) and may not bind any ligand. It is unclear therefore when retinoid receptors developed the response to retinoids or

whether, through evolution, some retinoid receptors lost the ability to respond.

The first natural ligand to be identified for retinoid receptors was all-*trans*-retinoic acid (AtRA), the active metabolite of vitamin A. The AtRA was shown to bind with nanomolar affinity to all three isoforms of RAR. Although the homology of RXRs to RARs in the DNA-binding domain is relatively high (61%), the homology in the ligand-binding domain is less than 30%, suggesting that these receptors respond to different classes of ligands (Fig. 1). In experiments designed to identify RXR ligands, it was therefore surprising to find that AtRA could, at high levels, activate RXRα. Ligand-binding assays could not show binding of AtRA to RXR, and further testing of metabolites of retinoic acid (RA) resulted in the identification of 9-*cis*-RA as a high-affinity ligand for RXRs as well as RARs.

In addition to different ligand specificity, another important finding related to the mechanism of how retinoid receptors function was the identification of RXR as an obligatory heterodimeric partner for a number of nuclear hormone receptors including RARs, thyroid hormone receptor (TR), peroxisome proliferator-activated receptor (PPAR), liver X receptor (LXR), farnesoid X receptor (FXR), pregnane X receptor/steroid and xenobiotic receptor (PXR/SXR), constitutive androstane receptor (CAR), and vitamin D receptor (VDR). Although the consequences of heterodimerization between RXR and these receptors are discussed in greater detail below, it is important to introduce this as a central concept in the identification of ligands that are specific for both RAR and RXR independently as well as those ligands that may regulate heterodimer function through the RXR. Compounds that specifically bind and activate RXR have been termed rexinoids. Supporting the pharmacological importance of rexinoids are findings demonstrating that RXR ligands working through specific heterodimers can recapitulate the activities observed with ligands specific to the heterodimeric partner. One example of this is the result that an RXR ligand, LG100268, can activate a PPARγ/RXR heterodimer and function as an effective insulin sensitizer in animal models of insulin resistance, similar to that observed with the PPARγ-regulating thiazolidinediones. Another example has been the finding that rexinoids such as LG100268, LG100364, and LG101305 can affect both cholesterol levels and atherosclerotic lesion size by virtue of working through another permissive heterodimer partner, LXR. The evidence that rexinoids can control multiple aspects of physiology through the regulation of RXR heterodimers demonstrates the importance of retinoid receptors as tools for pharmacological intervention in a number of diseases. As with RXR, there are also significant efforts to develop synthetic RAR compounds that are isotype specific to both reduce unwanted side effects and focus the pharmacological action of such compounds to specific tissues and disease states. See Fig. 2 for a selection of RAR and RXR ligands.

III. RECEPTOR STRUCTURE

The retinoid receptors exhibit the general modular structure typical of nuclear hormone receptors in that they have five domains separable by sequence, structure, and function (Fig. 3). These domains are termed A/B, C, D, and E. In some receptors, there is also an F domain, for which a clear function has not yet been identified. The N-terminal part of the receptors contains the A/B domain, which harbors an autonomous transcriptional activation function domain termed AF-1. This domain has been shown to be important in regulating cell- and promoter-specific gene expression. The activity of this domain is ligand independent. AF-1 can be regulated by modifications such as phosphorylation in the case of PPARγ and estrogen receptor-β and these modifications result in the recruitment of transcriptional cofactors. The AF-1 can also affect the overall transcriptional activity of the receptor by modulating the activity of the other transcriptional regulator domain, AF-2, which is part of the C-terminal ligand-binding domain. Work by several groups using transgenic and knockout mice has established, among other things, that the primary mediator of many of the effects of RA during development is the RAR/RXRα heterodimer. Based on this observation, the contribution of the AF-1 region in the context of retinoid signaling was assessed by generating transgenic mice expressing wild-type and AF-1 deletion mutants of RXRα. The results indicate that the AF-1 domain is required for the transcriptional activity of the RAR/RXRα heterodimer, but that the ligand-dependent AF-2 domain plays a greater role in effecting most of the RAR/RXRα-mediated downstream events.

The C domain of nuclear receptors contains the DNA-binding domain (DBD) and a weak dimerization function. The approximately 66-amino-acid DNA-binding domain is the most conserved feature among the nuclear hormone receptor family. The DNA-binding domain consists of two zinc-fingers that have been well characterized as protein motifs utilized in many transcription factors for DNA

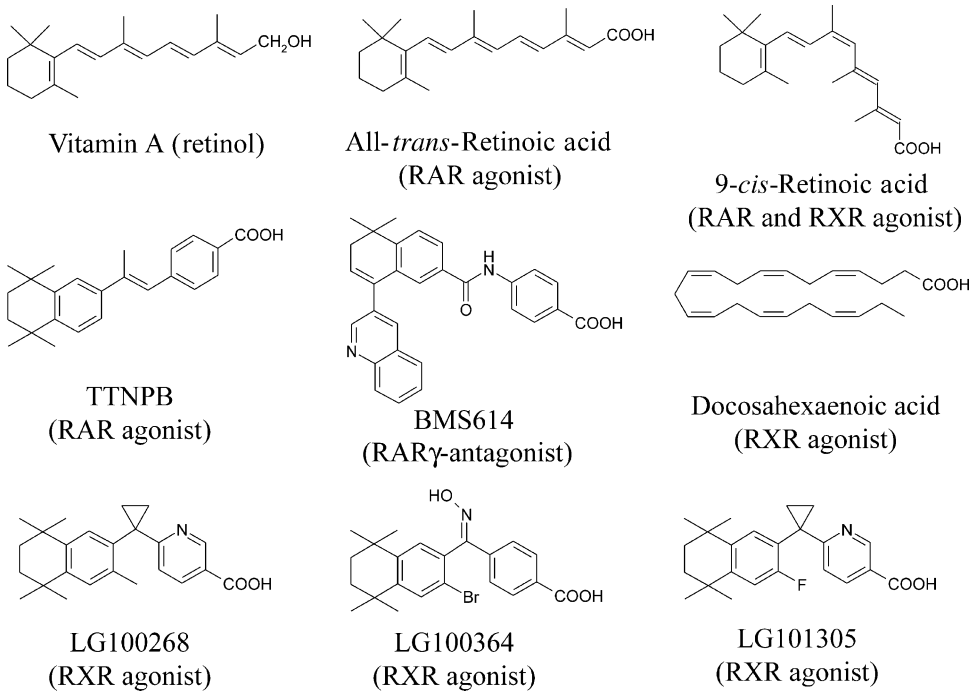

FIGURE 2 Selected retinoid receptor ligands. Several retinoid receptor ligands that represent both endogenous and synthetic small molecule regulators of RAR and RXR are depicted. The structures of vitamin A and the metabolites all-*trans*-retinoic acid and 9-*cis*-retinoic acid are provided as examples of high-affinity endogenous ligands. The other endogenous ligand shown is docosahexaenoic acid, an RXR agonist that may have effects on neural function. Examples of synthetic ligands that are referred to in the text include an RAR agonist, TTNPB, an RAR antagonist, BMS614, and a series of RXR agonists, LG100268, LG100364, and LG101305.

binding and protein–protein interactions. Within the first zinc-finger lies a highly conserved 13-amino-acid region termed the proximal or P-box (Fig. 3). The P-box determines the specificity of binding of the receptor to its half-site. In the second zinc-finger, there is a region, termed the distal (D)-box, that contributes to dimerization. A third functionally characterized region within the DNA-binding domain is an approximately 25-amino-acid carboxy-terminal extension (CTE). In the case of RAR/RXR heterodimer DNA binding, the CTE plays a role in promoting both receptor–DNA interactions and receptor–receptor contact. The DBDs of RARα, and RXRα have been crystallized as a heterodimer complex bound to a direct repeat of AGGTCA with spacing of 1 bp. The results of these studies indicate that both the DNA and the receptors induce conformational changes in each other, resulting in a more stable DNA-bound complex. The ability of nuclear receptors, specifically retinoid receptors, to bind and regulate through multiple DNA elements is therefore a function of both the flexibility of the receptor and the DNA site.

The region that connects the DBD and the ligand-binding domain (LBD) has been referred to as the hinge or D region. This is a highly variable domain both in sequence and in length. As the name implies, the main purpose of this part of the receptor is to connect the DNA-binding component to the ligand-binding domain and to allow a high degree of freedom of movement for these domains.

The most important domain for ligand-mediated activity is the LBD, also referred to as the E region. The LBD contains the ligand-binding site, a strong dimerization function, cofactor interaction sites, and a ligand-dependent activation domain (AF-2). The LBD consists of 12 α-helices that form the ligand-binding pocket. Helix 12, which is at the C-terminus of the LBD, contains AF-2. The ligand-binding domains of RARγ and RXRα have been crystallized in the presence of compounds and, in the case of RXRα, also in their absence. The RXRα LBD structure was solved in the presence of 9-*cis* retinoic acid, and the RARγ LBD structure was determined in the presence of both agonists such as all-*trans* retinoic acid and antagonists such as BMS614 (Fig. 2).

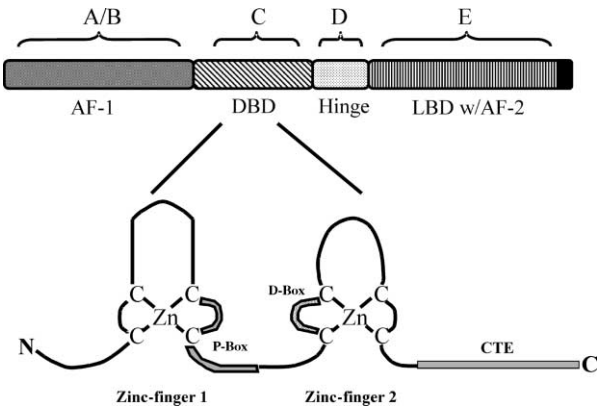

FIGURE 3 Nuclear hormone receptor functional domains. The diagram presents a general view of nuclear hormone receptor structure through delineation of the functional domains. The domains referred to in the text include the N-terminal A/B region that contains a ligand-independent transcriptional activation domain, the C or DNA-binding domain (DBD), the D or hinge region, and the E or ligand-binding domain (LBD). The LBD contains a ligand-dependent transcriptional activation function domain, AF-2 (in black). Shown in greater detail is the structure of the DNA-binding domain. There are two C_2C_2-type zinc-fingers that mediate protein–DNA and protein–protein interactions. Other regions highlighted include the P-box (DNA-binding specificity), the D-box (dimerization), and the carboxy-terminal extension (CTE; DNA and protein interactions).

These studies, along with the structures of other nuclear receptor ligand-binding domains, allowed several conclusions to be made. The 12 α-helices of the LBD form a novel fold termed an anti-parallel α-helical sandwich. In the apo state, helix 12 extends away from the ligand-binding pocket, whereas in the holo state, there is a significant rearrangement of H11, H12, and the region between H1 and H3. The shift in structure of these helices, e.g., H1–H3, H11, and H12, between the ligand-bound active state and the apo- or unbound inactive state has been referred to as a "mouse-trap" mechanism. As implied in this name, once a ligand enters the ligand-binding pocket, H12 is moved into a position in which it essentially traps the ligand in the pocket.

IV. MECHANISM OF ACTION

A. DNA Binding/Heterodimerization

Nuclear hormone receptors have been shown to bind to specific DNA-response element sequences as homodimers or heterodimers. The DNA binding is ligand independent. For RAR and RXR, the retinoid-responsive elements (RAREs and RXREs) that have been isolated in target gene promoters have the consensus half-site sequence AGGTCA organized in different conformations. One type consists of a direct repeat (DR) of the half-site with an intervening spacer of 1, 2, or 5 (DR1, DR2, or DR5, respectively) bp. The DR5 element is the most common RARE. Another element is a palindromic or inverted half-site repeat, and a third response element is an inverted palindrome or everted half-site repeat (Fig. 4). It is likely as well that sequences flanking the half-sites further contribute to the affinity and specificity of receptor binding to these response elements.

RAR binding to DNA requires formation of a heterodimer with RXR. In the RAR/RXR heterodimer, it is the RAR that determines the ligand-dependent activity of the receptors, so that an RXR ligand is unable to activate the heterodimer in the absence of an RAR ligand. In this situation, RAR is referred to as a nonpermissive partner for RXR activity. As mentioned previously, RXR has also been shown to heterodimerize with many other nuclear hormone receptors including TR, VDR, PPARs, FXR,

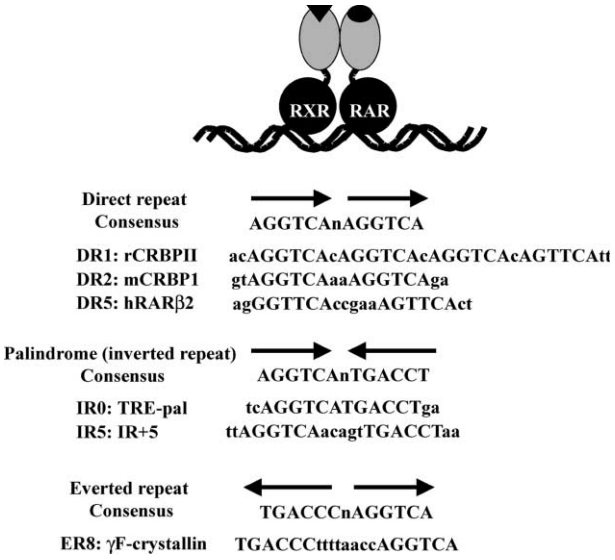

FIGURE 4 Retinoid receptor-response elements. There have been many retinoid receptor-response elements identified in the literature and examples of consensus and selected examples of these elements are shown in this figure. As indicated, the consensus half-site for retinoid receptors is AGGTCA, and the different elements are generated through variable spacing between these half-sites (DR1, DR2, and DR5) or orientation of the half-sites (IR0, IR5, and ER8). The DR1 is taken from the rat cellular retinal-binding protein II (rCRBPII); DR2 from mouse cellular retinal-binding protein I (mCRBPI); DR5 from human RARβ2 gene; IR0 and IR5 are synthetic elements; and ER8 is from the γF-crystallin promoter.

Nurr1, nur77/NGFI-B, and LXRs. Of these, TR and VDR are nonpermissive, and the others are referred to as permissive partners as they can be activated by RXR ligands or the appropriate dimer ligand. In addition to serving as a heterodimeric partner, RXR can bind as a homodimer to DR1 and certain palindrome elements. An important observation relating to how retinoid receptors respond to ligand is that the ternary structure of the receptor bound to DNA dictates the level of response to a given ligand. This is due to the specific RARE contributing to the determination of the affinity and specificity of a compound. This predicts that retinoids and/or small molecules can be synthesized to regulate specific target genes.

Similar to other steroid hormone receptors such as the glucocorticoid receptor, RAR and RXR can also directly or indirectly interact with other transcription factors to regulate target gene expression independent of binding to RAREs or RXREs. This has been demonstrated through inhibition of activator protein-1 (AP-1) and Ca^{2+}/cyclic AMP-response element-binding protein (CREB) activity by RAR and RXR ligands. In the case of RAR, the *trans*-repression can be observed in the absence of the induction of RAR transcriptional activity by certain compounds such as SR11203 and SR11238. It is likely that a combination of retinoid receptor-dependent events contribute to this repression, among which is competition for DNA-binding sites, sequestering of regulatory factors such as CREB-binding protein/p300 (CBP), and direct protein–protein interactions.

B. Transcriptional Regulation

The retinoid receptors function to regulate gene expression through the ability to adapt conformations that induce transcriptional activity in the presence of ligand or repress transcriptional activity in its absence. The gradient of activity that can be achieved, from full repression to full activation, is dependent on the ability of the ligand-binding domain to undergo a series of conformational changes. Much of the work over the past several years has established that large multisubunit protein complexes are recruited to DNA through binding to the receptors. As described previously, in the presence of an agonist, the LBD adopts a conformation in which the AF-2 containing helix 12 moves almost 90° to stabilize the receptor structure and create a binding interface for a class of proteins termed transcription co-activators. Examples of these factors include CBP, p300/CBP-associated factor (pCAF), thyroid hormone receptor-associated proteins (TRAPs), receptor interacting protein 140 (RIP140), and the p160 proteins including steroid receptor co-activator-1 (SRC-1), SRC-2, and SRC-3. A common characteristic of many of these cofactors is that they have intrinsic histone acetyltransferase activity. Another shared feature is the presence of a protein interaction motif composed of the amino acids Leu-X-X-Leu-Leu (LXXLL). This short peptide sequence is sufficient to promote interaction of the cofactor with the receptor. Amino acids flanking the core sequence have been demonstrated to regulate specificity between cofactor and receptor. The co-activator complex, which is predicted to be approximately 2 MDa, contains an overlapping set of these factors and it is likely that they have regulator functions in addition to acetylating histones. The number, diversity, and expression level of co-activators in different tissues correspond to the tissue- and promoter-specific effects of a given ligand on its receptor. Histone acetylation by the co-activator complex recruited to the receptor in the presence of ligand leads to a loosened and more accessible chromatin structure (Fig. 5). This is expected to facilitate and promote expression of the target gene. The co-activator complex also has been demonstrated to contain kinase and methyltransferase activity.

In the absence of an agonist or in the presence of some antagonists, retinoid receptors, like some other nuclear hormone receptors, have been shown to repress the basal activity of a target gene promoter. This silencing ability is attributed to the presence of another large multifactorial complex. Two co-repressor proteins, nuclear receptor co-repressor (N-CoR) and silencing mediator for retinoid and thyroid hormone receptor (SMRT), have been identified as playing a major role in receptor controlled repression. These proteins share structural similarities, such as multiple repression and receptor interaction domains. Analogous to co-activator proteins, consensus SMRT and N-CoR receptor interaction motifs have been isolated with a minimal shared sequence of Leu/Ile-X-X-Leu/Ile-Leu/Ile. SMRT and N-CoR appear to function partly as platform proteins upon which the remainder of the co-repressor complex is assembled. This complex contains multiple proteins that have intrinsic histone deacetylase (HDAC) activity. The HDAC activity is expected to maintain the chromatin structure in a tightly bound state that is incompatible with transcription. The ability of nuclear receptors, such as RAR and RXR, to interact in a ligand-dependent manner with at least two large protein complexes with opposing actions helps to explain the wide range of activities of these receptors

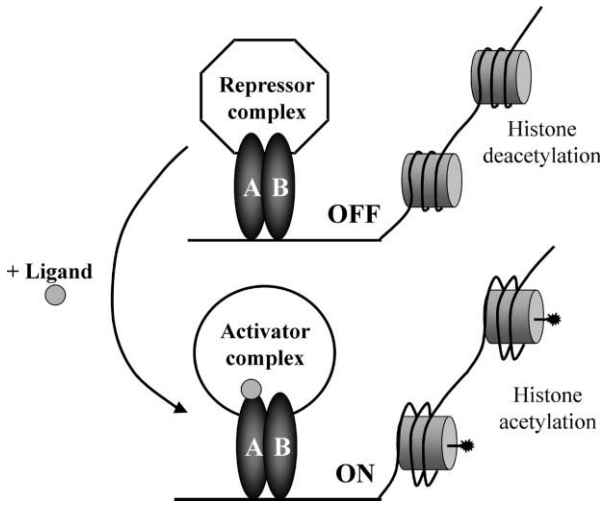

FIGURE 5 Mechanism of transcription regulation by retinoid receptors The diagram illustrates the ligand-mediated activation of transcription by retinoid receptors. A and B refer to any receptor heterodimer or homodimer partner. In the absence of ligand, the receptor dimer is bound to DNA and a large multiprotein co-repressor complex. The co-repressor complex is recruited to the receptors through specific protein–protein interactions between the receptor LBD and short hydrophobic peptide motifs found in various co-repressor proteins, such as SMRT and N-CoR (see text). The repressor complex contains certain enzyme activities, including histone deacetylases, that function to configure the chromatin structure into a state that is inhibitory to transcriptional activation. Upon ligand binding, the repressor complex is displaced through recruitment of a multiprotein activator complex. Similar to co-repressors, the co-activator complex is recruited through protein–protein interactions between the receptors and well-defined peptide motifs in the co-activator proteins. The co-activator complex contains enzyme activities, such as histone acetylases, that alter the chromatin structure to a more transcriptionally permissive state.

and their attractiveness as targets for therapeutic intervention.

The importance of the interaction of RAR with the co-repressors SMRT and/or N-CoR can be seen in the different responses of patients with acute promyelocytic leukemia (APL) to all-*trans*-retinoic acid therapy. Those patients with a translocation of the promyelocytic leukemia (PML) gene with the RARα gene (PML–RAR) respond well to RA, whereas those with a translocation of the promyelocytic leukemia zinc-finger (PLZF) gene with RARα (PLZF–RAR) respond poorly. This can be attributed to the ability of both PLZF and RAR to interact with co-repressors as opposed to just RAR in the PML–RAR fusion. The PLZF–co-repressor interaction is ligand independent and thus treatment by RA has minimal effect. This finding is discussed below in greater detail.

V. RECEPTOR PHYSIOLOGY

Vitamin A and retinoids have been shown to be essential for proper embryonic development and many physiological functions. Some of the characteristics of vitamin A deficiency include blindness, immune system dysfunction, infertility, congenital malformations, heart malformation, and epithelial hyperkeratinization. Vitamin A excess also can be detrimental and lead to birth defects. The effects of retinoids can be classified as receptor mediated and receptor independent. The use of retinoid receptor-specific ligands, cells from receptor null mice, overexpression of receptors, and overexpression of dominant-negative receptors have all contributed experimentally to linking retinoid effects with receptor-mediated effects. This next section provides a brief overview of a selected set of receptor-dependent activities that contribute to proper development and homeostasis, beginning with a review of the phenotypes of the various receptor null mice that have been made.

A. Receptor Mutant Mice

For the RARs, mice lacking the major isotypes have been generated. These mice have also been crossed with one another to generate compound mutants. RARα −/− mice died early after birth and showed signs of degenerative testis. Additional defects include homeotic transformations and congenital defects. RARγ −/− mice also have these defects, leading to improper development of the skull, vertebrae, and ribs. RARγ −/− mice also have decreased viability. RARβ −/− mice display some minor changes including some ocular and long-term memory defects. RARα −/− and RARγ −/− male mice are also sterile. The double mutants of RARα/β and RARα/γ, in which both alleles of a receptor subtype are deleted to maximize phenotypic effects that otherwise may be masked by receptor redundancy, show many more of the expected phenotypes that are observed in vitamin A-deprived animals. RXRα −/− mutant mice exhibit embryonic lethality, due to defects in placenta and heart. These mice also have defects related to eye development. RXRβ −/− mice show male sterility due to improper spermatogenesis, and RXRγ −/− mice exhibit no major phenotypes although long-term memory may be affected. Both RXRβ −/− and RXRγ −/− are viable.

B. Hematopoietic Differentiation

The observation that retinoic acid and its metabolite derivatives could induce differentiation of a number

of human leukemic cell lines suggested that retinoids and their receptors would play an important role in physiological myeloid cell development and differentiation. RAR/RXR heterodimers function as modulators of granulocyte differentiation depending on the presence or absence of a ligand. In the presence of retinoic acid, RAR activity promotes granulocyte differentiation, whereas unbound RAR is an inhibitor of promyelocyte differentiation. The role of RARα as a regulator of myeloid differentiation is further supported by the inability of promyelocytes that harbor translocations between RAR and PML and/or PLZF to differentiate, resulting in acute promyelocytic leukemia. The cells with the PML-RAR fusion can be treated with RA and be induced to differentiate, indicating RAR activity as a primary mediator of cellular differentiation in the myeloid system. RAR activity has also been shown to be important in regulation of neutrophil maturation.

C. Cell Proliferation/Apoptosis

The ability of retinoids to regulate cell cycle progression, profileration, and apoptosis has been well studied, although the mechanisms supporting the observations are not completely known. The inhibitory effect of the RARs and RXRs on cell growth can generally be attributed to their regulation of a number of proteins involved in the process of cell cycle and cell death. The targets of retinoid receptor activity include the AP-1 transcription factor, c-Myc, and retinoblastoma gene product Rb. These proteins are important in controlling the G1 to S phase of the cell cycle, and retinoid inhibition generally occurs at this transition stage.

A primary role for retinoid receptors in apoptosis was found when certain leukemic cells were treated with retinoic acid and other retinoid receptor-selective ligands. It was found that RAR and RXR ligands, when added together to HL60 cells, a promyelocytic cell line, induced apoptosis. These effects were receptor dependent and involved the down-regulation of certain anti-apoptotic proteins. In the development of myeloid cells from bone marrow progenitor cells, RXR also plays an important role through the regulation of apoptosis. In the absence of RXR activation, or down-regulation of RXR expression, myeloid cells undergo less apoptosis. RARs and RXRs have also been shown to regulate apoptosis in T and B lymphocytes. In T cells, rexinoids inhibit T-cell-receptor-mediated apoptosis by inhibiting the expression of the Fas ligand. Proper timing and regulation of cell death are critical in lymphocyte development to eliminate those cellular clones that would otherwise be self-reactive and lead to autoimmunity.

D. Reproduction

Vitamin A has been shown to be important in spermatogenesis and maturation of spermatozoa. Vitamin A deficiency leads to defective spermatogenesis and subsequent sterility. In agreement with this finding, RARα −/−, RARγ −/−, and RXRβ −/− male mice are sterile. These data indicate that the primary mediators of retinoid signaling in the testis are likely to be the RARα and RXRβ receptors and that these receptors are not redundant for proper reproductive development. These mice are sterile due to testicular defects, including degeneration of the seminiferous epithelium, in the case of RARα −/− mice. In the RXRβ −/− mice, the male sterility is due to defective spermatozoa and lipid accumulation in Sertoli cells.

E. Development

The importance of retinoid receptors to proper development and differentiation of tissues is well defined in experiments relating to limb formation as well as the finding that retinoids are teratogenic in humans. Studies in chickens show that placement of beads containing RA into developing limb bud sites can initiate novel developmental programs leading to a new limb structure. Consistent with these results, RAR/RXR antagonists can inhibit limb formation. Multiple limb abnormalities are also seen in RARα −/−, RXRα −/−, and double mutant RARα/RXRα, RARβ/RXRα, and RARα/RARγ mice. The mechanism of retinoid receptor function in limb development involves the induction of a cascade of gene expression, with induction of hox genes Hoxb-6 and Hoxb-8, which in turn lead to up-regulation of Sonic Hedgehog, which consequently up-regulates the bone morphogenic protein BMP-2. These proteins have been shown to be key factors in the process of limb development.

F. Neural Development

Retinoids have been long associated with the differentiation of neurons and the development of the nervous system. The expression patterns of retinoid receptors in the central nervous systems throughout development and into adulthood suggested a role for these receptors in regulating certain neural functions. Data from a variety of sources including phenotypes

associated with vitamin A deficiency, RAR/RXR mutant mice, and treatment of animals with retinoid receptor antagonist demonstrate an essential role for retinoid signaling in normal hindbrain development.

The results from RARβ/RXRβ, RARβ/RXRγ, and RXRβ/RXRγ double mutant mice also confirm a role for these receptors in the development of normal locomotor function. This defect in motor function is likely due to a reduction in expression levels of the dopamine receptors D1 and D2. This is consistent with RAR/RXR heterodimers binding to and regulating the promoter of the D2 receptor *in vitro*. These findings also hint at a link between retinoid receptor signaling and such neural disorders as Parkinson's disease and schizophrenia. Recent work that describes the search for endogenous RXR ligands has identified docosahexaenoic acid as a putative ligand. The ability of DHA to activate RXRs and the presence of learning abnormalities in DHA-deficient animals correlate well with the mutant mouse data and further support a role for retinoid receptors in neural development.

