Mice with a targeted deletion of the D2 gene (D2KO) have been generated recently. The mice have no obvious developmental, physiological, or behavioral abnormalities, and fertility is normal. However, while plasma T3 is normal, plasma T4 and TSH are both increased, suggesting that the pituitary gland of the D2KO mouse is resistant to the feedback effect of plasma T_4. The results are consistent with the view that local generation of T3 by pituitary D2 is important in the regulation of TSH secretion. The elevation of plasma T4 is likely due to decreased metabolic clearance as a result of decreased deiodination; whereas a contributing factor may be an increase in the release of T4 from the thyroid as a result of the elevated levels of TSH, plasma T4 is elevated also in thyroidectomized D2KO mice maintained on exogenous T4. In other tissues where local generation of T3 is considered to be important, the results are less clear. As pointed out above, thermogenesis in brown adipose tissue relies on local generation of T3 from T4. However, D2KO mice survive for several days at 4°C, although no basal or cold-inducible deiodinase activity occurs in BAT. It remains to be seen whether the absence of D2 in the brain impairs brain function in otherwise normal animals or whether it potentiates the effects of iodine deficiency.

IV. TYPE III DEIODINASE

Type III deiodinase (D3) inactivates iodothyronines and represents a potentially important mechanism for the control of intracellular T3 concentrations. D3 has

higher affinity for T3 than for T4, and therefore degradation of the active thyroid hormone is favored. The human *dio*3 gene is located at chromosome 14q32. The enzymatic mechanism for type III deiodination might be sequential, and *in vitro* D3 also needs reduced thiols for maximal activity. The reduced thiols might act as activators of the enzyme rather than as co-substrates. D3 activity is not inhibited by PTU or aurothioglucose.

A. D3 Expression and Physiological Role

The physiological role of D3 is the inactivation of thyroid hormones especially during development. The highest levels of D3 activity are found in the pregnant uterus and placenta. Lower levels of activity are found in fetal tissues, and, with the exception of skin, activity in these tissues decreases after birth. In the adult rat, D3 expression is limited to the skin, brain, and uterus. D3 has been cloned from amphibians and mammals. In the brain, it is expressed in neurons, in contrast to D2, which is expressed in glial cells, as already mentioned.

D3 is thought to play an important role in the control of T3 concentrations in developing tissues. In tadpoles, the tissue profiles of D3 and T3 expression are very similar, and maximal expression of both in a given tissue correlates well with the time of maximal metamorphic change. This suggests the need for very tight regulation of intracellular T3 levels. Indeed, metamorphosis is strongly inhibited by D3 overexpression in transgenic tadpoles, presumably by preventing the tissues from attaining the appropriate level of T3. In mammals, the placenta contains very high levels of D3 activity, and recent studies have demonstrated very high levels of D3 expression in the uterus in the decidual cells surrounding the developing embryo and at later stages in the epithelial cells of the uterus. The maternal/fetal concentration ratio of thyroid hormone is very high and it is thought that the high levels of D3 activity in uterus and placenta protect the embryos from overexposure to maternal thyroid hormone concentrations. In the newborn rat brain, a discrete and intense expression of D3 occurs in neurons located in just a few discrete nuclei, suggesting also that the availability of T3 to these regions is specifically controlled by D3.

V. SUMMARY

Deiodination is the most important metabolic pathway of thyroid hormones. It is catalyzed by enzymes that contain the amino acid selenocysteine in their active center. There are three types of deiodinases, known as D1, D2, and D3. D1 and D2 remove the iodine atom from the 5 or 3 position of the phenolic ring of iodothyronines, and D1 and D3 remove the iodine from the same positions of the tyrosyl ring. Thus, D1 and D2 can convert T4 to T3, which has a higher affinity than T4 for the thyroid hormone receptor. Therefore, this pathway represents a hormonal activation process. Deiodination of the tyrosyl ring, carried out by D3 and also by D1, degrades T4 and T3 to inactive metabolites. D1 is thought to be primarily responsible for generating T3 for export to plasma T3, and the primary role of D2 is the generation of T3 for local use. The activities of the deiodinases are regulated during development and by physiological factors including the thyroid hormones per se. D3 is highly expressed in placenta, pregnant uterus, and fetal tissues, whereas D1 and D2 are expressed postnatally and in the adult. Evidence suggests that deiodinases play a major role in regulating intracellular T3 levels in a tissue-specific manner and also in coordinating growth and development in vertebrate species.

Glossary

lactotrophs Cells from the anterior pituitary that secrete prolactin.

retinoic acid response element Short sequences present in regulatory regions of the genes regulated by retinoic acid that bind the retinoic acid receptor and modulate the rate of gene transcription.

selenocysteine insertion sequence element (SECIS) Selenoproteins contain the amino acid selenocysteine. This amino acid is incorporated into proteins by transfer RNAs that use the UGA codon. The UGA codon is usually a stop codon, which signals termination of translation. However, the selenoprotein-encoding mRNAs contain a signal that is able to convert a stop/UGA codon into a selenocysteine codon. This signal is known as a SECIS element and is present in the 3′-untranslated sequence of the mRNA.

somatotrophs Cells from the anterior pituitary that secrete growth hormone.

sulfhydryl group Chemical group (thiol, -SH) containing sulfur and hydrogen found in cysteine, glutathione, and other molecules.

TATA-, CAAT-, GC-boxes Sequences present in the promoter region of eukaryotic genes that recognize and bind ubiquitous transcription factors and allow transcription by RNA polymerase II.

thyrocytes The cells from the thyroid gland that produce thyroid hormones.

thyrotrophs Cells from the anterior pituitary that secrete thyrotropin.

TRE Short sequences present in regulatory regions of the genes regulated by thyroid hormone: that bind the T3 receptor and modulate the rate of gene transcription.

Diabetes Type 1 (Insulin-Dependent Diabetes Mellitus)

LISA K. GILLIAM AND ÅKE LERNMARK
University of Washington

Type 1 diabetes is the result of an autoimmune process targeting the pancreatic islet beta cells, resulting in insulin deficiency and hyperglycemia. Both genetic and environmental factors are important in the development of this disease. A defect in antigen presentation that leads to the loss of T-cell tolerance is most likely the pathogenic mechanism, although many questions still remain to be answered. The progression to clinical onset of type 1 diabetes is marked by the presence of autoantibodies to glutamic acid decarboxylase 65, IA-2, or insulin.

I. INTRODUCTION

Diabetes mellitus is a group of diseases characterized by an increase in blood sugar levels, or hyperglycemia, which occurs when an individual's insulin production does not meet the body's metabolic needs. Diabetes is divided into two major subtypes: type 1, formerly known as juvenile-onset diabetes or insulin-dependent diabetes mellitus (IDDM), and type 2, formerly known as adult-onset diabetes or non-insulin-dependent diabetes mellitus. Type 1 diabetes has traditionally been differentiated from type 2 diabetes based on an individual's age and features of clinical presentation. However, in

Diabetes Type 1 (Insulin-Dependent Diabetes Mellitus)

LISA K. GILLIAM AND ÅKE LERNMARK
University of Washington

Type 1 diabetes is the result of an autoimmune process targeting the pancreatic islet beta cells, resulting in insulin deficiency and hyperglycemia. Both genetic and environmental factors are important in the development of this disease. A defect in antigen presentation that leads to the loss of T-cell tolerance is most likely the pathogenic mechanism, although many questions still remain to be answered. The progression to clinical onset of type 1 diabetes is marked by the presence of autoantibodies to glutamic acid decarboxylase 65, IA-2, or insulin.

I. INTRODUCTION

Diabetes mellitus is a group of diseases characterized by an increase in blood sugar levels, or hyperglycemia, which occurs when an individual's insulin production does not meet the body's metabolic needs. Diabetes is divided into two major subtypes: type 1, formerly known as juvenile-onset diabetes or insulin-dependent diabetes mellitus (IDDM), and type 2, formerly known as adult-onset diabetes or non-insulin-dependent diabetes mellitus. Type 1 diabetes has traditionally been differentiated from type 2 diabetes based on an individual's age and features of clinical presentation. However, in

TABLE I Criteria for the Diagnosis of Diabetes Mellitus

1. Symptoms of diabetes plus casual plasma glucose concentration ≥200 mg/dl (11.1 mmol/liter). Casual is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydypsia, and unexplained weight loss.
   <or>
2. FPG ≥ 126 mg/dl (7.0 mmol/liter). Fasting is defined as no calorie intake for at least 8 h.
   <or>
3. 2hpG ≥ 200 mg/dl during an OGTT. The test should be performed as described by WHO, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

Note. Reprinted from Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. (1997). *Diabetes Care* **20**, 1183–1197, with permission. In the absence of unequivocal hyperglycemia with acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day. The third measure (OGTT) is not recommended for routine clinical use. FPG, fasting plasma glucose; 2hPG, 2 h plasma glucose; OGTT, oral glucose tolerance test; WHO, World Health Organization.

response to advances in the understanding of its pathogenesis, a new approach to the classification of diabetes was instituted by the American Diabetes Association (ADA) in 1997. The ADA guidelines now classify diabetes based on the pathogenic process, rather than the age of the patient and the modality used to treat the disease (insulin-requiring or non-insulin-requiring). According to these guidelines, type 1 diabetes is defined as a disorder in which the destruction of insulin-producing beta cells in the pancreas leads to absolute insulin deficiency. This is usually the consequence of an autoimmune mechanism, in which case it is referred to as type 1a diabetes. Occasionally the beta-cell destruction involves less well defined, non-autoimmune mechanisms, in which case it is referred to as type 1b diabetes. Type 2 diabetes is the result of a combination of defects, including an increase in endogenous hepatic glucose production, impaired insulin secretion by the pancreas, and peripheral tissue insulin resistance. Criteria for the diagnosis of diabetes, as outlined in the 1997 ADA report, are shown in Table 1.

II. HISTORY

The history of type 1 diabetes can be divided into the preinsulin and insulin eras. In the preinsulin era, the disease was recognized as a wasting syndrome of unknown etiology, in which excessive urination (polyuria) and excessive fluid intake (polydypsia) were key clinical features. The 2nd century Greek physician Aretaeus of Cappadocia first used the term diabetes, meaning "to run through" or "a siphon," describing the increased thirst and urine output, in one of the earliest recorded descriptions of this mysterious disease:

> Diabetes is a wonderful affection, not very frequent among men, being a melting down of the flesh and limbs into urine. The patients never stop making water, but the flow is incessant, as if the opening of aqueducts. Life is short, disgusting and painful; thirst unquenchable; drinking excessive, which, however, is disproportionate to the large quantity of urine, for more urine is passed; and one cannot stop them either from drinking nor making water. Or if for a time they abstain from drinking, their mouth becomes parched and their body dry; the viscera seems as if scorched up; they are affected with nausea, restlessness and a burning thirst; and at no distant term they expire. [Papaspyros, N. S. (1964). *The History of Diabetes Mellitus*, 2nd ed., pp. 7–8. Georg Thieme Verlag, Stuttgart, Germany]

Prior to the 1920s, type 1 diabetes was universally fatal. More than 100 years ago, it was reported that patients dying from acute-onset diabetes had inflammatory cells in their islets of Langerhans. The identification of the "anti-diabetogenic factor," insulin, and its first therapeutic use in diabetic individuals in 1922 forever changed the course of this disease. This breakthrough is considered one of the most extraordinary events in the history of disease treatment. With insulin therapy, patients with type 1 diabetes now are able to live for decades after disease onset, rather than months.

III. EPIDEMIOLOGY

Type 1 diabetes varies in incidence according to age of onset, gender, geography, and ethnicity. This disease is generally diagnosed in youth, with the peak age of onset falling in the 10- to 14-year-old age group. However, the onset of type 1 diabetes can occur at any age, and this disease is being recognized more frequently in older individuals, with the development of assays measuring antibodies that indicate an autoimmune etiology. The incidence of type 1 diabetes also varies geographically, with rates as low as 0.1 individuals per 100,000 per year in China, compared with more than 40 per 100,000 per year in Finland. Like many other autoimmune diseases, the geographic distribution of type 1 diabetes has traditionally been

thought of in a "polar–equatorial gradient," in which northern latitude countries suffer higher incidence rates than equatorial countries. However, other environmental and genetic factors confound this generalization. The two countries with the highest incidence rates in the world, Finland and Sardinia, are located at very distant latitudes. Other countries with high incidence rates include Kuwait, Puerto Rico, and several other European countries. Estonia, which neighbors Finland, has an incidence rate of one-quarter that of Finland's, further indicating that factors other than just climate are involved. According to dozens of epidemiological studies over the past 40 years, type 1 diabetes is increasing in incidence. This increase appears to be occurring worldwide, with a greater relative increase in populations with a historically lower incidence.

IV. ETIOLOGY

Type 1 diabetes is caused by both genetic and environmental factors. This disorder has long been known to run in families. Twin studies have found concordance rates (percentage of cases in which both twins will be affected when one twin has a diagnosis of diabetes) of 0–13% among dizygotic twins and 21–70% among monozygotic twins. In comparison, the risk of developing type 1 diabetes in the general population is 0.4%, and the risk for that of siblings of affected individuals is approximately 6%. The fact that the concordance is not 100% in monozygotic twins, yet monozygotic twins have a higher concordance rate than dizygotic twins, suggests that both genetic and environmental influences play a role in the etiology of type 1 diabetes. Current thinking about the complicated interplay between genes and the environment suggests that an inherited defect in immunomodulation, in combination with a series of modifying environmental influences, such as infections, dietary factors, environmental toxins, sanitation, vaccinations, and health care access, tips the scales in favor of, or against progression to, the development of type 1 diabetes.

A. Genetic Factors

Significant advances in knowledge about the genes involved in susceptibility to type 1 diabetes have been made in the past 30 years. In the 1970s, investigators identified a strong association between type 1 diabetes and human leukocyte antigen (HLA) alleles, in particular, certain class II molecules. Later, studies mapping genetic susceptibility loci confirmed that the HLA locus on chromosome 6, termed IDDM1, accounts for 45–60% of the genetic risk seen in families. The identification of particular alleles that confer risk has proven technically very difficult because of the strong linkage disequilbrium in that region of the genome. In other words, HLA haplotypes tend to be inherited in complete sets, making it very difficult to establish which of the alleles in that set is the actual diabetogenic factor. By combining data from several population studies, investigators have shown that the DQB1 * 0302-A1 * 0301 haplotype confers the greatest risk, with an additive diabetogenic effect if the DRB1 * 0401 allele is inherited as part of the haplotype. The highest genetic risk is conferred by the DQB1 * 0302-A1 * 0301/DQB1 * 0201-A1 * 0501 genotype. More than 40% of children with new onset type 1 diabetes have this genotype, compared with 3% of healthy children. Other alleles have been shown to have a negative association with risk for diabetes (a protective effect), most notably HLA DQB1 * 0602-A1 * 0102. A summary of the haplotypes associated with risk and protection is shown in Table 2. The mechanism of diabetogenicity of HLA alleles and haplotypes is under active investigation.

TABLE 2 Risk of Type 1 Diabetes Associated with DR and DQ Alleles

	DQA1	DQB1	DRB
High risk			
	0301	0302	0401
	0301	0302	0402
	0301	0302	0404
	0301	0302	0405
	0501	0201	0301
Moderate risk			
	0401	0402	0801
	0101	0501	0101
	0301	0303	0901
Weak protection			
	0301	0301	04
	0301	0302	0403
	0201	0201	0701
	0501	0301	1101
Strong protection			
	0102	0602	1501
	0101	0503	1401
	0201	0303	0701

Note. Reprinted from Redondo, M. J., Fain, P.R., and Eisenbarth, G. S. (2001). Genetics of type IA diabetes. *Rec. Prog. Horm. Res.* **56**, 69–89, with permission. © The Endocrine Society.

The underlying defect in type 1 diabetes is thought to be a disorder in antigen presentation, which generates self-reactive T helper cells specific for islet cell antigens. The "risk" HLA molecules could theoretically be involved in one of two ways: either they are ineffective at presenting relevant peptides to immature T cells in the thymus, failing to induce tolerance to these antigens, or they are better able than "nonrisk" alleles to present relevant peptides to these self-reactive T cells in the periphery.

Some non-HLA genetic factors have been shown to influence the development of type 1 diabetes. The insulin gene on chromosome 11, IDDM2, has polymorphisms within the noncoding region that confer either risk or protection for developing type 1 diabetes. This locus has been estimated to contribute less than 10% toward disease susceptibility. One proposed mechanism for the pathogenicity of the insulin susceptibility locus suggests that in diabetic individuals, the insulin gene is expressed in reduced amounts in the thymus during formative periods for the immune system, and the development of tolerance fails to occur properly. Another susceptibility locus for which a candidate gene has been cloned is the CTLA-4 gene on chromosome 2q (IDDM12). This gene is relevant to diabetic pathogenesis because the protein normally limits the proliferative response of activated T cells. Population studies have suggested that CTLA-4 gene polymorphisms may be a risk factor for diabetes. Furthermore, animal studies have shown that the recurrence of autoimmune diabetes in pancreatic islet-transplanted Bio Breeding (BB) rats, an animal model for type 1 diabetes, could be abrogated by adenovirus-mediated transfer of the CTLA-4 gene. Although the mechanism is not known, it has been postulated that the transfected CTLA-4 delivers a tolerogenic signal to the T cells, allowing the islet cell graft to survive.

In addition to the HLA complex, the insulin gene, and the CTLA-4 gene, several other loci have been identified in association with type 1 diabetes. Many of these genes have not yet been cloned, but with the rapid advancement in this area of research, a better understanding of the genetic influences on this heterogeneous disorder will likely be attained in the next few years. Defined and putative type 1 diabetes loci are shown in Table 3.

TABLE 3 Defined and Putative Genetic Factors for Type 1 Diabetes

Locus	Chromosome	Marker/candidate genes
IDDM1	6p21.31	HLA
IDDM2	11p15.5	5′ Insulin VNTR
IDDM3	15q26	D15S107
IDDM4	11q3	D11S1917, H0570polyA

B. Environmental Factors

Environmental triggers, in addition to genetic factors, are thought to play a role in the development of type 1 diabetes. Three of the best studied risk determinants include viral infections, early infant diet (cow's milk versus breast milk), and toxins. Although Finnish studies on diet suggested an association between early introduction of cow's milk components and diabetic risk, trials in the United States and Germany did not support these findings, and this point remains controversial. The concept that viral infections might play a role is based on numerous case-control studies in which infectious outbreaks are temporally associated with a higher incidence of diabetes. Furthermore, congenital infections with rubella and enterovirus have been strongly implicated in the subsequent development of diabetes by infants exposed *in utero*. Candidate viruses and other environmental factors are listed in Table 4. In addition to the possible contribution of congenital viral infections, other unidentified factors in the fetal environment appear to influence the risk of type 1 diabetes in the child. Both increasing maternal age and birth order (higher risk in the first born) have recently been shown to be related to risk of type 1 diabetes in the offspring. Further prospective studies are needed to better define environmental triggers for type 1 diabetes, as these have been very difficult to characterize.

TABLE 4 Viruses Implicated in Type 1 Diabetes

Virus	Host organism
Coxsackie	Human, mouse
Rubella	Human, hamster
Mumps	Human
Cytomegalovirus	Human
Rotavirus	Human
Encephalomyocarditis	Mouse
Meningovirus	Mouse
Reovirus	Mouse
Lymphocytic choriomeningitis	Rat
Kilham strain (mumps virus)	Rat

V. PATHOGENESIS AND IMMUNOLOGICAL ABNORMALITIES

The current understanding of the pathogenesis of type 1 diabetes has been aided by findings on autopsy of type 1 diabetic individuals, the presence of concomitant organ-specific autoimmune disease, such as thyroiditis, and measurements of disease markers, such as autoantibodies, in individuals with the disease. Prior to the 1970s, there was an understanding that two different types of diabetes existed; however, they were commonly thought to be gradations of the same basic disease, perhaps based on homozygous versus heterozygous inheritance of an unidentified "diabetes gene." Clues indicating that type 1 diabetes had a distinct, immune-based pathogenesis date back to the early 1900s. At that time, pathologists described "insulitis," a pathological feature seen in newly diagnosed type 1 diabetic patients in which the islets are infiltrated with mononuclear inflammatory cells. However, this finding was largely ignored because it was infrequently observed at the time of autopsy, by which time islet cell inflammation is already in its final stages and thus greatly diminished. Later evidence that cell-mediated immunity was involved in disease pathogenesis was provided in the 1960s by "leukocyte migration inhibition" tests, which demonstrated priming of patient T cells against islet cell antigens. The finding of delayed-type hypersensitivity reactivity to injected pig islet material in diabetic subjects further suggested a role for cell-mediated immunity against pancreatic antigens. The identification of islet cell antibodies in the 1970s provided the first evidence for humoral autoimmunity in type 1 diabetes. At the same time, two animal models helped to establish type 1 diabetes as an autoimmune disorder. Mice treated with subdiabetogenic doses of streptozotocin, a pancreatic toxin, were noted to have progressive islet cell destruction and insulin deficiency, even after the toxin was cleared from their systems. This process was therefore presumed to be immune-mediated. Also at that time, the first model of spontaneous type 1 diabetes was discovered, the BB rat. This animal, with classic insulin-deficient, ketosis-prone disease, had histological features of insulitis prior to disease onset. A second spontaneous diabetic animal model, the nonobese diabetic mouse, was later described in the 1980s. These rodent models have helped to further elucidate the pathogenesis of type 1 diabetes in humans, as outlined later in this article. Thus, the concept of type 1 diabetes as an autoimmune disorder first gained wide acceptance in the mid-1970s, and it is now recognized to be a process involving both the cellular and the humoral branches of the immune system.

It is now understood that the autoimmune process in type 1 diabetes results in the selective destruction of pancreatic beta cells. This process involves both cellular and humoral immunity, although it is thought to be mediated primarily by autoreactive T cells. This assumption is based on observations in both human subjects and animal models. In humans, lymphocytic islet cell infiltrates in newly diagnosed diabetics suggest that cytotoxic T-cell activity is the likely etiology of the islet cell destruction. In animal models, researchers have shown that transfer of diabetes from one animal to another requires both $CD4^+$ and $CD8^+$ T cells. The complete pathophysiological picture will likely involve a complex interaction between autoreactive T cells of both helper and cytotoxic subtypes, autoantibodies, and defective antigen-presenting cells. But what are the targets of these autoreactive lymphocytes? Ever since recognizing that type 1 diabetes is indeed an autoimmune disease, researchers have sought to define the targets of the immune response, as well as to understand why the immune system goes awry and begins to recognize these self-molecules as antigen. Answers to both of these questions will help to direct future interventions, defining what enemy to fight and what battle tactics to employ.

A. Humoral Immunopathophysiology

Humoral immunopathophysiology in diabetic individuals has proven fairly straightforward to establish because of the relative ease in measuring antibody responses to a specific antigen. Islet cell antibodies (ICA) were first identified in the 1970s by indirect immunofluorescence techniques. Specific autoantigens were later immunoprecipitated from human

islet cells, including glutamic acid decarboxylase 65 (GAD65), IA-2 (ICA-512), and IA-2β (phogrin). Insulin was also shown to be a target of the autoimmune response in newly diagnosed, previously untreated type 1 diabetic patients. Approximately 70–80% of children with new onset diabetes express GAD65 antibodies, compared with 1% of individuals in the general population and 8% of relatives of patients with type 1 diabetes. Similarly, IA-2 antibodies are seen in 60–70% of new onset diabetic patients, and insulin autoantibodies are seen in 50% of patients. Epidemiological studies have revealed several factors that seem to influence the expression of these autoantibodies, including age at diagnosis, gender, and HLA haplotype. Furthermore, prospective studies done in prediabetic individuals have shown that islet cell autoantibodies begin to appear between 9 months and 3 years of age, with insulin antibodies often being the first to appear, followed by GAD65 antibodies. Subjects may be positive for GAD65, IA-2, or insulin antibodies for many years without development of type 1 diabetes. However, the presence of two or more of these autoantibodies strongly predicts type 1 diabetes. Standardized antibody tests are now available and are beginning to be used to recruit participants to intervention trials. Although much has been learned about these autoantibodies as markers of disease, the role that they play in disease pathogenesis remains unclear.

B. Cellular Immunopathophysiology

Because of the lack of reproducible cellular immunoassays, less is known about the cell-mediated autoimmune process in diabetes. The same autoantigens against which antibodies are produced (GAD65 and IA-2) have been shown to stimulate *in vitro* T-cell proliferation, using lymphocytes from diabetic subjects. Furthermore, immunodominant epitopes of GAD65 and IA-2 have been identified both from antigen-specific T-cell lines generated from diabetic patients and from transgenic mice expressing human "diabetes risk" HLA class II molecules. Although these studies have been informative, the methods are cumbersome, and they also potentially reflect a skewed sample, depending on which T cells are isolated. Investigations are currently underway using soluble major histocompatibility complex (MHC) tetramers to directly identify specific peptide/MHC-restricted T cells, with specificities both for known and unknown epitopes, in order to better understand the important targets of T-cell-mediated immunity.

Several hypotheses have been proposed for mechanisms of induction of a pathogenic T-cell response in type 1 diabetes. One explanation is that molecular mimicry, or sharing of common epitopes between islet antigens and foreign antigens (such as viruses), leads to loss of T-cell tolerance to these epitopes and progression to diabetes. Other possibilities include aberrant islet beta-cell expression of costimulatory molecules, adhesion molecules, or MHC. A third hypothesis suggests that the cytokine milieu is very important in disease progression. Studies have shown that the predominance of a Th1-mediated immune response, in which secretion of interferon-γ, interleukin-2 (IL-2), IL-12, and tumor necrosis factor α (TNFα) activates mainly cytotoxic T cells and macrophages, is pathogenic. On the other hand, a Th2-mediated response, in which secretion of IL-4, IL-5, IL-6, or IL-10 activates the humoral branch of the immune system, may be protective. The Th1 versus Th2 polarizing signals are primarily derived from antigen-presenting cells (APC), and one interpretation is that an APC defect is responsible for the shift from a benign Th2-dependent immune response to a destructive Th1-dependent immune response in diabetic individuals. This putative APC defect has not been well defined but is under active investigation.

VI. CLINICAL COURSE

A. Patient Presentation

The signs and symptoms of type 1 diabetes are directly related to the lack of insulin and consequent hyperglycemia. Classically, patients present with polyuria, polydypsia, and weight loss, despite polyphagia. Polyuria and polydypsia result from the osmotic diuresis that occurs when the serum glucose level becomes high enough (generally in the range 300–500 mg/dl) that sugar begins to spill into the kidney collecting system, carrying with it free water. Hyperglycemia and its consequent hyperosmolality lead to electrolyte imbalances; sodium, potassium, magnesium, chloride, and bicarbonate are lost in the urine, resulting in the depletion of these electrolytes. Blurred vision and central nervous system (CNS) dysfunction result from intracellular dehydration. The CNS dysfunction manifests as altered mental status ranging from mild drowsiness to profound lethargy.

A prolonged lack of insulin eventually leads to diabetic ketoacidosis (DKA). Because the peripheral tissues are unable to utilize glucose without insulin,

protein catabolism and lipolysis are up-regulated, resulting in the production of ketones and a metabolic acidosis. The acidosis further contributes to electrolyte shifts and may cause life-threatening hyperkalemia (elevated serum potassium levels) resulting in cardiac arrhythmias, despite total body potassium depletion. Diabetic ketoacidosis may also be associated with abdominal pain, nausea, and vomiting. However, it is critical for the clinician to differentiate these symptoms of DKA from abdominal pain due to another process that may have played a role in triggering the disease onset, such as pyelonephritis, pancreatitis, or an acute abdomen of another etiology.

On physical examination, the patient generally has a thin body habitus, with signs of dehydration including decreased skin turgor, dry mucous membranes, tachycardia, and orthostatic hypotension. Patients often have rapid, deep breathing (Kussmaul's respirations), due to compensation for the metabolic acidosis with a respiratory alkalosis. Furthermore, the high plasma acetone level gives a distinctive fruity odor to the patient's breath.

B. Natural History

The current understanding of the natural history of type 1 diabetes prior to the clinical onset of disease is limited. Many individuals positive for one or several islet cell antibodies have been examined prior to the clinical onset of overt hyperglycemia. In some of these so-called prediabetic subjects, it has been possible to demonstrate that the release of insulin in response to glucose stimulation has deteriorated over time. Other subjects have had a decreased ability to release insulin but have remained normoglycemic, presumably because their insulin sensitivity has remained high. The natural history of type 1 diabetes prior to clinical diagnosis therefore seems variable and further studies are needed to uncover factors that are important in the precipitation of hyperglycemia.

While once culminating in death within weeks to months, the short-term outcome for patients with a new diagnosis of type 1 diabetes is now very good, assuming that the diagnosis is made and insulin therapy is initiated in a timely manner. However, diabetes remains a disease associated with a high lifetime mortality risk. Rather than succumbing to the immediate consequences of hyperglycemia and its associated metabolic derangements, diabetic patients now die as a result of secondary effects of the diabetes, primarily heart disease. Chronic hyperglycemia results in damage to and dysfunction of many organs, including the heart (cardiomyopathy), blood vessels (vasculopathy), eyes (retinopathy), kidneys (nephropathy), and nerves (neuropathy). Medical care for diabetic individuals therefore is targeted at both maintaining tight glycemic control and careful monitoring for and treatment of the secondary sequelae of the diabetes.

C. Diagnosis and Treatment

The diagnosis of diabetes mellitus is made based on a fasting blood glucose level greater than 126 mg/dl or a random blood glucose level greater than 200 mg/dl with associated signs and symptoms of diabetes, as outlined in Table 1. For type 1 patients, who generally present in DKA, the diagnosis is not subtle. In this case, the diagnosis is strongly suspected based on the clinical history and confirmed by the presence of hyperglycemia and acidosis. Initial treatment is directed at rehydrating the patient, correcting the electrolyte imbalances, and providing the deficient hormone, insulin, intravenously. Once clinically stable with blood sugars in the range 200–300 mg/dl, the patient is started on subcutaneous insulin injections, and measures to prevent the long-term consequences of diabetes are initiated.

The mainstay of treatment at this time for type 1 diabetics is subcutaneous insulin injections several times a day, with close monitoring of blood sugars. Glycemic control is monitored both by the patient on a day to day basis, with measured plasma glucose levels obtained by "finger sticks" four to seven times a day, and by the physician, who measures the hemoglobin A1C, a reflection of the mean blood glucose concentration over the previous 6 to 8 weeks. Target blood sugars are in the normal range (80 to 120 mg/dl), and target hemoglobin A1C values are between 6.5 and 7%. Newer modalities, such as insulin pumps, which control blood sugars minute to minute, peakless basal insulin, and aerosolized insulin (which is currently undergoing phase 3 clinical trials, expected to be available soon on the U. S. market), have contributed to improvements in diabetic management. Furthermore, the recent development of continuous glucose-monitoring systems and implantable insulin pumps is approaching the realization of an "artificial pancreas" concept, in which tight, hassle-free glycemic control may become a reality.

Prevention and treatment of the secondary effects of diabetes (target organ damage) include maintenance of tight blood pressure control, lowering LDL cholesterol, monitoring peripheral sensation with regular monofilament examinations of the feet, monitoring kidney function by measuring protein

loss in the urine, screening for diabetic retinopathy with regular ophthalmological exams, and screening for cardiovascular disease with aggressive medical and/or surgical interventions as needed.

D. Future Directions

During the past decade, pancreatic islet cell transplantation has also been under investigation as a treatment modality for type 1 diabetes. Initial results were disappointing, with success rates of only 8% (defined as patients still non-insulin-requiring at 1 year posttransplantation). However, with a better understanding of how to help these foreign grafts survive as well as how to alter the anti-islet cell autoimmune response in type 1 diabetics, success rates appear to be improving. Another area of active investigation is antigen-specific immunosuppression, in which prediabetic subjects with strong risk factors are vaccinated with targets of the autoimmune response, in an attempt to shift from pathogenic to protective immunity by inducing tolerance to the autoantigen. Studies in animal models have shown this to be an effective intervention, and phase 2 trials testing vaccination with the GAD65 antigen are currently underway. In addition, the ongoing Diabetes Prevention Trial 1 is examining whether low doses of injected or oral insulin can prevent progression to diabetes in susceptible individuals. Preliminary results suggest that injected insulin does *not* alter the natural history of the disease; results of the second arm of the study, using oral insulin, are not yet available. Furthermore, a host of immunosuppressive or immunomodulating agents are advancing to clinical trials.

At this time, a diagnosis of type 1 diabetes commits the individual to a lifetime of insulin injections. Studies seeking to elucidate why and how the immune system goes awry may provide clues about how to improve treatment options and even alter the course of this disease. Hopes for the future include immunomodulatory vaccines and islet cell transplantation.

Glossary

autoimmunity Abnormal immune response in which B cells, T cells, or both are directed against self-antigens.

cell-mediated immunity Host defenses mediated by antigen-specific T cells, which protect against intracellular bacteria, viruses, and cancer.

cytotoxic T-lymphocyte-associated antigen-4 Surface molecule on T cells that binds to the B7 molecule on antigen-presenting cells, resulting in delivery of a negative signal to the T cell and consequent downregulation of the immune response.

diabetic ketoacidosis Disease state characterized by hyperglycemia and acidosis, in which plasma ketones (β-hydroxybutyrate and acetoacetate) accumulate due to insulin deficiency and elevated glucagon levels.

epitope Site on an antigen that is recognized by a particular antibody or T-cell receptor.

glutamic acid decarboxylase 65 (GAD65) One of the major autoimmune targets in type 1 diabetes, GAD65 is an isoform of GAD, the enzyme that converts glutamic acid to γ-aminobutyric acid, an inhibitory neurotransmitter.

human leukocyte antigen Member of a family of cell surface heterodimers expressed on antigen-presenting cells that are responsible for presenting foreign antigens to T cells, via the T-cell receptor.

humoral immunity Host defenses, mediated by antibodies, which protect against extracellular bacteria and other foreign macromolecules.

IA-2 (ICA-512) One of the major autoimmune targets in type 1 diabetes, IA-2 is a protein tyrosine phosphatase-like molecule.

Diabetes Type 2 (Non-Insulin-Dependent Diabetes Mellitus)

R. PAUL ROBERTSON
University of Washington

Type 2 diabetes, also called non-insulin-dependent diabetes or adult-onset diabetes, refers to a pathologic condition that occurs commonly in humans and in some animals. This condition involves a chronic elevation of blood glucose and, over time, the development of secondary complications that adversely affect the function of many tissues and organs throughout the body.

I. INTRODUCTION: DEFINITION OF TYPE 2 DIABETES MELLITUS

The onset of type 2 diabetes, the hallmark of which is hyperglycemia, in most instances occurs in middle age and is associated with obesity. However, lean individuals can also develop type 2 diabetes and even children can develop this disease if they grow up under conditions of insufficient physical activity, improper diet, and excessive weight gain. It has been estimated that 7–9% of individuals in the United States will eventually develop type 2 diabetes. It is likely that type 2 diabetes is not a single disease and it is more accurately referred to as a syndrome that can have many causes. Clinical expression of the syndrome probably involves participation of more than one gene in a setting of adverse environmental influences favoring expression of the abnormal genes. For full expression, the syndrome of type 2 diabetes requires both an abnormality in pancreatic islet beta cell function and an abnormal resistance to the action of insulin in the cells throughout the body.

II. PHYSIOLOGY

A. Anatomy

The pancreas is located within the abdomen next to the stomach, intestines, and spleen. The pancreas is made up primarily (97%) of nonislet tissue, referred to as exocrine tissue. This tissue is drained by a pancreatic duct that runs the length of the pancreas and empties directly into the small intestine, where it delivers the digestive enzymes made by the exocrine pancreas. Scattered throughout the exocrine pancreas and comprising the remaining 3% of the pancreatic mass are the islets of Langerhans. The islets contain four major cell types, namely, alpha, beta, delta, and PP cells. These cells secrete glucagon, insulin, somatostatin, and pancreatic polypeptide, respectively.

B. Regulators of Islet Function

The primary stimulus for insulin secretion is glucose, but beta cells can also be stimulated by amino acids, other hormones, and drugs (Table 1). Insulin secretion automatically turns off when blood glucose levels become low, thus preventing the development of hypoglycemia. The primary regulators for alpha cell stimulation to release glucagon function in just

Diabetes Type 2 (Non-Insulin-Dependent Diabetes Mellitus)

R. PAUL ROBERTSON
University of Washington

Type 2 diabetes, also called non-insulin-dependent diabetes or adult-onset diabetes, refers to a pathologic condition that occurs commonly in humans and in some animals. This condition involves a chronic elevation of blood glucose and, over time, the development of secondary complications that adversely affect the function of many tissues and organs throughout the body.

I. INTRODUCTION: DEFINITION OF TYPE 2 DIABETES MELLITUS

The onset of type 2 diabetes, the hallmark of which is hyperglycemia, in most instances occurs in middle age and is associated with obesity. However, lean individuals can also develop type 2 diabetes and even children can develop this disease if they grow up under conditions of insufficient physical activity, improper diet, and excessive weight gain. It has been estimated that 7–9% of individuals in the United States will eventually develop type 2 diabetes. It is likely that type 2 diabetes is not a single disease and it is more accurately referred to as a syndrome that can have many causes. Clinical expression of the syndrome probably involves participation of more than one gene in a setting of adverse environmental influences favoring expression of the abnormal genes. For full expression, the syndrome of type 2 diabetes requires both an abnormality in pancreatic islet beta cell function and an abnormal resistance to the action of insulin in the cells throughout the body.

II. PHYSIOLOGY

A. Anatomy

The pancreas is located within the abdomen next to the stomach, intestines, and spleen. The pancreas is made up primarily (97%) of nonislet tissue, referred to as exocrine tissue. This tissue is drained by a pancreatic duct that runs the length of the pancreas and empties directly into the small intestine, where it delivers the digestive enzymes made by the exocrine pancreas. Scattered throughout the exocrine pancreas and comprising the remaining 3% of the pancreatic mass are the islets of Langerhans. The islets contain four major cell types, namely, alpha, beta, delta, and PP cells. These cells secrete glucagon, insulin, somatostatin, and pancreatic polypeptide, respectively.

B. Regulators of Islet Function

The primary stimulus for insulin secretion is glucose, but beta cells can also be stimulated by amino acids, other hormones, and drugs (Table 1). Insulin secretion automatically turns off when blood glucose levels become low, thus preventing the development of hypoglycemia. The primary regulators for alpha cell stimulation to release glucagon function in just

TABLE 1 Regulators of Pancreatic Islet Cell Secretion

Cell type	Product	Stimulators	Inhibitors
Alpha	Glucagon	Hypoglycemia, arginine	Hyperglycemia, somatostatin
Beta	Insulin	Hyperglycemia, arginine, acetylcholine, glucagon	Hypoglycemia, somatostatin, prostaglandin E2, galanin
Delta	Somatostatin	Glucose, arginine	α-Adrenergic agonists, dopamine
PP	Pancreatic polypeptide	Hypoglycemia, secretin	Atropine

the opposite way, i.e., hypoglycemia stimulates glucagon secretion and hyperglycemia inhibits the secretion of this hormone. Somatostatin secretion is stimulated by glucose and amino acids. Pancreatic polypeptide secretion is stimulated by hypoglycemia and another hormone called secretin. The interplay of these regulators of hormone secretion by the pancreatic islet provides a highly important and sophisticated means by which the products of the cells within the islet regulate overall body metabolism.

In general, the hormone insulin is essential for normal growth and for storage of fuels in body tissues. It is the primary regulator of blood glucose and is responsible for maintaining glucose within physiologic levels. Failure of pancreatic beta cells to secrete insulin inevitably is associated with very high levels of glucose and the development of diabetes. Beta cells sense the level of blood glucose and either release or stop releasing insulin, regulating blood glucose levels within a narrowly defined range both in the fasting and fed states. Hypoglycemia, however, can result from exogenous insulin, as in injected doses used to treat diabetes; overdosing can cause blood glucose to drop to abnormally low levels. In this scenario, glucagon secretion from alpha cells is then stimulated and recovery from hypoglycemia begins. Alpha cells sense when the blood glucose level becomes dangerously low (<56 mg/dl) and release the hormone glucagon, the main function of which is to prevent prolonged periods of hypoglycemia. As soon as the blood glucose level returns to normal, glucagon secretion is inhibited. Somatostatin is a local regulator of both insulin and glucagon secretion by virtue of its capacity to inhibit secretions from beta and alpha cells. The function of pancreatic polypeptide in humans is unknown.

C. Insulin and Glucagon Action

Insulin and glucagon have opposite actions on many important bodily processes (Table 2). Insulin inhibits and glucagon stimulates lipolysis, a process by which stored triglyceride within fat cells is released into the bloodstream in the form of fatty acids and glycerol. Insulin inhibits and glucagon stimulates gluconeogenesis, a biochemical process by which amino acids are used to synthesize glucose. Insulin inhibits and glucagon stimulates glycogenolysis, a process by which stored glycogen is broken down into glucose for release into the bloodstream. Insulin inhibits and glucagon stimulates ketogenesis, a biochemical process in the liver through which free fatty acids form ketones in the liver for release into the bloodstream. As mentioned previously, insulin decreases and glucagon increases blood glucose levels. The major function of these two partners is to finely regulate blood glucose levels so that neither prolonged hypoglycemia nor hyperglycemia is allowed to develop. The major sites for the regulatory actions of insulin and glucagon are the liver, fat tissue, and muscle. The liver is the major site for glycogenesis, glycogenolysis, gluconeogenesis, and ketogenesis. The fat cell is the major site for lipolysis. Insulin-induced removal of glucose from the blood occurs in most tissues of the body, with neural tissue being one important exception. The biochemical mechanism that insulin uses to exert its effects is a matter of debate. It is known that there are insulin binding sites, termed insulin receptors, on target tissues and that insulin phosphorylates many proteins subsequent to its binding. The ultimate phosphorylation step that is required for insulin action has not yet been identified and may differ from tissue to tissue. The biochemical mechanism of glucagon also involves specific binding sites and postreceptor effects involving

TABLE 2 Metabolic Actions of Insulin and Glucagon

Process	Insulin	Glucagon
Gluconeogenesis	Decrease	Increase
Glycemia	Decrease	Increase
Glycogenesis	Increase	Decrease
Glycogenolysis	Decrease	Increase
Lipolysis	Decrease	Increase
Ketogenesis	Decrease	Increase

phosphorylation of proteins, a common consequence of which is the formation of cyclic adenosine monophosphate (cAMP).

III. PATHOPHYSIOLOGY

A. Syndrome of Type 2 Diabetes

As previously discussed, type 2 diabetes is more appropriately referred to as a syndrome than a single disease entity. This condition has a polygenic cause and there is usually a strong family history of the disease in immediate family members. The onset of type 2 diabetes is usually insidious, with the patient noticing gradual weight loss and the development of thirst, increased appetite, and copious urination. Because the onset is so insidious, there are long periods of time when the patient can have diabetes without knowing it unless the blood glucose level is measured. The average age of onset of the disease is usually around 50 years, although young persons can also develop a form of the disease, referred to as maturity-onset diabetes of the young (MODY). It is not yet known which genes cause common type 2 diabetes mellitus, although much is known about genes contributing to MODY. The concordance rate for the development of type 2 diabetes is very high in identical twins.

B. Type 2 vs Type 1 Diabetes: Comparisons and Contrasts

Type 1 and type 2 diabetes mellitus are entirely different diseases. Many differences and a few similarities distinguish these diseases (Table 3). Middle age is the typical age of onset of type 2 diabetes, whereas onset is usually before adulthood in type 1 diabetes. Excess development of ketone bodies because of insulin deficiency is common in type 1 but not type 2 diabetes. Obesity is common in type 2 diabetes but not type 1. Type 2 diabetes is at least 20 times more prevalent than type 1 diabetes and in certain populations occurrence is much higher. There is no evidence for autoimmune causation of type 2 diabetes whereas an autoimmune process definitely contributes to type 1 diabetes. The concordance rate in identical twins is roughly 90% in type 2 diabetes but is only 50% in type 1 diabetes. Insulin therapy is absolutely required for type 1 diabetes but it is typically an option for type 2 diabetes. The only major similarity between these two diseases is that the secondary complications are frequent in both forms of the disease and are indistinguishable pathologically, reflecting the role of chronic elevations of high glucose as the cause of the complications.

C. Other Causes of Type 2 Diabetes

Other than the common syndrome of type 2 diabetes, the exact genetic causes of which are poorly understood, many other conditions are able to impact negatively on pancreatic islet function and/or insulin action on its target tissues, thereby causing hyperglycemia (Table 4). These adverse situations involve pancreatic disease, such as pancreatitis, trauma, tumors, cystic fibrosis, and hemochromatosis; endocrinopathies, such as excess secretion of steroids (Cushing syndrome), growth hormone (acromegaly), and glucagon (glucagonoma); drugs and chemicals, such as glucocorticoids and certain diuretics; abnormalities in the insulin receptor; and several genetic syndromes, such as diabetes insipidus/diabetes mellitus/optic atrophy/deafness (DIDMOAD) and myotonic dystrophy. In these instances, the development of chronic hyperglycemia very closely resembles that of classic type 2 diabetes, and the disease will be treated similarly.

TABLE 3 Clinical Manifestations of Type 1 vs Type 2 Diabetes Mellitus

Measure	Type 1	Type 2
Age of onset	<30 years	>40 years
Body weight	Lean	Obese
Prevalence	0.5–1.0%	7–8%
HLA-positive	Yes	No
Concordance in identical twins	50%	95%
Islet cell antibodies	85%	<10%
Insulin treatment	Required	Optional
Secondary complications	Frequent	Frequent

Genetic syndromes

D. Gestational Diabetes

The condition known as gestational diabetes refers to a temporary elevation in blood glucose level during pregnancy. It is an important condition because hyperglycemia can have adverse effects on a fetus. Consequentially, great care is taken by obstetricians to monitor patients for development of diabetes during the course of a pregnancy. Commonly, oral glucose tolerance tests are given; if abnormalities are observed, patients are advised to alter their diet and in some cases insulin treatment is required to maintain glucose levels in the normal range. Typically, after delivery, the diabetic state in the mother remits. The exact cause of gestational diabetes is not known but it is felt that a contributing factor is the complex array of hormonal changes that occur during pregnancy, coupled with an intrinsic borderline function of the maternal pancreatic islets. A greater percentage of women who develop gestational diabetes will later develop type 2 diabetes mellitus compared to women who are able to sustain pregnancies without developing hyperglycemia.

E. Maturity-Onset Diabetes of the Young

Onset of the MODY form of type 2 diabetes usually occurs before the age of 25 and frequently occurs in childhood. This disease involves a primary defect in beta cell function and can result from mutations in one of at least six different genes (Table 5). The genes that can be involved in specific types of MODY encode specific proteins, hepatic nuclear factors (HNFs), insulin promoter factors (IPFs), and transcription factors (NeuroD1/BETA2) as follows: HNF-4α (MODY 1), glucokinase (MODY 2), HNF-1α (MODY 3), IPF-1 (MODY 4), HNF-1β (MODY 5), and NeuroD1/BETA2 (MODY 6). All of the conditions that are the consequences of these genetic defects have similarities and differences, including abnormal regulation of insulin gene transcription, sensitivity of beta cells to glucose, defective storage of glucose as liver glycogen, and abnormal regulation of beta cell development and function. Treatment of the different forms of MODY can vary from control of diet and exercise to use of oral hypoglycemic agents or insulin. It has been estimated that MODY may account for 1–5% of all cases of diabetes in the United States and other western countries. The chief clinical characteristics distinguishing patients with MODY from those with conventional type 2 diabetes include a prominent family history of diabetes in three or more generations, absence of obesity, and the young age of presentation.

F. Relative Roles of Insulin Secretory Abnormalities and Insulin Resistance

In most instances, type 2 diabetes mellitus does not develop unless there is both a defect in beta cell function and a defect in insulin action at the level of its target tissues. This multiplicative effect has been referred to as the multiplier hypothesis (Fig. 1).

TABLE 5 Classification of Maturity-Onset Diabetes of the Young

MODY type	Protein encoded by abnormal gene[a]	Molecular defect	Usual treatment
1	HNF-4α	Abnormal beta cell gene transcription, causing defective signaling of beta cell mass and secretion	Oral hypoglycemic drugs
2	Glucokinase	Defective beta cell sensitivity to glucose; defective liver glycogen storage	Diet, exercise
3	HNF-1α	Abnormal beta cell gene transcription, causing defective signaling of beta cell mass and secretion	Oral hypoglycemic drugs
4	IPF-1	Abnormal beta cell gene transcription and function	Oral hypoglycemic drugs, insulin
5	HNF-1β	Abnormal beta cell gene transcription, causing defective signaling of beta cell mass and secretion	Insulin
6	NeuroD1 or BETA2	Abnormal beta cell gene transcription and function	Insulin

[a]HNF, Hepatic nuclear factor; IPF, insulin promoter factor.

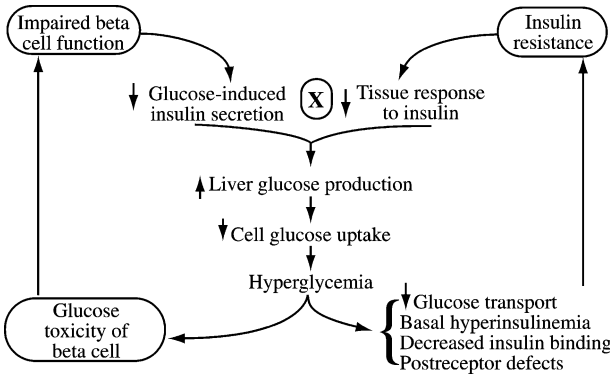

FIGURE 1 Multiplier hypothesis. The pathogenesis of type 2 diabetes mellitus involves a double defect of abnormal beta cell function coupled with resistance to the actions of insulin on its target tissues. This combination leads to elevated glucose levels and worsening of insulin resistance as well as glucotoxic effects on many tissues throughout the body, including the beta cell. Modified from Robertson, R. P. (1995), Diabetes and insulin resistance: Philosophy, science, and the multiplier hypothesis, *J. Lab. Clin. Med.* **125**, 560–564, with permission.

The overall hypothesis is that patients with type 2 diabetes mellitus are born with one of several possible genetic defects in beta cell mass or function and also have genetic or environmentally induced insulin resistance. The combination of these defects cause hyperglycemia in the diabetic patient, which in turn leads to worsening insulin resistance as well as worsening beta cell function and adverse effects of chronic hyperglycemia on tissues throughout the body. It is unlikely that insulin resistance alone can cause type 2 diabetes because virtually all obese individuals as well as individuals treated with exogenous glucocorticoids are insulin resistant, and yet most of these individuals never develop hypoglycemia. Similarly, certain disease states, such as cystic fibrosis, cause abnormalities in insulin secretion, yet these patients usually are lean and insulin sensitive and usually do not develop hyperglycemia. This multifactorial etiology of type 2 diabetes presents the opportunity for multiple modes of treatment to control the hyperglycemia. Treatment can be directed both toward improving beta cell function as well as decreasing insulin resistance.

G. Glucose Toxicity

Whatever the cause of hyperglycemia, the chronic elevation of glucose levels can have adverse metabolic effects in many tissues. Whereas glucose in normal concentrations is an important fuel for tissues, glucose in excess can be shunted away from its normal metabolic pathway into other pathways that produce compounds toxic to cell function. Some of these products are sorbitol, glucosamine, and highly reactive radicals involving either oxygen or nitrogen atoms. For example, glucose can generate reactive oxygen species (ROS), such as superoxide ions and hydroxyl radicals. The hydroxyl radical, in particular, is able to cross cell membranes rapidly and enter the nucleus, where, if in high enough concentrations, it can damage nuclear DNA. DNA mutations, in turn, can lead to abnormalities in protein synthesis and cell function.

IV. DIAGNOSTIC TESTING

The chief means by which diabetes is diagnosed is the blood glucose level. Current criteria use a fasting plasma glucose level of greater than 126 mg/dl as the cutoff point for diagnosing diabetes. Oral glucose tolerance testing is also utilized. The oral glucose test involves ingesting a set amount of glucose (usually 75 g) and measuring blood glucose levels over the ensuing 2 h. Current diagnostic criteria indicate impaired glucose tolerance if the 2-h level is greater than 140 mg/dl and frank diabetes if the 2-h level is greater than 200 mg/dl. Beyond these clinical criteria, research data indicate that a fasting plasma glucose level greater than 100 mg/dl may be abnormal because individuals with a fasting glucose level less than 100 mg/dl have twice the magnitude of insulin secretion in response to an intravenous glucose challenge.

V. SECONDARY COMPLICATIONS

The major secondary complications of hyperglycemia develop in the kidney, nerves, retinas, and walls of small and large arteries. Kidney disease, referred to as diabetic nephropathy, is a leading cause of death and disability in patients with diabetes. Roughly half the cases of end-stage renal disease in the United States are due to diabetic nephropathy. The prevalence of this complication varies from 15 to 60% of type 2 diabetes patients, depending on ethnic background. Typically, hyperglycemia over a period of 10–15 years is required before diabetic nephropathy is expressed at a clinical level. Abnormal consequences include the appearance of protein in the urine and excessive levels of creatinine in the blood, reflecting a decline in the ability of the kidney to filter proteins. Ultimately, diabetic nephropathy can lead to renal failure, which requires renal dialysis or kidney

transplantation to prevent death. The adverse effect of diabetes on nerves, referred to as diabetic neuropathy, takes many forms. The most common manifestations are sensory and motor neuropathies. Sensor neuropathy is expressed clinically by symptoms such as numbness, pain, and extreme sensitivity to touch. Motor neuropathies are expressed clinically by muscle weakness and incoordination. Treatment of diabetic neuropathy is largely ineffective, which causes sustained and significant stress for the diabetic patient. Involvement of the optic retinae is referred to as diabetic retinopathy. Diabetic retinopathy is the leading cause of blindness in the United States. Even though many patients develop the retinopathic changes, most diabetic patients do not become blind. Typically, retinopathy involves the formation of microaneurysms, dilated veins, proteinaceous exudates, retinal detachment, and vitreal hemorrhage. Retinopathy is usually not apparent in the first 5 years of diabetes but eventually greater than 50% of patients develop some form of this complication. The treatment for diabetic retinopathy is photocoagulation, which is performed to decrease the incidence of hemorrhaging and scarring and to prevent an advanced stage of retinopathy referred to as proliferative retinopathy. Both small and large arteries are adversely affected by chronic hyperglycemia, outcomes that are worsened by an often associated elevated level of lipoproteins. Oxidized low-density lipoproteins favor the formation of atherosclerotic lesions and this process appears to be accelerated in diabetes. Complications that follow the development of atherosclerosis in arteries include coronary heart disease and stroke as well as peripheral vascular disease, which in combination with peripheral neuropathy, predisposes diabetic patients to poor healing of skin lesions in the feet. The latter complication, if not properly attended to, can cause gangrene and the need for amputation to varying degrees.

This range of secondary complications of chronic hyperglycemia provides important incentives for patients and physicians to treat diabetes optimally. A very important clinical trial, the Diabetes Control and Complications Trial (DCCT), has established that the rate of development of secondary complications of diabetes involving eyes, nerves, and kidneys is inversely related to mean circulating glucose levels (Fig. 2). In this study, the major marker of hyperglycemia was hemoglobin A1c, a fraction of hemoglobin that is glycosylated by glucose in direct proportion to the circulating glucose level. A single hemoglobin A1c measurement reflects the average

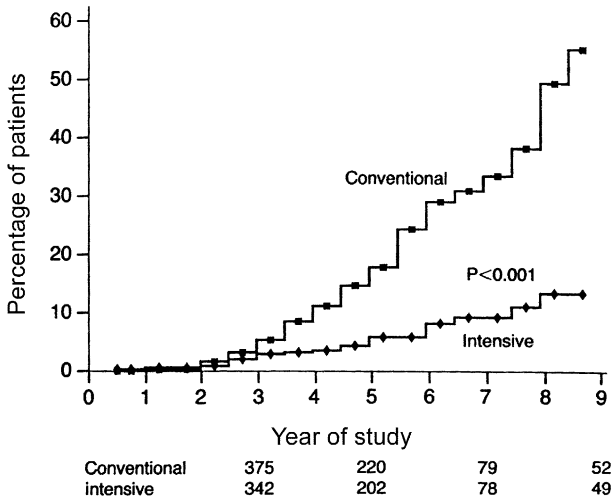

FIGURE 2 Cumulative incidence of a change in retinopathy in patients with type 1 diabetes receiving intensive or conventional treatment in the Diabetes Control and Complications Trial. Reprinted from The Diabetes Control and Complications Trial Research Group (1993), The effect of intensive treatment of diabetes on the development and progression of long-term complications in insulin-dependent diabetes mellitus, *N. Engl. J. Med.* **329**, 977–986, with permission.

daily mean blood glucose level for the prior 3 months. Ready access to this measurement, in conjunction with the ability of patients to monitor their own glucose levels at home with portable glucose meters, has greatly assisted patients in devising the proper therapeutic regimens to maintain their glucose levels as close to the normal range as possible, with the major goal of greatly diminishing the probability that they will develop secondary complications of chronic hyperglycemia.

VI. TREATMENT

Medical treatment for type 2 diabetes involves a wide spectrum of options involving exercise, dietary changes, and the use of oral hypoglycemic agents and exogenous insulin (Table 6). There is no single ideal diet for diabetic patients. Rather, each individual's diet should be tailored to suit their metabolic

needs, considering blood glucose, hemoglobin A1c, lipid levels, blood pressure, weight, and quality of life. Approaches to manage obesity include changes in the caloric content of the diet. In this case, restriction of fat is usually beneficial. If hypercholesterolemia is a problem, reduced cholesterol intake is recommended. The approach to carbohydrate intake is highly complicated and varies with the individual, with attention given to the type and fiber content of any carbohydrate under consideration. Dietary therapy is greatly facilitated by consultation with a nutritionist, who can create an individualized diet for the patient that meets individual metabolic needs and yet is reasonable enough that the patient is not discouraged from following it. All patients with diabetes benefit from exercise because physical exertion facilitates insulin action and the removal of glucose from blood. Oral hyperglycemic agents that can be used include sulfonylureas, biguanides, and thiazolidinediones. Sulfonylureas facilitate insulin release from the pancreatic beta cell when it is stimulated by glucose. Biguanides and thiazolidinediones are insulin sensitizers that facilitate the action of insulin at its major metabolic sites, mainly the liver, fat cells, and muscle. Commonly, combinations of sulfonylureas and insulin sensitizers are used to maintain the hemoglobin A1c level in the desired range. Exogenous insulin can also be used for type 2 diabetic patients in the same manner that it is used for type 1 diabetic patients. Typically, a dose of long-acting insulin given at bedtime will greatly facilitate controlling glucose levels in type 2 diabetic patients. However, these patients may also elect to use a shorter acting insulin prior to eating their evening meal to facilitate reduction of postprandial hyperglycemia. A point of common confusion that should be avoided is that the use of insulin by a type 2 diabetic patient does not mean that the patient has become a type 1 diabetic patient. Rather, it simply means that the type 2 diabetic patient has elected to use insulin to facilitate management of hyperglycemia. The difference between a type 1 and type 2 diabetic patient is that the former requires insulin for survival and oral hyperglycemic agents cannot manage the disease alone, whereas the latter elects to use insulin as an additional help to maintain glucose levels to as close to normal as possible.

Glossary

glucose toxicity Adverse biochemical effects in many tissues within the body resulting from prolonged elevations of glucose.

hyperglycemia Elevated blood glucose level.

insulin Major hormone released by the beta cells within pancreatic islets.

oral hyperglycemic agents Drugs that can be taken by mouth to treat hyperglycemia.

pancreatic islet Cluster of cells contained within the pancreas. The human pancreas contains approximately 1 million of these clusters, each of which contains four major cell types that release hormones directly into the bloodstream for distribution to all parts of the body.

secondary complications Adverse effects on many structures and organs in the body resulting from chronic diabetes.

Dihydrotestosterone, Active Androgen Metabolites and Related Pathology

GUIDO VERHOEVEN
Catholic University of Leuven, Belgium

Testosterone is the major steroid hormone produced by the testis and the major circulating androgen in men. Many effects of androgens, however, are not mediated by testosterone itself, but rather by so-called "active metabolites." In several androgen target tissues, a steroid 5α-reductase converts testosterone into the more potent androgen 5α-dihydrotestosterone (DHT). This conversion is absolutely required for the virilization of the external genitalia during embryonic development and DHT remains the main androgen acting in the prostate during adulthood as well. Aromatization of testosterone may result in a second active metabolite, 17β-estradiol, which plays an important role in some of the effects of androgens on bone and on the brain. The concept of active metabolites has had important repercussions on our understanding of the physiology and pathology of androgen action.

I. INTRODUCTION

This article focuses on 5α-dihydrotestosterone (DHT) (Fig. 1) and the enzymes responsible for its formation. The role of DHT in normal sexual differentiation as well as a form of male pseudo-hermaphroditism caused by the absence of 5α-reductase activity is discussed. Furthermore, the role of DHT in the prostate and in benign prostatic hyperplasia and the therapeutic potential of 5α-reductase inhibitors are examined.

II. DHT AND THE CONCEPT OF ACTIVE METABOLITES

In 1968, two independent studies focused attention on DHT as a critical intracellular mediator of androgen action. Bruchovsky and Wilson analyzed the fate of [^{3}H]testosterone in castrated, eviscerated, and functionally hepatectomized rats and came to the surprising conclusion that DHT rather than testosterone was the predominant radiolabeled hormone accumulating in nuclei from the rat ventral prostate.

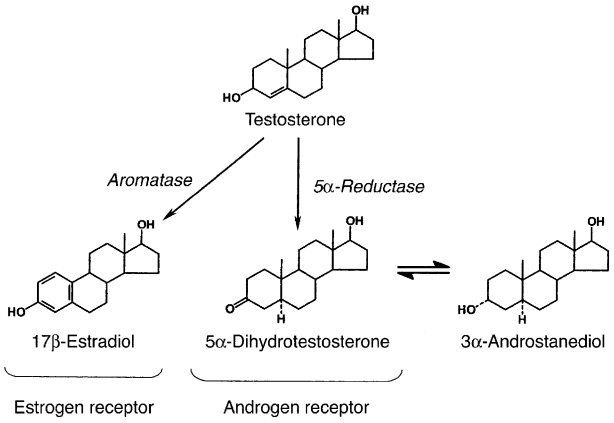

FIGURE 1 Production of active metabolites from testosterone. Five-α-reduction of the main circulating androgen, testosterone, results in the production of 5α-dihydrotestosterone, a more potent androgen that acts via the same receptor as testosterone (the androgen receptor). Aromatization of testosterone produces 17β-estradiol, which acts via the estrogen receptor. Some tissues may use 3α-androstanediol as a source of 5α-dihydrotestosterone.

Similar observations were made by Anderson and Liao after incubation of prostate slices with [^{3}H]testosterone. These initial findings were followed by the demonstration that several androgen target tissues actively convert testosterone into DHT and that this conversion is related to a 5α-reductase associated with the cell nucleus. The idea rapidly gained prominence that some and maybe all effects of androgens might require conversion of circulating testosterone into its active metabolite, DHT. This hypothesis received further support from bioassay data showing that—at least in some test systems—DHT is a more potent androgen than testosterone and from studies on the androgen receptor that revealed that this receptor has a higher affinity for DHT than for testosterone.

The full implications of these findings became evident after a detailed analysis of the embryologic development of the 5α-reductase in the genital tract. Androgens are essential for the virilization of the male genital tract during embryogenesis, and accordingly, the question was asked as to whether these effects were mediated by testosterone or whether they required conversion into the active metabolite DHT. The answer to this question proved complex. Comparison of 5α-reductase activity in urogenital tracts of various species including human revealed that, in the anlage of the prostate and external genitalia, the capacity to form DHT was present prior

to the onset of virilization and precedes testicular androgen secretion, whereas in the Wolffian duct, which gives rise to the epididymis, vas deferens, and seminal vesicle, the capacity to form DHT was not acquired until after the onset of androgen secretion and after male differentiation. Final proof for the contention that some androgen effects require DHT formation (virilization of the external genitalia) whereas others may be induced by testosterone itself (virilization of the genital ducts) came from a hereditary disorder of sexual differentiation shown to be due to 5α-reductase deficiency. Before discussing this disease, however, it may be good to take a closer look at the 5α-reductase enzyme.

III. STEROID 5α-REDUCTASE: TWO GENES/TWO ENZYMES

The steroid 5α-reductase was described in the 1950s and 1960s as an enzyme that irreversibly catalyzes the catabolism of various Δ4 steroids into their 5α-reduced metabolites using NADPH as a co-factor. The observation that the enzyme could also contribute to an anabolic reaction, converting testosterone into a more active metabolite, strongly stimulated attempts to purify the protein(s) involved. All efforts to solubilize or purify the protein remained unsuccessful, however, and the impasse was broken only after the introduction of expression cloning techniques. The first cDNA thus isolated encoded a rat liver 5α-reductase. Cross-hybridization screening of a human prostate cDNA library using this rat cDNA resulted in the identification of a human 5α-reductase. Surprisingly, the corresponding enzyme (5α-reductase 1) displayed an alkaline pH optimum (in contrast with the acidic pH optimum observed in prostate tissue and in genital skin fibroblasts). Moreover, it was only weakly inhibited by a 5α-reductase inhibitor (finasteride) known to be active in the above-mentioned androgen target tissues, and no mutations were found in the corresponding gene in patients with 5α-reductase deficiency. These findings suggested the existence of a second 5α-reductase. A new round of expression cloning indeed allowed the isolation of the relevant cDNA. The corresponding enzyme (5α-reductase 2) displayed the expected acidic pH optimum and proved sensitive to finasteride. In addition, the gene encoding this enzyme was mutated in patients with 5α-reductase deficiency. Some of the main characteristics of the type 1 and type 2 5α-reductases and the corresponding genes are summarized in Table 1. The genes encoding both human 5α-reductases show extensive structural homology, suggesting a common ancestor. Both have five exons separated by four intervening sequences. They are localized on different chromosomes and expression varies considerably in different tissues. Type 2 is predominantly expressed in the male urogenital tract and in genital skin, whereas type 1 is expressed in nongenital skin and particularly in the sebaceous glands. Both isozymes are expressed in the human liver. Some polymorphisms that may be useful for inheritance studies in the gene encoding type 2 have been described.

TABLE 1 Comparison of Human Steroid 5α-Reductase Isozymes

	Type 1	Type 2
pH optimum	6.5–9	5.5
Apparent K_m (μM)	1–5	0.1–1
M_r	29,462	28,398
Chromosomal localization	5p15	2p23
Gene	SRD5A1	SRD5A2
Tissue distribution		
Prostate	−	++
Genital skin	−	++
Liver	+	+
Nongenital skin	++	−

IV. STEROID 5α-REDUCTASE TYPE 2 DEFICIENCY

The link between the above-described fundamental observations on androgen action and a candidate disease due to 5α-reductase deficiency was established in 1974 by the study of two families, one in Dallas, Texas, and the other in the Dominican Republic. Both families presented a phenotype compatible with an autosomally recessive form of male pseudo-hermaphroditism previously known as pseudo-vaginal perineoscrotal hypospadias or incomplete male pseudo-hermaphroditism type 2. Patients were 46, XY males presenting at birth with an external female phenotype, bilateral testes, and normally virilized Wolffian structures terminating in the vagina (Fig. 2). In the Dallas family, 5α-reductase deficiency was demonstrated by measurements of the enzyme in slices and cell cultures of genital tissue and skin. In the large pedigree of the Dominican Republic, the diagnosis was made based upon the low levels of 5α-reduced metabolites in plasma and urine.

The clinical phenotype of 5α-reductase deficiency shows some variability. Classically, the external genitalia are not masculinized at birth, and affected

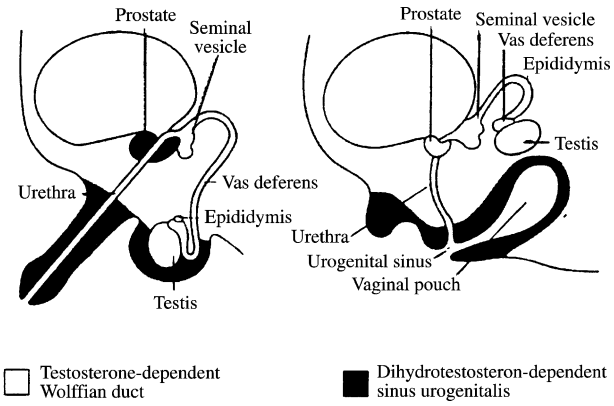

FIGURE 2 External and internal genitalia in the normal male (left) and in a patient with 5α-reductase type 2 deficiency (right). Reprinted with permission from Bartsch *et al.* (2000). Dihydrotestosterone and the concept of 5α-reductase inhibition in human benign prostatic hyperplasia. *Eur. Urol.* **37**, 367–380. Copyright Karger AG, Basel.

patients exhibit a blind-ending vagina or a urogenital sinus opening in a single perineal orifice. The phallus is hypospadic, resembling a clitoris, and the scrotum is bifid and labia-like. Most of the patients are therefore described as girls at birth. In some cases, however, the phallus may be so large that affected infants are identified as males with hypospadias. The internal genitalia—vas deferens, epididymis, and seminal vesicles—are fully formed and the Müllerian structures are lost The prostate is absent or severely hypoplastic. The testes are in the inguinal canal, labia, or scrotum.

At puberty, marked virilization takes place. The muscle mass gives the body a masculine shape, the voice deepens, the penis enlarges to 4–8 cm, and the testes enlarge and descend into the labioscrotal folds. There is no gynecomastia. These predictable changes in phenotype have led to descriptions of affected individuals in the Dominican Republic as "guevedoces" or "penis at 12." The prostate remains tiny (approximately 10% of the volume observed in matched controls) and the pattern of body hair is female with terminal hair in the axilla and pubic triangle only. Male pattern baldness has not been described and acne is very rare. In the absence of medical interventions or sociocultural factors interrupting the natural sequence of events, psychosexual orientation is male. Even when unambiguously raised as girls, the vast majority of subjects change to male gender identity and a male gender role during or after puberty. This suggests that testosterone itself is active in the brain or that it acts via another active metabolite (e.g., estrogens) to produce changes in psychosexual behavior.

The main endocrine features of 5α-reductase deficiency are normal male to high levels of plasma testosterone and low levels of DHT. The ratio of testosterone to DHT is elevated in adulthood and after stimulation with human chorionic gonadotropin in childhood. In urine, the ratios of 5β/5α androgen and C21 metabolites are increased. Gonadotropins are at normal or slightly elevated levels.

Early studies suggested that affected patients had a defect in the activity of a 5α-reductase with a pH optimum of approximately 5.5. In some patients, activity was absent, and in others, activity remained measurable but was kinetically abnormal. The cloning of the two 5α-reductase enzymes allowed unequivocal localization of the defect in the 5α-reductase 2 enzyme. This enzyme not only exhibited the expected acidic pH optimum, it also displayed preferential expression in genital tissues and sensitivity to a 5α-reductase inhibitor known to interfere with androgen action in the prostate. Approximately 30 different mutations in the type 2 gene have now been identified and characterized at the clinical, genetic, and biochemical levels. Mutations that affect the affinity for testosterone map to the two ends of the type 2 isozyme, and mutations that affect NADPH binding map throughout the carboxy-terminal half of the enzyme. The described form of male pseudohermaphroditism is now universally referred to as steroid 5α-reductase 2 deficiency.

V. BENIGN PROSTATIC HYPERPLASIA AND THE DEVELOPMENT OF 5α-REDUCTASE INHIBITORS

There is an overwhelming amount of evidence indicating that DHT is the major androgen acting in the human prostate. As already mentioned, the prostate remains vestigial in the absence of the 5α-reductase 2. Moreover, the level of DHT in the prostate is nearly 10 times higher than the level observed in the circulation, whereas the opposite is found for testosterone. These high intraprostatic levels of DHT are maintained with age, despite decreasing circulating levels of testosterone, and part of the intraprostatic DHT is derived from adrenal androgens. Finally, prolonged administration of DHT or 3α-androstanediol to dogs results in prostatic hyperplasia, an effect that can be markedly enhanced by simultaneous treatment with 17β-estradiol. The predominant 5α-reductase in the prostate is

the 5α-reductase 2 isozyme and this enzyme is located mainly in the stroma and in the basal cells, suggesting that DHT produced in the prostate may act as an autocrine agent in the stroma and as a paracrine factor in the lumenal cells.

There is little doubt that androgens and in particular DHT contribute to the pathogenesis and progression of benign prostatic hyperplasia (BPH) but the exact role of androgens in the pathophysiology of the disease remains unclear. BPH is the most common nonmalignant proliferative abnormality observed in any internal organ in men. Autopsy studies reveal that microscopic disease may be present as early as 25–30 years of age. With increasing age, the prevalence of microscopic BPH rapidly increases to reach approximately 80% in the eighth decade. Approximately 35% of men 60 years or older display one or more clinical symptoms of prostatism (hesitancy, straining, weak stream, and intermittency). Androgens play at least a permissive role in the pathogenesis of BPH. BPH does not occur in men castrated before puberty and is extremely rare in men castrated before the age of 40. Moreover, androgen ablation therapy reduces prostatic volume in patients with BPH. Nonetheless, other factors may be involved. In fact, in its initial stages, BPH is not a *diffuse* disease—as would be expected if an endocrine imbalance were the primary pathogenic factor—but a *focal* disease situated in the transition zone and the periurethral region of the prostate gland. Disturbed stromal–epithelial communications and a reawakening of embryonic inductive interactions between these tissue components have been suggested as important pathogenic events.

The reliance of the prostate on androgens and particularly on the active metabolite DHT stimulated the search for specific 5α-reductase inhibitors. A whole series of steroidal and nonsteroidal inhibitors have now been developed but the best studied remains the 4-azasteroid finasteride (17β-(*N*,t,-butyl) carbamoyl-4-aza-5α-androst-1-en-3-one). At low concentrations, finasteride acts as a time-dependent inactivator of the type 2 isozyme. Much higher concentrations are required to also block the type 1 enzyme. Finasteride reduces circulating levels of DHT by approximately 70% and increases testosterone only slightly, suggesting that the feedback of luteinizing hormone (LH) depends directly on testosterone or on other active metabolites such as estradiol. Intraprostatic levels of DHT drop to less than 15% of their original value but intraprostatic testosterone increases some sevenfold. In a U.S. trial, prostatic volume was reduced by 19%, the maximum urinary flow rate improved by 1.6 ml/s, and the total symptom score decreased by 2.6 after 12 months of therapy. Some further improvement was observed after longer treatment periods. Treatment proved more effective in men with large prostates. Complications such as acute urinary retention and BPH-related surgery were decreased by more than 50% after a 4-year treatment period. Very few side effects were noted, with a decrease in libido or impotence reported in approximately 5% of the patients, suggesting again that the latter effects may not be dependent on DHT but on testosterone and/or estradiol.

The remaining levels of circulating DHT in finasteride-treated patients are most likely due to residual activity of the type 1 5α-reductase. In fact, in recent studies, a more effective dual inhibitor of the type 1 and type 2 enzymes (GI 198745) decreased circulating DHT by 98%. Whether this decrease will result in further therapeutic benefit remains to be proven. In fact, it is conceivable that the residual and increasing intraprostatic testosterone levels may limit the therapeutic potential of 5α-reductase inhibitors.

VI. OTHER APPLICATIONS OF 5α-REDUCTASE INHIBITORS

Prostate cancer is obviously another common disease in which androgens play an important role. Taking into account that even low levels of androgens may be sufficient to permit continued growth of prostate cancer cells, it is unlikely that monotherapy with 5α-reductase inhibitors will have a future in the therapy of this disease. Reduction of prostate-specific antigen secretion has been observed in prostate cancer patients treated with finasteride, however, and combined with the anti-androgen flutamide, finasteride has been shown to be an effective form of maximal androgen blockade. Finasteride is being evaluated in a large primary prostate cancer prevention trial involving more than 18,800 healthy men at low to average risk. This landmark trial underscores the feasibility of chemoprevention but the size of the expected treatment is limited (25% reduction in the period prevalence of prostate cancer over 7 years of treatment), and there remains some concern that this form of prevention may select for androgen-resistant tumors.

Another important androgen target organ is the skin. Since patients with 5α-reductase deficiency have sparse facial and body hair and since they do not develop male pattern baldness, it might be expected

that DHT could contribute to conditions such as acne, hirsutism, and baldness. Acne is probably not a good indication. In fact, sebum production is not affected in patients treated with finasteride and is comparable in patients with 5α-reductase deficiency and in normal controls. Finasteride has proven to be effective, however, in the treatment of androgenic alopecia in men. After 2 years of treatment, approximately two-thirds of men show improved scalp coverage and approximately one-third have the same amount of hair as they did at the onset. With prolonged treatment, the clinical impression is that scalp coverage continues to increase. Increased 5α-reductase activity is considered a pathogenic mechanism of idiopathic hirsutism and higher levels of 5α-reductase activity have been reported in dermal papilla cells from follicles derived from beard and balding scalp than in comparable cells derived from nonbalding scalp. Accordingly, hirsutism might be another indication for the use of 5α-reductase inhibitors. Such inhibitors should not be used, however, in women who are or may become pregnant because of the potential interference with the development of the genital tract in male fetuses. Nonetheless, some studies suggest that finasteride is as effective for the treatment of hirsutism as the antiandrogens flutamide and spironolactone. Moreover, the 5α-reductase inhibitor seems to improve the results of contraceptives containing the anti-androgenic compound cyproterone acetate.

VII. REMAINING QUESTIONS

There remain several intriguing questions with respect to the physiological role of DHT. It remains unclear why some androgen-regulated processes (development of internal genital tract, feedback of LH, and spermatogenesis, etc.) rely on testosterone, whereas others require the active metabolite DHT. Is DHT simply a more active ligand or are there differences in the spectrum of genes activated by the DHT–receptor complex and the spectrum controlled by the testosterone–receptor complex? What is the role of circulating DHT in the response of some target organs (such as muscle) with low 5α-reductase activity? What is the role of the 5α-reductase 1 in health and disease? What is the role of genetic and dietary factors in differences in 5α-reductase activity reported in different populations? It is likely that many of these questions will be answered in the near future.

Glossary

hirsutism Excess facial and body hair in women in a pattern similar to that found in men.

male pseudo-hermaphroditism Condition in which the gonads are testes but the genital ducts and/or external genitalia are incompletely masculinized. Most often there is a normal XY karyotype.

steroid 5α-reductase NADPH-dependent 3-oxo-5α-steroid Δ4 dehydrogenase (EC 1.3.99.5). Enzyme that irreversibly catalyzes the conversion of various Δ4 steroids into their 5α-reduced metabolites using NADPH as a co-factor.

Diuretic Hormones and the Regulation of Water Balance in Insects

JEFFREY H. SPRING* AND
S. RENEE HAZELTON-ROBICHAUX†

University of Louisiana, Lafayette • †Louisiana State University, Eunice

Because of their small size, insects have a most unfavorable surface area-to-volume ratio, which makes them susceptible to rapid desiccation. They compensate for this by having a waxy, waterproof surface coating to limit evaporative water losses and by carefully regulating their internal water balance. There are a number of neuropeptides that stimulate fluid secretion (diuretic peptides; DPs) and fluid reabsorption (antidiuretic peptides; ADPs). Although there is some overlap, the DPs and the ADPs generally target different regions of the excretory system.

I. EXCRETORY ORGANS

Insects have an open circulatory system and the blind-ended Malpighian tubules extend throughout most areas of the hemocoel, or blood space. The tubules are a monolayer epithelium and are normally regionally segmented with up to four discrete segments per tubule. Most insects appear to have a single cell type within each region; however, the Diptera have two cell types, primary and stellate, which are quite different in both structure and function. Blood pressure is very low, precluding filtration for urine formation, and so the primary urine is generated by secretion. Vacuolar-type proton pumps (H-ATPases, also known as V-ATPases) located on the microvilli establish a pH gradient across the luminal membrane. Antiporters on the same membrane exchange H^+ for K^+ or Na^+, generating the observed cation gradient into the lumen. Counterions, primarily Cl^- or to a lesser extent HCO_3^-, follow passively. A very slight osmotic gradient ($\leq 1\%$) causes water and other hemolymph components to flow into the tubule lumen, often very rapidly. In most insects, this primary urine is rich in KCl and would rapidly alter the ionic composition of the hemolymph were it not for the action of the hindgut (ileum/rectum), where salts and water are reabsorbed. In most insects, there are four to six rectal pads with columnar transporting cells surrounded by layers of muscle and connective tissue. The hindgut is lined with cuticle, which provides mechanical and chemical protection from the gut contents. Here, the actively transported ion is Cl^-, with Na^+ and K^+ transported in various quantities as counterions. Both the Malpighian tubules and the rectum have specialized transport proteins to eliminate or recover specific organic substances (Fig. 1).

II. SOURCE OF HORMONES

The primary source of diuretic peptides (DPs) and antidiuretic peptides (ADPs) is a complex containing the median neurosecretory cells/corpora cardiacum (MNC/CC). The MNC are located near the anterior dorsal surface of the brain, in the central region known as the pars intercerebralis. In those insects where the lobes are separate and not fused, the MNC axons terminate in the storage lobes of the CC, much like the vertebrate hypothalamus/posterior pituitary. The glandular lobes of the CC are analogous to the anterior pituitary and contain neurosecretory cells that synthesize and secrete their own intrinsic hormones (Fig. 2). Some DPs

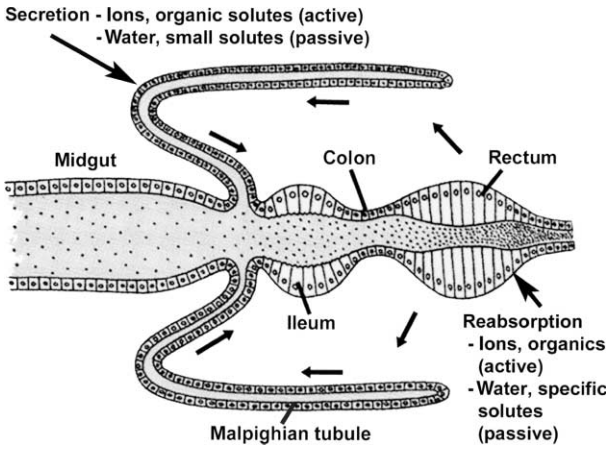

FIGURE 1 Diagram of the general structure of the insect excretory system, showing the anatomical relationships between the Malpighian tubules and the regions of the gut and the functions of each region.

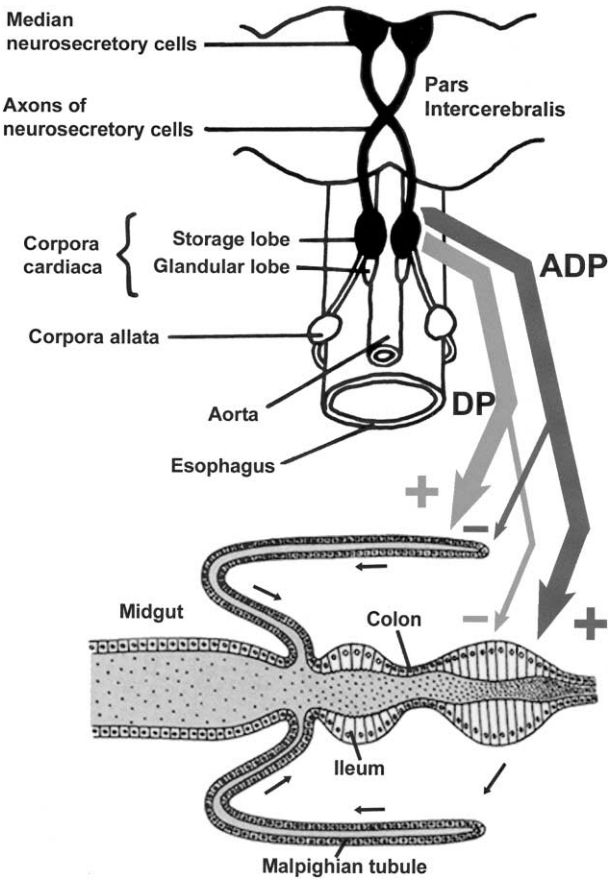

FIGURE 2 Diagram of the typical arrangement of the neurohemal organs (MNC/CC) and the primary and secondary targets of DPs and ADPs released from the CC. For further explanation, see text.

have been isolated from the ventral ganglia, and immunolocalization studies suggest that each ganglion contains a handful of neurosecretory cells that contain DPs and are presumed to act locally, affecting individual Malpighian tubules or segments of the ileum and rectum.

III. STRUCTURE

In general, most of the DPs fall into two groups: those with varying degrees of homology to the vertebrate corticotropin-releasing factor/urotensin/sauvagine family of peptides and the smaller kinins. There are, of course, exceptions. For example, a DP related to the arginine vasopressinpeptide family has been isolated from the subesophageal and thoracic ganglia of *Locusta migratoria*. The cardioacceleratory peptide, CAP_{2b}, apparently acts as a DP in *Drosophila melanogaster*, and the biogenic amine, serotonin (5-hydroxytryptamine), in addition to its known pharmacological effects on tubule secretion, may act as a true diuretic factor in the blood-sucking bug, *Rhodnius prolixus*.

There are approximately 10 known corticotropin-releasing factor-like diuretic peptides (CRF-DPs) (some have only been partially sequenced) found in several orders of insects. They range in size from 30 to 46 amino acids, and sequence homology is relatively low, approximately 50% in most cases, although it has been suggested that nucleotide homology may be much higher, perhaps 70–80%. In all cases, gaps are required in the sequences to show maximal homology with the other members of the family. With a single exception, only one CRF-DP per species has been noted.

Members of the second major family of diuretic peptides were initially isolated on the basis of their myotropic activity on the hindgut of *Leucophaea maderae* and were named the insect kinins. There are currently two dozen known kinins, and there are usually several different kinins (five to eight) within a single species. These peptides are small, 6–13 residues, and have a highly conserved C-terminal pentapeptide sequence.

Serotonin, of course, is a single amino acid derivative, and CAP_{2b} is an octapeptide. The situation with ADPs is much less clear-cut. The neuroparsins, a family of three larger neuropeptides (78, 81, and 83 residues), isolated from *L. migratoria* stimulate water reabsorption by the rectum. Two peptides isolated from *Schistocerca gregaria*, ion-transport peptide (72 residues) and chloride-transport stimulating hormone (structure unknown), act on the hindgut to stimulate ion and water reabsorption. Antidiuretic peptides (structure unknown) isolated from *Acheta domesticus* and *Formica polyctena* act to inhibit secretion by the Malpighian tubules.

IV. TARGETS AND TRANSDUCERS

All of the known DPs and ADPs are peptides and so require a second-messenger system to exert their effects at the cellular level. The mode of action of the CRF-DPs appears to be relatively uniform across species, and there are varying degrees of interspecific bioactivity. In most cases, interspecific activity is relatively low, so, for example, even at high doses, Mas-DP1 (the primary CRF-DP from *Manduca sexta*) produces only 60% of the maximal response in *A. domesticus* Malpighian tubules, as might be expected given the relatively low sequence homology

between peptides. The CRF-DPs activate an adenylate cyclase in the primary cells of the Malpighian tubules, elevating cAMP levels in these cells. The action of cAMP in the primary cells is to increase Na^+ conductance across the basolateral membrane, presenting the apical Na^+/H^+ antiporter with a higher concentration of substrate, thereby increasing cation transport, with water and other solutes following passively. In the tsetse fly, cAMP appears transiently to increase Malpighian tubule cell volume by increasing basolateral permeability to both Na^+ and Cl^-, with cell volume returning to normal as the transcellular movement of fluid increases. There is also electrophysiological evidence that in *D. melanogaster*, cAMP can act to stimulate the H-ATPase directly.

The effect of the kinins on Malpighian tubule secretion is both independent of and additive to the action of the CRF-DPs. In those systems where it has been studied, the kinins appear to act by increasing $[Ca^{2+}]_i$, which in turn increases the anion permeability of the tubules. It appears that by increasing the permeability of the tubules to anions, the driving force for cation transport is reduced, enhancing overall fluid transport. In the Diptera, a low-resistance Cl^- pathway transforms the Malpighian tubule from an electrically "tight" to a "leaky" epithelium. The change in Cl^- conductivity does not occur within the primary cells and has been shown to occur in the stellate cells characteristic of the Diptera. In *D. melanogaster* the kinins also stimulate fluid transport, mediated by $[Ca^{2+}]_i$, and activate a similar shunt pathway. In other insects, the kinins also open a low-resistance Cl^- pathway, although the tubules appear to be composed of a single cell type. It has been believed that the two systems (CRF-DPs and kinins) are independently regulated; however, recent evidence suggests that in mosquitoes there is a dose-dependent interaction, in which low concentrations of CRF-DP activate the shunt pathway, whereas higher concentrations activate both the shunt and the cAMP-mediated response. This is consistent with the observation that the 8-bromo analogue of cAMP activates both pathways in *D. melanogaster*.

The biogenic amine, serotonin, has long been known to be a potent *in vitro* stimulant of Malpighian tubule secretion, particularly in the blood-sucking bug, *R. prolixus*. Initially considered to be a pharmacological agent, recent evidence suggests that serotonin acts as a second DP in *R. prolixus*, promoting diuresis by elevating intracellular levels of cAMP in the Malpighian tubules. Serotonin acts synergistically with the presumptive CRF-DP found in the mesothoracic ganglionic mass, and blocking the release of serotonin with the neurotoxin 5, 7-dihydroxytryptamine delays or completely blocks the normal postprandial diuresis of fifth-instar *R. prolixus*.

V. SUMMARY OF EFFECTS

Most bioassays for diuretic activity involve an *in vitro* preparation of the Malpighian tubules or hindgut, which may or may not reflect actual diuretic activity in the whole animal. The Malpighian tubule assays are further complicated by the fact that many insects have tubules with as many as four segments, some of which are secretory and some of which are absorptive. For the sake of simplicity, in this article, we considered any factor that increases tubule secretion, inhibits hindgut reabsorption, or increases whole-animal water loss to be a DP and any factor that inhibits tubule function, promotes hindgut reabsorption, or inhibits whole animal water loss to be an ADP.

The effect of DPs on the Malpighian tubules is dramatic. In blood-feeding insects, such as *R. prolixus*, endocrine stimulation can increase the rate of fluid secretion more than 1000-fold and all insects show at least a doubling of the rate of primary urine formation. All insect species studied thus far, even the phytophagous ones whose diet is rich in K^+, show a shift in the Na^+/K^+ ratios, so that the urine becomes relatively more Na^+ rich.

Even with sophisticated chromatographic and immunological methods, detecting these peptides in the hemolymph is problematic. A few studies have linked increased levels of DP in the hemolymph with feeding, but there appear to be relatively high levels of DP in the hemolymph of normally hydrated animals. It has been suggested that many diuretics may in fact simply act to increase the filtration rate of the hemolymph to rid the animal of unwanted solutes. As long as increased secretion by the Malpighian tubules is matched by increased reabsorption by the rectum, there will be no net effect on water balance, but unwanted or toxic solutes will be more rapidly removed from the hemocoel. Thus, many of the DPs may better be termed "clearance factors" than diuretics.

Water balance in insects is crucial to their ability to exploit marginal habitats. There appear to be a suite of neuropeptides that regulate ionic balance, osmotic balance, hemolymph clearance, and the overall water budget of the animal. A great many aspects of this regulation, particularly the interactions among the DPs and ADPs, remain to be explored.

Glossary

corpora cardiaca (CC) The paired CC form part of the wall of the dorsal aorta and are analogous to the pituitary, having both intrinsic secretory cells and axon endings from the median neurosecretory cells.

corticotropin-releasing factor-like diuretic peptides (CRF-DP) The primary diuretic factors are the CRF-DP, which show a strong structural homology to the vertebrate corticotropin-releasing factor.

kinins Small diuretic peptides that were first isolated as myotropins on the basis of their ability to stimulate muscle contractions and act synergistically with the corticotropin-releasing factor-like diuretic peptides.

Malpighian tubules Numbering from two to several hundred, these blind-ended hollow tubules are the insect "kidneys," forming an isosmotic primary urine by cation secretion.

median neurosecretory cells (MNC) Functionally analogous to the vertebrate hypothalamus, the MNC have axon endings in the corpora cardiaca.

rectum Lined with cuticle, the ileum and rectum are the primary sites for water and salt reabsorption.

Drosophila Neuropeptides

PAUL H. TAGHERT

Washington University Medical School, St. Louis

In this article, _Drosophila_ neuropeptide genes are divided into three categories: behavioral, developmental, and homeostatic. These categories are neither comprehensive nor mutually exclusive; they simply offer a template by which to provide an overview of the identified fly neuropeptide genes, to illustrate some methods of analysis common in _Drosophila_ studies of neuropeptide signaling, and to convey some lessons learned. In addition, this article summarizes information concerning _Drosophila_ genes that encode neuropeptide biosynthetic enzymes. This field is very small compared to parallel studies in vertebrates. However, given the strengths of _Drosophila_ genetics, it has great potential regarding the manipulation and elucidation of neuropeptide functions _in vivo_. Finally, information concerning sequences encoding known or potential neuropeptide receptors is categorized according to their relatedness to vertebrate orthologues.

I. INTRODUCTION

Studies of insect neuropeptides have been particularly informative for two technical reasons: a high degree of cellular resolution and the power of genetic analysis. Concerning cellular resolution, in *Drosophila* and in other insects, such studies can be pursued at the level of single identifiable peptidergic neurons and single

identifiable target cells. This simplicity greatly facilitates the analysis and interpretation of peptidergic signaling. Likewise, fly genetics presents an ever-increasing array of sophisticated tools by which to examine specific gene function regardless of the complexity of the gene's expression pattern or the pleiotropic effects that the gene may have. For each category, examples are provided to illustrate the type of progress that has been achieved. As befits a complex and timely subject, several other, contemporaneous articles have recently covered, in part or in whole, similar information.

II. THE *DROSOPHILA* GENOME

A. Numbers of Genes

In the earliest annotations, the number of genes in the fly genome was estimated to approach 14,000. More recent estimates that include results from subsequent expressed sequence tag analyses have suggested that the final number may be higher, perhaps by a few thousand genes. The projected upward revision stems primarily from two technical issues. First, the genome sequence is largely, but not completely, finished. Second, the current estimate derives in large part from prediction programs that are not 100% accurate; these programs are still being optimized, by comparing results to those derived from other methods. In the near future, completion of genomic sequences from a related *Drosophila* species (work that is on-going and that will be very beneficial for several reasons) will help provide more precise estimates of the total gene number.

B. Identifying Neuropeptide Genes

Recent estimates place the number of neuropeptide-encoding genes in *Drosophila* at approximately 20; in this article, 32 such genes are described. That number is likely to be an underestimate. It is based largely on the identification of sequences related to those defined by functional studies in other insects. In some cases, the endogenous peptides have been purified directly from *Drosophila*, but this is the case for only a minority of predicted peptides. In general, peptide-encoding genes have certain features by which the majority can be recognized (including a signal sequence, specific motifs that promote posttranslational processing, and a repetitive structure). However, not all neuropeptide genes share all these features; additionally, certain nonneuropeptide genes include one or more such features and yet have different functions. The final number (if higher) is likely to be no more than twice the current estimate (i.e., a total of ~40); that prediction is based on the parallel estimates of the number of peptide receptor genes (~44; see below). However, the reader will recognize this as a circular argument and should remain skeptical until more direct observations are recorded.

C. Identifying Neuropeptide Biosynthetic Enzyme Genes

Fifteen genes encoding neuropeptide biosynthetic enzymes are reviewed here, based primarily on their sequence relatedness to known genes in vertebrates. For some of these genes, there is useful evidence based on direct observations of their expression patterns or of the enzymatic activities of the fly enzymes. For a single gene in this group, *PHM*, there is *in vivo* genetic evidence consistent with the hypothesis that it is required for normal neuropeptide biosynthesis. Hence, much work remains to be done to capitalize on the completed genomic sequences to identify and characterize all relevant neuropeptide biosynthetic enzyme genes in flies.

D. Identifying Neuropeptide Receptor Genes

Unlike neuropeptide-encoding genes, gene sequences for neuropeptide receptors can be more easily identified because most peptide receptors are seven-transmembrane, G-protein-coupled receptors (GPCRs). This large class of receptor proteins has well-defined and highly conserved structural features that make it possible to search among novel genomic sequences and efficiently identify most or all such genes. Current estimates for the peptide GPCR complement in *Drosophila* stand at 44, and these genes are briefly described in this article.

III. BEHAVIORAL NEUROPEPTIDES

In insects, neuropeptides play important roles in the modulation and triggering of specific behaviors or switching between behavioral states. At least 15 *Drosophila* neuropeptide genes can be grouped in the behavioral category based on behavioral observations and based on *in vitro* and *in vivo* muscle responses (Table 1). For example, many members of the "RFamide" neuropeptide family produce somatic,

TABLE 1 *Drosophila* Behavioral Neuropeptide Genes

Gene	Neuropeptide	CG No.	Location	Peptide(s) purified?	Alleles?
eh	Eclosion hormone	CG6400	90B1	No	No
eth	Ecdysis-triggering hormone	CG18105	60D15	No	No

crz	Corazonin	CG3302	87B7–8	No	No

Note. The involvement of these pro-hormones in behavioral regulation has been directly implicated or inferred on the basis of *in vitro* bioassays.

[a]Unpublished data (J. A. Veenstra, personal communication).

visceral, and/or cardiac muscle responses, and in flies, they derive from each of several genes (*dFMRFa*, *dms*, *dsk*, *npf*, and *sNPF*). Also, the tachykinin-like peptides, a proctolin-like peptide, certain *hugin*-derived peptides, and IFamide all affect (or are likely to affect) hindgut or oviduct motility, among other biological activities. Finally, corazonin is cardioactive, CCAP regulates a central motor pattern generator, and peptides predicted to be derived from the *amnesiac* gene product affect several central nervous system functions, including the consolidation of long-term memory. Three additional, behaviorally active neuropeptides are then described in more detail: ecdysis-triggering hormone and eclosion hormone, which together control ecydsis behavior, and pigment-dispersing factor, which controls daily circadian locomotion.

A. Ecdysial Behavior: Ecdysis-Triggering Hormone and Eclosion Hormone

Two distinct peptides contribute to the regulation of insect ecdysis/eclosion behavior and positively and directly regulate each other's release. One peptide is called the ecdysis-triggering hormone (ETH), and in *Drosophila*, it is produced by as many as 18 identified peripheral endocrine cells that release ETH in concert, rapidly, and in large amounts. A small deficiency of the ETH gene region produces larval lethality consistent with a critical role for ETH in coordinating ecdyses. The other peptide is called the eclosion hormone (EH), and in *Drosophila*, it is produced by only two identified neuroendocrine neurons of the brain. Genetic ablation of the EH-producing neurons has indicated the precise contribution of EH to the regulation of this complex behavior: A majority of animals display clear deficits in the temporal organization of adult eclosion, but a significant percentage of animals still succeed in completing the escape behavior. Thus, sophisticated genetic tools and the two very small cellular complements in *Drosophila* have made it possible to efficiently define the times of ETH and EH cellular activity, define the nature of their cross-regulatory activities, and begin to define the precise contributions of each peptidergic system to the control of movements that together generate the elaborate ecdysial behavior.

B. Circadian Locomotion: Pigment-Dispersing Factor

The neuropeptide pigment-dispersing factor (PDF) is the primary output of the circadian clock system; it does not appear to trigger behavior as much as shape its temporal organization. PDF is a *Drosophila* peptide as predicted by a gene encoding its pro-hormone (CG6496 at 97B2). Neuropeptides related to PDF were first studied in crustacea based on their hormonal activity in a pigment dispersion assay:

α- and β-PDHs (pigment-dispersing hormones) contribute to the dispersion and diurnal movements of pigment granules in the eye and in epithelial chromatophores. In larger insects, β-PDH has pharmacological properties consistent with a circadian role, and in *Drosophila*, a subset of the very limited number of β-PDH-positive neurons in the brain are also positive for *period* gene expression. The last two observations suggest that PDF-related peptides might be candidate transmitters for circadian pacemaker neurons.

pdf mutant animals (apparent nulls) are viable and can entrain to light:dark cycles with rhythmic daily locomotion, but the majority of flies are unable to sustain such rhythms under prolonged, constant conditions. The PDF neurons survive in the peptide mutant background, and the behavioral deficits can be largely attributed to lack of *pdf* expression. This phenotype is closely mimicked by selective ablation of PDF neurons following their expression of the *hid* and *reaper* cell death genes (this matches the experimental design by which EH neurons were studied; see above). Misexpression of the *pdf* prohormone in several ectopic locations within the brain causes disruption of circadian locomotor behavior. These and other data support the hypothesis that *pdf* encodes the principal circadian transmitter in *Drosophila*. No PDF-like peptide has been identified in vertebrate species to date. However, given the relatedness of sequences that encode the majority of peptide receptor genes in vertebrates and *Drosophila* (see below), PDF signaling may nevertheless be phylogenetically conserved. Identification of ligands for the orphan peptide GPCRs in *Drosophila* will permit a better interpretation of which hormonal signaling pathways have been conserved and which are phylogenetically specific.

IV. DEVELOPMENTAL NEUROPEPTIDES

The field of neuroendocrinology began nearly 100 years ago when Kopec first demonstrated a hormonal activity present in the silkmoth brain. Since that time, studies of insect endocrinology have focused on the numerous factors that regulate the precise embryonic and postembryonic developmental physiology of these animals. Numerous neuropeptides have been implicated in both positive and negative control of the steroid and steroid-like factors that trigger and modulate the molting cycle. In addition, other peptide factors regulate the timing of senescent states (diapause) and the maturation of the reproductive systems in adult insects. In the *Drosophila* genome, there is evidence for at least 11 genes encoding developmental neuropeptides (Table 2). A recently defined set of developmental neuropeptides in the insects are related to vertebrate insulins. This signaling system was initially studied in several insect species, not just *Drosophila*. However, sequencing of the *Drosophila* genome and renewed interest in fly insulins have brought a spate of new information in the past 2 years.

A. Example: Insulin

In *Drosophila*, elements of the entire insulin signaling pathway—from receptor to phosphorylation targets—have been functionally conserved. A *Drosophila* gene encoding an insulin receptor, *InR* (CG18402 at 93E9), was identified in 1985 and subsequently shown to be essential for normal growth. Further conserved

TABLE 2 ***Drosophila*** **Development Neuropeptide Genes**

Gene	Neuropeptide	CG No.	Location	Peptide purified?	Alleles?

Ast2	Allatostatin C	CG14919	32D2-3	No	No

Note. Neuropeptide genes that contribute primarily (though not exclusively) to developmental physiology.

elements include *chico* (a *Drosophila* homologue of the vertebrate insulin receptor substrates), phosphatidylinositol 3′ kinsase and its downstream target (the Akt serine/threonine kinase), the PTEN tumor suppressor, and S6 kinase. Mutants in most of the *Drosophila* homologues display predictable effects on body size, cell size, and cell number. Overexpression of *Dinr* in eye precursor cells leads to an increase in the number of ommatidia and in ommatidial cell size. Current models suggest that, in *Drosophila*, insulin signals through the mitogen-activated protein kinase to induce cell division and through phosphatidylinositol 3′kinase to stimulate growth.

Remarkably, there appear to be seven different *Drosophila* insulin genes encoding seven different *Drosophila* insulin-like peptides. Five of the *Drosophila* insulin genes—*dilp1–4* (CG14173, CG8167, CG14167, and CG6736, all at 67C1–2) and *dilp-5* (AE003550.1: 259,432–259,854)—form a gene cluster, whereas *dilp-6* (CG14049 at 2F4) and *dilp-7* (CG13317 at 3F1–2) are found on a different chromosome. Their sequence similarity to insulin is limited: *dilp-2* is most closely related to human insulin, with 35% identity. Overexpression of *dilp-2* also leads to increases in cell size and numbers, and these effects are dependent on *dinr*.

Evidence to date suggests that many of the *Drosophila* insulin genes are normally expressed at different times and places, suggesting some functional diversity. The occurrence of multiple insulin-encoding genes in insects has precedent in the silkworm, *Bombyx mori*, in which more than 30 insulin-like (bombyxin) genes have been identified. There is as yet little understanding of how such molecular diversity translates into (potential) functional diversity. Some hints come from parallel studies in the nematode *Caenorhabditis elegans*. In the past few years, rapid progress has been made in the analysis of insulin signaling in the worm, and recent work indicates the possibility that, under conditions of overexpression, some insulin-like peptides can act as functional antagonists. *C. elegans* insulin regulates metabolism, development, and longevity by mechanisms that are similar to the endocrine regulation of metabolism and fertility by mammalian insulin. In addition, the genetic analysis in the worm has extended our understanding of insulin signaling by revealing novel molecular features that may be variant in diabetic pedigrees. It is clear that continued studies of insulin signaling in developmental physiology, in both flies and worms, will continue to contribute useful information that may inform all branches of work on insulin signaling.

V. HOMEOSTATIC NEUROPEPTIDES

Several regulatory neuropeptide systems monitor the internal state of the insect to maintain electrolyte balance and energy reserves in the face of changing internal or environmental conditions. There are six *Drosophila* neuropeptide genes whose functions are thought primarily to involve such homeostatic functions (Table 3). At present, few to no physiological or genetic analyses of these genes have been reported. Most of what is thus far known reflects information from other insects or some initial expression data for RNAs and proteins. Below is offered a brief description of putative *Drosophila* hormones that are involved in water balance. The probable complexity argues for the use of *Drosophila* genetics to define redundant and compensatory roles of the various diuretic and anti-diuretic peptides. Such information will be a useful complement to the large amount of physiological data already accumulated.

A. Water Balance and Diuretic Hormones

Water and ion metabolism in insects is regulated in large part by the Malpighian tubules and the hindgut. Insect neuropeptides, called diuretic or anti-diuretic

TABLE 3 *Drosophila* Homeostatic Neuropeptide Genes

Gene	Neuropeptide	CG No.	Location	Peptides purified?	Alleles?
Akh	Adipokinetic hormone	CG1171	64A10	Yes	No

leukokinin	Leukokinin	CG13480	70E3-4	Yes	No
capa	Pyrokinin gene 1	CG15520	98C8-D1	No	No
ITP	Intestinal transport peptide-like	CG13586	60D5	No	No

hormones, stimulate fluid secretion by the Malpighian tubules and fluid reabsorption by the tubules or hindgut. A large number of insect neuropeptides are known to increase the rate of fluid secretion by the Malpighian tubules. They include the products of several distinct neuropeptide genes, including one related to corticotrophin-releasing factor (CRF *Dh*, CG8348 at 85E2) and another related to calcitonin (*Dh31*, CG13094 at 29D1). Two other neuropeptides also display diuretic effects—leukokinin and Cap_{2b}. In *Drosophila*, orthologous sequences are found in the genes *leukokinin* (CG13480 at 70E3–4) and *capa* (CG15520 at 99D1).

Malpighian tubules contain two main cell types, principal cells and stellate cells. Both cAMP and cGMP stimulate a vacuolar H^+-motive ATPase present in the apical membrane of the principal cells. Fluid secretion is achieved by the passive flow of water, following a net transport of K^+ in the principal cells and Cl^- flow in the stellate cells. The calcitonin-like Dh31 stimulates intracellular cAMP and increases transepithelial voltage in the Malpighian tubules, indicating that it acts on the principal cells. Although CRF-like Dhs have not yet been tested in *Drosophila*, studies in larger insects suggest that Dh also acts on the principal cells. Like Dh and Dh31, the CAPA-1 and CAPA-2 peptides (predicted to derive from the *capa* gene) appear to act on the principal cells, and these promote actions via calcium, nitric oxide, and cGMP. Notably, CAPA-related peptides have anti-diuretic actions in at least one other insect. Finally, leukokinin-like peptides act on the stellate cells to increase Cl^- conductance via an increase in intracellular calcium.

Of all the putative diuretic hormones, leukokinin appears 10 times more potent than the others in producing a significant increase in the rate of fluid secretion. Interestingly, synergistic effects have been described for leukokinin and the calcitonin-like diuretic hormone, as well as for Dh and leukokinin in locusts. Two other hormones have anti-diuretic effects in insects—neuroparsin and intestinal transport peptide (ITP); these stimulate fluid reabsorption by the hindgut. Neuroparsin-related sequences have not yet been identified in the *Drosophila* genome, but *Drosophila* prepro-ITP is encoded by CG13586 (at 60D5). Thus, the multiplicity of peptides, their alternative diuretic versus anti-diuretic actions, and their potential synergy of action all make for complex physiological processing. Clearly gain- and loss-of-function genetic analyses in *Drosophila* can help resolve important questions regarding the precise roles, mechanisms, and sites of action of peptides affecting homeostatic functions.

VI. NEUROPEPTIDE BIOSYNTHESIS

Secretory peptides are derived from pro-hormone precursors that undergo endoproteolytic cleavage and further processing to generate one or more final, bioactive products. While the basic outline of secretory peptide biosynthesis has advanced from biochemical and molecular studies, genetics has contributed to the understanding of these events *in vivo*. Such work has provided evidence for functional roles played by specific endoproteases and peptidases and has also suggested novel, alternative processing mechanisms. Further genetic analysis in a model system like *Drosophila* could help overcome difficulties that arise from studying limited amounts of critical biosynthetic components. The *Drosophila* genome includes 15 genes that appear to play roles in neuropeptide biosynthesis (Table 4).

A. Proteolytic Cleavage

Neural and endocrine peptide pro-hormones are cleaved by endoproteolytic enzymes that recognize definable *cis* amino acid motifs. In mammals, the best studied are the pro-hormone convertases (PCs), which are members of the subtilisin-like, serine

TABLE 4 ***Drosophila*** **Genes That Contribute (or That May Contribute) to Neuropeptide Biosynthesis**

Note. "Activities" refers to either known activity, or simply presumed based on sequence homologies to identified enzyme-encoding genes.

endopeptidase family of enzymes. Their substrates include polypeptide hormone precursors, growth factors, and viral envelope glycoproteins. For example, the PC1/3 and PC2 endopeptidases have well-defined roles in processing numerous neuropeptide pro-hormones in both neural and endocrine tissues, and both enzymes are packaged within secretory granules.

Sequence information supports the hypothesis that insect neuropeptide pro-hormones are also often cleaved at dibasic and monobasic residues. In *Drosophila*, there are three genes that are highly related to PCs, and at least some of these appear to be involved in neuropeptide biosynthesis. The *dfurin 1* (CG10772 at 96D1) and *dfurin 2* (CG18734 at 14C1) genes were identified by sequence homology to mammalian furin. When tested with specific substrates *in vitro*, both have enzymatic activities similar to that of mammalian furin and different from that of mammalian PC2. *dfurin1* is expressed in a small number of identified peptidergic neurons. No phenotypic analysis has been reported for either *dfurin* gene. The third *Drosophila* PC-like gene, called *amontillado* (*amon*, CG6438 at 97C3), is highly related to mammalian PC2. Reported alleles of *amon* include one with a deficiency in its genomic region and another that may also have a P-element in close proximity. Deletion analysis indicated that animals homozygous for *amon* deficiencies are morphologically normal but die trying to hatch from the egg. It is presumed that *amon* is required for the production of one or more secretory peptides needed to display the normal hatching behavior. AMON enzymatic activity has not been examined nor have its effects on neuropeptide biosynthesis been reported. However, the recombinant protein does display predicted interactions with both *Drosophila* and mammalian 7B2′, the protein normally associated with its maturation in mammals.

Angiotensin-converting enzyme (ACE) is a Zn^{2+} peptidyl-dipeptidase that plays an important role in blood pressure homeostasis in mammals. There are six ACE-related gene sequences in the *Drosophila* genome, of which only two, ACER (CG10593 at 29D1) and ANCE (CG10593 at 34D7), are predicted to be active enzymes. The active sites of ANCE and ACER have structural features that are (respectively) highly similar to those of the two adjacent, active domains of mammalian somatic ACE. In other insects, ACE protein distribution is consistent with a role in neuropeptide processing; it is especially enriched in neurons producing peptides of the FXPRLamide family. Insect ACE can process neuropeptide pro-hormone intermediates to remove C-terminal dibasic residues. In *Drosophila*, *ACER* is represented by a single recessive lethal and *ANCE* is represented by two recessive lethals. The possible consequences of these mutations on neuropeptide biosynthesis have not yet been evaluated.

After pro-hormone cleavage by the pro-protein convertases, C-terminal basic residues are removed by a separate carboxypeptidase (CP) activity. Of the >15 characterized mammalian metallocarboxypeptidase enzymes, only CPE/H and CPD are thought to participate in neuropeptide biosynthesis. In *Drosophila*, *silver* (CG4122 at 1B3) and a second gene (CG4678 at 15A2) are the two closest orthologues to the mammalian CP genes associated with neural and endocrine peptide biosynthesis. *silver* (*svr*) is a complex locus encoding large proteins that contain as many as four predicted enzymatic domains. It is represented by 40 null and hypomorphic alleles; some hypomorphic alleles display alterations in wing development and in melanization and sclerotization of the cuticle (the latter phenotypes generate the gene name). The degree to which neuropeptide biosynthesis is altered in *svr* mutant animals has not been determined. No alleles of CG4678 have yet been recorded.

B. Amidation

C-terminal peptide alpha-amidation is a late event in the biosynthesis of secretory peptides and likely to be the rate-limiting step in many instances. This modification is widespread: In vertebrates, more than half the known secretory peptides are amidated, whereas in insects, greater than 90% are amidated or predicted by DNA sequence to be amidated. Peptide amidation is functionally significant: Its absence often disrupts the activity or receptor-binding properties of peptide ligands. Finally, secretory peptides are the principal substrates for amidation—the enzymes catalyzing this reaction are exclusively associated with a lumenal intracellular compartment. Amidation results from the sequential actions of two enzymes: PHM (peptidylglycine α-hydroxylating mono-oxygenase) and PAL (peptidyl α-hydroxyglycine α-amidating lyase).

In vertebrates, the PHM and PAL enzymes are co-synthesized: The enzymes occupy adjacent domains of a bifunctional protein called PAM and, like the convertases, PAM is incorporated into nascent

Note. The expression and functionality of these putative receptors for neuropeptide ligands have been determined for only a subset. This table is adapted and updated from Table 1 of Hewes and Targhert (2001). ESTs are listed based on a BLASTP search conducted in March 2002 of BDGP using sequences listed at http://thalamus.wustl.edu/flyGPCR/sequences.html.

secretory granules. In *Drosophila*, both the PHM and the PAL enzyme activities are present but are physically and genetically distinct. The *Drosophila* genome predicts one unlinked *PHM* gene (CG3832 at 60B1–2) and two unlinked *PAL* genes (CG12130 at 46C6–7, and CG5472 at 59F4–6). The *Drosophila* PHM protein is found in most tissues, but within them, it is expressed in a cell type-specific fashion. *Drosophila* PHM enzyme activity mimics the properties of its mammalian counterpart. The *PHM* gene

mutates to give a lethal phenotype that is at least superficially similar of that of dPC2 (*amon*), a late embryo/early larval lethal phase, with no indication of gross morphological abnormality. *PHM* nulls and severe hypomorphs lack detectable PHM enzymatic activity; they display severely altered neuropeptide biosynthesis at both larval and adult stages. *PHM* nulls often die during early larval molts, whereas synthetic hypomorphs die attempting to complete later molts or pupal head eversion. These results indicate that PHM is required for the processing of one or more neuropeptides required for completion of different molt cycles.

VII. NEUROPEPTIDE RECEPTORS

Neuropeptides and peptide hormones signal primarily via GPCRs. These receptors define a very large gene family that provides sensitivity to a variety of environmental, developmental, and physiological signals. GPCRs display a uniform topology with seven-transmembrane domains, whose conserved features permit the use of sequence analysis to identify and classify those devoted to (for example) peptide hormones and neuropeptide ligands ("peptide GPCRs"). The *Drosophila* genome contains ~100 genes encoding GPCRs, including 21 receptors for classical neurotransmitters and neuromodulators (biogenic amines, related compounds, and purines) and ~44 peptide GPCRs (Table 5; see also http://thalamus.wustl.edu/flyGPCR/peptideGPCR.html). Peptide GPCRs are classified within Family A (rhodopsin-like) and Family B (secretin-like) of the GPCRs. Interestingly, the majority of *Drosophila* peptide GPCRs bear strong sequence similarities to different vertebrate peptide GPCRs, as described below. Thus, the set of 44 known and candidate *Drosophila* peptide GPCRs contains up to 39 representatives of Family A and 5 of Family B.

A. *Drosophila* Peptide GPCRs Are Closely Related to Those of Vertebrate Peptide GPCRs

Drosophila peptide GPCRs contain representatives related to at least 15 monophyletic vertebrate GPCR subgroups. There are at least 19 *Drosophila* peptide GPCRs belonging to Family A/Group III-B. Two of these bear strong resemblance to vertebrate gastrin/cholecystokinin receptors (CG6881 and CG6857, both at 17D3). Four fly GPCRs bear similarity to the Neuropeptide Y receptor subgroup (CG1147 at 83D2; CG7395 at 76F1; CG12610 at 17B1; and CG13995 at 26A8). There are six GPCRs related to vertebrate neurokinin receptors [CG6515 (*NKD*) at 86D; CG7887 (*DTKR*) at 99D; CG5811 (*NepYR*) at 97D14; CG10626 at 67B5; CG10823 at 93D1; and BACR48G21.1 at 45F4]. At least 6 *Drosophila* GPCRs are related to neurotensin and neurotensin-related receptors (CG8784 and CG8795, both at 87E6; CG14575 at 78C7; CG9918 at 88A7; CG5911 at 93D1; and CG14003 at 25F4). The bombesin-/gastrin-releasing peptide receptor group contains two *Drosophila* representatives (CG14494 and CG14593 at 41F10).

There are 11 representatives of Family A/Group V among *Drosophila* peptide GPCRs. Four genes are related to the vertebrate glycoprotein hormone-like receptors [CG4187 at 11D1; CG5042 at 96E9; CG7665 (*Fsh*) at 90C1; and CG8930 (*rk*) at 34E1]. The galanin- and somatostatin/opioid-like receptors include four loci [CG2872 (*AlstR*) at 3F1; CG7285 at 75C4; CG10001 (*DAR-2*) at 98E2; and CG13702 at 75C4], whereas the gonadotropin-releasing hormone- and oxytocin-/vasopressin-like receptors include three loci [CG6111 at 96F7; CG10698 at 69A4; and CG11325 (*DRHR*) at 26D7]. Among the 5 *Drosophila* peptide GPCRs that belong to Family B, 4 are clearly related to one or two vertebrate GPCR subgroups: the calcitonin-like (CG4395 at 11D1; and CG17415 at 49F2) and corticotropin-releasing factor-like receptors [CG8422 (*DHR1*) at 50F6 and CG12370 (*DHR2*) at 48F5]. The fifth (CG13578 at 3A7) may be distantly related to the corticotropin-releasing factor-like receptor clade. Thus, a large majority of the *Drosophila* and vertebrate neuropeptide GPCR signaling pathways appear to share common evolutionary origins. Functional and genetic analyses of individual receptor genes will be needed to determine whether the functions of these signals have been similarly conserved.

B. *Drosophila* Peptide GPCRs Are Distantly Related to Those of Vertebrate Peptide GPCRs

An additional seven genes (CG 2114 at 63A1; CG5936 at 17A2; CG6986 at 4C8; CG8985 at 62C4; CG13229 at 47C6; CG13803 at 62C4; and CG16727 at 67B5) likely encode peptide GPCRs and may also be members of the neurotensin-related receptor subgroup. In fact, all seven appear most closely related to a large set of orphan receptors that were previously identified in *C. elegans* (C. Bargmann, personal communication).

VIII. SUMMARY

A new era in the study of neuropeptide signaling has begun with the publication of whole genomes for the worm, for the fly, and for various mammals. The utility of the *Drosophila* model lies in the ease of manipulating gene expression to ask specific questions regarding the regulation or function of a particular neuropeptide signaling pathway in an organism that displays complex physiology and behavior. As most of the genes relevant to neuropeptide signaling continue to be identified, and as the DNA constructs and mutant stocks are made available, the opportunities for interesting experiments in the fly will continue to expand. However, as indicated in this article, our numerical estimates for any group of relevant molecules—whether neuropeptide genes, biosynthetic enzyme genes, or receptor genes—are all currently provisional and await experimental analysis. The point of providing a provisional overview such as this is to gauge the landscape and to estimate the measure of the work and the possibilities ahead. In this regard, the future looks busy and promising.

Glossary

deficiency A cytogenetic term referring to a deletion of specific genetic material that ranges in size from 100 s to 1000 s of basepairs and that may remove one or several genetic loci.

ecdysis A specific behavior that represents the final step in the molt of an insect—the shedding of the old cuticle—that differs among different insects and that may include distinct subbehaviors.

eclosion The specific ecdyses of embryonic and adult stage insects.

G-protein-coupled receptor Receptor that contains the characteristic seven-transmembrane motif representative of the large family of proteins that confers sensitivity to a variety of environmental and internal signals. A subset of these receptors confer sensitivity to most peptide hormones.

P-element A widely used transposable genetic element in *Drosophila* that is used to create transgenic animals and/or to mutate specific genes.

pro-hormone A precursor to an active peptide hormone or peptide transmitter; a pro-hormone is a direct gene product and is produced in an obligate biosynthetic pathway.

Eating Disorders

P. Södersten and C. Bergh
Karolinska Institute, Sweden

There are three classifications of eating disorders, anorexia nervosa (AN), bulimia nervosa (BN), and eating disorders not otherwise specified, as defined by the Diagnostic and Statistical Manual of Mental Disorders. AN can be further divided into two subtypes, restricting and binge-eating/purging types, and BN can be divided into two subtypes as well, purging and nonpurging types. The regulation of body weight is a main public health concern today because of the great increase in obesity, and it is now estimated that the medical consequences of too much food are as devastating as those of too little food worldwide. The focus here, however, is on the eating disorders listed above and their prevalence, incidence, prognosis, psychopathology, endocrine and physical effects, treatment, and causes.

I. INTRODUCTION

According to the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), eating disorders are classified broadly into three types: anorexia nervosa (AN), bulimia nervosa (BN), and eating disorders not otherwise specified (EDNOS). There are two subtypes of AN, restricting and binge-eating/purging types, and two subtypes of BN, purging and nonpurging types. The main symptom of AN is the refusal to maintain a normal body weight, so that the body mass index (BMI) is reduced to ≤ 17.5 (kg/m^2) from a normal of 19–24 for women and 20–25 for men. Because of their restricted food intake and their low body weight, anorexics do not menstruate and amenorrhea is a diagnostic criterion of AN. According to the DSM-IV, anorexics fear gaining weight and perceive their body as unrealistically large. Bulimic patients are of normal weight; their main behavioral disorder is that they eat large amounts of food in a brief period of time and subsequently display compensatory behavior to maintain their body weight. These behaviors include vomiting, the use of laxatives, and excessive exercise. Patients suffering from an EDNOS have some of the symptoms characteristic of AN and/or BN but not all these symptoms.

Other types of disordered eating behavior or eating behaviors that cause medical problems, e.g., obesity, are not included in the DSM-IV as eating disorders because they may not be associated with a psychological or behavioral syndrome. However, it is estimated that at least 20% of obese patients display a pattern of eating behavior that is similar to that of patients with BN, although they do not compensate for the increased intake of energy and hence become obese. Binge-eating disorder, i.e., intake of large amounts of food in a short period of time but no other signs of BN, may be viewed as an EDNOS.

In addition to the symptoms mentioned above, anorexic patients are often overactive physically and always hypothermic. These symptoms are obvious in most clinical settings and are likely to be included among the diagnostic criteria in future editions of the DSM. Likewise, patients with bulimia can display physical hyperactivity and deficiencies in thermoregulation.

II. PREVALENCE, INCIDENCE, AND PROGNOSIS

The specific condition of AN has been recognized for several hundred years, although it is debated whether the different types of emaciation that have been described during the course of medical history are equivalent to the present DSM-IV description of the condition. It is not surprising that AN has been observed for a long time in medical practice, because of its conspicuous physical marker, i.e., the low BMI. By contrast, the specific diagnosis of BN is only 20 years old. Most likely the condition was brought to medical attention only recently because bulimic patients are of normal weight and display no obvious external markers.

The prevalence of AN has remained constant, at approximately 1%, for as long as it has been documented. The patients are typically 14–19 years old at the onset of the disorder and approximately

95% are female. The prevalence of BN is approximately 1–1.5%, the patients are 20–25 years old at the onset of the disorder, and the majority are females and have a history of AN. However, the probability that a young woman may develop an eating disorder symptom, such as binge-eating or vomiting, during a restricted period of her life is as high as 5–25%. On the other hand, there is some evidence that the incidence of both AN and BN has increased somewhat during the past 40 years. The incidence of EDNOS, however, has most likely increased markedly.

The prognosis of patients with eating disorders is poor. Anorexics typically have less than a 50% chance of recovery in 10 years and 25% of the cases become chronically ill. Sadly, the mortality rate is high; as many as 6–15% may die within 10 to 20 years after the onset of the disorder. A low BMI is regarded a poor prognostic factor; with a BMI ≤ 13, the risk of becoming chronically ill approaches 100%, and with a BMI ≤ 10, the risk of dying approaches 50%. Bulimics have been reported to have a better prognosis, but at least one-third of the patients continue to binge-eat and purge 10 years after the onset of the disorder.

III. PSYCHOPATHOLOGY

Patients with AN suffer from concomitant psychopathology. This is not surprising, however, because animal studies have shown that food deprivation alters the concentration, synthesis, and turnover of the neurotransmitters that are involved in reward, mood, and emotion, e.g., dopamine. It is commonly recognized that humans subjected to experimental starvation develop the psychopathological symptoms found in patients with AN. These symptoms include depression, anxiety, and obsessive thoughts and actions. Patients with BN show a similar psychopathology, and periods of self-induced starvation are common among bulimics. Also, 10–20% of patients with AN show bulimic behavior and are, therefore, classified as a subgroup of AN, binge-eating/purging type. Although it has been argued that AN and BN are separable disorders and that EDNOS constitute several different disorders, the similarities between these disorders with regard to behavior and psychopathology are more conspicuous than are the differences. Moreover, there is a general consensus that the psychopathology of eating disorders is enhanced by food restriction. The most parsimonious interpretation, therefore, is that psychopathology emerges from the physical condition of eating-disorder patients. The alternative hypothesis, i.e., disordered eating behavior is an epiphenomenon of an underlying psychopathology, is not supported by any existing evidence. This hypothesis has been proposed in many versions, the most recent being that AN develops because of an underlying obsessive–compulsive disorder. Contradicting this view is the observation that obsessive-compulsive behaviors in AN patients are markedly reduced when the patient's body weight increases. Also, it is unclear how an obsessive personality trait translates into a disordered pattern of eating behavior. Most patients with eating disorders have been examined in a state of illness and, therefore, making a distinction between the potential effects of trait and those of state is not possible. Although patients show reductions in most psychopathological symptoms by the time of clinical discharge, there are no reports of patients who are free of all of their psychopathological symptoms. Consequently, these remaining symptoms may be an effect of a partially effective method of treatment rather than a personality trait of the patient.

IV. ENDOCRINE AND PHYSICAL EFFECTS

A. Reproduction

Reduction of food intake and a subsequent loss of body weight cause cessation of menstruation and amenorrhea in AN. Many patients do not experience menarche and therefore suffer from primary amenorrhea. The physical hyperactivity of anorexia may also contribute to their amenorrhea. Thus, amenorrhea is common among normal-weight elite female athletes; in fact, as many as 65% of those engaging in long-distance running are affected. Physical hyperactivity and reduction of food intake, therefore, both contribute to cessation of menstruation. An associated decrease in the level of pituitary gonadotropins and an increase in prolactin and pro-opiomelanocortin-derived hormones are also secondary to the reduced food intake and low body weight. Neither induction of menstrual cyclicity nor restoration of any of these hormonal imbalances has thus far been found useful in restoring the eating behavior of anorexics.

Approximately 50% of bulimics have menstrual disturbances. It is doubtful, however, that menstrual irregularities, including polycystic ovaries, predispose a woman for an eating disorder. Animal experiments suggest instead that the ovarian dysfunction in patients with eating disorders is caused by their disordered eating behavior.

Dieting and/or physical hyperactivity can cause functional hypothalamic amenorrhea, i.e., reduced pulsatile secretion of gonadotropin-releasing hormone (GnRH), and can therefore disrupt the menstrual cycle in women as well as testicular function in men. Consequently, the secretion of gonadal hormones (estradiol and progesterone in women and testosterone in men) is impaired. Puberty, therefore, is delayed.

Thus, the disturbances in reproductive neuroendocrine function in eating-disorder patients are secondary to reduced or altered intake of food and physical hyperactivity. Reproductive quiescence or disturbance induced in this way is reversible.

B. Adipose Tissue

Leptin is a 15 kDa protein secreted by adipocytes that was first thought to inhibit food intake and play a role in preventing excessive weight gain. However, it has become apparent that reduced leptin facilitates the adaptation to starvation by entraining a complex set of behavioral and neuroendocrine responses that favor survival during periods of limited energy availability. The concentration of leptin is directly proportional to the body fat mass. In anorexia, fat mass is gradually decreased, and leptin levels therefore decrease in parallel. The increase in physical activity that also occurs in anorexia causes a further decrease in fat mass and therefore leptin. It has also been suggested that physical hyperactivity per se might influence leptin levels independent of its effect on fat mass. In addition, experiments on animals suggest that leptin reduces physical activity. The inhibition of pulsatile GnRH secretion and menstrual cyclicity that is caused by both food restriction and excessive physical activity can be reversed by the administration of leptin. Changes in peripheral leptin levels may therefore provide a signal to the brain essential for the adaptations that occur during periods of food shortage and/or abundance.

In view of the fact that many studies have shown that leptin inhibits the food intake of animals, the low levels of leptin and low intake of food in anorexic patients are paradoxical. However, the role of leptin in food intake in humans has been examined only in the obese and has been found to have a minor inhibitory effect. The eating behavior and body weight of anorexics are, of course, radically different from those of the obese, including those who show a bulimic pattern of eating behavior. Yet it has been recently reported that both anorexics and bulimics have low levels of leptin. These findings argue against a direct role of leptin in the eating behavior of patients with eating disorders.

C. Other Hormonal and Physical Effects

Most likely, all of the other endocrine and physical changes that occur in eating-disorder patients are also the result of periods of dieting or continuous dieting; that is to say, the hormonal changes in starvation are the same independent of the way in which starvation is induced. Thus, hyperprolactinemia, hypercortisolism, bradycardia, hypotension, and hypothermia follow starvation in anorexia just as they do in starvation induced by enforced shortage of food. Other indirect effects of a restricted availability of food are reduced gastrointestinal motility and gastric emptying, constipation, and early satiation. Although most of the endocrine and physical effects in eating-disorder patients are reversible, some are not. Thus, reduced bone mass follows long periods of starvation and estrogen depletion. Physical activity is necessary for the development of bone mass, and the high physical activity in AN may counteract the effect of low food intake and low levels of circulating estrogens. However, normal-weight women with a history of AN will have a permanent reduction in bone mass, and osteoporosis may be a consequence in women with frequent periods of relapse. In BN, permanent dental damage may occur due to recurrent episodes of vomiting.

Interestingly, patients with AN rarely catch infections. This phenomenon is well known but has yet to be explained.

Patients suffering from type 2 diabetes have an increased prevalence of BN. The intriguing possibility that BN may be a risk factor for the development of diabetes deserves investigation.

V. NEUROTRANSMITTERS

The neural mechanisms controlling food intake are currently the subject of intensive investigation. Although pharmacological studies have shown that many neurotransmitters affect food intake in laboratory animals, these results have not yet allowed the formulation of a model for the development of either AN or BN.

A. Peptides

Work in animals has failed to demonstrate a factor that initiates feeding under physiological conditions. By contrast, gastrointestinal secretions during a meal

are known to cause a physiologically relevant inhibition of food intake. The mechanisms of inhibitory control are localized mainly in the caudal brainstem, and neural systems related to initiation of behavior, including ingestive behavior, are localized in the forebrain, particularly in the ventral striatum. As animals, including humans, eat meals, forebrain and brainstem control mechanisms must interact in the onset and termination of ingestion, but there is no information on how this occurs. The octapeptide cholecystokinin (CCK-8) is in all probability a physiological satiety signal. Inhibition of food intake by CCK-8 is mediated by the vagal nerve and occurs as a result of interplay among CCK, dopamine, and glutamate receptors in the brainstem satiety relay system in the nucleus of the solitary tract. Little is known about how these brainstem mechanisms interact with the neural networks in the forebrain, which are activated by food deprivation before an animal starts ingesting food.

The arcuate nucleus of the hypothalamus lies outside of the blood–brain barrier and senses the leptin signal from adipose tissue. High leptin levels down-regulate the synthesis and release of Neuropeptide Y (NPY) in the arcuate nucleus. Numerous studies over the past 15 years have demonstrated that an infusion of NPY into the brain of experimental animals stimulates food intake, carbohydrate intake in particular. Closer inspection of the behavioral effect of NPY shows, however, that NPY also causes an increase in physical activity and an increase in the intake of water. The effect on water intake is at least as marked as the effect on food intake. Thus, contrary to the common notion that NPY is a potent stimulator of food intake, i.e., an orexigen, its behavioral effect is far from specific.

The hypothalamic circuit activated by hypoleptinemia following fat depletion, and, conversely, the circuits activated by hyperleptinemia following fat repletion have been outlined in impressive detail in animal studies. The theoretical framework of these studies remains much the same as in the early days of regulatory physiology, i.e., that body weight is controlled by precise negative feedback loops. The increase in the incidence of eating disorders and particularly the marked increase in obesity suggest, however, that negative feedback of food intake in humans is easily disrupted. In addition, the rather small effect of most weight-reducing pharmacological treatments and the almost immediate relapse that occurs after the termination of such treatments suggest that food intake in humans has redundant controls.

Animal studies, therefore, have thus far had limited bearing on the understanding on human eating disorders. For example, there is no unequivocal evidence that CCK-8 has any relation to the enhanced feeling of satiety that anorexic patients experience during meals. And the low level of leptin and the associated increase in brain levels of NPY that occur in anorexia, as in starving animals, are not followed by an enhanced intake of food. Interestingly, however, NPY has a much smaller effect on food intake in food-deprived animals than in nondeprived animals. In view of the effects of leptin and NPY on behaviors other than food intake, e.g., water intake and physical activity, the absence of a stimulatory effect on food intake in anorexics is not surprising. In an anorexic state, NPY may cause enhancement of physical activity to facilitate the search for food rather than stimulating the actual intake of food. Food deprivation has long been known to stimulate physical activity, not only in mammals, but in other animal species as well.

B. The Hypothalamus–Pituitary–Adrenal Axis and Dopamine and Noradrenalin

Food deprivation activates the secretion of corticotropin-releasing hormone (CRH) by the hypothalamus and so acts as a stimulus for the activation of the hypothalamus–pituitary–adrenal (HPA) axis. As a consequence, patients with eating disorders have elevated plasma levels of cortisol. CRH is a well-known appetite suppressant per se, but the activity of the HPA axis can also influence food intake indirectly. Corticosterone, the rat adrenocortical equivalent to cortisol, stimulates the release of dopamine in the ventral striatum. This is the brain's reward pathway, which consequently is sensitized by food deprivation and also by enhanced physical activity. Adrencortical activation of the mesolimbic dopaminergic pathway provides an underlying substrate for the experience of reward, enjoyment, and pleasure that is typical in the beginning of an episode of self-imposed dieting or enhanced physical activity in humans. If dieting runs out of control, as occurs in AN, patients often say they must diet or run excessively, not for an experience of reward or enjoyment, but because they must get away from their feelings of anxiety and depression. Apparently, the neural substrate of reward is activated during the course of anorexia in a way not unlike the way the system is activated during the development of biologically based addictions.

Forebrain dopamine has long been thought of as an inhibitor of food intake, but recent work suggests that its main role is to initiate the behavioral sequences necessary to gain access to various rewards, while not affecting the consumption of those rewards. In addition, dopamine interacts with other transmitter systems, e.g., opioid peptides and benzodiazepines, to assign hedonic qualities to the ingestion of food.

Food restriction also activates the noradrenergic cell group in the locus coeruleus in the brainstem, the neural substrate for selective attention. CRH may mediate this effect as well.

C. Serotonin

Serotonin is one of the best-known anorexic neurotransmitters. Thus, it was demonstrated 40 years ago that peripheral administration of serotonin inhibits food intake by activating a stretch receptor in the muscular wall of the stomach, thereby stimulating a vagally mediated satiety message to the brain. Subsequently, it has been found that intracerebral administration of serotonin also inhibits food intake. These observations provide the basis for the use of serotonergic agonists in the treatment of obesity.

Given this background, it is surprising that selective serotonin reuptake inhibitors (SSRIs), which facilitate the activity at serotonergic synapses, have been used to treat AN. It is somewhat less surprising that SSRIs are used in bulimia but the risk that the patients might develop anorexia is obvious. Other well-known effects of serotonin, e.g., inhibition of pubertal development, gonadotropin secretion, sexual behavior, and induction of hypothermia, are also incompatible with the use of SSRIs in anorexia.

VI. TREATMENT

A. Evaluation of Treatment

There are few if any reports of effective treatments for patients with eating disorders. Over the past 20 years, it has been reported many times that fewer than half the anorexic patients who have been treated recover and that recovery occurs over a prolonged period of time and only after repeated episodes of treatment. There is some evidence that treatment of patients who are younger than 17 years, who have had the disorder for less than a year, and who have not been treated extensively before may recover after treatment with a family-based method. However, similar modestly ill patients have also been shown to recover spontaneously with time.

There is no evidence that older patients with AN benefit from currently available treatments. In fact, the possibility that they may has not been properly examined. Thus, treatment interventions have not been evaluated against a no-treatment or minimal intervention control group in randomized controlled trials (RCTs). It is commonly argued that such comparisons are difficult for ethical reasons, but unless such studies are performed we will never know the effect of such a treatment. Of the few RCTs performed to date, none have shown a major effect of treatment. Furthermore, it has been reported recently that treatment by specialist units is not a predictor of outcome at follow-up 5 years later. This latter situation should encourage investigators to examine the effect of current methods of treatment using RCT methodology.

It is generally thought that the situation for patients with BN is better because cognitive behavioral therapy is effective in this group of patients. This type of therapy aims at changing the way the patient thinks about his or her condition. However, only half of the patients respond to such treatment and the evidence suggests that other types of individualized treatment are equally effective.

Pharmacological treatment has no beneficial effect in AN but treatment with anti-depressants offers some help in BN. Although SSRIs are thought to be useful in BN, their effect is not as great as that of cognitive behavioral therapy and is therefore rather minor.

Follow-up studies have shown that relapse is a significant problem in weight-restored anorexics. Thus, 30–50% of the patients have been reported to relapse within a year after their weight has been restored. There are no reliable figures for relapse of bulimic patients. The existing studies are difficult to interpret because many of the patients were given additional treatment during the follow-up period.

In most studies, the patients are only in partial remission at clinical discharge. Thus, many of them display eating-disorder symptoms or psychopathological symptoms; i.e., they may suffer from an EDNOS. The problem, therefore, remains as to whether these residual symptoms are signs of trait-dependent patient characteristics or simply the effect of a less than optimal method of treatment. This issue is of considerable importance because most of the currently available diagnostic tools do not allow a clear distinction to be made between state- and trait-dependent psychopathological symptoms.

B. Treatment with Serotonin Agonists

The recent discussion on the possible role of serotonergic mechanisms in BN offers an example of the problem of distinguishing trait from state. Thus, it has been suggested that elevated levels of 5-hydroxyindole acetic acid in the spinal fluid and reduced 5-HT_{2A} receptor binding in the frontal cortex of bulimic patients in remission are signs of trait-dependent patient characteristics. Although these patients did not fulfill the DSM-IV criteria of BN, none of them were free of eating-disorder symptoms or other psychopathological symptoms. Therefore, most of these patients were merely in partial remission and suffered from an EDNOS. Experimental reduction of 5-HT levels by giving patients a diet free of the 5-HT precursor tryptophan has offered better support for the possible role of 5-HT in bulimia. Thus, patients in complete remission with a history of bulimia have been reported to develop symptoms such as feeling fat and fear of losing control over eating immediately after intake of such a diet.

Surprisingly, because of the difference in eating behavior, it has been suggested that the 5-HT_{2A} receptor may also be altered in patients with a history of AN or at risk of developing AN. The results thus far have been inconsistent. The evidence for the use of serotonergic agonists in the treatment of eating disorders is, therefore, weak. Not surprisingly, such drugs have minor effects.

In addition, the hypothesis has been advanced that treatment with SSRIs may prevent relapse in weight-restored anorexics. Some relapse prevention has been reported, but the main result in these studies has been a rapid relapse in both SSRI- and placebo-treated groups or a marked dropout rate. Thus, although it is well known that 5-HT has a role in the control of eating behavior in experimental animals, its possible involvement in eating disorders in humans remains unclear.

VII. CAUSES

It is commonly stated that eating disorders have multifactorial causes or unknown etiologies. This may reflect the fact that there are only partially effective methods of treatment available and that these methods may target the wrong symptoms.

Obviously, a reduced intake of food is necessary for a loss of body weight and therefore for the development of AN. Also, as mentioned above, reduced availability of food causes an increase in physical activity and it is known that those who are physically active, i.e., elite athletes and ballet dancers, are at risk of developing AN or an EDNOS. Thus, we know that dieting and physical activity are risk factors for the induction of self-starvation, a subsequent loss of the control of food intake, and, eventually, therefore, AN.

It has been demonstrated that animals will run in running wheels if offered the opportunity and that they will run progressively more if the supply of food is restricted. As food availability is further restricted in this situation, the animals will eventually lose control over body weight. This situation, activity-based anorexia (ABA), is virtually identical to the development of AN in humans with the exception that if the animals are allowed *ad libitum* access to food, they stop running, eat, gain weight, and return to a normal physiological state. By contrast, AN develops despite the continuous presence of food. Yet, animals that have developed ABA are conspicuously similar to patients with AN. For example, hypothermia is obvious in both conditions and it has been recently reported that when animals in a state of ABA are treated with external heat they run less, eat more, and gain weight. Similarly, it was noticed in the first description of AN that heat treatments enhance recovery. Treatment with heat, therefore, is likely to become part of a future effective treatment perhaps not only of AN but of other eating disorders as well.

In the first descriptions of AN it was noted that patients were restless. This physical hyperactivity was considered paradoxical because it was argued that the patients would be better off if they were less active and conserved energy. Also, the physical hyperactivity appeared "agreeable" to the patient, i.e., rewarding. In later clinical descriptions, it was noted that losing weight is "enjoyable, pleasurable, and rewarding" to a patient. These clinical observations are compatible with the research on the neural pathways of reward discussed briefly above. Thus, reduced food intake and(or) enhanced physical activity activate the mesolimbic dopaminergic reward pathway in the brain. Interestingly, both dieting and physical activity also activate the locus coeruleus noradrenergic pathway of selective attention. During conditions of reduced food intake and enhanced physical activity, the substrates for reward and attention are activated, thus providing an optimal situation for learning. Therefore, it can be hypothesized that AN develops because it is rewarding to reduce one's food intake and that it is maintained by conditioning to the stimuli that provided the reward.

This hypothesis offers an explanation for the development and maintenance of AN that is compatible with established neurophysiological principles. Because of the symptomatic similarities between anorexics and bulimics and because most bulimics have a history of anorexia, it is possible that AN and BN develop in similar ways. However, it must be added that the marked sex difference in eating disorders await an explanation. Based on the present hypothesis, an attempt to set up an effective treatment for eating disorders should include a method for teaching patients how to eat and how to reduce their physical activity. Although there are no pharmacological methods for reduction of physical activity, it is possible that a supply of external heat might be used.

It seem likely that most of the current methods of treating patients with eating disorders fail because most of them do not rely on sound physiologic hypotheses or are incompatible with basic neurophysiology, e.g., the frequent use of SSRIs. The hypothesis outlined above is offered as a starting point but is likely to be replaced by a better hypothesis as soon as our understanding of the neurobiology of ingestive behavior, physical activity, and temperature regulation has increased beyond its present state.

VIII. SUMMARY

A considerable amount of information has accumulated about the hypothalamic control of food intake and body weight through negative feedback signals from gastrointestinal and adipose tissues. Thus far, this information has had little influence on the management of patients with eating disorders. These patients still have a poor prognosis and there are few if any effective methods of treatment. Most pharmacological treatments have failed. Also, there are only a few investigations of the effect of treatment interventions that meet the criteria of random assignment and proper control. The effect of most of the methods that are currently used is, therefore, unknown. This situation is most likely caused by the absence of realistic explanations of why eating disorders develop and how they are maintained. Future attempts should take into consideration the possibility that eating disorders might be disorders of physical activity as much as they are disorders of eating behavior or mental disorders. Most endocrine and physical changes observed in patients with eating disorders are consequences rather than causes of self-imposed starvation that is maintained by conditioning to cues in the patient's environment.

Glossary

activity-based anorexia (ABA) Animals run excessively and lose control over body weight if very little food is provided and they enter a state of ABA, which is conspicuously similar to self-starvation in humans.

anorexia nervosa An eating disorder with severe, self-imposed starvation and commonly associated with a high level of physical activity and hypothermia.

body mass index An indicator used to define nutritional status and derived from the formula: weight divided by the square of height (kg/m^2). The acceptable range is 19–24 in women.

bulimia nervosa An eating disorder with episodes of excessive food intake, followed by compensatory methods to maintain a normal body weight.

eating disorder not otherwise specified An eating disorder that does not fulfill the diagnostic criteria of anorexia nervosa or bulimia nervosa.

5-hydroxytryptamine A neurotransmitter long known to inhibit food intake; it is the focus of many treatment interventions aimed at normalizing disordered eating behavior. Also known as 5-HT or serotonin.

neuropeptide Y A neuropeptide thought to increase food intake.

orexigen A compound that stimulates or increases food intake.

randomized controlled trial The standard method of random assignment to a treatment and a control condition necessary for the proper evaluation of medical interventions.

selective serotonin reuptake inhibitors Widely used antidepressants that enhance serotonin availability at synaptic sites thought to be altered in patients with eating disorders.

Ecdysone Action in Insect Development

MICHAEL BENDER

University of Georgia

During metamorphosis, a process in which many larval tissues are replaced by adult tissues, the insect steroid hormone ecdysone triggers distinct stage- and tissue-specific responses in its many target tissues. These responses are very diverse, including cell proliferation and differentiation in future adult tissues, programmed cell death in larval tissues, and remodeling of neuronal cell types during metamorphosis. Different forms of the ecdysone receptor may contribute to the specificity of ecdysone signaling.

I. INTRODUCTION

The insect steroid hormone 20-hydroxy-ecdysone is a key regulator that triggers transitions between developmental stages including larval molting and the metamorphosis from larva to adult. Ecdysone also regulates female reproduction and coordinates simple behaviors. During metamorphosis of the insect nervous system, ecdysone governs the remodeling of sets of neurons that function during both larval and adult stages.

Like the vertebrate steroid hormones and other small lipophilic hormones such as retinoic acid and thyroid hormone, ecdysone acts through a heterodimeric nuclear receptor that functions as a hormone-regulated transcription factor to activate or repress target genes. The ecdysone receptor is composed of the EcR and USP nuclear receptor proteins. Molecular mechanisms of steroid hormone signaling show remarkable evolutionary conservation in organisms as diverse as insects and human. This fact, coupled with the advantages for experimental endocrinology exhibited by insect species such as the lepidopterans *Bombyx mori*, *Manduca sexta*, and *Hyalophora cecropia* and the mosquito *Aedes aegypti* as well as the superb genetic and molecular tools available in the fruit fly *Drosophila melanogaster*, has made the study of ecdysone signaling an important model for understanding steroid hormone signaling during development.

The response to ecdysone is controlled by a genetic hierarchy in which a small number of primary response genes are directly induced by ecdysone and a larger set of secondary response genes execute specific biological responses to the hormone. Recent studies employing DNA microarray analysis of gene expression during metamorphosis have begun to identify the entire genomic complement of ecdysone-responsive genes active at this time. These experiments, and others that examine gene expression in a particular tissue, hold out the prospect of identifying batteries of ecdysone-regulated genes required for particular tissue-specific responses to ecdysone. Conventional molecular genetic and

Ecdysone Action in Insect Development

MICHAEL BENDER

University of Georgia

During metamorphosis, a process in which many larval tissues are replaced by adult tissues, the insect steroid hormone ecdysone triggers distinct stage- and tissue-specific responses in its many target tissues. These responses are very diverse, including cell proliferation and differentiation in future adult tissues, programmed cell death in larval tissues, and remodeling of neuronal cell types during metamorphosis. Different forms of the ecdysone receptor may contribute to the specificity of ecdysone signaling.

I. INTRODUCTION

The insect steroid hormone 20-hydroxy-ecdysone is a key regulator that triggers transitions between developmental stages including larval molting and the metamorphosis from larva to adult. Ecdysone also regulates female reproduction and coordinates simple behaviors. During metamorphosis of the insect nervous system, ecdysone governs the remodeling of sets of neurons that function during both larval and adult stages.

Like the vertebrate steroid hormones and other small lipophilic hormones such as retinoic acid and thyroid hormone, ecdysone acts through a heterodimeric nuclear receptor that functions as a hormone-regulated transcription factor to activate or repress target genes. The ecdysone receptor is composed of the EcR and USP nuclear receptor proteins. Molecular mechanisms of steroid hormone signaling show remarkable evolutionary conservation in organisms as diverse as insects and human. This fact, coupled with the advantages for experimental endocrinology exhibited by insect species such as the lepidopterans *Bombyx mori*, *Manduca sexta*, and *Hyalophora cecropia* and the mosquito *Aedes aegypti* as well as the superb genetic and molecular tools available in the fruit fly *Drosophila melanogaster*, has made the study of ecdysone signaling an important model for understanding steroid hormone signaling during development.

The response to ecdysone is controlled by a genetic hierarchy in which a small number of primary response genes are directly induced by ecdysone and a larger set of secondary response genes execute specific biological responses to the hormone. Recent studies employing DNA microarray analysis of gene expression during metamorphosis have begun to identify the entire genomic complement of ecdysone-responsive genes active at this time. These experiments, and others that examine gene expression in a particular tissue, hold out the prospect of identifying batteries of ecdysone-regulated genes required for particular tissue-specific responses to ecdysone. Conventional molecular genetic and

physiological analyses have revealed much about the genetic regulation of ecdysone response in individual tissues or cell types. Two examples are discussed here: the regulation of programmed cell death in larval tissues fated to die during metamorphosis and the control of neuronal remodeling during metamorphosis.

A general question in hormonal signaling is how tissue- and cell-specific responses are generated from a global signal. Expression of EcR isoforms in distinct temporal and spatial patterns suggests that distinct EcR isoforms may mediate different responses to ecdysone. This view is supported by *in vivo* rescue experiments carried out in cells of the larval salivary gland and in neurons undergoing remodeling during metamorphosis that show that EcR isoforms are not functionally identical in these cell types.

II. BIOLOGICAL RESPONSES TO ECDYSONE

During insect development, pulses of ecdysone act as temporal signals to coordinate the transitions between developmental stages. Careful measurements of ecdysteroid titers have been made throughout development for several insect species, including the tobacco hornworm *M. sexta* and the fruit fly *D. melanogaster*. A composite ecdysteroid titer profile for *Drosophila* is shown in Fig. 1. For simplicity, the description below pertains to ecdysone action during *Drosophila* development. Ecdysone carries out similar functions in other insects that undergo complete metamorphosis, although these insects vary in the number of larval molts and in the style of puparium formation. In *Drosophila*, ecdysone pulses during first- and second-instar larval development trigger molts to the next larval instar as the animal increases in size. Larval molting involves the separation of the larval cuticle from the underlying epidermis (apolysis), the formation of the new cuticle, and finally, the shedding of the old larval cuticle (ecdysis).

A series of three ecdysone pulses drives the metamorphic transitions between larval, prepupal, pupal, and adult stages (Fig. 1). A prominent pulse at the end of third-instar development triggers formation of the puparium, the hardened structure within which metamorphosis will take place. Puparium formation involves shortening of the larva to form a barrel-like structure, eversion of the anterior

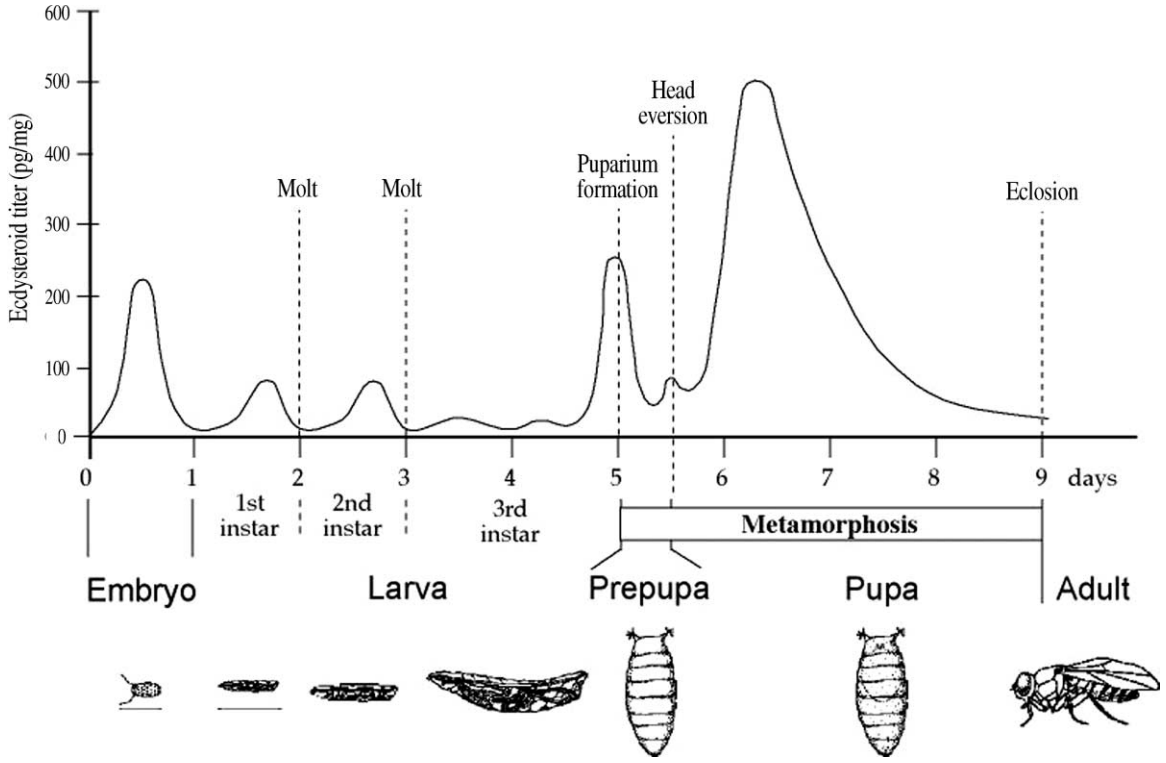

FIGURE 1 Ecdysone controls developmental transitions in *Drosophila*. Ecdysteroid titer is indicated on the y axis and developmental stage is indicated on the *x* axis. Reprinted from Thummel (2001), with permission from Elsevier Science.

spiracles, and formation of the operculum at the anterior end of the puparium, a structure through which the adult fly will ultimately emerge. Twelve hours after the pulse that triggers puparium formation, a smaller pulse of ecdysone drives head eversion, an event that marks the end of the prepupal period. Another large pulse occurs during the pupal period and is responsible for development of adult structures.

Two other ecdysone pulses can be detected in *Drosophila*. The function of the midembryonic pulse is not yet definitively established, although genetic studies suggest that it may play a role in morphogenesis and cuticle deposition. Finally, a small ecdysone pulse detected soon after the midpoint of the third instar may trigger larval wandering, a behavioral change characterized by the larva's departure from the food site and search for a suitable site for puparium formation.

During metamorphosis, the larva, which is specialized for feeding and growth, is completely reorganized into the reproductively competent adult. In this process, many larval tissues degenerate and are replaced by adult tissues. The timing of larval cell death varies between tissues. For example, the cells of the larval midgut initiate cell death in response to the ecdysone pulse that triggers puparium formation, and salivary gland cell death is triggered by the prepupal ecdysone pulse.

The cells that will give rise to adult structures, the imaginal cells, are set aside during embryogenesis and can be divided into two types, imaginal disc cells and imaginal histoblast cells. Imaginal disc cells, which will form the adult head, thorax, and genitalia, invaginate from the embryonic epidermis to form small sac-like structures and proliferate throughout larval development, finally forming discs containing thousands of cells at the end of the larval period. At the time of puparium formation, the imaginal discs respond to ecdysone by evaginating and elongating to form the rudiments of the adult appendages. The prepupal ecdysone pulse triggers head eversion, in which head structures assume their normal adult position, as well as further elongation of legs and wings as they assume their adult form. Differentiation of imaginal disc cells into adult cell types takes place in response to the pupal ecdysone pulse.

The imaginal histoblast cells are also set aside during embryogenesis but, in contrast to imaginal disc cells, do not proliferate during larval development, instead remaining in small clusters or rings until metamorphosis. The adult abdomen and internal tissues, including the adult foregut, midgut, hindgut, and salivary glands, arise from histoblast cells. The response of the histoblast imaginal cells to ecdysone is characterized by rapid cell proliferation, followed in some cases by cell migration to form the appropriate adult structures.

III. THE ECDYSONE RECEPTOR

In the early 1990s, the *Drosophila ecdysone receptor* (*EcR*) gene was cloned by homology to another *Drosophila* nuclear receptor, E75. The finding that the EcR protein bound a labeled ecdysone analogue, bound a previously identified ecdysone-response element, and rescued ecdysone responsiveness when transfected into a mutant cell line lacking EcR provided evidence that EcR was a necessary component of the *Drosophila* ecdysone receptor. The fact that an additional protein was necessary for activity when EcR was expressed in a heterologous system indicated that a second protein was required for ecdysone receptor activity and this protein was subsequently identified as the product of the *ultraspiracle* (*usp*) gene. Both the EcR subunit and the USP subunit of the ecdysone receptor are members of the nuclear receptor protein family. USP is the insect homologue of the vertebrate retinoic acid X receptor (RXR) protein that serves as a heterodimeric partner of a family of nuclear receptor proteins including the retinoic acid receptor, the thyroid hormone receptor, and the vitamin D receptor. EcR is most closely related to the farnesol X receptor, which functions in bile acid homeostasis in vertebrates. The recent purification of EcR and USP from *Drosophila* showed that a complex of molecular chaperones is required to activate the ecdysone receptor for DNA binding and that the EcR subunit is the primary target of the chaperone complex.

For certain nuclear receptors, binding of hormone leads to dissociation of co-repressors and their replacement by co-activators, leading to transcriptional activation of hormone target genes. Co-repressors and co-activators may act by recruitment of chromatin remodeling complexes that modify chromatin via histone deacetylation or histone acetylation, respectively. The *Drosophila* co-repressor SMRTER, a functional homologue of the vertebrate co-repressors SMRT and N-Cor, has been shown to associate with the ecdysone receptor. SMRTER mediates repression by interacting with the SIN3 adapter protein, a component of a histone deacetylase complex. These results suggest that gene regulation by the ecdysone receptor may involve

chromatin remodeling mediated by histone modification.

The EcR and USP subunits of the ecdysone receptor exist in several different forms. In *Drosophila*, multiple promoters and alternative splicing within the *EcR* gene result in a family of three EcR isoforms (EcR-A, EcR-B1, and EcR-B2). The isoforms share a common carboxy-terminal region containing DNA- and hormone-binding domains and differ in their amino-termini. Only one *Drosophila* USP protein is known based on cDNA sequence, although two proteins with different molecular weights can be distinguished, suggesting the possibility of an alternate translational start site. EcR and USP have been identified from a large number of insect species and from the Atlantic sand fiddler crab (*Uca pugilator*). Several insect species, including *M. sexta*, *B. mori*, the mealworm *Tenebrio molitor*, and the spruce budworm *Choristoneura fumiferana*, encode both EcR-A and EcR-B forms. Multiple USP isoforms are also common among insect species and two USP forms are encoded by separate genes in *M. sexta*, *B. mori*, and *A. aegypti*.

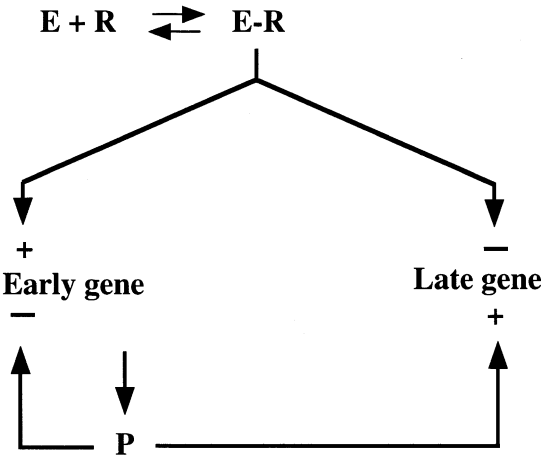

FIGURE 2 A regulatory model for ecdysone response. Ecdysone (E) binds to its receptor (R) and activates early gene expression while repressing late gene expression. An early gene product(s) (P) activates the late genes, overcoming the repressive effects of the receptor, and in addition acts negatively to limit early gene expression. Redrawn from Ashburner *et al.* (1974), with permission from Cold Spring Harbor Laboratory Press.

IV. GENETIC REGULATION OF THE ECDYSONE RESPONSE

The first global examination of genetic response to a steroid hormone was carried out in the 1960s in experiments examining ecdysone response in the midge *Chironomus tentans* and in *Drosophila*. These experiments took advantage of the giant polytene chromosomes of these species in which changes in gene activity could be directly visualized in the form of transcriptional puffs and provided evidence that ecdysone acted through a cascade of gene activation. Subsequent experimentation by Michael Ashburner and his colleagues in the 1970s, in which *Drosophila* polytene chromosome puffing responses were examined *in vitro* in the presence of ecdysone or in the presence of ecdysone plus protein synthesis inhibitors, established a regulatory model for ecdysone response (Fig. 2). At the time of metamorphosis, a temporal progression of polytene chromosome puffing can be seen in which a small set of early gene loci puff and then regress, followed by puffing and regression of a larger set of late gene loci. The puffing sequence was shown to be controlled by ecdysone *in vitro*, and a series of experiments demonstrated that late puff induction and early puff regression were sensitive to protein synthesis inhibitors but early puff induction was not. In addition, late puffs could be prematurely induced following ecdysone addition and withdrawal. In the model shown in Fig. 2, ecdysone acts via a receptor protein to directly activate the early response genes and to repress the late genes. The products of the early genes in turn activate the late response genes and repress their own expression.

Cloning of the early genes showed that a number of these genes encode transcriptional regulatory proteins, supporting the proposed regulatory model. Each of the *E74*, *E75*, and *BR-C* early genes encodes a family of transcription factors (of the ets [proto-oncogene], nuclear receptor, and zinc-finger types, respectively) through the use of multiple promoters and alternative splicing. Biochemical and mutational analyses have shown that each of these genes acts as an ecdysone-induced transcription factor and is required for normal ecdysone response early in metamorphosis. In contrast to these three early genes, the *E23* and *E63* early genes do not encode transcription factors, indicating that the primary genetic response to ecdysone is not limited to proteins that function directly in gene transcription. The *E63* gene encodes a calmodulin-related protein, and *E23* encodes a homologue of an ABC transporter protein. Because ABC proteins can function to transport steroids in other systems, this latter identity has led to the intriguing suggestion that *E23* may function to

regulate ecdysone response by controlling intracellular ecdysone levels in target cells. Among the late genes cloned, *L71* encodes a family of antimicrobial peptides, *L82* encodes a protein of unknown function, and *L63* encodes a protein with homology to cyclin-dependent protein kinases.

The recent sequencing of the *Drosophila* genome and the advent of DNA microarray technology have allowed the examination of ecdysone-induced gene expression on a genome-wide scale. A recent study by Kevin White and his colleagues examined the expression of genes in a temporal window encompassing the ecdysone pulse that triggers puparium formation and the subsequent pulse that triggers head eversion (see Fig. 1). In these experiments, RNA populations were isolated from wild-type animals at seven time points starting at 18 h prior to puparium formation and ending 30 h later at the time of the prepupal ecdysone pulse. Labeled probes prepared from each time point were hybridized along with a reference probe to DNA microarrays containing 4500 unique cDNA elements, representing approximately one-third of all genes in the *Drosophila* genome. Genes that increase or decrease in expression level relative to the time of pupariation were selected and grouped by similarities in expression patterns. Four hundred sixty-five genes, or approximately 10% of the genes tested, that reproducibly increase or decrease using the selection criteria chosen (a minimum of a threefold change in expression) were identified. In addition to known ecdysone-responsive genes, whose expression profiles from microarray analysis matched those determined earlier by RNA Northern analysis, a large number of candidate genes that may be induced or repressed by ecdysone at this time were identified in these experiments. Each of these newly identified genes potentially provides a new entry point for experiments designed to elucidate the molecular and cellular mechanisms underlying ecdysone response during early metamorphosis. Challenges that remain include distinguishing ecdysone-regulated genes within this set from those genes that are regulated by other developmental signals at this time, separation of primary from secondary ecdysone-responsive genes, and refinement of the technique to allow examination of gene expression within individual tissue types. The first two tasks should be aided by the availability of mutants that lack key ecdysone regulatory proteins or that are defective in ecdysone synthesis, as well as molecular genetic tools for overexpression of ecdysone regulatory proteins.

V. ECDYSONE AND THE CONTROL OF CELL DEATH

During metamorphosis, many larval tissues undergo programmed cell death and do not contribute to adult structures. Extensive molecular, genetic, and histological analyses of larval salivary gland and midgut destruction in *Drosophila* have revealed much about the molecular and genetic mechanisms by which cell death is carried out in these tissues. The ecdysone-induced *E93* gene plays a key role in programmed cell death of the midgut and salivary gland as these tissues are replaced by adult cells early in metamorphosis. *E93* expression precedes cell death in the midgut and salivary gland, and genetic studies have shown that *E93* is required for cell death in each of these tissues. Furthermore, ectopic expression of *E93* in wing imaginal disc cells can trigger cell death, even though these cells do not normally undergo this process.

In the larval salivary gland, *E93* is expressed in a stage-specific fashion, responding to the prepupal ecdysone pulse but not to the earlier pulse that triggers puparium formation. Fig. 3 shows the current regulatory model for how stage-specific expression of *E93* is achieved in this tissue. The late third-instar ecdysone pulse acts through the early genes *BR-C* and *E74* to repress glue genes, whose products are used early in puparium formation, and to induce the *L71* late genes. Following a sharp drop in ecdysone titer after puparium formation, expression of the early genes also drops. The early genes are then re-induced by the prepupal ecdysone pulse that occurs 12 h after puparium formation and triggers destruction of the larval salivary glands. Normal expression of *E93* during the prepupal ecdysone pulse requires βFTZ-F1, a nuclear receptor protein whose expression is limited to the low-ecdysone-titer environment of the mid-prepupal period. The expression of β*FTZ-F1* is tightly regulated. The timing of β*FTZ-F1* gene induction is determined by interaction of the E75B repressor and the DHR3 activator, both ecdysone-induced nuclear receptor proteins. The extent of β*FTZ-F1* expression is then limited by repression by the EcR/USP heterodimer in response to the rising prepupal ecdysone titer as well as by autorepression by the βFTZ-F1 protein. Inactivation of β*FTZ-F1* by mutation leads to submaximal induction of *E93* and failure of salivary gland destruction, suggesting that βFTZ-F1 acts as a competence factor to ensure stage-specific expression of *E93*. β*FTZ-F1* is also required for maximal expression of *BR-C* and *E74*. In contrast to the situation in the salivary gland, E93 is expressed in the larval midgut at the time of puparium

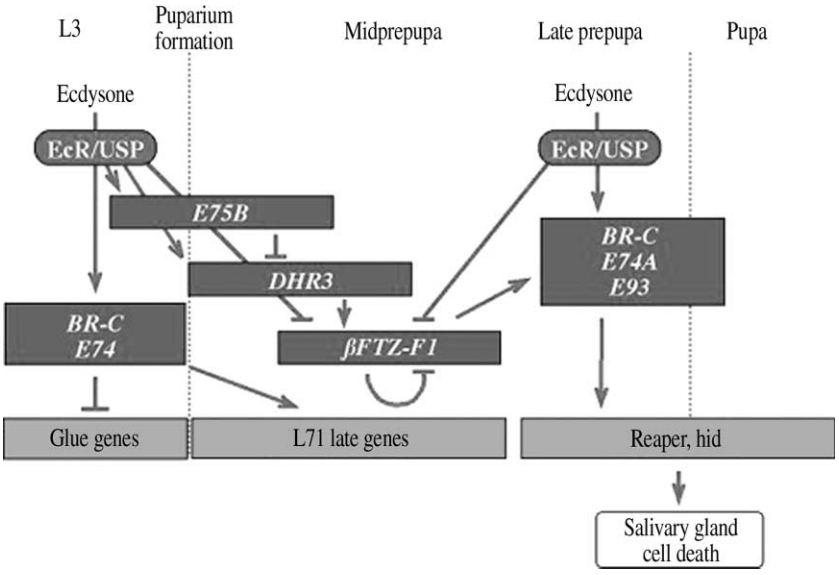

FIGURE 3 Genetic control of salivary gland cell death. Shaded bars indicate temporal patterns of expression of ecdysone regulatory genes relative to the developmental stages indicated at the top. Arrows indicate gene activation and bars indicate gene repression. Reprinted from Thummel (2001), with permission from Elsevier Science.

formation when midgut cell death is initiated. Although little is currently known about *E93* regulation in the midgut at this earlier time, comparison of *E93* regulatory mechanisms in this tissue to those operating during salivary gland destruction should reveal how the ecdysone-regulated cell death pathway is deployed at distinct developmental times to control cell death in different tissues.

E93 encodes a novel nuclear protein that has been shown to be associated with specific polytene chromosome sites, suggesting that *E93* may act through transcriptional activation of target genes. Transcription of genes involved in programmed cell death is defective in *E93* mutants. Thus, the *Drosophila* homologue of APAF-1/ced-4, the caspase DRONC, and the cell death genes *reaper* and *hid* require *E93* for normal induction at the time of the prepupal ecdysone pulse. *Croquemort*, a gene required for engulfment of apoptotic cell corpses during embryogenesis, is also expressed at the time of the prepupal ecdysone pulse and requires *E93* function for its expression at that time. In addition, *BR-C* function is required for *reaper* and *hid* expression and *E74* is required for maximal *hid* expression. These results suggest that *E93*, *BR-C*, and *E74* act to trigger a programmed cell death pathway involving known cell death genes in the larval salivary gland in response to the prepupal ecdysone pulse.

Recent work by Cheng-Yu Lee and Eric Baehrecke suggests that programmed cell death in the larval midgut and salivary gland proceeds by an autophagic pathway rather than by an apoptotic pathway. During autophagy, the cell is destroyed by its own lysosomal contents, whereas during apoptosis, remnants of dying cells are degraded by a second phagocytic cell. This observation suggests that the autophagic cell death pathway makes use of some of the same downstream components as apoptotic cell death pathways despite the morphological distinctions between the two cell death pathways. Lee and Baehrecke also show that some cellular aspects of cell death triggered by ectopic *E93* expression (including formation of cell corpses, engulfment by macrophages, and cell elimination) are independent of the cell death genes *reaper*, *grim*, and *hid* but other aspects of cell death (including DNA fragmentation and acridine orange staining) depend on these genes. These intriguing observations suggest the existence of genetically distinct pathways that regulate cellular changes during programmed cell death.

VI. ECDYSONE AND NEURONAL REMODELING

During metamorphosis of the insect central nervous system, ecdysone triggers the cell death of certain neurons that function only during the larval stage or during the larval and pupal stages, and it stimulates adult differentiation of other neurons that arise from neuronal stem cells that have proliferated during

the larval period. In contrast to these effects, which mirror ecdysone's influence on larval and imaginal tissues described earlier, ecdysone also controls the development of a third class of neurons that function during larval development and are then remodeled during metamorphosis to serve adult-specific functions. The study of remodeling neurons, which constitute a major fraction of the adult nervous system, was pioneered in *M. sexta*. The large size of *Manduca* allowed identification of individual neurons that could be marked and followed throughout the course of metamorphosis and allowed dye-filling experiments so that the extensive dendritic branching of these cells could be visualized. Fig. 4 shows the morphological changes during larval and pupal development in a *Manduca* abdominal motoneuron (MN-3) that innervates body wall muscles. During the final larval instar, this neuron innervates larval abdominal body wall muscles and has an extensive arbor of dendritic processes. Early in pupal development, however, MN-3 undergoes a severe pruning of these processes so that the extent of dendritic branching is much reduced soon after entry into the pupal stage. Regrowth of adult-specific processes takes place during pupal development, and the adult MN-3 cell that innervates the newly created adult abdominal muscles has extensive branching. These morphological changes are correlated with changes in ecdysteroid titer. Dendritic pruning is initiated after the late larval ecdysone pulse and regrowth takes place during the broad pupal ecdysone pulse (Fig. 4).

Hormone deprivation and restoration experiments in another *Manduca* cell type that undergoes dendritic loss prior to cell death (the PPR neurons) show that an ecdysone signal is required for dendritic pruning and that pruning can be rescued by restoration of ecdysone to ecdysone-deprived neurons. Ecdysone control of regrowth of dendritic processes was examined in the MN-1 abdominal motoneuron cells of *Manduca*. In these experiments, injection of ecdysone into diapausing pupae, a quiescent stage with low ecdysone levels, was sufficient to trigger the regrowth of adult processes in MN-1 cells. These experiments indicate that dendritic regression and outgrowth are controlled by ecdysone.

Cell-specific markers that identify individual neurons or sets of neurons have allowed the analysis of the *Drosophila* nervous system during metamorphosis, opening the door to genetic analysis of neuronal remodeling. Like *Manduca*, many *Drosophila* neurons are remodeled during the metamorphosis from the larval stage to the adult stage. One particularly well-characterized example of neuronal remodeling takes place in a set of neurosecretory cells that react with an antibody to a secreted peptide, SCP-B. SCP-B reactive cells undergo extensive pruning of dendritic and axonal processes after puparium formation and regrowth of adult-specific processes

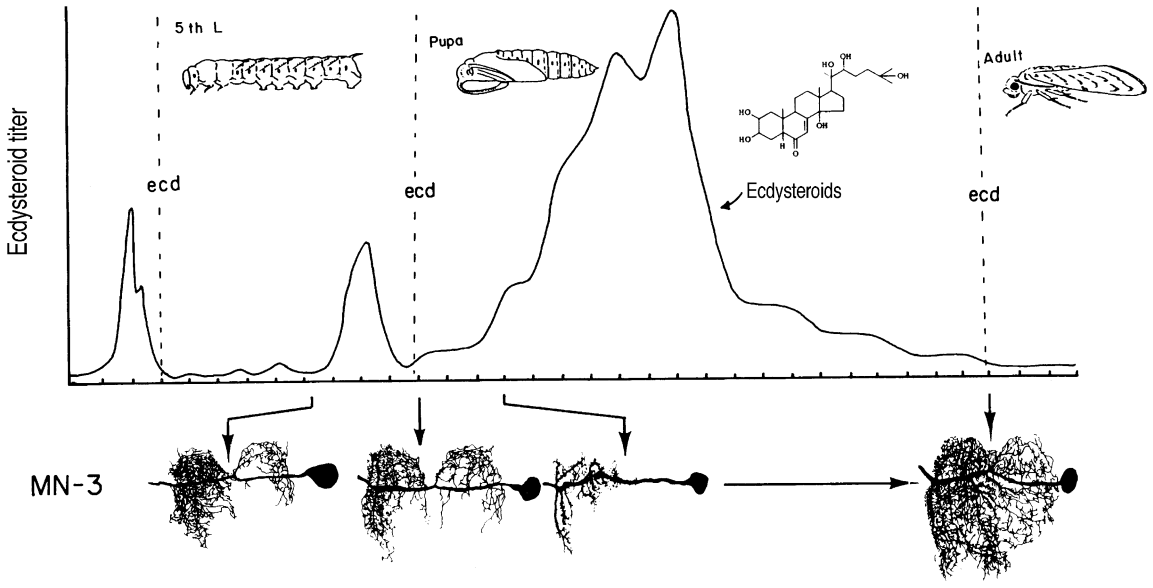

FIGURE 4 Neuronal remodeling during metamorphosis. The drawings at the bottom show the appearance of the *Manduca* MN-3 neuron at different stages during metamorphosis. The graph at the top shows ecdysteroid titers during *Manduca* metamorphosis. Ecdysis (ecd) at the end of each stage is indicated by a dashed line. Modified from Truman (1996), with permission from Academic Press.

during pupal development. Examination of *EcR* expression in the SCP-B reactive cells showed that expression of high levels of the EcR-B1 isoform precedes pruning of larval processes and that EcR-A is the predominant isoform during the later process of adult outgrowth. These observations led to the hypothesis that distinct forms of the ecdysone receptor might govern distinct responses in remodeling neurons, with an EcR-B1 form responsible for larval pruning and an EcR-A form responsible for adult outgrowth and maturation. This model is supported by analysis of neuronal remodeling in *EcR* mutants. Mutants lacking both EcR-B1 and EcR-B2 fail to undergo pruning, indicating that EcR-B functions are required for this aspect of neuronal remodeling. The unanticipated finding that pruning can proceed in an *EcR-B1* mutant suggests that either the EcR-B1 or the EcR-B2 receptor form alone is sufficient to trigger the pruning response. These experiments also suggest that neuronal remodeling in *Drosophila*, as in *Manduca*, is regulated by ecdysone.

Examination of another *Drosophila* neuronal cell type that undergoes remodeling, the mushroom body (MB) gamma neurons, showed that both USP and EcR-B1 components of the ecdysone receptor are required for axonal pruning in this cell type. Interestingly, the downstream ecdysone-response genes *BR-C*, *E75*, and *E74* were not required for remodeling of the MB gamma neurons. These results suggest that remodeling of these neurons proceeds via a novel pathway of ecdysone-induced genes.

VII. SPECIFICITY OF ECDYSONE SIGNALING

The sheer diversity of cellular responses to ecdysone prompts the question of how a global signal such as ecdysone can specify diverse cell- and tissue-specific responses. One model proposes that distinct responses to ecdysone would require particular combinations of ecdysone receptor isoforms. This model grew out of the finding that expression of specific EcR isoforms could be correlated with patterns of ecdysone response characteristic of particular cell or tissue types. Mutational analysis of the *EcR* gene is thus far consistent with this model. Mutations that inactivate EcR-B1 lead to a nonpupariating phenotype in which tissues that predominantly express EcR-B1 are blocked in their normal response to ecdysone, whereas EcR-A predominant tissues initiate their normal ecdysone response. Mutants that lack both EcR-B1 and EcR-B2 show defects in larval molting and, as described above, are blocked in an early stage of neuronal remodeling that is correlated with high levels of EcR-B1 expression. It will be interesting to examine *EcR-A* mutant phenotypes to determine whether these phenotypes are distinct from those of *EcR-B* mutants, thus indicating distinct developmental functions for EcR-A.

Several *in vivo* studies have addressed the question of whether the different EcR proteins are functionally interchangeable or functionally distinct by measuring the ability of an EcR isoform to rescue a defect caused by the loss of a different EcR isoform. In the first of these, the loss of transcriptional puffing in larval salivary gland cells of an *EcR-B1* mutant could be completely rescued by heat-shock-driven expression of EcR-B1 and partially rescued by EcR-B2 expression. In contrast, EcR-A expression was incapable of significant rescue. These experiments indicate that the EcR isoforms are functionally distinct in this cell type during early metamorphosis.