G. Retinoid Receptors in Skin

The effects of vitamin A deficiency or excess on skin growth and differentiation have been known for a number of years. A lack of vitamin A leads to hyperkeratosis, which could be reversed upon addition of vitamin A. An excess of vitamin A, however, can result in inhibition of the process of keratinization. Since the levels of vitamin A were shown to be important regulators of skin processes, this led to the use of natural retinoic acids, including AtRA and 13-*cis*-RA, as a treatment for skin disorders including acne and psoriasis and for correcting sun-induced skin damage. The use of retinoic acid, unfortunately also has some undesired side effects including irritation, dryness and peeling of the skin, hair loss, and teratogenicity. Some of the skin-related side effects might be partly due to binding to the intracellular protein cellular retinoic acid-binding protein types I and II. Recent experiments *in vitro* and in animal models has established that the major isoforms of the receptors expressed in adult skin are RARγ and RXRα, although the other isoforms are expressed at varying levels during development. The ability to target RARγ specifically with synthetic agonist or antagonists has the promise of providing the benefits of retinoic acid treatment without the side effects. Indeed, the successful use of RARγ agonists in the treatment of acne and psoriasis has been reported.

VI. RXR HETERODIMERIZATION

As introduced earlier, RXR functions as an obligatory heterodimeric partner for a large number of nuclear hormone receptors. Among the receptors that RXR can heterodimerize with are RARs, TR, VDR, PXR/SXR, PPARs, LXRs, FXR, CAR, and Nurr. Of these, PPARs, LXRs, FXR, PXR/SXR, CAR, and Nurr are permissive to the activation of the heterodimer via binding of an RXR ligand. The other receptors, RAR, TR, and VDR, are not permissive to activation by RXR ligands. The molecular mechanism for whether a heterodimer is permissive or not appears to depend on the recruitment of the co-repressor complex by the RXR partner in the absence of an agonist. In nonpermissive heterodimers such as RAR/RXR, even though an RXR ligand may bind, it is not sufficient to activate the complex, most likely due to an inability to displace the co-repressor from RAR. In this same complex, however, if an RAR agonist is added along with an RXR agonist, the net activation is higher than with the RAR compound alone. In permissive heterodimers, both receptors bind the co-repressor complex weakly so addition of an RXR agonist is sufficient to displace the co-repressor from the heterodimer and thus induce activity. Since these permissive heterodimers represent an important extension of the function of retinoid receptors, this section provides a general overview of the function of the PPAR, LXR, FXR, and xenobiotic receptor (PXR/SXR and CAR) heterodimers. The nonpermissive heterodimer receptors TR and VDR are not discussed, as other than mediating the target specificity through DNA binding of these heterodimers, there is as yet no other physiological role for RXR in these cases. RAR heterodimer function has previously been discussed and the Nurr receptors are also not included, as a physiological role for a Nurr/RXR heterodimer has not yet been established.

A. PPAR/RXR

The PPARs have been shown to be important regulators of lipid metabolism and adipogenesis. There are three isoforms, α, δ, and γ, that activate transcription by binding to promoter elements as heterodimers with RXR. The PPAR/RXR heterodimers can bind primarily to DR1 elements. Natural and synthetic ligands have been identified for all three PPAR isoforms and, along with receptor mutant mice, have allowed for detailed study of the function of these receptors. PPARα is involved in

the breakdown of fatty acids and PPARγ has been shown to be important in cellular differentiation of adipocytes and other cell types and to play a role in insulin sensitization, and thus diabetes, as well as atherosclerosis. PPARδ activity has also been linked to lipid metabolism. As PPARs are permissive to RXR ligand activation, it is possible to regulate the heterodimer through either a PPAR-selective agonist or an RXR ligand. Consistent with this, a combination of ligands for both PPAR and RXR leads to synergy in transcriptional activation. Acting presumably through the PPAR/RXR heterodimer, RXR agonists have been shown to have significant effects on insulin sensitization and therefore make RXR a potential therapeutic target for treatment of type II diabetes. Based on the finding that the DNA sequence can influence the activity of a compound, it is also possible that RXR ligands that potentiate the PPARγ/RXR heterodimer activity on specific target genes without activating RXR promiscuously can be found.

B. LXR/RXR

Liver X receptors LXRα and LXRβ function to regulate cholesterol homeostasis and fatty acid metabolism. LXRα −/− mice have been shown to have defects in the process of converting dietary cholesterol to bile acids in the liver due to a lack of activation of expression of the cholesterol-7α-hydroxylase (CYP7A1) enzyme. Additional defects include a reduced expression of genes involved in lipogenesis such as sterol regulatory element-binding protein 1 (SREBP1) and fatty acid synthase. An additional target for LXR/RXR regulation in the macrophage and intestine is the ATP-binding cassette A1 (ABCA1) transporter protein, which is involved in reverse cholesterol transport. Activation of ABCA1 and other genes involved in cholesterol efflux by LXR agonists has been shown to lead to a reduction in cholesterol absorption. Furthermore, LXR agonists have also been demonstrated to increase the circulating levels of high-density lipoprotein cholesterol. Consistent with the various functions of LXRs in regulating cholesterol and lipogenesis, recent results also implicate LXR agonists as having anti-atherosclerotic effects.

As with PPARs, LXRs are permissive to RXR activation and RXR agonists can elicit similar biological responses to LXR-specific agonists including up-regulation of ABCA1 and SREBP1 and inhibition of atherosclerosis in animal models. Consistent with the action of LXR or RXR agonists, both LXR null mutant mice and mice with RXR deleted from hepatocytes exhibit an increase in triglycerides. Additional evidence for a role for retinoid receptors in fatty acid synthesis comes from the observation that patients treated with RXR agonists have elevated triglycerides. The function of the LXR/RXR heterodimer as determined through multiple studies therefore represents an important point of pharmacological intervention, through the LXR receptors and/or RXR receptor, for cholesterol regulation, lipid homeostasis, and control or prevention of atherosclerosis.

C. FXR/RXR

The FXR was identified through homology screening and also by using RXR as bait in a yeast two-hybrid protein interaction assay. FXR functions as a permissive heterodimer with RXR and binds to an inverted repeat-1 DNA element. The finding that bile acids could function as ligands for FXR has established a role for FXR/RXR in bile acid metabolism. Targets for FXR regulation include ileal bile acid-binding protein and bile salt efflux pump in the intestine and CYP7A1 in the liver. FXR inhibits the expression of CYP7A1 and therefore opposes the function of LXR on this target, although the mechanism of how this repression occurs is not clear. Studies have demonstrated that an FXR agonist, when administered to rats, resulted in a lowering of triglycerides. The mechanism of how triglyceride production might be regulated by FXR is not yet known. Further experiments have demonstrated that guggulsterone, a steroid produced by the guggul tree and used for over 2500 years as a treatment for a number of disorders including high cholesterol, functions in the body primarily through FXR. The cholesterol-lowering effects of guggulsterone can be linked to its activity as an antagonist of FXR. The findings with FXR agonists and antagonists indicate that the FXR/RXR heterodimer also represents an important pharmacological intervention point for regulating cholesterol and triglyceride levels.

D. PXR/SXR and CAR

The xenobiotic sensing receptors PXR/SXR and CAR have been shown to regulate responses to foreign chemicals in the body, as well as endogenous compounds such as bile acids. The target genes for these receptors include the cytochrome P450 CYP3 genes for PXR/SXR and CYP2 genes for CAR. There is some overlap between the targets and functions of

these receptors, although important pharmacological and species differences exist. Implications for the regulation of these genes include mediating drug–drug interactions and elimination of toxic compounds from the body. As stated previously, these receptors bind to DNA-response elements (DR5) as heterodimers with RXR and are permissive to activation by RXR ligands. Although RXR ligands can activate the heterodimers on isolated response elements in transfection experiments, currently there is no conclusive evidence to suggest that synthetic or endogenous RXR ligands have a physiological role in regulating PXR/SXR or CAR target genes since it is unclear which heterodimer partner the compounds are working through.

As demonstrated in the previous sections, RXR heterodimers play important roles in many natural and disease states. A general statement regarding permissive versus nonpermissive heterodimers based on recent observations is that the RXR-permissive heterodimers appear to be "lipid" sensors that control many metabolic pathways including glucose, fatty acid, bile acid, and cholesterol signaling. Nonpermissive heterodimers alternatively regulate responses to classic endocrine hormones including steroids and nonsteroid hormones.

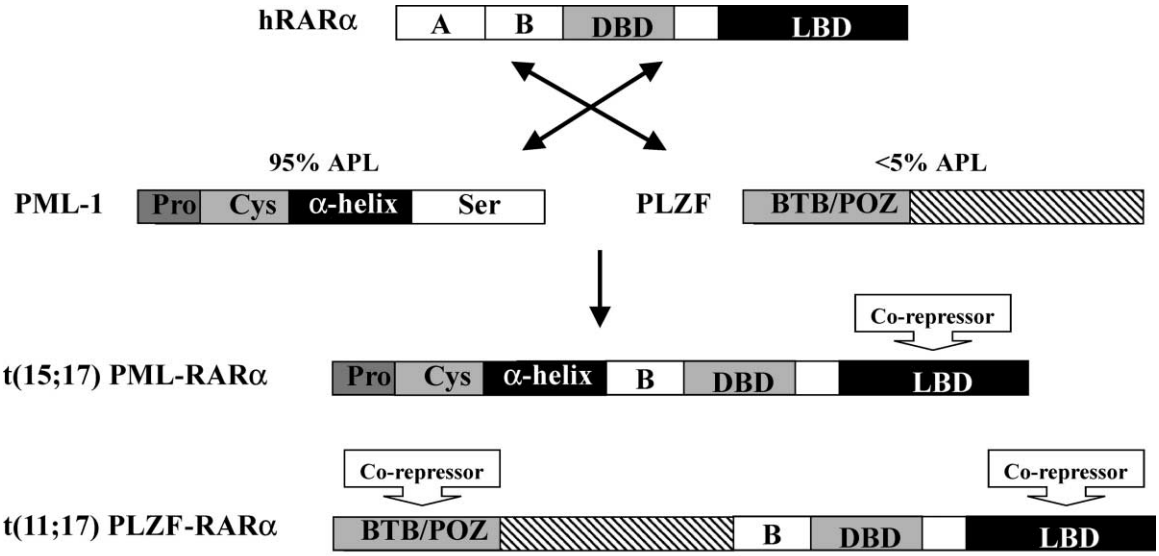
VII. RETINOID RECEPTORS AND CANCER

A. Acute Promyelocytic Leukemia

As described previously, the role of retinoids and retinoid receptors in regulating cell proliferation and differentiation is well established. As a result of these studies and the finding that translocations of the RARα gene are involved in certain leukemias, a clear link between retinoid signaling and cancer has been established. APL is characterized by abnormal proliferation of promyelocytes in the bone marrow and represents 10–15% of acute nonlymphoid leukemias. Experiments in which APL cells were treated with a variety of compounds demonstrated that AtRA could induce differentiation of these leukemic cells into granulocytes. This key finding has greatly improved the cure rate among patients with this form of leukemia and indicated that retinoid receptor signaling was involved. The majority of APL cases (95%) have been shown to develop as a result of a translocation between the RARα gene, which is on chromosome 17, and the PML gene, which is on chromosome 15. The resulting fusion proteins are shown in Fig. 6. The PML–RARα fusion proteins contain various lengths of the PML protein fused to a point in the second intron of RARα. The PML–RARα protein contains the N-terminus, the A domain of RARα, and the C-terminal parts of the PML protein. Experiments introducing a transgenic PML–RARα gene into mice result in development of leukemias that are similar to APL and confirm that this gene product is responsible for both the leukemia and the sensitivity of the cells to retinoic acid treatment.

The PML–RAR protein may inhibit myeloid differentiation in several ways. It is possible that PML–RAR inhibits the normal function of retinoic acid signaling by binding to and sequestering RXR, thus inhibiting the function of heterodimers reliant on RXR. Normal PML function may be inhibited through the disruption by PML–RAR of a nuclear structure known as promyelocytic organizing domains (PODs) or PML bodies. PODs have been implicated as sites of protein ubiquitination and turnover as well as storage of cellular factors involved in transcription. One important observation of PML–RAR leukemic cells is that upon treatment with RA, the normal nuclear organization of PODs is regained. Additional studies have demonstrated that the function of PML in regulating apoptosis is also impaired in the PML–RARα-expressing promyelocytes.

In addition to the PML–RARα translocation, APL has been characterized by two other translocations involving RARα that occur in 1–2% of APL cases. Translocation of the RARα gene with the PLZF gene on chromosome 11 results in a PLZF–RARα fusion protein, whereas a translocation with the nucleophosmin (NPM) gene on chromosome 5 results in a NPM–RARα fusion protein. The PLZF–RARα functions in a manner similar to PML–RARα to inhibit normal retinoid signaling and possibly to antagonize the activity of PLZF. Unlike PML–RARα cells, PLZF–RARα cells are unresponsive to retinoic acid treatment. Recent work has implicated the recruitment of a co-repressor protein complex, described in previous sections, to the fusion protein. The co-repressor SMRT has been shown to interact with both PLZF and RARα so that treatment with RA is not sufficient to disrupt the co-repressor–PLZF–RARα complex. Since PML does not interact with co-repressors, the addition of RA can lead to the displacement of the co-repressor complex from PML—RARα and restore transcriptional activity. These data highlight the importance of considering both the retinoid receptors and their cofactors when examining the normal physiology of retinoid signaling as well as the treatment of disease states.



Fusion protein	RA responsive
t(15;17) PML-RARα	Yes
t(11;17) PLZF-RARα	No

FIGURE 6 RAR translocations and APL. The fusion proteins resulting from translocations between the human RARα (hRARα), PML, and PLZF genes are shown. As indicated, 95% of acute promyelocytic leukemias are the result of a translocation between hRARα and PML-1, generating a fusion protein that contains up to the serine-rich region in PML and all but the A region of RARα. Since the fusion protein contains the RAR LBD, t(15;17) APL can be treated with retinoids such as AtRA. The co-repressor complex is shown bound to the RAR LBD, and presumably retinoids are effective through displacement of this complex. Another 5% of APL is due to a translocation with the PLZF gene. Binding of co-repressor to PLZF is not affected by retinoids, and thus t(11;17) APL patients are resistant to retinoids.

B. Breast Cancer

Based on the role of retinoid receptors in regulating multiple cellular processes, another pharmacological target for retinoids has been the treatment of breast cancer. Both RARs and RXRs are expressed in normal and cancerous breast cells and regulate important functions in these cells including proliferation, differentiation, and apoptosis. Studies using the retinoids AtRA and 9-*cis*-RA have demonstrated that activation of the RAR/RXR heterodimer in both breast cell lines and in animal models of breast cancer results in an inhibition of tumorigenesis. Based on the promising results obtained with the natural retinoids, synthetic retinoids and rexinoids that have reduced toxicity and unwanted side effects have been tested for breast cancer prevention and treatment. The results from prevention of breast cancer with these compounds in animal models indicate that synthetic, receptor-selective compounds that regulate RAR/RXR will prove to be an important addition to the currently available treatments for this disease.

VIII. SUMMARY

Retinoid signaling is an essential part of normal development and physiology. The discovery that RAR and RXR, members of the nuclear hormone receptor protein family, could mediate many of the *in vivo* effects of vitamin A and its metabolites has helped to uncover the mechanisms by which these effects are generated. The temporal and spatial expression of the retinoid receptors, isoforms, and many splice variants dictates the response to retinoids. It is clear that DNA binding to various response elements and the ability to recruit either co-activator or co-repressor complexes to the DNA are the ultimate result of natural or synthetic ligand addition.

The diversity of responses to retinoids and other physiological ligands is increased by the ability of RXR to function as a master regulator of nuclear receptor signaling through heterodimerization with a number of the receptors. The work identifying the retinoid receptors, characterizing their mechanism of action and role *in vivo*, has greatly influenced the knowledge of how retinoid function may be altered in disease states and how medicine can intervene to correct these defects.

Glossary

dimerization The generation of a multiprotein functional unit comprising proteins of the same class. A monomer is a single unit, and a dimer is two units. In homodimers, the receptors are the same, whereas in heterodimers the receptors are different. This represents a central concept in the function of nuclear hormone receptors, as the majority work as heterodimers or homodimers.

ligand agonist A small molecule that upon binding to the receptor induces a conformation in the ligand-binding domain that results in activation of transcription, leading to an increase in gene expression.

ligand antagonist A small molecule that upon binding to the receptor induces a conformation in the ligand-binding domain that results in an inhibition of transcription activation by agonists, leading to a decrease in gene expression.

ligand inverse agonist A small molecule that upon binding to the receptor induces a conformation in the ligand-binding domain that results in an inhibition of the basal ligand-independent activity of the receptor, leading to a decrease in gene expression.

nuclear hormone receptors These proteins belong to a class of transcription factors that regulate gene expression in response to binding of small molecules called ligands. The ligand-bound receptor can activate or repress gene expression by binding to specific DNA-response elements. In the absence of ligand, these receptors generally repress gene transcription.

response element A short region of DNA that is bound by a transcription factor and the deletion or addition of which affects the transcription of genes containing such elements. For nuclear hormone receptors, most response elements consist of two 6 bp half-sites that have variable spacing and orientation with respect to each other.

retinoids Any of a number of small molecules that can bind to and regulate the activity of the nuclear hormone retinoic acid receptor.

rexinoids Any of a number of small molecules that can bind to and regulate the activity of the nuclear hormone retinoid X receptor.

transcription The process of synthesizing RNA from DNA directed by the activities of the enzyme RNA polymerase. RNA is subsequently made into protein through a process referred to as translation. The transcription process consists of three parts: initiation, elongation, and termination. Transcription factors are those proteins that can bind to specific DNA elements and regulate the process of transcription by activating or repressing RNA polymerase function through different mechanisms.

Regulators of G-Protein Signaling (RGS) Superfamily

DAVID A. SIERRA AND THOMAS M. WILKIE

University of Texas Southwestern Medical Center, Dallas

G-protein signaling is dependent on a cycle of GTP binding on the G-protein α-subunit and GTP hydrolysis, which activate and inactivate signaling, respectively. Regulators of G-protein signaling (RGS) proteins are GTPase accelerating proteins for specific classes of G-protein α-subunits, serving as feedback inhibitors of G-protein signaling pathways by accelerating the rate of inactivation. RGS proteins may also facilitate signaling by serving as scaffolds and effector proteins. Thus, RGS proteins sharpen the kinetic response of both activation and termination of G-protein signaling in cells.

I. INTRODUCTION

G-protein signaling is regulated by the combined action of receptors and regulators of G-protein signaling (RGS) proteins to control intracellular responses to extracellular signals throughout an animal's lifetime. G-proteins regulate numerous essential functions in higher eukaryotes, including gametogenesis, fertilization, cell motility, feeding behavior, sleep, responses to light, and other environmental and hormonal cues. Signaling via heterotrimeric G-proteins initiates with agonist binding to heptahelical receptors. The role of heterotrimeric G-proteins, composed of α-, β-, and γ-subunits, is to transduce the signal received on agonist binding to the regulation of effector proteins and their downstream second-messenger systems. Signaling specificity is provided by the distinct receptor, G-protein α-subunit, and RGS protein that regulate the pathway.

II. RGS SUPERFAMILY: STRUCTURE AND PHYLOGENETIC RELATIONSHIPS

RGS proteins are expressed in all higher eukaryotes, except for plants, together with all other components of G-protein signaling complexes, including agonists, heptahelical receptors, heterotrimeric G-protein α-, β-, and γ-subunits, and effector proteins. The first RGS protein was discovered in baker's yeast and found to be an important feedback inhibitor of the mating response to pheromone. Yeast of the opposite mating types recognize each other's proximity and initiate the first steps of conjugation via a G-protein signaling pathway. In the absence of the RGS protein termed Sst2 (supersensitive to pheromone), yeast could not recover from pheromone-induced cell cycle arrest in preparation for mating. Several years later, sequence similarity to the yeast Sst2 protein was independently discovered in several RGS proteins by three groups studying B-cell maturation, vesicular transport, and roundworm motility and egg laying. Similarity within these proteins was restricted to a region of approximately 130 amino acids, termed the RGS domain (Figs. 1 and 2). Subsequent experiments demonstrated that the RGS domain of RGS proteins displayed GTPase accelerating protein (GAP) activity toward the corresponding G-protein α-subunits expressed in yeast, worms, and mammals.

The superfamily of RGS proteins expressed in metazoan organisms now contains five families of RGS-like proteins, including RGS, rgRGS, RGS-PX, GPRK, and AKAP-RGS (Fig. 1 and Table 1). Proteins in the RGS and rgRGS families have very similar three-dimensional structures but the amino acid sequences are only distantly related between the families (Fig. 2). Interestingly, the GAP activity of proteins within each RGS-like family is restricted to a specific class of G-protein α-subunit, indicative of regulatory specificity within different G-protein signaling pathways (Table 1).

A. The RGS Domain

Mammals express 22 RGS proteins that can be grouped into five subfamilies based on sequence

Until recently, the function of salicylates in plants was obscure; thus, they have traditionally been classified as secondary metabolites. By contrast, the pharmacological benefits of salicylates in humans are well documented. Aspirin (acetylsalicylic acid), for example, at various doses, protects against heart attack and stroke, inhibits blood clotting, and reduces pain, fever, and joint swelling. Only during the past 15 years have researchers discovered that SA serves important functions in plants. It is a signaling molecule that activates heat production, induces disease resistance, and, possibly, stimulates flowering.

II. SA-REGULATED PROCESSES IN PLANTS

The first conclusive demonstration that SA functions as an endogenous signaling molecule came from Raskin and co-workers, who were studying thermogenesis in the voodoo lily (*Sauromatum guttatum*). On the day of flowering, there are two distinct periods during which the temperature of the spadix (floral spike) can increase by approximately 14°C. Prior to each thermogenic event, a large, transient increase in endogenous SA levels is detected. Confirming the role of SA as the signal for this phenomenon, it has been shown that exogenously supplied SA, as well as its derivatives acetylsalicylic acid (ASA) (Fig. 1) and 2,6-dihydroxybenzoic acid, can induce thermogenesis in explants of the voodoo lily spadix, whereas 31 structurally similar compounds do not have this effect.

SA also has been shown to play an important signaling role in plant disease resistance, and the mechanisms through which it activates this phenomenon have been studied extensively. The ability of a plant to recognize a pathogen is sometimes regulated by the direct or indirect interaction between the products of a plant resistance (*R*) gene and a pathogen avirulence (*avr*) gene. If either of these gene products is lacking, the plant fails to activate defenses in a timely and/or effective manner and the pathogen colonizes the plant. By contrast, when both gene products are present, a wide variety of resistance responses are activated in the inoculated leaf. These may include increases in reactive oxygen species (ROS), strengthening of cell walls, and synthesis/activation of various defense-associated proteins, such as the pathogenesis-related (PR) proteins. In addition, resistant plants frequently develop a hypersensitive response (HR) (Fig. 2). Subsequent to these local responses, uninoculated leaves usually exhibit increased *PR* gene expression and systemic acquired resistance (SAR).

It has been known for many years that treatment of tobacco with SA or ASA enhances resistance to tobacco mosaic virus (TMV) and induces PR protein accumulation. SA has more recently been shown to activate *PR* gene expression in several plant species and to enhance resistance to a variety of pathogens. The first direct evidence that SA is an endogenous signal for disease resistance came from studies of pathogen-infected tobacco and cucumber plants. In tobacco resisting infection by TMV, SA levels increased 20- to 50-fold in inoculated leaves, with these increases preceding or paralleling the accumulation of *PR* gene transcripts. SA levels also increased 2- to 10-fold in the uninoculated leaves, and this rise correlated with increased systemic *PR* gene expression. Similarly, in cucumber infected with *Colletotrichum lagenarium*, *Pseudomonas syringae*, or tobacco necrosis virus, 10- to 100-fold increases in SA levels were detected in the phloem sap of infected leaves prior to SAR development and activation of a defense-associated peroxidase in the uninoculated tissue.

Analyses of SA-deficient tobacco and *Arabidopsis* plants [due to inhibition of the SA biosynthetic pathway or expression of the salicylate hydroxylase (SH)-encoding *nahG* transgene] have further confirmed that SA plays an important role in activating disease resistance. These plants fail to develop SAR or express *PR* genes in the uninoculated leaves following pathogen infection. Furthermore, they are susceptible to infection by pathogens that they normally would resist and exhibit heightened susceptibility to those that cause disease. HR development is also delayed in TMV-infected SH-expressing tobacco and the lesions that form grow substantially larger than do those on comparable wild-type (wt) plants. Based on these results, SA may also regulate cell death and pathogen containment. Consistent with this possibility, inhibition of the SA biosynthetic enzyme phenylalanine ammonia lyase (PAL) in soybean suspension cells blocks pathogen-induced HR cell death. Additionally, genetic analyses of certain *Arabidopsis* mutants reveal that SA is required for expression of a constitutive cell death phenotype that mimics an HR.

Whether SA is a mobile signal that induces defense responses in uninfected tissues has been the subject of much debate. The timing at which SA levels increase and SAR develops in both tobacco and cucumber is consistent with this possibility. Furthermore, SA clearly is mobile; it has been detected in the phloem

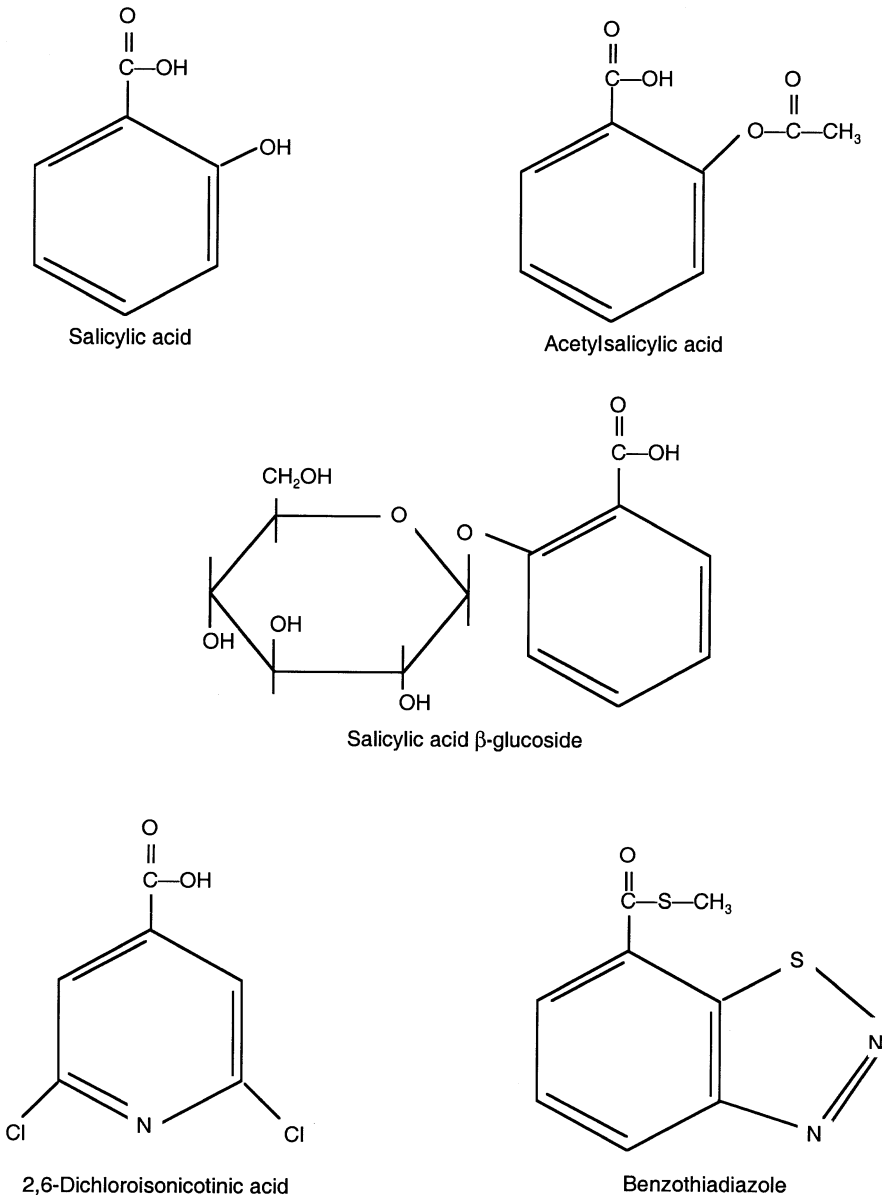

FIGURE 1 Salicylic acid and its derivatives or functional analogues. Salicylic acid and its derivative acetylsalicylic acid (aspirin) induce *PR* expression and systemic acquired resistance in plants; in contrast, salicylic acid β-glucoside is thought to be a storage form of salicylic acid. The synthetic compounds 2,6-dichloroisonicotinic acid and benzothiadiazole *S*-methyl ester, which exhibit structural similarity to salicylic acid, also induce defense responses in plants. In particular, benzothiadiazole *S*-methyl ester has been used commercially in the field to protect crop plants against certain pathogens.

sap of pathogen-infected cucumber and tobacco leaves. Tracer studies using $^{18}O_2$ or the SA precursor [^{14}C]benzoic acid (BA) also have suggested that much of the SA in the uninoculated leaves is transported there from the inoculated leaves. Alternatively, SA may be converted into methylsalicylate, a volatile compound that could serve as an airborne SAR signal.

A growing body of evidence, however, suggests that SA is not the long-distance SAR signal. In *P. syringae*-infected cucumber, the SAR signal is transmitted from the inoculated leaf several hours

FIGURE 2 The hypersensitive response (right) and systemic acquired resistance in tobacco following TMV infection. Tobacco plants resisting infection by TMV initially develop a hypersensitive response, characterized by necrotic lesions at the sites of pathogen entry. Subsequently, a broad-based, long-lasting systemic acquired resistance develops in uninoculated tissues. A secondary viral infection of the uninoculated leaves, occurring several days after the initial infection, results in much smaller lesions (left) as compared with those induced by the primary infection. The leaves are shown 4 days after infection. Reprinted from *Trends in Plant Science*, Vol. 2, pp. 266–274 (1997) (Durner *et al.*), with permission from Elsevier Science.

before an increase in SA levels can be detected in the petiole of the inoculated leaf. In addition, wild-type scions (the grafted tops of chimeric tobacco plants) develop SAR and express *PR* genes following TMV infection of SH-expressing or PAL-suppressed rootstocks. Because SA accumulation is not completely abolished in these rootstocks, it is possible that a small amount of SA travels to the scion and induces SAR. However, transgenic tobacco rootstocks that constitutively accumulate SA due to expression of the cholera toxin A1 subunit do not induce *PR* expression or SA accumulation in wt scions. Although these results suggest that SA is not the long-distance SAR signal, SA clearly plays an important downstream role in the defense pathway. SA-deficient scions fail to exhibit *PR* gene expression and/or SAR following infection of wt rootstocks.

Induction of flowering in various *Lemna* species, as well as in *Arabidopsis thaliana*, *Impatiens balsamina*, *Onacidium*, and *Pisita stratiotes* L, and flower bud formation in tobacco tissue cultures have been associated with SA treatment, thus SA has been proposed to be the inductive signal for flowering. However, other evidence does not support this conclusion. For example, SA levels are comparable in flowering and vegetative *Lemna* plants, and the ability of SA to stimulate flowering in several plant species appears to be a nonspecific effect. Thus, whether SA plays any role in flowering remains unclear.

III. SA METABOLISM

A large body of evidence suggests that SA, many phytoalexins, and lignin are synthesized by the shikimate–phenylpropanoid pathway. The first step of this pathway, which is rapidly induced following pathogen infection, is the conversion of phenylalanine (Phe) to *trans*-cinnamic acid (*t*-CA) by PAL. Depending on the plant species, SA is then generated from *t*-CA through one of two intermediates, benzoic acid or *ortho*-coumaric acid. Both tobacco and cucumber appear to utilize the BA intermediate. The mechanism through which BA is generated from *t*-CA is poorly understood. An oxidative pathway, analogous to β-oxidation of fatty acids, and a nonoxidative pathway, involving the intermediate benzaldehyde, have both been proposed. Supporting the former possibility, no labeled benzaldehyde is detected in TMV-infected tobacco supplied with 3-[$^{13}C_1$]Phe. Once BA is formed, it can be converted to SA by BA 2-hydroxylase (BA2H). Characterization of partially purified BA2H reveals that its activity is strongly induced by exogenously supplied BA or TMV infection. Because this activation is blocked by cycloheximide (CHX), *de novo* synthesis of BA2H appears to be required. Alternatively, a recent study has suggested that BA is not the direct precursor of SA. Rather, a conjugate of BA, consisting of BA and a glucose (BAG) molecule, may be converted to SA.

Like BA, SA also can be conjugated to a glucose molecule. The predominant SA conjugate in many plant species is SA 2-*O*-β-D-glucoside (SAG); the BAG recently identified in tobacco is benzoylglucose. In tobacco and *Arabidopsis*, free SA and SAG can be detected at low levels. After infection, SA and SAG levels rise, with SAG predominating in both the inoculated and uninoculated leaves. The kinetics of accumulation for free BA parallel those of SA; however, there are conflicting reports as to whether BAG levels increase following infection or are constitutively elevated. The enzyme responsible for conjugating SA, and possibly BA and other phenolics, is uridine diphosphate (UDP)-glucose:SA glucosyltransferase. This enzyme has been characterized in several plant species, and genes encoding this enzyme have been recently cloned from tobacco.

The role of SAG during the resistance response is unclear. Chemically synthesized SAG activates *PR-1*

expression in tobacco leaves. However, this induction probably is mediated by free SA, which is released from SAG by a nonspecific cell-wall-associated β-glucosidase. Thus, SAG does not appear to be the signal for defense responses. An alternative role for SAG is to serve as a storage form for SA. Conjugation of phenolic acids, as well as other phytohormones (e.g., auxin), to sugar molecules is a common and potentially reversible mechanism for the storage of various highly active or toxic compounds. In TMV-infected tobacco, deconjugation of SAG in the uninfected tissues of plants exhibiting SAR might therefore provide a rapid source of SA. In conjunction with other SAR-associated defenses, this SA might superinduce resistance, thereby ensuring the extremely rapid restriction of pathogen spread that is the hallmark of SAR.

In addition to the phenylpropanoid pathway, SA can be synthesized from isochorismate, which is derived from chorismate. This isochorismate pathway is utilized in microorganisms, and recent evidence suggests that it also functions in plants. Isoforms of isochorismate synthase have been purified and characterized from *Catharanthus roseus*. Furthermore, the *eds16* (also known as *sid2*) mutant of *Arabidopsis*, which exhibits enhanced disease susceptibility and fails to accumulate high levels of SA after pathogen attack, was recently found to contain a lesion in isochorismate synthase 1 (ICS1). Consistent with this possibility, transgenic tobacco and *Arabidopsis* expressing the two bacterial enzymes involved in the chorismate/isochorismate pathway exhibit elevated SA levels and enhanced disease resistance to viral, fungal, and oomycete pathogens.

IV. MECHANISMS OF SA ACTION

The mechanisms through which SA signals thermogenesis and disease resistance have been studied intensely. In voodoo lilies, SA has been shown to induce alternative oxidase (Aox) expression, which in turn activates the alternative respiratory pathway, thereby generating heat. By contrast, SA appears to utilize multiple mechanisms to induce defense responses.

In tobacco, some defense-associated responses, such as expression of *PR* genes, enhancement of disease resistance, activation of the SA-inducible protein kinase (SIPK), which is a mitogen-activated protein kinase (MAPK), and increases in cytosolic calcium levels, are directly induced by exogenously supplied SA. Interestingly, the ability of SA to enhance disease resistance appears to be mediated by at least two pathways. One pathway, which regulates resistance to several viruses, including TMV, potato virus X, and cucumber mosaic virus, is sensitive to the Aox inhibitor salicylhydroxyamic acid (SHAM). By contrast, the pathway conferring resistance to a bacterial pathogen (*Erwinia caratovora*) and a fungal pathogen (*Botrytis cinerea*), as well as activating *PR-1* gene expression, is SHAM insensitive.

In addition to the defenses directly activated by SA, some responses, including generation of ROS, activation of HR-like cell death, and induction of certain defense genes, are poorly, if at all, activated by SA alone. Rather, SA potentiates these responses; they are induced more rapidly and/or to a greater extent when SA is supplied prior to or at the time of pathogen infection or treatment with elicitors (biotic or abiotic compounds/factors that induce various defense responses). The relationship between the SA-activated and SA-potentiated response pathways is unclear. However, they may be linked by a proposed positive feedback loop that involves SA, the ROS H_2O_2, and cell death.

In an effort to elucidate the mechanisms through which SA signals defense responses, several SA-interacting proteins or SA-binding proteins (SABPs) have been identified in tobacco. The first SABP identified was the H_2O_2-degrading enzyme catalase (CAT). Because SA and its functional analogues (i.e., those capable of inducing *PR* expression and enhanced resistance) inhibit CAT activity, it has been proposed that SA-mediated CAT inhibition leads to elevated levels of ROS, which might play a role in HR and SAR. Consistent with this possibility, SA also inhibits ascorbate peroxidase (APX), the other major H_2O_2-scavenging enzyme found in plant cells. However, subsequent studies suggest that H_2O_2 functions upstream, rather than downstream of SA in the defense pathway. These conflicting results may yet be reconciled by the presence of a putative self-amplifying feedback loop involving SA and H_2O_2. Alternatively, SA-mediated CAT inhibition might signal resistance through the generation of SA free radicals, which could initiate lipid peroxidation and thereby activate defenses.

To date, at least two other tobacco SABPs have been identified and characterized. SABP2 exhibits high affinity for SA ($K_d = 90$ nM) and has been recently purified. SABP3 exhibits moderate affinity for SA ($K_d = 3–4$ μM) and has been shown to be the chloroplast carbonic anhydrase (CA). The ability of CA to reversibly convert carbon dioxide to bicarbonate is unaffected by SA, suggesting that its recently identified antioxidant activity is critical for defense

signaling. It is striking that three of the five SA-interacting proteins currently identified (CAT, APX, and CA) exhibit antioxidant activity. In addition, cytosolic aconitase has been shown to interact with SA. The SA-mediated inhibition of this enzyme may increase citrate levels, which are known to induce *Aox* gene expression. This induction, along with the ability of SA to activate *Aox* expression directly, may play a role in activating the SHAM-sensitive pathway for viral resistance.

It is interesting to note that several SA-interacting proteins, notably CAT, APX, and aconitase, are also regulated by nitric oxide (NO). This small molecule, which signals a wide variety of processes in animals, has been recently shown to regulate aspects of plant growth, development, and disease resistance. In particular, NO is required for pathogen-induced defense gene expression in tobacco and *Arabidopsis*. NO is also needed for HR development in pathogen-infected *Arabidopsis* and it synergizes with ROS to induce cell death in pathogen-treated soybean suspension cells. These findings, combined with the observation that NO induces SA accumulation in tobacco and that SA induces NO accumulation in soybean, suggest that NO, SA, ROS, and cell death are all part of a self-amplifying feedback loop that regulates defense responses. Whereas NO induces *PR-1* expression in tobacco via an SA- and cyclic adenosine diphosphate-ribose (cADPR)-dependent pathway, it activates *PAL* expression via an SA-independent, but cADPR- and cyclic guanosine monophosphate (cGMP)-dependent pathway. Thus, both SA-independent and SA-dependent pathways mediate NO-induced defense responses. Moreover, several critical players in the animal NO signaling pathway are also utilized in plants.

Beyond regulating components of the SA signaling pathway, SA also cross-modulates the activity of the ethylene-mediated and jasmonic acid (JA)-mediated defense pathways. Some of the defenses regulated by ethylene and/or JA include expression of the defensin (*PDF1.2*) and thionin (*Thi2.1*) genes, resistance to certain pathogens, and development of induced systemic resistance (ISR) following infection by nonpathogenic root-colonizing rhizobacteria. Although these pathways do not require SA, there is growing evidence that SA influences them in either a positive or a negative manner. For example, SA antagonizes ethylene/JA-induced defense gene expression in pathogen-inoculated tobacco and *Arabidopsis*; it also antagonizes JA-mediated resistance to herbivorous insects in tobacco. By contrast, SA works in conjunction with ethylene or JA to superinduce *PR* gene expression in tobacco. Furthermore, SA, ethylene, and JA are all required for the induction of apoptotic (HR-like) cell death in *Arabidopsis* protoplasts treated with the fungal toxin fumonisin B1. All of these signals also may be involved in mediating resistance to *B. cinerea* in *Arabidopsis*. The mechanisms by which SA positively interacts with ethylene and/or JA to induce defenses are not known; however, the ability of SA (or certain SA analogues) to inhibit JA synthesis or action in several plant species provides at least one mechanism for the negative regulation.

V. SA-INDUCED GENE EXPRESSION

SA treatment induces many of the same plant defense genes that are activated by pathogen attack. Traditionally, the SA-induced genes have been divided into one of two categories, immediate-early or late, depending on how rapidly they are activated by SA treatment and whether protein synthesis is required for their activation. Expression of the immediate-early genes, such as those encoding several glutathione *S*-transferases and the ethylene response element binding protein 1 (EREBP1), can be detected within 30 min of SA treatment. Expression of the *Agrobacterium tumefaciens* octopine (*ocs*) and nopaline (*nos*) synthase genes and activation of the cauliflower mosaic virus (CaMV 35S) promoter also are rapidly detected following SA treatment. Because induction of these genes is insensitive to the protein synthesis inhibitor CHX, their expression is probably regulated by preformed transcription factors. The promoters of genes belonging to this class contain an activator sequence-1 (*as-1*) or an *as-1*-like element; these cis-acting sequences partially mediate gene induction following SA, auxin, jasmonate, or H_2O_2 treatment. A family of basic leucine zipper (bZIP)-containing transcription factors that bind TGACG motifs, called TGA or OBF factors, binds these elements. SA treatment has been shown to enhance an *as-1* binding activity [presumed to be activation sequence factor-1 (ASF-1), a member of the TGA family] whereas phosphatase treatment of nuclear extracts decreases it. Based on these results, regulation of *as-1* binding activity by a phosphorylation event could provide a mechanism for the rapid, CHX-insensitive induction of immediate-early genes by SA. A MAPK (SIPK) that is rapidly activated in tobacco by TMV infection and SA treatment has been purified and characterized. Whether SIPK plays a role in activating the *as-1* binding activity following SA treatment is not known.

In contrast to the immediate-early genes, the late-response SA-induced genes are activated several hours after SA treatment and their induction is more sustained and is sensitive to CHX. Although the promoters for this class of genes, which includes the acidic *PR* genes, have been studied intensively, no common SA-responsive element has been identified. Analysis of the tobacco *PR-2d* promoter identified a TCA element that is common to several acidic *PR* promoters. However, this element is not required for SA inducibility of the *PR-2d* gene *in vivo*. Rather, a 25-bp element that contains sequences similar to W boxes is involved in SA-induced *PR-2d* expression. The W boxes are found in the promoters of several elicitor- and wound-induced genes. In addition, microarray analysis has revealed that they are found in the promoters of many genes induced during SAR development. The W boxes are bound by WRKY proteins; these proteins have been identified in parsley, tobacco, and *Arabidopsis*. They are a family of zinc-finger-type transcription factors, found exclusively in plants, that bind specifically to W box-type [(T)TGAC(C/T)] DNA sequence elements. The recent discovery that SA treatment and TMV infection induce a tobacco WRKY protein that binds an element in the basic class 1 chitinase (*PR-3*) gene provides an additional link between W boxes and SA-induced gene expression.

In the tobacco *PR-1a* promoter, researchers have identified an *as-1*-like motif that modulates, although is not obligately required for, SA-induced expression. Possibly, a second factor that is synthesized *de novo* after SA treatment works in conjunction with the *as-1* binding factor to induce this late class gene. By contrast, the *as-1*-like TGA binding site identified in the *Arabidopsis PR-1* promoter is required for SA-induced gene expression. The tobacco and the *Arabidopsis PR-1* genes also contain potential nuclear factor κB (NF-κB) binding sites. The significance of this element in tobacco is not known; however, mutations in the *Arabidopsis* sequence abolish inducibility of this promoter by the SA analogue 2,6-dichloroisonicotinic acid (INA). Analysis of the *Arabidopsis PR-1* promoter indicates that it also contains a W box. Because mutations in this box cause elevated levels of basal and induced gene expression, this element appears to regulate *PR-1* expression negatively. Finally, Myb binding sites have been identified in the tobacco *PR-1a* promoter. However, because overexpression or antisense expression of a TMV- and SA-inducible Myb gene (*myb1*) fails to affect SA-induced *PR-1a* expression, the importance of these sequences remains unclear.

VI. GENETIC ANALYSIS OF THE SA SIGNALING PATHWAY

To elucidate the SA signaling pathway, numerous mutants of *Arabidopsis* have been generated. Based on their phenotype, these mutants can be divided into several broad categories; due to space constraints, only some are discussed here. The first category, which includes the *lsd* (lesion-simulating disease resistance response), *cpr* (constitutive expresser of *PR* genes), *acd2* (accelerated cell death), *cim3* (constitutive immunity), and *dnd1* (defense with no HR cell death) mutants, exhibits constitutive *PR* expression and enhanced disease resistance. These mutants also accumulate elevated levels of SA, and several develop spontaneous HR-like lesions. Whether all of these mutations represent genes in the SA signaling pathway is unclear. Many stimuli, such as ozone, ultraviolet light, and the over- or underexpression of various transgenes, also induce constitutive SA accumulation, spontaneous lesion formation, elevated *PR* expression, and enhanced resistance. Thus, activation of these defense responses may result from perturbations in cellular metabolism. Consistent with this possibility, the *acd2* mutation has been recently shown to alter red chlorophyll catabolite reductase and the *dnd1* mutation affects a cyclic nucleotide-gated ion channel.

By contrast, another class of mutants, named *npr1* (nonexpresser of *PR* genes) or *nim1* (noninducible immunity), fails to express *PR* genes or develop SAR following treatment with SA or its analogues. Cloning of the *Npr1* gene revealed that this critical SA signal transducer contains ankyrin repeats and a broad-complex, tamtrack, and bric-à-brac/potxvirus, zinc finger (BTB/POZ) domain. These domains, which are involved in protein–protein interactions, are required for NPR1 to be functional. NPR1 was subsequently shown to accumulate in the nucleus following SA treatment, and this nuclear localization is necessary but not sufficient for *PR* gene activation. A direct link between NPR1 and *PR* gene expression was established by the discovery that NPR1 differentially binds various members of the TGA transcription factor family.

In addition to the NPR1-dependent pathway, there is growing evidence that SA can signal defenses via an NPR1-independent pathway. For example, crossing an *npr1* mutant allele into enhanced disease resistance mutants (*cpr5*, *cpr6-1*, *cpr22,* or *acd6*) has either no effect or only a partial effect on constitutive defense gene expression and/or disease resistance. Furthermore, several suppressors of the *npr1* mutation have

been identified. Some of these, including *ssi1*, *ssi2*, and *ssi4* (suppressor of SA insensitivity of *npr1–5*), constitutively express *PR* genes and exhibit enhanced disease resistance to bacterial and/or oomycete pathogens. By contrast, the *sni1* (suppressor of *npr1-1*, inducible) mutation restores the ability of INA to induce *PR* gene expression and resistance in the *npr1* background. Based on these observations, the SNI1 protein, which shares limited homology with the mammalian tumor suppressor retinoblastoma (Rb), may function as a negative regulator of SAR. Following SA treatment, SNI1-mediated suppression of the SAR signaling pathway would be alleviated by activated NPR1.

A category of mutants that affect SA synthesis has also been identified. These mutants, including *eds1*, *eds5*, and *eds16* [enhanced disease susceptibility; *eds5* and *eds16* correspond to *sid1* and *sid2* (SA induction deficient), respectively] and *pad4* (phytoalexin deficient), also exhibit increased pathogen susceptibility and/or depressed defense response activation following pathogen infection. The *EDS1* and *PAD4* genes encode proteins with some similarity to triacylglycerol lipases; their function in the SA signaling pathway is currently obscure. By contrast, *EDS16* encodes ICS1, which may catalyze SA synthesis via the chorismate/isochorismate pathway, as previously discussed.

VII. SUMMARY

Over the past 15 years, our understanding of the role of SA in plants has been transformed from the assumption that SA mimics an endogenous signal to the realization that SA is a *bona fide* signal that regulates thermogenesis, disease resistance, and possibly flowering. In addition, it has been demonstrated that SA is synthesized via the phenylpropanoid pathway, and possibly the chorismate/isochorismate pathway. Analyses of the mechanisms of action of SA have revealed that SA induces thermogenesis by activating *Aox* gene expression. How SA activates disease resistance is less clear, but the discovery that CAT, APX, aconitase, and CA are SA-interacting proteins provides several interesting leads to follow. The observation that several SA-interacting proteins also are regulated by H_2O_2 and NO suggests there is significant interplay between these signals. Moreover, these findings argue that parallel defense signaling strategies are used in plants and animals. Combined with the mounting evidence revealing positive and negative cross talk between the SA-, JA-, and ethylene-mediated defense pathways, there are multiple avenues yet to be explored in our quest to understand how SA signals disease resistance in plants.

Glossary

alternative oxidase The terminal oxidase of the alternative respiratory pathway; unlike the cytochrome respiratory pathway, which conserves energy from electron flow as chemical energy (ATP), the alternative respiratory pathway releases this energy as heat.

hypersensitive response Manifested by the formation of necrotic lesions at the site of pathogen entry; thought to play a role in reducing pathogen growth and spread.

pathogenesis-related proteins Encompass several families of proteins that are expressed first in the inoculated and subsequently in the uninoculated leaves of plants resisting pathogen attack; due to the correlation between *PR* gene expression and development of hypersensitive response and systemic acquired resistance, increased *PR* expression is frequently used as a marker for these phenomena.

phytoalexins Low molecular-weight compounds that exhibit antimicrobial activity.

salicylate hydroxylase Enzyme encoded by the bacterial *nahG* gene; converts salicylic acid into catechol, a compound that does not induce defense responses.

systemic acquired resistance Long-lasting enhanced resistance to a wide variety of pathogens; developed in the uninoculated tissues of a plant following a primary infection.

thermogenesis Generation of heat; occurs in certain plants during the flowering process; in voodoo lilies, the increased temperature of the spadix (the central column of the flower) volatilizes compounds, releasing a foul odor that attracts pollinating insects.

Secretin

SEBASTIAN G. DE LA FUENTE AND THEODORE N. PAPPAS

Duke University Medical Center

Secretin, a 27-amino-acid peptide hormone produced by intestinal S cells, is released into the duodenum primarily in response to pH changes following food ingestion. Its major target organs include the pancreas, stomach, and gallbladder. Secretin affects pancreatic bicarbonate secretion, gastric acid secretion, and motility and augmentation of bile flow. Secretin has been found to be altered in some clinical conditions and is currently used as a diagnostic tool for assessing pancreatic function in chronic pancreatitis, in identification of the main pancreatic duct, and in diagnosis of gastrinoma (Zollinger–Ellison syndrome).

I. INTRODUCTION

The polypeptide hormone secretin was discovered in 1902 by Starling and Bayliss as a substance capable of stimulating pancreatic bicarbonate secretion. Based on purified intestinal mucosa extracts, secretin is structurally a linear sequence of 27 amino acids. The advent of highly sensitive radioimmunoassay techniques has help to identify the physiological stimulus that triggers cellular release of secretin as well as its major biological effects. The homology between secretins of different species has facilitated the understanding of its actions and roles in gastrointestinal physiology.

Secretin is synthesized by the intestinal S cells and is secreted into the bloodstream when the upper segments of the small intestine are exposed to the acidic contents of the emptying stomach. The main target organ of the hormone is the pancreas, which is stimulated to discharge bicarbonate into the intestinal lumen, neutralizing the contents of the intestines. In addition, secretin augments the release of digestive enzymes from the pancreas and inhibits further production of acids in the stomach.

The stimulatory properties of secretin that impact the pancreas are pharmacologically useful as a diagnostic tool to examine pancreatic exocrine function and to assist in the recognition of the main pancreatic duct in imaging studies. Secretin is also a valuable tool in the diagnosis of gastrinoma. Of clinical importance is the fact that altered levels of secretin have been found in various pathological conditions, thus making

secretin a possible target for future therapeutic approaches.

II. STRUCTURE AND CHEMICAL PROPERTIES

The linear 27-amino-acid secretin polypeptide has a molecular weight of 3055. The amino acid sequence has been determined in pigs, cows, dogs, chickens, humans, and rats (Fig. 1). Bovine secretin is identical to porcine secretin, whereas chicken and porcine secretins are similar at only 14 amino acid positions. The secretin precursor structure consists of the secretin sequence, a signal peptide, an amidation–cleavage sequence, a 72-amino-acid carboxyl-terminal extension peptide, and a short N-terminal peptide (Fig. 2). The NH_2-terminal sequence seems to be required for full bioactivity. Alteration of this segment results in significant loss of secretin capacity to stimulate exocrine pancreatic secretion.

Secretin shares structural homology with many other peptides present in the gut and brain. These include vasoactive intestinal peptide (VIP), gastric inhibitory peptide (GIP), glucagon gene-related products (glucagon, GLP-1, GLP-2), and peptide histidine–isoleucine amide (PHI). Other compounds, such as growth hormone-releasing hormone (GHRH), pituitary adenylate cyclase-activating polypeptide (PACAP), and peptide HM (PHM), are also members of the secretin family. Prealbumin is somehow homologous to the secretin sequence. The similarities between some of these peptides are shown in Fig. 3.

Secretin is thermally stable at neutral pH, but at acidic pH it is labile and can be converted into β-aspartyl peptide. Secretin tends to be adsorbed by glass and plastic, thus it is necessary to add albumin to secretin solutions to avoid adsorption to these surfaces. Secretin has a short plasma half-life of 2–4 min and a metabolic clearance rate of approximately 13–15 $ml^{-1}\,kg^{-1}$. The kidneys are responsible for most of its clearance.