Another study made use of the EcR-B1-expressing MB gamma neurons, described above, that are remodeled during pupal development and require both EcR-B1 and USP to complete this process. Targeted expression of EcR to the MB gamma neurons using the GAL4-UAS system was used to rescue defective remodeling of these neurons in an *EcR-B1* mutant. In these experiments, the expression of EcR-B1 or EcR-B2, but not EcR-A, was sufficient to rescue remodeling defects. In a third study, a similar strategy was used to express EcR in SCP-B^+ neurons in an *EcR-B* mutant background. As described above, these cells express high levels of EcR-B1 prior to undergoing pruning of larval-specific processes and larval pruning is blocked in *EcR-B* mutants. In these experiments, EcR-B2 and EcR-B1 were most efficient at rescuing defective larval pruning and EcR-A rescued less well. In this study, the phenotypic consequences of expressing the different EcR isoforms in a wild-type background were also found to be distinct. Together, these experiments suggest that the EcR isoforms are not functionally interchangeable in the cellular contexts examined. In all cases, the functional distinction is greatest between EcR-A and the EcR-B isoforms, with the greatest degree of overlap between EcR-B1 and EcR-B2 function.

The various EcR isoforms differ in their amino-terminal A/B domains, domains that in vertebrate nuclear receptors encode a transcriptional activation function. Several studies have examined the transcriptional activation functions of EcR in cell culture and shown that the various EcR isoforms differ in their abilities to activate test promoters.

These experiments suggest that distinct EcR AF-1 domains may function to differentially control gene transcription of ecdysone target genes.

VIII. SUMMARY

Ecdysone acts through the ecdysone receptor, a heterodimer of the EcR and USP nuclear receptors, to regulate reproduction, larval molting, and metamorphosis in insects. The sets of genes regulated by ecdysone include early genes that are direct targets of the receptor and late genes that constitute a downstream response and execute cell- and tissue-specific hormone responses. Cellular responses to ecdysone are very diverse, including development and differentiation of adult tissues, programmed cell death of larval tissues fated to die, and remodeling of neuronal cell types during metamorphosis. Multiple isoforms of EcR and/or USP exist in most insect species examined. In *Drosophila*, expression of different EcR isoforms is correlated with distinct cell and tissue responses to ecdysone, suggesting that different ecdysone receptor forms contribute to the specificity of ecdysone signaling. *In vivo* rescue experiments that show that the EcR isoforms are generally incapable of complete functional substitution support this model.

Glossary

ecdysone receptor Insect specific nuclear receptor that mediates the action of the steroid hormone 20-hydroxy-ecdysone.

ecdysone-response element A specific DNA regulatory sequence found near the transcription start site of ecdysone-regulated genes that is bound by the ecdysone receptor heterodimer.

ecdysones Natural compounds (e.g., α-ecdysone and 20-hydroxy-ecdysone) that control molting and metamorphosis in insects. As used here, the term refers to biological activity and is analogous to "estrogens" and "androgens."

EcR A nuclear receptor that is the protein product of the *ecdysone receptor* gene.

metamorphosis A hormone-induced process in which the larval form of an organism is transformed into the adult form.

USP A nuclear receptor that is the protein product of the *ultraspiracle* gene.

Ecdysone Secretion in Lepidopteran Insects

HIROSHI KATAOKA
University of Tokyo

Ecdysones are poly-hydroxylated steroid hormones that control arthropod development and reproduction. This article focuses on the actions of a brain peptide prothoraciotropic hormone (PTTH) to promote the secretion of ecdysone by the prothoracic gland.

I. INTRODUCTION

Insects are characterized by molting and metamorphosis during postembryonic development. Approximately 80 years ago, the mechanisms of these physiologically important events were first investigated by a Polish scientist, Kopec.

During the following 40 years, the roles of the brain, the corpora allata (CA), and the prothoracic glands (PGs), along with their functional relationships, were clarified. Molting and metamorphosis are controlled by three hormones: prothoracicotropic hormone (PTTH), produced in the brain; juvenile hormone, produced in the CA; and ecdysone, produced in the PGs. PTTH activates the PGs to secrete ecdysone, thereby playing a central role in the endocrine control of insect molting and metamorphosis. PTTH was first isolated from heads of the adult silkworm, *Bombyx mori*, and subsequently, the cDNA coding for *Bombyx* PTTH and its cDNA homologues from several kinds of other lepidopteran insects were cloned. This article presents a history of the studies of *Bombyx* PTTH, the current status of lepidopteran PTTH research, and a description of other factors that regulate ecdysone secretion from the PGs.

II. PURIFICATION AND PRIMARY STRUCTURE OF *Bombyx* PTTH

During the purification of *Bombyx* PTTH, debrained dormant pupae were used for bioassay. When the brain is extirpated from *Bombyx* pupae shortly after pupation, brainless pupae remain as pupae for several months without undergoing adult development. Injection of material containing PTTH into debrained dormant pupae brings about the resumption of adult development, whereas material without PTTH caused no development. In 1986, *Bombyx* PTTH was first isolated from *Bombyx* adult heads and as little as approximately 0.1 ng of pure PTTH induced adult development in a *Bombyx* brainless pupa. The amino acid sequence of *Bombyx* PTTH up to the 104th residue from the amino-terminus was determined from the sequencing data of fragment peptides obtained by enzyme digestion of the sample from 3×10^6 heads and purified by the same purification scheme. The 41st residue was undetermined since no PTH amino acid was detected at this cycle of Edman degradation.

III. CDNA STRUCTURES OF *Bombyx* PTTH

A cDNA coding for *Bombyx* PTTH was cloned from a cDNA library by an expression cloning strategy using an antibody against a synthetic peptide corresponding to the first 15 amino acids at the amino-terminal. As shown schematically in Fig. 1, the *Bombyx* PTTH cDNA encodes, in the following order starting from the 5′-end, a signal peptide (29 amino acids), a 2 kDa peptide (21 amino acids), a 6 kDa peptide (57 amino acids), and PTTH (109 amino acids). The first 104 deduced amino acids exactly matched the amino acid sequence obtained from peptide sequencing of the purified PTTH. The 41st residue, which remained unidentified by peptide analysis, was eventually shown to be asparagine, indicating that a carbohydrate moiety is attached to this site. Thus, the entire amino acid sequence of *Bombyx* PTTH has been elucidated.

IV. DIMERIC STRUCTURE AND DISULFIDE BOND LOCATION OF *Bombyx* PTTH

By sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) analysis under nonreducing

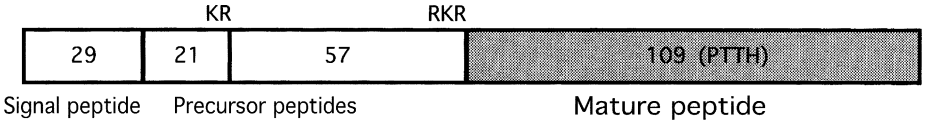

FIGURE 1 Schematic structure of *Bombyx* prepro-PTTH. The numbers in the boxes indicate the number of amino acid residues. K and R indicate the lysine and arginine residues in the amino acid sequence of PTTH. KR and RKR are the possible proteolytic processing sites in the *Bombyx* prepro-PTTH.

and reducing conditions, a broad band corresponding to 30 kDa and two bands of 17 and 16 kDa, respectively, were detected. When the purified PTTH was reduced, alkylated, and sequenced, all peaks obtained gave the same sequence as the amino-terminal sequence of the intact PTTH. Therefore, it was concluded that *Bombyx* PTTH is a homodimeric protein, the subunits of which are linked together by a disulfide bond(s).

When a portion of the cDNA designed to express only the PTTH subunit peptide was introduced into *Escherichia coli*, the cell lysate contained PTTH activity that was indistinguishable from that of natural PTTH, proving that the cloned cDNA encoded *Bombyx* PTTH. The purified recombinant PTTH possessed specific activity comparable with that of natural PTTH. Furthermore, SDS–PAGE analysis showed that the recombinant PTTH also had a dimeric structure linked by a disulfide bond(s). Determination of the disulfide bond location in this recombinant *Bombyx* PTTH has shown their positions at Cys-15–Cys-15′ as an interchain disulfide linkage and Cys-17–Cys-54, Cys-40–Cys-96, and Cys-48–Cys-98 as intrachain disulfide linkages (Fig. 2).

Interestingly, when PTTH was partially reduced with all intrachain disulfide bonds remaining intact, PTTH retained half of its biological activity compared with the intact dimeric PTTH. However, the fully reduced and S-alkylated PTTH monomer had no PTTH activity. This clearly indicates that the intrachain disulfide bonds are essential for attaining the peptide conformation required for manifesting the biological activity. The interchain disulfide bond has a clear additive effect by maintaining the dimeric structure of native PTTH. Although any significant sequence homology between PTTH and other peptide hormones or protein factors has not been discovered by database searching, the sequential arrangement of intrachain disulfide bonds indicates a striking similarity to that of several growth factors with a cysteine-knot motif, such as nerve growth factor and transforming growth factor-β (TGF-β).

V. STRUCTURE OF THE CARBOHYDRATE CHAIN OF *Bombyx* PTTH

The structure of the carbohydrate chain of recombinant *Bombyx* PTTH produced by the baculovirus system was determined to be Manα1-6Manβ1-4GlcNAcβ1-4(Fucα1-6)GlcNAc–. The saccharide chain of the native hormone has been determined to be identical to that of the recombinant hormone. The biological activities of the native hormone and the recombinant hormones, produced in *E. coli* and in the baculovirus expression system, were compared in the bioassay using brainless *Bombyx* pupae. The native hormone and the baculovirus-generated recombinant hormone showed identical dose responses, whereas the *E. coli*-produced recombinant hormone showed only slightly weaker activity. This finding suggests that the glycosidic side chain in PTTH is likely not essential for its biological activity; however, it might stabilize the hormone molecule in the hemolymph.

VI. MOLECULAR CLONING OF THE PTTH cDNAs FROM OTHER LEPIDOPTERAN INSECTS

Immunohistochemical studies using an antibody against *Bombyx* PTTH revealed that molecules homologous to *Bombyx* PTTH exist in the brains of other lepidopteran insects. Thus far, cDNAs for *Bombyx* PTTH homologues have been isolated and sequenced from three species of lepidopteran insects, *Samia cynthia ricini*, *Antheraea pernyi*, and *Manduca sexta*. The structure of each precursor molecule is similar to that of *Bombyx* PTTH, and each of these PTTHs contains seven cysteine residues and an *N*-glycosylation site in the mature domain, although the glycosylation site is slightly different. The positions of the seven cysteine residues are conserved, indicating that these hormones are all structurally similar to those of the TGF-β family. Amino acid sequences of the mature PTTH regions are shown in Fig. 3. The deduced amino acid sequence of *Bombyx* PTTH and the sequences of *Samia*, *Antheraea*, and *Manduca*

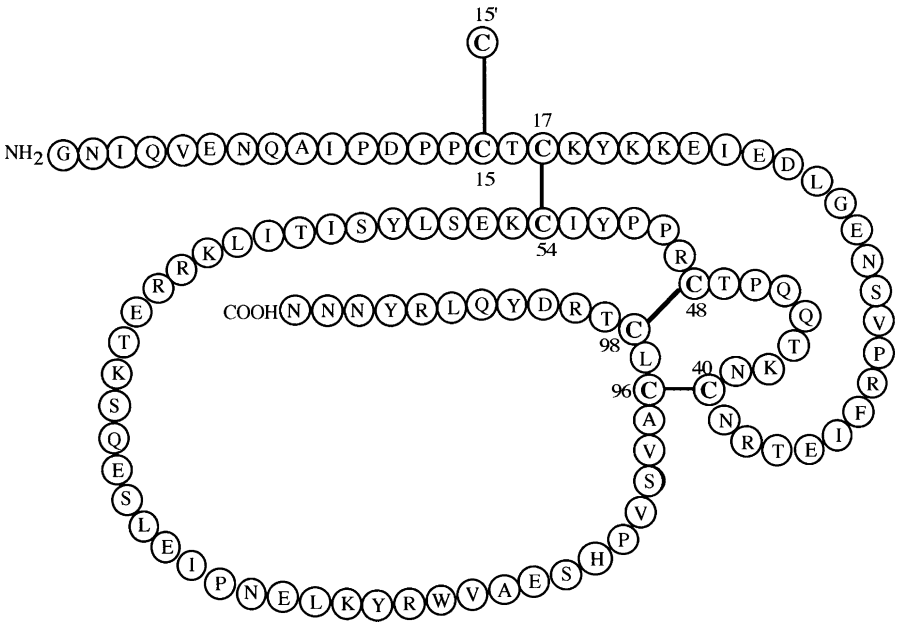

FIGURE 2 The amino acid sequence and the disulfide bond location of *Bombyx* PTTH. Circles represent amino acids. NH_2 and COOH indicate the N-terminus and C-terminus, respectively, of *Bombyx* PTTH. Two identical units are held together by the disulfide bond between Cys-15 and Cys-15′.

PTTHs show 51, 52, and 60% identity, respectively. The C-terminal portion following the last cysteine residue of these PTTHs was variable in length.

Samia PTTH and *Manduca* PTTH were expressed in *E. coli* and the biological activities of *Bombyx*, *Samia*, and *Manduca* PTTH were determined by debrained pupal assay systems. The recombinant *Samia* or *Manduca* PTTHs were capable of inducing adult development at a dose of approximately 0.3 ng/pupa when injected into brainless *Samia* or *Manduca* pupae, respectively. This activity is about the same as that of the recombinant *Bombyx* PTTH in debrained *Bombyx* pupae. Despite the relatively high level of sequence similarity, the biological activities of PTTHs were species specific. For example, *Samia* PTTH showed PTTH activity in *Samia* but not in *Bombyx* or *Manduca*. Conversely, *Manduca* PTTH showed PTTH activity in *Manduca* but not in *Samia*

or *Bombyx*, and *Bombyx* PTTH showed PTTH activity in *Bombyx* but not in *Samia* or *Manduca*.

VII. PHYSIOLOGY OF *Bombyx* PTTH AND OTHER FACTORS INVOLVED IN ECDYSONE SECRETION OR SIGNAL TRANSDUCTION CASCADES IN THE PGs

Immunohistochemistry with an antibody against *Bombyx* PTTH demonstrated that PTTH is produced by two pairs of dorsolateral neurosecretory cells of the brain and is transported to the CA by axons running through the contralateral hemisphere of the brain. The PTTH titer in the hemolymph was quantified using a very sensitive time-resolved fluoroimmunoassay, and it changed dramatically during *Bombyx* development, with a small peak in the middle of the fourth instar, medium-sized peaks at the wandering and prepupal stages in the fifth instar, and a large prolonged peak during early pupal-adult development. The changes were, overall, closely correlated with those in the hemolymph ecdysteroid titer.

Recently, a peptide inhibiting ecdysone secretion from the PGs, prothoracicostatic peptide (PTSP), was isolated from *Bombyx* larval brains and determined to have the amino acid sequence H-Ala-Trp-Gln-Asp-Leu-Asn-Ser-Ala-Trp-NH_2. This peptide inhibited PTTH-stimulated ecdysone secretion in the PGs at both the spinning and the feeding stages, indicating that PTSP interferes with PTTH-stimulated ecdysone secretion. In addition, two factors other than PTTH and PTSP involved in regulating signal cascades of ecdysteroidogenesis in the PGs were discovered in *Bombyx*. One of them is a factor that can elevate glandular cyclic AMP levels in the PGs in the early stages of the fifth instar, and the other is a factor that can elevate intracellular inositol 1,4,5-trisphospate levels in the PGs throughout the fifth instar and during the first day of the pupal stage. It is hoped that these two factors will be identified chemically and that the molecular mechanisms of endocrine control in ecdysteroidogenesis will be further clarified.

Glossary

prothoracic glands Glands in lepidopteran insects that synthesize and secrete the molting hormone ecdysone.

prothoracicostatic peptide A peptide hormone that acts on the prothoracic glands and inhibits ecdysone secretion.

prothoracicotropic hormone A neuropeptide hormone that is secreted in the insect brain and stimulates the prothoracic glands to secrete ecdysone.

Ecdysteroid Action in Insect Reproduction

ALEXANDER S. RAIKHEL*, LEEANNE MCGURK†, AND MARY BOWNES†

*University of California, Riverside • †University of Edinburgh

This article focuses on two insects for which the role of 20-hydroxyecdysone (20E) in reproduction is best understood at the molecular level. In the yellow fever mosquito, *Aedes aegypti*, the ecdysteroid-regulatory hierarchy governs transcription of yolk protein precursor (*YPP*) genes. Following blood feeding, the ecdysone receptor (EcR)-ultraspiracle (USP) heterodimer activates the early genes, *E74* and *E75*, as well as directly acting one the YPP gene vitellogenin, allowing its expression in the fat body. In turn, the products of *E74* and *E75* genes act as powerful activators of the gene transcription. Prior to blood feeding, such activation is prevented by USP heterodimerization with an orphan receptor AHR38, which is a repressor of the EcR-USP transcriptional activation. In the fruit fly, *Drosophila melanogaster*, *YPP* genes are expressed in two tissues, the fat body and the ovary. The regulation of *YPP* gene expression is quite different in these two sites of synthesis. In the fat body, ecdysteriods stimulate YPP synthesis. In the ovary, however, JH and 20E seem to be antagonistic, with JH promoting YPP synthesis and oocyte progression and ecdysone leading to apoptosis. The molecular control of *YPP* gene transcription in *Drosophila* is well understood in terms of sex-specific regulation. A great deal has been elucidated concerning the mechanism leading to expression of these genes in the female and not in the male. Mutations in genes controlling sex-specific expression of *YPP* genes lead to sexual transformations of males to females to males, as well as to intersex flies.

I. INTRODUCTION

As in vertebrates, some insects utilize a steroid hormone to govern key events in their reproduction. It was first established in *Aedes aegypti* that the female ovaries produce a precursor form of a steroid hormone, ecdysone (E), which is transformed by target tissues into its active form, 20-hydroxyecdysone (20E). The parallel with oviparous vertebrates is even more striking considering that E is produced by the follicular epithelium in the ovary in both instances. Moreover, in both vertebrates and insects, steroid hormones activate the expression of yolk protein genes in the liver and the fat body, respectively. Remarkably, only some groups of insects, mainly Diptera, represented by mosquitoes and flies, have 20E as the key regulator of reproduction. In contrast, in the majority of insects, it is juvenile hormone (JH) that plays this role in reproduction. The reason for such dramatic differences in the hormonal control of reproduction among insects remains an enigma.

II. MOLECULAR ENDOCRINOLOGY OF MOSQUITO VITELLOGENESIS

The yellow fever mosquito, *A. aegypti*, in addition to its importance as a pathogen vector, represents an outstanding model system for arthropod vector research due to the exceptional knowledge base amassed on its physiology, biochemistry, and development. The great wealth of information that has accumulated over the past two decades concerning vitellogenesis in *A. aegypti* has made it one of the best studied insects. The vitellogenic cycle of *A. aegypti* can be divided into three distinct periods. First, in the previtellogenic period, the mosquito undergoes a preparatory phase in which the fat body becomes capable of intense synthesis of yolk protein precursors (YPPs). This process is thought to be under the control of JH III. It is followed by a state of arrest that is maintained until a blood meal is taken, after which the mosquito enters the synthetic phase of the vitellogenic period. The fat body then produces YPPs to be accumulated and stored in the yolk bodies of the oocytes. 20-Hydroxyecdysone is involved in the control of the vitellogenic period. Finally, in the termination period, YPP production is halted in the fat body (Fig. 1).

Ecdysteroid Action in Insect Reproduction

ALEXANDER S. RAIKHEL*, LEEANNE MCGURK†, AND MARY BOWNES†

*University of California, Riverside • †University of Edinburgh

This article focuses on two insects for which the role of 20-hydroxyecdysone (20E) in reproduction is best understood at the molecular level. In the yellow fever mosquito, *Aedes aegypti*, the ecdysteroid-regulatory hierarchy governs transcription of yolk protein precursor (*YPP*) genes. Following blood feeding, the ecdysone receptor (EcR)-ultraspiracle (USP) heterodimer activates the early genes, *E74* and *E75*, as well as directly acting one the YPP gene vitellogenin, allowing its expression in the fat body. In turn, the products of *E74* and *E75* genes act as powerful activators of the gene transcription. Prior to blood feeding, such activation is prevented by USP heterodimerization with an orphan receptor AHR38, which is a repressor of the EcR-USP transcriptional activation. In the fruit fly, *Drosophila melanogaster*, *YPP* genes are expressed in two tissues, the fat body and the ovary. The regulation of *YPP* gene expression is quite different in these two sites of synthesis. In the fat body, ecdysteriods stimulate YPP synthesis. In the ovary, however, JH and 20E seem to be antagonistic, with JH promoting YPP synthesis and oocyte progression and ecdysone leading to apoptosis. The molecular control of *YPP* gene transcription in *Drosophila* is well understood in terms of sex-specific regulation. A great deal has been elucidated concerning the mechanism leading to expression of these genes in the female and not in the male. Mutations in genes controlling sex-specific expression of *YPP* genes lead to sexual transformations of males to females to males, as well as to intersex flies.

I. INTRODUCTION

As in vertebrates, some insects utilize a steroid hormone to govern key events in their reproduction. It was first established in *Aedes aegypti* that the female ovaries produce a precursor form of a steroid hormone, ecdysone (E), which is transformed by target tissues into its active form, 20-hydroxyecdysone (20E). The parallel with oviparous vertebrates is even more striking considering that E is produced by the follicular epithelium in the ovary in both instances. Moreover, in both vertebrates and insects, steroid hormones activate the expression of yolk protein genes in the liver and the fat body, respectively. Remarkably, only some groups of insects, mainly Diptera, represented by mosquitoes and flies, have 20E as the key regulator of reproduction. In contrast, in the majority of insects, it is juvenile hormone (JH) that plays this role in reproduction. The reason for such dramatic differences in the hormonal control of reproduction among insects remains an enigma.

II. MOLECULAR ENDOCRINOLOGY OF MOSQUITO VITELLOGENESIS

The yellow fever mosquito, *A. aegypti*, in addition to its importance as a pathogen vector, represents an outstanding model system for arthropod vector research due to the exceptional knowledge base amassed on its physiology, biochemistry, and development. The great wealth of information that has accumulated over the past two decades concerning vitellogenesis in *A. aegypti* has made it one of the best studied insects. The vitellogenic cycle of *A. aegypti* can be divided into three distinct periods. First, in the previtellogenic period, the mosquito undergoes a preparatory phase in which the fat body becomes capable of intense synthesis of yolk protein precursors (YPPs). This process is thought to be under the control of JH III. It is followed by a state of arrest that is maintained until a blood meal is taken, after which the mosquito enters the synthetic phase of the vitellogenic period. The fat body then produces YPPs to be accumulated and stored in the yolk bodies of the oocytes. 20-Hydroxyecdysone is involved in the control of the vitellogenic period. Finally, in the termination period, YPP production is halted in the fat body (Fig. 1).

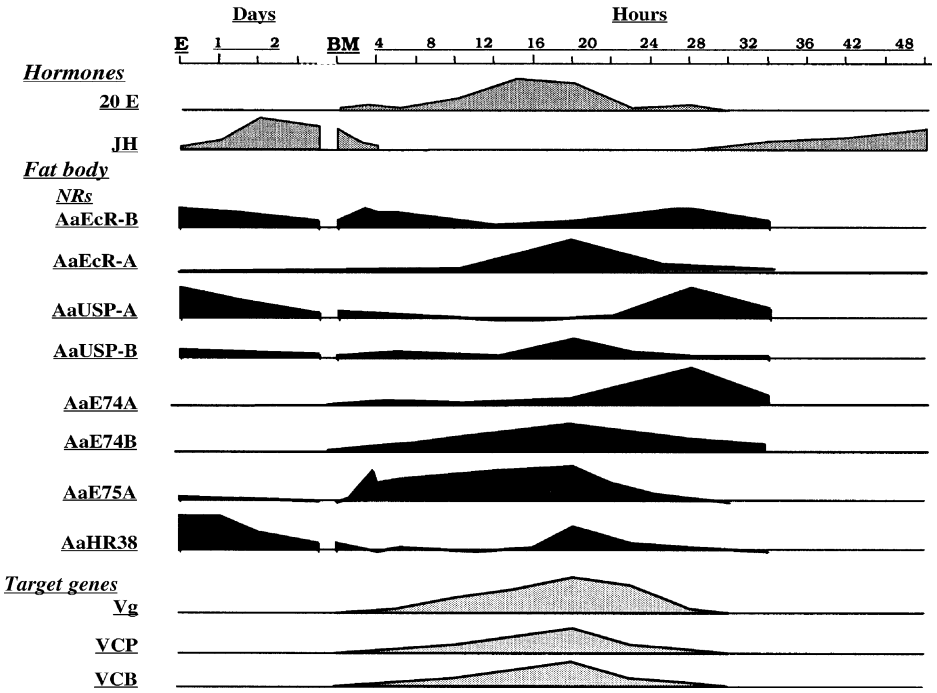

FIGURE 1 Transcript profiles of major genes of the ecdysteroid-regulatory hierarchy during the first cycle of egg maturation in the mosquito, *Aedes aegypti*. The previtellogenic period begins at eclosion (E) of the adult female. During the first 3 days of posteclosion life of the female, both the fat body and the ovary become competent for subsequent vitellogenesis. The female then enters a state of arrest; yolk protein precursors are not synthesized during the previtellogenic period. Only when the female mosquito ingests blood (BM) is vitellogenesis initiated. Hormones: hormonal titers of juvenile hormone (JH) and ecdysteroids (20E) in *A. aegypti* females. Fat body: relative levels of RNAs for nuclear receptors (NRs) determined by reverse transcription-polymerase chain reaction. AaEcRA, ecdysone receptor isoform A; AaEcRB, ecdysone receptor isoform B; AaUSPA, Ultraspiracle isoform A; AaUSPB, Ultraspiracle isoform B; AaE74B, E74 isoform B; AaE74A, E74 isoform A; AaE75A, E75 isoform A; AaHR38, mosquito homologue of *Drosophila* HR38; Vg, vitellogenin; VCP, vitellogenic carboxypeptidase; VCB, cathepsin B-like protease. Modified from Raikhel *et al.* (2002), Vitellogenesis of Disease Vectors, from Cell Biology to Genes. *Insect Biochemistry and Molecular Biology* **32** (10), with permission from Elsevier.

The gene encoding vitellogenin (Vg), a major YPP in most oviparous animals, is expressed in extraovarian tissues in a sex-, tissue-, and stage-specific manner. *A. aegypti* Vg is a member of large family of evolutionally conserved proteins serving as major yolk proteins in organisms ranging from nematodes to birds. In vitellogenic female insects, the fat body, a powerful metabolic and secretory organ, is engaged in massive production of YPPs for developing oocytes. The fat body's role in vitellogenesis in the female mosquito *A. aegypti* is not limited to the production of Vg. Together with Vg, the vitellogenic fat body of *Aedes* females produces two other YPPs, which are proenzymes deposited in developing oocytes and activated during embryogenesis: 53 kDa vitellogenic carboxypeptidase (VCP) and 44 kDa cathepsin B-like protease (VCB). Moreover, the regulation of these YPPs appears to be similar: they are synthesized exclusively by the fat body in response to a blood meal and are maximally expressed at 24 h post-blood meal (PBM). Lipophorin (Lp), the insect lipid transport molecule, also plays a role as a YPP in *A. aegypti*.

The hemolymph titers of ecdysteroids in female mosquitoes are correlated with the rate of YPP synthesis in the fat body (Fig. 1). The ecdysteroid titers are only slightly elevated at 4 h PBM; however, they rise sharply at 6–8 h PBM and reach their maximum level at 18–20 h PBM. Many studies have established that the ecdysteroid control of vitellogenesis is a central event in the blood meal-activated regulatory cascade leading to successful egg maturation.

A. Molecular Basis of Competence to the 20E Response

In *A. aegypti*, a preparatory, previtellogenic, developmental period is required for the mosquito fat body

to attain competence for 20E responsiveness as well as for the adult female to attain competence for blood feeding. βFTZ-F1, the orphan nuclear factor implicated as a competence factor for stage-specific responses to ecdysteroid during *Drosophila* metamorphosis, serves a similar function during mosquito vitellogenesis. The transcript of the *Drosophila* β*FTZ-F1* homologue is expressed at high levels in the mosquito fat body during pre- and postvitellogenic periods when ecdysteroid titers are low. However, there is a delay in the appearance of active *AaFTZ-F1* factor that coincides with the onset of competence for 20E response (Fig. 2). In addition, a homologue of *Drosophila HR3* is expressed in the vitellogenic tissues of the female mosquito. The expression of the mosquito homologue, *AHR3*, correlates with the titer of 20E, peaking in late pupae and adult vitellogenic females at 24 h PBM and preceding *AaFTZ-F1* expression peaks. The orphan nuclear receptor *DHR3*, an early-late gene, is one of the key genes in the ecdysone-mediated genetic regulatory network. Recent studies have revealed that during insect metamorphosis *DHR3* has a dual role in repressing the early genes while activating β*FTZ-F1*. Thus, the regulation and function of *FTZ-F1* during mosquito vitellogenesis closely resemble those shown at the onset of *Drosophila* metamorphosis, and *FTZ-F1* is therefore part of a conserved and broadly utilized molecular mechanism controlling the stage specificity of the ecdysteroid response.

B. Ecdysteroid-Regulatory Hierarchy in Mosquito Vitellogenesis

Analysis of ecdysone's effects on polytene chromosome puffing patterns in the late larval and prepupal salivary gland of *Drosophila* have suggested that the initial activation of a small number of early ecdysone-inducible genes leads to the subsequent induction of a large number of late target genes. Elucidation of this genetic hierarchy at the molecular level has led to the identification of the ecdysone receptor as a heterodimer of two nuclear receptors, the ecdysone receptor (EcR) and Ultraspiracle (USP), the insect homologue of the vertebrate retinoid X receptor. Furthermore, these studies have shown that the action of the ecdysone–receptor complex is indeed mediated by early genes such as the *BR-C*, *E74*, and *E75* genes encoding transcription factors involved in the regulation of late gene expression. The ecdysone-mediated regulatory network is further refined by the presence of genes that are involved in setting up the timing and stage-specificity of gene activation by this genetic hierarchy.

Consistent with the proposed role of 20E in activating mosquito vitellogenesis, experiments using an *in vitro* fat body culture have shown that physiological doses of 20E (10^{-7} to 10^{-6} M) activate two *YPP* genes, *Vg* and *VCP*. Transcripts of two different isoforms of EcR, EcR-A and EcR-B, are present in previtellogenic and vitellogenic ovaries and fat bodies. Transcripts encoding two different USP

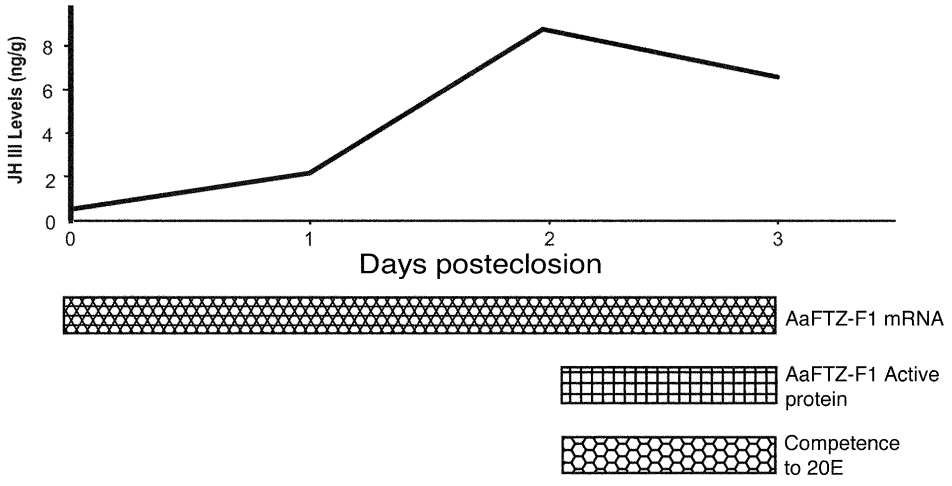

FIGURE 2 βFTZ-F1, the orphan nuclear factor, is implicated as a competence factor for stage-specific response to ecdysteroid in the mosquito fat body. The *AaFTZ-F1* mRNA is present at the late pupal and previtellogenic stages of newly eclosed females; however, the appearance of active *AaFTZ-F1* factor coincides with the onset of competence for 20E response. Based on Li *et al.* (2000); reprinted from Raikhel *et al.* (2002), with permission.

isoforms are differentially expressed in these tissues as well (Fig. 1). The mosquito EcR–USP heterodimer has been shown to bind to various ecdysteroid-response elements (EcREs) to modulate ecdysteroid regulation of target genes. EcREs are present in the *Vg* and *VCP* genes.

Several genes of the ecdysteroid-regulatory hierarchy are conserved between vitellogenesis in mosquitoes and metamorphosis in *Drosophila*. The *A. aegypti* homologue of the *Drosophila E75* gene, a representative of the next level in the ecdysteroid response hierarchy, is expressed in the ovary and fat body following a blood meal. Similar to *Drosophila*, there are three E75 isoforms in *A. aegypti* that are inducible by 20E. Interestingly, in the mosquito fat body, E75 transcripts show two peaks, with a small peak coinciding with the first peak of 20E. The correlation between midvitellogenic expression of the *E75* and *Vg* genes suggests that the *YPP* genes are direct targets of E75 (Fig. 1). Indeed, analysis of the *Vg* gene regulatory regions has identified an E75-binding site within a region required for high-level *Vg* expression. These findings suggest that *AaE75* mediates fat body ecdysteroid responses and that the ecdysteroid-triggered regulatory hierarchies, such as those implicated in the initiation of metamorphosis, are reiteratively utilized in the control of the reproductive ecdysteroid response.

Two isoforms of the homologue to the *Drosophila* transcription factor E74, which share a common C-terminal Ets DNA-binding domain, yet have unique N-terminal sequences, are present in the mosquito *A. aegypti*. They exhibit a high level of identity to DmE74 isoforms A and B and show structural features typical for members of the Ets transcriptional factor superfamily. Furthermore, both mosquito E74 isoforms bind to a *Drosophila* E74-binding site with the consensus motif C/AGGAA. The AaE74B transcript is induced by a blood meal-activated hormonal cascade in fat bodies and peaks at 24 h PBM, the peak of vitellogenesis (Fig. 1). In contrast, AaE74A is activated at the termination of vitellogenesis, exhibiting a peak at 36 h PBM in the fat body and at 48 h PBM in the ovary. AaE74A and AaE74B isoforms likely play different roles in the regulation of vitellogenesis in mosquitoes, as an activator and a repressor of *YPP* gene expression, respectively. The *Vg* gene regulatory portion containing an E74-binding site is required for the high level of *Vg* expression.

Analysis of the 5′-upstream regulatory region of the mosquito *Vg* gene has revealed the presence of putative binding sites for EcR–USP along with those to the early genes, E74 and E75. This suggests a complex system of regulation of this gene through a combination of direct and indirect hierarchies. The *Vg* gene contains a functionally active EcRE that binds the heterodimer EcR–USP. A direct repeat with a 1 bp spacer (DR-1) with the sequence AGGCCAaTGGTCG is the major part of the EcRE in the *Vg* gene. Thus, the *A. aegypti Vg* gene is the target of a direct and indirect regulation by 20E (Fig. 3).

C. Molecular Nature of Previtellogenic Arrest

Anautogeny is a fundamental phenomenon underlying the vectorial capacity of mosquitoes. It involves numerous adaptations, from host-seeking behavior to a complete repression of egg maturation prior to a blood meal. An important adaptation for anautogeny is the establishment of previtellogenic developmental arrest (the state of arrest) preventing the activation of *YPP* genes in previtellogenic competent females prior to blood feeding. In *A. aegypti*, both AaEcR and AaUSP proteins are abundant in the nuclei of the previtellogenic female fat body at the state of arrest; however, the EcR–USP heterodimer capable of binding to the specific EcREs is barely detectable in these nuclei. Studies have shown that the ecdysteroid

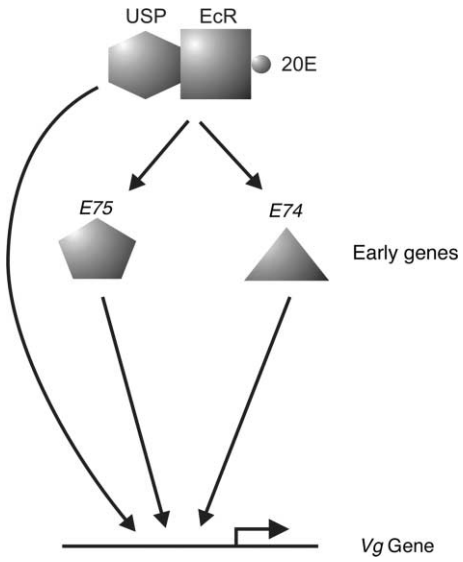

FIGURE 3 Direct and indirect regulation of the yolk protein precursor gene *Vg* by 20-hydroxyecdysone in the mosquito fat body. After binding 20E, the EcR–USP heterodimer activates the early genes *E74* and *E75* and directly acts on the *Vg* gene, allowing its expression. In turn, the products of the *E74* and *E75* genes act as powerful activators of *Vg* gene transcription. Based on Kokoza *et al.* (2001) and Martin *et al.* (2001); reprinted from Raikhel *et al.* (2002), with permission.

receptor is a primary target of the 20E signaling modulation in mosquito target tissues at the state of arrest. A possible mechanism through which the formation of ecdysteroid receptor activity can be regulated is the competitive binding of other factors to either EcR or USP. Indeed, at this stage, AaUSP exists as a heterodimer with the orphan nuclear receptor AHR38. AHR38, the mosquito homologue of *Drosophila* DHR38 and vertebrate NGFI-B (nerve growth factor-induced protein B) orphan receptors, is a repressor that disrupts the specific DNA binding of the ecdysteroid receptor and interacts strongly with AaUSP. However, in the presence of 10^{-6} M 20E, EcR can efficiently displace AHR38 and form an active heterodimer with USP, as occurs after a blood meal (Fig. 4).

D. Structure and Function of Regulatory Regions of Mosquito Yolk Protein Genes

Transcriptional activation of hormonally controlled, tissue-specific genes involves interactions of sequence-specific transcription factors with enhancer/promoter elements of these genes. Synergistic involvement of a

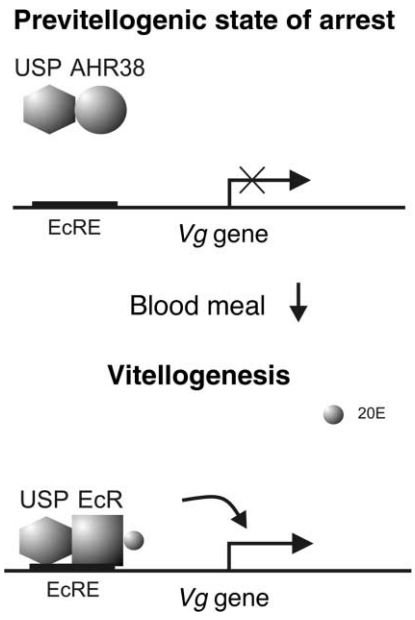

FIGURE 4 The ecdysteroid receptor is a primary target of the 20E signaling modulation in mosquito target tissues at the state of arrest. At the previtellogenic state of arrest, AaUSP exists as a heterodimer with the repressor AHR38, which prevents the formation of the functional ecdysteroid receptor. After a blood meal, EcR displaces AHR38 and forms a functional heterodimer with USP that is capable of activating ecdysteroid-regulated genes. Based on Zhu *et al.* (2000); reprinted from Raikhel *et al.* (2002), with permission.

number of regulatory factors governs the fat body-specific expression of the *Aedes Vg* gene. The 5′-regulatory region of the gene consists of three modules required for its blood meal activation and high-level expression. *Drosophila* and *Aedes* transformation and DNA-binding assays have been used to identify *cis*-regulatory sites in the *Vg* gene regulatory region, responsible for stage- and fat body-specific activation of this gene via a blood meal-triggered cascade. These analyses revealed three regulatory regions in the 2.1 kb upstream portion of the *Vg* gene that are sufficient to bring about the characteristic pattern of *Vg* gene expression (Fig. 5). The proximal region, adjacent to the basal transcription start site, contains binding sites to several transcription factors: EcR–USP, GATA (GATA-binding transcription factor), C/EBP (CAAT-binding protein), and HNF3/fkh (hepatocyte nuclear factor 3/forkhead transcription factor). This region is required for correct tissue- and stage-specific expression. It appears that a combinatorial action of these transcription factors is essential to bring about fat body-specific expression. EcR–USP acts as a timer, allowing the gene to be turned on. However, the level of expression driven by this regulatory region is low. Analysis of the mosquito *Vg* gene has revealed that the *Vg* 5′-regulatory region contains a functional ecdysteroid-responsive element (VgEcRE) that is necessary to confer responsiveness to 20E. VgEcRE is directly bound by EcR–USP produced *in vitro* or from extracts of vitellogenic fat body nuclei. The binding intensity of the EcR–USP–EcRE complex from nuclear extracts corresponds to the levels of ecdysteroids and of the Vg transcript during the vitellogenic cycle. However, given the modest level of 20E-dependent activation, it is likely that the EcR–USP receptor acts synergistically with other transcription factors to bring about the high level of *Vg* gene expression. The median region carries the sites for early gene factors E74 and E75. It is responsible for a stage-specific hormonal enhancement of *Vg* expression. The addition of this region increases the expression of the gene in a hormonally controlled manner. Finally, the distal region of the 2.1 kb upstream portion of the *Vg* gene is characterized by multiple response elements for the transcription factor GATA. In transgenic experiments utilizing both *Aedes* and *Drosophila*, this GATA-rich region has been found to be required for extremely high expression levels characteristic of the *Vg* gene (Fig. 5).

In the mosquito, VCP is the second most abundant YPP. The *VCP* gene is expressed in synchrony with the *Vg* gene: both their transcripts appear within 1 h PBM, reach maximal levels at 24 h

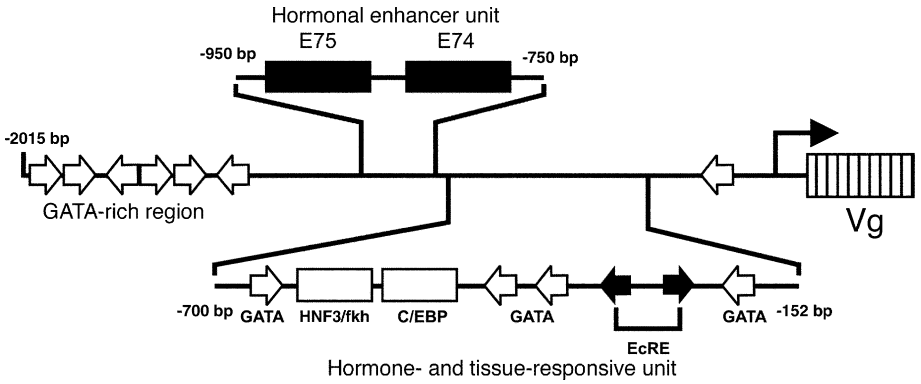

FIGURE 5 The regulatory regions of the *Aedes aegypti Vg* gene. Numbers refer to nucleotide positions relative to the transcription start site. C/EBP, response element of C/EBP transcription factor; EcRE, ecdysteroid-response element; E74 and E75, response elements for respective early gene products of the ecdysone hierarchy; GATA, response element for GATA transcription factor; HNF3/fkh, response element for HNF3/forkhead factor; Vg, coding region of the *Vg* gene. PBM, and rapidly decline to background levels by 36 h PMB (Fig. 1). 20-Hydroxyecdysone activates both these genes in fat body organ culture and in *in vitro* cell transfection assays. Furthermore, the same concentration of 20E (10^{-6} M) is required for maximal activation of both these genes. In both genes, most of the putative regulatory elements are located in the 2 kb upstream region of the transcription initiation site. Comparative analyses have revealed conservation of putative binding sites for transcription factors responsible for tissue- and stage-specific expression in the putative regulatory regions of both genes. Both genes contained sites for the EcRE and for the early ecdysone-regulatory gene E74. There are also similar tissue-specific binding sites including those for GATA, C/EBP, and HNF3/fkh.

Another level in the regulation of *YPP* gene expression in the mosquito fat body is provided by the control of transcription factors themselves. Levels of transcripts and active factors critical for transcription of *YPP* genes such as EcR, USP, E74, E75, and GATA are greatly enhanced during the vitellogenic cycle and are themselves targets of the blood meal-mediated regulatory cascade. This additional control provides yet another mechanism for the amplification of *YPP* gene expression levels.

III. MOLECULAR ENDOCRINOLOGY OF FRUIT FLY VITELLOGENESIS

The control of vitellogenesis in higher dipteran flies has been extensively studied in several species. The precise hormonal regulatory mechanisms depend upon whether the species lays eggs continuously or in batches. In the former case, as exemplified by the extensive studies on the model organism, the fruit fly *D. melanogaster*, each individual egg chamber differentiates and its progress through vitellogenesis is modulated by hormonal signals, thus linking its development to environmental factors. This has been studied using molecular, genetic, developmental, and physiological approaches. In species laying eggs in batches, the maturation of a synchronous group of oocytes is controlled by changes in hormone levels. Probably the best studied species in this category is the housefly, *Musca domestica*. Many aspects of the regulation of vitellogenesis in the housefly are quite similar to those described for the mosquito, *A. aegypti*, in the previous section. JH acts at an early stage to prime the fat body for yolk protein synthesis and ensure that the oocytes are arrested in a previtellogenic stage. Only after a protein feed does the fat body start to synthesize yolk, and vitellogenesis commences in the ovary as endocytosis of yolk begins. This phase is controlled by the circulatory levels of ecdysone in the hemolymph, which is produced by the egg chambers, and some time afterward the fat body shuts down yolk protein synthesis and the eggs are completed, ready to be laid.

In the fruit fly, the fat body matures and differentiates at eclosion, again under the control of JH, but it immediately begins to synthesize yolk proteins and secrete them into the hemolymph. Oocytes progress into vitellogenesis at once and begin to produce mature eggs, which are fertilized and laid continuously. However, if the fly does not

mate or does not have available food, these "ready to lay" eggs are retained and oocytes arrest at a previtellogenic stage and do not enter vitellogenesis. The fat body will gradually produce less yolk proteins, though it rarely ceases production completely, as in the housefly and mosquito. Whether an oocyte progresses into vitellogenesis or arrests is controlled by the balance of JH and ecdysone. Thus, the fruit fly does relate egg production to feeding but the mechanism is not by producing batches of eggs after a feed but rather by feeding and laying eggs continuously unless there is a reason not to do so, such as lack of sperm, lack of food, or crowded conditions. There must therefore be subtle mechanisms that relate egg production rates to food availability in *Drosophila*.

There are several *yolk protein* genes that encode a small family of related yolk proteins in most fly species. The genes have been cloned in *D. melanogaster*, *M. domestica, Calliphora erythrocephala*, *Calliphora*, *Ceratitus capitata*, and other species and are well conserved throughout evolution. These genes have functions that are similar to those of the vitellogenins of mosquitoes, although they are not closely related genes in evolutionary terms. Yolk proteins are made in the fat body, as in the mosquito, but there is a second site of synthesis in the follicle cells, which are associated with the oocyte in developing egg chambers. As far as is known, the gene products, the yolk proteins (YPs), are the same for each tissue. The proteins are approximately 45 kDa in size and are produced with a small leader sequence that is cleaved prior to secretion. Those made in the follicle cells are secreted unidirectionally toward the oocyte. Those made in the fat body travel to the ovary via the hemolymph.

The regulation of *yp* gene expression seems to be quite different in the two sites of synthesis. In the fat body, ecdysteroids can stimulate YP synthesis in males and up-regulate it in females and JH also increases YP synthesis in the fat body. However, these effects are rather modest in *Drosophila* compared to the dramatic effects in the mosquito. In the ovary, however, JH and 20E seem to be antagonistic, with JH promoting YP synthesis and oocyte progression and ecdysone tending to lead to apoptosis if it is present at high levels.

Many of the response genes that have been shown to be crucial in the mosquito and that are homologues of *Drosophila* genes used to regulate the response of the organism to ecdysone during metamorphosis have not been studied in *Drosophila* with respect to yolk protein synthesis in the fat body. This is largely because in normal, mated, well-fed females the genes are constitutively active rather than regulated in response to a blood meal; thus, the normal control seems secondary to their sex-specific activation in females. However, the same set of genes including *BR-C*, *E74*, *E75*, and the *Ecdysone receptor EcR* have all been shown to be crucial for oocyte development and the progression of vitellogenesis that leads to a mature egg. They are needed in the egg chambers themselves to decide how many eggs to develop in relation to environmental conditions (Fig. 6).

When flies are provided with a starvation diet rather than normal food, egg chambers stop developing prior to the vitellogenic period. Those already in the stages of active yolk accumulation are triggered to undergo apoptosis. This effect can be mimicked by injection of 20E into females or can be rescued by treatment with JH. When nutritionally challenged, the spatial and temporal expression patterns of *BR-C*, *E74*, *E75*, and *yp* mRNAs are altered, suggesting that the decision to undergo vitellogenesis or apoptosis is controlled by the same set of genes that regulate expression of the *yp* genes in the fat body of mosquitoes and perhaps *Drosophila*.

Although sites where ecdysone exerts its effects on *yp* gene expression in the fat body have been mapped, it is not clear how much of this effect is a direct action via binding of the EcR and how much is due to downstream genes such as *BR-C*, *E74*, and *E75*.

In the mosquito, three other yolk protein precursors are important in vitellogenesis, namely, Lp, VCP, and VCB. Lipophorin activity has been purified from *D. melanogaster*, but a gene was not identified. Searches of the *Drosophila* genome show that there are two genes that encode low-density lipoprotein receptors that could potentially be lipophorin equivalents and transport lipids (genes *CG4861* and *CG13257*) but they have not been studied in the context of fruit fly vitellogenesis. The VCP of *A. aegypti* has two related genes in *D. melanogaster*; these are a serine carboxypeptidase (gene *BG:DS00365.3*) and carboxypeptidase C (gene *CG4572*). *Drosophila* also has a cathepsin B-encoding gene (gene *CG10992*) but it is not clear whether this encodes the homologue of VCB. None of these genes have been studied during fruit fly oogenesis.

A. Structure and Function of Regulatory Regions of Fruit Fly Yolk Protein Genes

Rather little is known about the *cis*-acting regions of the *yp* genes needed for hormonal regulation in any

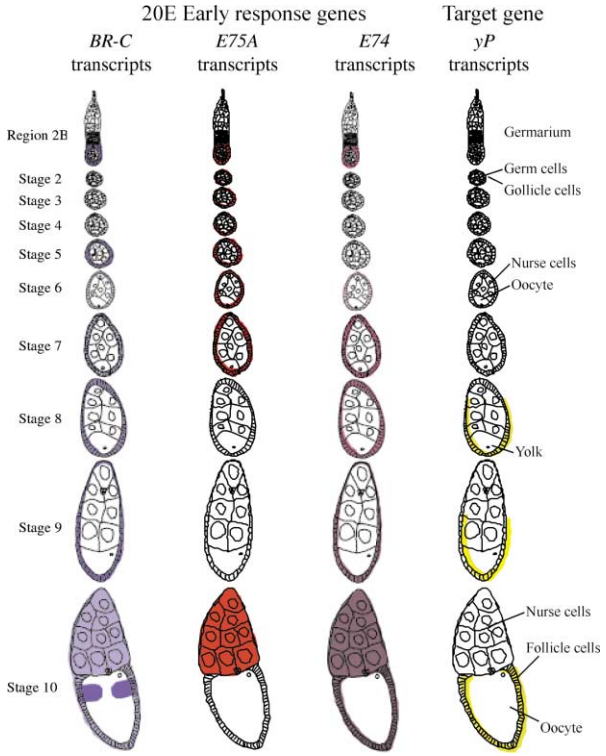

FIGURE 6 Ovariole of *Drosophila* indicating *BR-C*, *E75A*, *E74*, and *yp* expression patterns during oocyte development. The expression pattern of several key ecdysone-response genes during oogenesis is shown. Stem cells divide in the germarium to produce a cluster of 16 germ cells. One becomes the oocyte and the other 15 become the polyploid nurse cells that produce macromolecules needed for oogenesis. Oogenesis is divided into 14 morphologically distinct stages as the oocyte gradually matures. Yolk is produced in the follicle cells from stage 8 to stage 11. It is produced mostly in the columnar follicle cells that migrate to surround the oocyte. *yp* gene expression is shown. The ecdysone-response genes *BR-C*, *E75A*, and *E74* are also expressed in follicle cells at certain stages of oogenesis. The regulation of *yp* genes is certainly not their only function in the ovary and *yp* genes do not always respond to their expression since *BR-C*, *E75*, and *E74* are also expressed in the nurse cells late in oogenesis when *yp* genes are not expressed. They are also expressed much earlier in follicle cells than the *yp* genes. It is likely then that the genes interact with other tissue-specific factors in the follicle cells to modulate the progress of oogenesis, including the regulation of the *yp* genes. From Jun Terashima and Mary Bownes, unpublished work, with permission.

fly species. The most information pertains to *D. melanogaster*, in which several DNA sequences can confer ecdysone-inducible *yp* gene expression in males in response to injection of 20E. These are located 5′, 3′, and within the coding sequences of the *yp* genes. These regions do contain the putative EcRE sequences that have been shown to bind and respond to the EcRE–USP heterodimer and lead to the transcription of other genes in metamorphosis and of the vitellogenin genes in the mosquito. JH also up-regulates *yp* gene expression in the fat body, but those sites could not be mapped to flanking sequences and JH may in fact achieve its effect by affecting the stability of *yp* RNA.

Although in *Drosophila* the study of the molecular control of *yolk protein* gene transcription is less well understood in terms of hormonal regulation, a great deal is known about how it is that the genes are expressed only in the female and not in the male. A pathway of sex determination genes controls the male and female sexual characteristics, including the expression of the *yolk protein* genes. Mutations in these genes lead to sexual transformations of males to females and vice versa and to intersex flies. The most important gene for *yp* control is *dsx*. The *dsx* gene encodes different proteins in male and female adults as a result of alternate transcript splicing. The two proteins generated have similar DNA-binding domains but different carboxy-terminal extensions. Although the male and female proteins (DSXF and DSXM) bind to the same DNA sequences *in vitro*; *in vivo* DSXF and DSXM are essential for maintaining *yp* transcription in the female fat body and repressing it in males. YP expression in the ovarian follicle cells is not dependent on the sex determination pathway in the adult but depends on ovarian tissue-specific factors, which at the moment are poorly understood. It is likely that 20E is a key to their correct expression in the ovarian follicle cells.

A number of factors that interact with *cis*-acting sequences close to the *yp* genes have been identified by *in vitro* binding studies. Some of these *cis*-acting sites have been shown to be crucial for correct tissue-, sex-, and hormone-regulated gene expression by creating transgenic flies with normal or mutated response elements fused to reporter genes that can be monitored *in vivo*. There are also other genes that modify sexual differentiation in *Drosophila* that have been shown to be crucial for normal yolk protein gene expression.

There is overlap in the binding sites between DSX and some of these tissue-specific regulatory proteins, which suggests that it is a complex interaction between DNA-binding sites and multiple proteins that leads to the production of yolk being a female fat body-specific trait. The *dsx* gene is well conserved in different flies such as the housefly and Mediterranean fruit fly. It is alternately spliced in males and females in these species; thus, this mechanism of regulation is likely to be well conserved throughout evolution.

Somehow, the hormonal regulation is superimposed on this mechanism and can in fact overrule it in *Drosophila*, since the injection of 20E into males transiently overrides the repression by DSXM and leads to the expression of *yp* genes in the male fat body for a few hours. Somewhat surprisingly, however, the *cis*-acting sequences 5′ of the *yp* genes of *Calliphora* and *Musca* are not regulated in a sex-specific manner when they are transformed into *Drosophila*, despite having DNA-binding sites to which the *Drosophila* DSX proteins bind *in vitro*. It seems that in those species that lay their eggs in batches, the hormonal regulation is more important in the adult, and the *Drosophila* hormones present in the hemolymph in combination with the *Drosophila* DSX proteins lead to expression in both sexes. More detailed studies on the hormonal control of *yp* gene expression at the molecular level are needed in *D. melanogaster*, *M. domestica*, and *C. capitata* in order to understand how vitellogenesis is controlled in flies.

Glossary

ecdysone A precursor form of the steroid hormone 20-hydroxyecdysone.

ecdysone receptor Insect-specific nuclear receptor that mediates the action of the steroid hormone 20-hydroxyecdysone.

fat body Insect metabolic tissue analogous to the vertebrate liver and the adipose tissue combined.

20-hydroxyecdysone Active form of the steroid hormone found in insects and crustaceans.

juvenile hormone Insect-specific hormone of a sesquiterpenoid nature.

lipophorin Lipid carrier protein.

ultraspiracle The insect homologue of vertebrate retinoid X receptor, an obligatory partner of the ecdysone receptor.

vitellin A storage form of the major yolk protein.

vitellogenesis A major stage during egg maturation in egg-laying animals during which yolk protein precursors are synthesized and accumulate in developing oocytes.

vitellogenin A precursor form of the major yolk protein.

yolk protein Major yolk protein in flies.

Ecdysteroid Receptors (EcR/USP)

MARGARETHE SPINDLER-BARTH AND KLAUS-DIETER SPINDLER
University of Ulm, Germany

The heterodimer of the ligand-dependent transcription factors ecdysteroid receptor (EcR) and USP is considered as functional ecdysteroid receptor that coordinates arthropod development and metabolism and modifies the expression of a multitude of different genes in a tissue- and time-specific manner. As is typical for steroid hormone receptors in general, the different functions of this receptor are associated with defined molecular domains, which are modified by intra- and intermolecular interactions. Both EcR and USP can dimerize with several other transcription factors, but homodimerization has been described for both partners as well. Isoforms of EcR and USP are detected in various species and are engaged in different functional roles. Species-specific variations demonstrate that different solutions have evolved within arthropods. The ecdysteroid receptor is an important target for insecticides and is also used as a ligand-controlled switch in heterologous systems for gene expression.

I. MOLECULAR CHARACTERIZATION OF EcR

A. General Features

Thus far, the ecdysteroid receptor (EcR) has been sequenced from 12 insects, a crustacean, and a tick. The common features of EcRs include a highly conserved two-zinc-finger DNA-binding domain, which shares a considerable level of sequence identity with vertebrate steroid hormone receptors (Table 1), an A/B domain, which in most instances is responsible for transactivation, and a D–F domain, which, in addition to binding ligand, mediates various other functions (Fig. 1). The degree of sequence identity that EcRs share with vertebrate steroid receptors is considerably lower than that within arthropods.

TABLE 1 Sequence Identities of EcRs and Comparison with Human Nuclear Receptors

	A/B domain	DNA-binding domain	D domain	E domain
Diptera EcR	21[a], 44–49	95–96	50[a], 64–82	74[a], 87–95
Lepidoptera EcR	31–48	93–95	55–62	70–72
EcRs of other arthropods	25–44	86–89	52–62	58–70
Human nuclear receptors				
PPAR α	15	56	14	19
PPAR β	19	55	16	23
PPAR γ	5	53	15	20
TR α	17	59	18	23
TR β	4	59	22	27
VDR	21	57	20	27

Note. The *Drosophila melanogaster* EcR isoform B is set at 100%. Analysis was performed using ClustalW. PPAR, peroxisome proliferation-activated receptor; TR, thyroid hormone receptor; VDR, vitamin D receptor.

[a]Values for Chironomus tentans.

The EcR of *Chironomus tentans* shows pronounced differences compared to the EcRs of all other dipterans. As is also typical for vertebrate nuclear receptors, the hinge region D and the A/B domains are highly diverse.

B. Regulation of Expression

Expression and isoform patterns vary in a time- and tissue-specific manner and are regulated by ecdysteroids and juvenile hormone. This was investigated thoroughly in *Manduca sexta* but was also confirmed for other species. The highly complex gene-specific modulation of expression by EcR and USP is the basis for the hierarchic hormone-dependent gene cascades during development.

C. Nuclear Transport, Nuclear Localization, and DNA Binding

Using biochemical as well as immunocytochemical techniques, localization of EcR in the cytoplasm and nucleus has been demonstrated, but the underlying mechanisms of transport and nuclear localization signals have not yet been identified. Hormone response elements (HREs; receptor-binding motifs in the promoter region) have been characterized. Both naturally occurring and synthetic HREs are either palindromes or direct repeats with the consensus sequence AGGTCA, as tested by gel mobility shift assays, determination of affinity constants, and transactivation assays. Half-sites are not functional and do not bind EcR or EcR/USP, although their presence in the promoter region of ecdysteroid-dependent genes has been demonstrated. Not every ecdysteroid response element is active *in vivo* but the cellular context seems to determine the functionality of a certain response element.

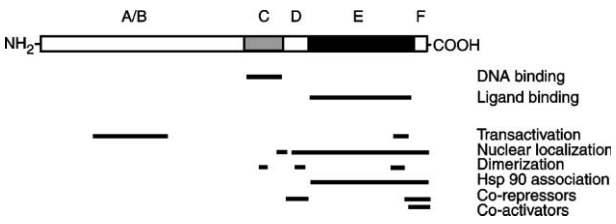

FIGURE 1 Generalized scheme of nuclear receptors and their functional domains.

D. Ligand Binding

The X-ray structure of the ligand-binding pocket of EcR has not been available until now. However, computer modeling of the two- and three-dimensional structures reveals the same general architecture as that determined for vertebrate steroid hormone receptors, which consist of 11–12 α-helices and a β-sheet arranged as anti-parallel sandwich. The dimerization partner has a profound influence and either enables or enhances ligand binding considerably. Ligand binding changes the interaction with co-modulators, enhances DNA binding, and promotes dimerization. As was determined for vertebrate nuclear receptors, it was concluded that these effects were due to a conformational change in the ligand-binding pocket, especially in helix 12.

E. Dimerization

Three different dimerization interfaces have been described for EcR. As in vertebrate nuclear receptors, a conserved region is present in the zinc-finger

domain, which mediates DNA-dependent dimerization. This was confirmed for vertebrate receptors by mutational analysis. Due to the high level of sequence identity, the same function also seems likely for EcR. An additional dimerization site in the hinge region was identified in *Choristoneura fumiferana* EcR by analysis of truncated versions of the receptor. A highly conserved region is present in arthropod receptors adjacent to the C-terminal end of the C domain. The T-box, which mediates dimerization, is located at the same position in vertebrate receptors. It remains to be clarified whether or not the same region is also involved in dimerization in arthropod receptors.

As shown for vertebrate nuclear receptors, ligand-controlled dimerization in the E domain is mediated primarily by helix 10. This has also been confirmed for EcR by mutational analysis using the ligand-binding pocket of *Drosophila melanogaster* EcR expressed in yeast cells. Heterodimerization between EcR and USP seems to be most common; however, interaction with other partners, such as seven-up (a homologue of vertebrate COUP-TF), can contribute to the diversity of ecdysteroid-regulated processes.

Whether or not all three dimerization sites are involved simultaneously is still unknown, and the question of dimerization partners remains unanswered. For example, it is reasonable to assume that binding to direct repeats or palindromic HREs has a profound influence on the type of dimerization, as has been demonstrated for vertebrate nuclear receptors.

F. Transactivation, Receptor Isoforms, and Co-modulators

The A/B domain, which harbors the ligand-independent transactivation domain (AF1), varies considerably between different arthropods, but also varies between isoforms within the same species. An indication of specific functions associated with a certain isoform is given by the different expression profiles in various tissues during development. Mutational analysis of EcR from *Drosophila* revealed that receptor isoforms cannot replace one another.

Depending on the species, the transactivation domain can be either activating (e.g., *Drosophila*) or repressing (e.g., *Chironomus*), as has been demonstrated using chimeric receptors.

For *Drosophila* imaginal discs, it has been shown that the ecdysteroid receptor exerts repressing functions in the absence of USP and activates gene expression in its presence. Ligand-dependent transactivation is mediated mainly by helix 12 of the E domain. The change in position of helix 12 following hormone binding seems to be a prerequisite for ligand-dependent activation and allows the release of co-repressors and the binding of co-activators. Some co-modulators, such as *alien*, are quite conserved between vertebrates and invertebrates, whereas others, such as *Smrter*, are insect specific. *Alien* and *Smrter* bind in transactivation domain AF2 (helix 12) in the signature motif between helix 3 and helix 4 of the ligand-binding domain.

II. MOLECULAR CHARACTERIZATION OF USP

A. Expression

The pattern of USP expression does not always follow in parallel with that of EcR, which suggests a possible separate functional role in addition to heterodimerization with EcR. This is further substantiated by specific effects of USP mutants during development. The discrepancies in specific mRNA titer and USP protein concentration are indicative of additional posttranscriptional control. As with EcR, different USP isoforms have been described for several insect species. The only exception is *Drosophila*, for which only one isoform has been described thus far.

B. Nuclear Transport and DNA Binding

USP is transported into the nucleus independent of the presence of EcR. *In vivo* and *in vitro* experiments have clearly demonstrated that USP also binds to specific HREs in the absence of EcR. In contrast to the heterodimer, direct repeats are preferred over palindromic structures.

C. Ligand Binding

USP is considered an orphan receptor since a specific ligand has not yet been identified. However, phospholipids are bound in the unusually large and hydrophobic ligand-binding pocket, as determined by X-ray studies. The lipid occupies only part of the ligand-binding pocket and leaves additional space for another presumably more specifically bound ligand. Juvenile hormone was proposed as a possible ligand but no definite proof has been made available yet.

The high level of sequence identity shared with human retinoic acid X receptor (RXR) (Table 2) suggests that USP can also be replaced functionally by RXR. This is in fact possible, when EcR is expressed in vertebrate cells. The ligand for RXR, retinoic acid, can also replace juvenile hormone functionally in crustaceans.

TABLE 2 Sequence Identities of USPs and Comparison with Human Nuclear Receptors

	A/B domain	DNA-binding domain	D domain	E domain
Diptera USP	26–50	90–92	46–70	49–72
Lepidoptera USP	20–21	95–96	65–70	44–45
USPs of other arthropods	23–30	90–93	57–70	38–48
Human nuclear receptors				
RXR α	6	86	50	51
RXR β	16	83	55	57
RXR γ	7	83	38	47
ER α	11	53	23	23

Note. The *Drosophila melanogaster* USP is set at 100%. Analysis was performed using ClustalW. RXR, retinoic X receptor; ER, estradiol receptor.

The sequence identity of the ligand-binding pocket is rather low not only compared to vertebrate receptors, but also within arthropods and even within Diptera or Lepidoptera. This may indicate either that no ligand, or no highly specific ligand, is necessary for USP function or that different ligands may be used in different species.

X-ray analysis revealed that the ligand-binding pocket of USP has a unique architecture. Helix 12 is fixed by hydrophobic interactions in a groove between helix 1 and helix 3 of USP even in the absence of a specific ligand. In vertebrate receptors, this configuration is observed only after binding of an antagonist. Interestingly, the three-dimensional structure of the ligand-binding domain of USP is more similar to estrogen receptor (ER) than to RXR, although the sequence identity to ER is considerably lower (Table 2). This finding demonstrates that conclusions based on alignments of different receptor sequences should be considered cautiously and that the two- or three-dimensional architecture must be taken into account.

D. Transactivation and Isoforms

In most arthropods investigated thus far, with the exception of *Drosophila*, isoforms with different A/B domains have been found. For *Drosophila*, it was shown that DNA binding of USP is necessary for repression of transcription, whereas for activation only the ligand-binding domain is required.

For *Choristoneura* USPs, it was shown that the A/B domain of USP is essential for basal transactivation of the EcR/USP complex in yeast cells. This confirms that dimerization of EcR/USP occurs in the absence of ligand as shown previously by electrophoretic mobility shift assay experiments with EcR/USP. These data also demonstrate that the A/B domains of both nuclear receptors are necessary for correct transcriptional regulation.

III. GENERAL COMMENTS

A. Posttranslational Modifications

Like nuclear receptors in general, EcR and USP occur in several isotypes with different degrees of phosphorylation. Although the specific phosphorylated amino acids have not yet been identified, phosphorylation is of functional importance, e.g., for the regulation of ecdysteroid synthesis. Numerous putative phosphorylation sites are present in the A/B and E domains of both nuclear receptors. In the DNA-binding domain, phosphorylation sites are present only in USP.

B. Interdomain Signaling

As outlined earlier for vertebrate nuclear receptors, the function of individual receptor domains is modulated by interdomain signaling. The most prominent example is the stimulation of DNA binding of EcR/USP by ecdysteroids. The degree to which different HREs are influenced by hormones varies and is more pronounced for palindromic HREs than for direct repeats. Another example is the inhibition of ligand-dependent activation, which is mediated by helix 12 in the E domain and by the A/B region of EcR.

C. Species-Specific Differences

Individual receptor domains have presumably evolved separately within arthropods.

The hinge region of EcR is quite conserved within Lepidoptera and within Diptera, but there are

pronounced differences between the taxa, which might contribute to their different sensitivities to hormone mimics, e.g., diacylhydrazines, since the C-terminal segment of the hinge region seems to be important for ligand binding.

In contrast to EcR from other species, e.g., *Chironomus*, EcR from *Drosophila* is capable of binding ligand in the absence of its heterodimerization partner USP. This offers an additional pathway for hormonal regulation by EcR alone. However, heterodimerization also enhances ligand binding to EcR considerably in *Drosophila*.

There are glycine stretches in the ligand-binding domain of *Drosophila* EcR that are absent in EcRs from other species.

The hydrophobic F domain, which is especially extended in *Drosophila*, is highly variable among insects and its contribution to receptor function is unclear.

Although helix 12 of USP is of functional importance for ligand binding to EcR in *Drosophila*, the amino acid sequences vary considerably among insects. Calculation of the two-dimensional structure revealed that even in *Bombyx mori* there is a helix 12 despite the low level of sequence identity. Only one leucine out of nine amino acids is conserved.

IV. APPLICATION AND PERSPECTIVES

The EcR ligand-binding domain of the ecdysteroid receptor has been characterized extensively, since molting hormone mimics are used successfully as pesticides with low vertebrate toxicity. Comparative aspects of ligand binding not only are of interest for target specificity of potential insecticides, but also provide new insight into the evolution of hormonal signal transduction pathways.

The ecdysteroid receptor is used as gene switch for ligand-dependent regulation of heterologous protein expression. The efficiency of the ecdysteroid-inducible expression system can be enhanced considerably using receptor chimeras of different arthropod species or combinations of insect and vertebrate receptor domains. Stable ecdysone-inducible systems, such as that described recently for mammalian colon cancer cells, are an important step toward the possible utilization of such systems in gene therapy.

Ecdysteroidogenic Pathway

HUW H. REES
University of Liverpool

In common with many other classes of arthropods, insects cannot synthesize sterols *de novo* from small molecules and must obtain them from the diet. Although carnivorous species obtain cholesterol directly from the diet, many, but not all, investigated phytophagous species, as well as omnivorous species, can dealkylate C_{28} and C_{29} phytosterols to yield cholesterol. In immature stages of insects, the prothoracic glands are the major site of ecdysteroid synthesis, whereas in adults, synthesis of the hormones occurs in the ovarian follicle cells and in testes. Although 7-dehydrocholesterol is an early intermediate in ecdysone biosynthesis, subsequent early steps of the pathway are not clear. Nonetheless, there is good evidence for the intermediacy of 5β-ketodiol (2,22,25-trideoxyecdysone) or its 3-dehydro derivative. The subsequent cytochrome P450-dependent hydroxylations (at C-25, C-22, and C-2) to yield ecdysone are somewhat better understood. Ecdysone then undergoes 20-monooxygenase-catalyzed hydroxylation to yield the major active hormone, 20-hydroxyecdysone, in several peripheral tissues. A major mechanism of regulation of ecdysone biosynthesis occurs via the neuropeptide, prothoracicotropic hormone.

I. INTRODUCTION

Elucidation of the pathway of biosynthesis of ecdysone from cholesterol has proven difficult, because ecdysteroids, being hormones, occur in low concentrations and because of the small size of insects and of the ecdysiosynthetic tissues investigated, primarily the prothoracic glands and, to a lesser extent, the follicle cells. Consequently, intermediates in the biosynthetic pathway do not generally accumulate in sufficient quantities for identification. Early studies have depended almost entirely on incorporation of synthetic, radioactive putative intermediates. More recently, the availability of the *Drosophila melanogaster* genome sequence has provided an impetus for studies in this area, coupled with detailed studies on various *Drosophila* embryonic cuticle mutants.

II. SIDE CHAIN DEALKYLATION OF PLANT STEROLS

Although insects, in common with other arthropods, lack the ability to synthesize sterols *de novo* from small molecules, the majority of insect species investigated require cholesterol (12), or a sterol that is convertible into cholesterol, for satisfactory growth, development, and reproduction. Whereas carnivorous insects obtain cholesterol directly from their diet, many but not all examined phytophagous species, together with omnivorous species, can obtain cholesterol or a related C_{27} sterol by dealkylation in the gut of dietary plant 24-alkyl sterols such as sitosterol (1), campestrol (2), or stigmasterol (3) (Fig. 1). There is much evidence that dealkylation of the latter three predominant phytosterols occurs via the analogous pathways shown in Fig. 1 in several insect species. In each case, the initial step involves oxidation to yield a $\Delta^{24(28)}$ bond, followed by an epoxidation reaction before dealkylation of the C_1 or C_2 fragment to yield a Δ^{24} bond. In the case of stigmasterol dealkylation, an extra step is involved, reduction of the Δ^{22} bond of 22*E*-cholesta-5,22,24-trien-3β-ol (11), to furnish the common terminal intermediate, desmosterol (10). There is very little information on the enzymes involved in the dealkylation pathways (Fig. 1), but it would be envisaged that cytochrome P450 is involved at more than one step.

Some phytophagous and omnivorous insect species, e.g., certain Hymenoptera, Hemiptera, and Diptera, as well as a coleopteran, cannot dealkylate the sterol side chain. Many such species use campesterol (2) as a precursor for the C_{28} ecdysteroid, makisterone A (13) (see Fig. 2).

Furthermore, identification of the C_{29} ecdysteroid makisterone C (14) as a major embryonic ecdysteroid in *Dysdercus fasciatus* (Hemiptera) suggests that a C_{29} steroid can serve as a molting hormone.

III. ECDYSTEROID BIOSYNTHESIS

A. Sites of Synthesis

The prothoracic glands are the major physiologically important source of ecdysteroid during insect

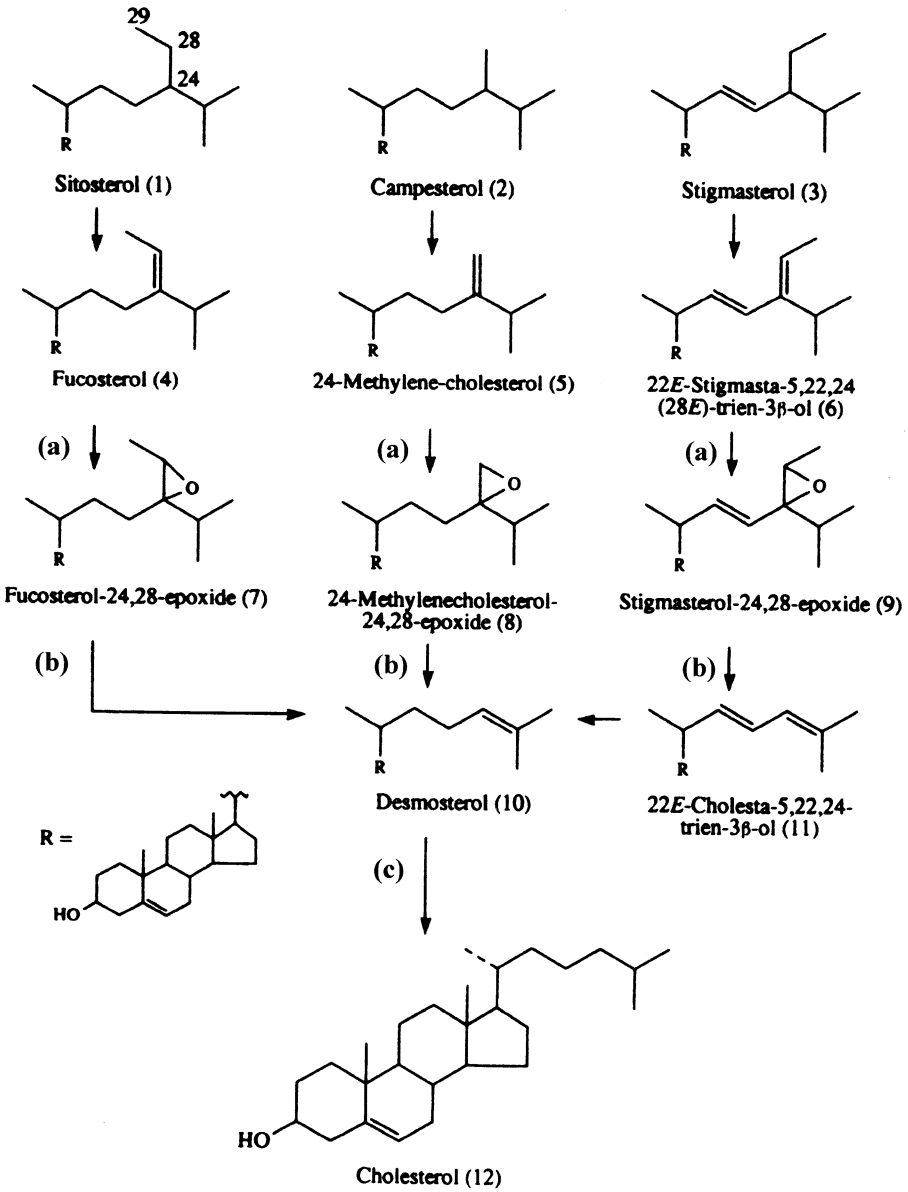

FIGURE 1 Pathways of side chain dealkylation of phytosterols. Dealkylation at C-24 of the major plant sterols occurs via analogous pathways. Initial oxidation produces a $\Delta^{24(28)}$ bond, followed by an epoxidation reaction, before dealkylation of the C_1 or C_2 fragment forming a Δ^{24} bond. In the case of stigmasterol dealkylation, an extra step is required to reduce the Δ^{22} bond. Finally, the common terminal intermediate, desmosterol (10), is reduced to cholesterol (12). Enzymes involved include (a) epoxidase; (b) epoxide lyase; and (c) desmosterol 24,25-reductase. Reprinted from Rees (1995), with permission.

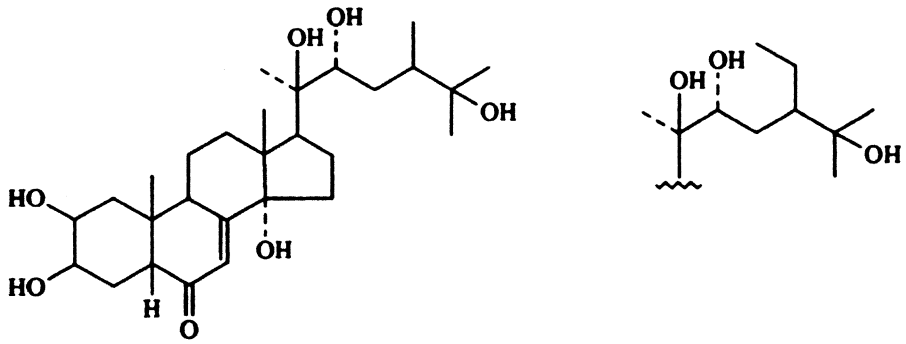
postembryonic development. However, physiological ecdysteroid production has been demonstrated in the abdomens of some species, with epidermal synthesis being observed in certain cases. During pupal–adult development, the prothoracic glands completely (or nearly completely) disappear by programmed cell death. In adult life, not only are ecdysteroids produced by the epidermis, but by the ovarian follicle cell epithelium in females and by the testes sheath in males.

In the Crustacea, another class of arthropod that has been extensively studied, the Y-organs have been established as an ecdysiosynthetic tissue.

Whereas the product of the prothoracic glands in most insect species is ecdysone (24), in many lepidopteran species, 3-dehydroecdysone (20),



Makisterone A (13) Makisterone C (14)

FIGURE 2 Formulae of makisterone A (13) and makisterone C (14). Reprinted from Rees (1995), with permission.

accompanied by varying amounts of ecdysone, is a major product of the prothoracic glands, being reduced to ecdysone by a hemolymph reductase enzyme. In a somewhat similar manner, in Crustacea, ecdysone, 3-dehydroecdysone, and 25-deoxyecdysone have been detected as products of Y-organs in various combinations, although reduction of 3-dehydroecdysone has not been detected in these cases.

B. Early Stages

It is now clear that during transformation of cholesterol (12) into ecdysteroids, there is extensive modification of the nucleus before side chain hydroxylation, with appreciable evidence for the intermediacy of 2,22,25-trideoxyecdysone [5β-ketodiol (21); Fig. 3].

The intermediacy of 7-dehydrocholesterol (15) in ecdysteroid biosynthesis has been firmly established. Introduction of the Δ^7 bond into cholesterol involves removal of the 7β- and 8β-hydrogens and is a rapid, basically irreversible reaction, catalyzed by a microsomal cytochrome P450-dependent activity. This raises the possibility of the intermediacy of 7β-hydroxycholesterol. Interestingly, a *D. melanogaster* low-ecdysteroid mutant (*woc*; *without children*) lacks the 7(8)-dehydrogenase and can be partially rescued by feeding 7-dehydrocholesterol. However, the *woc* gene codes for a novel zinc-finger protein that may function as a transcription factor, rather than the expected cytochrome P450.

Indirect evidence has suggested that transformation of 7-dehydrocholesterol (15) to trideoxyecdysone [5β-ketodiol (21)] occurs in the mitochondria. It has been postulated that the rate-limiting step in prothoracicotropic hormone-stimulated ecdysteroidogenesis in prothoracic glands is the movement of 7-dehydrocholesterol (poorly water soluble) from the endoplasmic reticulum, where it is formed, to the mitochondria, where it is oxidized to ecdysteroid. This process may well have some analogy with the adrenocorticotropic hormone-mediated control of cholesterol movement within the mammalian adrenal mitochondria and may involve uncharacterized regulatory proteins.

Our lack of understanding of the initial part of the pathway following 7-dehydrocholesterol led to its designation as the "black box." Formation of the A/B *cis*-ring junction of ecdysteroids apparently occurs early in the biosynthetic pathway. Analogous transformation of a Δ^5 bond to yield a 5β-hydrogen during formation of certain steroid hormone metabolites and bile acids in vertebrates involves a 3-oxo-Δ^4-steroid intermediate. Similarly, demonstration of specific elimination of the 3α- and 4β-hydrogens during ecdysteroid formation was interpreted by postulating the intermediacy of an analogous 3-oxo-Δ^4-steroid intermediate in the formation of the A/B *cis*-ring junction. More recently, evidence suggests that Δ^4-diketol (cholesta-4,7-diene-3,6-dione-14α-ol; 16) may be an intermediate. The demonstration that the 14α-hydroxy function could not be introduced after formation of the 6-keto-7-ene system and that ecdysteroid analogues having a 6-hydroxyl group could not be oxidized to 6-keto compounds led to the notion that the 3-dehydro-6-oxo-7-en-14α-ol functionality, which characterizes ecdysteroids, must be formed in a concerted manner, i.e., simultaneously. They might perhaps be mediated by a single cytochrome P450. Although it is not clear when oxidation of the 3β-hydroxyl of 7-dehydrocholesterol occurs, it may well be an integral part of the presumed concerted overall mitochondrial oxidations leading to the Δ^4-diketol (16) formation.

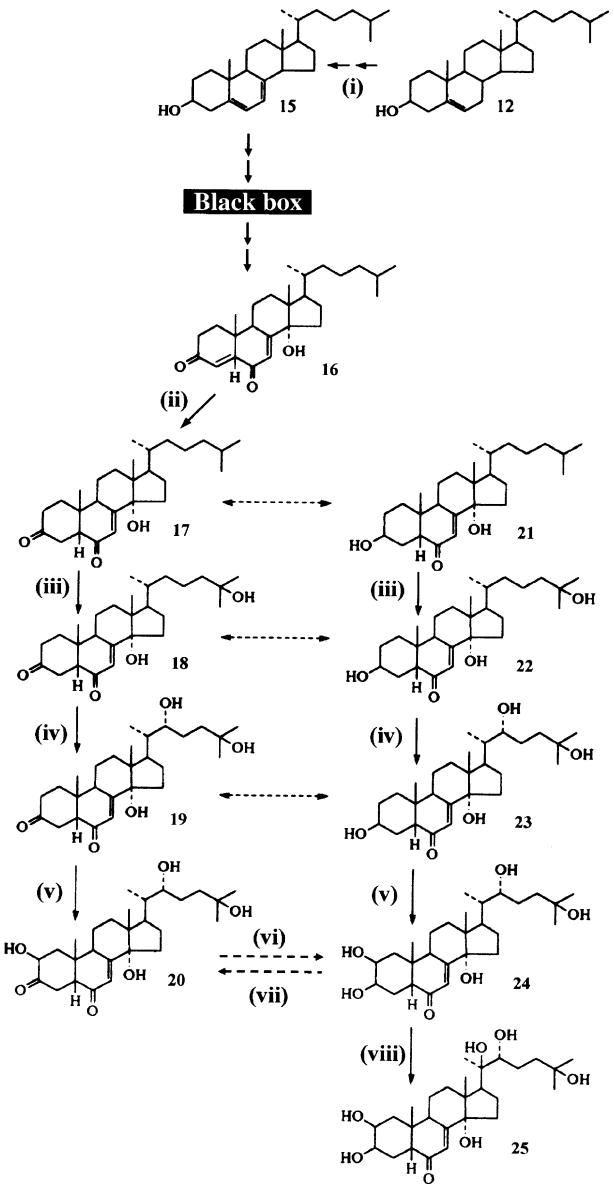


FIGURE 3 Composite scheme of ecdysteroid biosynthesis. Cytochrome P450-dependent formation of 7-dehydrocholesterol occurs in the microsomal fraction. Subsequent reactions (the "black box"; mitochondrial) yield the postulated intermediate, 5β-diketol (16), which then undergoes A-ring reduction to yield 3-dehydro-2,22,25-deoxy-ecdysone (17), and this may undergo further reduction to 2,22,25-deoxyecdysone (21; 5β-ketodiol). The latter two compounds may then undergo successive cytochrome P450-dependent hydroxylations at C-25 (microsomal) and C-22 and C-2 (both mitochondrial) to yield 3-dehydroecdysone (20) and ecdysone (24). Ecdysone undergoes 20-hydroxylation in certain peripheral tissues to yield the major active hormone, 20-hydroxyecdysone (25). Enzymes involved include (i) cholesterol 7,8-dehydrogenase; (ii) Δ^4-diketol-5β-reductase; (iii) 25-hydroxylase; (iv) 22-hydroxylase; (v) 2-hydroxylase; (vi) 3-dehydroecdysone 3β-reductase; (vii) ecdysone oxidase; and (viii) ecdysone 20-monooxygenase.

This Δ^4-diketol (16) intermediate can be reduced to diketol (17), thus, introducing the A/B *cis*-ring junction, characteristic of ecdysteroids. Such 5β-reductase activity has been demonstrated in crustacean tissues, being most active in the Y-organs. This NADPH-dependent enzymatic activity, which seems specific for 3-oxo-Δ^4 substrates, was characterized in the cytosolic fraction but is also present in the crude mitochondrial and microsomal fractions. Such characteristics appear to be similar to those of vertebrate 3-oxo-Δ^4-steroid 5β-reductases involved in steroid hormone catabolism and bile acid synthesis.

C. Terminal Hydroxylations

The terminal hydroxylation reactions leading to ecdysone (24) formation have been primarily investigated, until recently, using various high-specific-radioactivity ^{3}H-labeled substrates, including 5β-ketodiol (21) and 5β-diketol (17). As alluded to earlier, the demonstration that lepidopteran prothoracic glands produce 3-dehydroecdysone (20) in addition to ecdysone (24) raises the question as to the exact biosynthetic stage at which the 3-dehydro grouping arises. Evidence that a 3-oxo-Δ^4 moiety is likely involved in the formation of the A/B *cis*-ring junction was presented earlier. Whether such a putative 3-dehydro feature is preserved throughout the biosynthetic pathway to yield 3-dehydroecdysone (20) or whether the 3-dehydro moiety is (re)introduced independently at a subsequent stage(s) and the stage(s) at which reduction of any obligatory 3-dehydro moiety occurs to yield ecdysone (24) as the final product are all pertinent considerations. These questions will be considered again later and the various possibilities are exemplified in Fig. 3.

The C-2, C-22, and C-25 hydroxylases are all cytochrome P450-dependent enzymes, being O_2- and NADPH-dependent and inhibited by the classical cytochrome P450 inhibitors fenarimol, metyrapone, and piperonyl butoxide. However, surprisingly, unlike the 22- and 25-hydroxylases, the 2-hydroxylase activity is not inhibited by carbon monoxide. Hydroxylation at both C-2 and C-22 occurs with retention of configuration. As expected, these three hydroxylase activities occur in prothoracic glands, follicle cells, and crustacean Y-organs of all species examined, but surprisingly, several other tissues, in addition to these major accepted ecdysiosynthetic organs, can effect at least some of these hydroxylations, albeit at a much lower level. The physiological significance of this finding is an enigma, unless

such tissues can synthesize *de novo* or effect uptake from the hemolymph of a relevant precursor. Alternatively, such hydroxylations could conceivably be explained by the lack of substrate specificity of other unrelated cytochrome P450s.