III. GENE COMPOSITION AND EXPRESSION

The human secretin gene has been recently found to be located in chromosome 11p15.5. The locus is composed of four exons with a coding sequence spanning 713 bp of genomic DNA and encoding 123 amino acids. The human gene shares similarities to the gene in pigs and rodents, and all have a common four-exon structure. The first exon encodes a signal peptide and a segment of the N-terminal peptide; the bioactive secretin is encoded in the second exon. The third and four exons encode the C-terminal peptide of prosecretin. Although the posttranslational processing of secretin is not known in detail, a precursor has been isolated from the porcine intestine consisting of secretin plus 41 amino acids at the C terminus. The hormone-coding regions are highly comparable within secretin genes of different species; however, the C-terminal peptide differs substantially, suggesting that this portion is not of physiological importance. The secretin gene is also comparable to other genes of the secretin family. Among gene family members, VIP, glucagon, and secretin are all encoded in one exon. In contrast, GIP and growth hormone-releasing hormone peptides are encoded in separated exons.

IV. SYNTHESIS OF SECRETIN

Immunoreactive methods have identified the small intestine of most species as the major site of secretin production. Immunoreactivity of secretin is highest in the duodenum and decreases along the horizontal axis, reaching insignificant levels in the ileum; however, low-level immunoreactivity has also been found in the porcine colon. Biosynthesis of secretin takes place in intestinal S cells. These are enteroendocrine cells that are interspersed among other epithelial cells, occurring at a frequency of approximately 6 cells per 1000 epithelial cells. A majority of the S cells are distributed within the intestinal villi, with small numbers in the

Predicted functional domains are indicated above the amino acid sequences. Reproduced from "Comprehensive Endocrinology—Gut Peptides Biochemistry and Physiology" (J.H. Walsh and G.J. Dockray), p. 150 (1994), Raven Press, with permission from the publisher and the authors.

middle and upper crypt region. Ultrastructurally, S cells are characterized by a pear-shaped cytoplasm containing small, irregular granules of 200 nm displaying slight argyrophilia. Serotonin and substance P have been shown to be co-expressed in some duodenal S cells; however, this co-expression depends on the species studied and occurs in a small percentage of cells. The renewal time of S cells has been estimated to be 5 days. Guinea pigs and rodent secretin levels are relatively high at birth, falling in the postnatal period. Secretin cells have been identified in the rat duodenum as early as day 17 of gestation. Secretin mRNA is present in the developing pancreas, reaching maximal levels at day 19 of gestation.

Although extraintestinal sources of secretin have been experimentally located throughout the central nervous system, it is generally accepted that only the small intestine produces significant amounts.

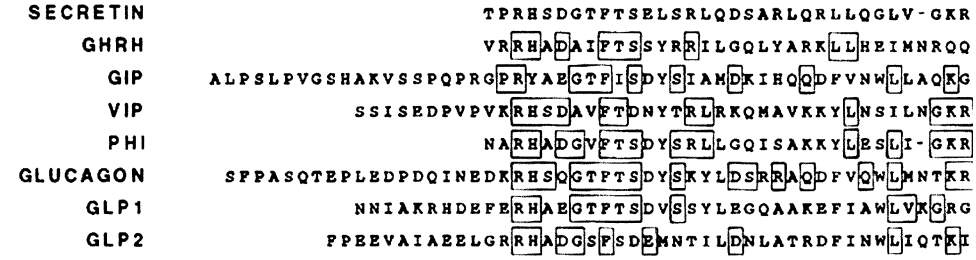

FIGURE 3 Alignment of the amino acid sequences encoded by the coding exons of the secretin family of genes. Amino acids identical to the corresponding exon in the secretin gene (top line) are enclosed in boxes. Sequences shown are encoded by the respective rat genes, with the exception of human gastric inhibitory peptide (GIP). GHRH, Growth hormone-releasing hormone; VIP, vasoactive intestinal peptide; PHI, peptide histidine–isoleucine amide; GLP, glucagon-like peptide. Reproduced from "Comprehensive Endocrinology—Gut Peptides Biochemistry and Physiology" (J. H. Walsh and G. J. Dockray), p. 152 (1994), Raven Press, with permission from the publisher and the authors.

Early experiments have demonstrated small concentrations in pituitary and pineal glands, hypothalamus, thalamus, and olfactory lobe. Secretin-like immunoreactivity has also been reported in the gastric antrum and pancreatic islets; however, these findings have not been corroborated. Measurements of secretin mRNA have failed to demonstrate significant concentrations in locations other than the intestines, but very low levels may simply be below the detection limits of Northern blot analysis techniques.

V. STIMULATORY RELEASE OF SECRETIN

Among the known factors that trigger the release of secretin (Table 1), intralumenal acidification of the duodenum and proximal jejunum results in the strongest stimulus for secretion. Considerable amounts of hydrochloric acid (HCl) are normally produced in the stomach, facilitating digestion of large pieces of ingested foods. Most of this gastric acid production is buffered by the food and by alkaline secretions, but a considerable quantity of acid enters the duodenum, reducing duodenal intralumenal acidity to a pH range of 3.0–5.0. Experimental studies have calculated the pH threshold for secretin release to be approximately 4–5 in humans and 4.5 in dogs. Experimentally, infusing acid into the intestinal lumen stimulates secretin release. The increase in plasma secretin concentration levels depends on the acid load delivered to the duodenum and parallels the increase in secretion of bicarbonate from the pancreas.

Many substances stimulate the release of secretin (see Table 1), including bile salts, fatty acids, and herbal extracts. Intralumenal infusion of bile salts triggers the pancreas to release bicarbonate-rich secretions in animals and humans; however, little is known about the physiological role of endogenous bile in stimulating secretin release. Fatty acids, specifically oleic acid, also stimulate secretin release. Additionally, geranyl-geranyl acetone (a cyclic polyisoprenoid experimentally used to heal ulcers) and L-phenylpentanol, which is used as a condiment in some cultures, when administered intraduodenally, increase plasma secretin concentrations and pancreatic bicarbonate secretion.

The role of the nervous system in controlling secretin secretion has long been a controversial issue. Based on animal studies, some investigators have proposed that secretin's actions depend heavily on cholinergic input; however, the fact that atropine (an anticholinergic drug) fails to inhibit secretin secretion in humans in response to duodenal acidification suggests a minor vagal control in secretin release. To date, the mechanisms by which a decreased duodenal pH stimulates secretin production remain unclear; nevertheless, *in vitro* studies have shown that secretin can be released after induction by Ca^{2+} and cAMP.

Three substances are known to inhibit the release of secretin: oxethazine, somatostatin, and Met-enkephalin. Oxethazine is a substance with local anesthetic properties; when infused in the duodenum of dogs, it suppresses the plasma concentration increment of secretin and bicarbonate secretion in response to acidification. Little is known about the mechanism of action of this drug. In addition, both somatostatin and Met-enkephalin have been shown to reduce secretin levels and pancreatic response to duodenal acidification, but it is unclear if this inhibition occurs at physiological concentrations.

TABLE 1 Substances That Influence Sectretin Release

Stimulants	Inhibitors

Sodium oleate	
Herbal extracts	
Geranyl-geranyl acetone	

[a]Intraduodenal acid is the strongest stimulus for secretin release.

VI. BIOLOGICAL AND PHYSIOLOGICAL ACTIONS

A. Receptor Structure

Characterization of the secretin receptor in pancreatic acinar cells of guinea pigs has led to distinguish two different receptor types–high affinity and low affinity-depending on the receptor avidity for secretin. Secretin is a potent agonist for the high-affinity receptor whereas VIP weakly stimulates it. The low-affinity receptor shows much lower affinity for secretin and higher affinity for VIP. Both are G-protein-linked receptors that activate the adenylyl cyclase enzyme, resulting in augmentation of intracellular cyclic AMP (cAMP). The receptor is composed of seven putative hydrophobic transmembrane domains with a 427-amino-acid sequence; the molecular weight is 48,696.

Secretin receptor mRNAs have been detected in several tissues in addition to the pancreas, including heart, stomach, and nervous system. Autoradiographic examination of rat pancreatic tissue demonstrates high-affinity binding sites in both acinar and ductal cells, with no binding on islets and vascular structures.

B. Secretin Effects and Mechanisms of Action

Secretin activity can be grouped into two categories: actions occurring at physiological levels and actions occurring at supraphysiological levels. Most of these actions are included in Table 2. Secretin effects can also be grouped into stimulatory or inhibitory actions.

Stimulation of pancreatic water and bicarbonate secretion represents the main physiologic action of secretin, resulting in neutralization of the acidic chyme entering the proximal intestines. Low intraduodenal pH triggers secretin secretion, which results in an incremental release of pancreatic water and bicarbonate. Among the components of the gastric chyme, titratable acid appears to be the main stimulant for secretin secretion. Immunoreactive levels of secretin are also significantly increased after ingestion of a meal of mixed types of foods. Additionally, fatty acids and the digestive by-products of fat cause release of significant amounts of immunoreactive secretin. It is well established that actions of secretin on the exocrine pancreas are potentiated by cholecystokinin (CCK) in dogs and humans. The concomitant release of CCK along with secretin produces a greater response, compared to the sum of their individual actions, because both hormones act together.

Animal studies have shown that secretin exerts inhibitory effects on gastric acid secretion and gastric motility, therefore acting as an enterogastrone. It is not clear whether these inhibitory actions result from a direct secretin effect on the stomach or as a consequence of various hormones and/or peptides acting in concert. Several hormones (serotonin, somatostatin, and peptide YY) are known to be released postprandially and modify acid secretion and gastric emptying rates. Interactions between such hormones and secretin may explain the inhibitory actions of secretin on gastric physiology. In rodents, for example, secretin strongly inhibits basal acid output by stimulating both somatostatin and prostaglandin release, thus indirectly influencing gastric secretion. However, these effects are less clear in humans; infusion of exogenous secretin at doses similar to levels seen following acidified meals fail to inhibit acid secretion. Furthermore, inhibition of acid output has not been achieved after administration of fivefold higher doses of exogenous secretin. On the other hand, both continuous and intermittent infusions of secretin have shown to retard gastric emptying of solid meals in humans. Pure secretin has shown to stimulate pepsin release in cats, dogs, and humans. Very small doses of secretin increase serum group pepsinogen I and pepsin output in young, healthy human volunteers. Gastric mucous secretion has been found to be increased by secretin in cats, dogs, and humans, but the physiological significance of these findings remains to be elucidated.

Biliary secretion is influenced by administration of supraphysiological doses of exogenous secretin. Pharmacological administration of secretin augments bile flow and bicarbonate concentration in bile, but it is unclear to date whether these effects are produced by endogenous secretin.

Other actions attributed to secretin include induction of bicarbonate secretion from duodenal

TABLE 2 Actions of Secretin

Level	Stimulation	Inhibition
Physiological	Secretion of water and electrolytes from pancreas Secretion of water and electrolytes in bile	Gastric emptying Gastric acid secretion Intestinal motility
Supraphysiological[a]	Bile flow Lower esophageal sphincter Release of insulin Secretion from Brunner's glands in the duodenum Renal excretion of water and electrolytes Cardiac output Splanchnic blood flow Lipolysis in fat cells	

[a]Pharmacological doses.

Brunner's glands, inhibition of lower esophageal sphincter tone, and lipolysis. Several studies have suggested a tropic effect of secretin on the pancreas. Pharmacological doses of secretin increase pancreatic weight, protein, DNA content, and thymidine incorporation in animals. These actions have been attributed to a costimulatory effect of secretin and CCK, which is known to have tropic properties. It is not known if theses actions take place in humans.

Secretin has also been found to mediate relaxation of intestinal smooth muscle in rats and to inhibit upper small intestinal motility in humans. Exogenous secretin influences the release of insulin, glucagon, parathyroid hormone, calcitonin, somatostatin, and pancreatic polypeptide (PP). Exogenous nonphysiologic secretin infusion rates can also produce incremental increases in pancreatic enzyme secretion. Most of these actions have been observed either at supraphysiological concentrations or in experimental models.

VII. CLINICAL APPLICATIONS OF SECRETIN/PATHOLOGICAL CONDITIONS

A. Pharmacological Uses of Secretin

Secretin has been used clinically for assessment of pancreatic exocrine function, identification of minor papilla during endoscopic retrograde cholangiopancreatography (ERCP), and diagnosis of gastrinoma (Zollinger–Ellison syndrome). Secretin is an adjunct to ultrasound and resonance magnetic imaging in inflammatory conditions of the pancreas, such as chronic pancreatitis. The periductal fibrosis present in the chronically inflamed pancreas limits the dilatation of the main duct after maximal secretin stimulation, which is used to distinguish chronic pancreatitis from the normal pancreas. The sensitivity, specificity, and efficacy of functional secretin studies have been estimated to be 67, 90, and 81%, respectively, as compared to histological evaluation. Pancreatic insufficiency can also be evaluated after administration of secretagogues (i.e., secretin and CCK). Secretin stimulatory effects are also used to collect pancreatic juices during ERCP. Concomitant utilization of secretin and ultrasound has been reported to be useful in selection of patients with pancreas divisum for accessory duct sphincteroplasty. In these patients, secretin is used to localize the site where the main pancreatic duct drains.

The differential effects of secretin on normal and gastrin-producing tumors are use to distinguish between hypergastrinemic conditions and patients with Zollinger–Ellison syndrome (ZES). ZES is characterized by gastrin-producing neuroendocrine tumors that are usually located in the pancreas or proximal duodenum; the tumors release excessive amounts of gastrin into the circulation. Intravenous administration of secretin in these patients produces an exaggerated gastrin response that is useful to identify ZES. Both synthetic porcine secretin and human synthetic secretin have been shown to be adequate testing agents. Additionally, secretin tests have been used to localize gastrinomas within the gut and to ensure a correct extirpation of the tumor during surgery. The two methods have been described for these purposes: selective intra-arterial secretin injection with successive recollection of venous hepatic sampling and intra-operative secretin testing to confirm resection of the tumor. Postoperatively, secretin tests have been used to detect subclinical disease recurrence. However, with the advent of octreotide scanning and intraoperative ultrasound, the secretin-dependent localization techniques are no longer commonly utilized. Secretin has recently elicited considerable attention due to alleged benefits of secretin in treating autism in children. Unfortunately, however, double-blind studies have found no evidence of such effectiveness.

B. Pathophysiology of Secretin: Conditions of Excess or Deficiency

Plasma secretin concentration levels have been found altered in various clinical conditions. Hypersecretinemia (blood secretin levels above normal) is seen in ZES, in some cases of duodenal ulcers with marked hypersecretion of acid, and in patients with advanced renal failure. One case has been reported in the medical literature of a patient with a pancreatic tumor secreting five different hormones, one of which included secretin; however, no cases of isolated secretin production have been documented. Patients with ZES present abnormally elevated plasma secretin levels, with fasting concentrations above 15 pg/ml, which is rarely seen in healthy persons. In healthy subjects, plasma secretin concentrations are elevated after a prolonged fast or with extenuated physical exercise. In both instances, oral or intravenous administration of glucose reduces secretin blood levels.

Hyposecretinemia, or a blood secretin level below normal, has been found in patients with untreated adult celiac disease or achlorhydia. Secretin concentrations in patients with celiac disease fail to increase after exogenous duodenal acidification or after a

mixed meal. In contrast, patients with achlorhydia present reduced secretin levels after a mixed meal, although the response to duodenal acidification remains normal.

Glossary

chyme Semifluid mixture consisting of partly digested food and gastric juices; passes from the stomach into the small intestine.
exon Portion of DNA that encodes a section of the mature messenger RNA.
intron Portion of DNA that lies between two exons; it is transcribed into RNA, but is not expressed in the final product.
locus Position in a chromosome of a particular gene or allele.
peptide Compound formed by two or more amino acids, in which a carboxyl group of one is united with the amino group of another.

Selective Estrogen Receptor Modulators

See *SERMs*

SERMs (Selective Estrogen Receptor Modulators)

DONALD P. MCDONNELL
Duke University Medical Center

Although estrogen was initially considered solely a reproductive hormone, extensive clinical findings have indicated that its influence extends to a variety of target tissues not generally considered to be involved in reproduction. Specifically, estrogen has positive actions in the skeleton, the cardiovascular system, and the central nervous system. Interestingly, the mechanism by which this hormone manifests its biological activities in different tissues is dissimilar, enabling the development of selective estrogen receptor modulators (SERMs), compounds whose relative estrogenic/antiestrogenic activities vary between cells.

I. INTRODUCTION

Despite the medical benefits afforded by estrogen replacement therapy, the number of women who initiate or remain on therapy for greater than 1 year is relatively small. This is due in part to the fear that estrogens increase the risk of developing breast cancer. Consequently, it was anticipated several years ago that there was an unmet medical need for novel estrogen receptor modulators that would retain the beneficial effects of estrogens in most target organs but which would be inactive in the breast.

The emergence of selective estrogen receptor modulators (SERMs), compounds whose agonist/antagonist activities are manifest in a cell-selective manner, indicates that considerable progress toward this goal has been made. It is likely that a clearer understanding of the mechanisms that determine the pharmacological activities of the currently available SERMs will assist in the discovery and development of additional compounds of this class for use in the treatment of conditions associated with long-term estrogen deprivation.

With few exceptions, the clinical studies supporting nonreproductive actions of estrogens have not been performed in a double-blinded, placebo-controlled manner. Therefore, it has been difficult to establish, in a definitive manner, whether estrogens have clinically important, beneficial activities in postmenopausal women outside of their utility to treat climacteric symptoms. In the absence of these definitive studies, there has been some reluctance on the part of the pharmaceutical industry to invest in the development of improved "estrogens." Some resolution to this issue was provided by the recent publication of the interim results of the National Institutes of Health-sponsored Women's Health Initiative (WHI). This trial was set up to examine the long-term effects of the most popular hormone replacement regimens in the cardiovascular system and in breast although many other secondary outcomes were considered. One arm of this trial, a combination of conjugated equine estrogens and the progestin medroxyprogesterone acetate (HRT), was terminated early because an interim analysis demonstrated a clear increase in the incidence of breast cancer and cardiovascular events. This was a disappointing result considering the general belief, based on multiple retrospective studies, that postmenopausal estrogen supplementation would be beneficial in the cardiovascular system. Although overshadowed by an enormous amount of negative media coverage, this study also proved in a definitive manner that estrogens reduced the incidence of hip fractures by approximately 40% and significantly reduced the incidence of colorectal cancer. However, aside from the established effects of estrogen on the quality of life of menopausal women, the additional positive and negative effects highlighted by the WHI study appear to cancel each other out and do not support long-term use of HRT. It remains to be determined whether estrogen alone (the second ongoing arm of the WHI study) provides an improved risk–benefit profile in women without a uterus.

From the perspective of drug discovery, the results from the WHI are very useful. It demonstrated conclusively that estrogens were beneficial in the skeleton and that they reduced the incidence of colorectal cancer. Furthermore, it made it clear that compounds that could manifest estrogenic activities in a tissue-selective manner would have utility in menopausal medicine. Although far from optimal, the clinical profiles of the first-generation SERMs have suggested that it will be possible to generate compounds that provide only the beneficial effects of estrogens and which significantly improve the health of postmenopausal women. As will be discussed below, the currently available SERMs arose from the accidental discovery that compounds designed as anti-estrogens could exhibit estrogenic activity in some tissues. It is likely that elucidation of the mechanisms of this tissue selectivity will enable the rational development of improved SERMs. Thus, although some consider the findings of the WHI study to signal the end of HRT, others see it as an impetus to develop compounds with improved specificity and share in the expectation that such medicines will have a positive impact on the health of menopausal women.

II. THE EMERGENCE OF THE SERM CONCEPT

Considering the classical models of estrogen action, it was initially difficult to understand how, beyond taking advantage of fortuitous pharmacokinetic properties, it would be possible to develop therapeutically useful SERMs. However, in the early 1990s a landmark study demonstrated that the "anti-estrogen" tamoxifen could actually function as an estrogen in the lumbar spine. Specifically, this placebo-controlled trial demonstrated that like estrogen, tamoxifen could increase bone mineral density in the lumbar spine of postmenopausal women who were being administered tamoxifen as adjuvant therapy for breast cancer. Indeed, were it not for the fact that this drug also functioned as an estrogen in the uterus and that this activity has been associated with an increased risk of endometrial cancer, it may have been used as a treatment for osteoporosis. Regardless, it was this finding that birthed the field of SERMs and provided the impetus to search for compounds that functioned like tamoxifen in bone but lacked uterotrophic activity. To date, these efforts have led to the development of one compound, raloxifene, which is approved for the treatment and prevention of osteoporosis. Several additional SERMs, with pharmaceutical properties superior to

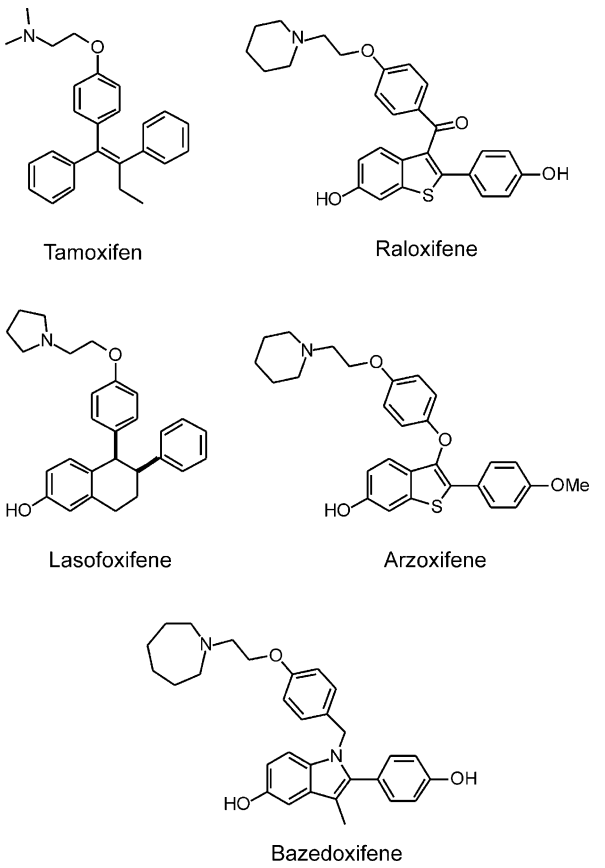

FIGURE 1 Structures of the most clinically important SERMs.

those of raloxifene, i.e., lasofoxifene, bazedoxifene, and arzoxifene, are in the late stages of clinical development and will likely emerge on the market in the near future (Fig. 1).

III. THE MECHANISM OF ACTION OF SERMS

The observation that the SERM tamoxifen could manifest estrogenic activities in some cells but oppose estrogen action in others suggested that a reevaluation of the classical models of ER pharmacology was needed. In the established models of estrogen action, the unoccupied nuclear estrogen receptor (ER) resides in the nuclei of target cells in an inactive form. Upon binding to an agonist, such as estradiol, the biochemical properties of the ER are altered in a way that allows the interaction of a receptor dimer with specific DNA sequences [estrogen-response elements (EREs)] within the promoters of responsive genes. The DNA-bound ER can then regulate target gene transcription, either positively or negatively. In this model, agonists function as "switches" that facilitate the conversion of ER from an inactive to an active form, whereas antagonists function by competitively inhibiting the binding of agonists. However, the realization that the relative agonist/antagonist activity of ER ligands can differ between cells and even between different promoters in the same cell suggests that the pharmacology of this class of compounds is more complex than originally anticipated. This complexity has allowed the development of SERMs, compounds whose agonist and antagonist activities are manifest in a cell- and promoter-restricted manner. Although SERMs are a relatively new classification, the observation that the biological character of ER ligands could differ between cells was first observed in the late 1960s when it was demonstrated that tamoxifen, then classified as an ER antagonist, could function as a partial agonist in the reproductive systems of rodents. Since that time, other SERMs that display unique agonist/antagonist profiles have emerged, leading to the realization that different compounds acting through the same receptor can manifest different activities in different cells. The explanation for this cellular discrimination is slowly being unraveled, providing a molecular mechanism to explain the differential activity of SERMs and suggesting ways to develop improved compounds of this class in the future.

A major advance in understanding estrogen action was the discovery and cloning in 1996 of a second estrogen receptor (ER-β) that is genetically distinct from ER-α, which was cloned in 1986. The expression patterns of these receptors and the phenotypic consequences of their disruption differ, indicating that each has a distinct role in ER pharmacology. It has been shown that ER-β can heterodimerize with ER-α and inhibit ER-α action *in vitro*, suggesting that differences in the relative expression levels of the two receptors may dictate cellular sensitivity to estrogens. Although the roles of these two receptors in SERM action remain to be established, raloxifene and tamoxifen have been shown to bind to both receptors. On classical ERE-containing genes, these SERMs function as pure antagonists when acting through ER-β but can function as partial agonists when acting through ER-α. However, it now appears that in certain circumstances tamoxifen and other SERMs, acting through ER-β, may manifest robust agonist activity. For instance, on some promoters ERs do not interact directly with EREs but rather are tethered to promoters through protein–protein interactions with transcription factors prebound to promoters.

When ER-β interacts with promoters in this manner, its transcriptional activity is suppressed by estrogens and activated by SERMs, and the reverse is true for ER-α. These indirect ER–promoter interactions have been demonstrated conclusively only *in vitro*; thus, although these findings are intriguing, the physiological significance of these alternate pathways remains to be established. Regardless, it is clear that the actions of estrogens and SERMs *in vivo* represent their composite activities through these two receptors as homo- or heterodimers.

In the uterus, a tissue that predominantly expresses ER-α, tamoxifen but not raloxifene (a second-generation SERM) manifests agonist activity, indicating that SERM pharmacology cannot be explained solely by differential receptor activation. This finding, which has been confirmed in several *in vitro* systems, suggests that some cells are able to distinguish between ER-α–tamoxifen and ER-α–raloxifene complexes. Using protein crystallography and techniques that evaluated the surface changes of the receptor that occur upon ligand binding, it was demonstrated that the structure of the ER was influenced by the nature of the bound ligand. Cumulatively, these studies indicate that the conformations of the tamoxifen–ER, raloxifene–ER, and estradiol–ER complexes are different from one another and from the unbound receptor. The relevance of receptor conformation to biological activity was strengthened recently by the observation that the structure of ER-α in the presence of the pure antagonist ICI164,384 is distinct from that observed in the presence of agonists or SERMs. Thus, receptor conformation appears to be the primary determinant of the pharmacological activity of SERMs, estrogens, and anti-estrogens.

The full significance of the differential effect of estrogens and SERMs on ER structure was not realized until the discovery of co-activators and co-repressors, proteins that interact with and modulate ER function. Co-activators such as SRC-1 (steroid receptor co-activator-1), GRIP1 (glucocorticoid receptor interacting protein-1), and AIB-1 (amplified in breast cancer-1) (p160 family), preferentially interact with agonist-activated ER and potentiate transcriptional activation by coupling the receptor to the transcription apparatus and by altering the architecture of the target promoter, thus facilitating transcription. Much of what is known about the role of the known co-activators in SERM action has come from studies of tamoxifen. Some studies have demonstrated that overexpression of the p160 co-activators (SRC-1, GRIP-1, and AIB-1) in target cells can convert tamoxifen from an antagonist into an agonist. Additional studies have indicated that tamoxifen-activated ER is capable of interacting, in an ectopic manner, with cofactors with which estradiol–ER would not normally couple. Whether these types of interactions occur when ER is occupied by other SERMs remains to be determined. In contrast to co-activators, co-repressors like nuclear receptor co-repressor (NCoR) and silencing mediator for retinoid and thyroid hormone receptor (SMRT) interact preferentially with antagonist-activated ER and suppress activation by altering the structure of the responsive promoter in such a way as to reduce its ability to be transcribed. The importance of co-repressors in SERM action was confirmed in studies demonstrating that tamoxifen could function as a full agonist in cells derived from mice bearing a genetic disruption of NCoR. It is not yet clear whether the co-repressors are physiologically important regulators of ER action or whether they are engaged only when the receptor is bound to a synthetic antagonist. To date, over 20 different ER-interacting co-activators and co-repressors have been identified. These have different relative and absolute expression levels among cells and display distinct preferences for different ER–ligand complexes. It appears that differential cofactor recruitment is a key determinant of SERM pharmacology and that progress will be made in the near future in ascribing the different activities of these compounds to specific ER–cofactor interactions.

It is not likely that differential cofactor recruitment alone is the only determinant of the agonist/antagonist activity of SERMs. For example, in cultured cells, ligand binding to ERs can activate extranuclear signaling pathways in a transcription-independent manner. Although the physiological importance of these activities is unclear, they highlight the extreme complexity of ER action and the multiplicity of the systems and signaling pathways that may be modulated by the ERs and their ligands.

To summarize, the complex pharmacological activities of SERMs are the result of at least three different factors (Fig. 2): (1) differential receptor expression; (2) receptor conformation (an activity that influences cofactor recruitment); and (3) differential expression of cofactors. Globally, these activities explain most of the tissue-selective activities of SERMs, although the specific contribution of each activity and the particular components that are important for a given tissue remain to be determined.

Upon binding to an agonist or an antagonist, the ER (α- and/or β-isoforms) undergoes a conformational change that permits its spontaneous dimerization

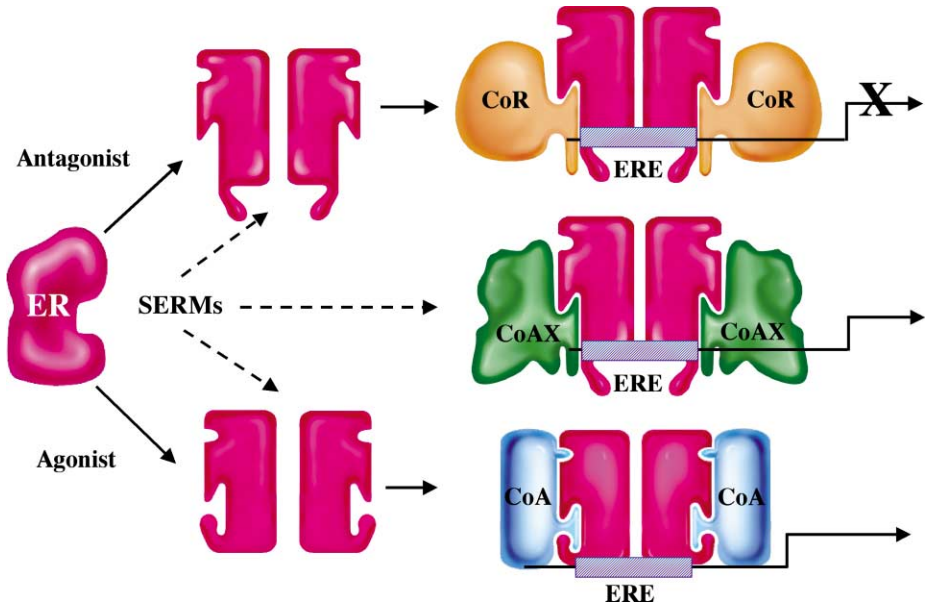

FIGURE 2 An updated model of estrogen receptor action may help to explain the activity of SERMs. CoA, co-activator; CoAX, co-activator X (yet to be identified); CoR, co-repressor.

and facilitates the subsequent interaction of the dimer with specific DNA sequences, EREs, located within the regulatory regions of target genes. It has now been determined that receptors activated with full agonists, such as 17β-estradiol, can couple with any one of a number of transcription co-activators. The resulting biological response will be determined by the cofactors that are available in a given cell and which of these proteins actually dock with the receptor. In the presence of a pure antagonist such as ICI182,780, it has been demonstrated that ER interacts preferentially with a co-repressor protein. Upon binding SERMs, however, the receptor has been shown to adopt overall conformations that make these complexes distinct from agonist- or antagonist-activated receptor. These complexes can interact with either co-activators or co-repressors and are very sensitive to the expression levels of these proteins. When co-repressors dominate, SERMs function as antagonists, whereas when co-activators dominate, partial agonist activity is observed. To complicate things further, it has also been shown that in certain circumstances SERM-activated ERs can interact in an ectopic manner with co-activators with which the ER–estradiol complex does not normally interact. The implication of this model is that the major determinants of SERM activity are receptor shape and the relative and absolute levels of co-activators in target cells.

Glossary

co-activators Proteins that interact with activated transcription factors at target gene promoters and facilitate their contact with the general transcription apparatus in cells. In addition, co-activators nucleate the assembly of a large complex of proteins at target gene promoters that enhance transcriptional activation by enzymatically modifying histones and effecting a local decondensation of chromatin.

co-repressors Proteins that interact with inactive transcription factors and help to inhibit the activity of these proteins by nucleating a large complex of proteins, which functions to condense chromatin structure and repress transcription.

Sex Hormone-Binding Globulin (SHBG)

GEOFFREY L. HAMMOND AND KEVIN N. HOGEVEEN
University of Western Ontario, Canada

Sex hormone-binding globulin (SHBG) transports androgens and estrogens in the blood and regulates the access of these sex steroids to their target tissues. Plasma SHBG is produced by the liver and is structurally identical to the androgen-binding protein (ABP) produced in Sertoli cells. A single *SHBG* gene encodes both SHBG and ABP, and its expression in the liver and testis responds differently to developmental, hormonal, and external cues. The *SHBG* gene is expressed in several other tissues, as well as in cancer cell lines that contain alternatively spliced *SHBG* transcripts of unknown function. Genetic variants of human *SHBG* that influence its expression and/or the plasma levels of SHBG have been identified. The biological significance of *SHBG* expression in the testis may vary between species, and this article will review the current understanding of the structure and function of SHBG in the context of its proposed roles in male reproduction.

I. STRUCTURE AND FUNCTION OF PLASMA SEX HORMONE-BINDING GLOBULIN AND TESTICULAR ANDROGEN-BINDING PROTEIN

Plasma sex hormone-binding globulin (SHBG) and testicular androgen-binding protein (ABP) are homodimeric glycoproteins, and each monomeric subunit comprises two laminin G-like (LG) domains (Fig. 1). These two laminin G-like domains are also found in several other proteins with diverse and unrelated functions, including protein S, GAS 6 (product of the growth arrest-specific gene 6), and several extracellular matrix-associated proteins (e.g., laminin, merosin, and agrin). The significance of these structural similarities is unknown but several of these proteins are ligands for plasma membrane receptors or interact in some way with other proteins. The amino-terminal LG domain of each subunit contains a steroid-binding site, the dimerization domain, and several metal-binding sites. Contrary to previous assumptions, it is now known that each subunit of the SHBG homodimer contains a functional steroid-binding site that may exist in different states of occupancy by various ligands. The structure and functional properties of the carboxyl-terminal LG domain of SHBG are less well understood but it normally contains two consensus sites for N-linked glycosylation, one of which is conserved phylogenetically and likely provides a specialized function. Although glycosylation is not necessary for steroid binding or dimerization, it may influence the biological half-life of the protein and/or its partitioning

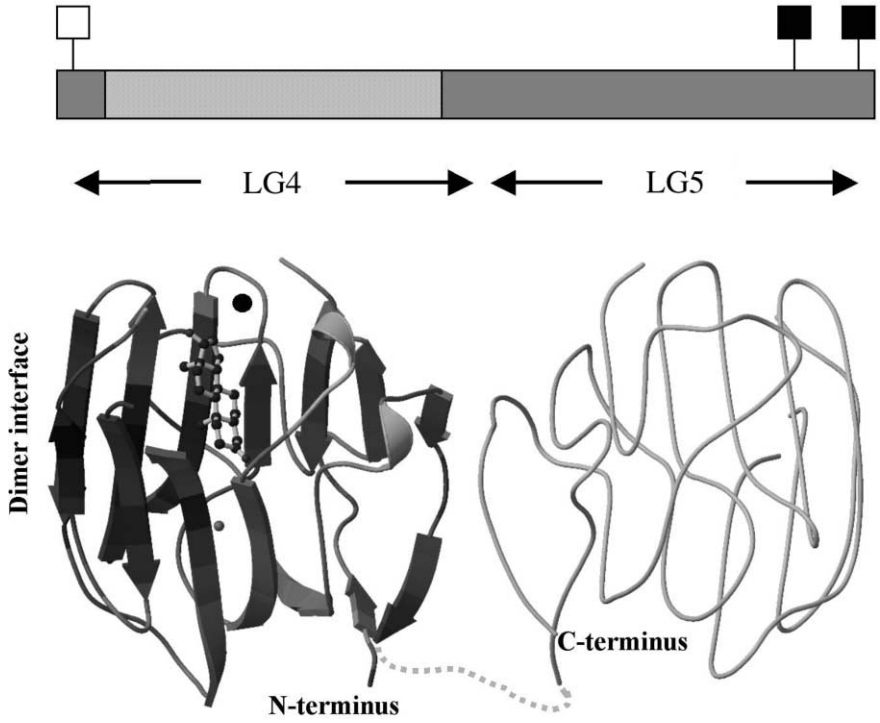

FIGURE 1 Structure of human sex hormone-binding globulin. Linear diagram of the 373 amino acid residues that constitute the mature human SHBG monomer (top) showing the positions of one O-linked (open box) and two N-linked (solid boxes) carbohydrate chains. The internal shaded region corresponds to the minimal sequence required to produce a truncated form of SHBG that contains a fully active steroid-binding site and dimerization domain. Each human SHBG monomer includes two laminin G-like domains (LG4 and LG5). The crystal structure of the amino-terminal LG4 domain (bottom) shows 5α-dihydrotestosterone in the steroid-binding site, the position of the homodimer interface, and a Ca^{2+} ion (small shaded ball). Also shown is a Zn^{2+} ion (solid ball) that occupies a potential zinc-binding site within a region (between residues P130 and P137) of disorder (not visible), which lies over the entrance of the steroid-binding site. Occupancy of this zinc-binding site specifically reduces the binding affinity of estradiol without changing the binding affinity of androgens. The predicted structure and relative position of the carboxy-terminal LG5 domain within the context of the overall SHBG monomer tertiary structure are also shown, with a dashed line corresponding to a short 5-residue sequence of unresolved structure connecting the LG4 and LG5 domains.

within extravascular compartments of sex steroid hormone-sensitive tissues.

In the blood, human SHBG binds biologically active androgens and estrogens with high affinity, and the plasma concentrations of SHBG play a key role in regulating the distribution of these steroids between the protein-bound (primarily SHBG-bound and albumin-bound) and the non-protein-bound or "free" fractions. This finding is considered to be important because only free steroids are generally considered to be available to target tissues. However, there is evidence that SHBG can enter the extravascular compartments of some tissues and may therefore exert a local effect on the access of steroids to their target cells. Human SHBG is also a zinc-binding protein, and occupancy of a zinc-binding site within the amino-terminal LG domain influences its steroid-binding specificity. This may be important in tissues where zinc concentrations are particularly high and where SHBG may accumulate, such as in the male reproductive tract.

Plasma SHBG and ABP interact with cell membranes of steroid-dependent tissues within the male reproductive tract. Although the significance of these interactions is not well understood, they may serve different functions. For instance, after being secreted into the seminiferous tubule fluid of male rats, ABP is actively taken up by epithelial cells within the epididymis. This is believed to facilitate the entry of testosterone into these cells and enhance the activation of androgen-responsive genes encoding proteins involved in sperm development. By contrast, only unliganded SHBG is capable of binding specific "receptor" sites within human prostate plasma

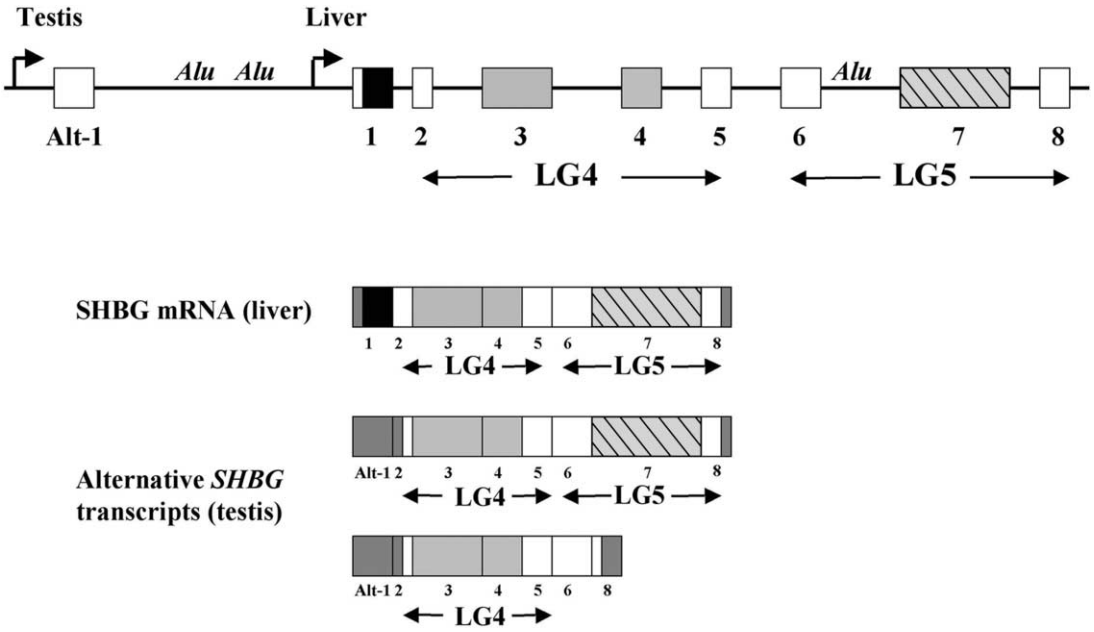

FIGURE 2 Diagrams of the human sex hormone-binding globulin (*SHBG*) gene and the major human *SHBG* transcripts in the liver and testis. The structure of the human *SHBG* gene (top) shows the positions of repetitive *Alu* sequences and the major transcription start sites (arrows) utilized in the liver and testis. The exons that produce SHBG mRNA in the liver and the alternative *SHBG* transcripts found in the testis are shown below the diagram of the *SHBG* gene structure with respect to sequences that encode the LG4 and LG5 domains of human SHBG. Boxes within the diagrams of these transcripts correspond to exon sequences. Exons (3 and 4) that encode sequences that constitute the steroid-binding site and dimerization domain are shaded in the gene sequence (top) and transcript sequences (bottom). The exon 1 sequence included within the SHBG mRNA found in the liver shows the sequence that encodes the secretion signal polypeptide (black area), which is removed during production of the mature form of plasma SHBG. In the testis, the two major *SHBG* transcripts contain an alternative exon 1 (Alt-1) sequence that replaces the exon 1 sequence present in the SHBG mRNA found in the liver, and they either contain or lack sequences corresponding to exon 7 (diagonally striped rectangles). The dark gray shaded areas within the exon 1 and exon 8 sequences present within the liver SHBG mRNA correspond to 5′ and 3′ noncoding sequences, respectively. Similarly, the dark gray shaded areas within Alt exon 1 and exon 2 sequences within the alternative transcripts found in the testis represent 5′ noncoding regions, whereas the dark gray shaded regions in exon 8 sequences correspond to the 3′ sequences that follow the termination of the major open reading frames.

membranes. In these circumstances, the membrane-bound SHBG can interact with biologically active androgens or estrogen, and if this occurs, SHBG appears to dissociate from the receptor, resulting in an increase in intracellular cyclic AMP levels and the activation of a signal transduction cascade. Although this receptor system has been characterized extensively at the biochemical level, the receptor itself has not been identified and its biological significance remains obscure.

II. CONTROL OF *SHBG* GENE EXPRESSION

Plasma SHBG and testicular ABP are encoded by eight exons within a single 4 kb gene (*SHBG*), which is located on the short arm (p12–p13) of human chromosome 17 (Fig. 2). The temporal and spatial expression of *SHBG* varies considerably between species, as does its sensitivity to various hormonal stimuli. Little is known about how *SHBG* is regulated during fetal life but it is expressed transiently in the livers of fetal rodents, resulting in fluctuations of plasma SHBG levels during critical periods of sexual development, and this likely occurs in other species including humans. In rats and mice, however, *SHBG* is not expressed in the liver during postnatal life and the very small amount of SHBG in the blood of mature rats most likely originates from gonadal sources. By contrast, *SHBG* expression in the livers of most other mammalian species increases after birth and represents the major source of plasma SHBG throughout life. In humans, changes in plasma SHBG

levels occur during puberty, leading to approximately twofold higher levels in women than in men. Plasma SHBG levels in humans are also under complex hormonal and metabolic control. For instance, exogenous estrogens and thyroid hormone markedly increase plasma SHBG levels, whereas anabolic androgens and androgenic progestins reduce plasma SHBG levels. Low plasma SHBG levels are found in obese men and women and this may in some way be related to the effects of insulin on reducing SHBG production by hepatocytes. The latter are of interest because several reports have indicated that low plasma SHBG levels are an early indicator of predisposition to diabetes and associated cardiovascular disease. However, it is not known whether any of these effects are mediated at the level of gene expression or reflect changes in the plasma half-life of SHBG.

The expression of *SHBG* in rat Sertoli cells has been studied extensively and is controlled directly by follicle-stimulating hormone and indirectly by testosterone through intermediary effects involving factors produced by the myoid cells surrounding the seminiferous tubules. The promoter responsible for controlling the production of ABP mRNA in Sertoli cells has been examined but the molecular mechanisms responsible for its regulation remain to be defined.

When the human *SHBG* proximal promoter sequence is compared with the corresponding regions of *SHBG* proximal promoter sequences in several other mammalian species, there is one major difference. The human *SHBG* promoter includes a region that contains two nuclear factor-binding sites that are not present in the promoters of other species. One of these sites binds hepatocyte nuclear factor-4, whereas the other binds the upstream stimulatory factor, and it is possible that this difference contributes to some of the species differences in *SHBG* expression.

III. SIGNIFICANCE OF ALTERNATIVE *SHBG* TRANSCRIPTS AND *SHBG* VARIANTS

The rat and human *SHBG* genes produce several other transcripts in addition to those encoding plasma SHBG and testicular ABP. These transcripts invariably contain alternative noncoding exon 1 sequences that replace the exon 1 that contains the translation initiation codon for the SHBG and ABP precursor polypeptides. The human alternative *SHBG* transcripts also often lack exon 7 sequences, and repetitive *Alu* sequences are located upstream of both the exon 1 and the exon 7 sequences that are either replaced or removed from these transcripts (Fig. 2). This may be significant because exons within the rat ABP that are differentially utilized are also preceded by repetitive DNA sequence elements. A rat *SHBG* transcript with an alternative exon 1 sequence has been shown to encode an ABP-related product containing a localization signal that directs it to the nucleus. However, the coding sequence for the unique amino-terminal sequence associated with this protein is not conserved in the alternative human *SHBG* transcripts identified to date. It has also been reported that *SHBG* is expressed in a variety of other tissues and cell types including rodent kidney, gut, and brain, the human uterus, placenta, and prostate, and several human cancer cell lines. The identity of the *SHBG* transcripts in most of these tissues and cell lines has not been defined but most of them are alternatively spliced transcripts with alternative exon 1 sequences.

Several human *SHBG* variants have been reported. The most common is a single-nucleotide polymorphism in exon 8, which results in a D327N substitution and introduces an additional N-glycosylation site in the carboxy-terminal laminin G-like domain. Although the steroid-binding affinities of this variant protein are normal, it may have an increased plasma half-life. However, even homozygous carriers of this allele display no obvious phenotype. A $(TAAAA)_n$ polymorphism in the human *SHBG* proximal promoter has been identified. The number of these repeats influences its transcriptional activity but it remains to be determined whether this polymorphism is associated with clinical disorders attributed to low plasma SHBG levels. It is likely that other variations in the coding and regulatory sequences of human *SHBG* exist and may explain the interindividual variations in plasma SHBG levels that may contribute to the etiology of diseases associated with inappropriate exposure to either androgens or estrogens.

IV. ROLE(S) OF *SHBG* GENE EXPRESSION IN MALE REPRODUCTION

The ABP produced by rat Sertoli cells is secreted into the lumen of the seminiferous tubule and accompanies the developing sperm as they migrate to the *caput* epididymis, where it is internalized by lumenal epithelial cells. Although it has been assumed that this plays an important role in maintaining a highly androgenic environment during sperm maturation, there is no evidence that this role is conserved across

species, and it may simply be restricted to mammals that lack SHBG in their blood circulation. Moreover, the mouse testis produces much less ABP than the rat testis, and transgenic mice that overexpress rat ABP in their Sertoli cells tend to become infertile due to meiotic arrest and a marked increase in germ cell apoptosis. The reason for this is not known but there is evidence that immunoreactive ABP produced in Sertoli cells is internalized by germ cells.

Early reports indicated that SHBG isolated from human testis homogenates differed from plasma SHBG in terms of its carbohydrate composition. However, it is virtually impossible to exclude the plasma contamination of SHBG from such extracts and there is evidence that plasma SHBG can readily enter the interstitial compartments of the testis. Thus, this difference in SHBG glycoforms between plasma and testis extracts might simply reflect the sequestration of a particular glycoform of plasma SHBG by the testis. Moreover, although *SHBG* transcripts can be readily detected in the human testis, what proportion of these transcripts encode an SHBG molecule with a leader sequence for secretion is not known. In fact, all of the near-full-length SHBG cDNAs isolated from human testis libraries contain alternative exon 1 sequences, and the testes of mice that express human *SHBG* transgenes contain only these same alternative transcripts. The biological significance of the alternative transcripts is obscure, but their abundance is tightly regulated throughout the spermatogenic cycle. These observations raise obvious questions about whether SHBG and ABP play distinct species-specific roles in controlling sex steroid hormone action in the testis and accessory reproductive tissues, and whether *SHBG* transcripts with alternative exon 1 sequences have some other function that remains to be defined.

In some human reproductive tissue, such as the prostate, there is evidence that plasma SHBG accumulates within extravascular compartments and within the stroma in particular. The mechanism responsible for this is unknown but SHBG in the extravascular compartments of these tissues might play a more direct role in regulating either the entry of active steroids into their target cells or the removal of metabolites. For instance, human SHBG not only binds testosterone with high affinity but also binds its major metabolites and with either higher (5α-dihydrotestosterone) or equal (5α-androstanediols) affinity. Furthermore, the possible interaction between SHBG and specific extracellular components within these locations may represent an additional means of modulating the actions of androgens and/or estrogens in reproductive tissues.

Glossary

androgen-binding protein A protein identical in sequence to the plasma sex hormone-binding globulin that is produced in the Sertoli cells of the testis. In rats, this protein displays a preference for biologically active androgens.

sex hormone-binding globulin A homodimeric plasma glycoprotein composed of two 42 kDa polypeptide subunits encoded by the *SHBG* gene. Each subunit contains a high-affinity steroid-binding site, which in humans binds both biologically active androgens and estrogens.

TABLE I Effects of Estrogen on the Immune System (Animal Model Data)

On sites of immune cell development
On bone marrow
– Increased estrogen levels reduce bone marrow mass and increase death of pre-B cells
– Hypogonadal mice (HPG/Bm–hpg/hpg or ovariectomized) have increased bone marrow cellularity with accumulation of B-cell precursors that reverts with estrogen treatment
On thymus
– Increased estrogen leads to thymus atrophy with apoptosis of $CD4^+$ $CD8^+$ T-cell precursors
– Prepubertal gonadecomy leads to thymus hypertrophy
Chronic administration of estrogen leads to development of alternative sites of lymphopoiesis in liver and spleen
In peripheral blood
On B cells
– Increased percentage of B cells in S and G2/M phases
– Reduced susceptibility to apoptosis, partly due to increased expression of Bcl/2
– Increased number and activity of plasma cells in peripheral blood and bone marrow, leading to elevated antibody levels
– Increased expression of autoantibodies (e.g., anti-dsDNA, cardiolipin phosphatidyl serine)
On T cells
– Decreased delayed-type hypersensitivity response in mice
– Reduced proliferation when stimulated *in vitro* with PHA or Con A
On the cytokine milieu
– Hormone-responsive elements identified upstream of IL-6 and IFN-γ-encoding genes
– Elevated estrogen levels increased frequency of IL-6 and IL-10 and reduced TNF-α-secreting cells in spleen
– Both increased and reduced IFN-γ and IL-2 reported in different mouse models
– Reduced IL-1 and TNF-α reported with anti-estrogens
On innate immunity
– Increased estrogen levels reduce NK-cell activity
– Increased estrogen levels reduce phagocytic and cytostatic activity of macrophages
– Elevated serum estrogens reduce macrophage production of reactive oxygen intermediates and IL-1
– At low concentrations, estrogen increased, TNF-α release by LPS-stimulated macrophages, whereas the opposite was evident at higher concentrations

high concentrations reduce—mixed lymphocyte reactions. Estrogens inhibit proliferation and facilitate apoptosis (by down-regulating Bcl-2) of $CD4^+$ T cells in a dose-dependent manner.

Cytokines have dramatic effects on the regulation of immune responses and the pathogenesis of a variety of diseases. Pro-inflammatory cytokines, such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor α (TNFα), are produced primarily by phagocytic monocytes in response to an infectious agent. The cytokines secreted by T cells have been categorized as type 1 or Th1 [secreting interferon-γ (IFN-γ)] and type 2 or Th2 (secreting IL-4, IL-5, and IL-10) and promote an adaptive response to the pathogen that is mainly cellular (type 1) or antibody (type 2) mediated. Estrogens favor a type 2 immune response by increasing the secretion of type 2 cytokines and by protecting type 2 $CD4^+$ T cells from death by apoptosis. Premenopausal women have larger numbers of cells secreting TNFα and IFN-γ than postmenopausal women and estrogen levels in their sera correlate with the number of cells secreting IL-4 on stimulation with phytohemagglutinin (PHA). In human $CD4^+$ Jurkat T-cell lines, estrogens suppress IL-2 secretion and receptor expression. This reduction is associated with decreased nuclear binding of nuclear factor kappa B and activator protein 1.

Estrogens modulate the innate immune response by altering the phagocytic and antigen-presenting properties of macrophages and dendritic cells. At low concentrations, estrogen increases TNFα release by lipopolysaccharide-stimulated macrophages, whereas the opposite is evident at higher concentrations. In addition, estrogens modulate the maturation of $CD14^+$ monocytes into dendritic cells by granulocyte/macrophage colony-stimulating factor (GM-CSF) and IL-4. With regard to natural killer (NK) cells, in mice, treatment with estrogens leads to stimulation of NK-cell activity during the first month, but prolonged exposure reduces NK-cell activity, both *in vivo* and *in vitro*. A similar reduction in NK-cell activity is observed in prostate cancer patients treated with estrogens.