Evidence in various species indicates that a major sequence of terminal hydroxylations involves hydroxylation at C-25, followed by C-22 and then C-2, without eliminating the possible operation of other sequences. Obviously, it is the combination of rates of individual steps that dictates the overall rate of a pathway and its dominance over others. The individual rates of the cytochrome P450-catalyzed reactions are reflected in the substrate and positional specificities of the P450s. In this respect, it is relevant that vertebrate steroidogenic P450s do not show absolute substrate or positional specificity. Clearly, the three terminal hydroxylases in ecdysone formation are distinct, since the two mitochondrial P450s (C-2 and C-22) not only differ in their CO sensitivity, but are encoded by different genes (see below), whereas the C-25 P450 is microsomal. Thus, it is also evident that extensive shuttling of intermediates between the endoplasmic reticulum and the mitochondria occurs during various stages of ecdysteroid biosynthesis, as occurs in vertebrate steroidogenesis.

Very recently, it has been shown that the wild-type genes corresponding to two members of the Halloween family of embryonic lethal mutations, *disembodied (dib)* and *shadow (sad)*, code for the mitochondrial cytochrome P450s that catalyze the 22- and 2-hydroxylations, respectively. Conceptual translation showed that both proteins possessed characteristic N-terminal mitochondrial import sequences. Hydroxylation activities of the expressed proteins were established by transfection of the *sad* (CYP315A1) and *dib* (CYP302A1) genes into *Drosophila* S2 cells, prior to incubation with appropriate [^{3}H]ecdysteroid precursors. Interestingly, *in situ* hybridization analyses have revealed that *sad* and *dib* expression is concentrated within the individual segments of the developing epidermis when there is a surge of ecdysteroid midway through embryogenesis, before the ring gland has developed, and suggests that the embryonic epidermis is a site of ecdysteroid biosynthesis. This expression then diminishes, and during late embryogenesis, expression of both genes is concentrated in the prothoracic gland cells of the developing ring gland. Furthermore, expression of both genes continues to be localized in these endocrine cells during larval development, being maximal at approximately the time of the premolt peaks in the ecdysteroid titer in late second- and third-instar larvae. As expected, expression was also observed in the follicle cells of the adult ovary.

Current evidence suggests parallel operation of both 3-dehydro and 3β-hydroxy routes to ecdysone (Fig. 3) but the exact points of interaction between them are uncertain. However, this may not apply to all systems, since the products of [^{3}H]5β-diketol (17) and [^{3}H]5β-ketodiol (21) metabolism may not always reflect the normal situation. The proportions of different ecdysteroid products may be explained by postulating that different steps are rate-limiting in various systems. For example, in lepidopteran prothoracic glands producing a preponderance of 3-dehydroecdysone, it can be assumed that a 3-dehydrosteroid 3β-reductase becomes limiting, thus, increasing the ratio of 3-dehydroecdysone/ecdysone product. There is no information on the enzymes catalyzing interconversion of the 3-dehydro and 3β-hydroxy moieties of the various intermediates in ecdysone biosynthesis in the prothoracic glands or follicle cells. Ecdysone oxidase, an enzyme that catalyzes oxidation of 3β-hydroxy ecdysteroids to the 3-dehydro derivatives, has been characterized in peripheral tissues and conceivably could be involved in oxidation of later intermediates in the pathway in prothoracic glands. As alluded to earlier, 3-dehydroecdysone (20), with lesser amounts of ecdysone (24), is a major product of the prothoracic glands in many lepidopteran species. The 3-dehydroecdysone (20) is reduced in the hemolymph by an NAD(P)H-dependent 3β-reductase enzyme, which is a member of the aldo-keto reductase superfamily. The 3-dehydroecdysone 3β-reductase mRNA transcripts in the cotton leafworm, *Spodoptera littoralis*, are widely distributed in various tissues, with a developmental profile that accounts for the peak in enzymatic activity just preceding the ecdysteroid peak during the instar.

IV. ECDYSONE 20-MONOOXYGENASE

In immature stages of insects, ecdysone (24) produced in the prothoracic glands is transported to certain peripheral tissues, where it undergoes ecdysone 20-monooxygenase-catalyzed hydroxylation to yield 20-hydroxyecdysone (25). This 20-hydroxylation reaction is important, since 20-hydroxyecdysone is generally far more active than ecdysone in most assays and is believed to generally represent the major active ecdysteroid, although other compounds, including ecdysone, may have activity per se in certain biological systems. The 20-monooxygenase

system occurs in several peripheral tissues, primarily in the fat body, midgut, and Malpighian tubules. Depending on species and tissue, it may occur in either mitochondrial or microsomal subcellular fractions or in both. The enzyme system requires NADPH and O_2 and is a typical cytochrome P450-dependent monooxygenase. The enzyme exhibits competitive inhibition by its product, 20-hydroxyecdysone.

It has been demonstrated in the final larval instar of several insect species that the 20-monooxygenase activity undergoes developmental changes, generally exhibiting a distinct peak. In some species, this peak coincides with the peak hemolymph ecdysteroid titer, whereas in others, the peaks are out of phase. The exact physiological significance of the latter situation is somewhat of an enigma. The molecular mechanisms involved in the regulation of the ecdysone 20-monooxygenase activity during development are not known. In the fat body of the cotton leafworm, *S. littoralis*, the ecdysone 20-monooxygenase is largely mitochondrial. When such extracts were subjected to immunoblot analyses using antibodies raised against components of vertebrate mitochondrial steroidogenic systems, anti-cytochrome $P450_{SCC}$, anti-cytochrome $P450_{11\beta}$, anti-adrenodoxin, and anti-adrenodoxin reductase antibodies revealed the presence of specific immunoreactive polypeptides. Furthermore, these antibodies effectively inhibited the mitochondrial ecdysone 20-monooxygenase activity, suggesting that the insect hydroxylating system may contain polypeptide components analogous to those in vertebrates. Correlation between developmental changes in mitochondrial 20-monooxygenase activity and the abundance of polypeptides recognized by anti-cytochrome $P450_{11\beta}$ antibody and a polypeptide recognized by the anti-adrenodoxin reductase antibody was observed, suggesting that developmental changes in the abundance of components of the monooxygenase system may be important in developmental regulation of enzyme expression. Furthermore, in these *S. littoralis* fat body mitochondrial (and microsomal) ecdysone 20-monooxygenase systems, indirect evidence that the enzyme may exist in an active phosphorylated state and an inactive dephosphorylated state has been furnished. This tenet awaits more direct confirmation, but such covalent modification potentially provides short-term, rapid modulation of the enzymatic activity in response to unidentified effectors. It is noteworthy that the adrenodoxin reductase gene (*dare*) has been identified in *Drosophila*, together with a sequence in the genome putatively encoding adrenodoxin.

V. SUMMARY

Insects cannot synthesize sterols *de novo* and thus must obtain cholesterol for ecdysteroid synthesis from the diet, either directly or following phytosterol dealkylation. The principal sites of ecdysteroid synthesis in immature stages of insects are the prothoracic glands, whereas in adults synthesis occurs either in the ovarian follicle cells or in the testes. 7-Dehydrocholesterol is an early intermediate in the pathway and although subsequent early steps are unclear, there is good evidence for the intermediacy of 2,22,25-trideoxy-ecdysone (5β-ketodiol) or its 3-dehydro derivative. Subsequent cytochrome P450-dependent hydroxylations at C-25, C-22, and C-2 yield ecdysone, which then undergoes 20-monooxygenase-catalyzed hydroxylation in several peripheral tissues to yield the major active hormone, 20-hydroxyecdysone.

Glossary

arthropods Animals possessing a hard, jointed exoskeleton and constituting the largest group (phylum) in the animal kingdom in terms of numbers of species, e.g., insects, crabs, spiders, and centipedes.

cytochrome P450 A family of heme-containing proteins that reduce molecular oxygen, one atom of which is incorporated into the substrate as a hydroxyl group. When these proteins use steroids as substrates, they are frequently called steroid hydroxylases. Cytochrome P450s derive their name from their characteristic absorption of light at 450 nm when carbon monoxide is bound.

Drosophila The fruit fly, a commonly used model organism.

ecdysteroids A unique class of steroids characteristic of arthropods, possessing the full cholesterol side chain (unlike most vertebrate steroids) and several hydroxyl groups. They act as hormones (regulators) controlling molting and aspects of reproduction.

microsomes Closed vesicles formed during fragmentation of the endoplasmic reticulum membrane system in eukaryotic cells, i.e., cells having the nucleus separated from the cytoplasm by a nuclear membrane and the genetic material borne on a number of chromosomes.

mitochondria Oval-shaped subcellular organelles in eukaryotic organisms that are responsible for producing ATP, the immediately available energy store.

monooxygenases A class of enzyme (catalyst) also called "mixed-function oxygenases" because one atom of oxygen appears in the reaction product and the other in water. The majority of hydroxylases, including the steroid hydroxylases, belong to this class of enzymes.

prothoracic glands Paired organs in the prothorax (region between the head and thorax) of insects, which are the major site of ecdysteroid synthesis in insect larvae.

sterols Compounds having three 6-sided carbon rings, one 5-sided carbon ring, and a side chain, e.g., cholesterol.

Ecdysteroid Receptors (EcR/USP)

MARGARETHE SPINDLER-BARTH AND KLAUS-DIETER SPINDLER
University of Ulm, Germany

The heterodimer of the ligand-dependent transcription factors ecdysteroid receptor (EcR) and USP is considered as functional ecdysteroid receptor that coordinates arthropod development and metabolism and modifies the expression of a multitude of different genes in a tissue- and time-specific manner. As is typical for steroid hormone receptors in general, the different functions of this receptor are associated with defined molecular domains, which are modified by intra- and intermolecular interactions. Both EcR and USP can dimerize with several other transcription factors, but homodimerization has been described for both partners as well. Isoforms of EcR and USP are detected in various species and are engaged in different functional roles. Species-specific variations demonstrate that different solutions have evolved within arthropods. The ecdysteroid receptor is an important target for insecticides and is also used as a ligand-controlled switch in heterologous systems for gene expression.

I. MOLECULAR CHARACTERIZATION OF EcR

A. General Features

Thus far, the ecdysteroid receptor (EcR) has been sequenced from 12 insects, a crustacean, and a tick. The common features of EcRs include a highly conserved two-zinc-finger DNA-binding domain, which shares a considerable level of sequence identity with vertebrate steroid hormone receptors (Table 1), an A/B domain, which in most instances is responsible for transactivation, and a D–F domain, which, in addition to binding ligand, mediates various other functions (Fig. 1). The degree of sequence identity that EcRs share with vertebrate steroid receptors is considerably lower than that within arthropods.

Ecdysteroids, Overview

RENÉ LAFONT, CHANTAL DAUPHIN-VILLEMANT, AND CATHERINE BLAIS
Université Pierre et Marie Curie, Paris

Ecdysteroids are polyhydroxylated steroid hormones that control arthropod development and reproduction. Whether they also fulfill endocrine functions in lower invertebrate phyla is still conjectural. Their wide distribution in the plant kingdom as secondary metabolites results in their frequent presence in animals' diets; hence, when they are found in a given animal species, a demonstration of their endogenous origin is required. Different arthropod species may contain different ecdysteroids, and the variations concern in particular the number of carbon atoms (which is related to the sterol precursors used) and the number of hydroxyl groups. In addition, a single insect species may contain several molecules, but whether those have specific receptors (and thus possibly different physiological roles) or simply bind with various affinities to a single type of receptor remains an unanswered question.

I. INTRODUCTION

Evidence that molting and metamorphosis of insects are under hormonal control was provided by Kopec's pioneering experiments as early as 1917. Kopec demonstrated that a blood-borne factor originating in the brain was necessary for caterpillar molting, and this was in fact the first demonstration that the nervous system was able to secrete hormones (i.e., the first experimental demonstration of neurosecretion). Evidence that this brain hormone was relayed by a molting hormone produced by (pro)thoracic glands was obtained much later by Fukuda in 1941.

Ligation experiments by Fraenkel in 1935 provided the basis for a molting hormone bioassay; posterior portions (i.e., lacking the molting glands) of ligated *Calliphora erythrocephala* larvae could pupate when injected with a solution containing molting hormone, and this bioassay was used for the isolation of the hormone from silkworm pupae. Starting from 500 kg of pupae and using a combination of several chromatographic procedures, in 1954 Butenandt and Karlson obtained 25 mg of pure crystalline ecdysone, a quantity that did not allow determination of its structure by the physicochemical techniques available at that time (by comparison, modern nuclear magnetic resonance techniques would have allowed this to be completed within a single day using a few milligrams of ecdysone). The structure of ecdysone was elucidated 11 years later thanks to X-ray analysis.

The identification of ecdysone as a steroid was a surprise, as this molecule is very polar due to a large number of hydroxyl groups (Fig. 1). Ecdysone (E) was at first termed α-ecdysone, and a minor compound simultaneously isolated from *Bombyx mori* pupae was termed β-ecdysone. The latter was also isolated from a crustacean and proved to be in fact the major hormone in most arthropod species; it is now called 20-hydroxyecdysone (20E). Related compounds were then found in plants and this discovery stimulated extensive research. The generic name "ecdysteroid" was proposed by Goodwin *et al.* in 1978 for all the compounds "structurally related to ecdysone." The discovery of large amounts of ecdysteroids in plants made them available to many laboratories and was decisive for the development of research in insect endocrinology.

II. CHEMICAL DIVERSITY (IN ARTHROPODS)

A. Definition of Ecdysteroids

Whether ecdysteroids should be defined by using their chemical structure and/or their biological activity (as molting hormones) is a matter of debate, and a chemical definition is used in this article.

Their definition as compounds structurally related to ecdysone is indeed simple but it does not seem precise enough from a chemical point of view. In 1989, Lafont and Horn defined true ecdysteroids as "compounds where the steroid nucleus bears a *cis*-fused A/B ring junction, a 7-ene-6-one chromophore and a 14 α-OH" (Fig. 2), irrespective of being biologically active. Such a definition is still not fully satisfactory, as it leaves out very closely related compounds that may even co-occur with true ecdysteroids within the same animal or plant. Therefore, the limits of the ecdysteroid family are quite difficult to define, as will be exemplified below.

B. Ecdysteroids and Their Parent Sterols

Arthropods are auxotroph for sterols, which are the precursors of ecdysteroids. The food of carnivorous or phytophagous insects contains either zoosterols, which are 27C molecules (in fact, mainly cholesterol), or phytosterols, which have either a 28C (e.g., campesterol, ergosterol) or a 29C (e.g., sitosterol, stigmasterol) skeleton. Most but not all phytophagous insects are able to dealkylate phytosterols and to convert them into cholesterol. Thus, according to their diet and their ability or inability to dealkylate phytosterols, insects contain 27C, 28C, and/or 29C sterols and they will accordingly produce ecdysteroids with different carbon skeletons (Table 1). The 28C and 29C ecdysteroids are found in phytophagous Hemiptera and Hymenoptera and also in *Drosophila melanogaster*. In *Drosophila*, as is also the case in some Hymenoptera, it has been shown that the proportions of the different ecdysteroids depend on the nature of the dietary sterols. This finding raises an interesting question concerning the substrate specificity of the ecdysteroid biosynthetic enzymes and also the ligand-binding properties of insect receptors. *Drosophila* can use both 27C and 28C molecules, whereas other species require specifically 27C or 28C molecules, as shown by the relative biological activities of exogenous 20E or makisterone A.

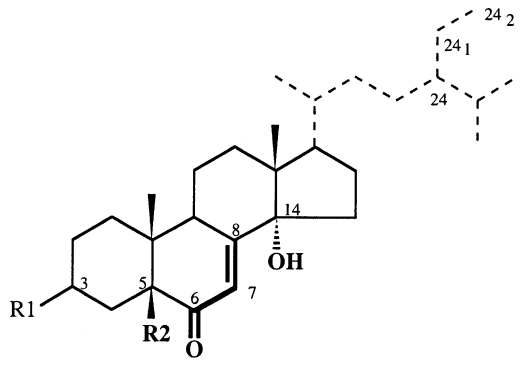

FIGURE 2 Common structural features of ecdysteroids (R1 = OH or O; R2 = H or OH).

TABLE 1 Relationship between Dietary Sterols and Ecdysteroid Structures

Dietary sterols	Dealkylation	Major ecdysteroid
27C	Indifferent	20-Hydroxyecdysone (or ponasterone A)
28C/29C	+	20-Hydroxyecdysone
28C	−	Makisterone A (or 24-epi-makisterone A)
29C	−	Makisterone C

C. The Major Ecdysteroid Hormones

In all classes of arthropods, similar major ecdysteroid hormones are produced by steroidogenic organs. The major circulating hormone or "active ecdysteroid" of insects and crustaceans is most commonly 20E and makisterone A or makisterone C, respectively, for the phytophagous species that produce 28C or 29C ecdysteroids. Endocrine glands usually release a "pro-hormone," a precursor that is E, 3-dehydroecdysone (3DE), or a mixture of the two (or their 24-Me or 24-Et analogues in the above-mentioned phytophagous species). Conversion to the biologically active form always requires a hydroxylation at position 20 and eventually a reduction of the 3-ketone into the corresponding 3β alcohol. 20-Hydroxylation takes place mainly in fat body, gut, and Malpighian tubules and most probably occurs in all tissues, whereas 3β reduction takes place both in hemolymph (immediately following 3DE secretion) and in peripheral tissues. As a consequence, the half-life of molting gland secretory products is usually very short; thus, the isolation of E from *Bombyx* pupae resulted from the use of a very particular biological system in which this compound accumulates temporarily, which is not at all representative of the general situation. There are other exceptions to the rule; e.g., the molting glands of the beetle *Zophobas atratus*

produce 2-deoxyecdysone (2dE) together with E. Given the small number of insect species analyzed thus far relative to the one million species known, it is possible that more variability exists.

The situation in Crustacea is very similar to that in Insecta, and the molting glands (Y-organs) of crustaceans usually secrete E and (or) 3DE, but in this case 3β-reductase seems only tissular. Several crab species contain another major ecdysteroid, ponasterone A (PonA), i.e., the 25-deoxy analogue of 20E. Their molting glands produce 25-deoxyecdysone, due to a low level of activity of the enzyme responsible for the 25-hydroxylation. These crabs contain a mixture of PonA and 20E, and it is not known whether these molecules have specific functions. PonA has also been found in *Thermobia*, a primitive insect. Amazingly, PonA is much more active than 20E in many bioassays using insect species (including *Drosophila*) although they do not produce this molecule.

The question of the biologically active form(s) of ecdysteroids in a given species is still open. Although several biological systems exist in which E and 20E elicit different responses, attempts to find specific receptors for a given ecdysteroid have thus far been unsuccessful. The *Drosophila* ecdysone (20E) receptors exist as three isoforms, but all of them share the same ligand-binding domain, a situation that does not support their specific binding to different ecdysteroids. The existence of a receptor that would specifically bind E cannot be ruled out, and this would make sense for the accumulation of E at specific developmental stages: E is the major ecdysteroid in young *Bombyx* pupae, and during pupal–adult development of *Pieris brassicae* and *Manduca sexta*, successive peaks of E and 20E are observed. E is also present in mid third-instar larvae of *Drosophila* and might activate a specific nuclear receptor. A role for 3-oxo ecdysteroids is more difficult to establish, due to their rapid interconversion with 3β-OH molecules.

D. Other Biologically Active Ecdysteroids

Ecdysteroids are not only produced during larval development, they are also involved in the control of insect reproduction. The gonads of adult insects synthesize ecdysteroids. Both vitellogenic oocytes and newly laid eggs often contain high levels of ecdysteroids, which are produced by the follicular cells of the ovaries, are stored within the vitellus, and are probably used during early embryogenesis, before molting glands begin to differentiate.

In many insect species, these "maternal" ecdysteroids are E and 20E or analogues of E that either lack some –OH groups, mainly at positions 2 and/or 22 (precursors perhaps?), or bear additional –OH groups at unusual positions (positions 16, 23, or 26). They are essentially conjugated to polar or apolar moieties, and these conjugates are considered biologically inactive storage compounds. For example, large amounts of 2dE are stored in *Locusta migratoria* eggs, which are later activated by "steroidogenic enzymes" present in embryonic tissues. Such a conclusion is supported by the observation that normal development can take place within both anterior and posterior half-cut embryos and by recent expression studies on a steroidogenic cytochrome P450 enzyme (CYP302A1, the product of the *dib* gene) in early *Drosophila* embryos. Alternatively, less hydroxylated compounds could function as true "hormones"; thus, in *Locusta*, a role for 2dE in the control of meiotic reinitiation has been suggested.

M. sexta eggs accumulate huge amounts of another ecdysteroid, 26-hydroxyecdysone (26E). This ecdysteroid, which is considered a catabolite devoid of biological activity during larval and adult stages, appears to be a likely candidate hormone in the embryo, since the level of free 26E peaks during early embryonic development, when embryonic cuticle is secreted.

In *Bombyx* eggs, a wide array of ecdysteroids have been identified, including minor compounds that bear additional –OH groups at unusual positions (positions 16, 23, etc.). It is not clear whether this molecular diversity has any biological significance, whether it is unique to this stage, or whether it has been found here simply because the large amounts of available biological material and the extremely high ecdysteroid levels have allowed the identification of the minor ecdysteroids. Similar "cocktails" have also been found in several ecdysteroid-rich plant species in which extensive chemical investigations have been undertaken.

III. DISTRIBUTION–EVOLUTION

A. Which Animals Contain Ecdysteroids?

The ecdysteroid family comprises more than 300 members, i.e., ca. 70 molecules isolated from animals (zooecdysteroids) and 250 from plants (phytoecdysteroids), with some compounds being found in both phyla. These molecules are listed in the *Ecdysone Handbook* (see http://ecdybase.org) (see also Table 2).

TABLE 2 Major Variations on the 20-Hydroxyecdysone Molecule (Zooecdysteroids Only)

Type	Positions on the molecule
Hydroxyl groups	
Additional –OH	11α, 16β, 23, 26
Missing –OH	2, 14, 20, 22, 25
Oxidation	
(>CHOH ⇒ >C=O)	3
($-CH_2OH$ ⇒ –COOH)	26
Epimerization	3α/3β
Alkyl substitution	24 (Me, Et)
Side-chain cleavage between C20 and C22	Poststerone
Esterification	
Acetic acid	2, 3, 22, 25
Glycolic acid	22
Fatty acid	22
Phosphoric acid	2, 22, 26
Nucleotide	22
Etherification	
Glucosides	22, 25, 26

Note: ME, methyl; ET, ethyl.

Ecdysteroids are not restricted to Arthropoda. They have also been isolated from more primitive invertebrates, including Annelida, Helmintha, Cnidaria, and even Porifera, but (with the exception of Cnidaria and Porifera) their concentrations are very low. An endogenous origin (i.e., the unambiguous demonstration of *de novo* biosynthesis from cholesterol) has thus far been obtained only in arthropods. There is in fact a discrepancy between the chemical nature of the compounds (E, 20E, and 20,26-dihydroxy-ecdysone) identified in helminths and annelids and the failure to detect several key hydroxylation steps that would be required to produce them (at least when using the precursors that are efficiently converted in insects). Thus, no 2-hydroxylation could be demonstrated in myriapods, annelids, or helminths, and 22-hydroxylation was observed only in arthropods.

In many instances, a dietary origin of these ecdysteroids cannot be ruled out (e.g., for sea anemones, which feed on planktonic Crustacea), but such an explanation does not apply so easily to all cases (e.g., for leeches).

B. Ecdysteroid-Related Molecules and the Origin of Ecdysteroids

Ecdysteroids are multifunctional molecules and their biosynthesis requires probably at least 8–10 steps and thus 8–10 enzymes (including a large set of cytochrome P450 mono-oxygenases, a 3β-hydroxysteroid dehydrogenase, and a 5β-reductase). As is the case for vertebrate-type steroids, it seems unlikely that all these enzymes have appeared simultaneously, and we may therefore expect to find "protoecdysteroids" in primitive arthropods and also in nonarthropod invertebrates.

Although the lack of biosynthetic studies does not allow determination of whether these molecules have an endogenous origin, an impressive number of ecdysteroid-related molecules have been isolated from nonarthropod invertebrates. At present, such molecules do not have any established function, but the structures of some of these make them likely candidate protoecdysteroids. We may assume that classical ecdysteroids arose from the progressive appearance of CYP450-catalyzed hydroxylation reactions, and in this respect, the mitochondrial steps (2- and 22-hydroxylations) would probably have been the last to appear. This hypothesis is consistent with the isolation from invertebrates of cholesterol derivatives bearing hydroxyl groups at positions 20 and 25 and lacking hydroxyl groups at positions 2 and 22. For the B ring substituents, many oxysterols that have a 7,8-ene and a 6-one, a 5,6-diol, or a 5,7-diene-3,6-dione (Fig. 3) have been isolated.

The incomplete elucidation of the ecdysteroid biosynthetic pathway, concerning in particular the formation of the 7-ene-6-one-14αOH chromophore, does not allow a precise evolutionary scenario to be proposed as yet. Steroids of interest include compounds isolated from insects, which co-occur with ecdysteroids, e.g., bombycosterol in *Bombyx* ovaries and a steroid from exocrine (defensive) secretions of a Chrysomelid beetle (Fig. 3). It would be of great interest to determine whether bombycosterol is synthesized by follicle cells that produce ecdysteroids.

Oxysterols have recently become the subject of increasing interest, as they are natural ligands for formerly termed "orphan" nuclear receptors and they control a large set of cellular processes in vertebrates. It seems reasonable to expect that oxysterols play fundamental roles in invertebrates too and that among these molecules some have further evolved to give the currently known ecdysteroids.

Finally, it is worth mentioning that ecdysteroids do not always act as hormones. They can also be used as signaling substances by diverse sensory systems, which most probably involves their binding to membrane proteins. Very low concentrations of ecdysteroids evoke action potentials on lobster antennae, and it has been suggested that they might be used as sex pheromones. The huge amounts

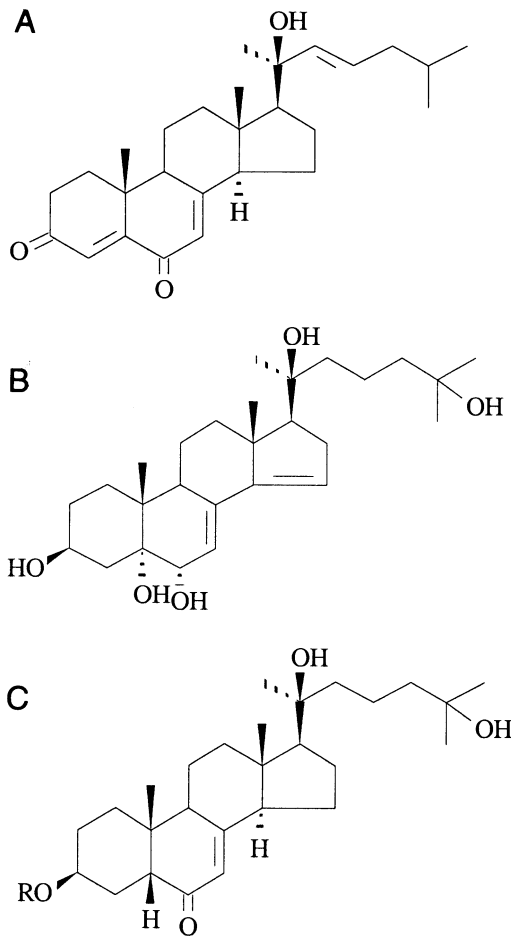

FIGURE 3 (A) An oxysterol from a sponge. (B) Structure of bombycosterol from silkworm ovaries/eggs. (C) A defensive steroid from a Chrysomelid beetle (R = sophorose).

of ecdysteroids that accumulate in the integument of pycnogonids can be rapidly released in water when the animal is attacked by crabs, and this reaction seems efficient enough to deter the crabs from eating them. These defensive effects are to some extent similar to those that phytoecdysteroids have on insects; when the phytoecdysteroids are detected by insect taste receptors, they exert an anti-feedant effect, and this could be the *raison d'être* for the presence of ecdysteroids in so many plant species.

Glossary

cytochrome P450 A heme–iron protein that uses molecular oxygen and NADPH to oxidize a substrate and produce a water molecule (this reaction is termed mono-oxygenation).

ecdysone 2β,3β,14α,22*R*,25-Pentahydroxy-5β-cholest-7-ene-6-one.

20-hydroxyecdysone 2β,3β,14α,20*S*,22*R*,25-Hexahydroxy-5β-cholest-7-ene-6-one.

3*β*-hydroxysteroid dehydrogenase A membrane-bound enzyme that catalyzes the reversible conversion of a 3β-OH into a 3-keto group.

makisterone A 2β,3β,14α,20*S*,22*R*,25-Hexahydroxy-5β-ergost-7-ene-6-one.

makisterone C 2β,3β,14α,20*S*,22*R*,25-Hexahydroxy-5β-stigmast-7-ene-6-one.

ponasterone A 2β,3β,14α,20*S*,22*R*-Penta-hydroxy-5β-cholest-7-ene-6-one.

prohormone The product of an endocrine gland that requires further modification (before or after its secretion) to become biologically active.

5*β*-reductase A cytosolic enzyme that reduces a 4,5 double bond with the formation of a *cis*-bond between cycles A and B.

Effectors

TAE H. JI, YONG SANG SONG, AND INHAE JI
University of Kentucky

Effectors are enzymes that can generate second messengers, which in turn trigger other molecules in hormone signaling pathways. Common effectors include adenylyl cyclase, phospholipase C, and Ca^{2+} channels. Effectors are usually regulated by guanine nucleotide-binding proteins in response to hormones binding to receptors.

I. INTRODUCTION

Nearly 2000 seven-transmembrane domain (TM) receptors have been reported, and they share a general structure consisting of an N-terminal extracellular domain (exodomain), seven TMs, three extracellular loops (exoloops), three cytoplasmic loops (cytoloops), and a C-terminal cytoplasmic tail (cytotail) as shown in Fig. 1. These receptors associate with guanine nucleotide-binding protein (G-protein) and therefore are referred to as G-protein-coupled receptors (GPCRs). This receptor family is the major class of hormone receptor and represents more than 1% of the human genome. GPCRs are responsible for binding a wide spectrum of hormones from odorants, biogenic amines, nucleosides, eicosanoids, and lipid moieties (lysophosphatidic acid and sphingosine-1-phosphate) at the cell surface and trigger hormone actions. Hormones are considered first messengers that are produced by an originating tissue and sent to targets. At the target they bind to the exodomain, exoloops, and/or TM domain of the receptors, which is thought to modulate the receptor conformation and interaction with G-proteins. G-protein is a heterotrimeric protein consisting of the α-, β-, and γ-subunits. Gα has 17 isoforms, which are divided into four groups. The Gαs group has Gαs and Gαo; the Gαi group consists of Gαi1, Gαi2, Gαi3, GαoA, GαoB, Gαt1, and Gαt2; the Gαq group comprises Gαq, Gα11, Gα14, Gα15, and Gα16; and the Gα12 group consists of Gα12 and Gα13. Seven Gβ isoforms and 12 Gγ isoforms have been cloned. The combination of these isoforms of the three G-subunits produces a wide variety of the trimeric G-proteins specific for effectors and tissues.

Effectors are generally enzymes that are capable of generating second messengers, which in turn trigger other molecules along the hormone signal pathways. The common effectors are adenylyl cyclase, phospholipase C, and Ca^{2+} channels. Generally, adenylyl cyclase is activated by Gαs to produce cAMP and is suppressed by Gαi to reduce the cAMP concentration. Phospholipase Cβ (PLCβ) is activated by Gαq to hydrolyze phospholipids and to produce diacylglycerol (DAG) and inositol phosphate (IP). Ca^{2+} channels are activated by protein kinase C and suppressed by Gβγ. Ca^{2+} channels also regulate adenylyl cyclases, PLCβ, ion channels, and phosphoinositide 3-kinases.

Although the majority of GPCRs mediate signal transduction via G-proteins, recent evidence indicates that some of these receptors are also capable of interacting with and sending signals to alternative signal molecules independent of G-proteins, e.g., Jak2 kinase, phospholipase Cγ, or protein kinase C. These alternative pathways are an indication of the functional diversity of the GPCR superfamily. Furthermore, there are putative seven-transmembrane molecules that do not appear to be coupled to a G-protein.

This article describes common effectors such as adenylyl cyclase, phospholipase Cβ, and Ca^{2+} channels and briefly describes some other effectors as well.

II. ADENYLYL CYCLASE

Adenylyl cyclase is an enzyme that produces cAMP by hydrolyzing ATP to produce cAMP, which in turn activates protein kinase A to phosphorylate target proteins and induces protein–protein interactions independent of phosphorylation. In response, target cells undergo physiological changes and gene expression. It is generally known that the enzyme is activated by Gαs and inactivated by Gαi. It has

Effectors

TAE H. JI, YONG SANG SONG, AND INHAE JI
University of Kentucky

Effectors are enzymes that can generate second messengers, which in turn trigger other molecules in hormone signaling pathways. Common effectors include adenylyl cyclase, phospholipase C, and Ca^{2+} channels. Effectors are usually regulated by guanine nucleotide-binding proteins in response to hormones binding to receptors.

I. INTRODUCTION

Nearly 2000 seven-transmembrane domain (TM) receptors have been reported, and they share a general structure consisting of an N-terminal extracellular domain (exodomain), seven TMs, three extracellular loops (exoloops), three cytoplasmic loops (cytoloops), and a C-terminal cytoplasmic tail (cytotail) as shown in Fig. 1. These receptors associate with guanine nucleotide-binding protein (G-protein) and therefore are referred to as G-protein-coupled receptors (GPCRs). This receptor family is the major class of hormone receptor and represents more than 1% of the human genome. GPCRs are responsible for binding a wide spectrum of hormones from odorants, biogenic amines, nucleosides, eicosanoids, and lipid moieties (lysophosphatidic acid and sphingosine-1-phosphate) at the cell surface and trigger hormone actions. Hormones are considered first messengers that are produced by an originating tissue and sent to targets. At the target they bind to the exodomain, exoloops, and/or TM domain of the receptors, which is thought to modulate the receptor conformation and interaction with G-proteins. G-protein is a heterotrimeric protein consisting of the α-, β-, and γ-subunits. Gα has 17 isoforms, which are divided into four groups. The Gαs group has Gαs and Gαo; the Gαi group consists of Gαi1, Gαi2, Gαi3, GαoA, GαoB, Gαt1, and Gαt2; the Gαq group comprises Gαq, Gα11, Gα14, Gα15, and Gα16; and the Gα12 group consists of Gα12 and Gα13. Seven Gβ isoforms and 12 Gγ isoforms have been cloned. The combination of these isoforms of the three G-subunits produces a wide variety of the trimeric G-proteins specific for effectors and tissues.

Effectors are generally enzymes that are capable of generating second messengers, which in turn trigger other molecules along the hormone signal pathways. The common effectors are adenylyl cyclase, phospholipase C, and Ca^{2+} channels. Generally, adenylyl cyclase is activated by Gαs to produce cAMP and is suppressed by Gαi to reduce the cAMP concentration. Phospholipase Cβ (PLCβ) is activated by Gαq to hydrolyze phospholipids and to produce diacylglycerol (DAG) and inositol phosphate (IP). Ca^{2+} channels are activated by protein kinase C and suppressed by Gβγ. Ca^{2+} channels also regulate adenylyl cyclases, PLCβ, ion channels, and phosphoinositide 3-kinases.

Although the majority of GPCRs mediate signal transduction via G-proteins, recent evidence indicates that some of these receptors are also capable of interacting with and sending signals to alternative signal molecules independent of G-proteins, e.g., Jak2 kinase, phospholipase Cγ, or protein kinase C. These alternative pathways are an indication of the functional diversity of the GPCR superfamily. Furthermore, there are putative seven-transmembrane molecules that do not appear to be coupled to a G-protein.

This article describes common effectors such as adenylyl cyclase, phospholipase Cβ, and Ca^{2+} channels and briefly describes some other effectors as well.

II. ADENYLYL CYCLASE

Adenylyl cyclase is an enzyme that produces cAMP by hydrolyzing ATP to produce cAMP, which in turn activates protein kinase A to phosphorylate target proteins and induces protein–protein interactions independent of phosphorylation. In response, target cells undergo physiological changes and gene expression. It is generally known that the enzyme is activated by Gαs and inactivated by Gαi. It has

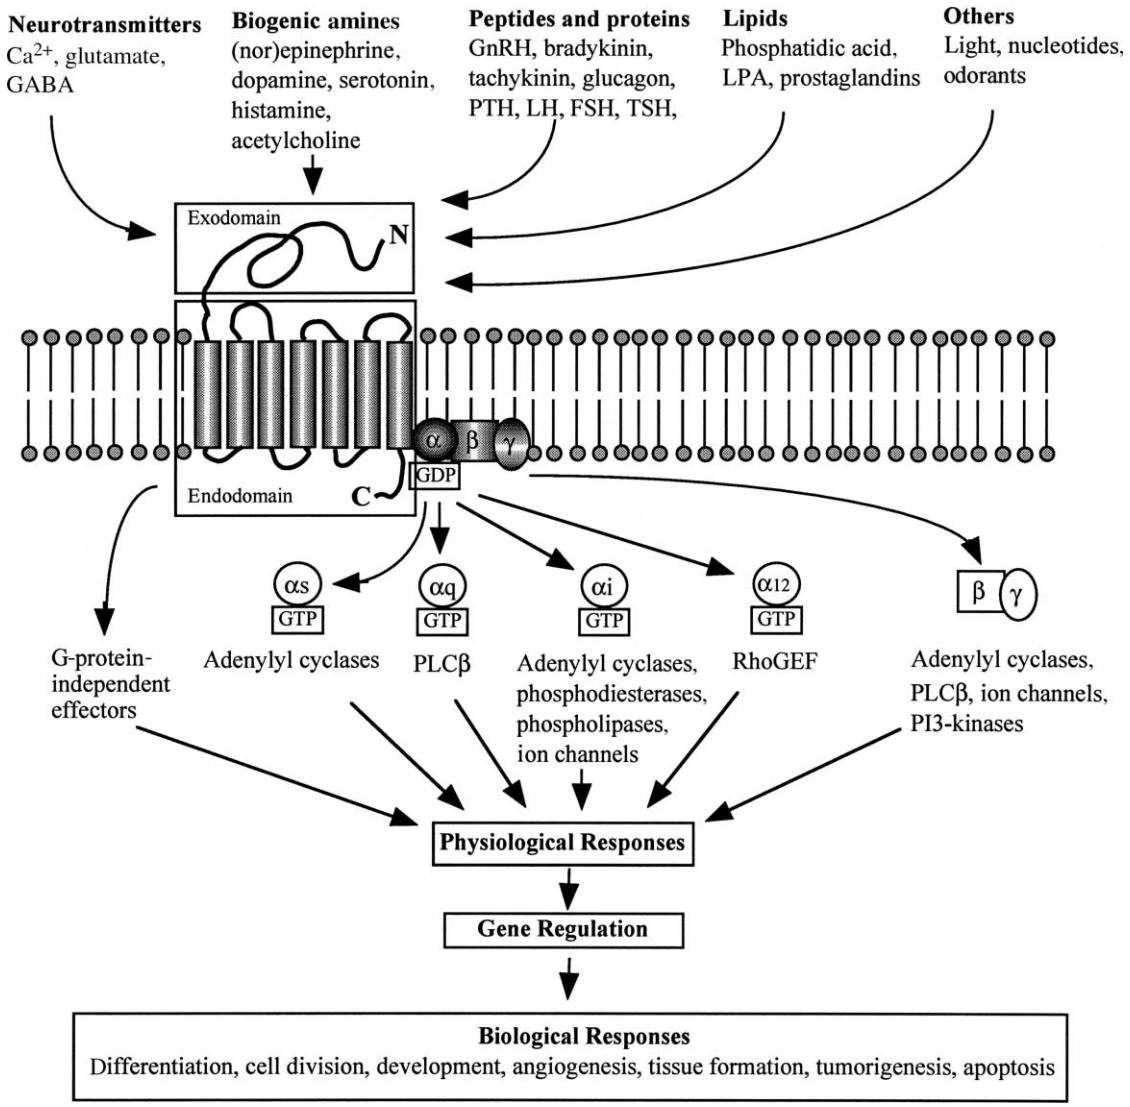

FIGURE 1 Network of G-protein-coupled receptors from hormones to effectors and their biological responses. A wide variety of hormones from small neurotransmitters, biogenic amines, peptides, proteins, lipids, and other molecules bind to the large number of G-protein-coupled receptors. The hormone binding activates diverse G-protein isoforms, which in turn regulate a wide spectrum of effectors. Other effectors that are not linked to G-proteins are also regulated by the receptors. These effectors elicit various physiological responses and regulation of various genes, leading to diverse biological responses.

a number of isoforms: nine membrane-bound isoforms and one soluble form have been cloned.

A. Activity and Structure

All adenylyl cyclases are activated by both forskolin (a diterpene extracted from plants) or GTP-bound Gαs (GTP/Gαs). Adenylyl cyclase is inhibited by adenosine analogues termed P-site inhibitors such as 2′-deoxy-3′-cAMP. In addition, Ca^{2+}/calmodulin can activate some isoforms (Table 1). The membrane-bound adenylyl cyclases have molecular weights of approximately 120 kDa with nearly 1200 amino acids. Amino acid sequence analysis show a short amino-terminal extension, 12 TMs, suggesting a complex organization (Fig. 2). The 12 TMs indicate the presence of six exoloops, five cytoloops, the N-terminus, and the C-terminus. This orientation suggests that both the N- and the C-termini are exposed to the cytoplasm. This structure can roughly be divided into two sections, with the N-terminal section containing the first 6 TMs, three exoloops,

TABLE 1 Properties of Adenylyl Cyclase Isoforms

Group	Isoform	Chromosome	Activators	Suppressors	Tissue distribution	Function
1	AC1	7p12–p13	Gαs, Ca^{2+}/calmodulin	Gαi, Gβγ	Brain, adrenal gland	Learning, memory
1	AC3	2p22–p242	Gαs, Ca^{2+}/calmodulin	Gαi	Brain, heart, lung, uterus	Odor stimulation
1	AC8	8q24.2	Gαs, Ca^{2+}/calmodulin	Gαi	Brain, heart, lung, uterus	
2	AC2	5p15.3	Gαs, Gβγ		Brain, heart, lung muscle	
2	AC4	14q11.2	Gαs, Gβγ		Brain, heart, lung, uterus	
2	AC7	16q12–q13	Gαs, Gβγ, PKC		Brain, platelets, ubiquitous	
3	AC5	3q13.2–q21	Gαs	Gαi, Gβ1γ2, Ca^{2+}, PKC, PKA	Brain, heart, lung, uterus	
3	AC6	12q12–q13	Gαs	Gαi, Gβ1γ2, Ca^{2+}, PKC, PKA	Ubiquitous	Cell proliferation
4	AC9	16p13.3	Gαs		Brain, muscle, ubiquitous	

and three cytoloops. The third cytoloop connecting TMs 6 and 7 is ~40 kDa with ~360 amino acids and is one of the catalytic domains (C1) of the enzyme. The C-terminal section comprises the next 6 TMs, three exoloops, two cytoloops, and the long C-terminal tail. This ~40 kDa (~350 amino acids) tail is the second catalytic domain (C2) of the enzyme. The upstream amino acid sequences of the C1 and C2 domains are conserved. When the synthetic polypeptides corresponding to these upstream sequences are expressed together, they show the adenylyl cyclase activity necessary to produce cAMP from ATP. This reaction is activated by GTP-bound Gαs or forskolin, a hallmark of adenylyl cyclase. However, neither of the two peptides is active alone, indicating that both peptides are required for the enzyme activity. These observations indicate that the C1 and C2 domains interact with each other and form an active catalytic site. This is proved to be correct according to the crystal structure. In fact, the two polypeptides form a forskolin-binding site, and forskolin binding promotes their interaction, leading to the active form. They also show a site for GTP-bound Gαs at the interface between the domains but primarily toward the C2 domain. It is thought that GTP-bound Gαs or forskolin stabilizes the dimer interaction, promotes a favorable structure, in particular, by bringing the Asp440 and 3′-hydroxyl group of ATP together, and thus, facilitates the enzyme activity. The inhibitory Gαi-subunit is also thought to bind to a similar site in the C1/C2 dimer as the stimulatory Gαs does, but has the opposite effect of inhibiting the enzyme activity, probably by inducing an unfavorable structure. However, the exact mechanism of this inhibition is unclear.

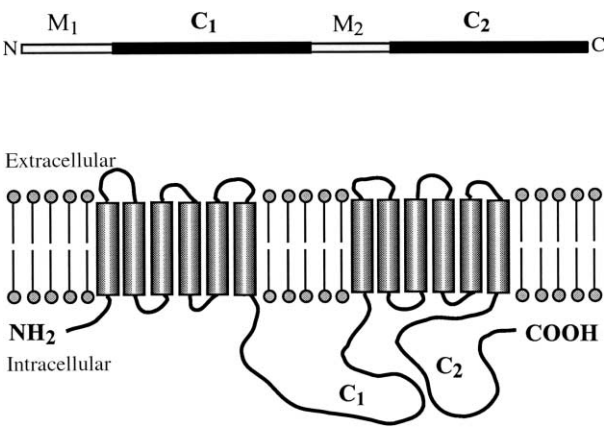

FIGURE 2 Domain structure and membrane topology of adenylyl cyclases. Adenylyl cyclases have two halves, each consisting of a membrane-associated domain (M) and a catalytic domain (C). The membrane domains (M1, M2) have six transmembrane domains. The two catalytic domains (C1, C2) form a catalytic site.

B. Termination of the Adenylyl Cyclase Activity

It is essential to terminate the activity of an effector soon after a second messenger is produced, otherwise the overproduction of second messengers will poison a cell as clearly shown by cholera toxin, pertussis toxin, and forskolin. The activity of adenylyl cyclase can be terminated by dissociation of Gαs from the C1/C2 complex most likely when the bound GTP is hydrolyzed to GDP by the GTPase activity of the GTP-bound Gαs. It has been suggested that activated adenylyl cyclase may activate the GTPase activity of Gαs, thus producing the inactive form Gαs (GDP-bound Gαs) and terminating its own activity. If this is

true, adenylyl cyclase is likely to activate the GTPase activity of Gαi, also.

C. Isoforms, Tissue Distribution, and Functions

Nine different membrane-associated adenylyl cyclases, AC1–9, have been cloned, and two different isoforms are alternately spliced from AC8. These isoform genes are widely distributed among human chromosomes and the encoded enzymes share amino acid sequence homology (Table 1). Based on the sequence homology, the nine isoforms can be classified into four groups, 1–4 (Fig. 3). Group 1 comprises AC5 and AC6; group 2 consists of AC1, AC3, and AC8; group3 consists of AC2, AC4, and AC7; and group 4 consists of AC9.

The tissue distribution of the isoforms examined by mRNA hybridization is not ubiquitous, indicating that there may be some tissue-specific functions. Some isoforms are found in the same tissues and cells, but it is unclear whether their functional and regulatory specificities are the same or different. The enzymes have been extensively examined in the brain. AC1 and AC2 are highly expressed in certain brain regions that are associated with learning and memory, such as the hippocampus, cerebral cortex, and cerebellum. In AC1 knockout mice, the adenylyl cyclase activity of cerebellar cortex is reduced by 65% and cerebellar long-term potentiation is blocked. Mice with a double knockout of AC1 and AC3 show no long-term memory. Studies using AC3 knockout mice indicate an important role for AC3 in the sense of smell. In addition, AC8 appears to be involved in long-term memory. These studies taken together suggest crucial roles for AC1 and AC3 in brain function, particularly in long-term memory. In addition to the knockout mice study, transgenic mice have been generated to overexpress AC5 or AC6. Mice overexpressing AC5 show myocardial damage over their lifetime, and those with overexpressed AC6 exhibit increased cardiac responsiveness to adrenergic stimulation.

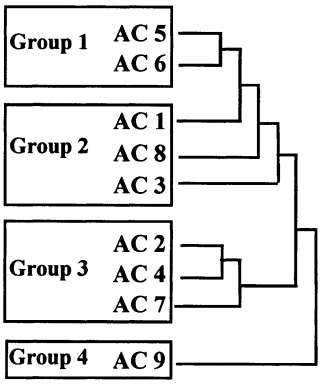

FIGURE 3 Classification of adenylyl cyclase isoforms. Nine isoforms of the enzyme have been cloned, and they can be classified into four distinct groups based on their sequence homology.

These isoforms are activated and suppressed differently by a number of distinct regulators. For example, Gαs can stimulate all AC isoforms but Gαi can suppress group 1 and group 3 adenylyl cyclases. Gβγ is capable of stimulating group 2 enzymes and it can suppress AC1. In addition to these G-proteins, Ca^{2+}/calmodulin can stimulate the group 1 enzymes, particularly AC1 and AC 8 in the brain. Ca^{2+}/calmodulin activates AC3 only in the presence of forskolin, and it is unclear whether AC3 is stimulated by Ca^{2+}/calmodulin *in vivo*. In contrast to the Ca^{2+}/calmodulin-sensitive group 1 enzymes, other groups are insensitive to Ca^{2+}/calmodulin. AC1 and the 1 and 3 enzymes are suppressed by Gβγ. AC5 and AC6 are also suppressed by protein kinases A and C, indicating the diversity in the regulatory mechanisms.

III. PHOSPHOLIPASE C

Phospholipase C cleaves phospholipids to generate two products: one is DAG and the other can be inositol phosphate, phosphoethanol amine, phosphocholine, or phosphoserine. DAG and inositol phosphate, in particular, inositol 1,4,5-trisphosphate (IP_3), are recognized as important second messengers (Fig. 4). In addition, phosphoserine, phosphoethanol amine, and phosphocholine have been suggested to be second messengers. IP_3 is also generated by the interconversion of various inositol phosphates by a number of kinases that can phosphorylate and phosphatases that can dephosphorylate. These various inositol phosphates are also suggested to be second messengers. DAG activates protein kinase C, and IP_3 mobilizes Ca^{2+} from intracellular stores such as the endoplasmic reticulum. This is accomplished by IP_3 binding to its receptor on the endoplasmic reticulum membrane, which in turn releases Ca^{2+} from the endoplasmic reticulum lumen. Then, the released Ca^{2+} regulates various molecules in the cell. IP_3 is also capable of modulating other molecules. For example, it interacts with actin-binding proteins and modulates actin polymerization; it is a co-factor for phosphatidylcholine-specific phospholipase D and a substrate for phosphoinositide 3-kinase, an important signal molecule.

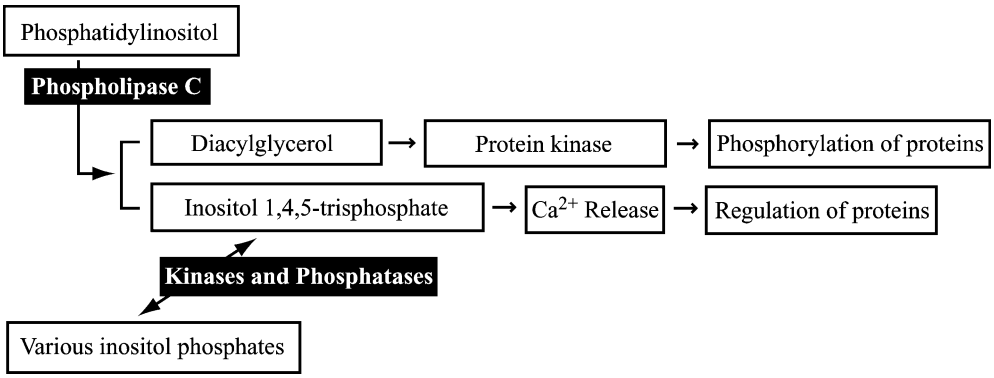

FIGURE 4 Phospholipase Cβ and production and conversion of inositol phosphates. Phosphatidyl-inositol is hydrolyzed by phospholipase Cβ to generate DAG and IP. DAG activates protein kinase C, which can phosphorylate various proteins and modulate them, whereas IP mobilizes Ca^{2+} from intracellular stores, which regulates a variety of proteins. Various inositol phosphates are interconverted by kinases and phosphatases and are involved in signaling.

A. Isoforms

There are 11 PLC isoforms, which are classified into four groups of different molecular weights, PLCβ with 4 isoforms (120–155 kDa), PLCγ with 2 isoforms (120–155 kDa), PLCδ with 4 isoforms (85 kDa), and PLCε with 1 isoform (230–260 kDa). These 4 PLC groups are found in higher eukaryotes, and lower eukaryotes such as yeast and slime molds have only PLCδ, suggesting the evolution of PLCβ, PLCγ, and PLCε from PLCδ.

PLC isoforms share a general domain structure (Fig. 5) although they have diverse amino acid sequences except for the conserved X and Y domains. The X and Y domains consist of 40–110 amino acids in PLCβ and PLCδ and 190 amino acids in PLCβε. The stretch of the X and Y domains in PLCγ spans ~400 amino acids and includes two Src homology 2 (SH2) domains of ~100 residues and one SH3 domain of ~50 residues, which recognize the sequences containing phospho-Tyr and multiple Pro residues, respectively. These isoforms also have a PH domain of ~100 amino acids that can bind inositol polyphosphates near the N-terminus of PLCβ, PLCγ, and PLCδ and at the center of PLCε. PLCγ has an additional PH domain that is split between the SH2 and the SH3 complexes. The PH domain is thought to interact with the inositol phosphate group of phosphatidylinositol of the cell membrane, thus anchoring it to the membrane, whereas the SH2 and SH3 domains mediate the interaction with other proteins. The isoforms also have the EF-hand domain and C2 domain, which is considered as an extension of the Y domain. PLCε is unique in possessing a domain similar to the Ras guanine nucleotide exchange factor (RasGEF) near the N-terminus and two Ras-binding (RA) domains near the C-terminus.

B. Catalytic Site

The X and Y domains show ~60% amino acid similarity and form the core of the catalytic domain,

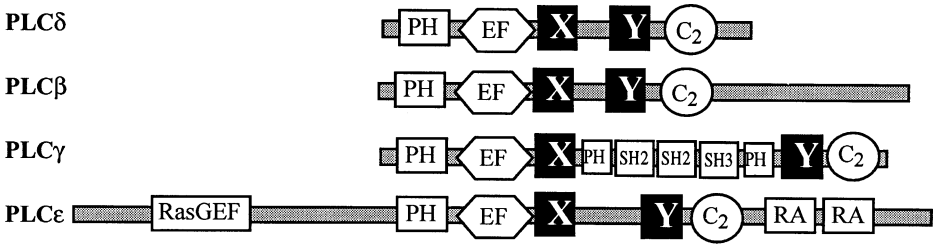

FIGURE 5 Domain structure of phospholipase C isoforms. There are four groups of PLC isoforms, PLCδ, PLCβ, PLCγ, and PLCε. All of them possess X, Y, PH, EF, and C2 domains. The X and Y domains form the catalytic core, and the PH domain binds to the IP moiety of phosphatidylinositol.

TABLE 2 Phospholipase Cβ Isoforms

Group	Isoform	Activators	Receptors	Tissue distribution	Function
PLCβ	1	Gαq (K_d = 40–60 nM), Gα11, Gα14, Gα16, Gβγ	α, β, angiotensin II, bradykinin, bombasin	Hematopoietic cells	Learning, memory
	2	Gαq (K_d = 400 nM), Gα11, Gα14, Gα16, Gβγ	Chemokines, histamine, GnRH, TSH, LH	Ubiquitous	Odor stimulation
	3	Gaq (K_d = 40–60 nM), Gα11, Gα14, Gα16, Gβγ	Muscarinic acetylcholine, endothelin-1	Ubiquitous	
	4	Gαq, Gα11, Gα14, Gα16	Thromboxane, vasopressin, formyl	Retina, neuronal cells	
PLCγ	1	Gβγ, Gαs, Gαi	β2, angiotensin II, thrombin, acetylcholine		
PLCδ		Gαh (activator or suppressor)	α1		
PLCε	2	Gα12	Thrombin, lysophosphatidic acid		

which is lined with eight ionic residues consisting of two Lys, one Arg, two His, two Glu, and one Asp, and one each of Asn, Ser, and Tyr according to the crystal structure of PLCδ. Their side chains bond with the phosphate and hydroxyl groups of polyphosphoinositol and Ca^{2+}, thus stabilizing them as well as the interaction between the two. The interaction explains why Ca^{2+} is necessary for catalysis. The loss of the basic side chains impairs PLC's interaction with the substrate and catalysis. Therefore, the phosphoryl groups of the substrate lipid, phosphatidylinositol, are important for the affinity for the substrate binding and catalysis. In contrast, the products of the lipid hydrolysis, free inositolphosphates, are likely to suppress catalysis. The basic amino acids in the pleckstrin homology (PH) domain of PLC isoforms are likely to be involved in recruiting the enzyme to the cell membrane where the substrate is located. However, their sequences are not conserved and therefore, the interactions of the various PH domains with the phosphatidylinositol may not be the same. This further suggests that individual PLC isoforms may have differential affinity toward different inositol phosphate groups of the substrate lipid. In addition, the PH domains of PLCβ1 and PLCβ2 appear to be the contact sites for the Gβγ complex.

C. Activation of PLCβ

All four PLCβ isoforms are directly activated by G-proteins linked to a vast number of G-protein-coupled receptors (Table 2), but their tissue distribution and activation mechanisms are diverse. All four isoforms of PLCβ can be activated by all four Gαq isoforms: Gαq, Gα11, Gα14, and Gα16 (Table 2). The Gβγ complex facilitates the activation of PLCβ1 and PLCβ2. In addition, there is evidence suggesting that Gβγ, Gαs, and Gαi are involved in the regulation of PLCγ. PLCδ may also be regulated by Gαh, whereas PLCε may be activated by Gα12.

Among the Gα-subunits, all of the Gαq family members are capable of activating all four isoforms of PLCβ, but their activation affinities vary widely. For example, Gαq and Gα11 activate the isoforms in the following order of activation affinity: PLCβ1 ≥ PLCβ3 ≥ PLCβ2. These activation affinities reflect the affinities of GTP-γ-S-bound Gαq for PLCβ1, PLCβ3, and PLCβ2. The equilibrium dissociation constants (K_d) of GTP-γ-S-bound Gαq isoforms are 40–60 nM for PLCβ1 and PLCβ3 and 400 nM for PLCβ2. Gα16 shares the least homology with the other Gαq family members; it is found to be expressed only in hematopoietic cells, but activates the PLCβ isoforms in a manner similar to other Gαq family members. Despite the Gαq family members' general affinities for the PLCβ isoforms, some receptors show a preference toward them. For example, the receptor for macrophage chemotactic protein-1 couples to Gα14 and Gα16, but not to Gαq or Gα11.

Before hydrolyzing membrane phospholipids, PLCβ must interact with the membrane. One mechanism to anchor it to the membrane is the interaction with the G-protein subunits. G-protein subunits are not hydrophobic but are anchored to the membrane. Gα is covalently linked to a fatty acid (myristic acid) near the N-terminus, and Gγ is either farnesylated or geranylated near the C-terminus.

Through these fatty chains, the two G-protein subunits are anchored to the cell membrane. Although Gβ does not have a fatty acyl chain, it is complexed with the Gγ-subunit, through which it is attached to the membrane. The C2 domain of the PLCβ isoforms binds to the activated GTP-bound Gαq with a K_d value of 18 nM, showing a high affinity. When the activated GTP-bound Gαq is deactivated to become GDP-bound Gαq, the affinity between the GDP-bound Gαq and the C2 domain of the PLCβ drops significantly to K_d values of 60–120 nM. This could provide a mechanism to release the enzyme from the membrane. Another mechanism of recruiting PLCβ to the membrane is the interaction of the PH domain of the enzyme with the inositol phosphate moiety of membrane-associated phosphatidylinositol. In fact, this interaction of the substrate might facilitate the enzyme catalysis.

Gβγ is also capable of activating PLCβ isoforms with varying affinities. Gβγ does not activate PLCβ4. Gβγ interacts with PLCβ2 with a high affinity, but the affinity for PLCβ1 and PLCβ3 is not high. PLCβ1 is the least sensitive to Gβγ. The PLCβ2 activation by Gβγ has been documented in a large number of receptors including those for luteinizing hormone (LH), β1, β2, formyl, V2 vasopressin, interleukin-8, and muscarinic acetylcholine. PLCβ2 is also activated by some of these receptors via Gαq. Although the Gβγ concentration necessary for activation is higher than that for Gαq, the maximum level of activation is similar. Therefore, both Gβγ and Gαq are likely to be involved in the activation of PLCβ but the existing evidence shows that Gαq is essential. Gαq and Gβγ interact with PLCβ at different sites: Gαq near the C-terminus and Gβγ at the PH domain. Although Gβγ and the inositol phosphates bind to the PH domain, their contact points are distinct. Interestingly, PLCβ and Gαq bind to Gβγ at the same site, and therefore, Gβγ can interact with one of them but not both. The 7 Gβ isoforms and 12 Gγ isoforms can produce a large number of combinations. Different Gβγ complexes show a specificity for PLCβ isoforms. For example, Gβ1γ can activate PLCβ1, PLCβ2, and PLCβ3, whereas Gβ5γ can activate PLCβ1 and PLCβ2, but not PLCβ3.

D. Deactivation of PLCβ

PLCβ isoforms activated by the GTP-bound Gα-subunits can be turned off by the hydrolysis of the GTP bound to Gα-subunits. This hydrolysis is catalyzed by the GTPase activity of Gα-subunits, which is intrinsic to Gα-subunits but low in the absence of PLCβ. Activated PLCβ stimulates the GTPase activity by 6–60 fold, and therefore, PLCβ serves as a GTPase-activating protein (GAP) as is adenylyl cyclase. In the case of PLCβ1, the C-terminal fragment consisting of amino acid residues 903–1042 is involved in the activation.

The GTPase activity is also stimulated by regulators of G-protein signaling (RGS). Although they serve as GTPase activating proteins, their action mechanism differs from those of PLCβ and adenylyl cyclase. For example, RGS interact with receptors unlike the interaction of PLCβ and adenylyl cyclase with Gα. More than 20 isoforms of RGS have been cloned to date, and they are effective to Gαq and Gαi, but not for Gαs and Gα12. When the GTPase activity of Gα is activated and the GTP that is bound to Gα is hydrolyzed to GDP, the Gα disengages from PLCβ and adenylyl cyclase, leading to deactivation of the enzymes. The dissociated Gα now engages with the Gβγ complex, thus completing the activation and deactivation cycle of G-protein.

E. Activation of PLCδ and PLCε

Gαh (high-molecular-weight G-protein) is co-immunoprecipitated with the thromboxane A2α receptor, but not the A2β, receptor. It has been shown that the receptors for α1 and oxytocin stimulate Gh to complex with PLCδ1 and activate the enzyme in the presence of GT-γ-S. These results suggest that the receptors interact with Gαh and activate it. Interestingly, these receptors are also capable of binding Gαq and activating PLCβ. Gα12 appears to activate PLCε. For example, a Gα12 mutant lacking the GTPase activity enhances the enzyme activity. This suggests the interesting possibility that Gα12 may activate PLCε, perhaps via a G-protein-coupled receptor.

IV. ION CHANNELS

Nerve cells communicate one another and with other cells such as muscle and sensory cells through their contact points, referred to as synapses, which have specialized structures containing hormone receptors and ion (Na^+, K^+, Ca^{2+}, and Cl^-) channels. They communicate by two distinct signal mechanisms, electrical and chemical. Electrical signals are generated by differential ion concentrations and pass from presynaptic cells to postsynaptic cells through

voltage-dependent ion channels. Chemical signals include neurotransmitters such as acetylcholine, glycine, glutamate, γ-amino butyric acid, serotonin, dopamine, epinephrine, and norepinephrine. They are released from presynaptic cells and bind to their cognate receptors on postsynaptic cells, which opens ion channels.

Voltage-dependent ion channels comprise several subunits, α (170–250 kDa) β (50–78 kDa), γ (36 kDa), and δ, and various ion channels have different subunit compositions. Among ion channels, Ca^{2+} channels have been extensively investigated and play essential roles in neuronal activity. They modulate the release of neurotransmitters, activation of Ca^{2+}-dependent enzymes and regulators, and neuronal excitation. Defective Ca^{2+} channels are associated with disorders including migraine, cerebella ataxia, night blindness, and epilepsy. There are several types (N, P/Q, L, R, and T) of Ca^{2+} channels, which have specific α isoforms: α1A for P/Q, α1B for N, α1D for L, α1E for R, and α1G-I for R. The N-type channel is activated by protein kinase C, whereas the N- and P/Q-type channels are suppressed by G-protein-coupled receptors via the Gβγ-subunits of Gi and Go. This inhibition appears to occur by Gβγ-dependent tyrosine phosphorylation of the channel α-subunit. Involved in this regulation are the receptors for a wide variety of hormones including α2 and β2 adrenalines, dopamine D5, GABAa, a metabotropic glutamate, opioid, adenosine, and muscarinic acetylcholine. The β-subunit is primarily involved in the equimolar interaction with the channels. Gβ isoforms show a specificity toward the channels as Gβ1, but not Gβ2–4, is effective for the N-type channel. It appears to interact with the domain I and II linkers and C-terminal region of the α1 of the N-type channel. In addition, the channel β-subunits play a role in the interaction and the Gβ isoforms show specificity.

V. OTHER EFFECTORS

Phosphodiesterases are activated by rhodopsin via Gαo, and phospholipase A2 is also activated by G-protein-coupled receptors for Ca^{2+}, α1 adrenaline, ATP, bradykinin, muscarinic acetylcholine, and endothelin-A. The Ca^{2+} receptor activates phospholipase A2 via Gαq, and the endothelin-A receptor activates the enzyme through the Gαq–phospholipase Cβ–DAG–protein kinase C pathway. Gβγ interacts with phosphoinositide 3-kinase and activates it.

Receptor tyrosine kinases such as the epidermal growth factor receptor are stimulated by G-protein-coupled receptors such as the β adrenergic receptor. This appears to follow complex pathways involving Gβγ, phosphoinositide 3 kinase, Src, and receptor tyrosine kinase. Mitogen-activated protein kinase is one of the central components in the cell signaling pathways and is activated by Gαq-coupled receptors. Jun N-terminal kinase is also activated by a G-protein-coupled receptor but the pathway is unclear.

Arrestin is an adaptor molecule and binds to phosphorylated G-protein-coupled receptors, leading to endocytosis of the receptors. ADP ribosylation factor 6 is directly activated by liganded LH receptors, which in turn stimulate the desensitization and internalization of the receptors. In addition, there is evidence for the interaction of G-protein-coupled receptors with Jak2 kinase, phospholipase Cγ, and protein kinase C. Clearly, these observations predict a vast number of signal molecules to complex directly or indirectly with G-protein-coupled receptors and to elicit various hormonal responses.

Glossary

adenylyl cyclase An extensively investigated effector that hydrolyzes ATP to produce cAMP, a second messenger.

effectors Usually enzymes that are regulated by G-proteins in response to hormones binding to receptors.

G-protein-coupled receptor Hormone receptors that are present on the cell surface and coupled to G-proteins in the cell. These receptors generally transfer hormone signals to G-proteins to trigger hormone actions from the cells.

guanine nucleotide-binding protein (G-protein) This protein binds the guanine nucleotides GDP or GTP and has three different subunits, the α-, β-, and γ-subunits. It interacts with G-protein-coupled receptors, receives hormone signals from the receptors, and modulates effectors in the cell.

hormone receptor Molecules on the cell surface that bind specific hormones. More than 1000 receptors have been cloned.

hormones Biological molecules, such as proteins, peptides, amino acid derivatives, and lipids, that are produced from an endocrine gland and spread to target tissues and cells, often through the circulatory system. They bind to specific receptors and trigger specific effects; therefore, they are considered first messengers.

isoform Variants of proteins and enzymes that share the same functions and similar structures.

phospholipase C An effector of G-protein-coupled receptors that is capable of hydrolyzing phospholipids to generate two second messengers, diacylglycerol and inositol phosphate.

Eicosanoids

ODETTE LANEUVILLE
University of Ottawa

The goals of this article are to describe the chemical structure of eicosanoids, their enzymatic synthesis, and the mechanisms by which they exert their actions on various physiological systems.

I. INTRODUCTION

Establishing the biological significance of eicosanoids was particularly laborious and still constitutes a very active area of research. The large number of eicosanoid family members, over 50, posed a difficulty in establishing their importance. The chemical structures of those eicosanoids and their metabolites have been determined, along with those of some recently added to the list. The general chemical structure of eicosanoids corresponds to that of oxygenated fatty acids formed from arachidonic acid by the addition of oxygen catalyzed enzymatically. There are three pathways for the formation of eicosanoids: the cyclo-oxygenase, lipoxygenase, and epoxygenase pathways. To add to the difficulty of establishing this ever-growing family of substances as hormones, they are, as a rule, synthesized and released on demand. In most cases, they do not circulate at considerably high levels and have a very short half-life. Moreover, eicosanoids are recognized as naturally occurring active substances produced by many organs and affecting multiple functions. The situation is much easier for hormones produced by specialized organs, where removal of the endocrine gland generally gives information about its biological significance. In the case of eicosanoids, their importance in the regulation of physiological functions and homeostasis was revealed by the availability of inhibitors of the three pathways for the formation of eicosanoids. The most important are the inhibitors of the cyclo-oxygenase enzymes extensively used in clinical settings for the treatment of inflammation in various contexts. Still, the most popular and lucrative representative of the nonsteroidal anti-inflammatory drugs is aspirin.

II. NOMENCLATURE AND CHEMICAL STRUCTURES

Eicosanoid derives from the Greek "eicosa," which means 20; eicosanoids constitute a broad group of compounds derived from 20-carbon polyunsaturated fatty acids. Arachidonic acid (AA) serves as the most common precursor and consists of a 20-carbon chain with a methyl ($-CH_3$) group at one end of the chain and a carboxyl (-COOH) group at the other end.

phospholipase C An effector of G-protein-coupled receptors that is capable of hydrolyzing phospholipids to generate two second messengers, diacylglycerol and inositol phosphate.

In the case of eicosanoids, their importance in the regulation of physiological functions and homeostasis was revealed by the availability of inhibitors of the three pathways for the formation of eicosanoids. The most important are the inhibitors of the cyclo-oxygenase enzymes extensively used in clinical settings for the treatment of inflammation in various contexts. Still, the most popular and lucrative representative of the nonsteroidal anti-inflammatory drugs is aspirin.

II. NOMENCLATURE AND CHEMICAL STRUCTURES

Eicosanoid derives from the Greek "eicosa," which means 20; eicosanoids constitute a broad group of compounds derived from 20-carbon polyunsaturated fatty acids. Arachidonic acid (AA) serves as the most common precursor and consists of a 20-carbon chain with a methyl ($-CH_3$) group at one end of the chain and a carboxyl (-COOH) group at the other end.

The carbon chain forming arachidonate also includes 4 unsaturated double bonds and is designated 20:4 (20 carbons and 4 double bonds). The carbons are numbered 1 to 20 from the -COOH terminal; the COOH end is designated C1 and the CH_3 end is designated C20. According to this nomenclature, the COOH-terminal is termed the alpha-terminal and the double bonds in arachidonate are formed between carbons 5 and 6, 8 and 9, 11 and 12, and 14 and 15. This designation will be used in this article. The carbon chain can also be numbered from the CH_3-terminal and this is the omega (ω) or biological numeration. According to the ω nomenclature, the double bonds in arachidonate are formed between carbons 6 and 7, 9 and 10, 12 and 13, and 15 and 16. AA is also referred to as 20:4ω6 since the first double bond involves C6 in the chain. All the double bonds of AA are conjugated, which signifies they are interrupted by a methylene (-CH_3-) group and have a *cis* configuration.

All eicosanoids are biosynthesized by molecular oxygen fixation at well-determined sites on the AA molecules. There are three pathways for the formation of eicosanoids: the cyclo-oxygenase, lipoxygenase, and epoxygenase pathways (Fig. 1). The three pathways are collectively known as the arachidonate cascade. The cyclo-oxygenase pathway leads to the formation of prostanoids, including prostaglandins and thromboxanes. The lipoxygenase pathway leads to the formation of leukotrienes, hepoxilins, and lipoxins, and the P450 pathway leads to the formation of monohydroxylated fatty acids.

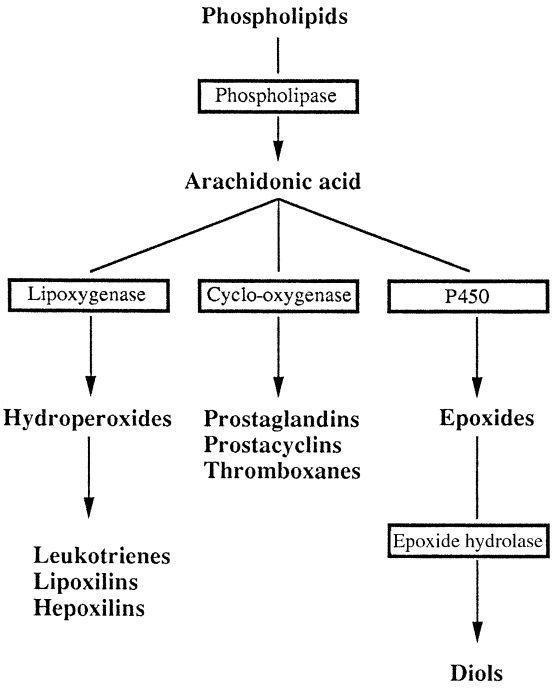

FIGURE 1 Arachidonic acid cascade. From the substrate arachidonic acid, three pathways lead to the formation of the various eicosanoids. The cyclo-oxygenase forms the prostanoids, which includes the prostaglandins and thromboxanes. The lipoxygenase pathway leads to the formation of HPETEs, HETEs, leukotrienes, hepoxilins, and lipoxins. The P450 pathway forms EETs and HETEs.

A. Prostanoids

Prostanoids fall into several classes designated by letters (A to J) (Fig. 2). From the substrate AA, the unstable endoperoxide prostaglandin G_2 (PGG_2) is first produced. The hydroperoxy group (-OOH) on carbon 15 of PGG_2 is then reduced to a hydroxyl group (-OH) and the product formed is prostaglandin H_2 (PGH_2). All other prostanoids are derived from PGH_2 and are distinguished by substitutions on the cyclopentane ring of PGH_2. Prostaglandins of the E and D series are hydroxy ketones and prostaglandins F_α are 1,3-diols. Prostaglandin I_2, also termed prostacyclin, has a double-ring structure; in addition to a cyclopentane ring, a second ring is formed by an oxygen bridge between carbons 6 and 9. Thromboxanes contain a six-member oxane ring instead of the cyclopentane ring of the prostaglandins. Both prostacyclins and thromboxanes also result from the metabolism of PGH_2. Prostaglandin J_2 derives from PGD_2 and contains a keto substitution on the cyclopentane ring. Prostaglandins A, B, and C are unsaturated ketones that arise nonenzymatically from PGE during extraction procedures; there is no evidence that they occur biologically.

B. Hydroperoxyeicosatetraenoic Acids, Hydroxyeicosatetraenoic Acids, Leukotrienes, Hepoxilins, and Lipoxins

The lipoxygenase pathway of AA leads to the formation of hydroperoxyeicosatetraenoic acids (HPETEs), hydroxyeicosatetraenoic acids (HETEs), leukotrienes, hepoxilins, and lipoxins. HPETE are named according to the location of the -OOH group; that is, 5-HPETE bears a hydroperoxide group at the carbon 5 position, and 8-HPETE, 9-HPETE, 11-HPETE, 12-HPETE, and 15-HPETE are designated in a similar manner.

HPETEs are short-lived compounds and are metabolized into more stable compounds belonging

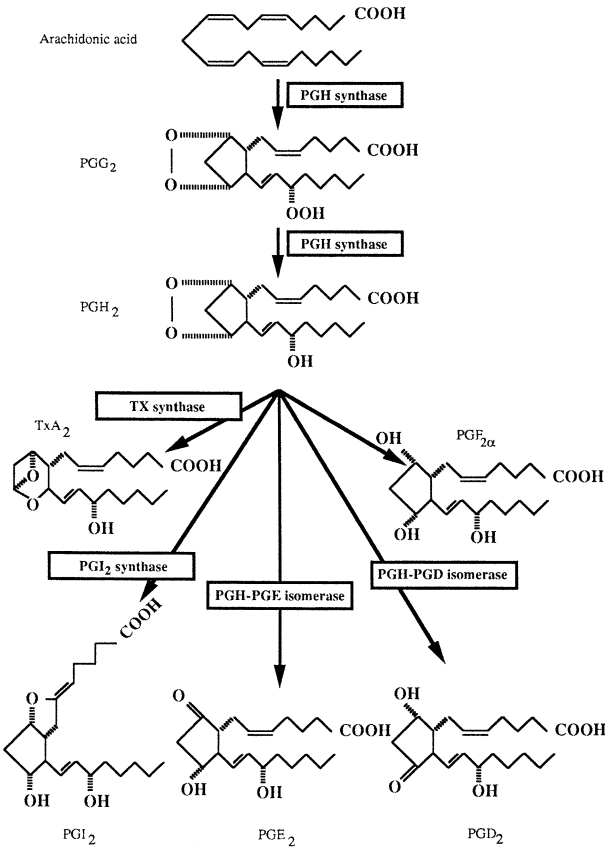

FIGURE 2 The cyclo-oxygenase pathway of arachidonic acid. The transformation of arachidonic acid into prostanoids is initiated by the action of the enzyme cyclo-oxygenase that consecutively forms prostaglandin G_2 and prostaglandin H_2. The product PGH_2 then serves as a substrate for the various isomerases and synthases to produce TXA_2, PGI_2, PGE_2, PGD_2, and PGD_2.

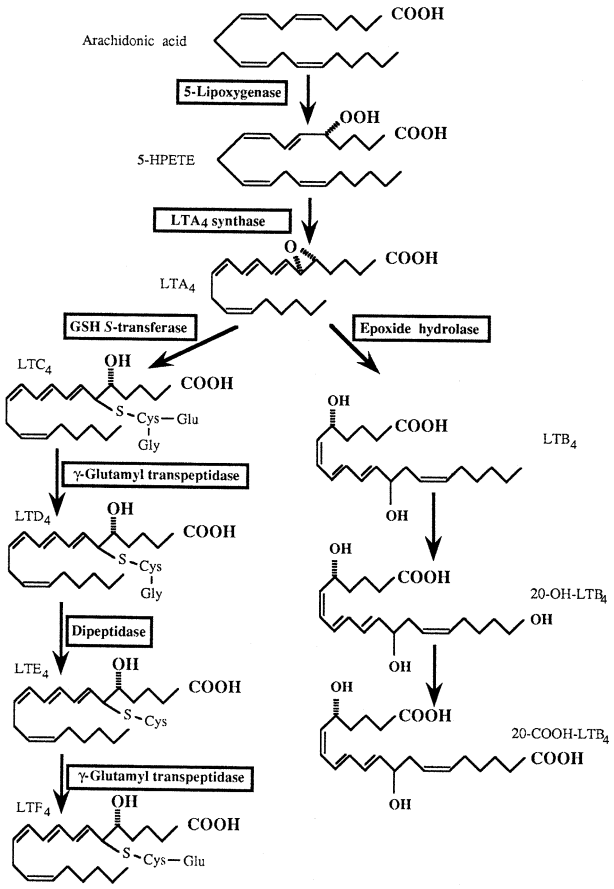

FIGURE 3 The lipoxygenase pathway of arachidonic acid. The specific incorporation of oxygen on carbon 5 of the arachidonic acid chain leads to the formation of 5-HPETE. This product becomes the substrate for LTA_4 synthase, which forms LTC_4. The product of the LTA_4 synthase reaction then becomes the substrate for both LTB_4 and LTC_4. The GSH moiety of LTC_4 is further metabolized to form LTD_4, LTE_4, and LTF_4.

to various families, of which the HETEs, leukotrienes, hepoxilins, and lipoxilins have been identified. The leukotriene family derives from 5(*S*)-HPETE, and the term leukotriene connotes the source from which the first substances in this family were isolated, the leukocytes, and the common essential structural feature, a conjugated triene. Leukotrienes (LTs) fall into classes designated by letters (A to F), in a manner consistent with the prostanoid nomenclature. Leukotriene A_4 (LTA_4) bears an epoxide group (-O-) on carbons 5 and 6 of the carbon chain, and leukotriene B_4 (LTB_4) has two hydroxyl groups, one on carbon 5 and one on carbon 12 (Fig. 3). Other leukotrienes derive from LTA_4.

Hepoxilins derive from 12(*S*)-HPETE and result from the rearrangement of the -OOH group. Two hepoxilins are formed, hepoxilin A_3 and B_3, and both compounds carry their epoxide group on carbon atoms 11 and 12. They are distinguished by the position of their hydroxyl group, on carbon atom 8 for hepoxilin A_3 and on carbon atom 10 for hepoxilin B_3. Lipoxins contain a conjugated tetraene structure, four conjugated double bonds, and three hydroxyl groups. The main compounds in this family were isolated from leukocytes and are named lipoxins A_4 and B_4.

C. EETs and HETEs

The P450 or epoxygenase pathway leads to the formation of two groups of monohydroxylated fatty acids: the epoxyeicosatrienoic acids (EETs) and the monohydroxyeicosatetraenoic acids. All products of the P450 pathway derived directly from the substrate

AA, to which one atom of oxygen derived from molecular oxygen (O_2) is added to the carbon chain. In the case of EETs, the oxygen atom is inserted in the form of an epoxy group (-O-) across each of the double bonds of AA. The four possible epoxides formed are 5,6-EET, 8,9-EET, 11,12-EET, and 14,16-EET (Fig. 4). EETs are then converted by epoxide hydrolases to their corresponding vicinal diols, the dihydroxyeicosatrienoic acids (DiHETEs). For the HETEs, the oxygen atom is added in the form of a hydroxyl group (-OH) onto one of the carbons of AA, 5, 8, 9, 11, 12, or 15, and the HETEs formed are designated based on the position of the hydroxyl group: 5-HETE, 8-HETE, 9-HETE, 11-HETE, 12-HETE, and 15-HETE. As detailed in the previous section, HETEs are also produced from the lipoxygenase in which case the insertion of the oxygen atom is position- and orientation-specific. Oxidation of AA by hepatic microsomal cytochrome P450 produces HETEs that are not stereo-and region-specific.

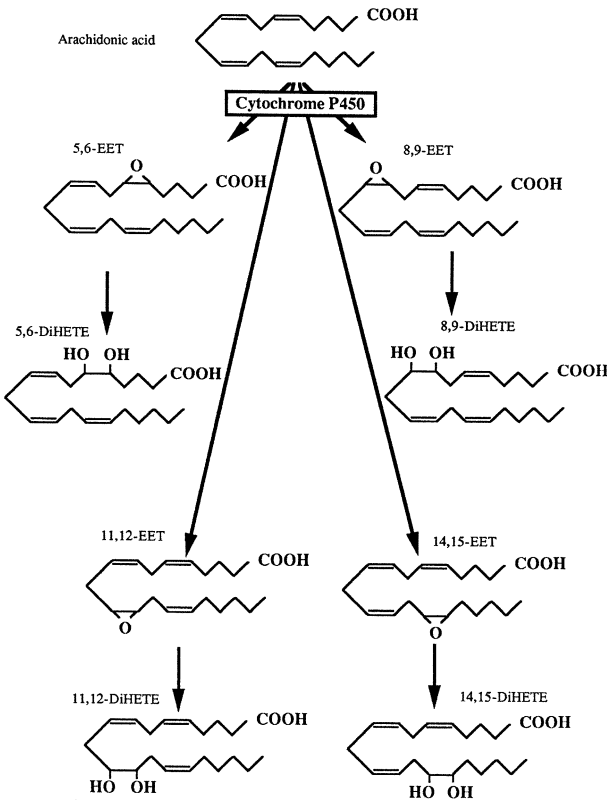

FIGURE 4 The cytochrome P450 pathway of arachidonic acid. P450 catalyzes the incorporation of oxygen to form all four possible EETs. The epoxide group is then subjected to hydrolysis catalyzed by epoxide hydrolases, and the products formed are diols.

III. SYNTHESIS

Prostaglandins were discovered as products of the only organ where they are stored in large amounts: as the secretion from the vesicular gland. The occurrence of prostaglandins in the seminal fluid of some species is unique, in the sense that similar amounts are not found elsewhere in the organism. As a rule, there are no stores of eicosanoids and they are formed in most tissues, in response to various stimuli. The first step in the synthesis of eicosanoids is the release of the substrate arachidonic acid from membrane phospholipids. Various biosynthetic enzymes then catalyze the oxygenation of arachidonic acid, which leads to the formation of eicosanoids.

A. Substrate Release

The most common and important substrate in the synthesis of eicosanoids is arachidonic acid. Two other polyunsaturated fatty acids can serve as substrates, homo-γ-linolenic acid (20:3) and eicosapentaenoic acid (20:5). Like arachidonic acid, they are composed of a chain of 20 carbons but differ in the number of double bonds that they possess: 3 for homo-γ-linolenic acid and 5 for eicosapentaenoic acid. The number of double bonds present in the fatty acid used for the synthesis of eicosanoids will dictate the number of double bonds present in the formed eicosanoids; homo-γ-linolenic acid, arachidonic acid, and eicosapentaenoic acid will be transformed in eicosanoids with 1, 2, and 3 double bonds, respectively. The number of double bonds is indicated in subscript; eicosanoids derived from arachidonic acid carry the subscript 2 and are the most abundant eicosanoid in mammals.

The substrates in the synthesis of eicosanoids are derived from two essential fatty acids, precursors that are provided by the diet. Linoleic acid (18:2), used to form homo-γ-linolenic and arachidonic acids, is particularly abundant in certain vegetable oil acids. α-Linolenic acid (18:3) is obtained mainly from marine animals and is used in the synthesis of eicosapentaenoic acid. In mammalian tissues, 18:2 and 18:3 are desaturated and elongated to produce the substrates in the synthesis of eicosanoids 20:3, 20:4, and 20:5, which are then stored in the membrane phospholipids. The cellular membrane is particularly rich in arachidonic acid and this is the most important substrate for the synthesis of eicosanoids.

B. Cyclo-oxygenase Pathway

Cyclo-oxygenases catalyze the incorporation of two molecules of oxygen (O_2) on the AA chain. The details of the reaction of insertion of oxygen have been reported. Initially, the enzyme cyclo-oxygenase abstracts the hydrogen on carbon 13, the 13 pro *S* hydrogen, and inserts one molecule of O_2 on carbon 11. The insertion of oxygen occurs from the plane opposite that from which the hydrogen is abstracted; the insertion is said to be antarafacial. At this stage, a double bond is created between carbons 12 and 13 of the arachidonic chain, and one atom of oxygen from the added O_2 will form a link with C9, eliminating the C8–C9 double bond of AA. The relocalization of electrons will lead to formation of the cyclopentane ring within the AA chain. The second molecule of oxygen is inserted on carbon 15 of the AA chain. The oxygen added on C15 remains in the form of a hydroperoxide (-OOH) and the product formed is prostaglandin G_2. The cyclo-oxygenase will then reduce the hydroperoxide at position 15 to a hydroxyl group (-OH), and the product formed is prostaglandin H_2. This reduction is catalyzed by the second enzyme activity of the cyclo-oxygenase enzyme: the peroxidase activity. Both enzyme activities of cyclo-oxygenase have been mapped to different sites on the protein. Therefore, the designation cyclo-oxygenase for this enzyme refers to only one of the two activities the enzyme has: the cyclo-oxygenase activity. The term prostaglandin endoperoxide H synthase is also used and refers to the two activities the enzyme has: the cyclo-oxygenase and the peroxidase activities.

Cyclo-oxygenase enzyme exists as two isoforms encoded by two separate genes. The two cyclo-oxygenases, cox-1 and cox-2, catalyze the same reaction: the formation of PGH_2 from AA. Their patterns of expression and regulation differ significantly. The cox-1 enzyme is constitutively expressed in most cell types, where it plays a housekeeping role. Cox-2 has been termed the inducible cyclo-oxygenase because of its rapid up-regulation in response to various stimuli, including inflammatory cytokines.

The formation of the biologically active prostanoids, a term that includes prostaglandins and thromboxanes, from PGH_2 occurs through the action of a set of isomerases and synthases (Fig. 2). Prostanoid-forming enzymes include PGH–PGD isomerase, PGH–PGE isomerase, PGF synthase, PGI synthase, and TX synthase and form PGD_2, PGE_2, $PGF_{2\alpha}$, PGI_2, and thromboxane A_2 (TXA_2). All prostanoid-forming cells produce PGH_2 through the action of cyclo-oxygenase, which is further metabolized into only one of these prostanoids because of the predominance of a single PGH_2 metabolizing enzyme. For instance, blood platelets contain mostly TX synthase and form mainly TXA_2.

C. Lipoxygenase Pathway

The lipoxygenase enzymes catalyze the formation of HPETEs and are named according to the site of entry of the -OOH group on the carbon chain, e.g., 5-LOX, 8-LOX, 9-LOX, 11-LOX, 12-LOX, and 15-LOX. The positions of insertion are all part the double bonds of the AA chain. The addition of molecular oxygen to AA by lipoxygenases is not only position-specific but also stereo-specific; the added -OOH has an *S* configuration. A single molecule of oxygen is added to the AA chain by the lipoxygenase enzymes, whereas two O_2 molecules are added by the enzyme cyclo-oxygenase. Like the cyclo-oxygenases, lipoxygenases insert oxygen antarafacially to the AA chain. Similar to the cyclo-oxygenase pathway, the first product formed from AA is an unstable hydroperoxide termed HPETE.

HPETEs are subjected to three reactions depending on the biosynthetic enzymes present. Peroxidases reduce the HPETEs to their hydroxy analogues, HETEs. The second possible reaction is a dehydration and the formation of an epoxide group at positions 5 and 6 on the carbon chain; the product formed is LTA_4. The epoxide group of LTA_4 can be hydrolyzed into two hydroxyl groups, and the product formed is LTB_4. LTA_4 is also subjected to epoxide opening by the enzyme glutathione *S*-transferase with the addition of glutathione to form the sulfidopeptide series of leukotrienes. The initial product is leukotriene C_4 (LTC_4), which carries the glutathione peptide, Gly-Cys-Glu, at position 6 of the carbon ring as well as a hydroxyl group on carbon 5. The glutathione moiety is further metabolized by a γ-glutamyltranspepdidase, which cleaves the glutamic acid residue to form leukotriene D_4 (LTD_4) following digestion by a dipeptidase to form leukotriene E_4 (LTE_4). LTD_4 can also be converted to LTF_4 by the γ-glutamyltransferase. The leukotrienes C_4 and D_4 were originally known as slow-reacting substances of anaphylaxis with respect to their smooth muscle-contracting activity in allergic reactions.