III. PROLACTIN

A variety of immune cells express receptors for prolactin. Estrogen stimulates pituitary production of prolactin through its inhibition of hypothalamic dopaminergic suppression. In addition, several lines of evidence suggest that lymphohematopoietic cells in the periphery secrete prolactin. Prolactin stimulates both cellular and humoral immunity. On T cells, it promotes type 1 responses by increasing the secretion of IL-2 and IFN-γ and the expression of IL-2 receptors. On B cells, prolactin appears to synergize with estrogen to promote Ig production. Hyperprolactinemia, created by the transplantation of syngeneic pituitary glands, accelerates the mortality from immune complex glomerulonephritis in autoimmune B/W [(New Zealand Black × New

Zealand White)F1] mice, suppresses T-cell proliferation, and increases autoantibody concentrations.

IV. PROGESTERONE

Studies have shown that high levels of progesterone *in vivo* prolong the survival of allogeneic skin grafts as well as xenogenic tumor cell implants in hamster uteri. Progesterone, in contrast with estrogen or testosterone, inhibits spontaneous or glucocorticoid-induced thymocyte apoptosis *in vivo* and *in vitro*. In addition, treatment of T cells with pharmacological concentrations of progesterone blocks T-cell activation and killing by PHA or concanavalin A (Con A).

The identification of progesterone receptors on B cells, plasma cells, and macrophages suggests a direct effect on lymphocytes. Interestingly, the progesterone receptors are at low to undetectable levels in lymphocytes from nonpregnant women. Lymphocyte expression of progesterone receptors is up-regulated on cell activation either by a mitogen (e.g., PHA) or by allogeneic stimuli (such as the fetus). In addition, progesterone induces the secretion of progesterone-induced blocking factor, which blocks NK-cell activity, augments the secretion of IL-3, IL-4, IL-5, and IL-10, and inhibits the secretion of IL-12 by $CD4^+$ and $CD8^+$ T cells. The resulting shift in the cytokine balance toward type 2 is required for a successful pregnancy (see below).

V. ANDROGENS

Expression of the androgen receptor has been documented in lymphoid and nonlymphoid cells of thymus and bone marrow, but its expression in mature peripheral lymphocytes remains controversial. This expression pattern suggests that the major impact of androgens must be on the developmental maturation of T and B lymphocytes rather than on the mature effector cells. Like estrogens, androgens induce thymus involution with apoptosis of $CD4^+CD8^+$ (DP) thymocytes that is mediated by increased local TNFα and reduced IL-3. Prepubertal castration of male mice induces hypertrophy of the thymus. The resulting thymus retains its normal architecture but has increased cellularity (mainly due to proliferation of DP immature thymocytes). Administration of androgens blocks the proliferation of immature T cells. Castration of male mice also results in expansion of the pre-B-cell population in the bone marrow that may be reversed by testosterone or dehydrotestosterone treatment. Despite the apparent lack of androgen receptor in peripheral mature immune cells, a 40% increase in spleen weight is observed in castrated male mice.

In vitro, androgens enhance the activity of $CD8^+$ T cells as demonstrated by the reduced proliferation of spleen cells in response to PHA. In addition, higher levels of IFN-γ and IL-2 and lower levels of IL-4 and IL-10 are secreted by phytohemagglutinin-stimulated lymphocyte culture supernatants of men compared with women. In mice, treatment *in vivo* or direct exposure of lymphocytes to androgens leads to increased production of IL-2. Androgens also reduce at high doses (or increase at low doses) TNFα secretion and nitric oxide synthesis by macrophages. On B cells, androgens reduce Ig secretion and proliferative responses to pokeweed mitogen. This effect is partially dependent on IL-10 secretion but independent of the hormonal status of the cell donor (male or female; luteal or follicular phase of menstrual cycle; postmenopausal).

In contrast to estrogens, androgens have favorable effects on the course of several autoimmune diseases. This has been shown in animal models of experimental autoimmune encephalitis, adjuvant arthritis, and systemic lupus erythematosus (SLE). The protective effects are mediated by the shift toward a type 1 immune response, the reduced B-cell activity with lower Ig secretion, and the reduced secretion of pro-inflammatory cytokines by macrophages. These encouraging results have led to several ongoing clinical trials in patients with multiple sclerosis and SLE.

VI. PREGNANCY AND THE IMMUNE SYSTEM

A special event in hormonal status, pregnancy, is known to down-regulate cell-mediated immune responses, especially of the Th1 type, to safeguard the fetus. The cytokine milieu is important during implantation and contributes to the maintenance of the feto-placental unit. Low doses of IL-4, IL-5, GM-CSF, IL-3, or anti-TNFα improve implantation and reduce resorption rates whereas administration of TNFα, IFN-γ, or IL-2 causes abortion. In addition, during pregnancy there is an increase in γ/δ T cells and reduced NK-cell activity. These changes in the immune milieu are partly mediated by sex hormones. As a result, the pregnant woman has reduced DTH and allograft rejection, increased susceptibility to intracellular infections, and higher immunoglobulin levels than nonpregnant women.

VII. SEX HORMONES AND AUTOIMMUNE DISEASE

Autoimmune diseases are disorders in which the immune system attacks self in an uncontrolled manner. The phenomenon of gender bias in the susceptibility to autoimmune diseases has been recognized for many years. The data on the incidence of human autoimmune disease in adulthood show that females account for 65–75% of rheumatoid arthritis, Addison's disease, and myastenia gravis patients; for 85% of Hashimoto thyroiditis and Grave's disease patients; and for >90% of SLE patients. Changes in sex hormone levels such as during puberty, pregnancy, and menopause impact on the course of these diseases. Although sex hormones alone do not cause autoimmune disease, abnormal hormone levels or an altered response to these sex hormones may provide fertile ground for other factors (genetic, infectious) to trigger disease. Abundant clinical evidence connects estrogen to the pathogenesis of SLE; SLE patients, in general, have increased levels of estrogen or active estrogen metabolites and reduced levels of androgens in sera. The majority of the symptomatic episodes in women with regular menstrual cycles occur during the luteal phase of the menstrual cycle. Flares commonly take place during or immediately after pregnancy. In postmenopausal women, the impact of hormonal replacement on the incidence and course of SLE remains controversial and has led to a large ongoing multicenter trial. Additional evidence for the pathogenic role of steroid hormones on SLE includes a report describing three cases of previously healthy women who developed SLE after repeated cycles of ovulation induction. Moreover, repeated cycles of ovulation induction therapy in SLE patients have resulted in severe (even fatal) flares in SLE patients with anti-cardiolipin antibodies. It should be noted, however, that SLE is a multifactorial disease and hundreds of women undergo repeated cycles of ovulation induction every year without developing autoimmune diseases.

Several lines of investigation suggest a pathogenic role for the reduced levels of dehydroepiandrosterone sulfate (DHEAS) in female SLE patients, including an association with reduced levels of IL-2 and IFN-γ that are characteristic of SLE. Recent clinical trials showed that supplementation with exogenous DHEAS resulted in a modest clinical improvement in patients with moderate disease. The proposed mechanistic basis for their therapeutic success is the modulation of T-cell activity and cytokine secretion *in vivo*.

Glossary

adaptive immunity Branch of the immune system that mediates antigen-specific immune responses and immunologic memory. It consists of two limbs, cellular immunity and humoral immunity, which are mediated respectively by T and B cells expressing rearranged clonotypic antigen receptors capable of specifically recognizing the diverse antigens of the myriad infectious agents in the environment.

cytokines Soluble proteins that are involved in the regulation of the growth and activation of immune cells and mediate normal and pathologic inflammatory and immune responses.

innate immunity Branch of the immune system that is activated by conserved pathogen-associated molecular patterns, mediates immediate pathogen elimination, and presents the pathogen's antigens to the adaptive immune system. Its effector cells include natural killer cells, monocytes/macrophages, dendritic cells, neutrophils, basophils, eosinophils, tissue mast cells, and epithelial cells.

Subsequent sexual development of the genitalia and the brain is dependent on the influence of gonadal hormones.

I. INTRODUCTION

Males and females have evolved to have distinct reproductive potentials marked by profound gender differences in the control of gonadal function and behavior by the central nervous system. Females exhibit cyclic ovarian cycles characterized by fluctuating levels of gonadotropins and gonadal steroids that lead to periodic ovulation. In many species, the expression of female reproductive behaviors is synchronized to occur at or around the time of ovulation by the sequential secretion of high levels of estradiol followed by progesterone. Males, on the other hand, exhibit tonic steady-state levels of gonadotropins and gonadal steroids that maintain an uninterrupted production of sperm and an unconstrained potential for fertilization.

II. INFLUENCE OF TESTOSTERONE ON THE DEVELOPING BRAIN: GONADOTROPIN SECRETION

Specific regions of the brain play important roles in controlling reproductive behavior, gonadal function, and ovulation. The concept of sexual differentiation of the brain began with studies of reproductive functions. Early studies on rats by Carroll Pfeiffer showed that testicular implants into neonatal female rats permanently blocked ovulation. Pfeiffer concluded, incorrectly, that anterior pituitary function was altered by exposure to testicular secretions. It was later shown through transplantation experiments that the pituitary from a male rat could support ovulation and that the sex difference resides in the brain, not in the pituitary. Subsequent studies demonstrated unequivocally that the ability of rats to ovulate is related to the absence of testes in neonatal life. Males castrated within the first few days of life are able to sustain estrogen-stimulated gonadotropin secretion necessary for cyclic gonadotropin secretion and ovulation. Females exposed to exogenous testosterone within a week of birth become permanently anovulatory. These studies in rats demonstrate that the secretion of gonadotropins is regulated by both a tonic and a cyclic neural feedback system. Both genetic males and neonatally androgen-exposed (androgenized) females lack the neural mechanisms that control the ovulatory discharge or surge of gonadotropin. In contrast, these neural mechanisms are functional in genetic females and in neonatally castrated males.

The surge mechanism for the control of gonadotropin is not sexually differentiated in nonhuman primates, as it is in rodents. Castrated male monkeys secrete surge levels of luteinizing hormone in response to an estrogen challenge, and ovulation can be sustained when ovarian implants are placed subcutaneously into castrated male monkeys.

III. INFLUENCE OF TESTOSTERONE ON THE DEVELOPING BRAIN: SEXUAL BEHAVIOR

Gonadal hormone exposure during development is also responsible for dimorphisms in neural mechanisms that regulate sexual behavior. Charles Phoenix and colleagues demonstrated that the exposure of fetal female guinea pigs to testosterone permanently suppressed the expression of female sexual receptivity and facilitated malelike mounting behavior in adulthood. Similar studies performed on rats demonstrate that exposing neonatal females to testosterone will suppress feminine sexual behavior and enhance masculine sexual behavior. Conversely, castration of male rats soon after birth permanently suppresses masculine sexual behavior and enhances feminine sexual behavior. Exogenous testosterone treatment during early pregnancy masculinizes the genitalia and behaviors of female rhesus monkeys in infancy and adulthood. These studies suggest that gonadal steroids influence the differentiation of the brain in nonhuman primates as well as in rodents.

Phoenix referred to the permanent developmental effects of gonadal steroids as organizational effects to distinguish them from the activational effects that steroids exert to influence behavior temporarily during adulthood. At the time that this terminology was proposed, there was no evidence for hormone-dependent structural or chemical sex differences in the central nervous system. However, scientists have now identified many hormone-dependent sex differences in the anatomy and chemistry of the brain, some of which may underlie the differences in neuroendocrine function and sexual behavior that have been described. Any sex difference in brain structure or function established during sexual differentiation should remain after gonadectomy in adulthood or after adults of either sex are exposed to equivalent hormone doses. On the other hand, sex differences that are the result of activational steroid effects should be eliminated after gonadectomy or in the presence of similar hormone environments.

IV. CRITICAL PERIODS

Steroid hormones have an organizational effect only when present during a sensitive developmental period, commonly referred to as the critical period for sexual differentiation. The critical period is an empirical concept that differs depending on the species and the various brain functions being considered. For rats, which are born in an immature state, androgens given just after birth can affect adult sexual behavior. Other species, such as guinea pigs and nonhuman primates, must be exposed to androgens prenatally for adult behaviors to be modified.

These landmark studies established the thesis that the sexual phenotype of the brain is caused by the differentiating actions of testosterone during early development. In this way, sexual differentiation of the brain is comparable to that of other components of the reproductive system. Moreover, like the reproductive system, the female-typical brain appears to develop in the relative absence of hormonal exposure. It is increasingly apparent that a diverse set of brain functions is sexually differentiated. Some, such as regulation of gonadotropin and prolactin secretion, sexual behavior, maternal behavior, and aggression, are closely related to reproductive function. Others, such as taste preference, play behavior, and learning behavior, are not directly related to reproduction but are influenced by early hormone exposure.

V. ROLE OF ESTROGENIC METABOLITES OF TESTOSTERONE

When newborn female rats are treated with estradiol they develop a pattern of anovulatory sterility in adulthood that is very similar to that observed with perinatal testosterone exposure. In fact, the neonatal brain is much more sensitive to estrogen than to androgen and the effects of neonatal androgen exposure can be blocked by antiestrogens. Although these results were at first puzzling, it is now known that the developing rat brain has the capacity to convert circulating androgen to estrogen because of the presence of cytochrome P450 aromatase within neurons. This evidence led to the formulation of the aromatization hypothesis, which suggests that circulating androgens are converted into estrogens by aromatase in the brain, and that these estrogens are responsible for masculinizing the developing nervous system. If estrogen is the masculinizing hormone, then what protects the fetal brain from maternal estrogens? In rats, a protein found in the blood, called alphafetoprotein, binds estrogen but not testosterone in the first few weeks after birth. Alphafetoprotein traps circulating estrogen and thus protects the female brain from steroid exposure. In males, testicular testosterone is not bound by alphafetoprotein. Testosterone readily enters the neonatal brain of the male and is converted to estradiol to exert masculinizing effects.

There is little evidence that aromatized metabolites of testosterone play a role in sexual differentiation in other animal models, including guinea pigs and nonhuman primates. In these species, testosterone or its major androgenic metabolite, dihydrotestosterone, masculinizes the central nervous system and behavior. Nonetheless, high levels of aromatase are present in developing brains of every species so far studied, suggesting that locally produced estrogen may be needed for neural growth. Alphafetoprotein does not protect the fetus from maternal steroids in nonrodent species; instead, the placenta is thought to be important as a barrier that regulates the exposure of the fetus to maternal as well as exogenous steroids.

VI. SEXUAL DIMORPHISMS IN THE MAMMALIAN BRAIN

Sex differences in brain function are thought to derive, in part, from structural or morphological differences in the central nervous system. Sex differences in neural morphology are referred to as sexual dimorphisms. Over the past 30 years, sexual dimorphisms in the nervous system have been described at virtually every anatomical level—molecular, ultrastructural, cellular, and neural. Moreover, structural and cellular differences leading to sex differences in neural function and behavior appear to be distributed throughout the nervous system rather than concentrated in a single structure or circuit.

The first demonstration of a sexual dimorphism in the brain was the discovery by Raisman and Field that the number of synapses in the preoptic area was greater in male rats than in females. More apparent sexual dimorphisms in the number, size, and shape of neurons were soon described in the song control circuits of zebra finches. The song control nuclei are five to six times larger in males than in females. Moreover, it is believed that early exposure to androgen or estrogen organizes the larger masculine song system.

In rats, there is an obvious sex difference in a group of neurons called the sexually dimorphic nucleus of the preoptic area (SDN-POA). Roger Gorski was first to note that the volume of the

SDN-POA is about five times larger in the male than in the female. Most of this difference arises because there are greater numbers of neurons in the male nucleus. Like the song control nuclei in zebra finches, the volume of the SDN-POA is controlled by perinatal exposure to gonadal steroids but is not affected by circulating hormones in adulthood. Males castrated at birth have much smaller SDN-POAs in adulthood, whereas females treated with testosterone perinatally have larger malelike SDN-POAs as adults. Thus, perinatal exposure to androgens permanently alters the structure of the SDN-POA. Moreover, development of the nucleus conforms to the aromatase hypothesis because it has been demonstrated that conversion of testosterone to estradiol in the brain is required to masculinize the SDN-POA. Further support for this hypothesis was provided when it was shown that the SDN-POA in androgen-insensitive rats is masculinized. These rats have nonfunctional androgen receptors and thus masculinization cannot be mediated through this pathway. However, androgen-insensitive neonatal rats have normal levels of aromatase and estrogen receptor function, suggesting that the aromatization pathway mediates sexual differentiation of the SDN-POA.

Perinatal steroid hormones seem to act, in part, by preventing apoptotic cell death in the SDN-POA. Studies have shown that the incidence of apoptosis in SDN-POA between postnatal day 7 (P7) and P10 is higher in female rats than in male rats. Administration of testosterone or estradiol reduces the incidence of apoptosis in the SDN-POA of female rats or neonatally castrated male rats. The exact function of the SDN-POA is not yet completely understood. An indication of its function is the positive correlation between volume of the SDN-POA of rats and quantitative measures of adult male copulatory behavior. However, lesions of SDN-POA in rats cause only a transitory decline in male copulatory behavior. The function of the SDN-POA is much better understood in gerbils, which have a similar sexually dimorphic area (SDA) within the preoptic hypothalamus. Bilateral lesions of this region eliminate mating behavior in male gerbils.

Sexual dimorphisms have been identified in homologous medial preoptic nuclei of many species, including rats, gerbils, mountain voles, guinea pigs, ferrets, quail, macaques, and humans (see Section VII). In each case, males exhibit a larger volume and cell density than do females. The presence of sexually dimorphic nuclei within the medial preoptic area of so many species supports the idea that these structures are evolutionarily homologous. Other sexual dimorphisms are evident in several regions of the rat nervous system that are associated with sexual behavior and gonadotropin secretion. Most, but not all, of these nuclei are larger in males than in females. In particular, a cell group in the preoptic area of the hypothalamus known as the anteroventral periventricular preoptic nucleus (AVPv) is larger and has more cells in females than in males. The AVPv has extensive projections throughout the hypothalamus and is thought mediate the feedback of ovarian hormones to control the release of gonadotropin-releasing hormone by the hypothalamus. The development of sex differences in AVPv appears to be due to the organizational effects of perinatal hormone exposure. The nuclear size differences can be reversed by castration of newborn males or administration of testosterone or its aromatized metabolites to females within the first week of life. In contrast to SDN-POA, testosterone and estradiol increase cell death in AVPv during perinatal development, accounting for the smaller nuclear size in males.

Another well-studied model of sexual differentiation is found in the spinal cord. A small cluster of motoneurons in the lower lumbar spinal cord form the spinal nucleus of the bulbocavernosus (SNB). These motoneurons innervate the striated bulbocavernosus muscle at the base of the penis and play a role in erection and ejaculation. This nucleus and its target musculature are absent in the adult female. The musculature and SNB are present in both sexes at birth. The sexual dimorphism arises as the result of perinatal steroid hormone exposure. The results of several studies show that exposure to testosterone or the nonaromatizable androgen dihydrotestosterone maintains the bulbocavernosus musculature. Moreover, estrogen is not effective, so aromatization seems to be unimportant for the masculine development of this system. In the absence of androgen exposure, the muscles and the motoneurons in females begin to die. Androgens, either endogenous or exogenously administered, enhance muscle differentiation, which in turn appears to promote the survival of SNB motoneurons. No one knows yet what neurotropic substance the bulbocavernosus muscles provide to keep the SNB neurons alive.

Aside from the critical role of steroid hormones and programmed cell death, other factors may contribute to sexual differentiation of the nervous system. The behavior of rat dams with their male pups constitutes an example of how experience might interact with steroids to alter neural systems and behavior. During the postnatal period, the dam grooms the anogenital region of her pups to stimulate

urination and defecation. Male pups are groomed more often than female pups. Injecting females with testosterone attracts more attention from the dam, suggesting that the dam may detect androgenic metabolites in the pup's urine. This maternal attention contributes directly to the expression of normal male sexual behavior and the size of the SNB in adult males.

In summary, steroid hormones play a pivotal role in the sexual differentiation of the nervous system. In most models that have been studied, one can manipulate the sexual dimorphism in the nervous system by manipulating steroid hormones. Steroids, powerful regulators of gene expression and cellular function, act during early life to control cell survival, synapse formation, cell migration, and cell differentiation within the nervous system. Most likely steroid hormones act together with neurotransmitters and growth factors to sculpt neural development. In addition, social and environmental factors have been shown to play a role in shaping sex differences in the nervous system. Collectively these mechanisms act together to determine the final sexual phenotype of the brain. Recent evidence suggests that steroids also produce temporary structural changes in the brain of the adult, highlighting the notion that some neural sexual dimorphisms require steroid hormone both during development and in adulthood to display sex differences fully in neuroendocrine function and behavior.

VII. SEXUAL DIFFERENTIATION OF THE HUMAN BRAIN

Male and female humans, like other animals, are exposed to different hormonal environments during early development. Males have elevated levels of testosterone toward the end of the first trimester and into the first few weeks of the second trimester and again during the first 6 months after birth. Females probably produce estrogens prenatally, although it is not clear that this contributes to development. The question of whether these hormonal differences influence sexual differentiation of the human brain and behavior cannot yet be answered unequivocally. This results, in part, from obvious ethical restrictions on hormonal manipulations in human fetuses. In addition, human males and females experience a very different process of socialization that undoubtedly contributes to behavioral sex differences. Consequently, it is difficult to determine the relative contribution that hormones and social environment make to psychosexual development in humans.

Sex differences have been reported in a variety of human behaviors. Males are typically more aggressive, exhibit more rough-and-tumble play behavior, and perform better on visuospatial tasks. Females typically excel at verbal skills, especially verbal fluency and perceptual speed. Although these differences are statistically significant, they are based on a large number of subjects and there is usually more variation within each sex than between sexes for most human behaviors. The largest behavioral sex differences are seen in childhood play, sexual orientation, and gender identity.

A number of structural sexual dimorphisms in the human brain have been described, but many of the reports are controversial and their functional significance is less well established than in animal models. The sexually dimorphic nucleus identified in the preoptic area of humans was named the SDN-POA because it was thought to be the analogue of the SDN-POA found in rats and is larger in males than in females. Two subsequent studies have failed to replicate this finding, although both reported a sex difference in a separate subregion of the preoptic area, i.e., the anterior hypothalamus, known as the third interstitial nucleus of the anterior hypothalamus (INAH-3). The INAH-3 is larger in males than in females. Although controversial, the size of INAH-3 has also been related to sexual orientation, with homosexual and bisexual men having smaller (i.e., female-typical) INAH-3s than presumed heterosexual men. Other hypothalamic regions reported to show sex differences in humans include the suprachiasmatic nucleus and the bed nucleus of the stria terminalis. Midline brain structures showing sex differences include portions of the corpus collosum, anterior commissure, and massa intermedia. The anterior commissure has been related to sexual orientation and the corpus collosum has been related to language lateralization.

An informative approach for asking whether fetal steroids affect neural development in humans is to study individuals with clinical conditions that disturb the normal relationship between genetic sex and hormonal sex. It must be remembered, however, that these studies are not true experiments, and data derived from them are not conclusive on their own. Nonetheless, one interesting set of patients is females that are exposed to excessive androgens *in utero*, typically due to congenital adrenal hyperplasia (CAH). Individuals with CAH lack synthetic enzymes needed to produce corticosteroids and as a consequence large

amounts of precursor androgens are produced prenatally. The external genitalia may be mildly or extensively virilized. CAH girls behave more like boys, showing a pattern of behavior consisting of rough active outdoor play and interest in toys generally preferred by boys, with less interest in feminine clothing and doll play. In adulthood, CAH women are usually attracted to men, but are more likely to be homosexual or bisexual than are non-CAH women. Although some researchers attribute the behavioral masculinization in CAH girls to influences of androgens on brain development, others have noted that many other influences exist in this condition, such as psychological and social issues associated with chronic illness, ambiguous genitalia, and reduced fertility.

A clinical condition that has provided information on the behavioral consequences of androgen deficiency is androgen insensitivity. Genetic males with androgen insensitivity produce androgens but exhibit a defect in the androgen receptor that makes the receptor incapable of responding. Completely androgen-insensitive individuals look like normal females at birth, are raised as females, and develop feminine secondary sexual characteristics at puberty; however, they fail to menstruate because they lack female internal reproductive organs. These individuals act like normal females, displaying feminine spatial learning behavior and verbal behavior, and are sexually attracted to men. The fact that androgen-insensitive humans exhibit unambiguous feminine behaviors and gender identity argues that, unlike the case of androgen-insensitive rats, aromatized metabolites of androgens cannot be playing a major role for masculinizing the human brain. In agreement, it has been reported that males having congenital estrogen deficiency due to mutation of the aromatase gene assume a heterosexual sexual orientation and male sexual identity. There is evidence that *in utero* exposure of females to the synthetic estrogen diethylstilbestrol (DES) can masculinize the development of language lateralization, but this effect is small. Taken as a whole, these observations suggest that estrogen does not have the critical effect on nervous system sexual differentiation described in some rodent models.

VIII. SUMMARY

Gonadal steroids have profound effects on the sexual development of the brain in many nonhuman species. Testosterone secretion by fetal testes in males during the critical period is both necessary and sufficient to masculinize and defeminize gonadotropin feedback and the expression of adult sexual behaviors. In some rodent species, the intracellular aromatization of testosterone to estradiol is critical for these events to occur. In contrast, females develop in the absence of high androgen exposure. Developmental exposure to androgens has a permanent influence over the cell morphology and circuitry of the brain, i.e., the size of specific regions, the patterns of synaptic connections, the distribution of various neurotransmitters, and the expression of steroid receptors and signaling molecules. However, in some cases the functional significance of these sexual dimorphisms remains to be established. The cellular and molecular processes by which androgens and estrogens act to organize sex specific brain functions are not completely understood, but have been shown to include the regulation of cell migration, neuronal growth and axonal branching, and programmed cell death. Steroid hormones have also been shown to interact with social and environmental factors ultimately to determine the final sexual phenotype of the brain. Because of the dramatic effects of perinatal androgens in lower species, it has been generally assumed that similar processes occur in humans. Indeed, a number of behaviors and morphological brain features are sexually dimorphic in humans. Studies of humans with clinical syndromes in which fetuses are exposed to too much or too little androgen provide some support for these suppositions. However, because social environment plays such a crucial role in human psychosocial development, the question of whether and to what degree hormones influence the sexual differentiation of the human brain and behavior cannot yet be answered.

Glossary

activational effect Postpubertal process by which sex steroids exert an effect that transiently activates preexisting hormone-sensitive neural circuits.

aromatase Cytochrome P450 enzyme that converts androgens to estrogens; an important signaling pathway by which testosterone affects neural development and function.

critical period Time during development when sex steroids exert their organizational effects.

organizational effect Early developmental process by which sex steroids exert an effect that causes permanent, hard-wired differences in the structure and function of the central nervous system.

sexual dimorphism Sex difference in brain structure or function.

sexual differentiation Developmental process by which the two sexes become different.

Sgk Protein (Serum- and Glucocorticoid-Inducible Protein Kinase)

GARY L. FIRESTONE

University of California, Berkeley

Serum- and glucocorticoid-inducible protein kinaseSerum- and glucocorticoid-inducible protein kinase (Sgk) is a unique point of crosstalk that is targeted by diverse hormone signaling cascades. Cell surface receptor, nuclear receptor, and cellular stress signal transduction pathways converge on Sgk to alter cellular function, control cell proliferation, activate osmoregulatory pathways, and/or determine whether a cell survives or undergoes apoptosis. An important biological feature of Sgk is that this protein kinase is regulated at three distinct levels of cellular control. Unlike most other protein kinases, the transcription, enzymatic activity, and subcellular localization of Sgk can be acutely controlled in a stimulus-dependent manner. Sgk mediates its downstream effects through phosphorylation of specific proteins and by its specific binding to certain target proteins, although only a limited number of Sgk substrates and non-substrate target proteins have been identified.