The third possible transformation of the HPETE formed by the lipoxygenase pathway is the intramolecular isomerization of the hydroperoxide group to form the hepoxilins and the lipoxilins. Hepoxilins are hydroxy epoxide metabolites of AA formed through

the 12-lipoxygenase pathway. The hydroperoxide group is rearranged into an epoxide group and a hydroxyl group to form HxA_3 and HxB_3. The formation of hepoxilins was initially described as a ferriheme-assisted reaction and more recently was shown to be catalyzed enzymatically. The term hepoxilin combines both the chemical structure and the function; hepoxi refers to the epoxide group of the molecule and lin refers to the first biological activity reported, the release of insulin. The name lipoxilins derives from lipoxygenase interaction products and these are formed as a result of an interaction between the 5- and the 15-lipoxygenases.

D. Cytochrome P450 Pathway

The formation of EETs and of HETEs from AA is catalyzed by the cytochrome P450 enzymes and requires molecular oxygen as well as NADPH in a 1:1 stoichiometry. The insertion of oxygen by cytochrome P450 enzymes is characterized by the use of reducing equivalents to split the oxygen–oxygen bond in molecular oxygen and the transfer of one activated oxygen atom to the substrate AA while the other oxygen atom appears in water. The addition of oxygen in the form of an epoxide group leads to the formation of four possible epoxides: 5,6-, 8,9-, 11,12-, 14,15-epoxyeicosatrienoic acids (Fig. 4). These in turn can be converted by epoxide hydrolases to the corresponding vicinal diols, the dihydroxyeicosatrienoic acids. The cytochrome P450 can also perform allylic oxidations of AA to form HETEs. The distinction between P450 and lipoxygenase-derived HETEs is found in the stereoselectivity of the product formed. The lipoxygenase products are enantiospecific with an *S* configuration of the hydroxyl group. Hepatic P450 enzymes produce both *R* and *S* monohydroxylated fatty acids.

IV. EICOSANOIDS IN THE ENDOCRINE SYSTEM

Prostanoids may serve both specific and general functions. All of the main systems contributing to homeostasis of mammals are under the influence of eicosanoids. In the circulatory system, the interaction between the circulating platelets and the vascular endothelial cells is of significant importance for the treatment and prevention of cardiovascular diseases. Under normal physiological conditions, eicosanoids produced by the cyclo-oxygenase pathway generally induce vasorelaxation and prevent platelet aggregation. In contrast, thromboxane A_2 produced by platelets will induce vasoconstriction and platelet aggregation. Inhibiting eicosanoid formation with aspirin will be more significant for platelets than for endothelial cells since platelets are anucleated cells and cannot replenish their pool of cyclo-oxygenase enzyme. Aspirin induces an irreversible inhibition of cyclo-oxygenase, which means that the enzyme is condemned and new enzyme must be resynthesized in order to produce prostanoids. Under aspirin exposure, platelets are irreversibly inhibited and will be less likely to aggregate and to form thrombus since their production of the pro-aggregatory thromboxane A_2 is inhibited. The production of the anti-aggregatory prostanoid PGI_2 by endothelial cells can be reestablished after aspirin exposure since endothelial cells are nucleated and active cyclo-oxygenase can be synthesized. The net result of aspirin inhibition is to favor the action of the anti-aggregatory substance PGI_2 and the net effect on the circulatory system is the reduction in cardiovascular diseases associated with hyperplatelet functions.

The digestive system is also under the influence of eicosanoids. Prostanoids regulate gastric acid secretion, intestinal mobility, and intestinal ion transport, prevent liver damage due to hepatotoxin, participate in liver regeneration, and regulate pancreatic secretions, to name a few functions. Most P450 enzymes are primarily expressed in the liver, where they oxidize, peroxidize, and reduce cholesterol, vitamins, steroids, and xenobiotics in an oxygen- and NADPH-dependent manner. Many P450 isozymes in the extrahepatic tissues are also capable of metabolizing AA to biologically active products such as EETs, which regulate vascular tone. The nervous system is influenced by the hormonal action of eicosanoids. PGD_2 regulates sleep episodes; PGE_2 regulates body temperature, cerebral vasospasm, and the transmission of pain signals to the central nervous system.

Prostaglandins were originally isolated in the seminal fluid where they accumulate and the name prostaglandins derives from the prostate. The reproductive system of females is largely influenced by eicosanoids. They seems to play a role in female fertility as demonstrated in cox-2 knockout mice, which have a significantly reduced fertility. The regression of the corpus luteum is influenced by $PGF_{2\alpha}$ produced by the uterus. PGE_2 is necessary for parturition and causes cervical dilation and myometrial contractions. There is substantial evidence that different prostaglandins are involved in the regulation of normal uterine contractility, dysmenorrhea, and menstruation. In the newborn, PGE_2 is responsible for the closure of the ductus arteriosus, a direct

connection between the main pulmonary artery and the descending aorta that allows the circulation of the newborn to be directed to the left ventricule of the heart and then to the lungs. Several lines of evidence indicate that the fetal ductus arteriosus is relaxed and dilated by prostaglandin actions.

The four classical cardinal signs of inflammation, redness, swelling, heat, and pain, are all induced by different prostaglandins. This is due in part to their ability to dilate vessels, to increase vascular permeability, and to sensitize nerve terminals transmitting pain information. Experimental evidence also indicates that prostanoids are capable of potentiating the effects of other mediators of inflammation such as bradykinin and histamine. The most popular treatment for the symptoms of inflammation comprises the inhibitors of prostanoid synthesis, nonsteroidal anti-inflammatory drugs (NSAIDs), largely because of their anti-pyretic and analgesic properties.

The concept that leukotrienes play a pivotal role in airway disease such as asthma is derived mainly from evidence that several cell types that produce leukotrienes—mast cells, basophils, and eosinophils—are present in increased numbers in the lungs of patients with asthma. In addition, metabolites of leukotrienes detected in biological fluids from subjects with asthma further support this concept.

A. Receptors

In agreement with the adopted theory of hormone action, eicosanoids attach to receptors on the cell surface or inside the cell before these initiate the process of response action. The receptors for prostanoids and leukotrienes have been extensively studied and all share a common topography, being composed of a single polypeptide with seven transmembrane-spanning domains. The receptor structure is linked to a G-protein responsible for initiating the cascade of reactions leading to the transduction of the message, the binding of the eicosanoid to its receptor inside the cell. The signal transduction system involves sequential phosphorylation reactions initiated by the hydrolysis of GTP by the G-protein.

Receptors for prostanoids and leukotrienes have been characterized pharmacologically in many bioassay systems using various prostanoids and leukotrienes and their stable analogues. Based on these studies, a pharmacological classification of the prostanoid and the leukotriene receptors is currently used. Receptors specific for PGD, PGE, PGF, PGI, and TX are named the DP, EP, FP, IP, and TP receptors, respectively. The EP receptors are further classified into four subtypes, EP_1, EP_2, EP_3, and EP_4, all of which respond to PGE_2 but differ in their actions and their responses to various analogues. Like the prostanoid receptors, the leukotriene receptors have seven transmembrane domains and are coupled to a G-protein. At least two distinct leukotriene receptors have been extensively studied and are termed $CysLT_1$ and $CysLT_2$. The prostanoid and leukotriene receptors have now been cloned and are currently used to screen and design chemical compounds that could either mimic or block the effect of endogenous eicosanoids with the goal of controlling conditions in which a lack of eicosanoid or an excess of a response to eicosanoids creates a pathological situation.

B. Autocrine and Paracrine Hormones

Prostanoids are produced by a variety of cells in response to both physiological and pathological stimuli and are released outside the cells immediately after synthesis. They exert a variety of actions in the body, which are mediated via specific cell surface receptors. The evidence leading to the conclusion that eicosanoids are hormones is that they act as chemical messengers that possess receptors and generate a specific biological response.

The eicosanoids can be considered local hormones since, with few exceptions, they exert their effects principally in the tissues or organs in which they are synthesized. The very active catabolic system of eicosanoids at the site of their synthesis led to the widely accepted view that eicosanoids are local rather than circulating hormones acting at or near their site of synthesis. To support the notion of eicosanoids as local hormones, both the synthetic enzymes involved in their synthesis and the receptors conferring their activities have been co-localized in the same cell or system.

C. Metabolism

Under basal conditions, prostanoids are considered to be formed and inactivated within the same cell prior to their release into the circulation as inactive catabolites. However, under conditions of stress when prostanoid synthesis is greatly activated, prostanoids accumulate in the circulation. The lungs contain a very active prostanoid catabolic system and the accumulation of prostanoids in the circulation is controlled through rapid degradation upon passage through the lungs. The low plasma concentrations of eicosanoids are a consequence of a combination of instability and/or active catabolism. In the case

prostacyclin, the half-life at 37°C is less than 30 s. Prostanoid catabolism begins with the oxidation of the hydroxyl group on carbon 15 to yield 15-keto metabolites. These metabolites have 10- to 100- fold less activity than their parent compounds. The oxidation is catalyzed by 15-hydroxyprostaglandin dehydrogenases specific for the different prostanoids and concentrated in the lung, kidney, and placenta. Metabolites of eicosanoids are excreted in the urine mainly in the form of 16-carbon dicarboxylic acids, which result from the ω-oxidation and β-oxidation.

V. PHARMACOLOGICAL IMPORTANCE

The importance of eicosanoids in the regulation of physiological functions and in the development of pathophysiological conditions was essentially demonstrated by inhibiting their synthesis. The major impetus for development of drugs to control the production of prostanoids and thromboxanes came from the work of Vane and co-workers in the early 1970s; these researchers showed that the inhibition of prostanoid production was a central feature of the mode of action of nonsteroidal anti-inflammatory drugs. Since then and based on that premise, drug companies have been actively developing drugs to control inflammation. In recent years, new inhibitors of prostanoid synthesis have been made available on the market, the cyclo-oxygenase-2-selective inhibitors with reduced side-effect profiles. The rationale for their development was the association of cox-1 with physiologically necessary prostanoids such as those involved in gastric cytoprotection and cox-2 with the production of prostanoids in inflammatory pathologic states such as rheumatoid arthritis. It was suggested, therefore, that the selective inhibition of cox-2 could be anti-inflammatory while avoiding the unwanted side effects of cox-1 inhibition.

It is now recognized that inhibition of prostanoid production could be beneficial in a wide variety of other physiopathologic conditions: prevention of thrombus formation, control of the menstrual cycle, correction of a patent ductus arteriosus in the newborn, or as an adjunct in the therapy of cancer. Considerable development is under way to produce selective inhibitors of the leukotrienes and their receptors for the treatment of asthma.

The complementary DNAs and genomic DNAs of the eicosanoid-forming enzymes and their receptors have all been cloned and sequenced. Their regulation of expression is being documented. The crystal structures of cyclo-oxygenases have revealed the molecular details in the formation of eicosanoids from the substrate AA as well as the mechanisms of inhibition of their formation by NSAIDs. Based on the information resulting from this work, new anti-inflammatory drugs are constantly being developed and added to the list of the most used medications in our society, NSAIDs.

VI. SUMMARY

Although the cells of an organism all contain identical genetic material, they are physically different and perform different functions. This is in part because they switch different genes on and off depending on where the cells are located in the body and what information they receive. Information in the form of hormones takes various chemical forms and is delivered to the target cells via the bloodstream. Compared to other hormones, eicosanoids constitute a very unique form of information sent to cells. They are a family of lipid messengers produced on demand by a variety of different cells; they do not travel appreciably but instead affect the cells that are producing them or nearby cells. Eicosanoids act by affecting gene expression, cellular physiology, and overall organ function. Their importance was revealed by the use of inhibitors of their synthesis, the NSAIDs, which are used extensively for the treatment of pain and fever. The effects of eicosanoids on the various systems clearly place the eicosanoids in a conspicuous position among hormones.

Glossary

arachidonic acid Polyunsaturated fatty acid that has 20 carbons and four double bonds.
cyclo-oxygenase Enzyme that catalyzes the formation of prostanoids from arachidonic acid.
eicosanoids Polyunsaturated fatty acids with 20 carbons.
enzyme A protein that catalyzes the transformation of a substrate into a product.
epoxyeicosatrienoic acids Eicosanoids that are the products of the P450 pathway.
hepoxilins Eicosanoids that are the products of the 12-lipoxygenase pathway.
hydroxyeicosatetraenoic acids Eicosanoids that are the products of the P450 and lipoxygenase pathways.
hydroperoxyeicosatetraenoic acids Eicosanoids that are the products of the lipoxygenase pathway.
leukotrienes Eicosanoids that are the products of the lipoxygenase pathway.
lipoxins Eicosanoids that are the products of the 5- and 15-lipoxygenase pathways.

lipoxygenase Enzyme that catalyzes the formation of leukotrienes, hepoxilins, and lipoxilins from arachidonic acid.

nonsteroidal anti-inflammatory drugs (NSAIDs) A class of drugs that inhibit the formation of prostanoids. NSAIDs are used in clinic mainly for the treatment of fever and pain.

P450 Enzyme that catalyzes the formation of epoxyeicosatrienoic acids and of hydroxyeicosatetraenoic acids from arachidonic acid.

prostanoids Products of the cyclo-oxygenase pathway.

Endocrine Rhythms: Generation, Regulation, and Integration

FRED J. KARSCH* AND SUZANNE M. MOENTER†

**University of Michigan, Ann Arbor • †University of Virginia*

Hormones are secreted in a periodic manner, and endocrine rhythms have frequencies that operate on various time scales. Various types of endocrine rhythms can interact, and rhythms on one time scale affect the generation and regulation of those on other time scales. The interplay among endocrine rhythms is important in the integration and timely expression of physiological and behavioral processes.

I. INTRODUCTION

Periodicity of hormone secretion is a characteristic of endocrine function. For example, a marked diurnal secretory pattern is evident for growth hormone, adrenocorticotropic hormone, and prolactin secretion from the anterior pituitary gland. These secretory patterns of pituitary hormones are the consequence of

lipoxygenase Enzyme that catalyzes the formation of leukotrienes, hepoxilins, and lipoxilins from arachidonic acid.

nonsteroidal anti-inflammatory drugs (NSAIDs) A class of drugs that inhibit the formation of prostanoids. NSAIDs are used in clinic mainly for the treatment of fever and pain.

P450 Enzyme that catalyzes the formation of epoxyeicosatrienoic acids and of hydroxyeicosatetraenoic acids from arachidonic acid.

prostanoids Products of the cyclo-oxygenase pathway.

Endocrine Rhythms: Generation, Regulation, and Integration

FRED J. KARSCH* AND SUZANNE M. MOENTER†

**University of Michigan, Ann Arbor • †University of Virginia*

Hormones are secreted in a periodic manner, and endocrine rhythms have frequencies that operate on various time scales. Various types of endocrine rhythms can interact, and rhythms on one time scale affect the generation and regulation of those on other time scales. The interplay among endocrine rhythms is important in the integration and timely expression of physiological and behavioral processes.

I. INTRODUCTION

Periodicity of hormone secretion is a characteristic of endocrine function. For example, a marked diurnal secretory pattern is evident for growth hormone, adrenocorticotropic hormone, and prolactin secretion from the anterior pituitary gland. These secretory patterns of pituitary hormones are the consequence of

diurnal secretion of hypothalamic-releasing and/or -inhibiting hormones and, in the case of pituitary hormones that target another gland downstream in the endocrine system, there is a corresponding periodicity in target gland hormone secretion (e.g., glucocorticoid secretion from the adrenal cortex). Endocrine rhythms occur with different frequencies ranging from minutes, to hours, to days, to weeks, and even up to 1 year. Furthermore, a single hormone may exhibit cycles in more than one time domain. The goal of this article is to identify various types of endocrine rhythms, how they interact, and the importance of these interactions to the integration and timely expression of physiological and behavioral processes. In particular, the concept to be developed is that rhythms on one time scale are important to the generation and regulation of rhythms on other time scales.

II. BASIC CONCEPTS AND THEORETICAL FRAMEWORK

At the outset, it is important to expand upon important terminology and to introduce a few basic concepts. In this article, a rhythm is considered to be a periodicity that is generated endogenously, from within the organism, rather than being driven by cyclical changes in the environment. Not all cyclical changes in endocrine function are due to rhythms in the sense used here. For example, the swings in insulin secretion that surround the periodic eating of meals are not due to a rhythm of pancreatic islet cell function. Rather, they are driven by external input, the periodic ingestion of food. In contrast, melatonin is secreted from the pineal gland on a 24 h basis in the complete absence of input from the external environment, due to an oscillatory process within the body. Thus, this is considered to be a rhythm. Establishing that cyclicity of hormone secretion is driven endogenously rather than by external input can be difficult, especially in the case of long-term (e.g., yearly) cycles, because it requires demonstration that they persist repeatedly in the absence of cyclical changes in relevant environmental variables.

The interval between repeated occurrences of the rhythm is its period, for example, 24 h in the case of the circadian rhythm of melatonin secretion. The period of many endocrine rhythms is regulated by variation in the internal and external environments. In the case of external cues, the period of the rhythm is adjusted to match that of a cyclical swing in ambient conditions (e.g., 24 h for circadian rhythms and 365 days for circannual rhythms). In addition, external cues set the rhythm phase, i.e., align rhythm stages appropriately to the environmental cycle. Such regulation of phase and period by the external environment is referred to as entrainment.

For illustrative purposes and to maintain focus, the remainder of this article describes how endocrine rhythms that have different periods interact to generate and regulate the ovulatory cycle of a seasonally breeding species. This specific example nicely illustrates how different types of rhythms are integrated to sustain a critically important biological function—reproduction. From an evolutionary perspective, seasonal reproduction is a common trait with significant selective advantage because it allows birth to occur at a time when the young stand the greatest chance of survival. From a practical perspective, seasonal reproduction is a natural process of reversible fertility. Knowledge of the underlying mechanisms should provide leads to novel approaches for manipulating and managing reproduction.

Figure 1 presents the conceptual framework: the seasonal expression of ovulatory cycles is the consequence of interactions among endocrine rhythms that operate in different time domains. Among these, the endocrine rhythm with the shortest period is the pulsatile rhythm of gonadotropin-releasing hormone (GnRH) secreted by neurons located in the hypothalamus (Rhythm No. 1 in Fig. 1). In its unregulated state, this rhythm has a period ranging from ~20 to 60 min, depending on species, and thus it has been classified as ultradian (period less than 1 day) or circhoral (period ~1 h). It is more commonly referred to as a pulsatile rhythm because GnRH is secreted in brief bursts (pulses) with

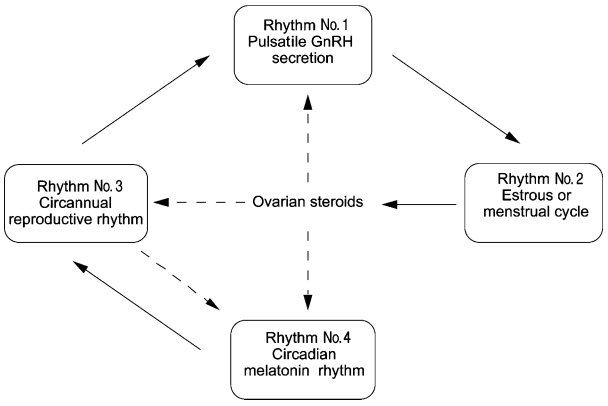

FIGURE 1 Theoretical framework for interactions among endocrine rhythms that coordinate seasonal reproduction.

little or no intervening secretion. The period (i.e., frequency) of the rhythm is tightly regulated and this is critically important to fertility. When the period is appropriate, GnRH pulses drive the estrous or menstrual cycle; inappropriate GnRH pulse frequency leads to infertility.

The ovulatory cycle itself is a true rhythm as it is endogenously generated (Rhythm No. 2 in Fig. 1). There is great species variability in the period of this rhythm. Cycles last 4 or 5 days in rodents, approximately 2 weeks in sheep, 1 month in primates, and even longer in some other species. In a number of seasonal breeders, the pulsatile GnRH rhythm and thus the ovulatory cycle are influenced by a much slower rhythm, referred to as a circannual rhythm because its period is in the range of 1 year (Rhythm No. 3 in Fig. 1). This low-frequency rhythm drives the seasonal reproductive cycle. The circannual reproductive rhythm is, in turn, regulated by yet another rhythm, the circadian rhythm of melatonin secretion from the pineal gland (Rhythm No. 4 in Fig. 1). The circadian melatonin rhythm entrains the circannual reproductive rhythm so that the fertile phase occurs during the appropriate season.

One final generality, illustrated by the dashed lines in Fig. 1, is that reciprocal interactions regulate and integrate the various types of rhythms identified above. Among these, the best described are the feedback actions of gonadal steroid hormones on the pulsatile rhythm of GnRH secretion (other interactions considered at the end of the article). In the sections that follow, pertinent concepts related to each of the rhythms identified in Fig. 1 are developed. Of particular interest is how these different types of rhythms are integrated to regulate and coordinate the reproductive process.

III. PULSATILE GONADOTROPIN-RELEASING HORMONE SECRETION—A HIGH-FREQUENCY NEUROENDOCRINE RHYTHM

A. Description

GnRH is synthesized by a small population of neurons scattered throughout the preoptic area and medial ventral hypothalamus (800–2500 neurons in mammals) (Fig. 2a). Axons of these neurons project to the median eminence where GnRH is released in the vicinity of pituitary portal capillaries, carrying this and other hypothalamic hormones to the pituitary gland (Fig. 2b). The arrival of GnRH pulses at the pituitary drives a corresponding pulsatile secretion of the two gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which in turn regulate gonadal function (Fig. 2c).

The earliest evidence for a circhoral rhythm of GnRH secretion was obtained in the early 1970s from studies of primates. This led to the surprising discovery that the concentration of circulating LH oscillated. Values increased from a nadir to a peak within a matter of minutes and then declined more gradually at a rate reflecting the half-life of this gonadotropin. These early observations led to the concept that a hypothalamic oscillator or "pulse generator" drives episodic secretion of GnRH. This idea was substantiated and embellished by the following important observations: (1) LH pulses are eliminated by obliterating GnRH secretion. (2) Episodic administration of GnRH to individuals lacking endogenous GnRH restores LH pulsatility. (3) A GnRH pulse in pituitary portal blood accompanies each LH pulse secreted from the pituitary. (4) The pulsatile release of LH is coupled to a corresponding oscillation of hypothalamic electrical activity.

The phenomenon of pulsatile GnRH secretion has had a profound impact on our understanding of the brain mechanisms governing reproduction. In addition, it has driven investigations into the functional significance and mechanisms for generation and regulation of the pulsatile mode of release.

B. Functional Significance

GnRH pulses are a prerequisite for fertility. The importance of the pulsatile pattern *per se* can be seen by testing pituitary responses to various patterns of GnRH delivery in animals lacking their own GnRH secretion. Pulsatile delivery profoundly stimulates gonadotropin synthesis and secretion, whereas continuous delivery does not. GnRH pulses vary in their amplitude, frequency, and shape. Among these characteristics, frequency modulation appears to be most important for driving changes in reproductive state. Shifts in GnRH pulse frequency are associated with progression of the ovulatory cycle and seasonal reproductive transitions, as discussed below. In addition, GnRH pulse frequency is an important determinant of differential secretion of the two gonadotropic hormones. Higher frequency favors LH release, whereas lower frequency favors FSH release. A change in the relative levels of the gonadotropins can be critical for ovarian follicular maturation.

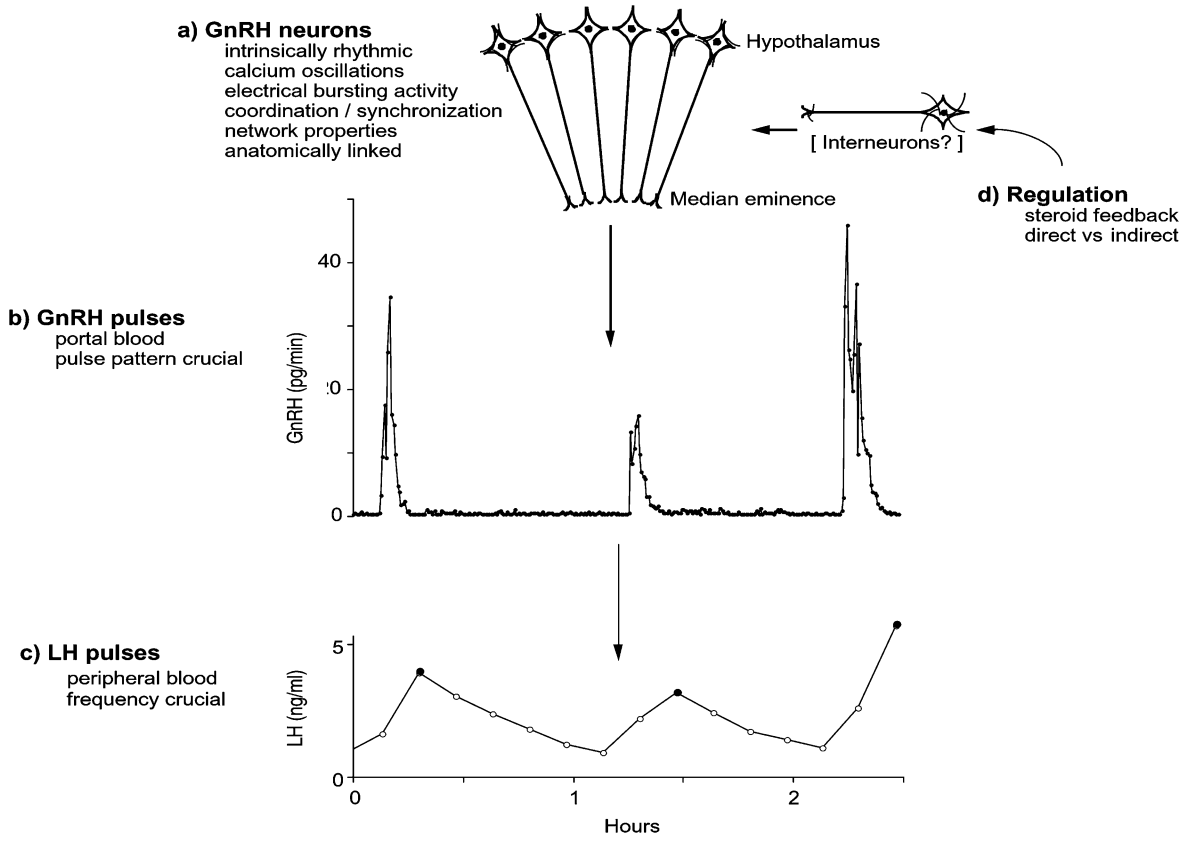

FIGURE 2 Neuroendocrine processes involved in the generation and regulation of the pulsatile rhythm of GnRH and LH secretion (see text for details). GnRH in pituitary portal blood was determined at 30 s intervals and LH in jugular blood at 10 min intervals in ovariectomized sheep. Adapted from Moenter *et al.* (1992).

C. Mechanism for GnRH Pulse Generation and Coordination

Perhaps the most fundamental question in the area of pulse generation is whether separate pacemaker cells drive the rhythm or whether GnRH neurons themselves are intrinsically rhythmic. Strong evidence that the oscillation arises within the GnRH neural network itself comes from studies using transformed GnRH neuronal cell lines or native GnRH neurons in culture. These cells exhibit spontaneous rhythmic electrical activity, rhythmic uptake of an exocytotic marker, and rhythmic secretion of GnRH. Whether or not single GnRH cells are rhythmic remains unknown. Emerging evidence favors the concept that, whereas individual cells are rhythmic, the overall pulsatile pattern of secretion emerges as a network property of multiple GnRH neurons. For example, individual GnRH neurons in culture exhibit oscillations of intracellular calcium. The oscillations, however, are generally not synchronized among cells and the oscillatory period is much shorter than that of GnRH pulses. Remarkably, calcium oscillations periodically synchronize at a frequency similar to that of pulsatile GnRH release *in vivo*, suggesting that the activity of multiple GnRH neurons is coordinated at the time of a pulse.

The foregoing observations suggest the following hypotheses, which are summarized in Fig. 2a: (1) individual GnRH neurons are intrinsically rhythmic; (2) firing patterns leading to the release of a GnRH pulse emerge from a more rapid oscillation (e.g., intracellular Ca^{2+}); (3) coordination of individual cells is required for secretion; and (4) hormone release emerges as a network property of GnRH neurons.

Another basic question concerning the mechanism of GnRH pulse generation is the molecular nature of the series of reactions within GnRH neurons that result in a pulse. Although this question has not been answered, pulse generation does not appear to be directly linked to GnRH synthesis. The GnRH gene is

transcribed in a rhythmic manner, but the period of transcription (several hours) is much slower than that of GnRH release, and pulsatile release still occurs when mRNA or protein synthesis is blocked. Thus, rather than synthesis of new proteins, the molecular mechanism for pulsatile release more likely includes posttranslational events such as changes in the phosphorylation state of proteins, including ion channels and pumps that contribute to changes in membrane properties.

The above findings indicate the importance of coordination among multiple GnRH neurons in the generation of a pulse. Neuroanatomical observations suggest that coordination could occur at cell bodies, terminals, or both (Fig. 2a). Both axo-dendritic and axo-somatic synapses have been demonstrated between GnRH neurons. Furthermore, GnRH neurons form cytoplasmic bridges with one another, suggesting that cells may be linked into syncytia. Coordination of GnRH neuronal activity may also occur at the median eminence where terminals converge, as suggested by the finding that explants containing just the isolated median eminence retain some characteristics of pulsatile release.

Several types of chemical mediators coordinating GnRH neurons may be considered. GnRH cells have both large dense core vesicles filled with GnRH and small clear vesicles containing unidentified transmitter(s). Thus, either neurotransmitters in these vesicles or GnRH itself may serve to coordinate GnRH cells. Cultured GnRH cells contain GnRH receptors, although it remains to be determined whether GnRH receptor expression is induced in GnRH neurons *in vivo*. It is also possible that GnRH or transmitters could coordinate activity among neighboring GnRH cells by diffusion through gap junctions. GnRH cells express several connexins, proteins that form gap junctions, and dye transfer has been demonstrated between GnRH neuron cell bodies. Another proposed chemical mediator of coordinated GnRH neuronal activity is the gaseous transmitter nitric oxide, which alters GnRH release both *in vivo* and in cultured GnRH cells. Clearly, many questions remain as to how GnRH pulses are generated and coordinated at the cellular level. This is an area of intense current investigation using diverse model systems.

D. Mechanisms for Regulation of GnRH Pulses by Gonadal Steroids

Feedback regulation of GnRH pulses by gonadal steroids is highly important to the generation of ovarian cyclicity and seasonality. At the cellular level, steroidal regulation of GnRH neurons has long been thought to be indirect, via steroid-sensitive afferents, as there was scant evidence for steroid receptor expression in GnRH neurons. Recent studies, however, indicate that GnRH neurons express estrogen receptor-β, a newly discovered form of the estradiol receptor. Progesterone receptors have also been identified in subpopulations of GnRH neurons in some species. Thus, it is likely that both direct and transsynaptic mechanisms cooperate in steroid feedback regulation of GnRH release (Fig. 2d).

Potential cellular mechanisms of steroid action include modulation of gene expression and nongenomic effects. Examples of gene expression include the regulated synthesis of GnRH or enzymes for neurotransmitters that regulate GnRH transsynaptically. Examples of nongenomic effects include activation of kinase signaling cascades and the opening of potassium channels on the membrane of GnRH cells. The latter actions may provide a means for rapid effects of steroids on GnRH pulsatility.

Regardless of whether steroids exert direct, indirect, genomic, or nongenomic actions, their effects are critically important to the ovulatory cycle. How their influence on the pulsatile GnRH rhythm leads to the generation of cyclicity is discussed in the next section.

IV. OVULATORY CYCLE—A LOWER FREQUENCY RHYTHM

A. Description

In its simplest sense, the ovulatory cycle (estrous or menstrual cycle) may be conceptualized as a circular series of causally related events in which each step leads to a subsequent step in the sequence. Because the series is circular, the sequence eventually loops back upon itself, forming a self-sustained cycle, i.e., a rhythm. From a regulatory perspective, the ovulatory cycle is the outcome of a well-orchestrated interplay of endocrine and neuroendocrine interactions. Ovulation is the most prominent single event, preceded by a follicular phase when estradiol rises, leading up to the preovulatory LH surge, and followed by a luteal phase when progesterone predominates.

Because this article emphasizes interactions among endocrine rhythms of different time domains ranging from circhoral (pulsatile) to circannual (seasonal), it is appropriate to consider the basis for ovarian cyclicity in a seasonal breeder. For this purpose, the sheep has been selected as a species of

focus. Not only does the large blood volume of sheep facilitate detailed analysis of rhythmic hormone secretion, powerful techniques have been developed for direct measurement of the minute-to-minute secretory pattern of GnRH secretion in this species (example in Fig. 2b). Information from such studies enables us to piece together how interactions among the pulsatile rhythm of GnRH secretion and cycles of other reproductive hormones are integrated into a self-sustaining ovulatory cycle.

B. Cycle Generation—Role of Pulsatile GnRH Rhythm

In its unregulated state, the period of the pulsatile GnRH rhythm in the ewe is 30 to 60 min and the amplitude of GnRH pulses is relatively large. Each of the ovarian steroids, progesterone and estradiol, exerts negative feedback on the pulsatile pattern, but they do so by very different mechanisms. The action of progesterone is relatively simple; it inhibits the frequency of the GnRH oscillation. Estradiol, in contrast, affects the dynamics of individual GnRH pulses, decreasing their amplitude, duration, and rate of increase, each of which reduces the mass of hormone released during a pulse. Moreover, estradiol enhances basal GnRH release between pulses. All of these parameters alter the response of pituitary gonadotropes and thus have physiological relevance to the reproductive state. Of importance, estradiol does not inhibit GnRH pulse frequency during the cycle and, if anything, this steroid increases frequency during the follicular phase. Because GnRH pulses drive LH pulses, these ovarian steroids similarly affect the episodic secretion of LH from the pituitary gland. At the ovarian level, high-frequency LH pulses promote steroidogenesis and, in particular, the follicular phase rise in estradiol secretion from the developing preovulatory follicle.

The above basic hormonal relationships can now be integrated into a schema for estrous cycle generation (the major steps in the preovulatory sequence are illustrated in Fig. 3). During the midluteal phase of the cycle, the corpus luteum secretes copious quantities of progesterone, which applies a brake to the GnRH neurosecretory system. The resulting low frequency of GnRH and LH pulses (one pulse every 4 to 8 h) is not sufficient to initiate the preovulatory chain of events. Near the end of the luteal phase (~12 to 13 days after ovulation), progesterone secretion drops precipitously as the corpus luteum regresses (step 1 in Fig. 3). Within ~24 h after the onset of luteolysis, circulating progesterone reaches an undetectable level, liberating the GnRH neurosecretory system from frequency inhibition. Estradiol inhibits the amplitude of GnRH pulses but itself cannot reduce frequency. Thus, the brake on rhythmic GnRH secretion is removed; GnRH pulse frequency accelerates to one pulse every 30–60 min, and the pituitary responds with high-frequency LH pulses (step 2). This gonadotropic stimulus, in conjunction with the basal concentration of FSH, promotes maturation of the ovarian follicle and drives a sustained increase in estradiol synthesis (step 3). The circulating estradiol concentration thus rises steadily, eventually reaching a threshold for initiating two critically important events, estrous behavior and the preovulatory LH surge (step 4).

Two separate actions of estradiol are coordinated to induce the LH surge, one at the hypothalamus to

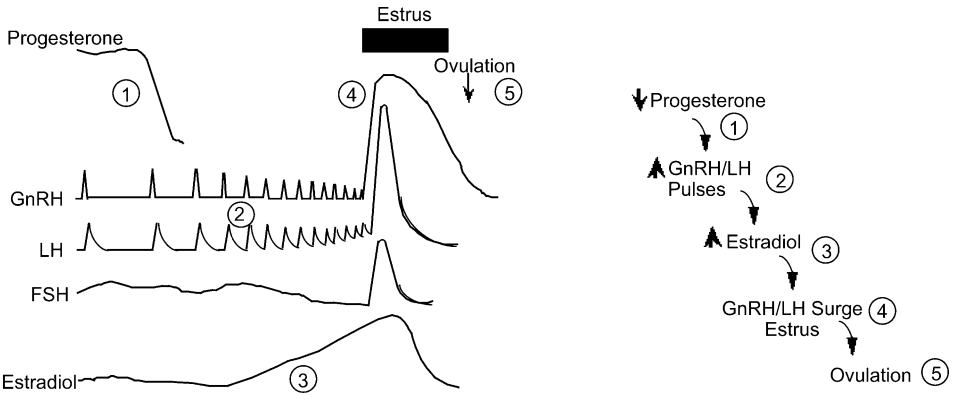

FIGURE 3 Schematic representation of major steps in the preovulatory sequence of events in the ewe. The patterns of various reproductive hormones and the approximate times of estrous behavior and ovulation are shown on the left. The stepwise preovulatory sequence is shown at the right. See text for details. Reprinted from Battaglia *et al.* (2000), with permission.

induce a large and sustained (18–24 h) GnRH surge and the other at the pituitary to enhance responsiveness to GnRH. The LH surge, in turn, initiates a cascade of enzymatic and hemodynamic changes within the preovulatory follicle, resulting in digestion of the outer follicular wall and ovulation some 12 to 24 h later (step 5). Of interest, the GnRH surge also stimulates brain behavioral centers to increase the duration and intensity of sexual receptivity. This highly integrated coupling of ovarian, neuroendocrine, and behavioral events provides a means of coordinating the time of ovulation and insemination, thus maximizing chances for conception.

From the above perspective, the pulsatile rhythm of GnRH, and particularly its frequency, is critically important in generating the ovulatory cycle. Increased frequency initiates the preovulatory cascade. In situations where GnRH pulse frequency fails to increase, such as during pregnancy (when progesterone remains elevated) or during the nonbreeding season (see below), the estrous cycle ceases. Of key importance to cyclicity, estradiol itself does not inhibit frequency and this allows LH and estradiol to increase in parallel during the follicular phase. The end result is the GnRH and LH surges, estrous behavior, ovulation, and progression to the luteal phase of the cycle. With the luteal phase rise in progesterone secretion, GnRH pulse frequency is again inhibited until subsequent regression of the corpus luteum, initiating a new preovulatory sequence.

There is much interest in the mechanisms of the feedback actions of ovarian steroids on gonadotropin secretion. This is a point at which reproduction can be managed and fertility regulated, not only artificially but also naturally, as is the case with seasonal breeding. Within the present framework of interactions among endocrine rhythms, the following section addresses how steroid feedback responses, pulsatile GnRH secretion, and ovarian cyclicity are all influenced by a lower frequency rhythm that regulates seasonal reproduction.

V. SEASONAL REPRODUCTION—EXPRESSION OF A CIRCANNUAL RHYTHM

A. Description

Various strategies have evolved to enable seasonal reproduction. Among these are delayed fertilization, embryonic diapause, and an annually recurring decline and restoration of gonadal activity. Although vastly different mechanistically, these strategies all serve a common purpose, ensuring that young are born at the time optimal for their survival. In ewes, seasonal breeding is the consequence of an annual rhythm that causes periodic switching on and off of the estrous cycle. Typically, the breeding season begins in autumn (Fig. 4a). Unless pregnancy is established, estrous cycles persist until mid to late winter, at which time cyclicity ceases during a 6- to 7-month period of anestrus (the duration of anestrus and breeding season varies among different sheep breeds). Under natural conditions, pregnancy is usually established early in the breeding season. Given the 5-month gestation period, lambs are born in spring, which is early in the anestrous season, and thus the next opportunity for pregnancy must await the subsequent breeding season.

B. Neuroendocrine Regulation

Given that the estrous cycle is a rhythm generated by a circular series of interrelated events, only one step in the sequence needs to be disrupted for the loop to be broken and cyclicity to cease. Extensive evidence indicates that the disrupted step is the development of sustained, high-frequency GnRH and LH pulses

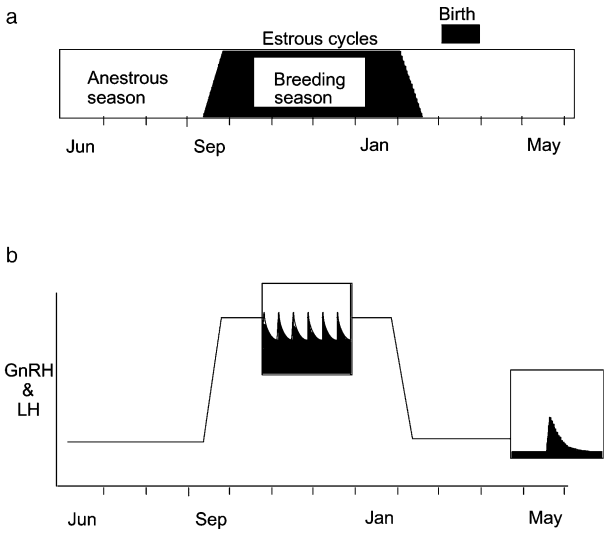

FIGURE 4 (a) Timing of breeding and anestrous seasons (expressed as occurrence of estrous cycles) and births in ewes in Northern Hemisphere temperature zone. (b) Schematic representation of an experiment demonstrating the seasonal change in responsiveness to the negative feedback action of estradiol in the ewe. Adapted from Legan *et al.* (1977). Changes in response to estradiol negative feedback as determined by LH and GnRH pulses in ovariectomized ewes treated with constant-release estradiol implants (ovx + E). See text for further details.

between luteolysis and the preovulatory LH surge (step 2 in the preovulatory sequence; see Fig. 3). Despite the absence of corpora lutea and elevated progesterone during the anestrous season, due to the absence of ovulation, GnRH pulses remain infrequent (only two to four pulses each day). Since highly frequent LH and thus GnRH pulses are essential for preovulatory follicular development and a sustained increase in estradiol secretion, there is no estradiol rise, LH surge, estrous behavior, or ovulation. Although some studies suggest that ewes also become less responsive to the behavioral and LH surge-inducing effects of estradiol, such changes are relatively minor and, in the case of the LH surge mechanism, there is also evidence that there is no seasonal change in response to estradiol. Rather, it is the pulsatile GnRH rhythm that ultimately dictates the seasonal reproductive state.

The lack of high-frequency GnRH pulses during anestrus is not due to a dysfunction of the GnRH system itself, because removal of negative feedback by ovariectomy causes GnRH pulses to accelerate to a high frequency. Rather, estradiol, which does not inhibit frequency during the breeding season, becomes highly effective at suppressing frequency during anestrus. This powerful inhibitory action of estradiol enables the follicle to restrict its own development during anestrus via a highly effective negative feedback loop involving the ovary and the hypothalamic GnRH pulse-generating mechanism. Because of this restricted follicular development and limited estradiol production, the preovulatory sequence is halted.

The profound seasonal change in responsiveness to estradiol negative feedback was disclosed in the 1970s by experiments in which ovariectomized ewes were treated with constant-release estradiol implants that clamped circulating estradiol chronically at an early follicular phase level (the experiment is summarized in Fig. 4b). Such ewes exhibit a high-amplitude annual cycle of circulating LH, with values being extremely low during the spring and summer and increasing some 50-fold during the autumn and winter. The seasonal rises and falls in LH, which coincide with the transitions between breeding and anestrous seasons in ovary-intact ewes, were subsequently found to result from a marked change in GnRH pulse frequency. During anestrus, estradiol powerfully inhibits GnRH pulse frequency, whereas, during the breeding season, it does not. In essence, the change in period of the pulsatile GnRH rhythm in the presence of estradiol constitutes the neuroendocrine basis for seasonal reproduction in the ewe.

C. Neural Basis for Altered Estradiol Negative Feedback

The changes within the brain that lead to shifts in estradiol negative feedback effects are of great interest because they underlie a natural process of reversible fertility and infertility. Several potential mechanisms have been addressed, three of which are now considered briefly: (1) estradiol receptors, (2) neurotransmitter activity, and (3) neuroplasticity.

1. Estradiol Receptors

Since estradiol negative feedback requires interaction with target cells, a seasonal alteration in hypothalamic estradiol receptor is an attractive potential mechanism for the shift in feedback efficacy. This possibility, however, has been difficult to address experimentally because estradiol influences several hypothalamic functions, only one of which is inhibition of GnRH secretion, and it is not known which estrogen-sensitive hypothalamic area(s) and cell type(s) are relevant to suppression of GnRH pulse frequency. Complicating this matter further, estradiol feedback may be achieved indirectly via interneurons, rather than directly on GnRH neurons, and several different types of estradiol receptors exist (see section on pulsatile GnRH rhythm and Fig. 2d). Initial studies in this area did not reveal seasonal differences in estradiol binding or receptor levels in the hypothalamic tissue of ewes. More recent work, employing immunocytochemistry to localize estradiol receptor-α, did reveal a greater number of estradiol receptor-containing cells in the preoptic area of ewes during anestrus than during the breeding season. Although this difference is consistent with more potent negative feedback during anestrus, the neurotransmitter phenotype of the cells exhibiting increased estradiol receptor and their importance to inhibition of GnRH pulse frequency are not known.

2. Neurotransmitters

Seasonal alteration in neurotransmitter activity is of interest because estradiol can affect GnRH secretion indirectly via neurotransmitters linking estrogen-sensitive interneurons to GnRH cells. Among these, dopaminergic and serotonergic systems have received the greatest attention and, in particular, dopamine is implicated in the seasonal shift in estradiol negative feedback in the ewe. Multiple complementary approaches have revealed that a group of dopamine neurons having cell bodies located in the retrochiasmatic region of the hypothalamus (A15 dopaminergic cell group) are critically important to seasonality. These dopaminergic

cells are preferentially activated by estradiol during anestrus and they are necessary for the inhibitory effect of estradiol on GnRH pulse frequency. The dopamine neurons themselves do not appear to contain the α form of the estradiol receptor, but they receive input from sites that do and they project to hypothalamic regions that contain GnRH neurons. Nevertheless, the specific cell types and pathways by which estradiol activates these dopamine neurons and whether or not they directly innervate GnRH neurons to regulate pulse frequency remain to be determined.

3. Neuroplasticity

Investigation of seasonal morphological changes in the GnRH system was prompted by the demonstration that a marked seasonal plasticity occurs in brain regions that regulate other seasonal variations, most notably singing in birds. At the level of the GnRH system of mammals, structural rearrangements have been documented during the course of puberty, the estrous cycle, and reproductive aging. Recent observations in ewes have revealed a seasonal difference in synaptic input to GnRH neurons, the input being twofold greater during the breeding season than during anestrus. The seasonal difference in the innervation of GnRH neurons was identified in both ovary-intact ewes and ovariectomized ewes bearing constant-release estradiol implants. Thus, this finding reflects an intrinsic seasonal plasticity of the GnRH neurosecretory system rather than seasonal differences in ovarian hormone secretion. Complementing the change in synaptic input is the recent finding that a protein promoting neuroplasticity, the polysialylated form of neural cell adhesion molecule (PSA-NCAM), is closely associated anatomically with GnRH neurons of the ewe. This association is more prominent during the breeding season than during anestrus. Despite these interesting observations, the functional significance of the seasonal change in synaptic input to GnRH neurons, and of PSA-NCAM, to seasonal changes in pulsatile GnRH secretion is not known.

D. Seasonal Reproductive Rhythm

Given the seasonal swings in estradiol feedback and the corresponding shifts in ovarian cyclicity, it is important to consider how endocrine rhythms participate in the generation and timing of seasonal cyclicity. Timing is considered in the depth in the next section. Suffice it to say here that a number of geophysical variables have the potential to influence the reproductive pattern of seasonal breeders. Among these, the annual change in day length is the most influential. Because photoperiodic changes are stable from year to year, they provide a highly reliable time cue for predicting future environmental conditions and thus for aligning the fertile period to the appropriate season. The seasonal breeding pattern of sheep, like that in other seasonal breeders, can readily be manipulated photoperiodically. For example, the pattern can be shifted so that the breeding season is 6 months out of phase or the period of the annual cycle can be accelerated so that two breeding seasons occur each year. At a neuroendocrine level, photoperiodic manipulations that influence the timing of the breeding season do so by altering the seasonal swings in response to the negative feedback action of estradiol on pulsatile GnRH secretion.

Importantly, endogenous rhythms provide the driving force for seasonal reproductive cycles in a number of long-lived seasonal breeders. In these species, repeated long-term cycles of reproduction and other biological processes (e.g., hibernation and molt) continue to be expressed when the influence of seasonal photoperiodic change is eliminated. For example, such cycles are evident during exposure to a constant photoperiod. In mammals, they also persist following blinding, pinealectomy, or denervation of the pineal gland, all of which functionally disconnect animals from their photoperiodic environment. The long-term cycles are referred to as circannual since their period approximates 1 year. Circannual cycles are considered to be driven by an endogenous rhythm because, in the absence of photoperiodic regulation, their period differs from 365 days and the various cycle stages (e.g., onset of the breeding season) drift out of phase with respect to time of the year (i.e., the rhythm is free-running).

The existence of a circannual reproductive rhythm is well documented in sheep. In ovariectomized ewes treated with constant-release estradiol implants, the rhythm is expressed as a free-running cycle in the serum LH concentration, which gradually shifts with respect to time of year. An example of a free-running, circannual LH cycle in a ewe maintained in a fixed photoperiod is shown in Fig. 5. As described above, the seasonal swings in LH in this animal model reflect changes in the frequency of the pulsatile GnRH rhythm.

The foregoing discussion indicates that seasonal shifts in the pulsatile GnRH rhythm of a circannual species such as sheep are not driven by seasonal changes in the environment. Rather, they are driven internally by a circannual rhythm. Photoperiod serves

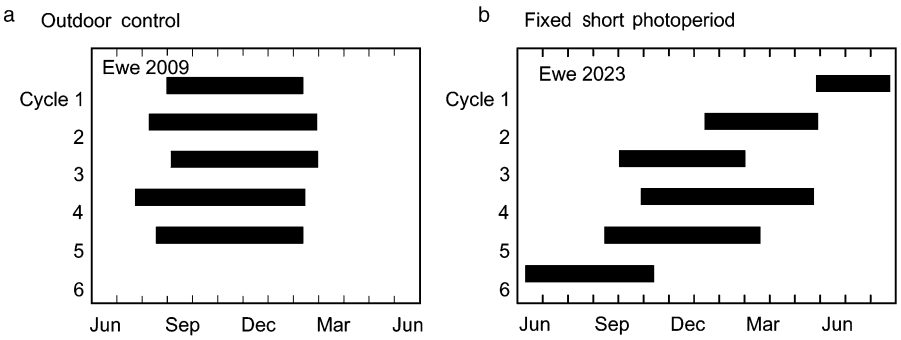

FIGURE 5 Circannual cycle of reproductive neuroendocrine activity in ewes. (a) The yearly occurrence and timing of the seasonal LH cycle in an estradiol-treated ovariectomized ewe maintained outdoors in natural photoperiod for 5 years. High LH (solid bars) is indicative of the neuroendocrine breeding season (see Fig. 4b). (b) Results in a ewe maintained indoors in a fixed short photoperiod during the same time span. Note that the circannual cycle is entrained in the ewe maintained outdoors (no net change in timing of high-LH phase), whereas the cycle in the ewe kept in the fixed photoperiod is free-running. In the latter case, the average period of the circannual cycle is less than 365 days, so that the high-LH phase advances over successive cycles and six cycles are evident over the 5-year period compared to five in the outdoor control. Adapted from Karsch *et al.* (1989), with permission. See Fig. 4 for further representation of seasonal changes in GnRH and LH secretion in this animal model.

to set the period and phase of this rhythm (i.e., entrain the rhythm) so that reproductive activity occurs at the appropriate time. This entrainment process is achieved via interaction of the circannual mechanism with a rhythm that operates in yet another time domain, the circadian rhythm of melatonin secretion, as discussed in the following section.

VI. CIRCANNUAL RHYTHM ENTRAINMENT—ROLE OF CIRCADIAN RHYTHMICITY

A. Description

Circadian pacemakers generate 24 h rhythms and provide important timekeeping functions for all forms of life. Such rhythms drive a broad range of biochemical, behavioral, and physiological cycles, including secretory activity of endocrine glands, thereby enabling organisms to align daily activities to diurnal changes in their environment. Circadian rhythms also serve important timekeeping functions for rhythms that have a period longer than 24 h. For example, circadian rhythms determine when ovulation occurs in certain rodents, thus timing the ovarian cycle in these species. Circadian rhythms also participate in timing annual cycles; it is this influence that is crucial for entrainment of circannual rhythms.

B. Role of Melatonin in Photoperiodic Time Measurement

The 24 h cycle of light and darkness entrains a circadian rhythm of melatonin secretion from the pineal gland, so that elevated secretion is confined to the hours of darkness and the duration of this elevation is directly proportional to length of the night. The importance of melatonin to photoperiodic regulation of seasonal processes was initially recognized by findings in the Syrian hamster. Pinealectomized hamsters, which lack the melatonin rhythm, fail to express short-day-induced testicular regression, but regression can be induced by replacement with melatonin. Subsequent work extended these findings to other seasonally breeding mammals and also demonstrated that melatonin is not simply inhibitory to reproduction. Rather, melatonin acts to mediate the effects of seasonal changes in photoperiod. Furthermore, the influence of melatonin extends beyond reproduction to a broad spectrum of seasonal processes. In essence, the circadian melatonin rhythm provides a hormonal code for photoperiod.

The mechanisms by which melatonin achieves its timekeeping function have been investigated from several perspectives including the entrainment of circannual rhythms. Before addressing this, it is pertinent to identify two characteristics of the circadian melatonin pattern that have been postulated to relay photoperiodic information. One is the phase relationship between nocturnal melatonin secretion and other circadian rhythms; this changes through the course of the year and thus could provide input for seasonal timing. The second is duration of the nocturnal increase in melatonin secretion, which varies seasonally in direct proportion to the hours of darkness and thus could provide a seasonal time cue.

Support for a role of both phase and duration has been obtained but in neither case has it been determined how these characteristics of the melatonin pattern are transcribed into altered seasonal functions.

C. Melatonin Entrains the Circannual Reproductive Rhythm

The finding that pinealectomy causes circannual rhythms to free-run, in conjunction with observations that the circadian melatonin pattern provides a code for day length, has prompted investigation into the role of melatonin in circannual rhythm entrainment. This line of research has been facilitated by the development of experimental paradigms in which circadian delivery of melatonin, by timed infusion, can mimic neuroendocrine effects of photoperiod in animals rendered photoperiodically unresponsive by pinealectomy. Importantly, this approach has revealed that nocturnal melatonin infusions of differing durations, which match the duration of endogenous melatonin under specific photoperiods, can restore responses characteristic of those specific photoperiods.

Using this experimental paradigm, the involvement of the circadian rhythm of melatonin secretion in entraining the circannual rhythm of reproductive neuroendocrine activity has been investigated in pinealectomized ewes. Initial work demonstrated that the circadian delivery of melatonin can entrain the circannual reproductive rhythm, regulating both period and phase with respect to the seasons. In addition, exposure to melatonin for as little as 2 months each year was found to be fully sufficient for entrainment. Next, by gradually changing the duration of the nocturnal melatonin infusions to mimic the gradually changing melatonin patterns secreted during different seasons, it was determined that a seasonal specificity exists with respect to the melatonin patterns that entrain the rhythm. Patterns mimicking those secreted naturally during summer are most effective, whereas those secreted during the winter are ineffective (see Fig. 6 for a more complete synopsis of those findings). Finally, the winter melatonin pattern, which does not entrain the rhythm when delivered

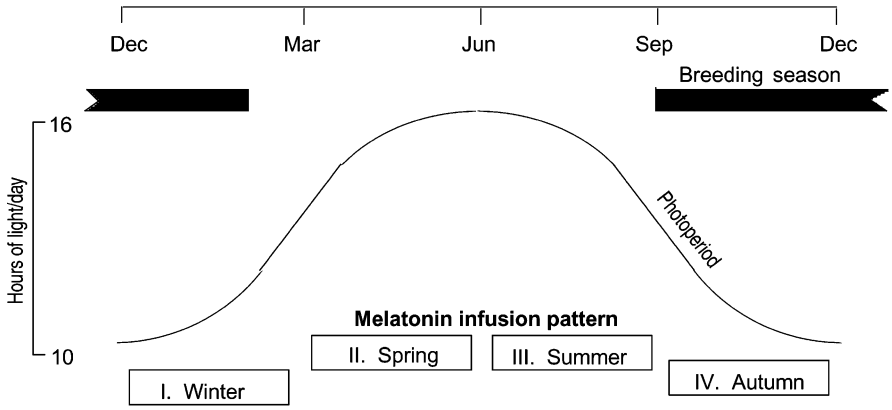

FIGURE 6 Summary of a study to determine the influence of four different melatonin infusion patterns, which mimicked endogenous circadian melatonin patterns during the four seasons, on entraining the circannual rhythm of reproductive neuroendocrine activity in pinealectomized ewes. Separate groups of sheep each received one of four season-specific melatonin infusion patterns [(I) winter; (II) spring; (III) summer; (IV) autumn] for 3 months during the corresponding season each year. For example, the spring melatonin pattern (II) consisted of a gradually decreasing duration of nightly melatonin infusion between the spring equinox and the summer solstice, mimicking the endogenous melatonin secretory pattern at that time of the year. Following the 3-month infusions, no melatonin was given for the remaining 9 months of the year. This yearly treatment cycle was repeated over a 3-year period. The efficacy of each treatment in entraining the circannual rhythm of reproductive neuroendocrine activity is indicated at the bottom. The black bars near the top indicate timing of the natural breeding season and the curved line depicts the photoperiod. Adapted from Woodfill *et al.* (1994).

in winter, is also ineffective when infused in summer, whereas the summer melatonin pattern is effective when infused during other rhythm stages. This supports the concept that the specific characteristics of the circadian pattern of melatonin secretion appear to be key to circannual rhythm entrainment.

The capability of melatonin to entrain the circannual rhythm of reproductive neuroendocrine activity in a season-specific fashion only begins to scratch the surface of the entrainment process. Clearly, it is important to know how and where circannual rhythms are generated and how melatonin interacts with the circannual mechanism. Recent work provides evidence that the melatonin relevant to seasonal GnRH regulation in sheep is secreted into the third cerebral ventricle and that it interacts with receptors located in the premamillary region of the hypothalamus. These findings provide an important clue as to where to look for mechanisms that generate and entrain the circannual reproductive rhythm of this species. It is also important to note that, beyond reproduction, melatonin may act elsewhere to regulate seasonal cycles of other neuroendocrine activities. For example, melatonin appears to mediate photoperiodic regulation of prolactin secretion in sheep by acting on the pars tuberalis of the pituitary gland.

VII. SUMMARY AND FINAL CONSIDERATIONS

This article has examined how different types of endocrine rhythms are integrated to regulate a critically important biological process—reproduction. At the outset, a conceptual framework was presented: the seasonal expression of ovulatory cycles reflects a finely tuned interplay among endocrine rhythms that operate on different time domains (see Fig. 1). This concept was exemplified in this article by considering evidence that a circadian rhythm (melatonin secretion) entrains a circannual rhythm (neuroendocrine feedback responsiveness) and this dictates the frequency of a circhoral rhythm (GnRH pulses) that, in turn, drives a biweekly rhythm of ovarian activity (estrous cycle). Collectively, this integrated system of rhythms dictates if and when ovulatory cycles occur.

In closing, it is important to point out that the schema developed here is almost certainly overly simplistic. Other interactions among these endocrine rhythms are likely to contribute to the coordinated activity of the system. Some of these are illustrated by the dashed lines in Fig. 1. For example, estradiol can cause phase shifts of circannual cycles, as revealed by studies in ground squirrels. In this manner, the seasonal changes in ovarian activity themselves may influence the expression of the underlying circannual rhythm. Furthermore, under conditions in which circannual rhythms free-run, the expression of circadian rhythms has been found to change on a circannual basis. One such change of particular interest here is the duration of the nocturnal secretion of melatonin in sheep. Thus, the hormonal message that entrains the circannual reproductive rhythm itself appears to be reciprocally regulated by the circannual mechanism. Such findings document the enormous complexity of the interplay of rhythmic processes and they serve to emphasize that much still remains to be learned about the generation, regulation, and integration of endocrine rhythms.

Glossary

circadian rhythm Endogenous oscillation having a period of ~24 h.
circannual rhythm Endogenous oscillation having a period of ~365 days.
circhoral rhythm Endogenous oscillation having a period of ~1 h.
endocrine rhythm An oscillation of hormone secretion that is generated endogenously.
entrainment Regulation of rhythm period and phase by time cues in the external environment.
free-run Persistence of a rhythm in the absence of entrainment.
period Interval between repeated occurrences of a rhythm.
phase Characteristic of a rhythm at any given point in its progression, for example, onset of the breeding season in the case of the seasonal reproductive rhythm.

Endometrial Remodeling

LOIS A. SALAMONSEN AND REBECCA L. JONES
Prince Henry's Institute of Medical Research, Australia

The human endometrium undergoes remarkable remodeling across the menstrual cycle, with phases of regeneration and proliferation, differentiation, and breakdown and shedding. It is one of the few adult nonpathological tissues that actively remodels and thus produces a wide range of growth factors, cytokines, and enzymes that are generally associated with embryonic development or tumorigenesis. The remodeling is driven overall by the maternal ovarian hormones estrogen and progesterone, but their actions are mediated by a myriad of local regulators acting in concert. The changes across the menstrual cycle and their regulation by steroid hormones will be the focus of this article.

I. INTRODUCTION

The primary function of the endometrium is to provide an environment that is permissive to attachment of a conceptus but that also regulates subsequent trophoblast invasion, enabling optimal development of an intimate contact between maternal and fetal blood supplies. As it is important that embryos implant only when they are at the correct stage of development, the endometrium is nonreceptive to embryo implantation for the majority of the menstrual cycle. Implantation occurs only when there is perfect synchrony between embryonic and endometrial development, during the brief window of endometrial receptivity. The mechanisms of implantation differ widely between different mammalian species: the extent of endometrial preparation or remodeling required also varies. Human implantation involves a very high degree of trophoblast invasion into the maternal blood vessels and myometrium, and thus, the human endometrium undergoes more extensive preparative remodeling and differentiation than that of any other species, to tightly regulate placentation. Many of these changes are irreversible, and thus there is a requirement for shedding of the endometrium during menstruation, if pregnancy is not achieved.

Endometrial Remodeling

LOIS A. SALAMONSEN AND REBECCA L. JONES
Prince Henry's Institute of Medical Research, Australia

The human endometrium undergoes remarkable remodeling across the menstrual cycle, with phases of regeneration and proliferation, differentiation, and breakdown and shedding. It is one of the few adult nonpathological tissues that actively remodels and thus produces a wide range of growth factors, cytokines, and enzymes that are generally associated with embryonic development or tumorigenesis. The remodeling is driven overall by the maternal ovarian hormones estrogen and progesterone, but their actions are mediated by a myriad of local regulators acting in concert. The changes across the menstrual cycle and their regulation by steroid hormones will be the focus of this article.

I. INTRODUCTION

The primary function of the endometrium is to provide an environment that is permissive to attachment of a conceptus but that also regulates subsequent trophoblast invasion, enabling optimal development of an intimate contact between maternal and fetal blood supplies. As it is important that embryos implant only when they are at the correct stage of development, the endometrium is nonreceptive to embryo implantation for the majority of the menstrual cycle. Implantation occurs only when there is perfect synchrony between embryonic and endometrial development, during the brief window of endometrial receptivity. The mechanisms of implantation differ widely between different mammalian species: the extent of endometrial preparation or remodeling required also varies. Human implantation involves a very high degree of trophoblast invasion into the maternal blood vessels and myometrium, and thus, the human endometrium undergoes more extensive preparative remodeling and differentiation than that of any other species, to tightly regulate placentation. Many of these changes are irreversible, and thus there is a requirement for shedding of the endometrium during menstruation, if pregnancy is not achieved.

II. MORPHOLOGICAL CHANGES ACROSS THE MENSTRUAL CYCLE

The human endometrium comprises two histologically and functionally distinct layers, the basalis, which is adjacent to the myometrium, and the functionalis, which extends from the basalis to the uterine lumen. During each menstrual cycle, the basalis is retained, whereas the functionalis undergoes cyclical remodeling. The endometrium is composed of epithelial, stromal, vascular, and lymphomyeloid cells, surrounded by a complex extracellular matrix (ECM). The normal menstrual cycle can vary from 21 to 35 days, with menstruation lasting for 3–7 days. In the normalized cycle of 28 days, day 1 is defined as the first day of menstrual bleeding. The major phases are the menstrual phase, the proliferative (follicular) phase, during which tissue regrowth occurs, and the secretory (luteal) phase when differentiative changes in preparation for implantation predominate (Fig. 1). Normal ovulatory menstrual cycles are associated with consistent morphological changes. Clearly defined morphological parameters have enabled the classification of the histological changes in the proliferative and secretory phases, to provide a method for accurately dating the endometrial biopsy.

A. Proliferative Phase (Normalized Cycle: Days 5–13)

The proliferative phase is of variable length and is overall regulated by estrogen originating from the developing ovarian follicle. Estrogen levels rise as the phase progresses, to reach a peak just prior to ovulation. Reepithelialization of the denuded endometrial surface is initiated during the menstrual phase in parallel with tissue breakdown in adjacent areas. This resembles tissue repair in the fetus, which, unlike that in the adult, is devoid of scarring. The damaged endometrial vessels are also repaired within 5 days of menstrual onset. Once the luminal epithelium is restored, there is a rapid proliferation of all resident cell types—stromal cells, glandular epithelium, and blood vessels—and new ECM is laid down by synthesis from these cells. Stromal edema is apparent in the midproliferative phase. The overall result is thickening of the endometrial layer.

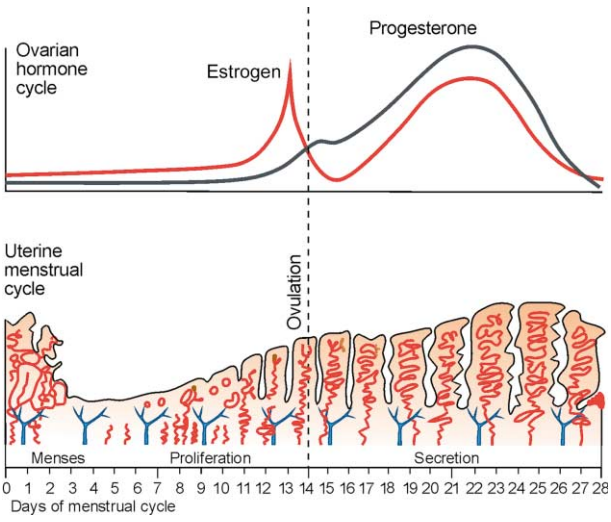

FIGURE 1 Ovarian hormone fluctuations and endometrial remodeling across a standardized 28-day menstrual cycle.

B. Secretory Phase (Normalized Cycle: Days 14–28)

Following ovulation (at approximately day 14 of an idealized 28-day cycle), the endometrium undergoes functional differentiation events under the control of progesterone released from the corpus luteum, to provide a suitable environment for embryo implantation. The sequential changes in the appearance of the endometrium during the secretory phase enable accurate assessment of the timing after the luteinizing hormone (LH) surge, and subdivision into early, mid, and late secretory phases. The early secretory phase is characterized by the development of subnuclear vacuoles in epithelial cells, resulting in an altered intracellular location of the nuclei during the early proliferative phase. Over the early to midsecretory phases, epithelial glands become increasingly tortuous and have increased secretory activity. During the midsecretory phase, there is prominent stromal edema, accompanying the development and coiling of the specialized spiral arterioles. After day 22, the stromal cells begin a differentiation process known as decidualization, which is a prerequisite for successful implantation and placentation. This involves widespread morphological changes and tissue remodeling, as fibroblast-type cells become enlarged and rounded and deposit a pericellular matrix. The resultant decidual cells have a markedly different phenotype than the fibroblasts from which they are derived, producing a wide array of growth factors and cytokines that act both to promote and to regulate trophoblast invasion during embryo implantation. Elevated numbers of leukocytes (particularly macrophages and the specialized uterine natural killer cells) are present in the endometrial stroma as decidualization commences (Table 1). If pregnancy occurs, decidualization progresses

TABLE 1 Relative Distributions of Specific Inflammatory Cells in the Functional Endometrium at Three Stages of the Normal Menstrual Cycle

Cell type	Proliferative phase days 10–12	Secretory phase days 22–23	Menses days 26–28
Macrophages	+	++	+++
Eosinophils	−	−	++
Neutrophils	−	−	+++
Mast cells	++	++	++
T lymphocytes	+	+	+
B lymphocytes	−/+	−/+	+
Uterine NK cells	−	+/++	+++

Note. −, +, ++, and +++ represent values of 0, 1–2, 3–5, and 6–15% of total endometrial cells, respectively.

throughout the endometrium, providing the maternal component of the placenta.

C. Menstrual Phase (Normalized Cycle: Days 1–4)

In the absence of a pregnancy, falling progesterone levels in the late secretory phase trigger endometrial regression. Menstruation involves the partial breakdown and loss of the functionalis layer of the endometrium that occurs in association with uterine bleeding. Interestingly, other organs such as the breast, vagina, and oviduct contain the same complement of steroid receptors and undergo considerable tissue remodeling, but none break down, suggesting that it is the unique characteristics of decidualized stroma, spiral arterioles, and leukocyte infiltrate that define the endometrium as a tissue targeted for destruction.

Tissue destruction at menstruation is very focal and reepithelialization occurs at some foci coincident with tissue degradation while bleeding is still in progress at other sites, indicating the importance of local molecular triggers. There is a further influx of leukocytes, primarily polymorphonuclear leukocytes and macrophages, in the premenstrual phase and these are postulated to play a major role in the local initiation of tissue breakdown (Table 1). Even before menstruation, widespread degeneration is seen in the basal lamina supporting the decidualized cells and the endothelium of blood vessels. This is most likely a result of extensive degradation of the ECM; small lesions are apparent by scanning electron microscopy in the luminal epithelium on day 28 of the cycle. The classic concept of menstruation originated from studies in the rhesus monkey in the 1940s and proposed that it is an event resulting from vasoconstriction/reperfusion. It is now, however, widely accepted that menstruation is a result of both vascular and inflammatory events driven by local regulatory factors and that the tissue destruction is caused by the action of matrix-degrading enzymes.

III. CYCLE-RELATED CHANGES IN THE ENDOMETRIAL EXTRACELLULAR MATRIX

The endometrial interstitial ECM is primarily a product of stromal fibroblasts and comprises a variety of collagens, glycosaminoglycans, and proteoglycans. As in other tissues, the basal lamina is associated with epithelial and vascular structures. The ECM components demonstrate spatial variation within the endometrium and also undergo specific cyclical changes during the menstrual cycle; however, the regulatory mechanisms involved are unclear (Table 2). As the proliferative phase progresses, an initial fine network of reticulum fibers in the functionalis progressively becomes denser and thicker. This network comprises collagens type I, III, V, and VI, along with vitronectin, which stains most densely adjacent to the glandular basal lamina. A peak of hyaluronan (whose extreme hydrophilic nature contributes to the hydration of tissue) is seen in the midproliferative phase, coincident with stromal edema. Also during the proliferative phase, components of the basal lamina (collagen type IV, laminin, nidogen) increase with restoration of the epithelium and development of the glands. During the midsecretory phase, a number of important alterations occur in the ECM of the functionalis, at the time when implantation would occur and immediately prior to decidualization. The stroma becomes more edematous in concert with a second peak of hyaluronan, and the fibrillar components become more loosely arranged. Collagen V epitopes become unmasked, and a system of matrix channels is seen between decidual cells. There is also a progressive loss of collagen type VI (an interfibrillar cross-linker). The decidual cells lay down components of basal lamina that surround these cells,

TABLE 2 Components of Endometrial Extracellular Matrix

Matrix component		Variation during menstrual cycle		
		Proliferative	Mid secretory	Late secretory
Interstitial components				
Fibronectin		++	+++	++
Vitronectin		+	−	−
Collagen type I		+++	++	++
Collagen type III		+++	++	++

reflecting the change from a mesenchymal type fibroblast to a more epithelial-like phenotype. Endometrial regression prior to menstruation correlates with a loss of hyaluronan and water of hydration. Extensive destruction of the both fibrillar and basement membrane ECM is observed immediately prior to and during menstruation.

IV. ROLE OF STEROID HORMONES IN MEDIATING ENDOMETRIAL REMODELING

All of the remodeling events throughout the menstrual cycle are governed by estrogen and progesterone, with estrogen stimulating the regrowth and proliferation after menses and progesterone driving differentiation in preparation for implantation. Steroid hormone action is dependent on the presence of specific ligand-activated nuclear receptors in target tissues.

A. Estrogen Receptors

Two receptors for estrogen have been described, ER-α and ER-β. There is a high degree of sequence homology between the two and both stimulate the transcription of ER target genes. The most significant disparity between the two receptors lies in their tissue distribution. In the human endometrium, both ER-α and ER-β are expressed. ER-α is found in both the epithelial glands and the stroma of the functionalis layer, is maximal during the late proliferative phase, and declines during the secretory phase (Table 3). The epithelium also expresses ER-β with a decline during the secretory phase. ER-β is not expressed in the stroma. In the vascular endothelium, only ER-β is present, whereas both subtypes are found in the perivascular cells surrounding endometrial blood vessels. The functional importance of ER-α for human fertility has been highlighted by studies using mice in which both ER-α and ER-β were separately disrupted (ERKO and BERKO, respectively). The loss of ER-α expression in the uteri of ERKO mice is associated with the loss of estrogen responsiveness, whereas mice lacking ER-β exhibit a relatively normal uterine phenotype and are fertile.

TABLE 3 Steroid Hormone Receptors in Endometrial Glands and Stroma during the Human Menstrual Cycle

	Menstrual		Proliferative		Secretory	
Receptor	Epi	Str	Epi	Str	Epi	Str
ER-α	+/−	+/−	++	+	+/−	+/−
ER-β	+/−	+/−	+	+/−	+/−	+/−
PRA	−	+	+++	+++	−	+
PRB	+	−	+++	+	+	−
AR	−	+	−	++	−	+

Note. Epi, epithelial glands; Str, stromal cells; ER, estrogen receptor; PR, progesterone receptor; AR, androgen receptor.

B. Progesterone Receptors

The human progesterone receptor (PR) is also expressed as two isoforms, PRA and PRB. They are products of a single gene, translated from individual mRNA species under the control of different promoters, and they differ only in that the smaller isoform PRA lacks 164 amino acids from the N-terminus. On the basis of *in vitro* studies, it appears that the two proteins are functionally different. PRB is the more transcriptionally active isoform, whereas the truncated PRA can act as a dominant repressor of PRB activation of progestin-sensitive genes. Thus, it is likely that the relative levels of PRA and PRB within target cells determine the nature and magnitude of the response to progesterone. In the normal endometrium during the menstrual cycle, PRA and PRB are coexpressed in target cells. PR expression is stimulated by estrogen in the proliferative phase, but there is selective down-regulation by progesterone itself in the secretory phase. Before ovulation, PRA and PRB are expressed at equivalent levels in glandular epithelium. PRB, but not PRA, persists in the glands during the midsecretory phase, suggesting that PRB is of utmost importance in glandular secretion at this time (Table 3). In the stroma, the predominance of the PRA isoform throughout the cycle implicates this isoform in events such as stromal mitosis, decidualization, and regulation of ECM composition. PRs are also expressed on endometrial endothelial cells but are absent from leukocytes in the endometrium. Mice with a null mutation of PR display uterine hyperplasia and inflammation.

C. Androgen Receptors

Androgen receptors (ARs) are also expressed by the human endometrium. Two forms of AR exist, ARA and ARB. ARs predominate in stroma during the proliferative phase; little expression is seen in the epithelium (Table 3). Anti-progestins such as mifepristone (RU486) induce ARs in the glands and enhance their levels in the stroma. Importantly, many progestins used in contraceptive preparations, particularly levonorgestrel, exhibit potent androgenic actions, and thus understanding the effects of androgen action on the endometrium is of clinical importance.

V. STEROID-REGULATED PARACRINE FACTORS IN HUMAN ENDOMETRIUM

Estrogen and progesterone drive endometrial remodeling through the downstream regulation of a wide range of cytokines, growth factors, and enzymes, which act locally to mediate cellular events. The local regulation of proliferation, differentiation, and breakdown is evident in the focal nature of these changes. Many cytokines and growth factors that act as paracrine and autocrine regulators are produced within the endometrium by one or more cellular components and display cyclical variation consistent with their actions on the endometrium.

A. Cytokines and Growth Factors

A range of cytokines and growth factors, whose expression is generally limited to pathological conditions in the adult, are produced by the endometrium and are essential for the complex cellular interactions throughout the menstrual cycle. These include proinflammatory cytokines, such as interleukin-1 (IL-1), tumor necrosis factor α (TNFα), and IL-6; leukocyte-attracting chemokines, such as IL-8, monocyte chemoattractant protein-1 (MCP-1), and eotaxin; immunomodulatory cytokines, such as IL-4, IL-10, IL-11, leukemia inhibitory factor (LIF), colony-stimulating factor 1 (CSF-1), and granulocyte/macrophage colony-stimulating factor (GM-CSF); and growth factors, such as epidermal growth factor, insulin-like growth factors (IGFs), transforming growth factor-βs (TGF-βs), and activins.

Cytokines are produced by epithelial cells, vascular endothelium, and decidualized stroma, in addition to infiltrating leukocytes, with cyclical variation consistent with regulation by steroid hormones and the paracrine environment (Fig. 2). A number of cytokines have been shown to regulate endometrial function *in vivo* or *in vitro*. Among the known functions of these regulators are modulation of proliferation, induction of other cytokines/growth factors and adhesion molecules, stimulation of extracellular matrix molecule synthesis, alteration of protease/protease inhibitor synthesis, activation

of lymphomyeloid cells, and regulation of differentiation.

B. Angiogenic and Vasoactive Factors

Numerous angiogenic promoters and their receptors, along with inhibitors of angiogenesis, have been identified in human endometrium, some with cyclical variation (Table 4). Furthermore, molecules containing angiogenesis inhibitors that are released by proteases acting at cryptic sites are also abundant in the endometrium; these include plasminogen (the source of angiostatin) and collagen IV (the source of canstatin).

Vasoactive agents of importance in the endometrium include prostaglandins (PGs), endothelin (ET), and nitric oxide (NO). PGs are produced within the endometrium by both epithelial cells and decidualized stroma and are present in the menstrual fluid at high concentrations. Both PG synthesis (via cyclooxygenases 1 and 2) and metabolism (by PG dehydrogenases) are influenced by estrogen and progesterone. The major cellular source of ET, a potent vasoconstrictor, is the epithelium, although endothelium and decidualized stroma are additional sites of production. ET mRNA expression varies across the menstrual cycle, reaching maximal levels in the premenstrual phase. NO relaxes myometrial and vascular smooth muscle and thus is a strong candidate for mediating various steroid hormone and cytokine effects in the endometrium and decidua in the processes of developing receptivity, implantation, and menstruation. Both inducible NO synthase and endothelial NO synthase are present in endometrium, in a variety of cell types including inflammatory cells.

C. Matrix Metalloproteinases

Matrix metalloproteinases (MMPs) are the enzymes that degrade components of both interstitial and basement membrane ECM. Their synthesis is negligible in normal connective tissue. MMP activity is tightly regulated; most MMPs are secreted as latent zymogens that require activation extracellularly. Their local activity can be inhibited by tissue inhibitors of MMPs (TIMPs) by the formation of 1:1 complexes. Growth factors, cytokines, steroid hormones (including progesterone and androgens), and other regulatory molecules differentially regulate the genes for MMPs. A number of MMPs have been identified within the endometrium. Their pattern of expression during the normal menstrual cycle is consistent with local actions in remodeling processes. In particular, a dramatic increase in their expression and activation premenstrually, at foci within the functionalis, supports a pivotal and critical role for these degradative enzymes in the process of normal menstruation.

VI. PARACRINE REGULATION OF ENDOMETRIAL REMODELING EVENTS

A. Proliferation, Angiogenesis, and Apoptosis

Significant epithelial cell mitotic activity and DNA synthesis very early in the cycle indicate

the regeneration of epithelium from remaining glands and persisting areas of surface epithelium rather than from stem cells during the repair phase (days 3–4). Mitotic activity is a key feature of all endometrial components during the proliferative phase but declines during the secretory phase, persisting at low levels in surface epithelia and predecidual cells only. IGFs are likely candidates for conveying estrogen action throughout the endometrium, with the balance of ligand (IGFs) and binding proteins shifting from the proliferative to the secretory phase, corresponding to the stimulation and inhibition of estrogen-driven proliferation. Other growth factors, including EGF and TGF-β are prevalent in proliferating endometrium. Following ovulation, progesterone plays a key role in regulating endometrial proliferation by suppressing estrogen-driven mitosis in both glands and stroma. Specific mechanisms proposed include down-regulation of estrogen receptors, induction of the enzyme catalyzing conversion of estradiol to the less active estrone, and the decrease of estrogen-induced specific gene expression.

Angiogenesis, including proliferation of endothelial cells, occurs in three episodes during the menstrual cycle, representing initial repair during the early proliferative phase, estrogen-driven angiogenesis during the midproliferative phase, and progesterone-driven growth of the coiled arterioles during the secretory phase. Dynamic expression of epithelial and endothelial vascular endothelial growth factor and its receptors, as well as other angiogenic agents (Table 4), throughout the cycle indicates that complex and distinct mechanisms are involved in the regeneration of blood vessels and the remodeling of spiral arterioles.

Coincident with cellular proliferation is the controlled apoptosis of individual epithelial cells, presumably those unable to pass successfully through the cell cycle due to DNA damage. Apoptotic incidence increases later in the cycle, during the receptive phase (day 19–20) and in normal late secretory and menstrual endometrium. Members of the Bcl family protect against apoptosis and Bax protein increases the apoptotic susceptibility of cells. Bcl-2 expression is prominent during the proliferative phase but decreases toward the secretory phase and is absent or negligible in the midsecretory phase. Bax expression also decreases after the proliferative phase, though it remains detectable throughout the entire secretory phase, indicating that the decreased Bcl-2:Bax ratio determines the susceptibility to apoptosis. A number of other apoptotic-regulatory factors such as the Fas/Fas ligand system are also expressed in the endometrium but their contribution to the apoptosis trigger remains to be determined. Given that a large proportion of the cells shed at menstruation are viable (cells from menstrual fluid can be cultured and endometriosis is postulated to arise from retrograde menstruation), the contribution of apoptosis to this process must be limited.

B. Decidualization

Decidualization is a major remodeling event and is critical for the modulation of trophoblast invasion and optimal placentation. Progesterone initiates

the decidual reaction in estrogen-primed stromal cells, and products of epithelial cells, leukocytes, and the decidualized stromal cells themselves have contributory actions in mediating the differentiation and remodeling processes. Major differences exist in the initiation and progression of decidualization between humans and most other mammalian species, meaning that studies on human endometrium are critical. Some key factors involved in mediating stromal decidualization have been identified in mouse knockout models, in which the endometrium fails to decidualize and thus implantation is blocked. These include IL-11, prolactin, and prostaglandins. These factors have subsequently been shown to be also important for the decidual transformation in human endometrium. *In vitro* models of decidualization have been widely utilized to delineate the roles of paracrine agents in the regulation of decidualization in the human uterus. These generally involve stimulating decidual transformation of isolated endometrial cells with combined estrogen and progesterone or with cAMP. Thus, corticotrophin-releasing hormone, activin A, IL-11 and prostaglandin E_2 have been shown to promote decidualization, whereas IL-1, TNFα, and macrophage CSF play inhibitory roles. MMPs (particularly the gelatinases MMP-2 and MMP-9) and TIMPs play roles in the tissue remodeling associated with decidualization and help restrict cytotrophoblast invasion during implantation. Recent microarray analysis identified a range of genes regulated during *in vitro* decidualization of human stromal cells: these included cytokines, growth factors, nuclear transcription factors, and mediators of the cAMP signal transduction pathway. Further study of these factors will contribute to a greater understanding of the mechanisms involved in decidualization in the human uterus.

C. Menstruation

Menstruation is triggered in a nonconception cycle by the withdrawal of progesterone from the decidualizing endometrium, resulting in inflammation, tissue destruction, and shedding. Steroid-regulated chemokines, including IL-8, MCP-1, MCP-2, RANTES, and eotaxin, may be responsible for the chemoattraction and activation of neutrophils, macrophages, and eosinophils into the endometrium. Activated leukocytes distributed throughout the stroma are a source of pro-inflammatory cytokines, PGs, and MMPs, which together have the potential to instigate cascades of inflammation and breakdown at localized foci. PGs have integral roles during menstruation, as inflammatory and vasoactive mediators augmenting leukocyte infiltration. Administration of intrauterine $PGF_{2\alpha}$ causes menses and increases uterine contractility as it is overall a vasoconstrictor. By contrast, PGI_2 causes vasodilatation. COX-2, the inducible cyclooxygenase isoform, is up-regulated with progesterone withdrawal, coincident with falling expression of the progesterone-dependent metabolizing enzyme PGDH, resulting in elevated concentrations of bioactive PGs in the endometrium and menstrual fluid. ET-1, a potent vasoconstrictor, is made and released by human endometrium and can act on both epithelial cells and endothelial cells. Its production increases around the time of menstruation, suggesting a paracrine role in endometrial bleeding and/or repair.

MMPs have the capacity to digest all components of the endometrial ECM, and there are dramatic increases in MMP mRNA and protein levels between cycle days 26 and 4. MMP-1, -2, -3, and -9 in particular have been shown to be increased in association with endometrial degradation while MMP-7 appears more likely to have a role in endometrial repair. Active forms of the enzymes have been demonstrated in perimenstrual and menstrual endometrium. TIMPs are also present in the endometrium but smaller cyclical changes are observed, suggesting that the major regulation of MMP action is at the levels of MMP expression and activation. Although progesterone is a negative transcriptional regulator of most MMPs, the very focal nature of their expression suggests local regulation. Leukocytes scattered throughout the stroma produce MMPs and other enzymes, such as mast cell tryptase and neutrophil elastase, which can activate certain MMPs and thus contribute to the cascade of matrix-degrading activity at menstruation.

VII. SUMMARY

Estrogen and progesterone overall regulate endometrial remodeling across the menstrual cycle, although many of their actions are indirect and are mediated by an array of paracrine agents produced locally by the various cellular components of the endometrium. Cytokines and growth factors form complex networks that facilitate communication between epithelial and stromal cells, leading to the regulation of decidualization and endometrial receptivity for embryo implantation. Interactions between leukocytes, endothelial components, and stromal components are necessary for the initiation of menstruation. Identification of the molecules

involved in mediating these processes in the human endometrium is essential for the future development of novel contraceptive agents for women, for detecting endometrial causes of infertility, and for the treatment of infertility.

Glossary

chemokine A chemotactic cytokine that directs the migration of leukocytes.

decidualization The differentiation of stromal fibroblasts into decidual cells.

extracellular matrix The complex, collagenous matrices to which cells are attached within a tissue; it includes both interstitial matrix and basal lamina.

menstruation The process whereby the functional layer of the endometrium is shed, accompanied by bleeding at the end of each nonpregnant cycle.

steroid hormone One of a group of steroids that function as hormones, includes estrogens, progestogens, and androgens.

Endometriosis

KHALED ZEITOUN* AND SERDAR E. BULUN†

*Columbia University • †University of Illinois

Endometriosis is a heterogeneous and complex disorder that is characterized by the presence of endometrial glands and stroma outside of the endometrial cavity. Adenomyosis arising as the result of infiltration or invagination of the myometrium by endometrial glands is

considered a different entity from endometriosis. Both conditions affect women throughout the world, resulting in infertility, pelvic pain, and decreased quality of life.

I. EPIDEMIOLOGY

The exact incidence or prevalence of endometriosis is unknown. It is estimated that 2–10% of women of reproductive age are afflicted with this disease. Diagnosis has improved because of widespread use of laparoscopy and also with increased awareness of the disease. At laparoscopy for chronic pelvic pain and infertility, endometriosis is detected in 25 and 33% of patients, respectively.

Endometriosis is typically diagnosed at the age of approximately 30 to 35 years. This disorder is believed to begin after puberty with establishment of menses and to resolve with menopause. However, it is not uncommon for patients to develop endometriosis during the two extremes of the female reproductive life. Approximately 10% of cases are diagnosed in teenagers and up to 5% in postmenopausal women. Significant endometriosis diagnosed at the time of puberty or shortly afterward is primarily associated with obstructive Müllerian anomalies. However, there are also reports of severe cases in adolescents with normal pelvic anatomy.

The natural history of endometriosis is subject to speculation and debate. Establishment of endometriotic lesions and their clinical courses are often not well defined secondary to the multiple factors affecting the initiation and progression of the disease. Nonetheless, endometriosis remains one of the most common gynecologic disorders resulting in hospitalization and is a leading cause of pelvic pain and infertility.

II. ETIOLOGY

Multiple theories have been developed in an attempt to explain the etiology of endometriosis. Unfortunately, no single theory is sufficient for the explanation of highly variant pathologic and clinical presentations of endometriosis. Endometriosis may actually represent a spectrum of abnormalities where the exact line between normal and disease states is not completely defined. One of the most widely accepted theories explaining the development of endometriosis is the implantation of viable endometrium at ectopic sites. Sampson hypothesized that during menstruation, retrograde bleeding deposits endometrial fragments into the peritoneal cavity via the oviducts. In animal models, menstrual efflux that was diverted into the peritoneal cavity developed into endometriotic lesions. Furthermore, endometrial cells present in human menstrual efflux are viable and can be grown in tissue cultures as well as in immunologically compromised animals. The predominance of endometriotic lesions in the dependent parts of the pelvis and the common association of endometriosis with obstructive Müllerian anomalies lend clinical support to Sampson's theory. However, retrograde menstruation alone does not explain why only 5–10% of women develop pelvic endometriosis when menstrual reflux is believed to be a universal phenomenon.

Other forms of implantation are also possible. Iatrogenic implantation of endometrium in abdominal and episiotomy scars at the time of delivery resulting in endometriosis has been reported. Also, lymphatic or hematogenous dissemination of endometrium explains some cases of endometriotic implants found in lymph nodes or in distant sites such as the lungs or extremities.

Coelomic metaplasia of the peritoneal lining and growth of lesions from embryonic rests within the pelvis and peritoneal cavity may also explain the development of endometriosis when endometrial implantation is not possible. Endometrioid tumors of the ovary suggest the capacity for coelomic epithelium, lining the ovary and the peritoneal cavity, to transform into endometrial tissue. However, an initiating factor such as exposure to estrogen is needed.

The presence of immunologic abnormalities in patients with endometriosis has been suggested by studies demonstrating alterations in cell-mediated immunity and by demonstration of antibodies against the endometrium. The absence of associated immune defects in cases with endometriosis, the complexity of the immune system, and the inconclusive nature of these studies cast doubts on theories implicating the immune system. However, a subtle immunological defect in the clearance of endometrial fragments at the time of retrograde menstruation might contribute to the initiation of the disease process.

A genetic basis for endometriosis is suggested by the increased incidence in women with a family history of this disease. In these individuals, endometriosis develops earlier in life and is found to be more severe. The inheritance pattern is probably polygenic or multifactorial.

After demonstration of an increased incidence of severe endometriosis in a colony of rhesus monkeys chronically exposed to the environmental toxin dioxin by Rier *et al.* in 1993, there was enthusiasm

in the scientific community for clarifying the association between environmental toxins and endometriosis. This was enhanced by the observation that elevated dioxin levels have been reported in a significantly higher number of patients with endometriosis compared to healthy controls in a population of women with infertility. These and other studies suggested an association between dioxin exposure and development of endometriosis in women.

Since a single theory is not sufficient to explain all pathophysiologic aspects of endometriosis, it is now proposed that a multitude of factors might be involved in the etiology of this enigmatic and complex disorder. Retrograde menstruation transports viable endometrium into the peritoneal cavity but may also act as an initiating factor for metaplasia of the coelomic epithelium into endometriotic lesions. At the same time, defective clearance of shed endometrial fragments due to a local or general immunologic defect may further contribute to the development of endometriosis. An individual's genetic predisposition or environmental toxins may impede clearance of the endometrial fragments from the peritoneal cavity or enhance implantation and then growth of lesions. These environmental factors may also enhance metaplasia of the coelomic endothelium into endometrial-like tissue. In all circumstances, estrogen is an important factor for the progression and persistence of the disease. With further investigation, more information about the pathophysiologic origin of endometriosis may become available in the future.

III. ESTROGEN BIOSYNTHESIS AND METABOLISM IN ENDOMETRIOSIS

Several molecular aberrations were found in endometriotic lesions (in contrast to eutopic endometrium) that favor increased local concentrations of estradiol. These aberrations are important in view of the fact that endometriosis is an estrogen-dependent disease.

The conversion of androstenedione and testosterone to estrone and estradiol is catalyzed by aromatase P450, which is expressed in a number of human tissues and cells such as ovarian granulosa cells, placental syncytiotrophoblasts, adipose and skin fibroblasts, and the brain. In a woman of reproductive age, the ovary is the most important site of estrogen biosynthesis. On the other hand, estrogen formation can also take place in extraglandular tissues such as adipose and skin. The latter source of estrogen is important when ovarian estrogen formation is decreased in the postmenopausal period and also when endometriosis is treated by agents that inhibit ovarian estrogen production. Recently, it was also demonstrated that endometriotic stromal cells aberrantly express aromatase, which converts C_{19} steroids to estrogens within the lesions (Fig. 1). Aromatase activity in these cells is regulated via cyclic AMP and vigorously stimulated by prostaglandin E2 (PGE2). Estrogen stimulates cyclooxygenase-2, giving rise to increased PGE2 formation. Thus, this positive feedback loop serves to produce increasing quantities of estradiol and PGE2 in endometriosis. Furthermore, the lack of aromatase expression in eutopic endometrium seems to be maintained by binding of an inhibitory transcription factor, COUP-TF (chick ovalbumin upstream promoter-transcription factor), to the aromatase promoter. In endometriosis, however, an aberrantly expressed factor, SF-1, displaces COUP-TF to bind to this same promoter and activates aromatase expression and thus local estrogen biosynthesis (Fig. 2).

In addition, endometriotic glandular cells are deficient in 17β-hydroxysteroid dehydrogenase (17β-HSD) type 2, which inactivates estradiol by converting it to estrone in the eutopic endometrium in response to progesterone. A deficiency of this enzyme in endometriosis impairs the inactivation of estradiol

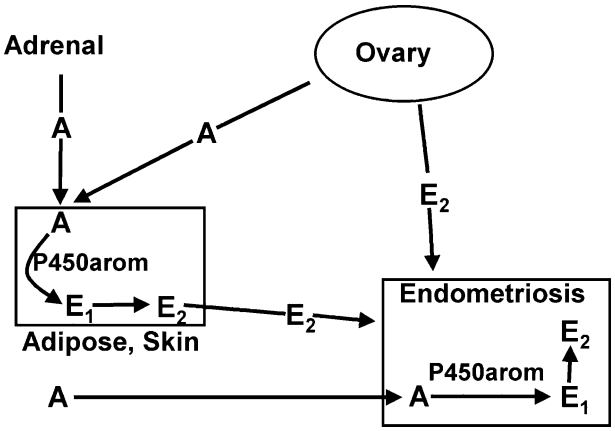

FIGURE 1 Origin of estradiol in endometriosis: Androstenedione (A) of adrenal and ovarian origin is the principal precursor of estrogen in the ovary, adipose, skin, and also endometriotic lesions. Estradiol (E_2) from the ovary and peripheral tissues reaches the endometriotic lesions via the bloodstream. Aromatase (P450arom) in the stromal cell also catalyzes the conversion of androstenedione to estrone (E_1), which is further reduced to E_2 by 17β-HSD type 1 in the endometriotic tissue. Both circulating estradiol and locally produced estradiol will lead to maintenance and growth of the lesions.

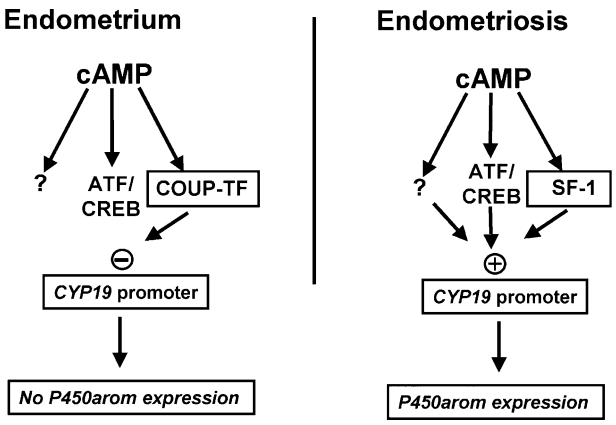

FIGURE 2 Proposed mechanism of regulation of aromatase (P450arom) expression by SF-1 and COUP-TF in eutopic endometrium and endometriosis: COUP-TF binds to a specific regulatory DNA sequence upstream of the aromatase promoter II in eutopic endometrial stromal cells in the absence of any competition by SF-1, since SF-1 expression is not detected in the majority of endometrial samples. Thus, COUP-TF exerts its inhibitory effect on the complex of general transcription factors, which binds to the TATA box. In the endometriotic stromal cell, however, SF-1 is present and binds to the identical DNA sequence with a higher affinity than that of COUP-TF. Upon replacing COUP-TF, SF-1 synergizes with other transcription factors such as a member of the activating transcription factor/cAMP-responsive element-binding protein (ATF/CREB) family of transcription factors and others to initiate the transcription of the aromatase gene in response to cAMP.

and may be a consequence of progesterone insensitivity. Aforementioned molecular aberrations that increase local estradiol concentrations may be important in the etiology of endometriosis and also offer an explanation for the high failure rates obtained with current treatment modalities. These molecules may be targeted to develop novel therapeutic strategies.

IV. ESTROGEN AND PROGESTERONE RECEPTORS

In order to better understand the behavior of endometriosis, many studies have focused on comparing and contrasting eutopic versus ectopic endometrial tissues in terms of their estrogen receptor (ER) and progesterone receptor (PR) profile. To date, the presence of estrogen and progesterone receptors in the glandular epithelium and the stroma of ectopic endometriotic tissue has been confirmed by multiple studies. However, investigations on the biologic behavior of these receptors have not yielded consistent results.

When compared to the eutopic endometrium, it is still unclear whether ectopic endometrium has higher, similar, or lower ER/PR contents. Earlier studies have mostly found levels of ERs in endometriotic tissues that are lower than or similar to those in the endometrium. More recently, Jones and colleagues found that ectopic ER content is actually higher than that in the eutopic endometrial tissue. Although the scientific methodology of this study is purportedly more sensitive, the investigators also sampled ectopic endometrial tissue mostly from ovaries rather than from pelvic implants as was done in the previous studies. Thus, this variation may account for the observed difference in ER content.

The presence of cyclic variation in ER/PR contents in ectopic endometrial tissue that is normally exhibited in eutopic tissue has also been studied extensively. Although some authors described no predictable cyclic menstrual pattern in the ectopic ER, others have found that ERs in endometriotic implants have a predictable decline during the secretory phase of the menstrual cycle. Similarly, ectopic PRs have been found to either decline during the late secretory phase in some studies or remain elevated throughout the secretory phase in other studies.

Although these conflicting results can perhaps be partially attributed to the variations in laboratory methods, i.e., tissue preservation or immunohistochemical staining methods, true biologic differences among endometriotic implants have been documented. Taking simultaneous biopsies from the endometrium and multiple endometriotic implants from the same patient, Howell found marked heterogeneity in the expression of estrogen and progesterone receptors in endometriosis. These differences could be demonstrated when comparing endometriotic lesions with the corresponding endometrium and also between samples of endometriosis collected from different sites within the same patient. Hence, it is possible that microenvironmental factors related to the site, depth, and degree of fibrosis of each individual lesion could determine the amount of steroid hormone stimulation reaching the lesion. This could account for the observed differences in ER/PR profiles between endometriosis and the endometrium. More importantly, it may be responsible for the differences among endometriotic lesions from different sites within the same patient. Therefore, the ER/PR profile of a single endometriosis sample from a patient cannot be assumed to represent the status of all endometriosis lesions within the patient. In a recent study, it was also shown that the main progesterone receptor in

extraovarian endometriotic lesions is progesterone receptor A, whereas progesterone receptor B (PRB) is the receptor predominantly expressed in normal endometrium. A deficiency of PRB in endometriosis might cause an impaired response to progesterone and hence progesterone resistance. Clinically, this heterogeneity in ER/PR content may account for the disparate response of endometriosis to medical treatment among different patients.

V. CLASSIFICATION

Several classification systems have been suggested over the years to stage endometriosis according to the severity of the disease. The goal was to divide the disease into stages that correlated with pregnancy rate or response to treatment. This goal was, however, never completely realized. The staging systems were complex and not widely used, and studies did not show a good correlation between pregnancy rates and stage of the disease.

The American Fertility Society (AFS) original and revised classifications were an effort to predict the probability of pregnancy following treatment of endometriosis, according to disease severity. The revised AFS classification introduced in 1985 divided endometriosis into four stages (minimal, mild, moderate, and severe). In this classification, higher scores were given to deep endometriosis, dense adhesions, and obliteration of the cul-de-sac. Numerous studies could not demonstrate a difference in pregnancy rates after treatment according to stage.

A new attempt at scoring the disease was made with the revised American Society for Reproductive Medicine (ASRM) classification of endometriosis in 1996. The new classification encouraged the recording of lesion color and morphology. Like previous AFS classifications, it contained a standardized form to record findings. Again, data did not support any improvement in prediction of pregnancy after treatment in the ASRM classification.

Despite the subjective nature of laparoscopic evaluation and the limitations of the ASRM system, it is hoped that accumulation of data from the current scoring systems and accurate morphological description may permit future development of a classification system that would be more helpful in predicting pregnancy. Future classifications might include serum or tissue markers for endometriosis in addition to anatomical description of the lesions as recent data indicate the presence of multiple molecular aberrations in endometriosis, some of which might affect fertility.

VI. DIAGNOSTIC TESTS

The importance of an accurate noninvasive test for a common disorder like endometriosis cannot be overemphasized. Unfortunately available nonsurgical tests are still too insensitive or nonspecific.

A. CA-125 Measurement

CA-125 is a cell surface antigen and a useful marker in monitoring patients with epithelial ovarian cancer. This antigen is found in coelomic epithelial-derived tissues and thus is also expressed by the endometrium. Elevated CA-125 serum levels were demonstrated in patients with endometriosis especially in advanced stages of the disease. The use of this assay as a screening test for diagnosis was, however, disappointing because of low sensitivity (between 20 and 80%). Its use in monitoring treatment and recurrences is also limited. CA-125 elevations can also occur due to other concurrent conditions such as pregnancy, menstruation, uterine leiomyomata, and pelvic inflammatory disease. In conclusion, there is no accurate serum marker for diagnosing endometriosis at present. However, several molecular aberrations in this abnormal tissue are currently being studied. The characterization of a marker that could predict the presence of the disease and be used to monitor therapy will be invaluable.

B. Pelvic Imaging

Ultrasound is the preferred imaging method for endometriomas. It is best performed using the vaginal probe because of better resolution. Ultrasound, however, is not very useful in the detection of endometriotic implants and cannot differentiate these from other masses. In contrast, endometriomas are diagnosed with excellent sensitivity and specificity. The use of Doppler flow studies to differentiate endometriosis from other ovarian masses, especially malignant tumors, has also been described. A specific ultrasound description is reported with pericystic vessels, scanty blood supply, high resistance index, and an avascular cavity. The role of Doppler studies is, however, not well defined.

The use of magnetic resonance imaging (MRI) has been used for diagnosis of endometriosis. MRI might be more useful in the detection of endometriotic implants than ultrasound. However, the sensitivity and specificity for detection of endometriomas are not better. At present, the use of MRI for diagnosis of endometriosis has a very limited role. Other imaging studies including computerized tomography (CT)

scans, barium enemas, and chest X rays may be needed in complicated and advanced cases involving extra-abdominal sites or bowel. These studies, however, are nonspecific, and endometriotic lesions cannot be differentiated from other disease states with certainty.

C. Laparoscopy

Despite attempts to use imaging studies to diagnose endometriosis, surgical diagnosis remains the gold standard. A definite diagnosis of endometriosis will usually need pelvic and abdominal exploration. Laparoscopy has assisted in the pathologic diagnosis of endometriosis while decreasing patient morbidity and has replaced laparotomy in all but very rare cases. Tissue biopsy is recommended to obtain histologic confirmation of endometriosis; however, in experienced hands, the presence of typical lesions is usually sufficient for diagnosis. The recent appreciation and description of different lesion types are probably among the causes for the increase in frequency of diagnosis. Atypical lesions such as clear papules might be difficult to detect, and a thorough examination by a surgeon familiar with the disease is ideal. Also, techniques such as infusion of crystalloids into the cul-de-sac or painting of peritoneal surfaces with blood-tinged peritoneal fluid can be used to enhance the detection of these subtle lesions.

Deep infiltrating lesions are sometimes difficult to visualize because they are extraperitoneal. However, they should be suspected and looked for. Careful examination under anesthesia and palpation with a probe might aid in detecting these active lesions. Endometriomas are usually easily detected by laparoscopy, but sometimes aspiration of a suspicious cyst is helpful in confirming the diagnosis before excision. Furthermore, inspection of the bowel is mandatory because a significant number of cases contain bowel lesions.

VII. SYMPTOMS

Endometriosis is a leading cause of pelvic pain and is strongly associated with infertility. However, endometriosis has also been implicated in a variety of other disorders including spontaneous abortions and abnormal uterine bleeding. In many instances, these associations could not be confirmed by more recent studies.

A. Pain

Pain is a common symptom attributed to endometriosis. Actually, more than half of the patients presenting with pelvic pain and dysmenorrhea are diagnosed with endometriosis. The typical endometriosis-associated pain starts 1 to 2 days before onset of bleeding and lasts throughout menstruation, but it should be suspected in secondary or worsening primary dysmenorrhea. Dyspareunia is also a symptom of endometriosis and is usually associated with endometriosis of the uterosacral ligaments, deep pelvic implants, lesions of the rectovaginal septum, or a fixed retroverted uterus. The presence of noncyclic pelvic pain, backache, and rectal pressure is also commonly described. Endometriosis might present by acute abdominal pain in 3% of cases and one of the reasons is a leaking or ruptured endometrioma. Pain related to specific organ involvement such as bowel (e.g., dyschezia), lung (chest pain), or nerves (sciatica) is also described. Often endometriosis-related pain does not correlate with the severity of the lesion and the actual pathophysiology of the pain in milder stages is not well understood but may be related to prostaglandin production in the lesions.

B. Infertility

Infertility is another symptom commonly attributed to endometriosis. Up to 30% of cases of infertility are associated with laparoscopically proven endometriosis but the disease has been detected in only a small percentage of fertile patients undergoing tubal ligation. The exact incidence of endometriosis is, however, unknown and so the percentage of cases associated with infertility is difficult to assess. Furthermore, no correlation has been demonstrated between the different stages of endometriosis and pregnancy rates or response to therapy in infertile patients. Another factor complicating the picture is that the exact mechanism causing infertility in milder forms of endometriosis is unknown; thus, doubts still exist as to whether endometriosis is a direct cause of infertility.

Factors implicated in causing endometriosis-associated infertility include anatomic distortion and fibrosis of the fallopian tubes in severe cases, anovulation, luteal-phase defects, luteinized unruptured follicle syndrome, autoimmune factors, spontaneous early abortions, altered peritoneal fluid environment by prostaglandins or inflammatory cells, and hyperprolactinemia.

C. Spontaneous Abortion

The older studies indicating an increased rate of spontaneous abortion in patients with endometriosis could not be validated by more recent, controlled studies.

D. Abnormal Uterine Bleeding

Many different patterns of abnormal bleeding in endometriosis have been described, including premenstrual spotting, hypermenorrhea, and oligomenorrhea. The incidence of anovulation and luteal-phase defects is, however, similar in endometriosis patients compared to women without the disease. Available data do not support an association between endometriosis and abnormal uterine bleeding.

E. Other Symptoms

Other uncommon symptoms related to specific organ involvement are sometimes seen, such as recurrent pneumothorax or hemoptysis in lung involvement, rectal bleeding or hematuria in rectal or bladder involvement, ureteric obstruction, and skin, perineal, or vaginal masses.

VIII. CLINICAL EXAMINATION

Physical findings in endometriosis are not specific and in many instances do not correlate with the disease severity confirmed at laparoscopy. In many cases, minimal endometriosis lesions are found despite significant pelvic pathology and severe symptoms.

Cul-de-sac tenderness is one of the most common findings. Nodularity along the uterosacral ligaments and in the cul-de-sac is also very suggestive. The lesions will be more prominent at the time of menstruation and tenderness will usually increase. Significant endometriomas will be appreciated as adnexal masses, but other lesions such as ovarian tumors may give a similar picture.

Severe adhesions obliterating the cul-de-sac can cause the uterus to remain in a retroverted position, and movement of the uterus during examination will elicit tenderness. Deep lesions in the rectovaginal septum are better appreciated by a combined rectovaginal examination. This is important because they might be missed during laparoscopy.

IX. TREATMENT

The inadequate number of prospective, randomized, controlled studies together with our ignorance about the natural course of endometriosis makes assessment of treatment modalities a difficult task. Moreover, treatment often depends on the presentation of the disease in individual patients, their ages, and their reproductive desires. Unfortunately, no ideal long-term treatment is available at present and many of the current options are temporarily curative or associated with significant morbidity.

A. Expectant Management/Prophylactic Treatment

Expectant management has the advantage of being cheaper and avoids the side effects of therapy. On the other hand, surgical ablation of the lesions might prevent or slow the progression of the disease in at least some cases. Until recently, there was no evidence that medical or surgical therapy is superior to expectant management in infertile patients with milder forms of endometriosis. In 1998, a Canadian prospective randomized study demonstrated that surgical ablation of lesions in minimal and mild cases of endometriosis enhanced fertility in this group of patients. Although this is only one study, it nonetheless points in favor of ablation of even milder lesions discovered during laparoscopy. In younger patients diagnosed with endometriosis and not yet seeking pregnancy, the long-term use of oral contraceptives in an attempt to suppress the disease or slow progression might be a reasonable option. Data demonstrating the long-term efficacy of such an approach, however, are not available.

B. Medical Suppression

The medical options available for treatment of endometriosis include danazol, progestins, gonadotropin-releasing hormone (GnRH) agonists, and experimental modalities such as mifepristone and aromatase inhibitors. All medical modalities are of proven effectiveness in managing pelvic pain and in decreasing the size of the endometriotic lesions. For treating infertility, these medical therapies have no proven beneficial effect. In fact, they may be a cause of delay in pregnancy due to their suppressive effect on ovulation. The effect of medical suppression is not permanent and recurrence rates after discontinuation of therapy are high. The different medications used are not expected to have any effect on adhesions or larger endometriomas.

C. Danazol

Danazol is an isoxazol derivative of 17α-ethynyl-testosterone and is well absorbed and active when

given orally. It has a central effect by which it attenuates the midcycle gonadotropin surge and this is associated with anovulation and a reduction of estradiol levels. The drug also inhibits steroidogenic enzymes within the ovary. Danazol's binding to the androgen receptor may have a local suppressive effect on endometriosis lesions but is also the cause of some of its most disturbing side effects.

Danazol is usually used in divided doses ranging from 400 to 800 mg per day for 6 to 9 months. The drug is very effective, relieving pelvic pain associated with endometriosis in approximately 90% of cases. Reports have also indicated its success in reducing the size of endometriotic lesions. The effectiveness of therapy is directly related to induction of amenorrhea. Side effects of danazol are related to both its androgenic effect and the resulting hypoestrogenic environment.

Danazol's side effects include weight gain, mood changes, depression, oily skin, muscle cramps, headaches, edema, altered appetite, acne, hirsutism, fatigue, decreased breast size, hot flashes, voice changes, and irregular bleeding. The drug has an adverse effect on the lipoprotein profile, resulting in a decrease of high-density lipoproteins (HDLs) and an increase of low-density lipoproteins, and may be associated with increased liver enzymes. Pregnancy must be excluded because of the potential for virilization of a female fetus. The majority of patients taking the medication will experience side effects and at least 20% will discontinue the drug because of them. Recurrence rates are as high as 30% in 2 years after cessation of therapy. Danazol was once a very popular drug for the treatment of endometriosis but its significant side effects limit its current use in the advent of GnRH agonists.

D. Gestrinone

Gestrinone is a 19-nortestosterone derivative with progesterone agonist and antagonist effects. Its use results in amenorrhea and endometrial atrophy. It has been studied extensively in Europe for the treatment of endometriosis. It has a long half-life and is given orally 1 to 3 times a week (2.5 to 7.5 mg). The potential side effects are similar to those of danazol but are much milder and better tolerated. There is no adverse effect on lipoproteins or liver function tests.

E. Progestins

Progestins are believed to act by inducing decidualization and atrophy of the endometrial tissue within endometriotic implants. Progestins also interfere with follicular growth probably via a central mechanism on the pituitary–hypothalamic unit, but a local ovarian effect is also possible. This will result in decreased estrogen levels.

Progestins can be given orally, e.g., medroxyprogesterone acetate 20–30 mg orally per day or via the intramuscular (im) route as in case of Depo-medroxyprogesterone acetate at a dose of 150 mg im every 1 to 3 months. Norethindrone acetate, an orally active 19-nortestosterone progestin, was also successful in controlling painful endometriosis in small studies. The side effects of progestins include abnormal bleeding, mood changes, depression, headaches, weight gain, bloating, nausea, and a decrease in HDLs. Overall, progestins are better tolerated than danazol, and few patients discontinue their medications due to their side effects. Progestins do have a beneficial effect on pain and lead to regression of lesions. However, the effect on pregnancy rate is no different than expectant management. Progestins are an effective and cheap alternative for patients who do not tolerate danazol, GnRH agonists, or oral contraceptives.

F. Oral Contraceptives

Oral contraceptive-induced amenorrhea has been used to treat endometriosis, and this regimen was termed "pseudo-pregnancy." Initially, high-dose oral contraceptive pills were preferred, but the more recent low-dose estrogen pills seem to have similar effects on endometriosis. Oral contraceptives can be used in a continuous fashion, resulting in amenorrhea, or in a cyclic fashion. The therapeutic effect is probably due to the progestin in the pill causing decidualization and atrophy of the endometriotic lesions. The common side effects of oral contraceptives may be more severe in larger doses or in continuous regimens.

Oral contraceptives are a low-cost option for suppressive therapy and seem to be effective in alleviating pelvic pain. The role of oral contraceptive therapy for decreasing recurrence is less clear, but it seems to be a reasonable option in cases where pregnancy is not desired at the time of therapy.

G. Gonadotropin-Releasing Hormone Agonists

Continuous administration of GnRH agonists downregulates the pituitary–hypothalamic unit, leading to decreased gonadotropin levels. The resultant hypoestrogenic environment due to ovarian inactivity seems to cause regression of endometriotic implants. GnRH agonists are modified GnRH peptides with a longer

half-life and greater potency than the naturally occurring molecule. GnRH agonists can be used as a nasal spray (Nafarelin at a dose of 200 to 400 mg twice daily) or as an injection (the depot form of Leuprolide acetate at a dose of 3.75 mg every 4 weeks). Also available are a long-acting injectable form of Leuprolide administered every 3 months and a subcutaneous implant (goserelin acetate).

GnRH agonists are used widely and have replaced danazol for the treatment of endometriosis. GnRH agonists do not have androgenic or progestogenic side effects and have no reported adverse effect on the lipid profile. The hypoestrogenic effect of GnRH agonists is, however, more profound and is the primary cause of the side effects from this agent. These include vaginal dryness, hot flashes, abnormal vaginal bleeding, insomnia, depression, libido changes, headache, fatigue, and skin changes. The side effect of greatest concern is the decrease of bone density with GnRH agonists. A decrease in trabecular bone density of up to 6% in 6 months has been reported. Although this effect is considered reversible after discontinuation of therapy, it limits the long-term use of this agent. Recent studies have also indicated the relative safety of a second 6-month course of GnRH agonist in cases with recurrence of symptoms. The long-term effect of multiple courses in these young women is, however, not known, and there is a potential for delayed adverse effects on bone integrity.

Add-back therapy combines GnRH agonists with other agents such as estrogen and progestins or anti-resorptive agents such as biphosphonates. The goal is to decrease vasomotor symptoms and detrimental effects on bone density in order to use GnRH agonists for prolonged periods of time. Medroxyprogesterone was not effective when used as an add-back to GnRH agonists. Although norethindrone decreased side effects without changing the therapeutic efficacy, it had an adverse effect on lipoproteins. Although the use of an estrogen/progestin combination add-back therapy would be excellent for vasomotor symptoms and can help preserve bone density, it may also decrease the efficiency of GnRH agonists in controlling endometriosis. Further investigations are needed to study the impact of this line of therapy. In addition, preliminary studies using biphosphonates and norethindrone showed a beneficial effect in preserving bone mass.

GnRH agonist treatment results in amelioration of pain in up to 90% of patients during therapy, comparable to the efficacy of danazol. Reduction of lesion size is also reported. Side effects are more tolerable to patients than those of danazol. Similar to danazol, there was no beneficial effect on pregnancy rates following discontinuation of GnRH agonist therapy. Also, significant recurrence rates were reported, as with other medical lines of management.

H. Other Modalities

The anti-progesterone mefiprostone (RU486) was reported to have a beneficial effect on endometriosis in small studies. Because RU486 disrupts the endometrium along with the decidua in early pregnancy, it was hypothesized that RU486 might arrest or cause regression of endometriosis. In addition, there is preliminary evidence suggesting that RU486's antioxidant effect is also responsible for the suppression of endometriosis. Clinically, RU486 has provided symptomatic relief to patients with symptomatic endometriosis based on several small studies. Although this group of agents might prove to be of benefit, a major concern is the consequence of a long-term anti-progesterone effect. Although no cases of hyperplasia or atypia have been found in the clinical trials, all patients who received long-term treatment with RU486 exhibited abnormal endometrial pathology consistent with chronically unopposed estrogen. Thus, the long-term use of these agents will require careful follow-up.

Recently, the aromatase inhibitor amastrozole was used in combination with alendronate and calcium to successfully treat a patient with severe recurrent endometriosis after total hysterectomy and salpingo-oophorectomy resistant to large doses of progestins. Amastrozole caused a profound decrease of estrogen levels and consequently resulted in the disappearance of a recurrent fungating endometriotic lesion in the vaginal vault. The successful alleviation of severe chronic pain in this patient was impressive.

Bone loss, however, was significant (from 2.5 to 6.5% in 9 months) despite addition of a bisphosphonate. The effect of aromatase enzyme inhibitors merits further study in a larger number of patients. It might have a role in the treatment of resistant cases of endometriosis unresponsive to other medical modalities. It might also increase the pain-free interval after discontinuation of therapy.

I. Surgical Treatment

Surgical therapy is the most common treatment modality used in endometriosis. Most cases affected with endometriosis are subjected to diagnostic laparoscopy, as this is still the only means of obtaining a definite diagnosis. Since it is now possible

to accomplish surgical resection and/or ablation in nearly all cases via laparoscopy, this route is preferred to laparotomy except in very special circumstances. Surgical therapy for endometriosis is effective in relieving symptoms of pain in debilitating lesions. Actually, large lesions such as endometriomas and adhesions can be treated only surgically, as medical therapy is not effective.

In contrast to medical treatment, surgical treatment of endometriosis did prove of value in improving pregnancy rates. Surgical excision of endometriosis was considered beneficial in more severe cases of endometriosis, but the effect of surgery on milder stages of the disease was controversial. Recently, a prospective randomized study comparing surgical ablation of minimal and mild endometriosis to expectant management demonstrated a higher pregnancy rate in the surgically treated group. This study provides preliminary evidence that even milder lesions should probably be ablated when discovered at diagnostic laparoscopy.

Recurrence after surgery will depend on the severity of the disease and the completeness of the procedure. Recurrence rates are approximately 20% over 5 years following complete surgical excision or ablation.

The role of medical treatment modalities used with surgery is controversial. Preoperative medical suppression may be used in an attempt to decrease lesion size and vascularity before surgery. The disadvantage of this approach is potential changes in the appearance of lesions, making diagnosis and treatment more difficult as a result. A delay in diagnosis will consequently also delay pregnancy.

Postoperative medical therapy might be used for patients with pain after incomplete excision especially in severe disease. Postoperative medical therapy should never be used in patients seeking pregnancy as this will delay pregnancy throughout the duration of therapy. In conclusion, a beneficial effect of perioperative medical therapy is not supported by available data and thus its use should be restricted to special circumstances. Cases with intractable pain awaiting surgery might benefit from such an approach.

J. Principles of Surgery in Endometriosis

Surgery for endometriosis might range from a simple ablation of small superficial lesions to complicated cases with massive adhesions involving nearby organs such as the bowel and the urinary tract.

- The goal during surgery is complete extrication of the disease whenever possible. Adequate definition of the extent of the lesions is important.
- Visualization should be adequate and careful exploration of the pelvis is a must.
- In many cases, anatomy is distorted and identification of vital organs such as rectum, ureters, and bladder is mandatory to prevent injury.
- Endometriotic lesions are in many instances deeper than they appear, and this is important for complete excision or ablation of the lesions.
- The surgeon must be familiar with the use of electrocautery and laser as well as sharp dissection using laparoscopic scissors.
- It is sometimes important to recognize the need for help from a gastrointestinal surgeon or urologist in complicated cases.
- Adequate preoperative bowel preparation might be necessary especially in more advanced endometriosis.

In patients not desiring future fertility, removal of the uterus and the ovaries together with excision of the lesions might be the reasonable and definitive treatment. Recurrence rates after hysterectomy with or without salpingo-oophorectomy are low and range from 2 to 6%.

K. The Role of Assisted Reproduction

Controlled ovarian hyperstimulation (COH) with gonadotropins or clomiphene citrate followed by intrauterine insemination (IUI) enhances monthly fecundity rates in endometriosis patients with patent fallopian tubes. The effect on long-term pregnancy rates is, however, controversial, with no demonstrated improvement over expectant management in most studies. Ovarian stimulation with intrauterine insemination seems to have better results than stimulation with timed intercourse. From the data available, the routine use of COH/IUI is probably not recommended but may be of value in older couples or if pregnancy is delayed after surgical excision.

Most patients with endometriosis have a least one patent fallopian tube. In these patients, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer, or tubal embryo transfer are possible. Several groups reported excellent success rates with GIFT in patients with endometriosis seeking pregnancy. Nowadays, with the decreasing frequency of GIFT and increased information gained by *in vitro* fertilization (IVF), GIFT might have a role in only a few centers experienced with the procedure.

In vitro fertilization and embryo transfer (IVF/ET) is probably the preferred alternative when advanced assisted reproductive technology is needed. IVF/ET should be considered after 1 year of follow-up or after failure of conventional therapy. The procedure should be used earlier in cases with extensive tubal damage, in older patients, and in cases with associated factors leading to infertility.

The effect of endometriosis on pregnancy rates with IVF/ET is another debated issue, especially in more severe forms of the disease. Endometriosis was implicated in decreased ovarian response, interference with monitoring, decreased fertilization/cleavage rates, decreased pregnancy rates, and increased early abortions. Recent studies, however, suggest no adverse effect of endometriosis on pregnancy rates with IVF/ET. Down-regulation of the ovary with a GnRH agonist for 6 months before IVF/ET has also been suggested by some to improve outcome, but currently there are no conclusive data to recommend this.

In conclusion, COH/IUI seems to accelerate the occurrence of pregnancy but does not change overall fertility. With improved techniques in IVF/ET, the pregnancy rates in endometriosis, even in severe cases, seem to be similar to those for tubal factor infertility. IVF/ET should be utilized after an adequate trial of less invasive procedures.

Glossary

adenomyosis The infiltration or invagination of the myometrium with endometrial glands.

endometriosis The presence of endometrial glands and stroma outside their normal location within the endometrial cavity.

endometrium The inner lining of the uterine cavity.

gonadotropin- releasing hormone agonists Synthetic hormones that suppress the pituitary gonadotropin secretion leading to secondary ovarian suppression.

infertility The failure to achieve pregnancy within a year of unprotected intercourse.

menstruation The monthly shedding of the nonpregnant endometrium.

retrograde menstruation The flow of menstrual effluent via the fallopian tubes into the peritoneal cavity.

Environmental Disrupters of Thyroid Hormone Action

FRANÇOISE BRUCKER-DAVIS
Hôpital l'Archet 1, Nice, France

The thyroid gland is easily disturbed by numerous external factors, both natural and synthetic. Endemic environmental goitrogenesis, the enlargement of the thyroid gland, has long been associated with diets deficient in iodine or with diets rich in goitrogenic substances (phytogoitrogens). In addition to goiter development, thyroid hormone imbalance and/or exposure to thyroid-toxic chemicals during pregnancy can have devastating effects on fetal brain development, as illustrated by the endemic cretinism observed in areas where native diets are iodine deficient.

I. INTRODUCTION

The goiter, or enlarged thyroid gland, has long been recognized to be the result of a dietary deficiency of iodine-containing foods. The question of environmental thyroid disruption, however, has been recently assessed in the more global context of the impact of environmental synthetic chemicals on endocrine system function. Many synthetic chemicals have been found to have deleterious effects on the thyroid, both *in vitro* and *in vivo* in fauna, laboratory animals,

and humans. The clinical significance of exposure to environmental chemicals and contaminants with respect to normal thyroid development and function is currently under investigation. It is important to determine whether, beyond their goitrogenic effects, these chemicals may also have an effect on thyroid tumorigenesis and cognitive functions.

II. NATURAL ENVIRONMENTAL THYROID DISRUPTERS

The primary natural thyroid disrupters, excluding dietary iodine deficiency, are goitrogens found in food or water supplies as a result of bacterial contamination or mineral compound decomposition (Table 1). Goitrogenic substances are also found in many vegetables: thiocyanates and isothiocyanates in Cruciferae; goitrin in turnips; cyanogenic glucosides in cassava or sweet potatoes; disulfides in onion and garlic; and flavonoids in millet, sorghum, and beans. In addition, degradation of humic substances, i.e., soil decomposition of plant and animal tissues, leads to the production of resorcinol, a phenol derivative with potent antithyroid effects. Distinguishing between natural mineral compounds (such as coals or shales) and synthetic contamination is sometimes fuzzy, because mineral compound decomposition and industrial manufacturing processes may produce similar chemical products.

III. SYNTHETIC ENVIRONMENTAL THYROID DISRUPTERS

The twentieth century witnessed vast developments in the chemical industry, particularly following the end of the Second World War. Thousands of new compounds are now produced annually for both agricultural and industrial purposes. Few if any of the routinely manufactured chemicals have been tested for their endocrine effects, and in cases in which tests have been made, the test doses are not relevant to endocrine systems or to levels of probable environmental exposure.

Synthetic chemicals are used to make every imaginable type of product: computers, automobiles, toys, clothing, food containers, cosmetics, and perfumes. The chemicals, as the manufactured products are discarded and break down, are eventually released into the environment and are found in water, soils, and foodstuffs, including vegetables, fruits, diary products, meats, and fish. Evidence of the ubiquity of contaminating chemicals is supported by their presence in urine, adipose tissue, and even amniotic fluid. They are found in most cord blood samples, proof of human *in utero* transplacental contamination. Additionally, early postnatal exposure can occur through maternal breast milk, potentially impeding the well-known benefits of breast-feeding.

Some compounds, such as pesticides, are released intentionally into the environment and are designed to be toxic. Others, such as plastics and industrial compounds, until recently were considered benign. They are released unintentionally as a result of pollution. A number of synthetic chemicals are persistent, in some cases by design, and are able to travel long distances under the influence of winds and water currents. They also bioconcentrate and biomagnify in live organisms as they move up the food chain.

TABLE 1 Chemicals with Thyroid-Disrupting Properties

Family	Name[a]	Natural or synthetic[b]
Sulfurated organics	Thiocyanate, isothiocyanate, goitrin, disulfides	N
Flavonoids	Glycosides, aglycones	N
Phenol derivatives	Resorcinol, DNP, pyrogallol	N, S
Pyridines and hydroxypyridines	—	N, S
Phthalate esters and metabolites	—	N, S
Polyhalogenated hydrocarbons	PCB, PBB, dioxin	S
Polycyclic aromatic hydrocarbons	Benzopyrene, methylcolanthrene, dimethylbenzanthracene	N, S
Pesticides		
Chlorinated	DDT and others	S
Others	Amides, benzonitriles, carbamates, organophosphates, pyrethroid, pyridinoxy, thiocarbamates, thiourea, triazine, triazole	S
Heavy metals, inorganics	Hg, Pb, I, Cd, perchlorate	N

[a]Abbreviations: DNP, dinitrophenol; DDT, dichlorodiphenyldichloroethane; PCB, polychlorinated biphenyl; PBB, polybrominated biphenyl; Hg, mercury; Pb, lead; I, iodine; Li, lithium; Cd, cadmium.

[b]N, Naturally occurring even though it may be used for industrial or other anthropological purpose; S, synthetic.

Importantly, animal and human species have been exposed to these chemicals for less than a century. This extremely short period of time with respect to the evolution of species has not allowed for adaptation. Indeed, differences in how humans and animals handle man-made compounds and natural compounds involve detoxification and metabolism pathways and binding affinities for protein carriers.

Many synthetic chemicals have thyroid system effects (see Table 1). Interestingly, some chemicals, e.g., dichlorodiphenyldichloroethane (DDT) and polychlorinated biphenyls (PCBs) or their metabolites, also have estrogenic and antiandrogenic activities. Field studies in fauna have supported evidence of environmental thyroid disruption in salmon and birds from the Great Lakes and in the Florida panther. However, no specific correlation has been established between these observations and a given chemical, because environmental exposure has been to a mixture of chemicals. On the other hand, experimental studies in laboratory rodents and birds, for example, have shown specific thyroid system effects of many compounds, either alone or in mixtures.

IV. MECHANISMS OF THYROID DISRUPTION

Chemicals may disrupt the thyroid economy at virtually all stages, as shown in Table 2. This complicates the screening of chemicals for their impact on the thyroid gland. Disruption is primarily at the level of thyroid gland morphology and thyroid hormone metabolism. An effect at one stage of thyroid function or development also induces compensatory mechanisms at other stages. For example, increased glucuronidation of thyroxine (T4) by PCBs results in increased thyroid gland production of thyroid hormones to keep up with the elimination. The effects of some chemicals may be profound: the antithyroperoxidase (antiTPO) activity of resorcinol is 26 times the activity of propylthiouracil, one of the main medications for treating thyroid overactivity. Many halogenated compounds compete with natural hormones for binding to protein carriers (transthyretin, and to a lesser degree thyroxine-binding globulin), although the clinical consequences are unclear. Preliminary data suggest a possible effect of PCBs on thyroid hormone regulated genes.

V. FACTORS PREDISPOSING TO THYROID DISRUPTION

The nature of thyroid system disruption by environmental chemicals depends on the chemical and on the exposed individual. Among the factors linked to the chemical are its persistence and environmental concentrations, as well as its ability to cross the placenta and the blood–brain barrier and whether it is eliminated in breast milk. Chemical structure occasionally indicates a possible thyroid effect. For example, DDT, PCBs, and thyroid hormones have similar structures; compounds with structures unrelated to thyroid hormone structure are less predictable (Fig. 1). In addition, the compounding effects of iodine deficiency and/or the presence of co-contaminants are important.

Inherent differences in individuals and species exposed to chemicals dictate thyroid effects. For example, compared to humans, rats are more susceptible to goiter; there are also differences based

TABLE 2 Mechanisms of Thyroid Disruption

Level of disruption	Examples of chemicals	Frequency
Thyroid hormone synthesis		
Iodine uptake	Iodine, thiocyanate, sulfurated agents, aldrin, perchlorate	+++
AntiTPO[a] action	Thiourea, triazole, phenols, phtalate	++
Inhibition of thyroid hormone secretion	Iodine, PCBs?	+
Transport of thyroid hormone	Polyhalogenated, chlorinated pesticides; phenol, phthalate	+++
Metabolism		
Deiodinase, glucuronyltransferase, sulfatase	Pesticides, heavy metals, polyhalogenated pesticides, polycyclic aromatics, polyhalogenated PCBs, pentachlorophenols	+++
Central effect	Lead, dinitrophenol, PCBs?, pentachlorophenol?	+/−
Autoimmunity	PBBs?, methylcholanthrene, furan?	+?
Tumorigenesis[b]	Iodine isotopes, acetochlor	+/−
Genomic effect	PCBs?	+/−?

[a] AntiTPO, Antithyroperoxidase.
[b] Independently of effect through hormonal effects.

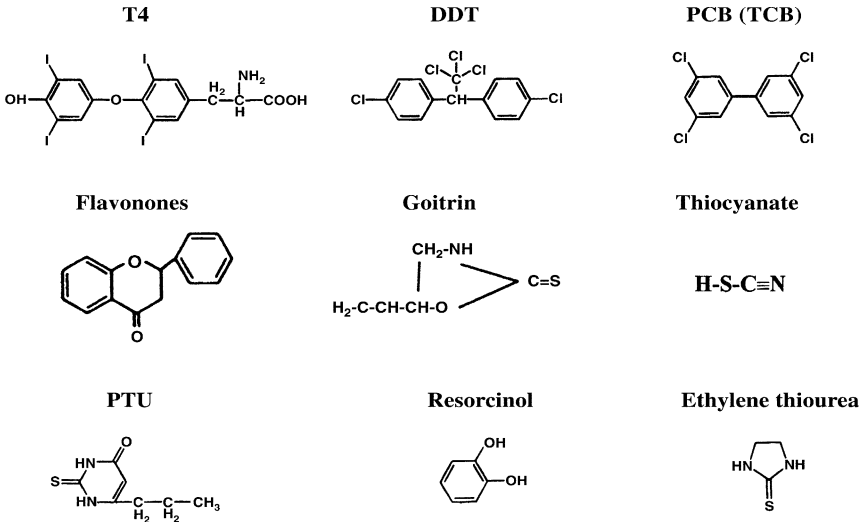

FIGURE 1 Comparison of the chemical structure of thyroxine (T4) with the structures of selected pesticides and industrial and natural chemicals with documented thyroid activity. DDT, Dichlorodiphenyldichloroethane; TCB, tetrachlorobiphenyl; PTU, propylthiouracil.

on sex (women are more susceptible than men) genetic susceptibility and endogenous thyroid status (borderline state of dysthyroidism). Diets rich in goitrogenic substances play an obvious role. Most importantly, the effect on fetal thyroid economy will depend on the timing of exposure and on maternal thyroid status.

VI. CLINICAL IMPACT OF THYROID DISRUPTERS

Although the deleterious effects of natural thyroid disrupters are well documented, much less is known regarding the effects of synthetic chemicals. The potential effects are different in individual adults ("activational phenotype") and fetuses ("developmental phenotype"). However, it is fair to say that there is currently no consensus on the real impact of synthetic thyroid disrupters in humans.

In adults, the potential risks of chemical exposure are goiter, thyroid cancer, and autoimmune thyroid disease. There are some scanty reports of thyroid abnormalities observed in the context of occupational exposure to pesticides or industrial chemicals. Those suggest at best a minor effect on genetically predisposed individuals, for both the occurrence of goiter and/or autoimmune thyroid disease. The main interest of these studies is that they involve mainly men, who are supposedly less likely than women to develop thyroid diseases.

In fetuses, the potential phenotype involves cognitive functions and behavior. Several studies have found neurological impairments linked to *in utero* exposure to synthetic chemicals such as PCBs or dioxins. However, even though those compounds have well-documented experimental thyroid effects, it is not clear whether the observed neurocognitive effects in the children are linked to those thyroid effects or to more direct neurotoxic effects.

Thus, the impact of chemical thyroid disruption following environmental exposure is largely unknown in human adults and fetuses, mainly because of methodological difficulties. There are no comprehensive data on human exposure and the number of potential chemical culprits is large. Consequently, analysis is limited to the resultant effects of a mixture of chemicals. In addition, thyroid disruption may be only one of the toxicity pathways of chemicals, because many compounds express different properties (direct neurotoxicity, estrogenicity, etc.).

Glossary

endemic cretinism Mental retardation, associated with various neurological phenotypes, due to the deleterious effect of iodine deficiency on fetal brain development. This pathology occurs in areas where normal diets are iodine deficient, in the absence of an efficient program of iodination.

endocrine disrupter Exogenous agent that interferes with the production, release, transport, metabolism, binding,

action, or elimination of the natural hormones that are responsible for maintenance of homeostasis and regulation of developmental processes. Disrupters can directly affect an exposed individual and can affect fetuses through *in utero* exposure.

goiter Thyroid gland enlargement, the most common thyroid abnormality, is present in about 200 million people worldwide.

polyhalogenated hydrocarbons Synthetic chemicals, chlorinated or brominated, such as polychlorinated biphenyls, dioxin, or polybrominated biphenyls.

Ephrins and Their Receptors

MARTIN LACKMANN* AND ANDREW W. BOYD†

*Ludwig Institute for Cancer Research, Australia • †Queensland Institute for Medical Research, Australia

Ephrins are cell-surface-associated ligands for a family of ephrin receptors (Eph). Ephrins and Ephs act as guidance cues to facilitate and direct the movement of cells and cell layers during various developmental processes.

I. INTRODUCTION

Ephrins are cell-surface-associated ligands for ephrin receptor (Eph) tyrosine kinases (RTKs), the largest subgroup of the RTK superfamily. In contrast to other cytokine receptors, Eph RTKs (Ephs) have been discovered in the past decade as orphan receptors mostly by homology (complementary DNA) cloning approaches. The founding family member, EphA1, was isolated in a low-stringency screen with a v-*fps* oncogene cDNA probe from an erythropoietin-producing hepatocellular (EPH) carcinoma cell line; EPH receptor-interacting proteins (i.e., ephrins) were isolated in a simultaneous effort by several laboratories to unravel Eph RTK function. Although several

Environmental Disruptors of Sex Hormone Action

CAROLINE M. MARKEY, ANA M. SOTO, AND CARLOS SONNENSCHEIN
Tufts University School of Medicine

The field of "environmental endocrine disruption" has emerged from repeated observations, made by biologists and physicians, that a link exists between the exposure of wildlife and humans to synthetic chemicals and the development of reproductive, neurological, and endocrine abnormalities.

I. INTRODUCTION

Since the beginning of World War II to the present date, industrialized nations have been actively engaged in the development and manufacture of a plethora of synthetic chemicals, a subset of which are hormonally active. These chemicals have been introduced into the environment deliberately for use in agriculture and medicine, inadvertently as by-products of industrial use, or irresponsibly as waste released into rivers, lakes, and the atmosphere. It is noteworthy that, within this period, there has been a rising incidence of hormone-related conditions such as early onset of puberty and diseases such as breast cancer, ovarian tumors, cervico-vaginal adenocarcinoma, endometriosis and uterine leiomyomas in women, and decreased sperm production, cryptorchidism, hypospadias, and increased testicular cancer in men. This article aims to provide a historical account of the relatively new field of "environmental endocrine disruptors" and its impact on wildlife and humans at different levels of biological complexity.

II. HISTORICAL PERSPECTIVE

The Second World War stimulated the advent of technological breakthroughs in the nuclear, chemical and agricultural industries, the magnitude of which precipitated the introduction of the terms the "Second Industrial Revolution" and the "Green Revolution" into our vernacular. The excitement of man's ability to manipulate nature to his perceived gain would not be shadowed by the specter of negative consequences until many years later.

The first indication that some of these new chemicals demonstrated biological activity other than that of their designed intent was observed with the pesticide 2,2-bis(*p*-chlorophenyl)-1,1,1-trichloroethane (DDT), the results of which were published in 1950. However, it was not until the repeated observations of acute death, spasms, altered behavior, eggshell thinning, impeded hatching, and a dramatic decline in the population of several bird species, most notably the American bald eagle and peregrine falcon, that the harmful effects of DDT were acknowledged in the United States of America. Rachel Carson, through her 1962 book *Silent Spring*, warned that the adverse effects observed in wildlife were indicators of deleterious health effects in humans. Motivated by fears that some of these chemicals may induce cancer in humans, the U.S. government banned the agricultural use of DDT in 1973 and the industrial use of polychlorinated biphenyls (PCBs) in 1977. DDT is still being used in some Latin American countries, Asia, and Africa under the pretext that it is the most effective and inexpensive way to run sanitation campaigns against malaria. Although the World Health Organization recommends the use of DDT for malarial outbreaks only, public health experts do not uniformly endorse its use since it is acknowledged that this chemical can target only adult insects, not larvae, and its repeated use has resulted in resistance.

The policy of banning DDT had the effect of reestablishing the bald eagle population, and it allowed the more subtle effects of DDT exposure to be revealed. The metabolites of this chemical still remained in the environment due to its half-life of 58 years, and its ability to induce a diversity of developmental malformations in hatchling birds became apparent particularly in the Great Lakes region of the United States. The growing awareness that lower levels of DDT, and other agricultural and industrial chemicals of a hormonally active nature, could have profound effects on the development and reproduction of wildlife species and humans

stimulated Dr. Theo Colborn, currently at the World Wildlife Fund, to convene the 1991 Wingspread Conference in Wisconsin. Its participants concluded that "a large number of manmade chemicals that have been released into the environment…have the potential to disrupt the endocrine system of animals, including humans." The participants also observed that some of the developmental defects documented in the genital tract of wildlife species had already been seen in the daughters and sons of women who had been exposed to the synthetic estrogen diethylstilbestrol (DES) during pregnancy. This chemical, which caused functional and anatomical anomalies of the genital tract and induced clear cell adenocarcinoma of the vagina in exposed daughters, had been administered therapeutically to prevent spontaneous abortion between the years 1948 and 1971 in the United States, Europe, and Australia. The DES phenomenon provided a template for the potential effects that other hormonally active agents could have on human health.

On the basis of these and additional findings, amendments to the 1996 Safe Drinking Water Act and the 1996 Food Quality Protection Act required the U.S. Environmental Protection Agency (EPA) to develop a program aimed at screening and testing chemicals used in large volumes that were suspected of contaminating water and food in order to assess their potential activity as endocrine disruptors. At that time, the EPA defined an endocrine disruptor as "an exogenous agent that interferes with the synthesis, secretion, transport, binding, action, or elimination of natural hormones in the body that are responsible for the maintenance of homeostasis, reproduction, development, and/or behavior."

III. ENDOCRINE DISRUPTING CHEMICALS

A. Synthetic and Natural Chemicals

Estimates suggest that approximately 75,000 synthetic chemicals are currently manufactured in the United States. The first of the synthetic chemicals that alerted biologists to their hormonal effects in wildlife were the organochlorines DDT, PCBs, and kepone, all of which show estrogenic activity. This list of estrogenic chemicals has grown to include the contraceptive pill ethinylestradiol, the pesticides endosulfan, dieldrin, toxaphene, and lindane, antioxidants such as *p*-hydroxyanisol and various alkylphenols, disinfectants such as *o*-phenyl-phenol, the ultraviolet screening agent 3-(4-methylbenzylidene) camphor, and some of the various PCB congeners. Similarly, the alkylphenols, including nonylphenol and octylphenol, which are used in industrial processes, industrial detergents, and personal hygiene products, have been added to this list, as have bisphenol A (BPA), which is used in epoxy resins (dental materials) and polycarbonate plastics (food and beverage containers), and phthalates, which are used as plasticizers. Natural plant compounds, such as the phytoestrogens coumestrol, genistein, and zearalenone, also show significant estrogenic activity. These products are ingested commonly in soy-based infant formula and other food products, encouraging some researchers to voice concern about the indiscriminate consumption of these estrogens during early childhood.

In addition to these xenoestrogens, it has become apparent that certain compounds released into the environment induce effects that can be characterized as anti-estrogenic or anti-androgenic. Procymidone and metabolites of the fungicide vinclozolin act as androgen antagonists by competitively binding mammalian androgen receptor (AR), which inhibits AR binding to DNA and thus androgen-dependent gene expression. In some instances, compounds such as the DDT metabolite 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene (DDE) and methoxychlor metabolites can induce a combination of hormonal effects that are both estrogenic and anti-androgenic. Although classically considered estrogenic, DDT, BPA, and butyl benzyl phthalate have been shown to possess some anti-androgenic qualities, based on the findings that they induce changes in reproductive endpoints that are believed to be androgen-dependent. For example, *in utero* exposure of mice to low doses of BPA decreases anogenital distance in males.

Some endocrine disrupting chemicals such as 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), a halogenated aromatic hydrocarbon that binds the aryl hydrocarbon receptor (AhR), affect androgen, estrogen, thyroid, and glucocorticoid functions. A known human carcinogen, TCDD is a trace contaminant of industrial processes and is generated during the production of chlorinated products such as herbicides and wood preservatives, the incineration of trash containing papers and plastics, and the burning of fossil fuels. Polycyclic aromatic hydrocarbons, which are found in diesel exhaust, cigarette smoke, and charbroiled foods, also bind the AhR. In addition to the estrogenic PCB congeners mentioned above, PCB congeners with zero or one ortho chlorine, two para chlorines, and at least two meta chlorines adopt a planar conformation similar to that of TCDD and bind the AhR. This complexity of effects highlights

the growing belief that many of these endocrine disrupting chemicals alter hormone action through multiple mechanisms. A further confounding factor in this categorization of chemicals is that some can have a different effect depending upon the tissue in which exposure occurs. For example, tamoxifen, which shows anti-estrogenic behavior in breast tissue, and as such is used for breast cancer therapy, has estrogenic behavior in the uterus, which can cause the growth of endometrial lesions in these patients.

Hormonally active agents such as estrogens (ethynylestradiol and Zeranol), progestagens (medroxyprogesterone acetate and pregnenedione), and androgen agonists (Trenbolone and methyltestosterone) are used in food-producing animals, such as beef cattle, within the United States for improved feed efficiency and weight gain. In contrast, the European Union has banned the importation of hormone-treated beef into its territory based on the tenets of the precautionary principle.

B. Metabolism, Pharmacokinetics, and Pharmacodynamics

The categorization of the hormonal activity of chemicals has been based largely upon a battery of *in vitro* and *in vivo* assays. Regarding estrogenic activity, the most notable of the bioassays are the (1) estrogen receptor (ER) competitive binding assay, (2) yeast-based reporter gene assay, (3) E-SCREEN assay, and (4) mouse uterotropic assay. These assays measure the ability of a suspected hormonally active chemical to (1) competitively bind the mouse uterine ER, (2) transcriptionally and translationally activate a reporter gene construct via an estrogen-response element, (3) induce the proliferation of estrogen-responsive human MCF-7 cells, and (4) induce increased uterine wet weight in the prepubertal or adult ovariectomized mouse, respectively. Although these methods have certainly provided insight into the hormonal nature of both synthetic and natural chemicals, they are not equivalent. The ER binding, reporter gene, and E-SCREEN assays are consistent in detecting estrogenic activity, albeit with different sensitivities; the uterotropic assay, although quite insensitive, is able to detect pro-estrogens, that is, chemicals that do not bind to the ER until they undergo metabolism. For example, methoxychlor is able to induce a positive uterotropic effect (increased uterine weight) but shows neither positive competitive binding of ER nor transcriptional activation of the ERE-reporter gene construct. This is due to the fact that "pro-estrogens" require metabolic activation in the liver, inducible only in an *in vivo* model, to attain their hormonal character. Thus, *in vitro* assays, though valuable in the characterization of receptor-binding chemicals, do not take into account the metabolism, pharmacokinetics, and pharmacodynamics of compounds originally suspected of being estrogenic as do *in vivo* models. These latter assays provide the most pertinent indicators of possible endocrine effects in wildlife species and humans. Of equal importance is the binding affinity of hormonally active chemicals to various serum proteins, including albumin, sex hormone-binding globulin, corticosteroid-binding globulin, and α-fetoprotein, in terms of assessing the chemicals' potency. For example, although BPA is considered a weak estrogen, it binds α-fetoprotein with negligible affinity relative to estradiol, thereby making it more available systemically to bind ER. This protein acts as an estrogen sink in the rodent fetus and neonate, protecting them against high levels of maternal estrogens, which unbound have a detrimental impact on development.

Yet, even *in vivo* models demonstrate that there are species- and strain-specific differences in terms of the effects that endocrine disrupting chemicals have on tissues and organs. For example, administration of approximately 0.3 mg/kg BPA per day to Fisher 344 rats for 3 days will induce a 2.5-fold increase in the height of uterine epithelial cells, an increase in uterine wet weight, and proliferation and cornification of the vaginal epithelium. The exact same treatment has no effect on these parameters in Sprague–Dawley rats.

IV. MODE OF ACTION

Endocrine disrupting chemicals are believed to exert their effect by (1) mimicking normal, endogenous hormones such as estrogens and androgens, (2) antagonizing endogenous hormones, (3) altering the pattern of synthesis and metabolism of endogenous hormones, and (4) modifying hormone receptor levels. Natural, endogenous estrogens are involved in the development and maintenance of the female reproductive tract and secondary sexual characteristics and regulation of the menstrual cycle, pregnancy, and lactation. At the cellular level, these endogenous hormones promote cell proliferation and the synthesis and secretion of cell-specific proteins in reproductive tissues such as the ovary, oviduct, uterus, vagina, hypothalamus, pituitary, and mammary gland. Similarly, androgens are involved in the development and maintenance of the male reproductive tract and secondary sexual characteristics

through comparable cellular mechanisms, which function in the testis, epididymis, vas deferens, prostate, seminal vesicle, hypothalamus, and pituitary. These effects are mediated, for the most part, by ER-α and ER-β in the female, and AR in the male. However, various tissues of the male reproductive tract also express ER just as various tissues of the female reproductive tract express AR. In both sexes, nonreproductive organs, including the thyroid, cardiovascular system, and bone, also express ER.

On the basis of even this simplistic description of the role of estrogens and androgens in development and reproduction, it can be appreciated that exposure to chemicals that possess the ability to mimic, antagonize, or modulate endogenous hormones has a potentially striking impact. Although the environmental chemicals are usually less potent than endogenous hormones, such as estradiol, it is now clear that they act additively with them. This explains how low, seemingly insignificant levels of xenoestrogens, such as the "weak" BPA, may have an impact when added to the already significant levels of endogenous steroidal hormones. Further, several endocrine disruptors have unequivocally been shown to induce nonmonotonic dose-response curves of biological effects; that is, lower doses induce a more profound effect than higher doses ("low-dose effect"). This phenomenon, which has been known for a long time regarding sex steroid action, was first described for endocrine disrupting agents in the mouse prostate, using organ weight as the endpoint, in response to fetal exposure to increasing doses of DES, and later by the "weak" xenoestrogen BPA. Endogenous hormones act on hormone-sensitive endpoints in this manner, as evidenced by the observation that prostate cells undergo increased cell proliferation in response to low doses of androgen but decreased cell proliferation in response to high doses of androgens, a phenomenon that is due to the operation of different and discrete pathways at low and high doses. In other instances, low-dose effects have been observed to occur due to down-regulation of the receptor by the ligand.

The deleterious effects of endocrine disrupting chemicals also depend on the period during which an organism is exposed to the chemicals. The developing organism is critically sensitive to both endogenous and exogenous hormones. The "critical window" of exposure differs depending upon the time at which specific developmental events occur in particular tissues or organs. For example, clear cell adenocarcinoma of the vagina was observed in daughters of pregnant women exposed *in utero* to DES, but only if exposure occurred before the 13th week of gestation. It is clear that the developing fetus and neonate are profoundly sensitive to hormonally active chemicals, as demonstrated also by the observation that mammary gland dysgenesis occurs in the adult following fetal exposure to concentrations of BPA that are 4000-fold lower than those required to induce a uterotropic effect in the prepubertal mouse. The finding in 1998 that the DDT metabolite DDE and other chemicals such as PCBs and phytoestrogens are the most frequently recovered contaminant in amniotic fluid of women ages 35 years and over in the United States attests to the need for concern. This occurred despite a restriction in the use of the parental chemical DDT in 1973.

A. Receptor Mediation

The ER knockout (ERKO) and AR knockout mouse models have confirmed the mediating role played by estrogen and androgen receptors on the effects of sex hormones. By analogy, the sex steroid receptors were also thought to be the mediators of effects of endocrine disrupting chemicals on sex hormone-sensitive tissues. Many *in vitro* studies revealed that suspected xenoestrogens bind to ER-α, ER-β, and AR. It was then concluded that certain endocrine disrupting chemicals, such as DES and ethinyl estradiol, which showed high binding affinity for ERs, were potent estrogens, whereas BPA and alkylphenols, which showed low binding affinity, were called "weak" estrogens. The latter chemicals were, however, full agonists, able to elicit a response of magnitude similar to that elicited by the former chemicals. Further, these studies revealed that some endocrine disruptors, such as genistein, had an approximately 50-fold higher binding affinity for ER-β than for ER-α; this provided insight into how specific organs may be affected by various chemicals based on their distribution patterns of sex steroid hormone receptors. Although this information is factual, it overemphasized the importance of models in which xenoestrogen activity is measured in the absence of endogenous estrogens. For example, BPA was considered to be a weak estrogen on the basis of the receptor-binding assay, yet subsequent studies have revealed that fetal exposure to low doses of this chemical had significant effects on the development of the male and female reproductive tracts and mammary glands.

Certain endocrine disrupting chemicals act as selective ER modulators (SERMs); that is, their agonist and/or antagonist activity may differ among

cells and tissues. As described earlier in this article, tamoxifen has this capacity, and other chemicals are now being added to the list of SERMs. This is prompting a reevaluation of the pharmacological classification of ER ligands. Several studies including transgenic mouse models, in which a reporter of ER-α and ER-β activity is expressed, have confirmed that ER activity is found not only in the brain and the reproductive system but also in the liver, the kidney, and the thyroid and adrenal glands. These findings suggest that these organs are additional potential sites for endocrine disruptor activity. Further, the study revealed that the pituitary gland is 25-fold more sensitive to DES than the uterus and that BPA is a potent agonist in stimulating ER transcriptional activity in the pituitary but induces a limited uterotropic effect. These data indicate that considerable differences in the efficacy and potency of different ER ligands, such as the endocrine disrupting chemicals, may be influenced by the differential expression of cell- and tissue-specific factors, such as co-activator and co-repressor proteins.

B. Nonreceptor Mediation

Transgenic ERKO models have revealed that certain estrogenic chemicals may exert their effect through alternative pathways that do not involve ER-α or ER-β. This was shown to occur with the catecholestrogen 4-hydroxyestradiol-17β (10 μg/kg) and the environmental estrogens kepone (15 mg/kg) and methoxychlor (1.8–60 mg/kg), which in ERKO mice are able to up-regulate uterine expression of the estrogen-responsive lactoferrin and glucose-6-phosphate dehydrogenase (G6PD) genes. In both studies, treatment of the ERKO mice with estradiol had little or no effect. It is possible that the observed effects were mediated through other nuclear receptors, such as ER-γ, or may have been due to the effect of alternatively spliced forms of ER that contain the ligand-binding domain. Nonetheless, these data raise the possibility that endocrine disruptors may exert their effects on hormone-sensitive tissues by additional independent signaling pathways that exclude the classical sex steroid hormone receptors. Some phthalates, such as dibutyl phthalate, and the herbicide atrazine show non-receptor-mediated effects on the androgen system. Atrazine, the most commonly used herbicide in the United States and possibly the world, acts by increasing aromatase activity, resulting in the promoted conversion of testosterone to estrogens, as shown in the alligator. This non-receptor-mediated mechanism has been postulated to induce demasculinization of laryngeal size and hermaphroditism in African clawed frogs (*Xenopus laevis*) following larval exposure to environmentally relevant levels of atrazine.

V. EFFECTS AT THE MOLECULAR, CELLULAR, AND TISSUE LEVELS

A. Developmental Genes

Although significant progress has been made in establishing that environmental chemicals induce developmental and reproductive anomalies through either receptor-mediated or non-receptor-mediated pathways, limited information is available describing the signals that link these two events. Members of the *homeobox* (Hox) and *wingless* (Wnt) family of genes have recently been identified as hormone-sensitive candidates that relay information on tissue patterning within the developing uterus, vagina, and mammary gland, particularly as regards the relationship between the epithelial and the stromal compartments, which is critical to normal development. Hoxa-9, hoxa-10, hoxa-11, and hoxa-13 are all expressed along the paramesonephric duct in the embryonic mouse, and by birth and into adulthood, these genes establish a spatial co-linearity such that they are expressed in the fallopian tubes, uterus, uterus and uterine cervix, and upper vagina, respectively. In late gestation, hoxd-10 and hoxd-11, hoxd-12, and hoxd-13 are also expressed in the oviduct, uterus, and posterior uterus/vagina, respectively. Wnt 4, Wnt 5a, and Wnt 7a are expressed in specific mesenchymo-epithelial patterns during perinatal development of the uterus, and Msx 1, Msx 2, and Wnt 10b are expressed during prenatal mammary gland morphogenesis.

Recently, the expression of some of these developmental genes was shown to oscillate in response to changes in circulating levels of steroid hormones during the murine estrous cycle or down-regulate following ovariectomy. Therefore, the subsequent findings that prenatal exposure to the potent estrogen DES altered the expression of Wnt 7a and Hoxa-10 during uterine morphogenesis in the mouse established an important correlation between chemical exposure and the ensuing developmental abnormalities associated with endocrine disruption. This link was made even more definitive when the phenotype of mice carrying specific Hox and Wnt null mutations was observed to be strikingly similar to that of human and mouse "DES daughters." The Wnt genes are associated with cellular responses such as cell

proliferation, apoptosis, and cell–cell communication (through the β-catenin/E-cadherin complex), and as such, changing patterns of expression due to environmental chemical exposure can provide insight into how these chemicals influence cell fate determination and tissue morphogenesis in hormone-sensitive organs.

B. Cell Cycle Dynamics and Sex Steroid Receptor Expression

Induction of cell proliferation is considered the hallmark of estrogen action in the female genital tract. Thus, it has been adopted as a critical determinant of whether an environmental chemical is an estrogen. The mechanisms underlying this effect have not been completely elucidated; however, data gathered using diverse models such as established cell lines, primary cultures, and organ cultures indicate that the proliferative effect of estrogens is not directly stimulatory. Nonetheless, estradiol and DES have triggered opposite effects on cell number (and presumably cell proliferation) depending upon the time of exposure, the dose used, and the cell or tissue in which this parameter is measured. Similarly, apoptosis and the expression of sex steroid receptors within the female reproductive tract are modulated differentially depending upon the circumstances of exposure. For example, neonatal exposure of rodents to high doses of estradiol results in a severely hypoplastic mammary gland in adulthood characterized by reduced ductal-alveolar development, but the same exposure regimen with low doses of this chemical results in a hyperplastic mammary gland associated with increased lactational activity. Furthermore, prenatal exposure to estradiol or DES alters the timing of developmental events in the mouse uterus and vagina, specifically the precocious development of glands, which in adulthood become the very site at which adenocarcinoma develops. Prenatal exposure to TCDD results in the persistence of terminal end buds in the mammary glands, the same structural site in which a dramatic reduction of apoptosis is observed following prenatal exposure to BPA; these structures are the sites at which carcinogenesis develops in rodents and humans. All of these hormone-induced modulations of proliferation and apoptosis suggest that environmental chemicals can induce changes in the timing of developmental events, such that tissue organization is permanently altered; in turn, this may predispose these organs to disease or carcinogenesis.

Hormone-induced changes in the expression of sex steroid receptors have a profound impact on disease and normal functioning of tissues. Approximately 70% of human breast tumors exhibit an overexpression of ER. Transgenic mouse models in which ER expression is up-regulated by 25% have been shown to develop uterine adenocarcinoma at a far earlier stage in adult life relative to the wild type following neonatal exposure to DES. Subsequently, the finding that prenatal exposure to low doses of BPA induces a significant increase in the expression of both ER and PR within the lumenal epithelium of the adult mouse uterus is of concern, as this may predispose the organ to disease. The down-regulation of sex steroid receptors within reproductive organs can elicit an impact of equal importance since such a phenomenon can compromise fertility. For example, neonatal exposure of mice to DES affects the ability of the uterus to respond to estradiol; lower DES doses induce an enhanced response and higher doses induce a dampened response (uterotropic assay). In summary, these findings highlight the potential for environmental chemicals to induce alterations in normal relationships between proliferation, apoptosis, and expression of sex steroid receptors and reveal how such events may predispose organisms to infertility, disease, and/or carcinogenesis.

VI. ENVIRONMENTAL EXPOSURE OF WILDLIFE

Lakes and rivers are one of the primary sites of chemical contamination for many wildlife species. This can occur either directly through skin absorption and respiration within chemical-laden waters, as is the case with invertebrates, fishes, and amphibians, or indirectly through preying upon these aquatic species. One of the earliest observations of chemical toxicity of aquatic species was made in 1964, when the high incidence of tumors in fish within the Los Angeles harbor, Southern Californian waters, and a Maryland lake was believed to be associated with exposure to sewage outlets. Other reports in sites throughout the United States unveiled a link between neoplasms in fish and high levels of PCBs from heavy manufacturing industries, chemical plants, wood product plants, and large shipping industries. These chemicals also induced developmental and reproductive abnormalities in fish by their ability to disrupt the endocrine system. This was first noted in the Great Lakes region that lies between Canada and the United States and also in rivers in the United Kingdom. In this latter

case, the incidence of hermaphroditism and feminization observed in male fish residing in waters downstream of industrial effluent outlets from wool mills was reversed when the offending mills switched voluntarily from using estrogenic alkylphenol polyethoxylates to nonestrogenic detergents (alkyl ethoxylates).

Aquatic species act as "sentinels" of endocrine disrupting activity since changes in their development, reproduction, and ultimately population size provide the first indication of damage to an ecosystem. This was realized too late for the human populations residing in the Great Lakes region who relied upon local fish as a food source; their infants subsequently showed increasing evidence of motor and cognitive skill dysfunction. Aquatic species are the first organisms to suffer the effects of pesticide- and herbicide-laden water run-off from nearby agricultural areas and the direct dumping of industrial waste products, such as PCBs, into local waterways. Similarly, the use of biocides, such as tributyltin, in marine paints and wood preservatives increases the exposure of aquatic species to endocrine disrupting chemicals. Organisms that rely on algae in lakes and ponds as a food source, such as the crustacean *Daphnia magna*, show a reduced diversity in populations when exposed to hormonal chemicals, in part due to the effects of these chemicals on sex ratios. Laboratory experiments have shown that exposure of these invertebrates to fungicides, detergents, and agricultural effluents induces metabolic androgenization by significantly inhibiting the metabolic clearance of testosterone while enhancing the conversion of testosterone to other androgenic steroid hormones. Similarly, snails respond to tributyltin exposure by developing a hermaphroditic phenotype. The worldwide decline in frog populations has been attributed to chemical exposure, in large part from the herbicide atrazine to which amphibians are critically sensitive. Exposure of male frogs to this chemical causes the development of ovaries and reduces testosterone levels by increasing the production of aromatase, which catalyzes the conversion of testosterone to estrogen. Atrazine was one of numerous chemicals that were found to contaminate certain lakes in Florida and were directly associated with developmental abnormalities in alligators, such as micro-penis in the males. Chemically induced effects in lower invertebrates and vertebrates have repercussions in species that are higher on the food chain, such as birds, mammals, and ultimately humans, by the phenomenon known as biomagnification. An initial concentration of the persistent organochlorine DDT, which bioaccumulates within adipose tissue and organs, magnifies 10-fold each time it moves up the food chain. However, certain chemicals make it into the food chain by different means. PCBs and alkyl phenols from industrial effluent and pesticides and herbicides from agricultural water run-off often make it into groundwater via percolation through soil and into the air due to their volatility. Similarly, pesticides are sprayed directly onto fruit and vegetables, and plants have also been shown to take up endocrine disrupting chemicals from water.

BPA is released into the environment by a variety of means, including air, water, and soil. Humans are exposed directly to this estrogenic chemical through leaching from dental materials, food and beverage containers, and babies' formula bottles. It is also used in the manufacture of a multitude of products including optical lenses, adhesives, powder paints, building materials, compact disks, and for the encapsulation of electrical and electronic parts. Although humans may be the primary targets of BPA exposure, recent evidence has revealed that it is also present in lakes and rivers in concentrations that have experimentally generated "superfemale" phenotypes in prosobranch mollusk species; these exhibit additional reproductive organs such as two vaginas.

VII. IMPLICATIONS FOR HUMAN DEVELOPMENT AND CARCINOGENESIS

Descriptions of the effects of fetal exposure to endocrine disruptors on the female and male reproductive system have predominated in the literature; however, two hormone-dependent systems that are beginning to receive attention are the mammary glands and the thyroid gland. These will be focused on next due to their importance in potentially linking exposure to endocrine disruptors with carcinogenesis and neurological/motor dysfunction.

A. Mammary Glands

Estrogen exposure throughout a woman's life is a major risk factor for the development of breast cancer. Early age of menarche, late age of menopause, and obesity in the postmenopausal period (and thus increased aromatase activity and estrogen production) all correlate positively with breast cancer incidence. Also, the intrauterine milieu has an influential role since differences in intrauterine levels of estrogens correlate positively (twin births) and

negatively (preeclampsia) with breast cancer incidence in the daughters from these pregnancies. Hence, fetal exposure to hormonally active chemicals may predispose humans to breast cancer. Various epidemiological case-control and cohort North American and European studies have revealed a positive correlation between blood serum levels of dieldrin, DDT, and PCBs in women and breast cancer incidence. Controversy abounds on this interpretation of the data mainly because none of these chemicals can be construed to be a marker of a total xenoestrogen exposure. It is worth noting that women who were exposed therapeutically to DES while pregnant between the years 1948 and 1971 now show a higher incidence of breast cancer.

Studies on rodents have shed light on fetal and neonatal exposure to estrogens during development and carcinogenesis of the mammary gland. However, it should be highlighted that tumors would not generally develop in the absence of either the mouse mammary tumor virus in mice or a 9,10-Dimethyl-1, 2-benzanthracene/N-methyl-N-Nitrosourea (DMBA/NMU) insult in both mice and rats. Using these models, several protocols of perinatal exposure to DES have resulted in an increased incidence of mammary tumors. In addition, fetal exposure to certain hormonally active chemicals has been shown to result in changes in the timing of developmental events and ultimately tissue architecture within the mammary gland, alterations that may predispose it to neoplastic transformation. *In utero* exposure of mice to 25 and 250 μg/kg BPA induces alterations in DNA synthesis within the epithelium and stroma, a striking reduction in apoptosis within the terminal end buds, and increased expression of progesterone receptors at puberty (postnatal day 30). These developmental changes preceded permanent changes that were characterized by a striking proliferation of all epithelial structures (ducts, terminal ducts, terminal ends, and alveolar buds) and increased expression of ER at 6 months of age. This disruption of the relationship between the epithelial and stromal tissue compartments and the relationship between DNA synthesis and apoptosis has been shown to predispose the mammary gland to carcinogenesis.

Other endocrine disruptors have been shown to alter mammary gland development and favor carcinogenesis. Perinatal exposure of rats to TCDD has been shown to induce the impairment of ductal growth, side branching, and alveolar development, accompanied by a persistence of terminal end buds and increased expression of ER. These animals also developed a higher incidence of chemically induced mammary adenocarcinomas. Typically present only at puberty, terminal end buds are very active sites of DNA synthesis and apoptosis, and thus their persistence into adulthood appears to provide a structural template for the development of carcinogenesis, which has been shown to arise specifically from these sites in both rodents and humans. Furthermore, neonatal exposure of rats to a combination of the organochlorines DDT, DDE, and 19 PCBs favored the development of chemically induced mammary tumors. This occurred following exposure to 100 × the concentration of endocrine disrupting chemicals that are found in the breast milk of Canadian women.

Mice are not susceptible to the spontaneous development of mammary tumors the way humans are, and in addition, humans are exposed to more than one environmental chemical throughout their lives. Thus, if a morphological template for the development of mammary gland carcinogenesis is established through the influence of endocrine disrupting chemicals, additional hormonal insults may initiate neoplastic transformation. The multitude of environmental chemicals to which humans are all exposed involuntarily, in addition to medically used hormones (hormonal contraceptives or hormone replacement therapy), may be a cumulative cause in the increase of breast cancer incidence that has been observed during the past 50 years.

B. Thyroid Gland

The critical role of thyroid hormone in normal brain development has been revealed by the intellectual deficits that characterize congenital hypothyroidism, most notably mental retardation, deaf-mutism, and motor dysfunction. Thus, reports that a large number of endocrine disrupting chemicals can alter thyroid function are of grave concern. Epidemiological studies of pregnant women and newborns exposed to PCB-contaminated fish from the Great Lakes have demonstrated an association between PCB exposure and the development of cognitive and behavioral changes in children. Other studies have shown an inverse relationship between serum levels of PCBs in infants, children, and adults and levels of triiodothyronine and thyroxine (T4) and a positive correlation between serum PCBs and thyrotropin (TSH); some conflicting data have also been reported.

The mechanisms by which PCBs impact thyroid function are becoming apparent by *in vitro* and *in vivo* studies. Exposure to PCB congeners has been shown to (1) competitively bind thyroid hormone-binding proteins, thus potentially reducing

the carrying capacity of the blood for T4, (2) reduce the serum half-life of T4 by increasing the rate of biliary excretion of T4 and facilitating clearance through liver metabolism, and (3) reduce the ability of the thyroid gland to respond to TSH. Furthermore, PCB congeners may affect brain development by directly interacting with the thyroid hormone receptors α and β; these mediate the majority of the biological actions of thyroid hormone. In rats, a number of thyroid hormone-responsive endpoints, such as the expression of RC3/neurogranin mRNA in the forebrain and myelin basic protein mRNA in the cerebellum, are up-regulated in a dose-dependent manner by postnatal exposure to Arochlor 1254. Similarly, fetal exposure to the same chemical has been shown to increase expression of RC3/neurogranin and Oct-1 mRNA in the embryonic day 16 fetal cortex and also the *notch* signaling gene HES-1; this increases gliogenesis at the expense of neurogenesis. If PCB congeners do indeed alter the balance of neuron to glia production in the brain, this finding may contribute to the understanding of how environmental chemicals can alter brain development and subsequently cognitive and motor function in humans.

VIII. HUMAN DISEASE AND FERTILITY

The observation that the average sperm count has significantly declined in men from various countries in Europe and in the United States, though still controversial, led to the hypothesis that exposure to environmental chemicals may be associated with an increase in the incidence of male genital tract abnormalities and infertility. This hypothesis is supported by trends in these endpoints in several European countries as well as the United States. Studies on cohorts exposed through industrial accidents (Seveso, Italy; Yu-Cheng, Taiwan; Yucho, Japan) and in occupational settings to high levels of hormonally active chemicals, as well as rodent models, lend further support to this hypothesis, as do the limited data on men exposed *in utero* to DES ("DES sons"). The impact of exposure to estrogens on female reproductive health was made abundantly clear by the case of the DES daughters, as mentioned earlier in this article. The increased incidence of endocrine-related diseases, such as uterine cervix adenocarcinoma, specific ovarian tumors, and uterine leiomyomas, that have been observed in human populations over the past few decades also suggest a link with chemical exposure. As with males, numerous animal studies have demonstrated that *in utero* exposure to a variety of hormonally active chemicals induces developmental and reproductive abnormalities, which range from precocious puberty to the onset of endometriosis.

Recent work has demonstrated that perinatal exposure of mice to the phytoestrogen genistein, at doses comparable to those used in soy-based infant formula, induces an increased incidence of uterine adenocarcinoma in adults. Therefore, the increasingly popular consumption of this natural, unregulated estrogen by women and infants is becoming a cause for alarm. Western populations enthusiastically adopted the use of soy products in their diet, based upon the fact that Asians, who traditionally eat a high-soy-content diet, have a significantly lower incidence of both breast and prostate cancer. However, the Asian and Western diets differ in many other aspects, which preclude for the moment making a correlation between cancer incidence rates and one specific dietary component. Yet, average measurements of the levels of genistein (one soy component) revealed that Western diets contain 5 parts per million (ppm), Asian diets contain 100 ppm, and Western infant soy-based formula contains 500 ppm. This discrepancy highlights the need to practice caution when it comes to extrapolations of anecdotal evidence to human health policy.

Endocrine disruption seems to have consequences that are transmitted transgenerationally. For example, daughters of rats that were exposed to DES during perinatal development have a significantly greater incidence of malignant reproductive tract tumors, including uterine adenocarcinoma, compared to daughters of vehicle-exposed controls. The mechanisms underlying these effects are unknown, although it has been suggested that they may be mediated by epigenetic phenomena such as DNA methylation. As with all the anomalies described above, the evolutionary consequences of such developmental and reproductive alterations in human populations are unknown at this stage, but there is adequate evidence, based on wildlife indices, to suggest that population size and diversity would be impacted significantly.

A. Susceptible Populations or Individuals

Evidence that individuals might show a different response to the same chemical exposure was first established in studies that showed a differential response in the prostate weight of mice following prenatal estradiol exposure; the difference depended upon the intrauterine position of the developing mouse.

Specifically, males situated *in utero* between two females showed a significantly greater increase in their adult prostate weight than those males situated between two males when exposed prenatally to estrogens. Minor differences in the local concentrations of intrauterine estradiol, which appeared to be gender-specific, were determined as the basis for different adult outcomes. This phenomenon should be taken into consideration when dealing with xenoestrogen exposure. For example, the positional effect has been shown to act additively with fetal BPA exposure in determining the age at which puberty initiates in female offspring. In this regard, one major issue that has arisen in the field of environmental endocrine disruption is that wildlife populations and outbred rodent strains are composed of nonidentical individuals and thus vary in their susceptibility to any particular noxious agent. This was made clear by a study showing that different strains of mice (inbred and outbred) responded very differently (in terms of testicular parameters) to estradiol exposure.

A new area of molecular investigation has suggested that the phenomenon of single-nucleotide polymorphisms (SNPs) may be implicated in the differential response of individual animals and humans to toxicological insult. SNPs are common DNA sequence variations that exist between genders, races, ethnicities, and individuals. Although most of these sequence variations do not affect protein function directly, they may have an indirect influence by altering the function of regulatory sequences that control gene expression or the stability and processing of the mRNA transcript. These subtle differences may contribute to the future understanding of how exposure to endocrine disrupting chemicals impacts wildlife and human health.

IX. CONCLUDING REMARKS

The Second Industrial Revolution and the Green Revolution, which heralded the massive synthesis and release of chemicals into our environment, are having a profound and continued effect on the development, reproductive health, and disease status of wildlife and humans. As a result of the hormonal activity of many chemicals, phenomena such as changes in the sex ratio, gender status, and genetic diversity of aquatic species, birds, and mammals have emerged. The implications for human health are serious and well founded, since there is increasing evidence of the presence of pesticides, herbicides, plasticizers, and other industrial chemicals in human breast milk, amniotic fluid, blood serum, and fat samples. Some of these compounds, such as the chlorinated compounds, are persistent and therefore bioaccumulate. A plethora of experimental data collected in rodents reveal that fetal exposure to similar doses of these chemicals can induce imbalances in gene expression, cell proliferation and apoptosis, communication between tissue compartments, and changes in sex steroid receptor expression in many hormone-sensitive organs. These changes often translate into morphological and functional alterations. The resultant susceptibility of these experimental species to developmental and behavioral anomalies, diseases of the reproductive tract and other organs, compromised fertility, immune deficiencies, and in some instances, carcinogenesis portends comparable vulnerability in humans. If one agrees with the oft-quoted maxim by Theodosius Dobzhanski that "nothing makes sense in Biology if not in the context of evolution," it becomes inescapable to conclude that all living things are participants of a man-made evolutionary experiment. Scientists have presented sufficient evidence that the outcome of this experiment may not be to the benefit of humans and the ecosystem on which all humans depend. Thoughtful, conscientious citizens and responsible politicians must now bear the responsibility of offering less risky alternatives to provide a balanced accommodation between a reasonable standard of living for humans and the perils that endocrine disruptors pose to all.

Glossary

aryl hydrocarbon receptor An intracellular protein expressed in several tissues of most mammals, including humans, whose three-dimensional structure and endogenous ligand are unknown. It is assumed that this receptor mediates the toxic effects of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin and structurally related halogenated aromatic hydrocarbons, including polychlorinated biphenyls.

biomagnification The phenomenon in which the tissue concentrations of some pollutants are increased as they transfer from one organism to another through the food chain due to their lipophilic nature.

endocrine disruptor An exogenous agent that interferes with the synthesis, secretion, transport, binding, action, or elimination of natural hormones in the body. These hormones are responsible for the maintenance of homeostasis, reproduction, development, and/or behavior.

hermaphroditism Derived from the Greek god and goddess Hermes and Aphrodite, this phenomenon describes the developmental condition in which an individual displays both male and female sexual phenotypes.

selective estrogen receptor modulators Natural or synthetic ligands that exhibit either estrogen agonist or antagonist activity among different cells and tissues. Most likely, this is due to the differential expression of cell- and tissue-specific factors, such as co-activator and co-repressor proteins.

Environmental Disrupters of Thyroid Hormone Action

FRANÇOISE BRUCKER-DAVIS
Hôpital l'Archet 1, Nice, France

The thyroid gland is easily disturbed by numerous external factors, both natural and synthetic. Endemic environmental goitrogenesis, the enlargement of the thyroid gland, has long been associated with diets deficient in iodine or with diets rich in goitrogenic substances (phytogoitrogens). In addition to goiter development, thyroid hormone imbalance and/or exposure to thyroid-toxic chemicals during pregnancy can have devastating effects on fetal brain development, as illustrated by the endemic cretinism observed in areas where native diets are iodine deficient.

I. INTRODUCTION

The goiter, or enlarged thyroid gland, has long been recognized to be the result of a dietary deficiency of iodine-containing foods. The question of environmental thyroid disruption, however, has been recently assessed in the more global context of the impact of environmental synthetic chemicals on endocrine system function. Many synthetic chemicals have been found to have deleterious effects on the thyroid, both *in vitro* and *in vivo* in fauna, laboratory animals,

action, or elimination of the natural hormones that are responsible for maintenance of homeostasis and regulation of developmental processes. Disrupters can directly affect an exposed individual and can affect fetuses through *in utero* exposure.

goiter Thyroid gland enlargement, the most common thyroid abnormality, is present in about 200 million people worldwide.

Ephrins and Their Receptors

MARTIN LACKMANN* AND ANDREW W. BOYD†

*Ludwig Institute for Cancer Research, Australia • †Queensland Institute for Medical Research, Australia

Ephrins are cell-surface-associated ligands for a family of ephrin receptors (Eph). Ephrins and Ephs act as guidance cues to facilitate and direct the movement of cells and cell layers during various developmental processes.

I. INTRODUCTION

Ephrins are cell-surface-associated ligands for ephrin receptor (Eph) tyrosine kinases (RTKs), the largest subgroup of the RTK superfamily. In contrast to other cytokine receptors, Eph RTKs (Ephs) have been discovered in the past decade as orphan receptors mostly by homology (complementary DNA) cloning approaches. The founding family member, EphA1, was isolated in a low-stringency screen with a v-*fps* oncogene cDNA probe from an erythropoietin-producing hepatocellular (EPH) carcinoma cell line; EPH receptor-interacting proteins (i.e., ephrins) were isolated in a simultaneous effort by several laboratories to unravel Eph RTK function. Although several

ephrins, including the first identified EphA2 ligand, now known as type A1 ephrin, were isolated as soluble proteins, it rapidly became apparent that ephrins are produced as cell-associated proteins. Structures and functions of the 14 transmembrane Ephs and the 9 cell-membrane-associated ephrins (Fig. 1) are highly conserved in metazoans, ranging from *Caenorhabditis elegans* to humans. Ephs and ephrins are dynamically expressed in spatially restricted patterns at discrete phases during vertebrate embryogenesis; they guide the migration and positioning of cells and cell layers during gastrulation and during the development of nervous system and vasculature. In contrast to other RTK systems, Eph signaling does not promote proliferation and differentiation; rather, engagement of ephrins with corresponding Ephs on opposing cells triggers cell morphological changes that underlie cell adhesion and cell repulsion. There is little indication for a role of Ephs and ephrins in normal adult tissue, although their unscheduled overexpression in many human cancers emphasizes emerging functions in tumor progression and metastasis.