TABLE 1 Genes Involved in Sexual Determination

Gene	Gene localization	Protein	Protein function	Affected pathway/metabolite synthesized
WT1	11p13	WT1	Transcription factor	Development of bipotential gonad
FTZ1-F1	9q33	Steroidogenic factor-1	Receptor	Gonadal development; steroidogenesis
DAX-1	Xp21	DAX-1	Transcription factor	Adrenal and gonadal development
SRY	Yp11.3	TDF	Transcription factor	Testicular development
SOX-9	17q24	SOX-9	Transcription factor	Testicular and cartilage development
DMRT1 and *DMRT2*	9p24	DMRT1 and DMRT2	Unknown	Testicular development
Wnt-4	1p31	Wnt-4	Growth factor	Ovarian development
AMH	—	Amh	Peptide hormone	Regression of Müllerian ducts
AMH II R	12	AMH receptor type 2	Receptor	Regression of Müllerian ducts
LHR	2p21	LH receptor	Receptor	Induction of testosterone synthesis
StAR	8p11	Steroidogenic acute regulatory protein	Transporter protein	Regulator of rapid steroid synthesis
CYP11A	15q23–24	P450 side chain cleavage	Enzyme; gonads and adrenals	Pregnenolone
CYP17	10q24	P450c17	Enzyme; gonads and adrenals	17α-OH pregnenolone, 17α-OH progesterone, dehydroepiandrosterone, androstenedione
HSD3B2	1p11	3β-Hydroxysteroid dehydrogenase type 2	Enzyme; gonads and adrenals	Progesterone, 17α-OH, progesterone, androstenedione
CYP21B	6p21	21-Hydroxylase	Enzyme; adrenals	11-Deoxycortisol, deoxycorticosterone
HSD17B3	9p22	17β-Hydroxysteroid dehydrogenase type 3	Enzyme; testis	Testosterone
SRD5A2	2p23	5α-Reductase type 2	Enzyme; androgen target tissues	Dihydrotestosterone
CYP19	15q21	Aromatase	Enzyme	Estradiol formation
AR	Xq12	Androgen receptor	Receptor	Androgen action

Another gene involved in the development of the bipotential gonad and the kidneys is the recently cloned *LIM1* gene. Homozygous deletions in this gene in mice lead to developmental failure of both gonads and kidneys. To date, no human mutations in this gene have been described, although a phenotype of renal and gonadal developmental defects in association with brain abnormalities might be anticipated. The role of steroidogenic factor-1 (SF-1) in gonadal formation is not yet clear. SF-1 is the product of the *FTZ1-F1* gene and is believed to be a nuclear orphan hormone receptor due to the presence of two zinc fingers and a ligand-binding domain in its molecular structure. *FTZ1-F1* mRNA is expressed in the urogenital ridge, which forms both the gonads and the adrenals, and is also found in developing brain regions. Mice lacking SF-1 fail to develop gonads, adrenals, and the hypothalamus. In humans, SF-1 mutation leads to adrenal insufficiency and sex reversal in 46,XY individuals. However, SF-1 is probably also involved in other aspects of sexual development, because it regulates expression of steroidogenic enzymes as well as transcription of the anti-Müllerian hormone (AMH).

Progession of gonadal differentiation beyond the bipotential gonad stage is mediated through gonosomal and autosomal genes. It was long believed and has been proved that a specific testis-determining factor (TDF) is essential for testicular development and that the encoding gene is located on the Y chromosome. This gene, named *sex-determining region of the Y chromosome* (*SRY*), is a single-exon gene; it encodes a protein with a DNA-binding motif that acts as a transcription factor and in turn regulates the expression of other genes. There is evidence that *SRY* binds to the promoter of the *AMH* gene and also controls expression of steroidogenic enzymes. Thus, *SRY* probably induces expression of *AMH*, preventing the formation of Müllerian duct derivatives. Genetically engineered mice with a normal male phenotype have been produced by introducing the mouse homologue *sry* into female mouse embryos, evidence that *SRY* is the TDF. Furthermore, naturally occurring mutations of *SRY* have been described in humans.

Autosomal genes that are structurally related to *SRY* genes have been described. These "*SRY*-box-related," or *SOX*, genes are to some extent involved in testicular development. *SOX-9* is connected with chondrogenesis and gonadal differentiation. This gene is transcribed especially following *SRY* expression in male gonadal structures. Additionally, *SOX-9* is an activator of the type II collagen gene, which is essential for formation of the extracellular matrix of cartilage. Defects in *SOX-9* therefore lead to skeletal malformations known as campomelic dysplasia as well as to sex reversal in 46,XY species.

The *DAX-1* gene is involved in adrenal, ovarian, and testicular development. This gene is located on the X chromosome; the name *DAX-1* derives from the gene location: the dosage-sensitive sex reversal locus (adrenal hypoplasia congenital critical region) on X gene 1. *DAX-1* is expressed during ovarian development but is silent during testis formation, implying a critical role in ovarian formation. Interestingly, *DAX-1* is repressed by *SRY* during testicular development. However, if a duplication of the *DAX-1* region on Xp21 is present in a 46,XY patient, and, thus, the activity of its gene product is enhanced, testicular formation is impaired. In contrast, mutations in *DAX-1* diminishing its activity lead to a lack of adrenal formation and also to hypogonadal hypogonadism in congenital adrenal hypoplasia. Additional genes involved in testicular differentiation have been localized on chromosome 10 and on chromosome 9 (*DMRT1* and *DMRT2*).

Until recently, the genetic events leading to ovarian development have not been well understood. Ovarian differentiation has been presumed to be a passive event, dependent on the absence of the dominant effects of the genes involved in testicular differentiation. However, there is a role for an active genetic pathway mediating ovarian development. Wnt-4 is an example of a member of the Wnt family of locally acting secreted growth factors. The corresponding gene is located on chromosome 1. In mice, deletion of *Wnt-4* causes virilization of XX animals. In contrast, it has been recently demonstrated that a duplication of 1p31–p35, which includes the *Wnt-4* locus in a 46,XY human, is associated with sex reversal and hence a female phenotype. *Wnt-4* is known to up-regulate *DAX-1,* which in turn antagonizes *SRY.* These findings suggest that *Wnt-4* has a key role in gonadal development and is also actively involved in ovarian differentiation.

III. SEXUAL DIFFERENTIATION

In early gestation, the anlagen for the Wolffian and Müllerian ducts are present in the fetus, regardless of the karyotype. If testicular formation is unhindered, the Sertoli cells will produce AMH. High concentrations of AMH and active binding to membrane receptors in the mesenchymal cells surrounding the Müllerian ducts are necessary to exert the

action of AMH. Reduced AMH excretion due to reduced Sertoli cell numbers is thus responsible for partial uterus formation in sex determination disorders. The AMH gene is under transcriptional control of several proteins involved in sexual differentiation. SF-1 binds directly to the AMH gene promoter and activates its transcription in Sertoli cells. A regulatory effect of SRY on AMH receptor expression has also been reported. Both lack of AMH and insensitivity to this hormone have been described in human disease. In persistent Müllerian duct syndrome (PMDS), 46,XY males are characterized by the presence of fallopian tubes and a uterus. The external genitalia are unequivocally male because steroid hormone formation is normal. Mutations within the AMH gene have been demonstrated in AMH deficiency. Although patients with AMH deficiency may have low serum AMH levels, in approximately 50% of the cases, AMH is within the normal limit or even elevated. This is assumed to be due to a defect of the type II AMH receptor, which is necessary for binding of ligand and exertion of AMH action. This receptor has been cloned and functionally relevant mutations have been demonstrated in patients with PMDS. The AMH type II receptor gene has been localized on chromosome 12. PMDS due to both AMH and AMH type II receptor gene mutations is inherited in an autosomal recessive fashion.

IV. ENZYMATIC PATHWAYS OF SEX STEROID SYNTHESIS

Unhindered steroid hormone formation and action are necessary for normal development of the external genitalia. Furthermore, defects in cholesterol synthesis may also lead to distinct sex phenotypes, including defects in genital development. The Smith–Lemli–Opitz syndrome is an autosomal recessive disorder with several congenital abnormalities and mental retardation. In addition to genital malformations, polydactyly, cardiac abnormalities, and growth disorders are noted. This syndrome is caused by defects in 7-dehydrocholesterol reductase, with elevated levels of the cholesterol precursor 7-dehydrocholesterol and low serum cholesterol levels. Analysis of mutations in the 7-dehydrocholesterol reductase gene in patients with biochemically proved Smith–Lemli–Opitz syndrome has for the first time demonstrated the importance of intact cholesterol synthesis for steroid production.

The first steps of steroid biosynthesis are common pathways for glucocorticoids, mineralocorticoids, and sex steroids. Testosterone synthesis in the developing testes is controlled during early fetal life by human chorionic gonadotropin (hCG) and only later by the fetal luteinizing hormone (LH). Both hCG and LH stimulate testosterone synthesis via the LH receptor (LHR). The LHR belongs to a family of G-protein-coupled receptors with seven transmembrane helices. It has a long extracellular domain involved in ligand binding, in contrast to other receptors of this family, e.g., the thyroid-stimulating hormone (TSH) receptor. The genetic organization of LHR was elucidated in 1995. The gene is localized on chromosome 2p21 and spans over 90 kb, with a coding region divided into 11 exons. Naturally occurring mutations within the LHR, depending on their localization, have been demonstrated to result both in loss as well as gain of function. Inactivating mutations of the LHR are associated with gonadotropin unresponsiveness and lead to Leydig cell agenesis and subsequently to defective sexual differentiation. More often the result is a completely female phenotype, but incomplete virilization due to partial receptor responsiveness with subnormal androgen synthesis has been described. These mutations are typically located in the transmembrane domain of the receptor, but mutations within the extracellular domain have also been reported to result in loss of function. These molecular abnormalities imply an active role of the LHR in Leydig cell growth and differentiation. In contrast, constitutive activation of the LHR leads to normal male phenotype, although precocious pseudopuberty occurs due to mutation of the LHR, with excessive secretion of testosterone by the Leydig cells (familial testotoxicosis). Microscopically, Leydig cell hyperplasia is evident in the testes of these patients. Activating mutations of the LHR are also located in the transmembrane domain, frequently near the third intracellular loop of the receptor.

Defects within the first steps of steroid synthesis will affect either all or at least two of the final metabolites within the gonads and the adrenals. Steroid hormones are synthesized from cholesterol within the mitochondria. The acute stimulation of steroid synthesis is mediated by the steroidogenic acute regulatory (StAR) protein, which is an active transporter of cholesterol through the inner mitochondrial membrane. Mutations within StAR lead to severe lack of adrenal steroidogenesis as well as lack of virilization in 46,XY individuals in lipoid congenital adrenal hyperplasia. Intrauterine survival of affected embryos is possible, because placental steroidogenesis is not StAR dependent. Due to

accumulation of cholesterol, the adrenals and testes are further damaged and the residual non-StAR-dependent steroid synthesis is also diminished. Therefore, at birth, low levels of steroids may be measurable, but these may be depleted later. The StAR gene has been cloned and several mutations have been characterized in patients with lipoid congenital adrenal hyperplasia. StAR mutations, as are all other genetic defects of steroid biosynthesis, are inherited in an autosomal recessive fashion, and both genetic female and male individuals can be affected.

The first enzymatic step in steroid synthesis from cholesterol to pregnenolone is mediated by the mitochondrial cytochrome P450 enzyme, which cleaves the cholesterol side chain. Until recently, only one naturally occurring mutation in this enzyme had been described in association with human disease. It was hypothesized that although the mutation did not exert a dominant negative effect, it would still cause 46,XY sex reversal and adrenal insufficiency because haploinsufficiency would lead to slow accumulation of cholesterol in the target organs, and hence to their destruction. It has been postulated that homozygous P450 side chain cleavage (P450scc) mutations would also—in contrast to defects in StAR—affect placental steroid synthesis and therefore these fetuses would not survive. This does not hold true for the other enzymes of early androgen biosynthesis. The P450c17 enzyme is a qualitative regulator of steroid synthesis with two distinct activities. The activities of both 17α-hydroxylase and 17,20 lyase can be differentially regulated. Although 17α-hydroxylase catalyzes the conversion of pregnenolone to 17-OH pregnenolone and progesterone to 17-OH progesterone, the 17,20 lyase activity is necessary for the enzymatic reaction from 17-OH pregnenolone to dehydroepiandrosterone and 17-OH progesterone to androstenedione. P450c17 is encoded by a single-copy gene on chromosome 10q24.3 and mutations within this gene can inhibit both functions, or, selectively, only the 17,20 lyase activity, of the resulting protein. Patients with isolated 17,20 lyase deficiency have been described only recently. The underlying molecular abnormalities within the P450c17 protein result in a severely diminished 17,20 lyase activity but only moderately inhibited 17α-hydroxylase function. Interestingly, 17,20 lyase activity depends largely on phosphorylation of the protein, and dephosphorylation of P450c17 may be a major factor in isolated 17,20 lyase deficiency. To date, only two mutations in the P450c17 gene fulfill the criteria for causing isolated 17,20 lyase deficiency. Differentiation of the two enzyme activities is important in diagnosing human disorders of P450c17 deficiency, because a combined defect will cause hyperaldosteronism and endocrine hypertension, whereas patients with isolated 17,20 lyase deficiency will have normal glucocorticoid synthesis.

The third important enzyme of ubiquitous steroidogenesis is 3β-hydroxysteroid dehydrogenase (3β-HSD), which also plays a major role in androgen biosynthesis. 3β-HSD catalyzes the formation of Δ^4 steroids, thus also the synthesis of androstenedione, the major precursor of testosterone. Two isoforms of the human enzyme have been cloned. The type 1 enzyme catalyzes the formation of progesterone, androstenedione, and 17-OH progesterone from pregnenolone, dehydroepiandrostenedione, and 17-OH pregnenolone. Type 2 3β-HSD shares a 90% sequence homology with the type 1 form, but has a lower catalytic efficiency. Genes for both types are located on chromosome 1p13.1 and consist of four exons. In 3β-HSD deficiency, mutations within the gene encoding for the type 2 enzyme have been found. Type 2 3β-HSD is predominantly expressed in the adrenals and gonads, hence its blockade results in congenital adrenal hyperplasia. In males, defective virilization due to diminished testosterone synthesis is also noted. Females may demonstrate signs of excessive virilization due to elevated adrenal androgens.

The classic form of congenital adrenal hyperplasia and the most common cause of intersex disorders in 46,XX individuals is 21-hydroxylase deficiency. The enzymatic step from 17α-hydroxyprogesterone to 11-deoxycortisol is inhibited in the glucocorticoid pathway, and this inhibition occurs in part also in the synthesis of deoxycorticosterone from progesterone in mineralocorticoid synthesis. Patients with severe 21-hydroxylase deficiency will have excessively high adrenal androgen levels and 46,XX children will display severe virilization of the external genitalia. In children with the 46,XY karyotype, the phenotype is not altered. The *CYP21* gene has been determined to be involved; *CYP21* is localized on chromosome 6p21.3 and direct genetic analysis is performed on a regular basis for diagnostic purposes. This is the prerequisite not only for genetic counseling, but also for approaches for experimental prenatal maternal therapy with glucocorticoids.

Late sex steroid synthesis defects comprise enzymatic reactions that do not inhibit glucocorticoid and mineralocorticoid formation. Although 17β-hydroxysteroid dehydrogenase (17β-HSD)

converts androstenedione to testosterone within the testes, 5α-reductase (5α-R) catalyzes the conversion of testosterone to dihydrotestosterone (DHT) in the peripheral target cells. At least five different 17β-HSD isoenzymes exist. Only mutations in the type 3 enzyme have been demonstrated to be responsible for defective sex differentiation in patients with 17β-HSD deficiency. This disorder is characterized by a severe virilization defect in 46,XY individuals, although they show strong signs of virilization during puberty, with marked phallic enlargement. The type 3 17β-HSD gene is located on chromosome 9p22, spanning over 11 exons and encoding a protein of 310 amino acids. This enzyme is expressed only in the testes, compatible with its important role in testicular androgen formation. However, no strict genotype–phenotype correlation has been demonstrated in 17β-HSD deficiency. It remains to be investigated whether the other 17β-HSD isoenzymes play a critical role in the phenotypic expression of 17β-HSD deficiency due to decreased peripheral conversion of testosterone to androstenedione.

Further conversion of testosterone to DHT is catalyzed in the peripheral target tissues and not within the gonads. The two isoenzymes of 5α-reductase are expressed in diverse tissues, but type 2 5α-reductase is more abundant in genital structures. The type 1 enzyme is necessary for reduction of androgens to inhibit excess formation of estrogens, and thus mice lacking this enzyme fail to maintain normal pregnancies. A specific role of the 5α-reductase type 1 enzyme in male sexual differentiation has not been demonstrated. In contrast, several mutations have been described in the type 2 enzyme in patients with defective virilization. The underlying gene has been localized to chromosome 2p23 and is divided into five exons. In 5α-reductase deficiency, DHT formation is severely diminished. However, testosterone levels are normal or even elevated. Affected 46,XY individuals are usually born with ambiguous external genitalia, but the phenotype may be highly variable. The differentiation of Wolffian structures, which is largely dependent on testosterone, is not impaired. At the time of puberty, strong virilization may occur due to high endogenous testosterone levels. Gynecomastia due to estrogen excess has rarely been described.

In 46,XX patients, a rare cause for virilization is a defect in the aromatization of estradiol from testosterone. The aromatase complex belongs to the cytochrome P450 enzymes and is expressed in the gonads and in a variety of other tissues. There is only one corresponding gene, localized on chromosome 15q21. The mother carrying a fetus with aromatase deficiency may suffer from excessive masculinization. Biochemical analysis showing low or absent estradiol in conjunction with elevated androstenedione and testosterone is diagnostic. In males, aromatase deficiency will not lead to a genital abnormality, but due to the diminished estradiol, skeletal maturation is delayed extensively.

V. MECHANISMS OF ANDROGEN ACTION

The final biological steps in the cellular cascade of normal male sexual differentiation are initiated by the molecular interaction of testosterone and dihydrotestosterone with the androgen receptor (AR) in androgen-responsive target tissues. The AR is a ligand-activated transcription factor of androgen-regulated genes. It is commonly assumed, though not experimentally proven to date, that a controlled temporal and spatial expression of androgen-regulated genes during early embryogenesis provokes a distinct spectrum of functional and structural alterations of the internal and external genitalia, ultimately resulting in the irreversible formation of the normal male phenotype. However, the AR is also expressed in females during embryogenesis, and elevated androgens during this stage, as in congenital adrenal hyperplasia, will lead to virilization in genetic females.

The AR belongs to the intracellular family of structurally related steroid hormone receptors. Transcriptional regulation through the AR is a complex multistep process involving androgen binding, conformational changes of the AR protein, receptor phosphorylation, nuclear trafficking, DNA binding, cofactor interaction, and, finally, transcription activation. The human AR gene was cloned more than a decade ago by several groups and has been mapped to Xq11–q12. It spans approximately 90 kilobases (kb) and comprises eight exons(1–8, or A–H). Transcription of the AR gene and subsequent splicing usually results in distinct AR mRNA populations in genital fibroblasts. Translation of the mRNA to the AR protein usually leads to a product migrating at about 110 kDa in Western immunoblots, comprising between 910 and 919 amino acids.

The AR shares its particular modular composition of three major functional domains with the other steroid hormone receptors. A large N-terminal domain precedes the DNA-binding domain, followed by the C-terminal ligand-binding domain. Additional functional subdomains can be identified by *in vitro* studies of artificially truncated, deleted, or point-mutated ARs. Upon entering target cells, androgens

interact very specifically with the ligand-binding pocket of the AR. This initiates an activation cascade with conformational changes and nuclear translocation of the AR. Prior to receptor binding to target DNA, homodimerization of two AR proteins occurs in a ligand-dependent manner. This is mediated by distinct sequences within the second zinc finger of the DNA-binding domain as well as through specific structural N–C-terminal interactions. The AR homodimer binds to hormone response elements (HREs) that usually consist of two palindromic (half-site) sequences within the promoter of androgen regulated genes. Through chromatin remodeling, direct interaction with other transcription factors, and specific coactivators and corepressors, a steroid receptor-specific modulation of the assembly of the preinitiation complex is achieved, resulting in specific activation or repression of target gene transcription.

Defective androgen action due to cellular resistance to androgens causes the androgen insensitivity syndrome (AIS). The end-organ resistance to androgens results in a wide clinical spectrum of defective masculinization of the external genitalia in 46,XY individuals. Müllerian duct derivatives are usually completely absent because of the normal ability of the fetal testes to produce AMH. Cloning of the AR gene made it obvious that inactivating mutations of the AR gene represent the major molecular genetic basis of AIS. Due to the X-chromosomal recessive inheritance, female carriers may typically be conductors. Partial impairment of AR function is usually associated with partial androgen insensitivity syndrome (PAIS). The considerable variability in the degree of impaired AR activity accounts for a wide clinical spectrum of external undervirilization observed in PAIS. In the complete androgen insensitivity syndrome (CAIS), any *in vivo* androgen action is abolished due to complete inactivation of *in vivo* AR signaling. Therefore, these patients have normal female external genitalia with a short and blind-ending vagina. At puberty, CAIS patients acquire a normal female body shape and they show normal breast development. This is due to increasing estradiol levels that accompany elevated pubertal testosterone biosynthesis and conversion to estradiol by aromatization. Usually, pubic or axillary hair is absent.

More than 300 different mutations have been identified in AIS to date. Extensive structural alterations of the AR can result from complete or partial deletions of the AR gene. Smaller deletions may introduce a frameshift into the open reading frame, leading to a premature stop codon downstream of the mutation. Similar molecular consequences arise from the direct introduction of a premature stop codon due to point mutations. Such alterations usually lead to severe functional defects of the AR and are associated with CAIS. Extensive disruption of the AR protein structure can also be due to mutations leading to aberrant splicing of the AR mRNA. However, because aberrant splicing can be partial, thus enabling expression of the wild-type AR, the AIS phenotype is not necessarily CAIS but may also present as PAIS. The most common molecular defects of the AR gene are missense mutations. They may result either in CAIS or in PAIS because of complete or partial loss of AR function. Mutations within the ligand-binding domain may alter androgen binding but may also influence dimerization due to disruption of N–C-terminal structural interactions. Mutations within the DNA-binding domain can affect receptor binding to target DNA. The functional role of mutations within the N-terminal domain is not completely understood. Moderate extension of the polyglutamine trinucleotide segment (>30) may cause a moderate inhibition of transcriptional activity and therefore result in mild androgen insensitivity, i.e., gynecomastia. Isolated male infertility due to impaired spermatogenesis may be a symptom of mild AIS as well. Increasing knowledge about the cofactors of AR signaling continue to influence the concept of the pathogenesis of AIS on the molecular level. Recently, the first female patient with complete AIS without an AR gene mutation, but with clear experimental evidence for an AR co-activator deficiency as the only underlying molecular mechanism of defective androgen action, has been reported. Cofactors of the AR will presumably play a pivotal role in understanding the phenotypic variability in AIS. So far, only a few mechanisms contributing to the phenotypic diversity in AIS have been identified in affected individuals. A striking phenotypic variability in a family with partial AIS has been attributed to differential expression of the 5α-reductase type 2 enzyme in genital fibroblasts. Another mechanism may be the combination of varying androgen levels during early embryogenesis and partially inactivating mutations of the ligand-binding domain.

Moreover, postzygotic mutations of the AR gene resulting in a somatic mosaicism of mutant and wild-type AR genes can contribute to modulation of the phenotype. This can result in a higher degree of virilization than expected from the AR mutation alone, because of the expression of the wild-type AR in a subset of somatic cells. Because at least one-third of all *de novo* mutations of the AR gene occur at the postzygotic stage, this mechanism is not only

important for phenotypic variability in AIS but also crucial for genetic counseling.

Further decoding of the molecular and biochemical pathways is necessary for a comprehensive understanding of normal and abnormal sexual determination and differentiation. Based on the known molecular defects involved in impaired human sexual development, recent achievements in the fields of functional genomics and proteomics offer unique opportunities to identify the genetic programs downstream of these pathways, which are ultimately responsible for the structure and function of a normal or abnormal genital phenotype.

Glossary

gonads Testes and ovaries; develop from the urogenital ridge through a bipotential gonad. This process is mediated through differentiated genetic control.

hormone receptor A mediator for hormone action. In sexual differentiation, receptors for peptide hormones and steroid hormones play an active role.

sexual determination Gonadal development via genetically determined pathways.

steroid biosynthesis Synthetic pathways that start with cholesterol; defined enzymatic steps produce the final products, glucocorticoids, mineralocorticoids, and sex steroids. Intermediate products may induce distinct hormonal actions, as is seen in enzymatic pathway defects that lead to abnormal hormonal profiles and defined disorders in humanz.

Sexual Differentiation of the Brain

CHARLES E. ROSELLI

Oregon Health and Science University

The hormonal environment that exists during perinatal development is thought to be the predominant determinant for sex differences in reproductive endocrinology and behavior. In this way, the brain and the reproductive system appear to follow the same rules of sexual differentiation, and, as such, the brain conforms to the hormonal theory of sexual differentiation that was first elaborated by the classic work of Alfred Jost. Specifically, in mammals, sex chromosomes specify differentiation of the bipotential gonads into either testes or ovaries.

The list of hormone- and stimulus-dependent cascades that include Sgk as a key integrator of receptor signaling events continues to expand, and Sgk has been implicated in the pathology of several human endocrine disorders.

I. INTRODUCTION

In vertebrates and other multicellular organisms, individual cells are inundated with many types of hormonal cues and other extracellular stimuli that activate a diverse array of intracellular signal transduction pathways. The ability of cells to sense dynamic changes in their environment and then mount physiologically appropriate responses requires communication with regulatory molecules that can coordinately integrate the intracellular signals that emanate from different receptor signaling cascades. One such critical intracellular component is the serum- and glucocorticoid-inducible protein kinase, Sgk. This protein kinase was originally isolated in a differential screen for glucocorticoid-inducible transcripts from rat mammary epithelial tumor cells as a novel protein kinase that is under acute transcriptional control by serum and glucocorticoids.

Emerging evidence implicates Sgk as an important focal point by which cell surface receptors, nuclear receptors, and cellular stress signaling pathways converge to alter cellular function and the proliferative state and/or determine whether a cell survives or undergoes apoptosis. For example, in different cell and tissue types, Sgk can act as a stimulus-dependent switch in cellular responses to glucocorticoids, mineralocorticoids, follicle-stimulating hormone, growth factor-/insulin-activated cell survival and proliferative pathways, hyperosmotic shock, and transforming growth factor-β (TGF-β). Furthermore, Sgk has been implicated in the pathology of endocrine disorders such as diabetic nephropathy and in physiological abnormalities associated with alterations in the mineralocorticoid control of renal sodium transport.