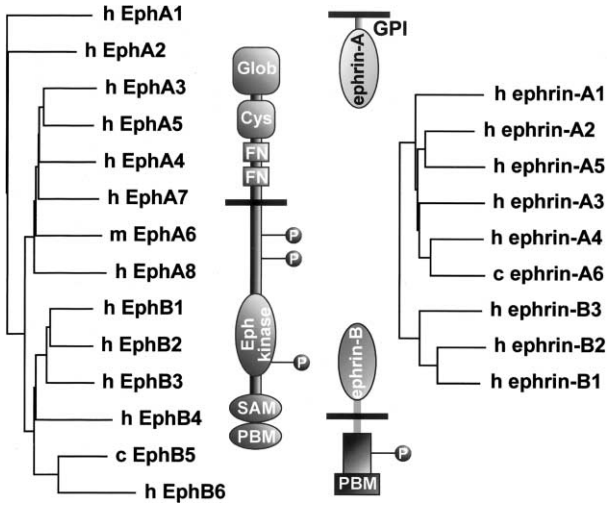

FIGURE 1 Protein domains and sequence homology of ephrin receptors (Eph) and ephrin families. The sequence homology trees were derived from alignment of the human (h) sequences except for (m, mouse) EphA6 and (c, chicken) EphB5 and type A6 ephrin (ephrin-A6), for which no human sequences were available. Glob, Globular ligand-binding domain; Cys, cysteine-rich epidermal growth factor-like domain; FN, fibronectin type III motif; ▬, cell membrane; SAM, sterile α-motif domain; PBM, PDZ-binding domain; GPI, glycosyl phosphatidylinositol membrane anchor; P, phosphotyrosine. We are grateful for Dr. Nathan Hall, Ludwig Institute of Cancer Research (Melbourne), for providing the Eph and ephrin alignments.

II. MOLECULAR PROPERTIES OF EPHRINS AND Eph RECEPTORS

A. Organization of Subfamilies

Ephrins are synthesized as cell-surface-bound proteins, with their mode of membrane attachment providing the criterion for classification into two subfamilies, type A and type B (Fig. 1). Type A ephrins (ephrins A1–A6) are anchored to the outer leaflet of the plasma membrane by a glycosyl phosphatidylinositol (GPI) moiety, whereas type B ephrins (ephrins B1–B3) contain a membrane-spanning domain and a short cytoplasmic tail. Likewise, Eph RTKs are subdivided, on the basis of distinct structural differences in their ligand-binding domain (see Section II.C), into eight type A receptors and six type B receptors. This structural subdivision of Ephs and ephrins correlates with binding specificities of ephrins to Eph receptors. With the exception of EphA4, which binds certain type A and type B ephrins with comparable affinities, type A ephrins bind preferentially to EphA receptors and transmembrane, type B ephrins bind EphB receptors. Accordingly, type A or type B receptors and ligands are named in chronological order of their discovery and depending on their preference for either GPI-linked (A) or transmembrane (B) ephrins, respectively. Within the two subclasses, individual ephrins bind multiple Eph RTKs and vice versa, whereby an ordering of binding affinities indicates preferred interactions between certain Eph RTKs and ephrins. *In vivo*, interactions between cell-surface-tethered Eph RTKs and ephrins are necessarily multivalent and of high avidity, and even weak interactions between the individual proteins can be physiologically relevant. However, different Eph/ephrin signaling complexes are not functionally interchangeable. As a consequence, the formation of biologically relevant Eph/ephrin complexes and the "net biological response" are determined by both the expression profiles and the affinity of competing receptor/ligand interactions.

B. Ephrins: Protein Origin and Structure

Nine closely related ephrins, with sequence similarities of 30–70% in their core sequences, have been identified in vertebrates. Orthologues have been unambiguously defined in mammals and birds and, in addition to a high sequence identity (~80–95%), are functionally interchangeable. Ephrins have also been identified and characterized functionally in the frog (*Xenopus laevis*), the zebrafish (*Brachydanio rerio*), nematodes (*Caenorhabditis elegans*), and flies

(*Drosophila melanogaster*), suggesting that ephrins have developed from an ancestral ephrin protein dating back to the origin of metazoans. At least some of these proteins are likely orthologues of particular mammalian molecules, and human or mouse ephrins exert physiological functions in zebrafish animal studies. Analysis of the full genomes reveals four GPI-linked ephrins in *C. elegans*, but only one ephrin in *Drosophila*. Thus, despite development of a more complex body plan, the fly requires fewer Eph and ephrin genes than does the worm. Both type A and type B ephrins share a highly conserved, N-glycosylated, receptor-binding core domain of approximately 125 amino acids that has no sequence similarities to other proteins. The protein structure of their 28- to 30-kDa extracellular domain resembles that of copper-binding plant cupredoxins. However, ephrins do not bind metal ions and differ structurally by two distinct loops that are involved in the formation of receptor/ligand dimers and higher order oligomers (see Section II.D). The ephrin core domain folds into a β-barrel of eight parallel and antiparallel β-strands, arranged in a Greek key topology and stabilized by two intermolecular disulfide bonds. This protein fold is interspersed by two short α-helices and a single-turn 3_{10}-helix, which is missing in type A ephrins.

The receptor-binding domain is followed by a less conserved spacer region that in type A ephrins contains a disintegrin and a metalloprotease (ADAM) cleavage site essential for Eph/ephrin-mediated cell repulsion (see Section III.A) and the GPI cleavage/transfer consensus sequence. In type B ephrins, a single transmembrane-spanning segment connects to a short, essentially invariant, cytoplasmic domain containing several tyrosine phosphorylation and one PDZ domain binding motifs, which serve as docking sites for cytoplasmic ligands during "reverse signaling" by type B ephrins (see Section III.B).

C. Ephs: Protein Origin and Structure

Ephs have diversified in vertebrates into a closely related family of 14 receptors, related by highly homologous core regions in their extracellular and cytoplasmic domains (Fig. 1). An Eph RTK has been cloned from the freshwater sponge *Ephydatia fluviatilis*, indicating the origin of this protein family before the parazoan-eumetazoan evolutionary split. A characteristic arrangement of protein domains (Fig. 1) is conserved from the single Eph receptor found in *Drosophila* and *C. elegans* to all the classes found in vertebrates. A failure to find homologues in some vertebrate species suggests that not all 14 Ephs occur in all vertebrates. Ephs consist of modular extracellular and intracellular subdomains common to many other receptor tyrosine kinase subfamilies, with the exemption of the N-terminal, ligand-binding domain, which is unique to the Eph family (Fig. 1). The genomic organization of several vertebrate Ephs indicates composition of at least 16 exons and highly conserved exon/intron boundaries that correlate with the protein subdomain structure.

The EphB2 ligand-binding domain, solved by X-ray crystallography, contains two antiparallel β-sheets of six concave and five convex β-strands that form a compact β-sandwich. Its topology has remarkable structural similarity to the carbohydrate-binding domain of lectins, in particular influenza virus hemagglutinin. However, the two families are not related by sequence and Eph/ephrin interactions are independent of carbohydrate moieties. Type A Ephs differ structurally from type B Ephs by a four-residue truncation within one of the loops connecting the β-strands of the core structure. This "specificity loop" is part of the low-affinity ligand-binding interface, which facilitates oligomerization of Eph/ephrin complexes (see Section II.D). The Eph ligand-binding domain is followed by a cysteine-rich epidermal growth factor (EGF)-like motif that is involved in ligand-independent receptor dimerization and two typical fibronectin-type III repeats preceding its single membrane-spanning segment.

The cytoplasmic domain is composed of a short 50- to 65-residue juxtamembrane region, which regulates kinase activity and provides biologically important docking sites for SH2 domain-containing cytoplasmic ligands (Fig. 2). It is followed by an uninterrupted kinase domain, an α-helical sterile α-motif (SAM), and a C-terminal PDZ domain binding motif. The EphB2 kinase domain conforms to a prototypic protein kinase structure, consisting of a small N-terminal lobe that, in the catalytically active conformation, clamps onto the bigger C-terminal lobe to form the interfacial nucleotide-binding site and catalytic cleft. Importantly, and characteristic for the regulation of Eph RTK activity (see Section III.A), the C-terminal half of the nonphosphorylated juxtamembrane region in the latent Eph kinase interacts tightly with the N-terminal lobe of the kinase domain, thereby stabilizing an inactive conformation of the catalytic cleft.

The Eph SAM domain is a protein/protein interaction motif common to various cytosolic signaling proteins. Although a homodimeric configuration of the EphA4 SAM domain in its crystal

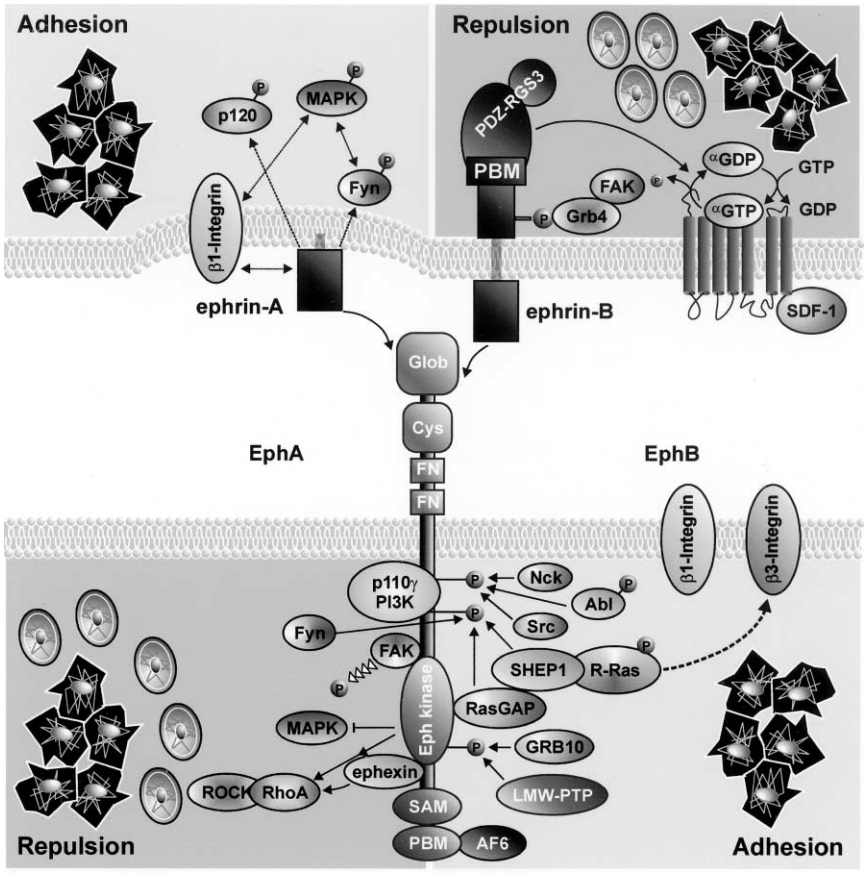

FIGURE 2 Signaling components of ephrins and Ephs that modulate cell shape, adhesion, and motility. Motifs of Eph and ephrin proteins are labeled as in Fig. 1, showing the signaling proteins mitogen-activated protein kinase (MAPK), focal adhesion kinase (FAK), and Abl, and the Src family kinases, Src and Fyn. Heterotrimeric GTP-binding protein (G-protein) signaling components include the regulator of G-protein signaling (RGS3) and the chemokine receptor and its ligand SDF-1. Small guanosine triphosphatase pathway components include RhoA, R-Ras, Ras GTPase-activating protein (RasGAP), Rho-associated kinase (ROCK), and Eph receptor-interacting nucleotide exchange factor (ephexin). Other Eph/ephrin signaling proteins include low-molecular-weight protein tyrosine phosphatase (LMW-PTP), the SH2 and SH3 adapter proteins Nck and Grb4, SH2 domain-containing Eph receptor-binding protein 1 (SHEP1), phosphatidylinositol 3′-kinase (the p110γ isoform of phosphatidylinositol 3-kinase), the acute myeloid leukemia-1/chromosome 6 fusion protein (AF6), and p120, a 120-kDa tyrosine phosphorylated raft protein. Reprinted from Boyd and Lackmann (2001), with permission.

structure is thought to suggest involvement in Eph receptor dimerization, its function in Eph signaling is currently unknown.

D. Receptor–Ligand Interactions and Binding Affinities

Ephrins bind Eph receptors in a strict one-to-one stoichiometry and require membrane attachment and/or clustering to trigger biological responses. Within each subclass, receptors and ligands interact with a distinct ordering of affinities, with dissociation constants ranging from 5 to 500 n*M*. However, *in vivo* the interactions between membrane-bound ephrins and transmembrane Ephs are multivalent and of high avidity. In many cases, corresponding Eph receptor and ephrin classes are expressed in reciprocally graded and apparently mutually exclusive distributions in adjacent cell populations. Thus, receptor-bearing and ligand-presenting cells encounter each other only at the border of compartments, whereby Eph/ephrin interactions trigger responses, often cell repulsion, in both types of cells. Simultaneous expression of different type A or type B receptors and corresponding ligands occurs frequently during vertebrate development, leading to competing

interactions between various receptor/ligand combinations. This interaction scheme serves to relay positional information: the location of an Eph-expressing cell (or axon) in a given microenvironment of ephrin expression is determined, through repulsive and/or adhesive responses, by affinity and abundance of its Eph receptor population in relation to that of neighboring cells (Fig. 3).

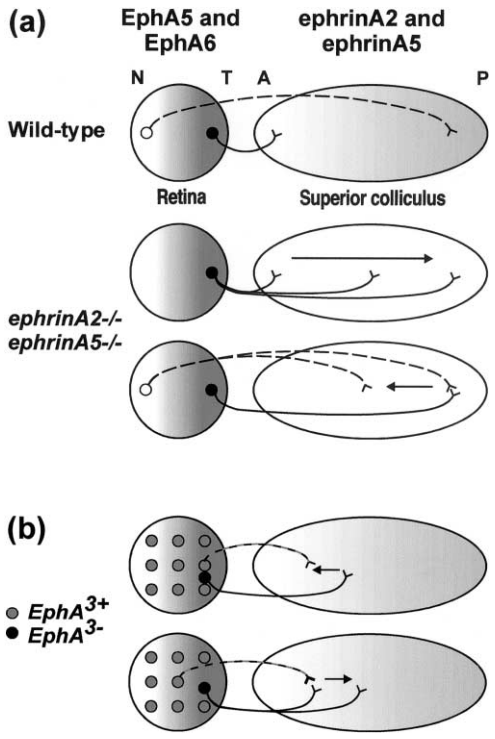

FIGURE 3 Eph-mediated topographic mapping in the vertebrate visual system. Shading indicates graded expression of EphA5 and EphA6 in the retina and of types A2 and A5 ephrin in the superior colliculus. (a) EphA5 and EphA6 are expressed in the mouse retina (EphA3 in the chicken) in a high temporal (T, solid line), low nasal (N, dashed line) gradient and are positioned by a corresponding high posterior (P) to low anterior (A) gradient of types A5 and A2 ephrin in the superior colliculus. Temporal axons (high EphA5/EphA6), repelled by low-level expression of types A2 and A5 ephrin, position to anterior positions, whereas nasal axons (low EphA5/EphA6) require high ephrin concentrations for repulsion and project to posterior positions. Lack of type A2 ephrin and type A5 ephrin allows axons to move to more posterior positions (→). Competition forces nasal axons to project more anteriorly (←). (b) Forced, uniform overexpression of EphA3 (which interacts with both ephrins) in 50% of retinal ganglion cells not only stops those axons earlier (more anterior position, ←), but, due to competition for ephrin-expressing targets, pushes neighboring EphA3$^-$ retinal ganglion cell axons to more posterior positions (→). Reprinted from Klein (2001), with permission from Elsevier Science.

Combined findings from kinetic and *in vivo* experiments suggest a stepwise mechanism of Eph receptor activation: initial high-affinity interactions between membrane-associated ephrin clusters and Eph receptors facilitate accumulation of receptors to a critical concentration, which triggers oligomerization through the cysteine-rich domain. Receptor transphosphorylation occurs also at high local receptor concentration in the absence of ligand, whereby ligand-independent receptor dimerization is mediated predominantly by the cysteine-rich Eph domain. These findings are in agreement with structural features of the complex between the EphB2 ligand-binding domain and ephrin-B2, indicating two distinct interfaces that furnish the receptor/ligand interaction. An extensive high-affinity Eph/ephrin binding interface occupies 13 and 16% of the receptor and ligand surface areas, respectively. It includes an extended, hydrophobic loop of the ligand, which inserts into a deep channel defined by receptor β-strands. A smaller, low-affinity oligomerization interface occupies only 5–6% of mostly polar receptor and ligand surface areas, and includes interactions between a ligand β-strand and the Eph receptor specificity loop. Molecular details of the involvement of the cysteine-rich dimerization domain with higher order oligomers await elucidation of its structure.

III. SIGNALING FUNCTIONS OF EPHRINS AND Eph RECEPTORS

A. Receptor (Forward) Signaling

Receptor dimerization or oligomerization (clustering) leads to a release of the conformational constraint imposed by the juxtamembrane domain and to transphosphorylation of multiple receptor tyrosine residues. In particular, the phosphorylated juxtamembrane tyrosines no longer associate with the N-terminal kinase lobe and are docking sites for downstream SH2 domain signaling molecules. Eph signals modify the cytoskeletal cell architecture through recruitment and activation of proteins directly involved in regulating cytoskeletal organization, including Fyn, Src, Abl, Ras GTPase-activating protein (RasGAP), Rho, Rac, SHEP1, SHP2, Cbl, Crk, and Nck (Fig. 2). Their involvement in signaling pathways of downstream-activated integrin receptors supports evidence from functional experiments for a direct communication between activated Eph receptors and mechanisms that regulate cell adhesion and cytoskeletal plasticity. Eph/ephrin signals also directly

modulate integrin function and are regulated by cadherins. Eph RTK signaling commonly results in loss of actin stress fibers, focal adhesions, cell processes, and cell attachment, and culminates in contact repulsion. However, initially, high-avidity interactions between Ephs and ephrins tether the reacting cells, implying a mechanism that disrupts this bond before opposing cells can disengage. Indeed, clustered Ephs activate an ephrin-associated ADAM protease that specifically releases the ephrin exodomain from the cell membrane to allow repulsion to proceed.

Not all biological responses of ephrin-tethered Ephs are mediated by tyrosine kinase signaling and trigger cell repulsion. Kinase-deficient Eph splice variants, which are expressed during mouse development, and kinase-independent signaling functions of cytoplasmic domains of certain Ephs switch the cell response from repulsion to cell adhesion.

B. Ligand (Reverse) Signaling

Evidence for essential signaling functions of ephrins stems primarily from *in vivo* studies of animals with mutations/deletions in Eph/ephrin components. The almost invariant 33-amino-acid C-terminal tail of type B ephrins contains five tyrosines that become phosphorylated on receptor binding and is followed by an invariant PDZ-binding motif. Several noncatalytic adapter proteins containing multiple PDZ domains have been identified as cytoplasmic ligands for the conserved ephrin B PDZ-binding motif. Importantly, type B ephrin signaling regulates cerebellar granular cell migration by affecting the chemoattraction of the cells to SDF-1: via its PDZ motif EphB-clustered ephrin type B recruits the GTPase-activating protein PDZ-RGS3. The GAP activity of its RGS domain inhibits heterotrimeric G-protein-mediated signaling of the SDF-1 chemoattractant receptor, CXCR4, thereby abrogating its chemotactic response to SDF-1. GRAB4 is the first known SH2 domain signaling molecule known to bind to clustered, phosphorylated type B1 ephrin. GRAB4 binding results in the recruitment of a signaling complex containing Cbl-associated protein (CAP), Abl-interacting protein-1, dynamin, PAK1, and axin; activation of FAK; and subsequent loss of focal adhesions and cell rounding.

Although it is clear that Eph binding to GPI-anchored ephrins triggers cellular responses, the involved mechanisms remain unexplored. Increased adhesion of type A8 ephrin-expressing cells to fibronectin due to up-regulation of β1-integrin involves recruitment and activation of Src and mitogen-activated protein (MAP) kinase pathways to ephrin clusters localized within lipid raft membrane microdomains.

C. Bidirectional Signaling

Once initiated, Eph and ephrin signal transduction mechanisms converge on the regulation of processes involved in cell shape, adhesion, and movement. Perhaps the best documented example for bidirectional signaling by Eph receptors and type B ephrin ligands is the formation of hindbrain segments and somites during zebrafish development. Studies with truncated, dominant-negative ephrins or Ephs have demonstrated that repulsive and deadhesive responses from differentially activated Ephs and ephrins segregate mixed cell populations into ligand-and receptor-expressing domains. Importantly, only bidirectional activation of both Eph- and type B ephrin-expressing cells can prevent cell intermingling, which still occurs if signaling by one of the components is defective. Studies in mice with targeted deletion of type B Eph receptors and ephrins indicate that their bidirectional signals are also essential for the development of the vascular system. Although the involved molecular mechanisms require further investigation, effective partition of cells fated to form arteries from cells fated to form veins requires signals from EphB receptors and "reverse signals" from type B ephrin ligands.

IV. BIOLOGICAL ACTIVITIES OF EPHRINS AND Eph RECEPTORS

A. Functions During Embryogenesis

Signaling by Ephs and ephrins is important in the positioning of cells and cell populations during many developmental processes, including gastrulation, patterning of the neural tube and paraxial mesoderm, and development of the neural and vascular network. Eph signaling during vasculogenesis is essential, and disruption of mouse type B2 ephrin (EphB4 or EphB2/EphB3; double knockout) genes results in early (day 10) embryonal death due to arrest of vasculogenesis during development of the primitive vascular plexus and lack of angiogenic remodeling.

Analysis of *C. elegans* Eph and ephrin mutants indicates importance of kinase-dependent and kinase-independent Eph signaling for neuronal cells during gastrulation cleft closure, and for epidermal cells to complete the ventral closure of the epidermis. Likewise, navigation of cells during zebrafish and

Xenopus gastrulation and boundary formation during zebrafish segmentation is dependent on Eph/ephrin signals, and in the mouse fusion of the neural folds at the dorsal midline requires adhesion between cells expressing type A5 ephrin and a kinase-deficient splice variant of EphA7. Possibly the most prominent role of Eph/ephrin signaling in vertebrates is found during development of the nervous systems, and most of the receptors and ligands are expressed here, in strictly spatially and temporally defined patterns. The migration of neural crest cells and their targeting to the correct destination are governed by Eph/ephrin activities. Targeted disruptions in mouse Eph and ephrin genes demonstrate essential guidance functions for limb motor axons (EphA4), corticospinal neurons (EphA4, type B3 ephrin), superior colliculus axons (EphA8), anterior commissure and corpus callosum axons (EphB2, EphB3), and retinal ganglion cell (RGC) axons (EphA3, EphA5, EphA6, EphB2). The current model of Eph/ephrin signaling in directing pathfinding suggests that the migration of an Eph receptor-bearing cell or growth cone into a gradient of ephrin expression leads to cell-contact-dependent Eph receptor activation. The resulting signals instruct the cell or growth cone to change direction and avoid the ligand-rich area. The molecular mechanism underlying the formation of topographic maps in the visual system demonstrates this principle (Fig. 3). Interestingly, the single *Drosophila* Eph receptor functions in a similar manner during development of a topographic map in the developing fly visual system.

B. Functions in Pathology

Generally, expression of Eph RTKs in adult tissues is low or undetectable and, apart from postulated functions in synaptic plasticity, neuroblast migration, and adult angiogenesis, there is no evidence to suggest roles in adult tissues. However, high expression levels of several Eph RTKs and ephrins, including EphA1, EphA2, EphA3, EphB2, EphB4, type A1 ephrin, type A5 ephrin, and type B2 ephrin, are found in various tumors and tumor cell lines and in many cases correlate with invasive potential and metastasis. EphA1, EphA3, and EphB4 have been isolated from tumor cell lines, but their elevated expression is clearly not due to gene amplification or rearrangement. Although most studies to date provide circumstantial evidence for Eph functions in oncogenesis, several findings suggest that Eph/ephrin overexpression in tumors is prometastatic due to mechanisms that are normally executed during embryogenesis. EphA2/type A1 ephrin and type B2 ephrin signaling is involved in tumor neovascularization, and activation of endogenous EphA2 or EphA3 triggers transient, rapid deadhesion of prostate carcinoma or malignant melanoma cells, respectively.

V. SUMMARY

The coordinated movement of cells and cell layers is an essential process involved in shaping the vertebrate body during normal development, whereas aberrant cell migration and adhesion in adult organisms are hallmarks of metastatic cancer progression. Ephrins and their Eph receptors act as guidance cues and the molecular mechanisms of their interactions are tailored to facilitate and direct the movement of cells and cell layers during various developmental processes. Emerging evidence suggests that these molecules may fulfill similar functions during tumor invasion and metastasis.

Glossary

avidity The functional combining strength of the contact between a protein and an interaction partner (or protein complex, e.g., antibody or receptor, containing multiple binding sites for the interaction partner, e.g., antigen or ligand). Avidity is governed by the affinity of the individual reaction, the number of binding epitopes (valency), and sterical hindrance of the interacting components.

axon projection Long extensions of neurons that conduct nerve impulses to terminals distant from the nerve cell body. The axon projection is the defined path and destination point of the axon.

clustering The occurrence of crowded groups of receptors or ligands on the cell membrane.

contact repulsion Guidance force acting on the leading part (growth cone) of an axon; the force is relayed by the substratum on direct contact rather than by chemical diffusion.

expression gradient Graded expression of a molecule (protein, RNA) in a defined compartment of the organism.

forward and reverse signaling Traditionally, the signal transduction mechanism originating from activated receptors is referred to as forward signaling. Reverse signaling, a signaling cascade within the ligand-expressing cell, is triggered on receptor binding to membrane-bound ligands.

plasticity Ability of a cell, cell body, or organelle (i.e., generally a system) to adapt to a changed environment.

receptor tyrosine kinase Transmembrane receptor protein; harbors an enzyme domain with protein tyrosine kinase activity as part of its cytoplasmic portion. Many growth factor receptors are receptor tyrosine kinases.

SH2 domain Src homology domain; a protein domain common to many cytoplasmic signal transduction molecules; interacts specifically with a linear epitope containing a phosphorylated tyrosine residue as part of defined consensus sequences.

Epidermal Growth Factor (EGF) Family

ANTONY W. BURGESS

Ludwig Institute for Cancer Research, Australia

The biosynthesis and release of different epidermal growth factor (EGF) family members are important in many physiological and pathological situations. Recent discoveries have linked one of the EGF family members, transforming growth factor-α (TGF-α), and the EGF receptor to the determination of mammalian circadian rhythms. Several hormones that act via G-protein-coupled receptors are known to stimulate the expression of a metalloproteinase that releases (and activates) heparin-binding EGF on the cell surface. Many tumors secrete TGF-α and stimulate tumor cell proliferation and survival by activating the EGF receptors on the same cell. Antagonists of TGF-α action and/or inhibitors of the EGF receptor kinase are potential antitumor agents.

I. INTRODUCTION

Modern growth factor research was initiated in the late 1940s when Victor Hamburger reported that a chicken tumor was innervated. He hypothesized that many tumors secreted substances that attract host neurites to the tumor. These concepts led Stanley Cohen to discover epidermal growth factor as a contaminant of nerve growth factor purified from mouse salivary glands. Cohen identified EGF as the protein that accelerated incisor eruption and eyelid opening in newborn mice. Although it took several years to purify the EGF protein, it quickly became obvious that EGF was a potent peptide mitogen for tissue culture cells. The human form of EGF (called urogastrone) was actually isolated from human urine by Harry Gregory in 1975 on the basis of its ability to inhibit the secretion of gastric acid in the stomachs of dogs. Human and mouse EGFs are clearly related, the homology being almost 70% (Fig. 1).

The disulfide bonds are conserved in all EGF family members (suggesting that the fold of the peptide is likely to be similar).

II. EGF RECEPTOR DISCOVERY AND CANCER

The search for the cell surface receptor for EGF led to some of the first glimpses of growth factor receptor biology and the first direct connection between growth factors and the transforming processes associated with cancer. As soon as Cohen and his colleagues detected the EGF receptor (by the binding of the radiolabeled ligand), it was clear that the ligand-bound receptor was activated (i.e., the tyrosine kinase was stimulated) and internalized quickly.

SH2 domain Src homology domain; a protein domain common to many cytoplasmic signal transduction molecules; interacts specifically with a linear epitope containing a phosphorylated tyrosine residue as part of defined consensus sequences.

FIGURE 1 Comparison of the amino acid sequences of human and mouse EGF. As indicated by the asterisks, the two are nearly 70% identical.

When studying the binding of radioiodinated EGF to normal and cancer cells, it became clear that the cell surface EGF receptors were missing from the cancer cells. When oncogenic viruses transform mouse fibroblasts, the EGF receptors disappear from the cell surface. In a set of remarkable observations, Stanley Cohen (the discoverer of EGF and a Nobel Prize winner) and his colleagues linked the induction of receptor disappearance by oncogenic viruses to the induction of a secreted protein that bound to the EGF receptor. At first, this transforming protein was thought to be a unique product of cancer cells [and as a consequence it was named sarcoma growth factor (SGF)], but subsequently, the biological activities attributed to SGF were shown to be due to two separate proteins: transforming growth factor-α and transforming growth factor-β (TGF-β). TGF-α binds to the EGF receptor and initiates activation, down-regulation, and intracellular signaling in the usual way. TGF-β binds to a separate class of cell surface receptors. The signaling from the TGF-β receptors is complex, sometimes synergizing with TGF-α, sometimes inhibiting cell division.

These studies opened the pathway to an understanding of some of the most important biochemical events associated with mitogenic signaling in both normal and cancer cells. As Cohen and his colleagues were investigating the EGF receptor, other cancer biologists were studying the oncogenic proteins associated with the acute transforming viruses of animal cells, such as v-src. It was shown that v-src was actually a constitutively active form of a cellular tyrosine kinase enzyme (c-src). Although serine/threonine kinases had been studied intensely, tyrosine kinases had hardly been recognized, and indeed they are a minor component of the total protein kinase activity of most cells. The EGF receptor was shown to be a ligand-dependent tyrosine kinase. Biological and biochemical studies on the EGF/EGF receptor system have led the way to a profound change in our understanding of the intracellular signaling processes that are important for regulating cell differentiation, division, and survival.

III. STRUCTURES OF EGF/TGF-α

It required the advent of molecular biological cloning and sequencing techniques to determine the amino acid sequence for TGF-α. Clearly, TGF-α is related to EGF (Fig. 2).

Despite the fact that only 40% of the TGF-α residues are homologous to EGF, all of the disulfide bonds are conserved and the peptides compete for the same high-affinity EGF receptor binding. Although in low abundance, the broad biological distribution and potency of TGF-α suggest that in many tissues it is more likely than EGF to be a physiological ligand of the EGF receptor. Both EGF and TGF-α are synthesized as cell surface transmembrane proteins. Although the cell surface forms are capable of activating receptors, the mitogenic peptides are released from the cell surface by metalloproteases. Until recently, our understanding of the regulation of TGF-α secretion, degradation, and physiology has been extremely limited. In a fascinating study on circadian rhythms, a case has been made that the release, action, and degradation of TGF-α are responsible for both the underlying rhythm and the light responses.

FIGURE 2 Amino acid sequence of human TGF-α and EGF, which shows 41% identity.

Once EGF and TGF-α had been cloned, a considerable effort was made to determine their three-dimensional structures by X-ray crystallography; however, both peptides proved difficult to crystallize. Nuclear magnetic resonance (NMR) studies were more successful, and despite the sequence differences and difficulties in achieving high resolution, it was clear that the three-dimensional structures of the different family members were closely related. These structural studies led to an immediate reevaluation of the domain structure of the peptide backbone. Although the primary structure emphasized a three-loop structure based around the disulfide bond assignment, the three-dimensional structures indicated that both EGF and TGF-α have two distinct regions, the N- and C-terminal domains, and that there is only minimal contact between the domains. The N-terminal domain contains a significant length of antiparallel β-sheet. The family of mammalian peptides that bind with high affinity to the EGF receptor has been extended to include heparin-binding EGF (HB-EGF) and betacellulin (Fig. 3).

Leaving aside the disulfide residues, only seven residues are common to all four peptides; the three glycine residues are presumably involved in forming the EGF-like fold. His-16 is not conserved in other mammalian EGFs. Arg-41 and Leu-47 appear to be critical determinants of receptor binding. The three-dimensional structure of the EGF receptor/TGF-α complex has been solved and although many of the TGF-α residues are in contact with the receptor, the residues equivalent to Arg-41 and Leu-47 in EGF clearly form strong interactions with distinct receptor pockets. Crystal structures for EGF, HB-EGF, and TGF-α have now been solved; although there is overall similarity to the NMR structures, some of the details are quite different. Strong interactions with the receptors, which may induce a structural change in the ligand, appear to occur at the N- and C-termini. Overall, the C^{α} atom homology between TGF-α bound to its receptor, EGF free in solution, or HB-EGF bound to diphtheria toxin is extraordinary: the average deviation between these coordinate sets is less than 1 nm.

IV. BIOSYNTHESIS

All members of the EGF/TGF-α are synthesized as larger precursors. The mitogenic fragments are released after proteolytic processing. The membrane-bound forms of the ligand appear to be important both biologically and as regulatory elements in several tissue systems. Receptor cross talk between G-protein systems and the EGF receptor system can occur when G-protein signaling induces the production of the metalloproteinase, which processes the membrane precursor of HB-EGF. The 160-amino-acid precursor pro-TGF-α is processed at residue 40 to yield the mitogenic TGF-α peptide. The EGF mitogenic peptide is synthesized and stored in the mouse salivary gland; it is associated with a binding protein and the protease that is responsible for cleaving the mitogenic 53-residue form of the growth factor from its 1207-residue precursor. HB-EGF is processed to at least five forms, mostly with different N-terminal cleavage patterns, but there also appear to be several differentially glycosylated forms of HB-EGF. The differential glycosylation may alter the pharmacokinetic properties of this growth factor, facilitating a prolonged action of the factor in different tissues.

V. PHYSIOLOGY OF EGF FAMILY MEMBERS

Even after 50 years of intense research, the physiology of EGF is still obscure. The situation is not much better for the more recently identified family members such as TGF-α, betacellulin, amphiregulin (AR), Schwannoma-derived growth factor (SDGF), or

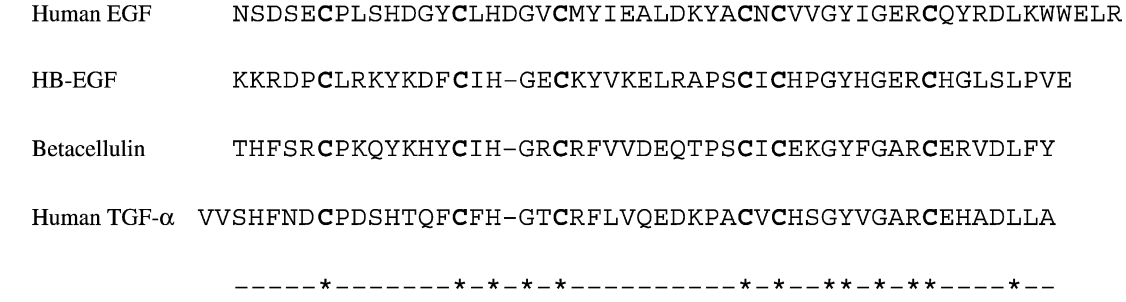

FIGURE 3 Members of the EGF family that bind with high affinity to the EGF receptor. HB-EGF, heparin-binding EGF.

HB-EGF. EGF was isolated originally from the salivary glands of male mice, which have extraordinary concentrations of the growth factor; in contrast, female mice have barely detectable levels of EGF in their salivary glands. Attempts to detect EGF in human and mouse tissues are made difficult by the low levels, although the precursor form (prepro-EGF) is detectable in the kidneys of male mice. Most tissues contain considerably more TGF-α than EGF. Gradually, a paradigm has emerged that in epithelial tissues, e.g., skin and the intestines, where there is a continuous production of cells, the levels of TGF-α control receptor activation and, consequently, the proliferation, differentiation, survival, and movement of cells in these tissues. However, when the TGF-α gene is removed from mice, cell production and differentiation in the self-renewing epithelial tissues are unaffected. In the absence of TGF-α, cell production continues unabated in both the skin and intestines. It is still not clear whether the other EGF family members replace the TGF-α or whether epithelial cell production in these tissues is regulated primarily by other cytokines or hormone systems. Mice that lack three EGF family members, namely EGF, TGF-α and amphiregulin, have been produced; although these triple-knockout mice are smaller than normal, there are no obvious differences in the skin or intestines. They do have impaired responses to injury: for example, when cysteamine is used to induce ulcers in mice, the lesions are more severe in the triple-knockout mice.

The biological actions of particular family members appear to depend on tissue-specific factors and/or the differentiation state of the target cells. AR and SDGF bind weakly to the EGF receptor on both NIH 3T3 and A-431 cells. The mitogenic action of both regulators on these cells is barely detectable (more than 1000-fold less potent), but on PC12 cells, at 100 n*M*, SDGF induces neurite outgrowth. Although AR is not as potent as SDGF or EGF for inducing neurite outgrowth, at 100 n*M*, AR induces differentiation of PC12 cells. Clearly, some of the regulators appear to be more potent as differentiation agents than as proliferative agents.

Interestingly, even when EGF and TGF-α stimulate cells via the EGF receptor, they can induce different effects. It has been determined that after ligand binding, the EGF receptor internalizes and partitions to the endosomes, where the vesicle acidifies. For the TGF-α: EGF receptor complex, acidification is sufficient to dissociate the complex, reduce tyrosine kinase signaling, and facilitate receptor recycling. In contrast, the EGF:EGF receptor complex is resistant to acidification and the ligand–receptor kinase continues to signal in the endosome, leading to the formation of multivesiculate bodies and degradation of both the ligand and receptor. Discovery of some EGF mutants that dissociate from the EGF receptor complex in the acidified endosome has revealed that these mutants block degradation, permit receptor recycling, and prolong signaling, i.e., they appear to be superagonists.

VI. PATHOLOGY AND TUMORIGENESIS: EGF AND EGF RECEPTOR FAMILY

From the earliest descriptions of growth factor biochemistry, the EGF family members have been linked with particular tissue pathologies and tumorigenesis. Indeed, it was the search for the tumor-derived factors responsible for the innervation of a chicken sarcoma that led directly to the discovery of EGF. During the initial search for EGF receptors, it quickly became evident that many tumors secrete an EGF-like growth factor. Activation of EGF receptors is a critical process in many malignancies. Many of the acute oncogenic retroviruses induce the secretion of TGF-α, which maintains the viability and proliferative state of transformed cells. Inhibitors that interfere with the action of the EGF receptor and/or erbB-2 have promising antitumor effects in animals.

TGF-α is normally secreted at low levels in the epidermis, but there is also a strong association between the overexpression of TGF-α and the development of psoriasis, a chronic skin disease characterized by scaly patches. Excessive levels of TGF-α have also been associated with poor prognosis of some carcinomas, e.g., bladder tumors. Analysis of bladder tumor mRNA for the presence of EGF, amphiregulin, HB-EGF, betacellulin, epiregulin, the EGF receptor, and erbB-2 detected all of the messages except that for EGF. Interestingly, there was an extraordinarily strong correlation between a good prognosis and the presence of epiregulin mRNA (Fig. 4).

A high proportion of many carcinomas express activated, overexpressed, or mutated members of the erbB family of receptors. Indeed all advanced glioblastomas are associated with amplified EGF receptors and more than half of all head and neck cancers overexpress the EGF receptor. Except for the hair follicle, normal tissues do not express high levels of the EGF receptor nor is there any evidence that the EGF receptor is activated in unstimulated normal tissues. In contrast, tumor cells that overexpress the EGF receptor usually contain tyrosine

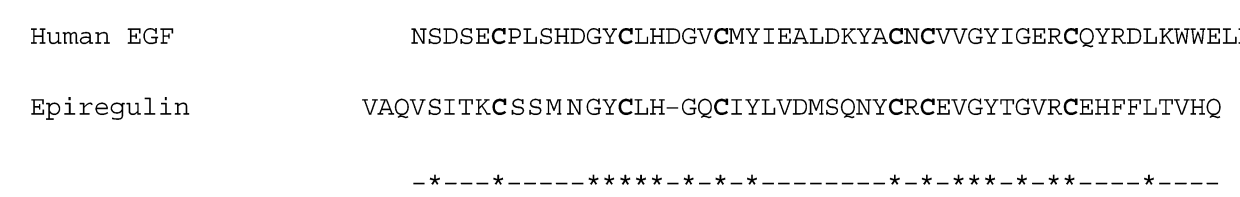

FIGURE 4 Comparison of the amino acid sequences of human EGF and epiregulin, a member of the EGF family.

phosphorylated receptors, an indication that the receptor is activated and is providing the cells with proliferative and/or survival signals. These observations have prompted the search for therapeutic agents that inhibit the EGF receptor kinase or prevent the receptor from being activated. There is now considerable evidence from mouse xenograft studies that these inhibitors and/or antagonists can reduce the growth of many human tumors. EGF receptor kinase inhibitors and neutralizing antibodies are in early-phase clinical trials, both as single agents and in conjunction with other antitumor cytotoxic drugs. Most recently, there have been reports of lung tumor regressions in patients being treated with the EGF receptor kinase inhibitors. Similarly, some breast cancer patients who overexpress erbB-2 respond to treatment with antibodies (herceptin), which bind to this receptor. As we learn to combine signaling therapeutics, such as the EGF receptor inhibitors, with the conventional anticancer therapies, more effective cancer treatments will be developed.

Several cancers involve the erbB family members indirectly; in particular, tumors with the activated *ras* oncogene secrete ligands for the EGF receptor (e.g., TGF-α). Consequently, inhibitors of the EGF receptor kinase and erbB-2 block the proliferation of many *ras*-associated tumors. Other opportunities to block the action of the EGF receptor in tumor cells are available: for example, there are inhibitors that block kinases [e.g., p21-activated kinase (PAK)] downstream of the EGF receptor. When several points in tumorigenic signal transduction are blocked, the tumor cells are likely to die a rapid apoptotic death. Signaling therapeutics based on the molecular etiology of the tumorigenic processes are more likely to produce better outcomes for cancer patients. When it becomes possible to treat oncogenic lesions or the tumor suppressor lesions in humans, more effective treatments will be developed.

Glossary

growth factor Small peptide that regulates cell production and differentiation in the tissue in which it is produced; often produced in excess by tumor cells.

knockout mice Species in which particular genes have been removed by homologous recombination in embryonic stem cells, by blastocyst injection, by transplantation, and by subsequent breeding programs.

receptor Cell surface protein in which the extracellular portion binds a growth factor. After formation of the growth factor:receptor complex, the intracellular portion becomes an active enzyme capable of initiating cytoplasmic signaling processes.

tyrosine kinase Enzyme with an activity associated with the epidermal growth factor receptor family; using ATP as the phosphate donor, catalyzes the addition of phosphate groups to specific tyrosine residues on protein substrates.

Epidermal Growth Factor (EGF) Receptor Signaling

OLEG TIKHOMIROV AND GRAHAM CARPENTER
Vanderbilt University

The epidermal growth factor (EGF) receptor is a signal transducer belonging to the tyrosine kinase family of proteins that control cell functions such as growth, migration, and survival. The EGF receptor system, including its ligands and downstream effector molecules, has been well conserved throughout evolution, as genetic studies in flies and worms have demonstrated. The clinical significance of this receptor is evidenced by the development of reagents (antibodies, kinase inhibitors) that block EGF receptor activity in cancer patients. The EGF receptor, also referred to as HER-1 or ErbB-1, is the prototype for a small family of molecules known as the ErbB receptors. This article will concentrate on the EGF receptor in terms of its known ligands, structure, activation mechanism, signal transduction pathways, endocytosis, and transmodulation.

I. EPIDERMAL GROWTH FACTOR RECEPTOR LIGANDS

Activation of the epidermal growth factor (EGF) receptor in mammalian cells depends on the presence of one of its specific ligands: EGF, transforming growth factor α, amphiregulin, betacellulin, epiregulin, heparin-binding growth factor (HB-EGF), or epigen (Fig. 1). Each ligand is the product of an independent gene and the major distinction among these growth factors is found in their individual patterns of expression. All members of the EGF ligand family are characterized by six conserved and similarly spaced cysteine residues that form three intramolecular disulfides. All ligands bind to the EGF receptor with approximately equivalent affinity and qualitatively provoke the same biological responses. Of these ligands, HB-EGF, betacellulin, and epiregulin are reported to also bind to ErbB-4, another receptor within the ErbB family (Fig. 1). Also, each ligand is initially expressed at the plasma membrane as a glycosylated membrane-anchored precursor, which is proteolytically cleaved from the cell surface to release the soluble growth factor that acts as an autocrine or a paracrine signal.

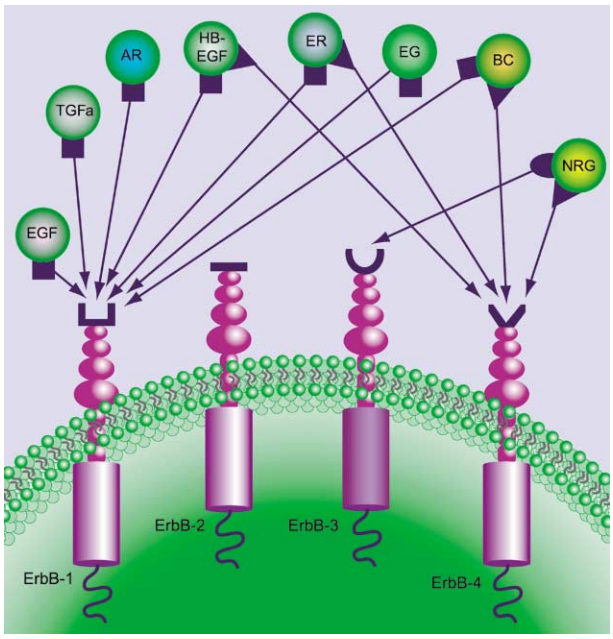

FIGURE 1 The family of ErbB receptors and ligands. The EGF receptor can bind seven different ligands with high affinity. ErbB-2 has no known ligand, ErbB-3 is a receptor with impaired kinase function and can bind neuregulins, and ErbB-4 can bind neuregulin, betacellulin, and HB-EGF. Epidermal Growth Factor (EGF) Receptor Signaling

OLEG TIKHOMIROV AND GRAHAM CARPENTER
Vanderbilt University

The epidermal growth factor (EGF) receptor is a signal transducer belonging to the tyrosine kinase family of proteins that control cell functions such as growth, migration, and survival. The EGF receptor system, including its ligands and downstream effector molecules, has been well conserved throughout evolution, as genetic studies in flies and worms have demonstrated. The clinical significance of this receptor is evidenced by the development of reagents (antibodies, kinase inhibitors) that block EGF receptor activity in cancer patients. The EGF receptor, also referred to as HER-1 or ErbB-1, is the prototype for a small family of molecules known as the ErbB receptors. This article will concentrate on the EGF receptor in terms of its known ligands, structure, activation mechanism, signal transduction pathways, endocytosis, and transmodulation.

I. EPIDERMAL GROWTH FACTOR RECEPTOR LIGANDS

Activation of the epidermal growth factor (EGF) receptor in mammalian cells depends on the presence of one of its specific ligands: EGF, transforming growth factor α, amphiregulin, betacellulin, epiregulin, heparin-binding growth factor (HB-EGF), or epigen (Fig. 1). Each ligand is the product of an independent gene and the major distinction among these growth factors is found in their individual patterns of expression. All members of the EGF ligand family are characterized by six conserved and similarly spaced cysteine residues that form three intramolecular disulfides. All ligands bind to the EGF receptor with approximately equivalent affinity and qualitatively provoke the same biological responses. Of these ligands, HB-EGF, betacellulin, and epiregulin are reported to also bind to ErbB-4, another receptor within the ErbB family (Fig. 1). Also, each ligand is initially expressed at the plasma membrane as a glycosylated membrane-anchored precursor, which is proteolytically cleaved from the cell surface to release the soluble growth factor that acts as an autocrine or a paracrine signal.

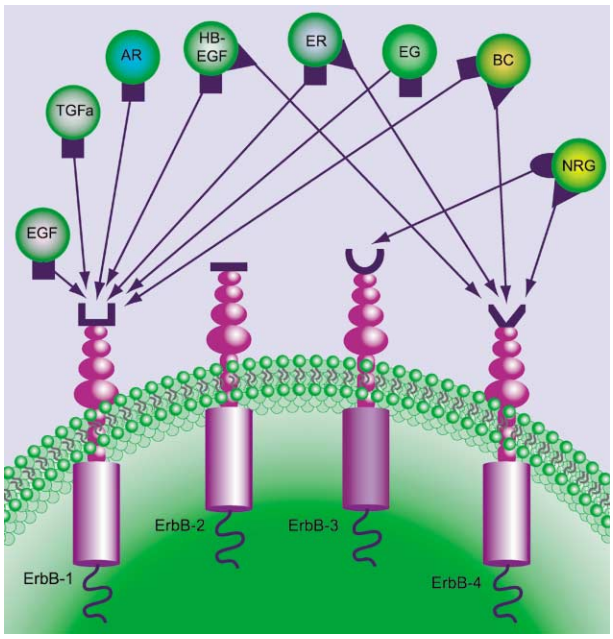

FIGURE 1 The family of ErbB receptors and ligands. The EGF receptor can bind seven different ligands with high affinity. ErbB-2 has no known ligand, ErbB-3 is a receptor with impaired kinase function and can bind neuregulins, and ErbB-4 can bind neuregulin, betacellulin, and HB-EGF. EGF, epidermal growth factor; TGFα, transforming growth factor α; AR, amphiregulin; ER, epiregulin; EG, epigen; HB-EGF, heparin-binding EGF; BC, betacellulin; NRG, neuregulin.

II. EGF RECEPTOR STRUCTURE AND ACTIVATION

In mammals, the EGF receptor family comprises four members: EGF receptor (ErbB-1/HER-1), ErbB-2 (HER-2/c-neu), ErbB-3 (HER-3), and ErbB-4 (HER-4) (Fig. 1). All members of the EGF receptor family have similar structural features: each is a Type I transmembrane receptor tyrosine kinase with two cysteine-rich extracellular domains, a single transmembrane domain, an uninterrupted kinase domain, and multiple autophosphorylation sites in a carboxy-terminal domain. Sequence homology is greatest within the kinase domains and least within the carboxy-terminal domains.

Ligand binding to the receptor extracellular domain results in activation of tyrosine kinase function in the cytoplasmic domain. The receptor's kinase activity is essential for biologic responses to cognate ligands because inactivation of the kinase by mutagenesis prevents growth factor activation of signaling pathways and cellular responses. The growth factor neuregulin (also known as heregulin) specifically binds to the ErbB-3 and ErbB-4 receptors (Fig. 1). A ligand for the ErbB-2 receptor has not been identified.

Following ligand binding, the ErbB-1 and ErbB-4 receptors are activated by dimerization between two identical receptors (homodimerization) or between two different ErbB receptors (heterodimerization). Dimerization mediates activation of the kinase domains by facilitating transphosphorylation between receptor monomers. However, the molecular mechanism that promotes dimerization of ErbB receptors is unknown. Although each ligand-binding member of the EGF receptor family (ErbB-1, ErbB-3, and ErbB-4) can participate in homo- or heterodimer formation, ErbB-2 is the preferred heterodimerization partner for each receptor. Therefore, ErbB-2 is considered to be a co-receptor. Heterodimerization between ErbB-2 and other ErbB receptors is thought to explain how ErbB-2 participates in growth responses. As a co-receptor, it may decrease ligand dissociation from a receptor heterodimer, thereby enhancing and/or prolonging the activation of signaling pathways. Alternatively, interaction with ErbB-2 may allow other ErbB receptors to provoke qualitatively unique signaling pathways. Heterodimers containing ErbB-2 usually induce stronger biological activity than do homodimers. In the case of ErbB-3, which has an enzymatically deficient kinase domain, dimerization with ErbB-2 is an essential event for signal production and biological responses.

The EGF receptor extracellular region is composed of four domains. Domains II and IV contain many cysteine residues in the form of disulfide bonds, approximately 25 in total. Domain III is thought to bind directly to EGF, whereas Domain I is secondarily involved in ligand binding.

Many glioblastomas have amplified EGF receptor genes or structural alterations within the gene, such as in-frame deletions. The most prevalent mutation in glioblastomas contains an in-frame deletion resulting in the removal of residues 6 through 273 in the extracellular domain of the EGF receptor. This mutant, designated EGFRvIII/δEGFR, lacks Domain I and a part of Domain II and cannot bind EGF. However, this receptor mutant can form stable dimers in the absence of a ligand and has constitutively enhanced tyrosine kinase activity.

The EGF receptor extracellular domain contains 12 potential sites for N-linked glycosylation. If the EGF receptor is synthesized in the presence of a glycosylation inhibitor, it cannot bind ligands and activate signaling pathways. If N-linked oligosaccharide chains are enzymatically removed from the mature EGF receptor, the altered receptor can bind ligand and activate its kinase. Therefore, glycosylation is important during biosynthesis for proper folding of the receptor within the endoplasmic reticulum to generate a ligand-binding competent conformation.

Ligand-induced receptor dimerization results in tyrosine kinase activation and receptor autophosphorylation at six residues in the carboxy-terminal domain (Tyr992, Tyr 1045, Tyr1068, Tyr1086, Tyr1148, and Tyr1173). However, the stoichiometry of tyrosine phosphorylation is unknown as are the relative levels of phosphorylation at each of the six tyrosine residues. The EGF receptor also contains numerous phosphorylated threonine and serine residues, whose functions are not entirely clear. Unlike many other receptor tyrosine kinases, autophosphorylation sites within the tyrosine kinase or juxtamembrane domains of the EGF receptor have not been described. Interestingly, other tyrosine residues in the EGF receptor are phosphorylated by the Src tyrosine kinase in a cell-specific manner, e.g., Tyr845, Tyr 891, Tyr 920, and Tyr 1101. Phosphorylation of Tyr845 is potentially important due to its location within a putative activation loop of the EGF receptor tyrosine kinase domain.

III. ADAPTOR PROTEINS

Ligand-induced receptor dimerization and autophosphorylation create phosphotyrosine residues that serve as docking sites for various signal transducing proteins. The key to understanding how these sites initiate postreceptor signaling involves specialized protein motifs known as Src homology 2 (SH2) domains. SH2 domains were first identified as conserved sequences within the noncatalytic region of Src tyrosine kinases and subsequently have been found in a diverse range of proteins. Each SH2 domain is composed of approximately 100 residues and recognizes a phosphotyrosine residue together with adjacent C-terminal residues. This recognition determines the specificity of associations between individual SH2 domains and particular autophosphorylation sites.

Subsequent to the identification of SH2 domains, a second protein domain capable of recognizing phosphotyrosine residues, the phosphotyrosine-binding or PTB domain, was reported. PTB domain recognition of phosphotyrosine, in contrast to SH2 domains, depends on adjacent residues N-terminal to a phosphotyrosine residue. Cytoplasmic mediators that bind to EGF receptor phosphotyrosine residues through SH2 or PTB domains may be either adaptor proteins or enzymes. Adaptors, such as Shc, Grb2, or Crk, have a modular structure consisting of multiple protein-protein and/or protein-phospholipid interaction domains and function as signaling platforms to connect activated receptors with signaling pathways. The adaptor proteins may or may not be tyrosine phosphorylated. In some receptor tyrosine kinases, such as the platelet-derived growth factor receptor, each autophosphorylation site is dedicated to one or two associating proteins through their SH2 or PTB domains. However, in the EGF receptor, this is not the case, as mutagenesis of any single autophosphorylation site fails to abrogate interactions with any SH2/PTB domain-containing protein.

IV. Ras/MITOGEN-ACTIVATED PROTEIN KINASE PATHWAY

Mitogen-activated protein (MAP) kinases have a central role in the control of cell responses to growth factors. Several MAP kinases have been identified as targets of the EGF receptor, among them the extracellular signal-regulated kinases Erk1 and Erk2, the Jun kinase (JNK), the stress-activated p38 kinase, and Erk5. EGF-induced activation of these serine/threonine kinases, particularly Erk1 and 2, serves as a model for signal transmission from the cell surface to the nucleus (Fig. 2).

Following Shc and Grb2 recruitment to the tyrosine phosphorylated EGF receptor, the guanine nucleotide exchange factor Sos, which binds constitutively to Grb2, is recruited to the receptor. Receptor association locates Sos at the cytoplasmic face of the plasma membrane and thereby facilitates its activation of Ras, a constitutive membrane protein, by facilitating the exchange of Ras·GDP to Ras·GTP. The GTP form of Ras interacts with Raf, a serine/threonine protein kinase, and Raf, in turn, activates the dual-specificity kinase MEK. The activation of this kinase results in the phosphorylation of Erk1 and 2 on threonine and tyrosine residues, producing the activated species of Erk1 and 2. MAP kinases phosphorylate substrates on serine/threonine residues in both the cytoplasm and the nucleus. EGF receptor ligands activate Erk1 and 2 very rapidly but transiently. The mechanism by which EGF receptor activation promotes activation of other MAP kinase family members is less well characterized.

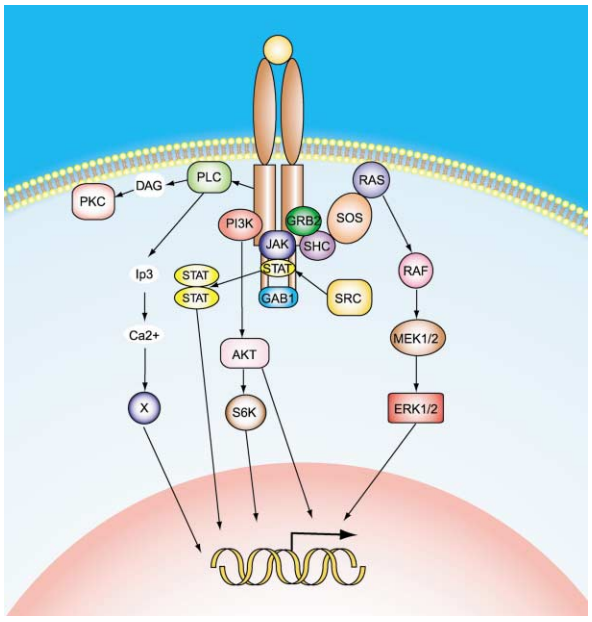

FIGURE 2 EGF receptor signaling network. EGF receptor dimerization stimulates kinase activation and phosphorylation of numerous substrates. The EGF receptor autophosphorylation provides docking sites within EGFR intracellular region for adaptor proteins, such as Grb2, Shc, and Gab1, plus enzymes, such as PI-3 kinase or PLCγ1, which, in turn, activate different signaling pathways and influence nuclear functions.

Erk1 and 2 substrates include (1) transcription factors, (2) downstream serine/threonine kinases, and (3) other regulatory molecules, such as phospholipase A2. A critical feature of Erk1 and 2 function is the capacity of the activated molecules to translocate to the nucleus and thereby participate in the control of the expression of immediate-early genes by growth factors. For example, a nuclear target of Erk1 and 2 is the transcription factor Elk-1, which participates in the promoter-dependent transcription of c-*fos*.

The Ras/MAP kinase pathway, therefore, represents a multicomponent mechanism whereby a signal generated by EGF at the plasma membrane is received in the nucleus. Most studies indicate that stimulation of the Ras/MAP kinase pathway is essential for EGF-dependent mitogenesis. It is important to keep in mind that EGF receptor activation of Ras is not dedicated to the activation of Erk1 and 2 only. Ras·GTP does communicate with other signaling pathways as well, exemplifying the fact that signal transduction is a network of interlocking pathways.

V. SIGNAL TRANSDUCERS AND ACTIVATORS OF TRANSCRIPTION PATHWAY

STAT (signal transducers and activators of transcription) proteins are a family of transcription factors that are activated by phosphorylation of a single tyrosine residue in response to extracellular ligands (Fig. 2). An active STAT dimer is formed through interactions between the SH2 domain of one monomer and the phosphotyrosine residue of the other monomer. Subsequently, the dimers translocate into the nucleus, recognize specific DNA elements in the promoters of genes, and thereby regulate transcription. In contrast to the Ras/MAP kinase pathway, the STAT mechanism represents a one-component pathway to transfer a signal from the EGF receptor at the plasma membrane to the nucleus. In many cell types, multiple STAT family members are expressed and phosphorylated by EGF. Since activated STATs can heterodimerize as well as homodimerize, the ultimate response is potentially diversified depending on promoter recognition of various STAT dimers.

The tyrosine kinase activity of the EGF receptor is required for STAT phosphorylation and activation. The EGF receptor, at least in A-431 cells, is associated with STAT1, STAT3, and STAT5 in the absence of EGF. Purified EGF receptor has been shown to tyrosine phosphorylate STATs, suggesting that the EGF receptor directly phosphorylates STAT molecules. However, EGF-induced STAT activation is also dependent on the tyrosine kinase Src. This suggests that following EGF stimulation, Src is rapidly recruited to STAT-EGF receptor complexes and the Src kinase then phosphorylates STAT. Pharmacologic inhibitors of Src kinase or a dominant-negative Src construct were shown to abrogate STAT tyrosine phosphorylation stimulated by EGF.

Although the exact role of STATs in the EGF-dependent cell responses is not entirely clear, there is evidence in some cell systems that certain STATs may mediate growth inhibition through the induction of $p21^{waf1}$, a cyclin-dependent kinase inhibitor. In other systems, STATs have been proposed to be necessary for EGF-induced cell proliferation or cell survival.

VI. PHOSPHOINOSITIDE SIGNALS

A major signaling pathway for the EGF receptor involves the metabolism of phosphoinositide 4,5-bisphosphate (PI4,5-P_2). Phosphoinositides, minor phospholipid components of the plasma membrane, are composed of a diacylglycerol group, usually 1-stearyl-2-arachidonylglycerol, linked at the 3-position by a phosphodiester bond to a phosphorylated inositol group. PI4,5-P_2 is formed at the cytoplasmic leaflet of the plasma membrane bilayer by the sequential phosphorylation of phosphatidylinositol (PI) to phosphatidylinositol 4-phosphate to PI4,5-P_2. EGF can affect the fate of PI4,5-P_2 in two ways, which are described in the following paragraphs.

Phosphoinositide-specific phospholipase C (PLC) activity catalyzes the hydrolysis of PI4,5-P_2 to produce two second messengers, inositol 1,4,5-trisphosphate ($InsP_3$) and diacylglycerol. IP_3 provokes the mobilization of intracellular Ca^{2+}, and diacylglycerol activates protein kinase C (Fig. 2). Mammalian cells express members of multiple PLC families designated β, γ, δ, and ϵ. Receptor tyrosine kinases, such as the EGF receptor, communicate with PLC-γ isoforms, especially PLCγ1. Three tyrosine residues in PLCγ1 have been identified as sites of tyrosine phosphorylation. Tyr783 and Tyr1254 are essential for maximal $InsP_3$ formation, but phosphorylation of Tyr771 seems dispensable. Following ligand stimulation, the EGF receptor is activated and the resulting autophosphorylation sites are recognized by the SH2 domains of PLCγ1. In contrast to the platelet-derived growth factor receptor, no single autophosphorylation site in the EGF receptor mediates this association with the two SH2 domains of PLCγ1, and both SH2 domains of PLCγ1 participate in its association with the EGF receptor, which is

a prerequisite for tyrosine phosphorylation of this enzyme.

EGF receptor stimulation induces the rapid, but transient, translocation of PLCγ1 from the cytoplasm to the plasma membrane and especially to a membrane microdomain termed caveolae. The mechanism of membrane association for PLCγ1 is not entirely defined, but the N-terminal pleckstrin homology (PH) domain of PLCγ1, which recognizes phosphorylated phosphoinositides, such as PI3,4,5-P_3, may provide a means to localize PLCγ1 at the cytoplasmic face of the plasma membrane. This translocation step is critical, as the substrate for PLC enzyme activity is membrane localized. Although in some cells, such as T cells, it is clear that PLCγ1 activation influences gene expression, this has not yet been demonstrated for EGF-treated cells. However, evidence has been presented to implicate PLCγ1 in EGF-dependent cell migration.

Multiple phosphoinositide-3 (P{I-3) kinases have been identified, which preferentially phosphorylate PI, PI4-P, or PI4,5-P_2 at the D-3 position of the inositol ring (Fig. 2). PI-3 kinase (PI-3K) consists of a regulatory subunit, p85, which interacts with activated receptor tyrosine kinases through two SH2 domains, and a catalytic subunit, p110. Although PI-3K can phosphorylate several phosphoinositides, the most significant substrate for signal transduction appears to be PI4,5-P_2, the phosphorylation of which generates the second messenger PI3,4,5-P_3. This novel phosphoinositide cannot be hydrolyzed by any known phospholipase. Instead, its removal depends on lipid phosphatases, particularly the tumor suppressor PTEN.

PI3,4,5-P_3 rapidly accumulates in growth factor-treated cells. In the case of EGF, the activation of PI-3 kinase appears to be cell type-dependent. In some cells, EGF does not provoke detectable increases in PI3,4,5-P_3, whereas in other cell types, such as PC-12 cells, it does so rapidly. In the latter case, EGF-dependent activation of PI-3 kinase seems to require the participation of ErbB-3 probably as a consequence of the formation of ErbB-1/ErbB-3 heterodimers. Apparently, ligand-dependent activation of the EGF receptor tyrosine kinase does not produce a phosphotyrosine docking site in the EGF receptor that is recognized by the p85 subunit of PI-3 kinase. However, ErbB-3 has such a docking site, which is produced by transphosphorylation in the context of a dimer with the activated EGF receptor. Alternatively, it is possible that the adaptor protein Gab1 may, when tyrosine phosphorylated by the EGF receptor, mediate the activation of PI-3 kinase.

An important downstream target of PI3,4,5-P_3 is protein kinase B (PKB)/Akt, which is phosphorylated and activated after membrane recruitment by both PKB/Akt and the serine/threonine kinase PDK1. Both PKB/Akt and PDK1 use PH domains to facilitate recognition of PI3,4,5-P_3 and translocation to the plasma membrane. Activation of PKB stimulates cell survival or anti-apoptotic pathways. The EGF receptor vIII (EGFRvIII) mutation is frequently found in human tumors and has enhanced tumorigenicity and constitutive kinase activity. This EGF receptor mutant produces a low level of activation of the Ras-MAP kinase pathway, yet a high level of PI-3 kinase activity is constitutively present in EGFRvIII-transformed cells. This suggests an important role for PI3,4,5-P_3 in EGFRvIII-mediated neoplastic transformation.

VII. TRANSACTIVATION

In a classical model, the EGF receptor is activated by the binding of its specific ligands. It has now become clear that receptor activation also can be achieved by a wide variety of stimuli that do not bind to the EGF receptor. These stimuli include hormones (e.g., angiotensin, thrombin, and bombesin) that bind to and activate various G-protein-coupled receptors, membrane depolarization (particularly Ca^{2+} fluxes in neuronal cells), adhesion receptors (integrins), cytokine receptors (e.g., growth hormone), and stress agents (e.g., arsenite, UV radiation, γ-irradiation, and oxidants). There seem to be two mechanisms by which these agents activate the EGF receptor. These are described in the following paragraphs, but it should be understood that the mechanisms are not mutually exclusive.

In one mechanism, activation of the EGF receptor is achieved by agents that regulate the production of soluble ligands for the EGF receptor. All EGF receptor ligands are produced as transmembrane precursors located on the cell surface so that the EGF-like domain is within the extracellular domain of the precursor. The available evidence indicates that transmembrane metalloproteases are able to cleave these precursor molecules within the extracellular domain close to the transmembrane domain and thereby produce soluble ligand. Hence, in this mechanism, the point of action for heterologous agents is not the EGF receptor, but rather the proteolytic system that converts growth factor precursors to soluble agonists. Whether this involves signaling pathways that influence the precursor molecules, the protease, or both is not yet clear.

A second mechanism does not involve liberation of soluble ligand but instead depends on the activation of a nonreceptor tyrosine kinase, such as Src or JAK, which in turn phosphorylates the EGF receptor. Novel Src-dependent tyrosine phosphorylation sites on the EGF receptor have been reported and in many cases these lie within the kinase domain of the EGF receptor. This phosphorylation may increase the catalytic activity of the EGF receptor kinase domain and/or create docking sites for SH2/PTB domain-containing adaptors and enzymes as previously described.

Regardless of the exact mechanism, transactivation of the EGF receptor seems to be a mechanism by which a variety of external agents or stimuli influence mitogenic pathways. To date, nearly all transactivation studies have been performed in cultured cells and it remains to be determined whether this represents a significant biological process in the animal.

VIII. ENDOCYTOSIS

Following ligand addition, the EGF receptor is rapidly endocytosed (Fig. 3). The most likely function of endocytosis is to remove activated ligand-receptor complexes from the plasma membrane and thereby attenuate the propagation of signaling pathways. Although internalization does not immediately deactivate the EGF receptor, these complexes are ultimately processed to the lysosome, where both receptor and growth factor are degraded. The net result of this receptor trafficking pathway is to substantially decrease the number of receptors present on the plasma membrane, a process termed down-regulation.

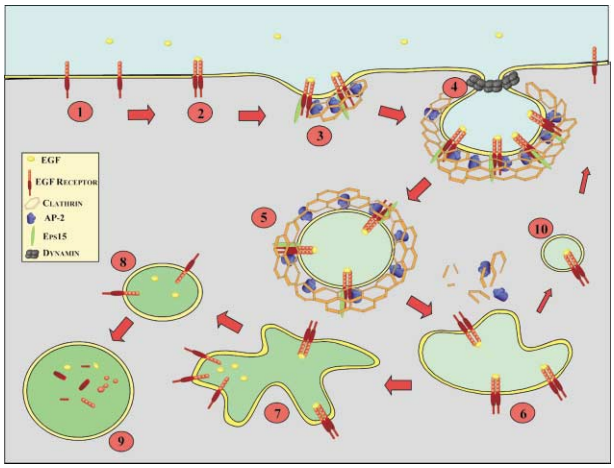

FIGURE 3 Model of EGF receptor endocytosis. In response to ligand binding (1), EGF receptor molecules dimerize (2) and bind Eps15, AP-2, and other proteins that localize the EGF receptor to clathrin-coated pits (3). It is not clear whether the EGF receptor is targeted to preformed coated pits or whether components of the coated pit are assembled around receptor dimers. Dynamin vesiculates the coated pit (4), which results in clathrin-coated vesicle formation (5). These vesicles mature into early endosomes, which involves removal of clathrin and other components (6). Early endosomes mature to multivesicular bodies (7). Although a minor fraction of internalized EGF receptors are recycled to the cell surface (10), most receptors degraded as late endosomes (8) fuse with lysosomes (9).

The EGF receptor is internalized by a mechanism that requires receptor kinase activity and ill-defined sequence motifs in the carboxy-terminal domain of the receptor. Certain tyrosine phosphorylation substrates, such as Eps15, are thought to be factors that recruit EGF receptors to the endocytic pathway. Eps15 is rapidly phosphorylated by the activated EGF receptor and is required for receptor internalization through clathrin-coated pits. Following ligand binding, Eps15 translocates to the plasma membrane and localizes to the rim of coated pits, ubiquitous structures that mediate internalization of activated EGF receptors and a variety of other receptors, such as the transferrin receptor. Although routes of internalization other than coated pits are known for some receptors, there is no evidence for entry of EGF receptor into cells other than through coated pits.

The major components of coated pits are clathrin, AP-2, and dynamin, plus the numerous proteins that associate with these components (Fig. 3). Activated receptors, having appropriate sorting signals for entry into and retention by coated pits, are then concentrated in coated pits, and following pit invagination, they are delivered into the cytoplasm in the form of clathrin-coated vesicles, termed endosomes. However, the specific mechanism by which activated EGF receptors are sorted to coated pits is unknown, but seems to involve association with AP-2 and the tyrosine phosphorylation of Eps15. The latter process seems to be relatively specific for the EGF receptor, as Eps15 mutants that cannot be tyrosine phosphorylated block internalization of EGF receptors but not transferrin receptors.

The GTPase dynamin is required for the formation of coated vesicles from coated pits. Dynamin binds to membrane-embedded phosphoinositides in coated pits through its PH domain to form helical tubes. Dynamin then constricts and fragments membrane tubules. Expression of dominant-negative dynamin mutants blocks EGF receptor internalization.

Following internalization through coated pits, the EGF receptor is sorted into early and late endosomes

prior to lysosomal delivery. Once it reaches the late endosomes, the EGF receptor is either targeted to lysosomes or recycled to the cell surface. In normal circumstances, the majority of EGF receptors are targeted to lysosomes, with a minor fraction recycled. Sorting between endosomal compartments appears to be independent of receptor kinase activity; rather, occupancy-induced conformational changes in the receptor are thought to be required.

Studies with native and chimeric ErbB receptors have revealed that although the ligand-occupied EGF receptor is rapidly internalized and degraded, all other members of this family are only slowly internalized at a rate equivalent to a kinase-negative EGF receptor. Overexpression of ErbB-2, which is commonly observed in many human cancers, retards lysosomal targeting and down-regulation of the EGF receptor. This appears to be due to the fact that heterodimers are inefficiently recognized by either the coated pit sorting proteins or subsequent intracellular sorting machinery. Dimerization of the EGF receptor with ErbB-2, therefore, may enhance signaling through the EGF receptor pathway by reducing endocytosis and down-regulation.

It remains an open question as to whether endocytosis is also a mechanism to initiate or propagate signaling pathways that influence cellular responses to EGF receptor ligands. The bulk of the evidence suggests that although postreceptor signaling components are found in endosomes together with internalized EGF receptors, these localizations are more related to ending signaling events than to initiating these events.

IX. SUMMARY

The EGF receptor is specifically activated by the binding of cognate ligand at the cell surface. Ligand binding promotes receptor dimerization and activation of receptor tyrosine kinase activity. As a consequence, receptor autophosphorylation creates docking sites that mediate tyrosine phosphorylation of cellular proteins and activation of signal transduction pathways, which relay biochemical information from the plasma membrane to the nucleus to provoke changes in cellular growth.

Glossary

adaptors Proteins composed of protein-protein and/or protein-phospholipid interaction domains, but without an enzymatic activity.

dimerization The process by which two related proteins become physically associated.

endocytosis The process by which molecules on the surface of cells are brought into the cell and then degraded or recycled back to the cell surface.

epidermal growth factor receptor A cell surface transmembrane protein that specifically binds cognate ligands and transduces a biologic response, usually related to the control of cell proliferation.

G-protein A low-molecular-weight protein that binds GTP in its active state and GDP in its inactive state and affects the activation of other proteins.

growth factors Polypeptides that act to stimulate cell proliferation by binding to a receptor.

phosphoinositides Plasma membrane-localized phospholipids that have a regulatory function as opposed to a structural function in the membrane.

phospholipase C An enzyme that hydrolyzes a particular polyphosphoinoside to produce two second-messenger molecules.

protein kinase An enzyme that transfers a phosphate group from ATP to the side chain of a tyrosine or serine/-threonine residues in a protein.

transcription factor A protein that regulates the transcription of a gene by interacting with DNA regulatory elements, directly or indirectly.

For many years it has been acknowledged that activation of the renin-angiotensin-aldosterone system (RAAS) is associated with deleterious outcomes in patients with congestive heart failure and hypertension. Because RAAS is the fundamental mechanism in the body responsible for blood pressure and volume homeostasis, a number of commonly prescribed medications for hypertension and heart failure target this system. Angiotensin-converting enzyme inhibitors block conversion of inactive angiotensin I peptide to the active vasoconstrictor molecule angiotensin II. Angiotensin receptor blockers block angiotensin II type 1 receptors. An additional mechanism for RAAS modulation has emerged based on blockade of aldosterone binding to its cognate receptor, the mineralocorticoid receptor.

I. INTRODUCTION

The classical mineralocorticoid effect of aldosterone on unidirectional transepithelial sodium transport in the kidney was long thought to be the predominant cardiorenal effect of this hormone. However, there is now convincing evidence that aldosterone mediates significant deleterious cardiovascular effects via activation of mineralocorticoid receptors (MR) localized outside the kidney-namely, in the heart, vasculature, and brain. It is now postulated that many of the detrimental effects of aldosterone are mediated through MR activation in these nonclassical target tissues.

The most direct and compelling evidence that aldosterone can negatively impact the cardiovascular system was provided by the Randomized Aldactone Evaluation Study (RALES) trial in heart-failure patients (New York Heart Association Class III/IV). In this study, when the nonselective mineralocorticoid receptor antagonist spironolactone was added to standard therapy for congestive heart failure [in most patients angiotensin-converting enzyme inhibitor (ACE-I), diuretic/digitalis], a 30% mortality benefit was achieved. Although the mortality benefit with spironolactone is clear, clinically significant endocrine side effects such as impotence, gynecomastia, menstrual irregularities, and breast pain as a result of limited MR selectivity associated with spironolactone prohibit widespread use of this agent.

Eplerenone (other names include SC-66110, CGP-30 083, and epoxymexrenone) is the first agent to block the mineralocorticoid receptor with a high degree of selectivity and is under development for human therapeutic use in the treatment of hypertension and heart failure postmyocardial infarction. Clinical and preclinical studies have linked elevated aldosterone to high blood pressure, cardiac hypertrophy, cardiac and vascular fibrosis, and increased risk of mortality in patients with congestive heart failure. Preclinical studies indicate that eplerenone is a selective MR antagonist that effectively attenuates the deleterious effects of aldosterone, displays antihypertensive properties, and provides end-organ protective effects in experimental models of hypertension and heart failure independent of blood pressure lowering.

II. MINERALOCORTICOID RECEPTOR SELECTIVITY

The affinity of eplerenone for human steroid receptors was quantitated *in vitro* using a transcriptional transactivation assay in which the ability of eplerenone to antagonize the aldosterone transcriptional response at human MR was evaluated. Eplerenone

For many years it has been acknowledged that activation of the renin-angiotensin-aldosterone system (RAAS) is associated with deleterious outcomes in patients with congestive heart failure and hypertension. Because RAAS is the fundamental mechanism in the body responsible for blood pressure and volume homeostasis, a number of commonly prescribed medications for hypertension and heart failure target this system. Angiotensin-converting enzyme inhibitors block conversion of inactive angiotensin I peptide to the active vasoconstrictor molecule angiotensin II. Angiotensin receptor blockers block angiotensin II type 1 receptors. An additional mechanism for RAAS modulation has emerged based on blockade of aldosterone binding to its cognate receptor, the mineralocorticoid receptor.

I. INTRODUCTION

The classical mineralocorticoid effect of aldosterone on unidirectional transepithelial sodium transport in the kidney was long thought to be the predominant cardiorenal effect of this hormone. However, there is now convincing evidence that aldosterone mediates significant deleterious cardiovascular effects via activation of mineralocorticoid receptors (MR) localized outside the kidney-namely, in the heart, vasculature, and brain. It is now postulated that many of the detrimental effects of aldosterone are mediated through MR activation in these nonclassical target tissues.

The most direct and compelling evidence that aldosterone can negatively impact the cardiovascular system was provided by the Randomized Aldactone Evaluation Study (RALES) trial in heart-failure patients (New York Heart Association Class III/IV). In this study, when the nonselective mineralocorticoid receptor antagonist spironolactone was added to standard therapy for congestive heart failure [in most patients angiotensin-converting enzyme inhibitor (ACE-I), diuretic/digitalis], a 30% mortality benefit was achieved. Although the mortality benefit with spironolactone is clear, clinically significant endocrine side effects such as impotence, gynecomastia, menstrual irregularities, and breast pain as a result of limited MR selectivity associated with spironolactone prohibit widespread use of this agent.

Eplerenone (other names include SC-66110, CGP-30 083, and epoxymexrenone) is the first agent to block the mineralocorticoid receptor with a high degree of selectivity and is under development for human therapeutic use in the treatment of hypertension and heart failure postmyocardial infarction. Clinical and preclinical studies have linked elevated aldosterone to high blood pressure, cardiac hypertrophy, cardiac and vascular fibrosis, and increased risk of mortality in patients with congestive heart failure. Preclinical studies indicate that eplerenone is a selective MR antagonist that effectively attenuates the deleterious effects of aldosterone, displays antihypertensive properties, and provides end-organ protective effects in experimental models of hypertension and heart failure independent of blood pressure lowering.

II. MINERALOCORTICOID RECEPTOR SELECTIVITY

The affinity of eplerenone for human steroid receptors was quantitated *in vitro* using a transcriptional transactivation assay in which the ability of eplerenone to antagonize the aldosterone transcriptional response at human MR was evaluated. Eplerenone

inhibits human MR transcriptional activation by aldosterone in a concentration-dependent manner with a calculated IC_{50} of 291 n*M*. In addition to binding the MR, the binding of eplerenone to other steroid receptors (androgen, glucocorticoid, and progesterone) isolated from appropriate tissues was also measured using [^{3}H]methyltrienolone for androgen receptors isolated from rat ventral prostate, [^{3}H]dexamethasone for glucocorticoid receptors isolated from rat kidney, and [^{3}H]progesterone for progesterone receptors isolated from rabbit uteri. Binding of eplerenone to these steroid receptors was compared to the nonselective mineralocorticoid receptor antagonist, spironolactone. As shown in Table 1, eplerenone binds MR with approximately 20-fold lower affinity compared to spironolactone. However, compared to spironolactone, eplerenone is devoid of appreciable binding to androgen or progesterone receptors and binds with lower affinity to glucocorticoid receptors. Despite the reduced binding affinity of eplerenone for MR compared to spironolactone, eplerenone has approximately 2-fold greater oral potency (ED_{50} = 0.8 vs 1.7 mg/kg) as an aldosterone antagonist at the renal mineralocorticoid receptor in adrenalectomized rats. These disparate findings may be attributed to the reduced plasma protein binding of eplerenone as compared to spironolactone. *In vitro* binding studies demonstrated that the addition of 5 or 20% rat plasma did not alter the IC_{50} calculated for eplerenone binding to isolated rat colon MR. In contrast, the IC_{50} value calculated for spironolactone increased by 2.5-fold in the presence of 20% rat plasma. Thus, eplerenone selectively binds MR and exhibits similar *in vivo* potency compared to spironolactone.

TABLE I Relative Binding Affinities of Eplerenone and Spironolactone for Steroid Receptors *In Vitro*[a]

Receptor (standard)	Eplerenone	Spironolactone
Mineralocorticoid (aldosterone)	0.005 ± 6.5% (n = 7)	0.11 ± 36.4% (n = 7)
Androgen (methyltrienolone)	0.0000076 ± 26.3% (n = 6)	0.009 ± 16.5% (n = 7)
Glucocorticoid (dexamethasone)	0.00018 ± 16.1% (n = 4)	0.0018 ± 22.2% (n = 4)
Progesterone (progesterone)	<0.00005 (n = 5)	0.007 ± 11.0% (n = 5)

[a]Affinities expressed as a fraction of the binding affinity of the standard ligand at each receptor. Binding affinity of the standard ligand is set at 1. Standard error mean reflects the percentage of the mean. Data reproduced from de Gasparo *et al.* (1987), with permission.

III. ANTIHYPERTENSIVE EFFECTS

In vivo, circulating glucocorticoids are in vast excess of mineralocorticoids (100- to 1000-fold); however, both hormones bind MR with similar affinity. The enzyme 11-β-hydroxysteroid dehydrogenase 2 (11-βHSD2) confers MR specificity for aldosterone by metabolizing endogenous glucocorticoids to their inactive 11-dehydro derivatives. Glycyrrhizic acid (GA), an established inhibitor of 11-βHSD2 found in licorice, enables endogenous glucocorticoids to activate MR, resulting in excessive sodium retention and severe hypertension. The antihypertensive properties of eplerenone were evaluated in rats with elevated blood pressure resulting from 21 days of GA administration [control systolic blood pressure (SBP), 142 ± 8 mmHg; GA SBP, 185 ± 9 mmHg). Two weeks of treatment with eplerenone lowered blood pressure to normal levels (143 ± 9 mmHg), restored impaired endothelial-dependent relaxation in response to acetylcholine (control, 73 ± 6%; eplerenone, 97 ± 3%), and normalized the 50% decrease in vascular nitrate levels induced by GA and the 2.5-fold elevation of aortic endothelin-1 levels associated with this form of hypertension. Thus, eplerenone normalizes blood pressure and improves endothelial function in a model of hypertension produced by overstimulation of MR with corticosteroids.

The antihypertensive effect of eplerenone exhibited in experimental models has also been demonstrated in clinical studies. A dose-dependent reduction in systolic and diastolic blood pressure (DBP) has been demonstrated in mildly and moderately hypertensive patients [DBP, ≥95 mmHg and <114 mmHg by cuff, and mean 24-h ambulatory blood pressure monitoring (ABPM) DBP ≥85 mmHg] without accompanying endocrine side effects. A group of 417 patients was randomized to receive placebo, eplerenone (either 25, 50, or 200 mg twice daily or 50, 100, or 400 mg daily), or spironolactone (50 mg twice daily). Within the eplerenone-treated groups, adjusted mean changes from baseline (SBP/DBP) at week 8 were as follows: seated, −4.4 to −15.0/ −4.4 to −8.9 mmHg; 24-h ABPM, −6.2 to −16.1/ −4.1 to −9.0 mmHg. Within the spironolactone-treated group, adjusted mean changes from baseline at week 8 were as follows: seated, −16.7/ −9.5 mmHg; 24-h ABPM, −15.8/ −8.7 mmHg. At daily doses of 50 to 400 mg, eplerenone dose-dependently reduced blood pressure compared to placebo ($P \leq 0.01$) and to a similar extent compared to spironolactone.

IV. END-ORGAN PROTECTION

Clinical studies have clearly demonstrated a positive correlation between plasma aldosterone levels and stroke, renal dysfunction, left ventricular hypertrophy, and decreased vascular compliance. The detrimental action of aldosterone on these target organs has been further elucidated using genetic and experimental models of hypertension showing that inappropriately high levels of aldosterone induce severe vascular injury in the brain, kidney, and heart. Preclinical studies have demonstrated that pharmacological antagonism of aldosterone or adrenalectomy markedly attenuates tissue and vascular damage and associated inflammation.

A. Brain

The cerebrovascular protective effects of eplerenone were evaluated in stroke-prone spontaneously hypertensive (SHRSP) rats. Saline-drinking SHRSP rats receiving vehicle developed stroke signs and died by 18 weeks of age. In contrast, eplerenone-treated littermates exhibited no signs of stroke until 18 weeks of age, at which point only one of the seven eplerenone-treated animals developed stroke and died. Histopathologic analysis of cerebral tissue from vehicle-treated animals revealed severe cerebrovascular injury with hallmark features of stroke, including liquefaction necrosis, fibrinoid necrosis of cerebral vessels, and focal hemorrhages. Eplerenone-treated rats, however, demonstrated a marked attenuation of cerebrovascular lesions accompanied by stroke prevention and reduced mortality, which was not associated with decreased arterial blood pressure. Cerebral protection was evidenced using semiquantitative injury scoring (vehicle, 3.1 ± 0.4; eplerenone, 0.8 ± 0.5; $P < 0.05$, scored from 0 to 4). These findings are consistent with the previously demonstrated cerebral protective effects of spironolactone and suggest a role for endogenous aldosterone in the development of stroke in rats with severe spontaneous hypertension.

B. Kidney

The impact of eplerenone on hypertension-induced renal vascular damage was evaluated in experimental rat models of spontaneous and induced hypertension. In saline-drinking, hypertensive SHRSP rats, eplerenone prevented the development of proteinuria (vehicle, 85 ± 11 mg/day; eplerenone, 16 ± 3 mg/day) and renal arteriopathy (vehicle, $34.2 \pm 4.1\%$; eplerenone, $1.3 \pm 0.6\%$; calculated as the number of arteries and arterioles with lesions per 100 glomeruli) without appreciably influencing blood pressure (SBP vehicle, 227 ± 4 mmHg; eplerenone, 219 ± 6 mmHg). Therefore, eplerenone protects renal vasculature via mechanisms independent of blood pressure reduction.

Angiotensin II has long been identified as the key mediator of hypertension-induced renal tissue and vascular injury, whereas the deleterious effects of aldosterone have not been comprehensively characterized. Therefore, the role of angiotensin II (AII) and aldosterone in the renal damage that accompanies hypertension in SHRSP rats was evaluated. Saline-drinking SHRSP rats were administered the ACE inhibitor captopril, captopril in the presence of AII, or captopril in the presence of AII and eplerenone. Captopril afforded marked protection against glomerular and renal vascular damage and proteinuria (Table 2). AII infusion in captopril-treated rats increased plasma aldosterone and, as expected, reversed the protection from ACE inhibition. In contrast, the pathology induced by AII infusion in captopril-treated rats was substantially attenuated by treatment with eplerenone in the absence of

TABLE 2 Renal Lesion Scores for Captopril-treated, AII-Infused, Saline-Drinking SHRSP Treated with Vehicle or Eplerenone[a]

Treatment	Glomerular damage (%)	Renal arteriopathy (% of glomeruli)
Captopril ($n = 10$)	0.0 ± 0.0	0.0 ± 0.0
Captopril + AII ($n = 7$)	14.9 ± 2.7^{b}	15.9 ± 2.2^{b}
Captopril + AII + eplerenone ($n = 7$)	$3.2 \pm 0.7^{b,c}$	$3.6 \pm 1.1^{b,c}$

[a] AII, Angiotensin II; SHRSP, stroke-prone spontaneously hypertensive rats. Values are mean ± standard error mean. Glomerular lesions were expressed as a percentage of the total number of glomeruli present per midcoronal section examined. Vascular damage was expressed as the number of arteries and arterioles with lesions per 100 glomeruli. Captopril dose was 50 mg/kg/day; AII dose was 25 ng/min; eplerenone dose was 100 mg/kg/day. Data from Rocha *et al.* (1998b).