The various hormone receptor-activated cascades regulate Sgk availability and function at three distinct levels of cellular control. First, an expanding set of hormonal and nonhormonal extracellular cues strongly stimulate Sgk gene expression. Second, Sgk is phosphorylated and enzymatically activated as a downstream component of the phosphatidylinositol 3-kinase (PI3-kinase) signaling cascade that mediates the mitogenic and cell survival response to many growth factors and insulin. Finally, the nuclear–cytoplasmic shuttling of Sgk is controlled by the cell cycle, as well as by exposure to specific hormones and to environmental stress. Thus, a biologically significant feature of Sgk is the simultaneous and stringent stimulus-dependent regulation of its transcription, subcellular localization, and enzymatic activity (Fig. 1).

II. Sgk PROTEIN STRUCTURE–FUNCTION

The *sgk* gene encodes a 431-amino-acid, 50 kDa protein, and its catalytic domain shows strong homology (45–55% identity) to the catalytic domains of several well-characterized members of the "AGC" family of serine/threonine protein kinases that are constitutively expressed. The protein kinases most closely related to Sgk are Akt/protein kinase B (PKB), protein kinase A, protein kinase C-ζ, and the rat $p70^{S6K}$/$p85^{S6K}$ kinases. In addition, two other Sgk isoforms have been uncovered (Sgk-2 and Sgk-3), although their cellular functions have not been well studied. This article will restrict its discussion to the originally isolated isoform of Sgk. Members of the related family of mammalian protein kinases that includes Sgk propagate cell signaling cascades associated with the control of cell growth, differentiation, and cell survival and are highly conserved between metazoans and mammals. For example, in addition to humans, rats, and mice, Sgk homologues have been identified in the genomes of diverse species such as frogs, the nematode *Caenorhabditis elegans*, and the budding yeast *Saccharomyces cerevisiae*. One rationale for the evolutionary conservation of Sgk is its role in allowing unicellular and multicellular organisms to adapt and survive environmental stresses such as extreme changes in nutrient levels, temperatures, or osmolarity. In this regard, the two yeast Sgk homologues can be functionally complemented with mammalian Sgk, which strengthens the notion of an evolutionarily important role for Sgk in integrating hormone-activated cellular signals.

As shown in Fig. 2, Sgk has several distinctive structural features that are likely to control aspects of Sgk function in a stimulus-specific context. Sgk has three general regions, a relatively short (70 amino acids) unique amino-terminal domain, a central region containing the catalytic domain, and a unique carboxy-terminal domain. Each of these subregions contains important structural features required for the cellular regulation of Sgk. The N-terminal domain contains a phosphorylation site at serine 78 (P-P-S78-P) that fits the P-x-S/T-P consensus requirements for certain proline-directed kinases and has been shown to be phosphorylated by the big mitogen

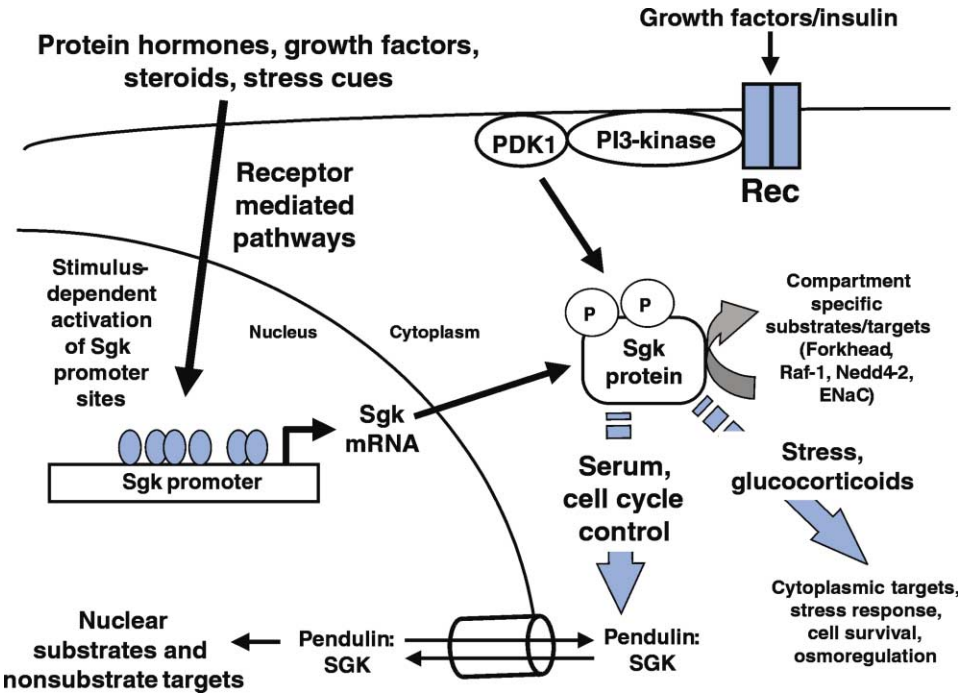

FIGURE 1 Hormone and stimulus control of Sgk expression, enzymatic activity, and subcellular localization. Sgk is regulated at three distinct levels of cellular control. The activation of hormone receptor-dependent cascades, as well as environmental stress, regulates Sgk expression by targeting distinct elements in the Sgk promoter. The growth factor/insulin activation of the PI3-kinase pathways results in the phosphorylation of Sgk and the generation of an enzymatically active Sgk. Under proliferative conditions, Sgk is imported by the actions of pendulin/importin-α into the nucleus, where Sgk has access to its nuclear target proteins. After treatment with glucocorticoids or exposure to environmental stress, Sgk resides in a cytoplasmic compartment and mediates the cell survival response.

activative protein kinase 1 (BMK1)/extracellular signal-related kinase 5 (ERK5) member of the mitogen-activated protein kinase (MAPK) family. There are several proline-rich tracts in the N-terminal domain that could conceivably be recognition sites for Sgk target proteins, as well as a putative mitochondrial import signal that may localize cytoplasmic Sgk to this organelle as part of the hormone-dependent cell survival response.

The central domain of Sgk contains all of the essential amino acid sequences necessary to be a functional serine/threonine protein kinase including lysine 127 in the ATP-binding region and threonine 256 in the activation loop. Mutation of lysine 127 (to methionine) forms a kinase-dead version of Sgk. As described in more detail in Section VI and diagrammed in Fig. 2, Sgk is enzymatically activated by phosphorylation of threonine 256 in the activation loop of Sgk, as well as by phosphorylation of serine 422 in the carboxy-terminal domain, by the PI3-kinase-dependent pathway through the direct actions of phosphoinositide-dependent protein kinase 1 (PDK1). The central domain also contains a nuclear localization signal between amino acids 131 and 138 in the central domain (see Section VIII) that controls the signal-dependent nuclear import of Sgk, as well as specific recognition sites for other proteins such as Nedd4-2 at a PY domain (see Section III). Similarly, the carboxy-terminal domain contains a putative PDZ-binding motif that is likely to be involved in Sgk recognition of target proteins. The Sgk structure domains suggest that this protein kinase acts through phosphorylation of specific substrates (see Section VII) and through specific sets of regulated protein–protein interactions.

III. CELLULAR AND PHYSIOLOGICAL FUNCTIONS OF STIMULUS-INDUCED Sgk

A. Role of Sgk in Glucocorticoid and Growth Factor Regulation of Cell Proliferation

Sgk is a transcriptionally induced component of glucocorticoid- and growth factor-regulated gene

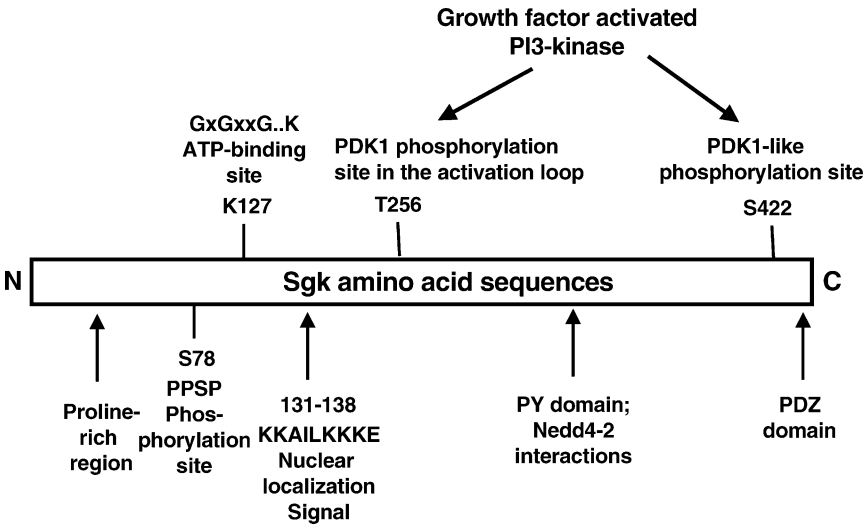

FIGURE 2 Sgk protein structure and functions. The Sgk protein contains three phosphorylation sites. Serine 78 is a proline-directed phosphorylated site that is recognized by members of the mitogen-activated protein kinase family. Threonine 256 and serine 422 are phosphorylated by PDK1 through a PI3-kinase-dependent cascade and are required for the growth factor/insulin activation of Sgk enzymatic activity. Lysine 127 is needed for ATP binding and protein kinase activity. Sgk also contains a proline-rich region in the N-terminal domain, a nuclear localization signal at 131–138, a PY domain required for the Sgk interactions with Nedd4-2, and a putative PDZ site that likely is involved in the recognition of Sgk target proteins.

networks that are highly associated with the control of cellular proliferation. In mammary tumor cells, the serum-induced expression and S-phase nuclear import of Sgk (see Section VIII) are necessary for cell cycle progression of mammary epithelial cells. The BMK1/ERK5 member of the mitogen-activated protein kinase gene family was shown to induce cell proliferation through its interaction with and phosphorylation of Sgk. Consistent with a role for Sgk in proliferative control in normal cells, the sgk gene resides in a single chromosomal locus assigned to band 6q23, a region frequently affected by deletion in various human neoplasias. Sgk appears to also be involved in certain hormone-regulated growth inhibitory responses. The glucocorticoid-induced G1 cell cycle arrest of mammary tumor cells is accompanied by and partially dependent on the stimulated expression of cytoplasmic localized Sgk in mammary tumor cells. Ectopic expression of Sgk in this cell system inhibits cell proliferation. Given that glucocorticoids are considered a physiological stress hormone, it is tempting to consider that the induction of Sgk by this steroid allows cells to mount physiologically appropriate responses to changes in the external milieu resulting from mitogenic cues and/or stress stimuli.

B. Role of Sgk in the Cellular Stress Response and in Cell Survival Cascades

Sgk has been shown to be a cell survival component of the responses to cellular stressors such as hyperosmotic shock in various epithelial cells. Subsequent to the original cloning of Sgk, this protein kinase was revealed in a screen for an osmotic shock-inducible gene from hepatocytes, and sgk transcripts have been shown to be induced by hyperosmolarity and secretagogues in shark rectal gland. Hyperosmotic shock strongly induces Sgk transcription in mammary epithelial cells by a pathway that utilizes the p38/MAPK cascade, which is the mammalian homologue of the stress-activated *S. cerevisiae* HOG1 proline-directed protein kinase. Expression of the wild-type enzymatically active Sgk, but not the kinase-dead forms of Sgk, protects the transfected cells from stress-induced apoptosis, whereas expression of kinase-dead forms of Sgk had no protective effects. Sgk was also shown to be an important component of the glucocorticoid cell survival response to growth factor deprivation in a human breast cancer cell line. The Sgk-3 isoform has been implicated in the interleukin-3-mediated survival of hematopoietic cells, suggesting that a subset of cellular responses are likely be Sgk isoform-specific.

C. Role of Sgk in Mineralocorticoid and Insulin Regulation of Sodium Homeostasis and in Osmotic Control of Cell Volume

Sgk stimulates epithelial sodium channel (ENaC) activity and enhances its membrane abundance in co-injected *Xenopus laevis* oocytes, suggesting that one function of Sgk is to control cell volume and sodium homeostasis following osmotic stress of cells. Evidence from several studies indicates that Sgk plays a central role in integrating mineralocorticoid and insulin signals as part of the osmoregulatory mechanism in the kidney. The current viewpoint is that aldosterone regulates sodium homeostasis by stimulating the expression of Sgk, which in turn causes an increase in total renal cell membrane ENaC activity. Sgk directly binds to the ENaC β-subunit, but does not phosphorylate this ion channel. Recent evidence shows that Sgk does phosphorylate the ubiquitin ligase Nedd4-2, which reduces the binding of Nedd4-2 to the C-terminal tail domain of the ENaC β-subunit. The Sgk-dependent phosphorylation of Nedd4-2 appears to require a PY domain recognition site within Sgk (see Fig. 2). As a result, the degradation of ENaC is reduced, with the net effect being an elevation in the steady state level of membrane-associated ENaC and subsequent stimulation of sodium transport in response to mineralocorticoids. Insulin signaling plays a role in the process, and in renal cells insulin can synergize with mineralocorticoids to regulate sodium transport. Insulin has been proposed to activate Sgk enzymatic activity through the PI3-kinase cascade (see Section VI), and consistent with this notion, an inhibition of PI3-kinase activity blocks insulin-stimulated sodium transport. This response, which has been generally observed in cell systems, has a physiological impact because in one study, decreased sodium excretion during sodium depletion was observed in Sgk knockout mice compared to littermate controls.

D. Other Biological Functions of Sgk

Although not directly linked to stimulus-regulated mechanisms, Sgk has been implicated in a variety of cellular functions that may eventually prove to be associated with hormonal mechanisms of action. For example, Sgk has been linked to the function and cellular utilization of several other ion channels, such as the cystic fibrosis transmembrane regulator-dependent chloride channel and certain voltage-gated potassium channels. The control of potassium ion channel activity suggests a role for Sgk in neuronal excitability. Consistent with this concept, a recent study has implicated Sgk in facilitating memory consolidation of spatial learning in rats. Sgk transcripts were shown to be expressed at significantly higher levels in the hippocampus, an area of the brain with a high level of glucocorticoid receptors, of fast learners compared to slower learners. Thus, it is likely that many functions of Sgk will eventually be revealed, beyond the stimulus-dependent control of proliferation, cell survival, and osmoregulatory processes.

IV. REGULATION OF Sgk EXPRESSION DURING DEVELOPMENT AND IN ADULT TISSUE

Sgk expression is under stringent developmental control during mouse embryogenesis. Sgk transcripts are first observed at embryonic day 8.5 (E8.5) in the decidua and yolk sac, and then during developmental stages E9.5 through E12.5, this kinase is highly localized in the heart chamber, otic vesicle, blood vessels surrounding the somites, and lung buds. At later stages of mouse embryogenesis, E13.5 through E16.5, sgk expression becomes highly concentrated in brain (choroid plexus), distal epithelium, terminal bronchi/bronchioles, adrenal gland, liver, thymus, and intestines, remains high in heart tissue, and is expressed at a low level in the other embryonic tissues. In the adult, Sgk is concentrated in the choroid plexus of the brain, which is involved in osmotic and pH regulation of cerebral spinal fluid. Sgk is also concentrated in specific areas of the adult kidney (glomeruli and nephrons in the cortical region, as well as in the medulla, papilla, and calyces), suggesting a role in regulating osmotic balance. Consistent with this concept, Sgk is induced by the mineralocorticoid aldosterone in the cortical collecting ducts of the rodent kidney. In adult rat tissue, Sgk is also highly expressed in the thymus, ovary, and lung. A high level of Sgk has been reported in phagocytes, which is consistent with Sgk being involved in the inflammatory response. The tissue-specific and temporal pattern of *sgk* expression during mouse embryogenesis suggests that *sgk* has a potential role in heart development and/or vasculogenesis at early developmental stages and may function in tissues involved in osmoregulation and other physiological stress pathways at later developmental stages and in the adult.

V. STIMULUS REGULATION OF Sgk PROMOTER ACTIVITY AND GENE TRANSCRIPTION

Sgk expression can be acutely regulated by a variety of hormones and extracellular stress cues that are known to target specific DNA elements in gene promoters. Only a few studies have used the Sgk promoter to rigorously establish the transcriptional control of Sgk gene expression. Glucocorticoids, the p53 tumor suppressor gene, follicle-stimulating hormone, and hyperosmotic stress have been shown to induce Sgk gene products by pathways that target specific DNA elements in the promoter (Fig. 3). In addition to these stimuli, Sgk transcript levels have been to shown to be stimulated in a tissue-specific manner by mineralocorticoids, TGF-β, cytokines such as granulocyte/macrophage colony-stimulating factor and tumor necrosis factor α, ischemic injury of the brain, growth factors such fibroblastic growth factor and platelet-derived growth factor, diabetic nephropathy, changes in hepatocyte cell volume, inflammatory disease, and fibroblast wound repair, whereas heparin suppresses Sgk expression. Although these studies have not characterized the precise level of regulation, it is likely that these responses involve selective changes in Sgk transcription through the control of Sgk promoter activity. In this regard, based on sequence analysis, a variety of intriguing putative DNA elements exist in this promoter for transcription factors known to play a role in cellular differentiation, proliferation, and stress responses and may thereby account for hormone-regulated changes in Sgk expression.

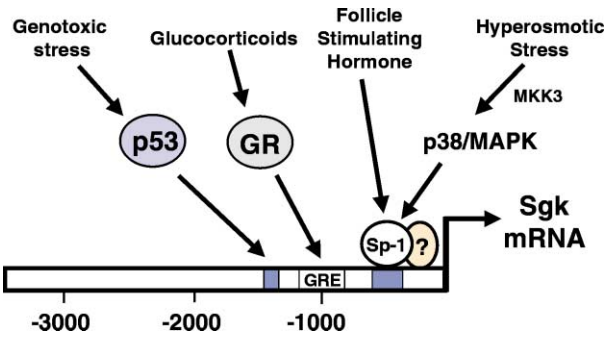

FIGURE 3 Hormone and environmental stress pathways target distinct elements in the Sgk promoter. Sgk is a primary glucocorticoid-responsive gene and contains a functional glucocorticoid-response element (GRE) in its promoter. The Sgk GRE is similar to consensus GREs in other systems and binds to the glucocorticoid receptor (GR) with high affinity. The Sgk promoter is also targeted by the p53 tumor suppressor gene as a downstream response to genotoxic stress. Follicle-stimulating hormone activates a receptor signaling pathway that simulates Sgk transcription through a Sp-1 transcription factor. Hyperosmotic stress activates a p38/mitogen-activated protein kinase (p38/MAPK) pathway through the actions of MKK3 (MAPK kinase kinase-3), which also targets Sp-1 in the Sgk promoter. Sp-1 interacts with other transcription factors in a tissue-dependent manner to stimulate Sgk transcription. The Sgk promoter contains many other putative transcription factor sites that likely account for the regulation of Sgk gene expression of other hormones and extracellular stimuli.

A. Sgk Is the Primary Glucocorticoid-Responsive Gene Containing a Glucocorticoid-Response Element in Its Promoter

Sgk expression is stimulated by glucocorticoids in a variety of cells and tissues, and the Sgk promoter contains a functional glucocorticoid-response element (GRE) that accounts for its glucocorticoid inducibility. A combination of mutagenesis, transfection of Sgk promoter-driven reporter plasmids, and DNA–glucocorticoid receptor-binding assays revealed the presence of the Sgk GRE, which is located at approximately −1000 bp of the Sgk promoter (Fig. 3). The Sgk GRE is highly homologous to the consensus glucocorticoid-response element and is sufficient to confer glucocorticoid responsiveness to a heterologous promoter in a manner that requires a functional receptor. Mutation of the Sgk GRE eliminates glucocorticoid responsiveness of the Sgk promoter. These decisive promoter studies support the notion that Sgk is a primary glucocorticoid-responsive gene. Given that glucocorticoid and mineralocorticoid receptors bind to the same DNA element, it is likely that the GRE in the Sgk promoter accounts for the aldosterone induction of Sgk transcripts in mammalian and amphibian renal cells.

B. Regulation of Sgk Promoter Activity by the p53 Tumor Suppressor Protein, Hyperosmotic Stress, and Follicle-Stimulating Hormone

The Sgk promoter is a transcriptional target of the p53 tumor suppressor protein, a known target of genotoxic stress. Using both functional and DNA-binding strategies, the wild-type p53 tumor suppressor protein was shown to strongly stimulate Sgk promoter activity in mouse mammary epithelial cells, but repressed Sgk promoter activity in Rat2 fibroblasts. The Sgk p53 sequences at −1380 bp and at −1345 bp were sufficient to confer p53-dependent transactivation or transrepression to a heterologous promoter in a cell type-specific manner. Interestingly,

both the murine and the human wild-type p53 tumor suppressor proteins, but not a mutant p53, can functionally interfere with the glucocorticoid receptor transactivation of the Sgk promoter through events converging on the Sgk GRE.

Sgk promoter activity can be stimulated by follicle-stimulating hormone in adult rat ovarian granulosa cells through activation of the Sp-1 transcription factor in the Sgk promoter. This response is also dependent on activation of the cyclic AMP pathway, although the precise upstream pathways that target Sp-1 have not characterized. A systematic mutagenic analysis of the Sgk promoter activity revealed a hyperosmotic stress-regulated element that is located between positions −50 and −40 in the Sgk promoter and that mediates the hyperosmotic response to the organic osmolyte 0.3 M sorbitol. This region of the Sgk promoter contains a consensus Sp-1 DNA element, and the stimulus-regulated binding of the Sp-1 transcription factor to this site accounts for the stimulation of Sgk transcription. The hyperosmotic stress cascade targets Sp-1 in the Sgk promoter by activating the p38/MAPK stress kinase. For example, incubation with the SB202190- or SB203580-specific inhibitors of p38/MAPK dampens the hyperosmotic stress stimulation of the Sgk promoter and Sgk protein production. Active MAPK kinase kinase-3 acts upstream of p38/MAPK to stimulate Sgk promoter activity in a sorbitol-dependent manner (Fig. 3). Sp-1 is known to interact with other transcription factors, and it is likely that the follicle-stimulating hormone and the hyperosmotic stress control of Sgk promoter activities require different Sp-1 protein–protein interactions.

VI. REGULATION OF Sgk PHOSPHORYLATION AND ENZYMATIC ACTIVITY THROUGH THE GROWTH FACTOR-ACTIVATED PI3-KINASE PATHWAY

The stimulus-dependent control of Sgk phosphorylation and enzymatic activity through a PI3-kinase cascade represents a second level of Sgk regulation in the cell (Fig. 1). The PI3-kinase-activated signal transduction pathway enhances cell survival and proliferation in response to a variety of growth factors. PI3-kinase directly binds to tyrosine kinase receptors (or to insulin substrate-1) via a SH2 domain in its p85 subunit. PI3-kinase converts phosphatidylinositol 4,5-biphosphate to phosphatidylinositol 3,4,5-triphosphate, which binds to the pleckstrin homology domain contained within PDK1, resulting in its activation. Active PDK1 then directly phosphorylates and enzymatically activates several serine/threonine protein kinases, including Sgk and several protein kinases most homologous to Sgk, such as Akt/PKB. Full stimulation of Sgk enzymatic activity requires the PDK1-dependent phosphorylation at threonine 256, which is located within the activation loop of Sgk, and at serine 422, in the carboxy-terminal domain. Ablation of both phosphorylation sites by mutation of threonine 256 and serine 422 to alanines inhibits Sgk enzymatic activity and in some systems forms a potent dominant negative form of Sgk. Furthermore, substitution of the PI3-kinase-dependent phosphorylation sites with aspartate to mimic the charge effects of phosphorylation generates a constitutively active protein kinase. Treatment of cells with the LY294002 chemical inhibitor of PI3-kinase abolishes the hormone activation of Sgk enzymatic activity and prevents the production of the hyperphosphorylated forms of Sgk in the cell systems that have been examined.

Sgk phosphorylation and enzymatic activity have been shown to be regulated as a downstream component of the PI3-kinase cascade in response to a variety of extracellular signals, such as serum growth factors, insulin-like growth factor-I, insulin, oxidative stress, and hyperosmotic stress. Importantly, the disruption of PI3-kinase-dependent phosphorylation and activation of Sgk abolishes many Sgk cellular functions, such as insulin-stimulated sodium transport, glucocorticoid-dependent effects on cell proliferation and cell survival, mitogenic cell survival responses, and the cellular response to osmotic changes. The precise role of Sgk in many of these cellular functions has not been established because the same sets of extracellular signals that activate the stimulus-induced Sgk enzymatic activity also activate constitutively expressed Akt/PKB, which is highly related to Sgk and contains analogous PDK-1-dependent phosphorylation sites. In studies examining its downstream targets, Akt/PKB, like Sgk, has been indicated to play roles in maintaining cell survival in response to growth factors, in insulin-regulated glucose metabolism, in transcriptional control, and in regulation of apoptosis after environmental stress in many different cell types. Although Sgk and Akt/PKB are highly homologous in their catalytic domains and have similar activation profiles, they display unique features that suggest that they provide complementary rather than redundant cell functions.

VII. Sgk SUBSTRATE SPECIFICITY AND TARGET PROTEINS

By screening of a peptide library, consensus Sgk substrate sites that are generally similar to the Akt/PKB enzymatic specificity (RXRXXS/T) and that suggest some overlap in protein substrates have been identified. Sgk phosphorylates several peptides, and the most selective peptide substrate for Sgk is KKRNRRLSVA, which was named Sgktide. Arginines at the −2/−3 and the −5/−6 positions, relative to the phosphorylated serine, were found to be required for Sgk activity. In mostly *in vitro* assays, several substrates for Sgk have been revealed. Both Sgk and Akt/PKB have been shown to phosphorylate *in vitro* glycogen synthase kinase 3, the apoptotic component Bad, the forkhead transcription factor FKHRL1, and the Raf-1 component of mitogen signaling cascades. In transfected cells, the T256A/S422A mutant Sgk acts as dominant negative for phosphorylation of the forkhead transcription factor and attenuates the cell survival response to extracellular stress. These results directly implicate Sgk in the hormone-dependent control of cell survival. There are subtle differences in the substrate specificity of Sgk and Akt/PKB that are likely to be biologically significant. The best example with an endogenous substrate is with the FKHRL1 forkhead transcription factor in that Sgk and Akt/PKB display preferences for different phosphorylation sites in this protein. Given the important role of forkhead transcription factors in controlling cell survival and apoptotic responses, one viewpoint is that this dual phosphorylation causes a more enhanced cell survival response. It is likely that hormone-regulated activation of both Sgk and Akt/PKB, for example, by insulin and other growth factors, similarly enhances the corresponding downstream cascades through the complementary actions of Sgk and Akt/PKB.

As mentioned earlier, Sgk phosphorylates the ubiquitin ligase Nedd4-2, which causes a significant reduction in the interaction of this ligase with the ENaC, resulting in a net mineralocorticoid-dependent elevation in ENaC levels in the membrane of renal cells. ENaC is a direct protein-binding target of Sgk, and although the precise mechanism underlying these interactions has not been established, it is tempting to consider that Sgk–ENaC protein–protein interactions allow the efficient access of Sgk to its Nedd4-2 substrate. Sgk was also shown to bind to, but not phosphorylate, the nuclear import receptor pendulin/importin-α, and the hormone-regulated implications of this observation are described below. Only a limited number of Sgk substrates and nonsubstrate target proteins have been identified, and a key future direction for the field will be to identify the many unknown Sgk target proteins that account for the stimulus-dependent responses associated with Sgk.

VIII. HORMONE AND STIMULUS-DEPENDENT CONTROL OF Sgk SUBCELLULAR COMPARTMENTALIZATION