[b] Significantly different from captopril treatment.

[c] Significantly different from captopril + AII treatment.

antihypertensive effects. These findings demonstrate that hypertension-induced renal pathology in this model is mediated through the renin-angiotensin-aldosterone system, and aldosterone, in addition to AII, appears to be a primary mediator of renal tissue damage.

The mechanisms of aldosterone-driven renal vascular injury were evaluated in uninephrectomized rats receiving salt and chronic aldosterone treatment in the presence or absence of eplerenone. Aldosterone/salt-treated rats developed severe hypertension, albuminuria, vascular damage, and renal lesions compared to rats receiving vehicle. Severe renal arteriopathy was accompanied by glomerular and tubular damage, marked perivascular inflammation, and elevated message levels for the cytokines osteopontin (OPN, ~18-fold), monocyte chemoattractant protein-1 (MCP-1, ~3-fold), interleukin-1β (IL-1β, ~2-fold), and interleukin-6 (IL-6, ~7-fold). Eplerenone significantly attenuated, although did not completely normalize, systolic blood pressure in rats treated with aldosterone/salt for 28 days (vehicle, 131 ± 4 mmHg; aldosterone/salt, 220 ± 4 mmHg; eplerenone, 187 ± 7 mmHg) and dramatically reduced renal vascular injury (vehicle, 0 ± 0; aldosterone/salt, 3.7 ± 0.2; eplerenone, 0.5 ± 0.3; scored from 0 to 4) and the concomitant inflammatory response. Thus, elevated aldosterone in combination with salt may be an important mechanism involved in the onset and development of hypertension-induced renal vascular disease.

C. Heart

Activation of the local renin-angiotensin-aldosterone system is known to occur during myocardial ischemia/reperfusion and elevated levels of aldosterone may negatively impact myocardial function under these conditions. The effect of acute exposure to aldosterone on functional recovery from an ischemia/reperfusion challenge and the ability of eplerenone to block the negative effects of aldosterone exposure were examined in a Langendorff isolated rat heart preparation. Hearts were perfused with vehicle, aldosterone, or aldosterone in the presence of eplerenone, and contractile recovery following ischemia/reperfusion was quantitated by monitoring left ventricular developed pressure (LVDP). Exposure to 1.39 n*M* aldosterone reduced the magnitude of recovery following ischemia/reperfusion challenge from 41.8 ± 3.1% of preischemia LVDP in vehicle-treated animals to 28.1 ± 3.4% in aldosterone-treated rats. However, the recovery response of hearts perfused with aldosterone in the presence of 1.13 μ*M* eplerenone was similar to that of vehicle-treated hearts (39.0 ± 5.9%, Fig. 1). Thus, eplerenone effectively blocks the negative effects of exogenous aldosterone following myocardial ischemia/reperfusion in the isolated rat heart.

In addition to the functional benefit afforded by eplerenone in isolated rat hearts exposed to aldosterone, myocardial protective properties of eplerenone have also been demonstrated *in vivo*. Myocardial infarction initiates adaptive tissue remodeling, which is initially reparative but evolves into a maladaptive sequela of events exemplified by reactive myocardial fibrosis and left ventricular dilatation. The effect of MR antagonism on these processes was evaluated in rats administered eplerenone or vehicle immediately following permanent ligation of the left coronary artery. Infarct healing and left ventricular remodeling were evaluated at 3, 7, and 28 days postmyocardial infarction (post-MI).

Eplerenone did not affect scar collagen deposition or infarct expansion as evidenced by a similar collagen volume fraction (CVF) in the infarcted myocardium and thinning ratio, respectively. At 7 days post-MI, the CVF was calculated at 47.1 ± 4.4 for vehicle-treated animals and 48.3 ± 4.6 for rats administered eplerenone; the thinning ratio was 0.42 ± 0.04 for vehicle-treated animals versus 0.50 ± 0.06 in eplerenone-treated rats. Moreover, a protective effect of eplerenone was demonstrated at 28 days post-MI; i.e., reactive fibrosis in the viable myocardium was elevated in vehicle-treated animals, but not in eplerenone-treated animals compared to

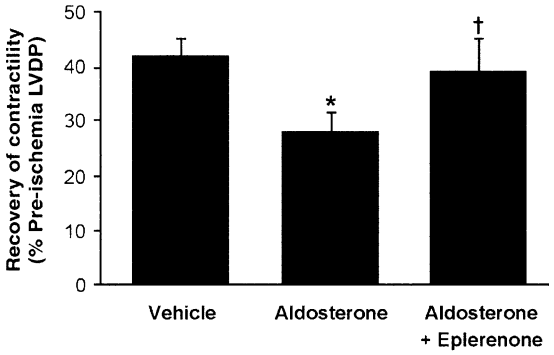

FIGURE 1 Effects of aldosterone and aldosterone plus eplerenone on the recovery of myocardial contractility measured 40 min after initiation of reperfusion and expressed as percent recovery from baseline of left ventricular developed pressure (LVDP) in an isolated heart model of ischemia and reperfusion. *, $p < 0.05$ vs vehicle. †, $p < 0.05$ vs eplerenone + aldosterone.

sham rats (CVF, vehicle, 3.2 ± 0.4%; eplerenone, 2.1 ± 0.4%; sham, 1.65 ± 0.2%). Thus, mineralocorticoid receptor antagonism with eplerenone does not retard infarct healing when initiated within 24 h of infarction in the rat. In addition, eplerenone administration protects against reactive fibrosis in the left ventricular viable myocardium.

The temporal relationship between molecular changes and myocardial injury in response to aldosterone/salt treatment was evaluated in rat cardiac tissue following 1, 2, or 4 weeks of exposure to exogenous aldosterone and salt. No significant increases in interstitial collagen fraction were detected throughout the study. However, histopathologic analysis in coronary arteries revealed severe vascular inflammatory lesions associated with leukocyte infiltration. Coronary injury was evident starting at 2 weeks and extended occasionally to the surrounding myocardium, resulting in focal ischemic/necrotic changes. Vascular lesions were preceded by the progressive up-regulation of cyclooxygenase 2 (COX-2, up to 4-fold), macrophage MCP-1 (up to 4-fold), and OPN (up to 13-fold) mRNA. Eplerenone reduced focal necrosis, myocardial vascular inflammation, and attenuated cardiac cytokine expression.

V. POTENTIAL MECHANISM OF ACTION

In addition to the antihypertensive effects of eplerenone demonstrated in preclinical and clinical studies, substantial end-organ protection has been observed in experimental models. Even in the absence of blood pressure reduction, eplerenone attenuates the progressive development of vascular inflammation and subsequent maladaptive remodeling in end organs, resulting in protection of the brain, kidney, and heart. Indeed, selective aldosterone blockade by eplerenone attenuates both the inflammatory cellular infiltration and the elevated cytokine expression that exemplify vascular inflammation in these target organs. Thus, current dogma is evolving from the classic paradigm of aldosterone modulation of sodium and water homeostasis to include a role for this steroid hormone as a catalyst for vascular inflammation and subsequent progressive tissue damage.

VI. SUMMARY

Eplerenone represents the first selective aldosterone blocker with proven antihypertensive efficacy in preclinical and clinical settings. End-organ protection has also been clearly demonstrated in experimental models, potentially via attenuation of the initial vascular inflammatory response and subsequent pathophysiology. Although animal models are invaluable tools for the dissection and understanding of eplerenone pharmacology, they represent only approximations of the complexity of human pathophysiology. The question remains if these protective effects translate to human disease states, a postulate that is now being carefully evaluated in clinical studies.

Glossary

aldosterone The principal mineralocorticoid; produced by the zona glomerulosa of the adrenal cortex, aldosterone facilitates potassium exchange for sodium in the distal renal tubule, causing sodium reabsorption and potassium and hydrogen loss.

angiotensin II A potent vasoconstrictor peptide that stimulates aldosterone synthesis and secretion from the adrenal zona glomerulosa and participates in the regulation of local and systemic hemodynamic regulation.

mineralocorticoid receptor A member of the steroid/thyroid/retinoid/orphan receptor family of nuclear transactivating factors.

proteinuria Elevated urinary protein as a result of renal dysfunction.

renin–angiotensin–aldosterone system The primary mechanism by which blood pressure and volume are maintained; prolonged activation of this system is associated with deleterious outcomes in patients with congestive heart failure and hypertension.

stroke-prone spontaneously hypertensive rats A genetic model of spontaneous hypertension accompanied by end-organ damage, including cardiac hypertrophy and renal dysfunction, with mortality primarily resulting from stroke.

University of California, Los Angeles

Erythropoeitin (EPO) is a cytokine that stimulates erythropoiesis, the formation of red blood cells. The mature EPO protein consists of 166 amino acids; its predicted tertiary structure is an anti-parallel bundle of four α-helices. The primary site of EPO production is the kidney. In addition to tissue-specific control, regulation of EPO production occurs mainly at the transcriptional level, and the production of EPO can be induced under anemic and hypoxic conditions.

I. INTRODUCTION

Oxygen is essential for life. The oxygen consumption of the human body varies based on an individual's metabolic demand and can be limited by the environmental oxygen concentration. Early observations provided links between symptoms such as fatigue, shortness of breath, and cardiac palpitations and either low oxygen tension or anemia. Further studies showed that low oxygen tension resulted in an increased number of red blood cells, the cells responsible for the delivery of oxygen to systemic organs and tissues.

The red blood cell was the first identified blood cell type, and its oxygen-carrying function by hemoglobin was observed by Hoppe-Seyler in the 19th century. However, the regulation of red blood cell formation, or erythropoiesis, remained unknown until 1906 when Carnot and Deflandre first introduced the idea of a humoral mediator for erythropoiesis. Almost 50 years later, Erslev and Reissmann formally tested this hypothesis experimentally by injecting serum from anemic rabbits into normal rabbits and noting a significant increase of red blood cells in the recipient animals. They further proved this hypothesis by using a parabiotic model in rats to demonstrate a circulating erythropoiesis-stimulating factor, now known as erythropoietin (EPO).

Erythropoeitin (EPO) is a cytokine that stimulates erythropoiesis, the formation of red blood cells. The mature EPO protein consists of 166 amino acids; its predicted tertiary structure is an anti-parallel bundle of four α-helices. The primary site of EPO production is the kidney. In addition to tissue-specific control, regulation of EPO production occurs mainly at the transcriptional level, and the production of EPO can be induced under anemic and hypoxic conditions.

I. INTRODUCTION

Oxygen is essential for life. The oxygen consumption of the human body varies based on an individual's metabolic demand and can be limited by the environmental oxygen concentration. Early observations provided links between symptoms such as fatigue, shortness of breath, and cardiac palpitations and either low oxygen tension or anemia. Further studies showed that low oxygen tension resulted in an increased number of red blood cells, the cells responsible for the delivery of oxygen to systemic organs and tissues.

The red blood cell was the first identified blood cell type, and its oxygen-carrying function by hemoglobin was observed by Hoppe-Seyler in the 19th century. However, the regulation of red blood cell formation, or erythropoiesis, remained unknown until 1906 when Carnot and Deflandre first introduced the idea of a humoral mediator for erythropoiesis. Almost 50 years later, Erslev and Reissmann formally tested this hypothesis experimentally by injecting serum from anemic rabbits into normal rabbits and noting a significant increase of red blood cells in the recipient animals. They further proved this hypothesis by using a parabiotic model in rats to demonstrate a circulating erythropoiesis-stimulating factor, now known as erythropoietin (EPO).

II. BIOCHEMICAL PROPERTIES OF EPO

Biochemical characterization of EPO became possible only after Goldwasser and colleagues obtained

partially purified protein from the urine of anemic patients in 1977. The molecular characterization of EPO was further advanced when Lin *et al*. and Jacobs *et al*. cloned the cDNA encoding human EPO in 1985. The human protein consists of a 193-amino-acid sequence with a 27-residue signal leader sequence, resulting in a 166-amino-acid mature protein (Fig. 1). The protein contains two disulfide linkages and multiple glycosylation sites. Sequence analysis indicates that EPO belongs to a family of cytokines, including growth hormone, prolactin, colony-stimulating factor, and the interleukins. The predicted EPO tertiary structure is an anti-parallel bundle of four α-helices, structurally analogous to the growth hormone molecule. The molecular weight of mature EPO is approximately 30.4 kDa with 40% of its mass derived from carbohydrates. As shown in Fig. 1, the mature protein contains one O-linked glycosylation site (Ser-126) and three N-linked glycosylation sites (Asn-24, Asn-38, and Asn-83). Different carbohydrate structures can be found on the same glycosylation site: e.g., the N-linked chains may contain two, three, or four branches, each ending with a sialic acid molecule. The O-linked site may contain zero to two sialic acid molecules. This posttranslational modification gives rise to heterogeneous EPO molecules with different numbers of sialic acid molecules attached, thereby varying the net negative charge. In order to study the effects of this microheterogeneity on EPO's biological activity, different isoforms of EPO were isolated and injected into animals. Isoforms with higher sialic acid content have greater *in vivo* biological activity and a longer serum half-life. In contrast, higher sialic acid content leads to lower *in vitro* receptor-binding affinity. These results suggest that the serum half-life and clearance rate have stronger effects on EPO's biological activity *in vivo* than does receptor-binding affinity.

III. EPO LEVELS AND ITS REGULATION

Although hypoxia clearly stimulates EPO production, how and where this is accomplished was unclear until Jacobsen demonstrated that nephrectomized animals

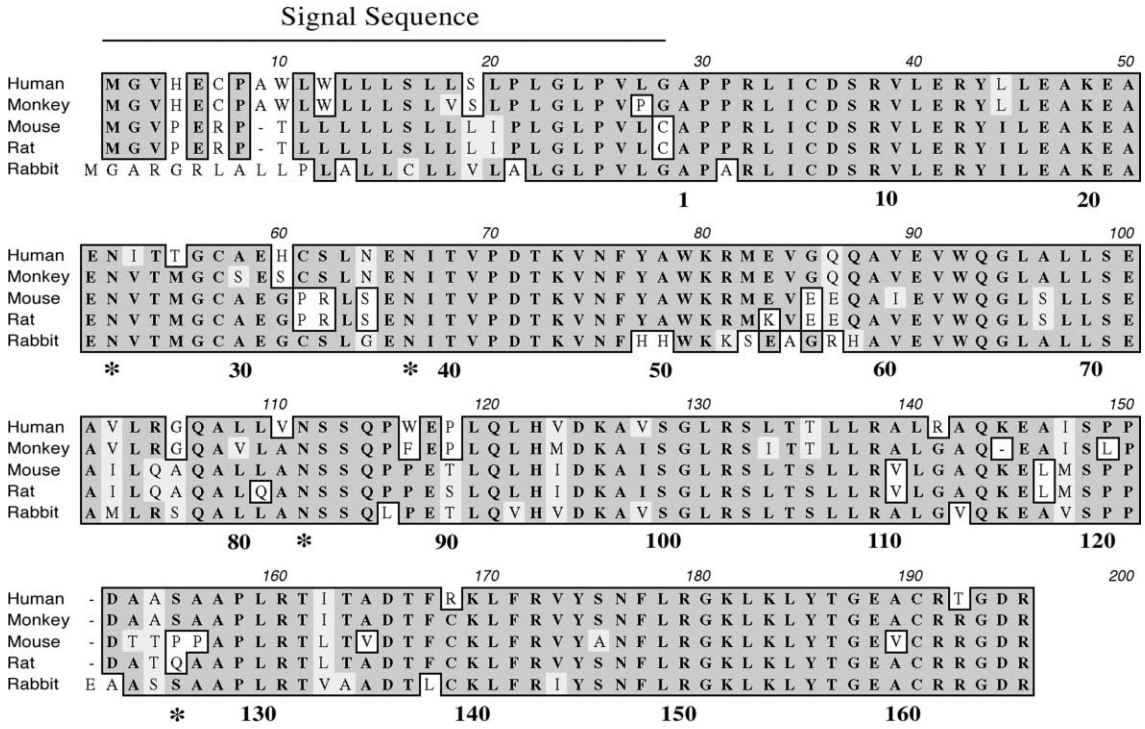

FIGURE 1 Alignment of the EPO amino acid sequence across human, monkey, mouse, rabbit, and rat showing a high degree of homology. Signal sequence comprises approximately the first 27 residues depending on the species. Glycosylation sites are marked with an asterisk below the asparagine (N) or serine (S) residues in relation to the human sequence. Boldface numbers below the alignment represent numbering of the mature sequence, and numbers at the top of the alignment represent numbering from the start of the signal sequence. Dark shaded residues indicate identity and lightly shaded residues indicate similarity.

failed to mount an EPO response to hypoxia, suggesting that the kidney was the primary site of EPO production in adult animals. Koury and Lacombe in 1988 localized erythropoietin expression to interstitial cells close to the proximal tubular cells of the kidney by *in situ* hybridization. The kidney is the primary site for EPO production, at least in part due to its function in sensing oxygen tension and extracellular volume. By regulating red cell mass through EPO production and plasma volume through excretion of salt and water, the kidney sets the hematocrit at a normal value of 45%. The adult liver is also capable of producing approximately 10–15% of the circulating EPO in anemic rats. These levels, however, are not sufficient to sustain a normal level of erythropoiesis in the absence of renal EPO production.

EPO released into the blood circulation travels to major erythropoietic organs, such as the bone marrow and the spleen (in rodent), and binds to its cell surface receptor (EPOR) on erythroid-specific precursors to stimulate red blood cell production and increase the peripheral red cell mass. In the normal healthy individual, the serum EPO level is very low, ranging from 10 to 30 mU/ml. No sex-related differences in EPO levels have been observed and EPO levels are not affected by the menstrual cycle.

In addition to tissue-specific control, regulation of EPO production occurs mainly at the level of transcription and can be induced under anemic and hypoxic conditions. *EPO* mRNA levels increase 200- to 1000-fold in mice with bleeding-induced anemia or severe hypoxia in order to compensate for the blood loss and reduced oxygen-carrying capacity. *EPO* expression is also carefully regulated to prevent the overproduction of red blood cells. In anemic mice, the level of EPO induction is proportional to the level of anemia induced. Abnormally high red cell mass or hematocrit, clinically defined as erythrocytosis, can increase blood viscosity and cause hypertension. A considerable amount of research has been invested in determining how the body is able to sense the changes in oxygen tension and how that translates into EPO production. Interestingly, EPO is found only in placental mammals. An 80–82% amino acid identity exists between the human sequence and that of monkey, mouse, rat, and rabbit (Fig. 1). Studies on the *EPO* locus itself have uncovered several transcriptional regulatory elements. The *EPO* gene consists of five exons and four introns. In addition to a high level of conservation within the *EPO* coding sequence across mammalian species, regions in the promoter, the first intron, and a small region 3′ to the polyadenylation site are also highly conserved. These similarities suggest the existence of conserved transcriptional regulatory mechanisms. Studies using transgenic mice carrying different regions of the putative regulatory sequences demonstrated that (1) *cis*-acting elements for tissue-specific and developmentally regulated *EPO* expression lie outside the 400 and 700 bp of 5′- and 3′-flanking sequences, respectively, and (2) *cis*-acting sequences within the 400-bp 5′ and 700 bp 3′-flanking regions are capable of mediating an oxygen-related response. Subsequent studies with larger regions of the 5′-promoter regions identified a region 0.4 to 6 kb upstream of the *EPO* gene that may possess binding sites for functionally relevant repressors. Further upstream, kidney-specific inducible elements were found between 9.5 and 14 kb upstream of the *EPO* gene. Study of the conserved region 3′ to the polyadenylation site (Fig. 2) also provided information crucial for *EPO* regulation. A hypoxia-inducible enhancer was discovered in a region 120 bp 3′ to the polyadenylation site. Its activity is independent of orientation or distance from the promoter. Fine-mapping of the 3′-enhancer sequence reveals three sites critical for regulation of the *EPO* gene by hypoxia (Fig. 2). The first site on the 5′-end has the sequence TACGTGCT, which is the consensus binding site for the transcription factor hypoxia-inducible factor-1a (HIF-1a) and the aryl hydrocarbon receptor nuclear translocator (ARNT) heterodimeric complex. This binding site is essential for HIF-1 dependent and hypoxia-induced *EPO* expression. A second site lies only 7 bp 3′ of the HIF-1 binding site with the sequence CACA. Although no protein is known to bind to this sequence, mutating this site leads to loss of the hypoxia-inducible function of the enhancer. The third site is located 10 bp further downstream from the CACA site and consists of two consensus binding sites for steroid hormone receptor. Screening for nuclear hormone receptors capable of binding to this site led to the identification of HNF-4. Using Hep3B, a liver cell line capable of producing EPO in response to hypoxia, HNF-4 is shown to be required for the response to low oxygen levels. Introducing dominant negative HNF-4 into Hep3B cells abolished their ability to respond to hypoxia by inducing *EPO* expression. Moreover, like *EPO*, HNF-4 is also expressed in the renal cortex of the kidney and the liver.

The aforementioned *cis*-acting element in the 5′-promoter region also has a role in the response to hypoxia, maintaining a 10-fold induction in response to hypoxia in the absence of the 3′-enhancer. In the

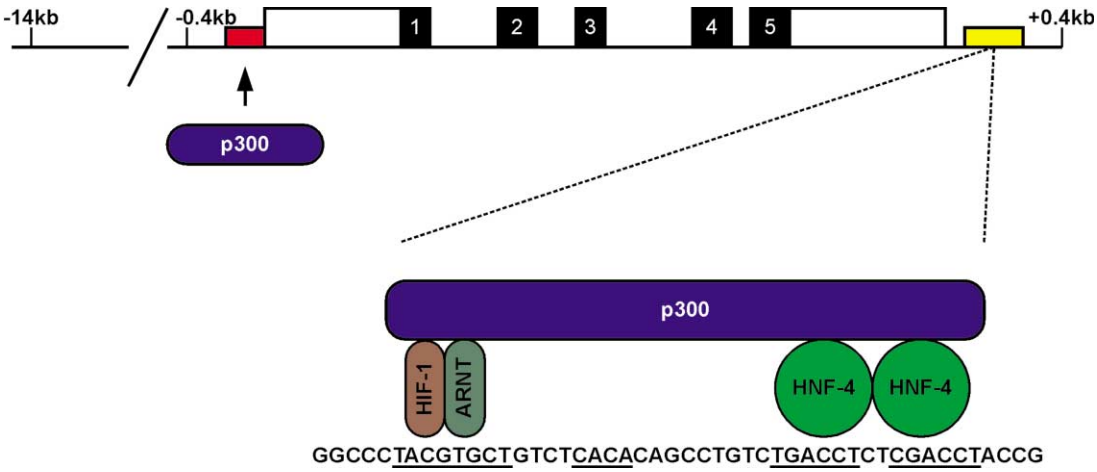

FIGURE 2 *EPO* gene regulation in adults. Coding regions of the five exons are shown in black. The 5′- and 3′-untranslated regions are shown as boxes. The 3′-enhancer (small box in upper right-hand side) is expanded. p300 is capable of binding and activating the minimal promoter (small box in upper left-hand side) and can act synergistically with the 3′-enhancer to increase *EPO* transcription in response to hypoxia. Consensus DNA sequences for hypoxia-inducible expression are underlined. Adapted from Ebert, B. L., and Bunn, H. F. Regulation of the erythropoietin gene. *Blood* 1999; 94: 1864–1877. Copyright American Society of Hematology. Used with permission.

presence of the 3′-enhancer, the 5′ *cis*- acting element synergistically activates *EPO* expression by 40-fold in response to hypoxia. Taken together, the 5′-promoter and 3′-enhancer of the *EPO* gene constitute a potent transcriptional control unit, which regulates EPO production in response to hypoxic conditions or anemic states.

IV. EPO AND EPOR: SIGNAL TRANSDUCTION

Given the thoroughness of our understanding of EPO signaling and the structural and functional similarities between members of the cytokine receptor superfamily, EPO signaling can serve as a model for understanding cytokine signal transduction in general. EPO signals through its cognate receptor, the EPOR, a protein expressed on the surface of appropriate target cells. Because the EPOR lacks any known catalytic function, it relies on the activity of associated Janus kinase 2 (JAK2). Upon EPO binding to dimerized EPORs, JAK2 molecules are brought into close proximity, phosphorylating and thereby activating one another. Activated JAK2 then phosphorylates individual tyrosine residues within the cytosolic region of EPOR, thereby creating docking sites for recruiting SH2 domain-containing signaling molecules, including (1) signal transducer and activator of transcription 5 (STAT5), molecules of which, once phosphorylated, dimerize and translocate into the nucleus, where they initiate transcription of target genes; and (2) the regulatory subunit of phosphatidylinositol 3-kinase (PI3K), which activates other downstream signaling molecules, such as serine/threonine kinase Akt; and (3) Grb2, an adapter molecule that mediates activation of the Ras-mitogen-activated protein kinase (MAPK) signaling pathway (Fig. 3). Ultimately, these and other signaling cascades produce alterations in the patterns of gene expression. Such "target genes" in erythrocytes include those involved in cellular proliferation (e.g., c-myc and c-fos) and survival (e.g., Bcl-X_L), as well as cell type-specific genes, such as those encoding globins (the protein component of hemoglobin), the transferrin receptor (which mediates entry of iron into cells), and certain membrane structural proteins (which contribute to the characteristic biconcave structure of erythrocytes).

Although it has long been presumed that cytokine signaling must be negatively regulated with respect to both duration and intensity, only in recent years has a better understanding of this process been achieved. To generate more precise control over cytokine signaling, several mechanisms of negative regulation exist. First of all, the hematopoietic protein tyrosine phosphatase SH-PTP1 (also called HCP and PTP1C) associates through its SH2 domain with a specific phosphotyrosine residue of the EPOR and is responsible for dephosphorylating and thus inactivating JAK2. In fact, mutating this tyrosine to phenylalanine renders cells that express the mutant receptor hyperresponsive to EPO stimulation.

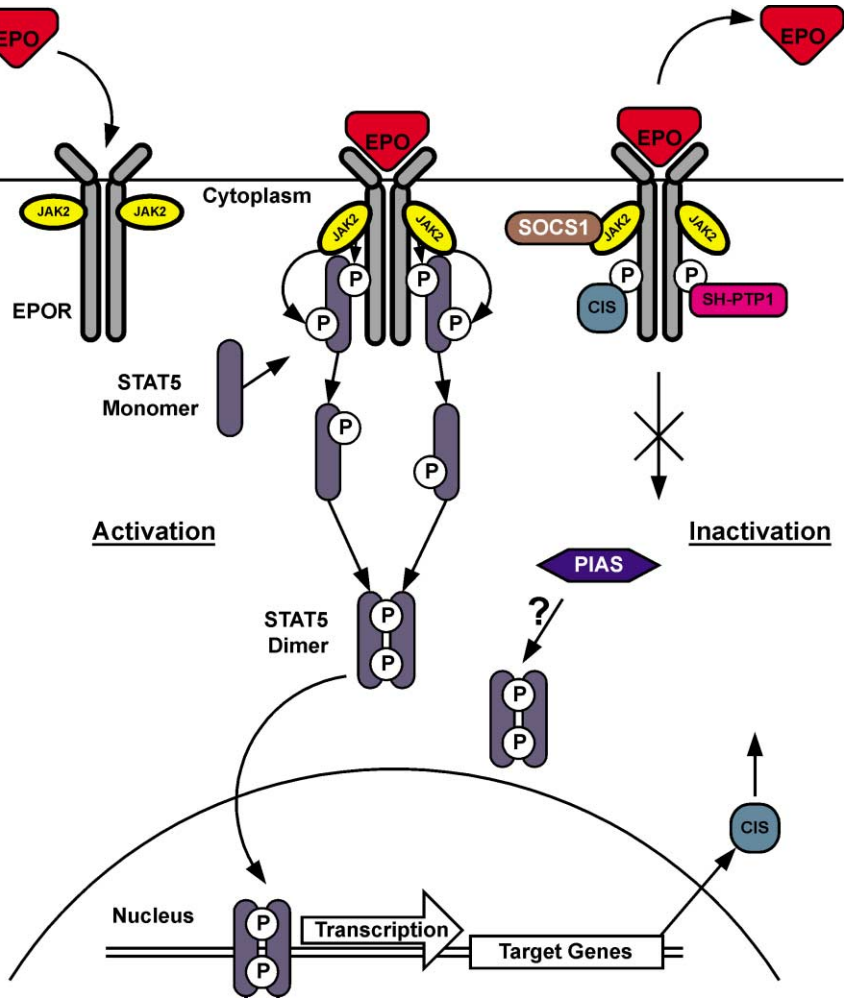

FIGURE 3 EPO/EPOR signal transduction. Activation: EPO binds the EPOR and activates JAK2. JAK2 then phosphorylates the tyrosine residues of the EPOR cytoplasmic tail, which provides a docking site for recruiting the SH2 domain-containing signaling molecules, such as STAT5. STAT5 is subsequently tyrosine phosphorylated, dimerizes, and translocates to the nucleus to activate the transcription of target genes. Inactivation of the receptor occurs through various means, including binding of the receptor and JAK2 molecule by various inhibitors, such as CIS and SOCS1, and dephosphorylation of JAK2 by SH-PTP1 phosphatase. It is unclear whether PIAS molecules participate in negative regulation of EPOR signaling by modulating the function of STAT5.

Naturally occurring variants of the human *EPOR* lacking the C-terminal negative regulatory domain, including this tyrosine residue, may give rise to familial erythrocytosis.

Also contributing to the attenuation of cytokine signaling are the protein families PIAS (protein inhibitors of activated STATs, with four mammalian family members identified) and SOCS (suppressor of cytokine signaling, with eight known mammalian family members). Although the role of PIAS family members in EPO signaling has not been addressed, multiple SOCS family members appear to counteract EPO signaling by acting on different targets. Whereas SOCS1 appears to bind to JAK2 to inhibit its activity, CIS, another SOCS family member, binds to the EPOR itself (1) to compete with STAT5 for binding to specific phosphotyrosine residues and (2) possibly to deliver active signaling complexes to the proteasome for degradation.

Finally, EPO signaling may be modulated by cell surface expression of the EPOR and EPO–EPOR complex internalization and degradation. The mechanisms controlling these events are poorly understood.

V. ANIMAL MODELS FOR EPO FUNCTION

Whereas biochemical analysis has helped identify key players involved in EPO signaling, genetic analysis, involving either the fruit fly, *Drosophila melanogaster*, or the house mouse, *Mus musculus*, has provided insight into their functional relevance. The hemolymph of insects is analogous to mammalian blood, in that it carries nutrients and cells involved in immunity. *D. melanogaster* does not need red blood cells as an oxygen carrier and sequencing information derived from the fly genome project shows no homologue to either *EPO* or *EPOR*. Nevertheless, signaling molecules known to be important for EPOR signaling do exist in the fly. In fact, gain-of-function mutations of the JAK homologue *hopscotch* lead to the overproliferation and premature differentiation of larval blood cells.

Although *D. melanogaster* permits powerful genetic analysis due to its low maintenance cost and short generation time, the mouse is physiologically more relevant to humans. A powerful technique for studying the role of a particular gene in mice is achieved through homologous recombination in embryonic stem cells. Mice lacking *EPO* or *EPOR* die with severe anemia at approximately embryonic day 13 (mouse gestation lasts for 18–21 days, depending on strain, diet, and other factors). Interestingly, *EPO* and *EPOR* are unnecessary for erythroid commitment, but instead are required for their terminal differentiation into mature red blood cells. Thus, as shown in Fig. 4, whereas normal fetal livers contain cells at various differentiation stages within the erythroid lineage, livers lacking *EPO* or *EPOR* are completely pale and fail to produce mature erythrocytes. Furthermore, "primitive" erythropoiesis, which occurs very early in development in the yolk sac compartment, appears to be intact in either knockout. This result would suggest that *EPO* and *EPOR* are necessary only for the production of adult-type or "definitive" red blood cells, which are generated at midgestation throughout adulthood. Finally, the fact that both deficient mouse strains exhibit very similar, if not identical, phenotypes suggests that only one receptor exists for EPO and that no other naturally occurring ligands or receptors can replace either protein.

JAK2-deficient mice are very reminiscent of *EPO*- and *EPOR*-deficient mice as they too die as embryos with anemia. However, the degree of anemia is greater in *JAK2* null mice, which is not surprising since JAK2 is implicated in signaling by many cytokines other than EPO, including thrombopoietin, interleukin-3, and granulocyte/macrophage-colony-stimulating

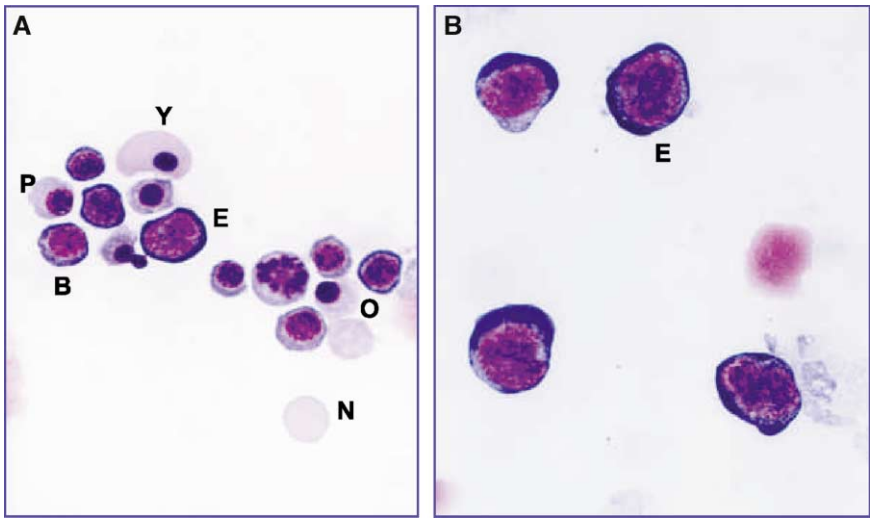

FIGURE 4 EPO is essential for the differentiation of erythroid progenitor cells in the fetal liver. Cytospin preparation of liver from a wild-type (A) and a homozygous mutant (B) liver stained with Giemsa. Numerous erythropoietic cells at all stages of differentiation are seen in the WT fetal liver, including proerythroblasts (E), basophilic erythroblasts (P), orthochromatic erythroblasts (O), and nonnucleated erythrocytes (N). Yolk sac-derived nucleated erythrocytes (Y) are also seen. In the mutant liver preparation, proerythroblasts are prominent with a noticeable absence of cells at later stages of differentiation. Reprinted from *Cell* 83, Wu, H., Liu, X., Jaenisch, R. and Losish, H. Generation of committed erythroid BFU-E and CFU-E progenitors does not require erythropoietin or the erythropoietin receptor. 56–67, 1995. With permission from Elsevier Science.

factor, all of which can positively regulate erythropoiesis although they are dispensable for steady-state erythropoiesis. Thus, *JAK2*, like *EPO* and *EPOR*, is both a critical and nonredundant player in erythropoiesis.

Among seven mammalian STAT family members, STAT5A and STAT5B have been implicated to be involved in EPO signaling based on *in vitro* experiments. However, disrupting either or both genes in mice does not result in erythropoietic defects similar to that in *EPO*, *EPOR*, or *JAK2* mutant mice, although deficiencies exist in signaling by other cytokines, namely, prolactin and growth hormone. Possible explanations for the relatively subtle effects of STAT5 on erythropoiesis *in vivo* include redundancy with other components of EPO signaling that are downstream of JAK2 (e.g., MAPK or PI3K) or possibly the existence of a hitherto unidentified STAT or STAT-related protein that plays a role in EPO signaling *in vivo*.

Members of the SOCS family have also been deleted in mice. Disruption of *SOCS3* results in erythrocytosis so severe that mice die during embryogenesis. In contrast, *SOCS3* overexpression results in a severe anemia, much like what is seen in the *EPO*-, *EPOR*-, or *JAK2*-deficient mice.

VI. CLINICAL APPLICATIONS

The pharmacological use of recombinant human EPO has been well established clinically in treating anemia associated with a variety of pathophysiological conditions. Anemia can be classified by hemoglobin (Hb) levels and subdivided into the following categories: mild (10–12 g/dl), moderate (8–10 g/dl), severe (6.5–7.9 g/dl), and life-threatening (<6.5 g/dl). Hb is contained mostly within erythrocytes, which function in binding, transporting, and delivering oxygen to the periphery. Loss of red blood cells results in a compensatory response by the body to maintain oxygen delivery to tissues. One such response is the induction of *EPO* expression, which subsequently results in an increase in red cell mass.

Anemia can present with a wide spectrum of symptoms involving virtually every organ system, including heart palpitations, pale and cold skin, dyspnea, headaches, dizziness, vertigo, decline in cognitive function, retinal damage, angina, heart failure, left ventricular hypertrophy, proteinuria, decreased libido, impotence, amenorrhea, irregular bowel movement, indigestion, malabsorption, tachypnea, pulmonary edema, generalized edema, and renal failure. Because of their many detrimental effects on quality of life, anemias can pose significant health problems.

Although they can result from a variety of causes, a large number of anemias in the clinical setting result from a decreased production of red cells. The most promising method in treating this type of anemia has been recombinant EPO. Recombinant human EPO (or Epoetin α) has been approved by the Food and Drug Administration for treatment of anemia associated with chronic renal failure. EPO has also proved to be beneficial for treatment of anemia associated with Zidovudine therapy for patients infected with human immunodeficiency virus, anemia associated with chemotherapy in cancer patients, and anemia associated with surgery. Recent studies have also suggested potential therapeutic uses for EPO in the treatment of disorders such as myelodysplastic syndrome, anemias of prematurity, and congestive heart failure.

Because of its relative safety and efficacy, athletes attempting to improve their oxygen-carrying capacity have frequently abused recombinant EPO. Given their similarity, recombinant EPO cannot be distinguished from endogenous EPO by currently available immunoassays. However, an electrophoresis method can distinguish endogenous EPO and synthetic EPO because of subtle discrepancies in posttranslational modifications that introduce charge differences between the EPO isoforms. In fact, when this technique was employed, urine samples of 28 of 102 tested cyclists of the 1998 Tour de France were found to have electrophoresis patterns indicative of recombinant EPO.

VII. EPO FUNCTION IN OTHER LINEAGES

The role of erythropoietin in stimulating red blood cell formation has been clearly defined. However, recent evidence suggests that EPO may have more diverse roles as well. For instance, *EPOR* expression has been detected in human umbilical cord and placental endothelial cell lines, and EPO was capable of stimulating endothelial cell proliferation *in vitro*. In addition, EPO is known to induce a pro-angiogenic phenotype in cultured endothelial cells and stimulated neovascularization in the chick chorioallantoic membrane. EPO also plays an important role in myoblast proliferation as well as in cardiac morphogenesis.

EPOR expression has also been found in PC12 cells (a cell line with neuronal-like properties), hippocampal and cortical neurons, and astrocytes. EPO-binding sites can be localized in both murine

and human fetal brains. Similar to EPO production in the kidney, endogenous EPO expression in neurons and astrocytes is controlled by oxygen-sensing mechanisms that involve the redox state of the brain. In animal models, EPO has been shown to protect neurons from glutamate-induced as well as ischemia-induced apoptotic cell death. Thus, research toward understanding all the *in vivo* functions of EPO can lead to new and improved therapeutic regimens and indications beyond the treatment of anemias.

VIII. SUMMARY

The study of EPO has gone from the concept that a hormone-like molecule exists and is capable of stimulating red blood cell formation to the cloning of the gene and its biochemical and molecular characterizations. Through decades of study on EPO, research that focused on its biological properties has led to the development of a highly successful therapeutic drug that has significantly improved the quality of human life. Further studies with elegant genetic animal models have proven its *in vivo* biological function, and the dissection of its signaling pathway has progressed to the level of not just exploring what EPO turns on but also what turns off the signal from the EPOR. In an attempt to improve on Mother Nature, researchers have begun to isolate small peptides or to identify small chemical molecules that can mimic EPO function by activating the EPOR. Even though an enormous amount of information has been generated, more remains to be learned, and researchers will strive to better understand the functions of this essential hormone in regulating red blood cell formation and its role in other lineages.

Glossary

anemia A significant reduction in red cell mass and a corresponding decrease in the oxygen-carrying capacity of the blood.

cytokine A member of a large family of secreted proteins, defined by structural similarities in their receptors, which regulate fundamental biological processes, such as hematopoiesis (the formation of blood cells), immunity, and wound healing.

enhancer A *cis*-acting sequence that increases the utilization of eukaryotic promoters and can function in either orientation and in any location (either upstream or downstream), relative to the promoter.

erythrocyte A mature red blood cell that circulates within the body to deliver oxygen to tissues and, in exchange, remove carbon dioxide and hydrogen ion from tissues.

erythrocytosis An abnormal increase in red blood cells in the circulating blood. This elevation is usually accompanied by corresponding increases in the quantity of hemoglobin and in the hematocrit.

glycosylation The conjugation of carbohydrate residues, which for proteins can occur through the side-chain oxygen atom of serine or threonine residues by O-glycosidic linkages or to the side-chain nitrogen of asparagine residues by N-glycosidic linkages.

hypoxia A condition in which oxygen tension is lower than the normal level.

kinase Any protein that catalyzes phosphorylation (the transfer of a phosphate group from a donor to a substrate molecule).

Erythropoietin, Genetics of

EUGENE GOLDWASSER
The University of Chicago

Erythropoietin is both a hormone and a growth factor. It fits the classical definition of a hormone being made in one organ, the mammalian kidney, being secreted into the bloodstream, and acting at another site, the blood-forming system, i.e., the bone marrow in adults. As a growth factor, it is required for red blood cell formation from more primitive cells of the hematopoietic system. In adult human beings, it regulates normal erythropoiesis, stimulating the production of approximately 2.5 million red cells per second.

I. HISTORY OF ERYTHROPOIETIN

The existence of erythropoietin (epo) was first suggested by Carnot and Deflandre in 1906. They described it (in current terminology) as a feedback regulator: when the number of red cells was below the normal setpoint, the mechanism to accelerate red cell formation was activated by secretion of epo; when the setpoint was regained, the mechanism was thought to turn off, keeping the number of red cells relatively constant. It is now known that normal red cell formation is regulated by continuous secretion of epo so that the formation of new red cells matches the loss of old cells. The system, however, can respond to a need for red cells, for example, due to blood loss or hypoxia, by increased secretion of epo and the consequent increased formation of red cells. The experimental evidence published by Carnot and Deflandre was neither convincing nor reproducible and for almost 50 years the question of whether they had demonstrated that there was such a substance was in serious doubt. Its existence is now unquestionable.

The contemporary era of epo research began with the purification of human urinary epo and, 8 years later, the cloning of its gene. These advancements set the stage for a great increase in research and publications on epo: in the period from 1906 to 1976, there was an average of 16 papers on the subject published per year; from 1976 to 2000, this number was 237 per year. Of course, the greater part of this increase was due to the advent of recombinant DNA technology, making it possible not only to clone the gene and study its expression, but to produce epo in cells engineered to carry the transgene, harvest epo, and purify it in industrial amounts for clinical use. Much of the increase in the number of publications was associated with molecular biology studies and clinical application.

II. THE ERYTHROPOIETIN GENE

The human epo gene is on chromosome 7 (7pter–q22) and is a 2144 bp stretch of DNA. The structural gene consists of four introns, comprising 1562 bp, and five exons, totaling 582 bp. There is an 81 bp sequence coding for a signal peptide immediately downstream of the ATG start site. For the sequence of the signal peptide, see Fig. 1. Upstream of the signal sequence there do not appear to be any canonical promoter sequences. Downstream of the termination site, there is an important sequence defining the enhancer, hypoxia-response element, coding for hypoxia-inducible factor-1. There is little if any homology between the epo gene and the sequences of other mammalian genes except for these regulatory elements in the 3′-flanking region.

III. THE ERYTHROPOIETIN PROTEIN

The amino acid sequence of human epo (Table 1) shows it to consist of approximately 34% hydrophobic amino acids. There is little significant homology between the amino acid sequence of human epo and that of any other human hormone, cytokine, or growth factor.

Asn-147 D helix	Leu-108 C helix
Arg-150 D helix	Arg-110 C helix
Gly-151 D helix	
Leu-155 D helix	

There are 166 codons in the gene but the circulating protein has only 165 amino acid residues; the C-terminal arginine is removed posttranscriptionally. There are two disulfide bonds, one linking cysteine 7 near the N-terminus with cysteine 161 near the C-terminus and the other linking residues 29 and 33. There are four glycosylation sites; three are N-linked at asparagine residues 23, 28, and 83. The fourth is an O-linked site at serine 126. The carbohydrate content of human epo is 30–40% depending on the source. Recombinant human epo has a molecular weight of 30.4 kDa by hydrodynamic measurements. As estimated by denaturing gel electrophoresis, its apparent molecular weight is 34–37 kDa. When size-exclusion chromatography (gel filtration) is used, the apparent molecular weight is approximately 60 kDa. These differences reflect the effect of the large amount of carbohydrate on the apparent molecular volume of the hormone.

Studies of the "active site" of human epo by chemical methods and by site-directed mutagenesis indicate that the following single amino acid residues are important for its biological activity: Val-11, Arg-14, Tyr-15, Arg-103, Ser-104, Leu-105, and Gly-151. The Cys-7 to Cys-161 disulfide bridge is also required for activity. These findings were verified by X-ray diffraction and solution of the three-dimensional structure of recombinant aglyco-epo complexed to the dimerized exo domain of its specific receptor. Aglyco-epo consists of a four-helix bundle with helices A and B plus B^1 in the up configuration and helices C, C^1, and D in the down configuration. The connecting loops have variable lengths: A–B has 20 residues, B–C has 7, and C–D has 16. Helices A and C are interrupted by small nonhelical regions (Table 2).

The dimerized receptor has asymmetric sites for binding its ligand. Site 1 on one of the monomers is a high-affinity site with a K_d of less than 1 nM. It interacts with residues on helices A, B^1, and D and part of the A–B loop. Site 2, with a K_d of approximately 1 μM, interacts with the A and C helices. The regions of epo involved in the more biologically important interactions with receptors, based on analysis of intermolecular contact areas, are summarized in Table 3.

The four branched oligosaccharide chains in naturally occurring recombinant epo all have multiple sialic acid termini and are clustered at the region of the molecule away from the region that interacts with the receptor. Structures of some of the oligosaccharides have been published. The carbohydrate is required for biological activity when tested *in vivo*, but for activity on cells in culture, the sugars are not required. The carbohydrate acts in the secretion process, stabilizes the hormone, increases its solubility in water, keeps it monomeric, and prevents rapid clearance from the circulation. Epo devoid of sialic acid termini has no activity *in vivo* because of its rapid uptake by a liver receptor that recognizes terminal galactose residues and removes the asialo-epo from

the circulation. The activity of asialo-epo *in vitro*, however, is greater than that of native epo and it binds to cellular receptors with a K_d approximately one-third that of sialylated epo. Whether of natural or recombinant origin, epo has a high degree of microheterogeneity; i.e., each glycosylated site has a number of different oligosaccharides associated with it.

A new epo derivative engineered to contain two additional N-linked oligosaccharide chains at amino acid positions 30 and 88 has been developed by recombinant methods. In comparison with native epo, it is more active, is more stable, and is cleared from the circulation with a half-time approximately three times greater than that for native epo containing four carbohydrate chains. Paradoxically, the new epo-like glycoprotein shows an inverse relationship between binding affinity and biological activity. Even though the affinity for the receptor seems to be decreased, the longer half-life results in greater biological activity *in vivo*.

There is ample evidence that epo action, prior to internalization, involves dimerization of the receptor. The studies cited above of the epo receptor–exo domain complex yielded information about the features of the epo molecule involved in the dimerization. Based on this information, peptides smaller than epo and nonpeptide mimetics of epo have been developed. Some of these are epo antagonists and others are agonists. Thus far, none of the epo agonists have proved to be as potent as natural epo in either *in vitro* or *in vivo* assays. The concept, however, is a valid one and it is likely that further research will result in the production of synthetic compounds capable of replacing epo as an inducer of red cell formation.

IV. SITE OF ORIGIN

Epo is normally formed by the adult mammalian kidney. Under an anemic or hypoxic stress, the system is capable of a several thousand-fold increase in synthesis and secretion. Under severe conditions, the adult liver is recruited to produce epo. Without such stimuli, the adult mammalian kidney secretes epo at a rate sufficient to maintain the steady state concentration in human plasma at approximately 5 pM (150 pg/ml). Early in fetal development, epo is made in the liver, which also contains epo-responsive cells. At around the time of birth, epo formation switches to the kidney, but the mechanism regulating this shift is unknown. The source of epo is still a point of experimental disagreement. One group of studies puts the source in the peritubular, interstitial cells of the renal cortex. Another group locates the source in renal tubular cells. Perhaps both are correct. Further experimentation is needed to resolve the question.

There is also some evidence showing epo and/or its mRNA to be present in some cells of the blood-forming system, suggesting that epo may have a role in some intracellular or autocrine processes in addition to its action as an inducer of red cell differentiation via external cellular receptors. Evidence is also accumulating for a role of epo and its receptor in neural tissue. Epo and the receptor are expressed in the brain as a result of hypoxic damage and appear to be involved in neuroprotection. This effect is probably not a function of its role in red cell formation, since any effect on the marrow would require days or weeks to result in increased red cell mass. The evidence suggests that epo can act on cell proliferation of some nonhematopoietic cells.

Epo is also made and regulated by hypoxia, in some transformed (notably hepatocarcinoma) that can be grown or studied *in vitro*. These systems have been greatly important in the study of epo gene expression.

V. ERYTHROPOIETIN GENE EXPRESSION

Whether by renal cells, brain cells, or some transformed cells (hepatocellular carcinoma), epo gene expression, primarily at the level of transcription, can be stimulated by hypoxia or by divalent metal cations, especially cobalt. The mechanisms by which these two different stimuli act on epo-producing cells may not be the same. This brief account will treat only the response to hypoxia.

In whole animals, the renal response is regulated by "available" oxygen; i.e., when the tissue's need for oxygen exceeds the capacity of the red cell mass to deliver oxygen, epo expression is accelerated. In kidney, the increase in epo expression is due to an increase in the number of cells with epo mRNA detectable by *in situ* hybridization rather than to an increase in epo mRNA per cell. In transformed cells, it is not yet clear which of the two possible alternatives is true. When oxygen supply is greater than the metabolic need for it, epo gene expression in whole animals is reduced. Despite the enormous effort devoted to identifying the nature of the intracellular element that can sense the level of ambient oxygen and compare it to the required oxygen level, the problem has not yet been solved.

The response to hypoxia in not limited to epo gene expression; several other genes are also activated by

reducing available oxygen, and the mechanism seems to be the same for all of them. Whatever the oxygen sensor may be in molecular terms, the transcription of hypoxia-responsive genes has a common early pathway. This pathway involves hypoxia-inducible factor-1 (HIF-1), which is a dimer of HIF-1α and the other subunit, HIF-1β, or aryl hydrocarbon receptor nuclear translocator (ARNT). HIF-1α under normoxic conditions is degraded very rapidly by the ubiquitin–proteasome pathway. The signal for HIF-1α ubiquitination is a specific hydroxylation of proline residue 564. Hydroxylated HIF-1α then binds to the tumor suppressor protein pVHL and is hydrolyzed. In the presence of oxygen levels that are lower than needed, HIF-1α is stabilized by complexing with HIF-1β and the heterodimer is translocated to the nucleus, where it acts as a transcriptional activator for a number of genes, including epo.

VI. CLINICAL APPLICATION

As might be expected from its source in the kidney, patients with chronic renal failure and those on dialysis are deficient in epo. This results in debilitating anemia, which now can be corrected by administration of human recombinant epo. The patients are then freed of the need for transfusions with all its attendant difficulties and have significantly improved lives. Anemias due to chemotherapy are also treatable with epo. It is also useful in building up a supply of blood to be used for autologous transfusions.

For much of the earlier research on epo, quantitative studies depended on assays *in vivo*. These methods were insensitive, lengthy, and expensive. When pure epo became generally available, assay methods based on the interaction of epo with highly specific antibodies were developed. Immuno-based assays are sensitive, rapid, and relatively inexpensive. Because of the potentially dangerous misuse of epo by athletes who try to build up their red cell mass prior to competition, newer methods capable of distinguishing between recombinant epo and natural, circulating epo would be very useful. Progress in developing such techniques is being made.

Glossary

aglyco-epo Erythropoietin containing no carbohydrate chains.

erythropoietin The hormone or growth factor that regulates red blood cell formation.

exon A coding sequence of DNA.

hypoxia A deficiency of oxygen reaching the body tissues.

intron Intervening segment of DNA separating sequences that code for proteins; introns carry no protein-coding information.

K_d Dissociation constant, generally applied to ligand-to-receptor binding.

kilodalton Unit of molecular weight.

Estrogen and Progesterone Receptors in Breast Cancer

TORSTEN A. HOPP AND SUZANNE A.W. FUQUA
Baylor College of Medicine

Breast cancer is a classical hormone-dependent neoplasm, and a large of body of epidemiological evidence suggests that increased hormonal exposure, such as early menarche, late menopause, postmenopausal obesity, and hormone replacement therapy, is associated with increased breast cancer risk.

I. INTRODUCTION

Common to the risk factors for breast cancer is the lifetime exposure of breast tissue to the ovarian hormones estrogen and progestin. On the other hand, these steroid hormones and their nuclear receptors, estrogen receptor-α (ER-α) and ER-β and progesterone receptor-A (PR-A) and PR-B, are essential for the proper development and maintenance of the mammary gland, and it is still uncertain how the receptors contribute to breast tumorigenesis.

The majority of breast cancers are at least initially hormone-dependent, and two-thirds of these tumors express ER-α and PR-A and/or PR-B. Expression of these hormone receptors is not only associated with a lower risk of relapse and prolonged overall survival, but is also a strong predictor for response to growth inhibition by anti-estrogens, such as tamoxifen. However, correlations between receptor content and response to anti-estrogen treatment are not perfect, and tumors often develop resistance to these treatment modalities. Even though both ER and PR measurements have been used for the clinical management of breast cancer for more than 20 years, the molecular mechanisms underlying how these receptor isoforms impact on tumor development and progression are still largely unclear. This article will relate the current knowledge about the role of ER and PR isoforms to breast cancer development, treatment, and progression.

II. NORMAL DEVELOPMENTAL PATTERN OF THE BREAST

The human breast is a highly dynamic organ comprising glandular tissue and surrounding stroma, both of which undergo cycles of proliferation, differentiation, and apoptosis during a female's lifetime. Growth usually occurs from the distal end of ducts at a club-shaped morphological structure, the terminal end bud, which bifurcates into two smaller but morphologically more developed ductules. The mammary gland is hierarchically organized with clusters of, on average, 11 ductules forming lobule type 1 (Lob1). Through a gradual process of new duct formation and continuous differentiation, Lob1 grows in size, resulting in lobule types 2 and 3, with the latter being the most differentiated structure, found mainly in premenopausal parous women. The mammary gland fully differentiates during pregnancy into lobule type 4. The proliferative activity of the breast depends on the degree of differentiation and is highest in the undifferentiated Lob1 present in young nulliparous women. Maximal proliferation occurs during the luteal phase when progesterone reaches its highest levels, not during the follicular phase when estrogen levels are highest.

Estrogens and their receptors, ER-α and ER-β, are considered to play a major role in promoting cell proliferation and ductal outgrowth in the mammary gland. Although there is a clear connection between estrogen and proliferation, ER-α-positive epithelial cells, which constitute only approximately 10–20% of the overall cell population in the normal breast, are not the cells that are actively dividing in the normal situation. Furthermore, recent studies have determined that the more widely expressed ER-β protein is expressed mostly in myoepithelial cells, ruling out the possibility that this receptor form is directly mediating proliferation in the normal breast. These observations have led to the current model of normal growth in the mammary gland where estrogen stimulates ER-positive cells to produce a growth factor that in turn results in proliferation of the neighboring ER-negative cells.

PR-A and PR-B expression is observed mostly in cells that also contain ER-α and is often viewed as a downstream marker for the proper functioning of ER-α. However, mice depleted of PR demonstrate that this hormone receptor functions in mammary gland development in a manner clearly different from that of the ER. These knockout mice show that PR is essential for lobulo-alveolar development but not ductal morphogenesis. Unlike ER-α and ER-β, PR-A and PR-B are co-expressed at similar levels within the same epithelial cells in the normal breast.

Although expression of ER-α and PR-A and PR-B in the normal breast is directly proportional to the rate of cell proliferation, only a very few epithelial cells expressing the hormone receptors progress through the cell cycle, as determined by the lack of markers associated with proliferation, such as Ki67 and cyclin D1 in proliferating cells. However, the indirect regulation of proliferation by estrogens and progestins seen in normal breast tissues is dramatically altered during tumorigenesis, when ER and PR are frequently found in the proliferating cells and thus are directly related to cell proliferation.

III. ER IN BREAST CANCER DEVELOPMENT AND PROGRESSION

Epidemiological studies suggest that invasive breast cancers arise from a series of putative precursor lesions, including typical ductal hyperplasia, atypical ductal hyperplasia, and ductal carcinoma *in situ*. Women with these lesions show approximately 2-, 4-, and 10-fold increased relative risk, respectively, of later developing invasive breast cancer. Moreover, it has been shown that these proliferative, premalignant lesions share their loss of heterozygosity pattern with more advanced lesions from the same breast, suggesting that invasive breast tumors indeed arise from these premalignant precursors.

Since premalignant lesions in the breast are most often characterized by elevated ER-α expression as well as intense proliferation, it has been hypothesized in several epidemiological studies that these ER-expressing premaligant lesions have a selective growth advantage in the presence of estrogen and may play a role in the progression of these premalignant lesions to cancer. ER-β expression appears to be inverse to ER-α expression. ER-β expression is lower in these premalignant precursors than in normal epithelium, leading some researchers to suggest that ER-β may play a "suppressor" role in malignant progression, although there are limited data to support this view.

IV. ER AS A PROGNOSTIC AND PREDICTIVE FACTOR IN BREAST CANCER

ER-α status as determined by ligand-binding assays, and more lately using immunohistochemistry, is one of only a few biological markers that are used to make treatment decisions in breast cancer. It is now well established that almost 70% of tumors in women contain ER-α, with older women being more likely to have ER-α-positive tumors. Furthermore, the presence of ER-α often correlates with low S-phase fraction, diploidy, well-differentiated histology, and the absence of mutations or amplification of oncogenes, such as p53, HER-2/neu, and epidermal growth factor receptor. For reasons that are currently unknown, metastases of ER-α-positive tumors are more likely to spread to soft tissue, bone, or reproductive organs, whereas metastases of ER-α-negative tumors tend to be commonly found in brain and liver. In addition, several clinical studies with long-term follow-up have established that patients with ER-α-positive tumors have a lower risk of developing a recurrence within 5 years than patients with ER-α-negative tumors. However, in studies with follow-up periods of longer than 5 years, the prognostic relevance of ER disappears, and patients with ER-positive tumors are as likely to relapse as patients with ER-negative tumors. The time-dependence of ER-α as a prognostic marker is not yet understood. Thus, ER is now thought to be a weak prognostic factor of the natural history of breast.

On the other hand, ER is a strong predictor for the likelihood of response to endocrine therapies such as estrogens, anti-estrogens, surgical and medical ovariectomy, aromatase inhibitors, or progesterones. Specifically, numerous large clinical studies over the past 30 years have revealed that approximately 60% of previously untreated patients with advanced, ER-positive tumors will receive benefit from treatment with the anti-estrogen tamoxifen, with low response rates of 5–10% in women with ER-negative breast cancer. It has also been observed that the higher the ER content (>100 fmol/mg protein as determined by ligand-binding assay) in breast tumors, the better the response rate to hormonal treatment. A major clinical use of the ER assay in breast cancer is to identify a group of patients who have little or no chance of benefiting from anti-estrogen treatment and who thus should receive other, more aggressive treatment

modalities. In addition to its use as a predictive marker for the likelihood of response to first-line hormonal therapy, ER status is important in predicting benefit from subsequent hormonal treatment, but response rates of relapsing ER-positive patients are considerably lower than those for previously untreated patients.

V. ER IN BREAST CANCER PREVENTION

Even though breast cancer treatment is successful in prolonging the survival of women afflicted by this malignancy, there are still more than 180,000 women newly diagnosed with breast cancer yearly in the United States alone. This represents a major public health issue, and research efforts are increasingly being focused on preventing breast cancer. Since ER-α levels are most often high in premalignant as well as malignant lesions of the breast, this receptor and its signaling pathway provide a rational target for prevention treatment strategies.

One of the first large-scale randomized clinical trials to test the effect of an anti-estrogen (tamoxifen) on breast cancer prevention was the NSABP P1 breast cancer trial, which enrolled more than 13,000 healthy women at high risk of developing this malignancy. This trial reported a 49% reduction in the incidence of invasive breast cancer in women taking tamoxifen for 5 years. Another anti-estrogen, raloxifene, which was originally developed for the treatment of osteoporosis and clinically tested in the Multiple Outcomes of Raloxifene Evaluation trial on more than 7500 postmenopausal women, also decreased the risk of invasive breast cancer in treated women. However, treatment with tamoxifen or raloxifene increased the relative risk of developing thromboembolic disease, but only tamoxifen treatment resulted in a significant increase in endometrial cancers. In 1999, a clinical trial, the Study of Tamoxifen and Raloxifene, was designed to directly compare both anti-estrogens in the prevention of breast cancer; results are anticipated to be released in 2006.

VI. ER VARIANTS IN BREAST CANCER

Both of the ER genes undergo excessive alternative splicing in normal and neoplastic estrogen-responsive tissues. Alternative splicing results in ER-α and ER-β mRNA variants with single or multiple exons being skipped, and these variants are usually co-expressed along with the wild-type receptors. It is still unclear whether any of the ER splicing variants are expressed at the protein level and to what extent the formation of heterodimers of these splice variants with ER-α and ER-β perturb the ER signaling pathway. In addition, very little is currently known about different ER-β splice variants, so this section will focus on four relatively commonly ER-α splice variants.

The most frequently observed ER-α mRNA splice variants are those lacking either exon 4 or exon 7. Deletion of exon 4 results in the removal of parts of the DNA-binding and hinge domains, as well as the amino-terminal region of the ligand-binding domain, whereas deletion of exon 7 removes part of the hormone-binding domain including the hormone-dependent transcriptional activation function AF-2. Both receptor splice variants act as dominant-negative inhibitors of normal ER-α function in a cell type-specific manner. Furthermore, expression of the exon 4-deleted variant in breast tumors has shown significant positive correlation with high histological grade and PR-positive levels, both of which are markers for good clinical outcomes in breast cancers.

Another dominant-negative inhibitor of normal ER-α function is the exon 3-deleted mRNA splice variant, which is missing part of the DNA-binding domain. This receptor variant is found in both normal and primary breast cancers, but the ratio of wild-type ER-α to the exon 3-deleted variant is approximately 30-fold reduced in breast cancer and breast cancer cell lines compared to normal tissue. Furthermore, stable expression of this variant in MCF-7 breast cancer cells reduced the expression of ER-regulated genes and also reduced invasiveness and estrogen-stimulated anchorage-independent growth. The reduced expression of the exon 3-deleted variant in breast cancer supports the emerging concept that the expression of ER-α mRNA splice variants is altered and may possibly play a role in tumorigenesis.

One of the best studied mRNA splice variants is the exon 5-deleted variant, which is also the only one demonstrated to be stably translated into protein in breast cancer cell lines and breast tumors. The variant encodes a truncated 40 kDa protein that lacks most of the ligand-binding domain but still contains the AF-1 transactivation function and the DNA-binding domain and demonstrates variable strengths of ligand-independent transcriptional activity. This variant was first detected in ER-negative/PR-positive tumors, and it was recently shown that expression of this variant is significantly increased in ER-positive breast cancers from relapsing patients.

In contrast to the abundant expression of ER-α mRNA splice variants in both normal and neoplastic tissue, mutations of the ER-α gene have not been

frequently reported in primary breast cancer. Polymorphisms and missense mutations of the ER-α gene have been found in primary and metastatic breast cancers, but these changes do not appear to correlate with clinical parameters, such as tumor size or tumor histology. In addition, mutations in the receptor that potentially affect its normal function and that might alter the downstream estrogen signaling pathway have been demonstrated; an example is the ER-α mutant with a tyrosine to asparagine substitution at amino acid 537. This mutant receptor was isolated from a metastatic breast cancer, and it exhibits a potent, estradiol-independent transcriptional activity that is only weakly affected by estrogens and antiestrogens. Tyrosine 537 in ER-α is a phosphorylated residue, and its phosphorylation may be required for efficient estrogen binding. The substitution of the tyrosine residue with an asparagine may produce a conformational change in ER-α that mimics hormone binding, resulting in constitutive receptor co-activator binding. Further work is required to determine whether other metastatic lesions contain this mutation.

It has also been discovered that ~30% of premalignant breast lesions contain a somatic mutation in ER-α that results in the replacement of lysine 303 with an arginine (K303R ER-α); this mutation confers an increased sensitivity to estrogen and causes cells to maximally proliferate in response to very low levels of estrogen. Thus, the presence of this hypersensitive mutation in many premalignant lesions with high levels of ER-α expression may serve to promote progression to cancer. The K303R ER-α mutation is thus a gain-of-function change, and interestingly, it occurs at the major acetylation site of the receptor. Similarly, mutations in the β-catenin protein acetylation site are frequent in cancers and represent a gain-of-function alteration, suggesting an important role for acetylation in key regulatory proteins.

VII. PR IN BREAST CANCER DEVELOPMENT AND PROGRESSION

The PR is a positively regulated estrogen-responsive gene, and its expression is thought to indicate that functional ER is present. However, it is becoming increasingly clear that PR has its own clinical and biological significance in breast cancer. Much of the current understanding of the expression of the two PR isoforms comes from studies using rodent mammary glands, in which PR-A predominates over PR-B at a ratio of 3:1. Since PR-A and PR-B possess different and sometimes opposing transcriptional activities, it is believed that the regulated expression of both receptors is critical for appropriate mammary responsiveness to progesterone. Indeed, in transgenic mice expressing additional PR-A, mammary gland development is characterized by excessive lateral ductal branching, whereas transgenic mice expressing additional PR-B show inappropriate alveolar growth. Clearly, these observations show that the balance of the two receptor isoforms is critical in the control of progesterone responses in normal breast tissue.

Unlike the rodent mammary gland, normal human breast co-expresses PR-A and PR-B at similar levels within the same cells throughout the menstrual cycle. It is thought that coordinate expression of PR-A and PR-B may be required for normal progesterone response of the mammary gland and that changes in this ratio occur early in tumorigenesis. Indeed, one recent study showed that loss of coordinate receptor isoform expression is found in 30% of ADH and more than 50% of DCIS and IBC. In addition, several *in vitro* and *in vivo* studies have shown that overexpression of PR-A is associated with the loss of adherent properties in T47D breast cancer cells and disruption of the basement membrane in the mouse mammary gland—both properties of cells with increased invasive potential. In contrast, PR-B overexpression results in premature growth arrest in the mouse mammary gland, suggesting that this receptor isoform might be involved in the down-regulation of cell growth. These data clearly demonstrate that coordinate expression of the PR isoforms is crucial for normal development and that an imbalance in their expression patterns can alter normal growth in the breast.

VIII. PR AS A PROGNOSTIC AND PREDICTIVE FACTOR IN BREAST CANCER

In breast tumor samples, PR (as measured by ligand-binding assay) has many of the same prognostic and predictive implications as ER. Approximately 50% of primary breast tumors are positive for both PR and ER, whereas only 4% are negative for ER but still positive for PR. In addition, well-differentiated tumors are more likely to be PR-positive than are poorly differentiated tumors. Several clinical studies have confirmed that elevated PR levels correlate with an increased probability of response to tamoxifen, longer time to treatment failure, and longer overall survival.

The classical methods for determining PR levels in clinical samples are various ligand-binding assays as well as receptor antibody-based assays such as immunohistochemistry. However, these assays cannot differentiate between the two PR isoforms, so that information about the expression and the potential separate roles of these two receptors as prognostic and/or predictive factors is lost. Only two papers have examined PR-A and PR-B levels in small datasets showing that expression of the PR isoforms is very heterogeneous. In addition, high PR-A levels have been associated with a less differentiated tumor phenotype. More studies examining the two forms separately are needed for definitive conclusions to be drawn.

IX. CONCLUSIONS

Normal mammary cells contain a small but distinct population of ductal epithelial cells expressing ER and PR, and these hormone receptor expression patterns are significantly altered during breast carcinogenesis. Much of the breast cancer research in the past 30 years has focused on ER-α, but recently it has become clear that PR is not just a marker for a functional ER signaling pathway, but has its own role in breast cancer development and progression. Furthermore, ER and PR status is routinely used in the clinic to make treatment decisions. Receptor levels are only very weak prognostic indicators, and receptor-positive patients have a better outcome during the first 5 years of treatment. However, ER and PR status is most important in predicting benefit from hormone therapy. The role of different ER somatic mutations such as the K303R ER-α mutation or the role of ER-β in clinical applications is the subject of continued study.

Glossary

anti-estrogens Drugs such as tamoxifen and raloxifene that bind to the estrogen receptor and inhibit transcriptional activation of estrogen-regulated genes; they are commonly used for the treatment and prevention of breast cancer.

breast cancer A hormone-dependent neoplasm that is commonly derived from epithelial cells lining the terminal duct lobular unit of the mammary gland.

estrogen receptor Nuclear transcription factor that binds the steroid hormone estrogen and modulates estrogen-mediated transcription of hormone-regulated genes such as PS2 and cyclin D1.

progesterone receptor Nuclear transcription factor that binds the steroid hormone progesterone and modulates progesterone-mediated transcription of hormone-regulated genes such as STAT5A.

Estrogen and Spermatogenesis

LIZA O'DONNELL

Prince Henry's Institute of Medical Research, Clayton, Victoria, Australia

Male fertility is dependent on sperm production, the process of spermatogenesis. Although this process is well known to be regulated by gonadotropins and androgens, it is now apparent that spermatogenesis and male fertility are dependent on estrogen action and can be disrupted by inappropriate exposure to estrogenic substances.

I. INTRODUCTION

Although androgens are considered "male" hormones and are produced in high concentrations by the testis, it is well known that the testis has the capacity to synthesize estrogen from testosterone in a reaction catalyzed by the aromatase enzyme. The testis also has the capacity to respond to estrogens because estrogen receptors (ERs) are present within the various cell types of the testis, although the cellular distribution of ER subtypes is still somewhat unclear.

It has been known for many years that administration of estradiol, usually in supraphysiological doses, or of potent estrogenic ligands, such as diethyl stilbestrol (DES), has deleterious effects on male fertility in rodent models. Such models of exogenous estrogen administration have been important for identifying sites in spermatogenesis that are responsive to estrogen, and provide support to the proposition that inappropriate exposure to environmental estrogens may harm male fertility. This proposition has received considerable interest due to reported decreases in sperm counts in humans over the past 50 years, although there is controversy as to the whether sperm counts have actually declined and whether exposure of humans to the relatively low levels of estrogens in the environment would cause significant health problems.

Definitive evidence of a physiological role for estrogen in spermatogenesis and male fertility, and of the key sites that are estrogen-dependent, has only recently been revealed by transgenic mouse models, in which either the ability to produce or to respond to estrogen is impaired. The characterization of defects to the process of spermatogenesis in these mouse models provides valuable clues as to where and how estrogen acts in the male reproductive system. The fact that estrogen overexposure or deficiency impairs sperm production and male fertility, together with the demonstration of estrogen production and action within the testis and epididymis, suggests that estrogen can now be considered a hormone important for spermatogenesis and for male fertility.

Male fertility is dependent on sperm production, the process of spermatogenesis. Although this process is well known to be regulated by gonadotropins and androgens, it is now apparent that spermatogenesis and male fertility are dependent on estrogen action and can be disrupted by inappropriate exposure to estrogenic substances.

I. INTRODUCTION

Although androgens are considered "male" hormones and are produced in high concentrations by the testis, it is well known that the testis has the capacity to synthesize estrogen from testosterone in a reaction catalyzed by the aromatase enzyme. The testis also has the capacity to respond to estrogens because estrogen receptors (ERs) are present within the various cell types of the testis, although the cellular distribution of ER subtypes is still somewhat unclear.

It has been known for many years that administration of estradiol, usually in supraphysiological doses, or of potent estrogenic ligands, such as diethyl stilbestrol (DES), has deleterious effects on male fertility in rodent models. Such models of exogenous estrogen administration have been important for identifying sites in spermatogenesis that are responsive to estrogen, and provide support to the proposition that inappropriate exposure to environmental estrogens may harm male fertility. This proposition has received considerable interest due to reported decreases in sperm counts in humans over the past 50 years, although there is controversy as to the whether sperm counts have actually declined and whether exposure of humans to the relatively low levels of estrogens in the environment would cause significant health problems.

Definitive evidence of a physiological role for estrogen in spermatogenesis and male fertility, and of the key sites that are estrogen-dependent, has only recently been revealed by transgenic mouse models, in which either the ability to produce or to respond to estrogen is impaired. The characterization of defects to the process of spermatogenesis in these mouse models provides valuable clues as to where and how estrogen acts in the male reproductive system. The fact that estrogen overexposure or deficiency impairs sperm production and male fertility, together with the demonstration of estrogen production and action within the testis and epididymis, suggests that estrogen can now be considered a hormone important for spermatogenesis and for male fertility.

II. BRIEF OVERVIEW OF SPERMATOGENESIS

A. Germ Cell Development

Spermatogenesis is the process of male germ cell development. Immature spermatogonia within the testis proliferate and differentiate to form meiotic spermatocytes in which DNA replication and pairing

of homologous chromosomes occur. Spermatocytes then undergo two meiotic divisions to yield haploid, round spermatids. Round spermatids differentiate, with no further division, into highly specialized mature, elongated spermatids in a process known as spermiogenesis, in which acrosome formation, DNA compaction, nuclear shaping, flagellum formation, and cytoplasm condensation and elimination occur. The mature spermatid is then released from the epithelium prior to its passage to the epididymis. The full fertilizing potential of the released spermatozoan is achieved during the progression and maturation of sperm through the excurrent duct system (efferent ductules) and epididymis.

B. Organization of the Testis

Spermatogenesis takes place within the seminiferous tubules of the testis. The series of convoluted tubules end in a "reservoir" known as the rete testis. Sperm exit the testis via the rete testis, which is connected to a series of extratesticular ductules, known as the efferent ductules, that connect the rete testis to the initial segment at the head of the epididymis. The efferent ductules resorb a majority of the fluid arising from the seminiferous tubules so that spermatozoa become concentrated as they enter the epididymis, thus ensuring that a large number of spermatozoa are released on ejaculation. Sperm then traverse the ducts of the initial segment, caput, corpus, and cauda epididymis during their final maturation phase, attaining motility.

Germ cells are supported and nurtured during their development in the seminiferous tubules by the somatic Sertoli cells. These morphologically complex epithelial cells have an extensive cytoplasm with numerous cup-shaped processes encompassing the various germ cell types. Sertoli cells reside on a basement membrane, under which are the lymphatic endothelium and the peritubular myoid cells, which surround the seminiferous tubules. The interstitial space between the seminiferous tubules contains the steroidogenic Leydig cells, which are primarily responsible for androgen production, and the blood and lymphatic vessels, which are essential for the movement of hormones and nutrients into and out of the testis.

C. Regulation of Spermatogenesis

Germ cell development relies on a highly coordinated interaction with the Sertoli cell, involving communication either directly via ligand/receptor-mediated interactions or via the release of paracrine factors. Spermatogenesis is absolutely dependent on gonadotropins and androgens. Luteinizing hormone (LH) from the pituitary acts on receptors within Leydig cells to stimulate the production of testosterone, which in turn acts on androgen receptors within Sertoli cells to promote spermatogenesis. Follicle-stimulating hormone (FSH) is not essential for spermatogenesis, although quantitatively normal sperm production and function require the action of FSH. Sertoli cells contain receptors for both androgen and FSH but germ cells apparently do not; thus the Sertoli cell receives endocrine signals from the interstitium and circulation and subsequently synthesizes factors that modulate germ cell development. Leydig and Sertoli cells can also be considered endocrine cells because they produce hormones that are secreted into the circulation and act on other tissues; Leydig cells secrete into the circulation high concentrations of testosterone, which has a negative feedback effect on pituitary gonadotropin secretion, whereas Sertoli cells produce hormones such as inhibin and activin, which regulate pituitary FSH release.

III. BIOSYNTHESIS AND ACTION OF ESTROGEN—GENERAL CONSIDERATIONS

A. Biosynthesis

The biosynthesis of estrogen from testosterone is catalyzed, in an irreversible reaction, by a microsomal member of the cytochrome P450 superfamily, namely, aromatase cytochrome P450 (P450arom, the product of the *CYP19* gene). This heme protein is responsible for binding the C_{19} androgenic steroid substrate and catalyzing the series of reactions leading to formation of the phenolic A ring characteristic of estrogens. The reducing equivalents for this reaction are supplied from NADPH via a ubiquitous microsomal flavoprotein, NADPH-cytochrome P450 reductase. Aromatase P450 is found in many tissues, including the testis, and is regulated in a cell- and tissue-specific manner via the use of alternative promoters and alternative exons I, which are spliced into the 5′-untranslated region of the aromatase transcript in a tissue-specific fashion.

B. Action

Estrogen receptors are members of the ligand-activated nuclear receptor family, which includes receptors for other steroid hormones. The first ER gene (encoding ERα) was cloned in the 1980s and for

several years it was thought that only one form of ER existed. However a second ER gene (encoding ERβ) was cloned in the mid-1990s. Both receptors have a high affinity for estradiol but exhibit various functional differences, including different affinities for other estrogenic ligands as well as cell and tissue specificity. The distinct properties exhibited by ERα and ERβ have been exploited for therapeutic use by the development of selective estrogen receptor modulators (SERMs). Estrogenic ligands can act on their receptors in a classic steroid receptor pathway involving ligand binding, receptor activation and dimerization (homo- or heterodimers), nuclear translocation and the subsequent binding of the ligand-receptor complex to estrogen-responsive elements within the promoter regions of target genes, recruitment of cofactors, and regulation of transcription. Ligand-bound ERs can also modulate transcription independently of direct DNA binding, by binding to proteins within a preformed transcriptional complex. Ligand-independent transcriptional activation of ERs by various growth factors, for example, is also possible.

Estrogen can also act in a nongenomic fashion, inducing rapid (within seconds to minutes) increases in the concentration of calcium or cyclic adenosine monophosphate (cAMP) second messengers, presumably via receptors on the plasma membrane. These receptors appear to be related to classic ERs in some, but not all, cases. There is also evidence to show that rapid plasma membrane-dependent actions of estrogen act in concert with the classic ER-mediated genomic pathway.

IV. AROMATASE AND ESTROGEN RECEPTORS IN THE TESTIS AND EPIDIDYMIS

It has been known for decades that the testis can produce estrogen, and the concentration of estrogen in the testis and rete testis fluid far exceeds circulating levels. The particular cell types within the testis that can produce and/or respond to estrogen (Fig. 1) has received considerable attention in recent years due to the increased interest in estrogen's role in male fertility.

A. Aromatase

Aromatase is found in the testis from the fetal stage to adulthood. During pubertal development, when germ cell development is in the early stages, aromatase expression is thought to be primarily in the Sertoli and Leydig cells. Estrogen production by Sertoli cells

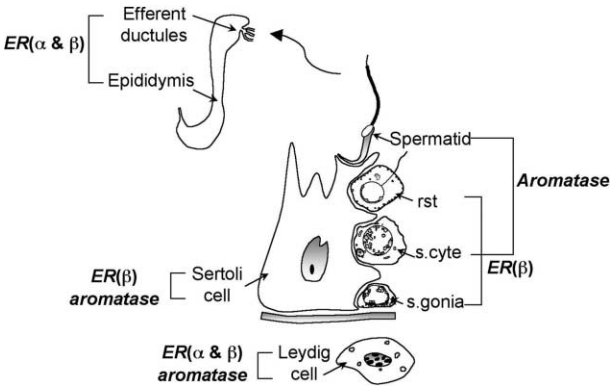

FIGURE 1 Diagram of the likely cellular localization of aromatase and estrogen receptors (ERs) in the testis. Efferent ductules and epididymis are also shown because these tissues are regulated by estrogen and have an impact on spermatogenesis. The likely ER subtype (α or β) is shown in parentheses, although controversy still exists as to the exact subtype present in each cell population. Abbreviations: rst, round spermatid; s.cyte, spermatocyte; s.gonia, spermatogonia.

is particularly high during the brief postnatal period of Sertoli cell division and is stimulated by FSH. In the adult testis, the Leydig cells express a high level of aromatase, but Sertoli cell expression has markedly decreased. Germ cells, which are the predominant cell type in the adult testis, are now known to express aromatase and synthesize estrogen. Along with Leydig cells, germ cells are a primary source of estrogen in the adult testis.

The ability of germ cells to produce estrogen is first apparent in the meiotic pachytene spermatocyte phase, when the expression of aromatase is first detected. Postmeiotic round spermatids also express aromatase and produce estrogen. The capacity to produce estrogen is retained throughout spermatid elongation and although most of the cytoplasm of the spermatid is shed prior to its release from the seminiferous epithelium, there is evidence to suggest that the remaining portion of cytoplasm, the cytoplasmic droplet that is attached to the flagella, can synthesize estrogen. The production of estrogen by germ cells and mature sperm has been hypothesized to be the reason why rete testis fluid in many species contains high concentrations of estrogen.

B. Estrogen Receptors

Leydig cells, Sertoli cells, and germ cells have the capacity to respond to estrogen by the expression of ERs. Thus actions of estrogen in the testis can conceivably be endocrine, paracrine, or autocrine. There is controversy to date as to the cellular

localization of the estrogen receptor subtypes within the testis, and a considerable amount of conflicting data. There is good evidence for both ERα and ERβ in the Leydig cells from various species and thus it seems likely that this cell type is capable of estrogen action via ERα- and ERβ-mediated actions. There are numerous reports of ERβ in Sertoli cells, but only limited studies demonstrating ERα. This also seems to be the case in germ cells, with numerous descriptions of ERβ, but more limited evidence for ERα in the various germ cell populations. The cell-specific expression of ER in the various germ cell populations is controversial, but there is good evidence in various species for ERβ expression in spermatogonia, some spermatocytes, and some spermatids.

Another important consideration is ER expression by the efferent ductules and epididymis, because these tissues are a target for estrogen action. ERα expression is particularly high in efferent ductules of rodents, but ERβ is also present in various cell types. Localization of ER subtypes within the various cells of the epididymis is again controversial, although it is likely that this tissue contains both subtypes.

V. EFFECTS OF ESTROGEN ADMINISTRATION ON SPERMATOGENESIS—IDENTIFICATION OF ESTROGEN-RESPONSIVE SITES

Experiments involving exogenous estrogen administration, usually to rodents, have been important for identifying the cells and processes in spermatogenesis (Table 1) that are responsive to estrogen.

A. Hypothalamo–Pituitary–Testis Axis

Initiation of spermatogenesis during neonatal development and maintenance during adulthood require the secretion of gonadotropins from the pituitary and thus are dependent on the balance of the hypothalamo–pituitary–testis axis. A major component of the negative feedback action of androgens on gonadotropin secretion is mediated via aromatization to estrogen. Administration of supraphysiological doses of estrogen during neonatal development or adulthood therefore suppresses gonadotropin secretion, leading to a secondary impairment of spermatogenesis. Neonatal estrogen exposure can have long-term effects on the hypothalamo–pituitary–testis axis and can permanently impair testicular function, as demonstrated in rodent models.

B. Testicular Descent

Testicular descent is also sensitive to estrogen, because exposure to high levels of estrogens *in utero* causes cryptorchidism (failure of testicular descent) in rodents, and perhaps in humans. The mechanism of estrogen action on testicular descent may be in part dependent on the regulation of the insulin-3 (*Insl3*) gene in fetal Leydig cells, because this gene appears to be down-regulated by estrogen overexposure and transgenic mice lacking this gene are cryptorchid.

C. Leydig Cells

Leydig cell precursors undergo rapid proliferation early in postnatal development and then differentiate into adult-type Leydig cells. Neonatal estrogen exposure can interfere with Leydig cell development and proliferation during puberty, perhaps causing permanent changes to Leydig cell function. Estrogen administration *in vivo* or *in vitro* appears to inhibit Leydig cell steroidogenic enzymes and decrease androgen production.

TABLE 1 Summary of Proposed Roles of Estrogen in Spermatogenesis Utilizing Estrogen Administration Models and Transgenic Mice

Model	Administration[a]	Deficiency[b]
Leydig cells	Interferes with proliferation, differentiation, and function	Hyperplasia in ArKO mice
Sertoli cells	Impairs maturation	Reduced fluid secretion by tubules in ERαKO
Germ cells	Promotes proliferation and survival *in vitro*	Apoptosis in ArKO; defects in ERαKO a consequence of efferent ductule dysfunction
Efferent ductules[c]	Impairs development and function	Impaired development and function in ERαKO
Epididymis[c]	Impairs development	Various morphological abnormalities in ERαKO

[a]Exposure to physiological or supraphysiological estrogen or estrogenic ligands *in vivo* or *in vitro*.
[b]Congenital deficiency due to targeted disruption of ER or aromatase.
[c]These tissues have been included because their function is important for normal sperm function, and efferent ductule dysfunction has a secondary impact on spermatogenesis.

D. Sertoli Cells

In rodents, Sertoli cells proliferate during the late fetal and early postnatal periods. This period of Sertoli cell proliferation, and the postproliferative differentiation and maturation of these cells, are essential for the full spermatogenic potential of the adult. The fact that proliferative Sertoli cells secrete high levels of estrogen, but nonproliferative Sertoli cells have decreased estrogen production, has led to the suggestion that estrogen is stimulatory for Sertoli cell proliferation and inhibitory for differentiation. Consistent with this, neonatal exposure to DES impairs Sertoli cell maturation, independent of its effects on gonadotropin secretion, causing permanent defects to spermatogenesis in adulthood.

E. Germ Cells

The localization of aromatase and ERs in various germ cell populations suggests a role for estrogen in germ cell development. Information on the effects of estrogen administration on germ cells has been gleaned from *in vitro* studies, thus effects on other hormones and cell populations do not confound the results. Estrogen administration stimulates proliferation of prespermatogonial cells, or gonocytes, and prevents germ cell apoptosis in seminiferous tubules *in vitro*. Thus, it is possible that endogenous estrogen, along with other hormones, controls germ cell proliferation and survival. Estrogen can also regulate the function of mature spermatozoa in an apparent nongenomic mechanism.

F. Efferent Ductules and Epididymis

Exposure to high doses of estrogen *in vivo* in rodents can impair the resorptive function of the efferent ductules. Exposure to high doses of estrogens during the first few days of life causes dilation of the rete testis and an accumulation of fluid in the testis, which then causes secondary defects in the seminiferous epithelium and spermatogenesis. The mechanism of this effect on the efferent ductules may be via changes in the expression of ERs and of genes important in fluid resorption, as well as changes in cellular morphology. Exposure to high doses of estrogens *in utero* causes epididymal granulomas, whereas exposure during the neonatal period causes a variety of defects in epididymal development.

VI. ESTROGEN AND SPERMATOGENESIS—LESSONS FROM TRANSGENIC MICE

In general, two important observations have been made in transgenic mouse models regarding estrogen and spermatogenesis. First, exogenous estrogen can stimulate spermatogenesis in a transgenic mouse that is congenitally deficient in gonadotropins (the *hpg* mouse). Second, transgenic mice that lack functional genes for aromatase (aromatase knockout, ArKO), ERα (ERαKO), and ERα + ERβ (ERαβKO) exhibit disruptions to spermatogenesis and infertility. These latter models have provided much information as to the requirement for estrogen in the development and maintenance of spermatogenesis and fertility (Table 1).

A. ERαKO

This mouse model was the first to show definitive roles for estrogen action in many physiological processes, including spermatogenesis. ERαKO mice are infertile, with disrupted germ cell development in the seminiferous epithelium. This disruption to spermatogenesis is now known to be secondary to abnormal development and function of the efferent ductules. The congenital absence of ERα causes marked disturbances in the ability of the efferent ductules to resorb fluid leaving the testis, causing a buildup of fluid in the rete testis and seminiferous tubules, which then interferes with normal germ cell development. Thus, efferent ductule dysfunction is thought to be a primary cause of infertility in these animals. Germ cell transplantation studies show that germ cells do not require ERα for development. ERαKO mice show some defects in cremaster muscle development, which is involved in testicular descent.

B. ERβKO (ERβ Null Mice)

Despite the widespread localization of ERβ in the testis and seminiferous epithelium, ERβKO male mice are fully fertile, and no defects in spermatogenesis have been reported. These observations perhaps suggest compensation by ERα, although such a proposition has not been tested.

C. ERαβKO

Breeding of mice lacking ERα or ERβ results in the generation of mice deficient in both ERs. The spermatogenic phenotype in ERαβKO mice is apparently similar to ERαKO mice, because ERαβKO mice also exhibit infertility, reduced

sperm numbers in the epididymis, and apparent dilation of seminiferous tubule lumens.

D. ArKO

Several independent lines of ArKO mice have been generated, all of which exhibit varying degrees of infertility. ArKO mice are initially fertile, with apparently normal testicular development. The lack of enlarged seminiferous tubule lumens at any age suggests that efferent ductule function is normal and fluid accumulation does not occur. In one line of ArKO mice, at the round spermatid stage a marked loss of germ cells by apoptosis was described, suggesting that endogenous estrogen is important for germ cell development. Leydig cell hyperplasia and defective acrosome biosynthesis were also observed in these animals.

E. Aromatase Overexpression

Mice overexpressing aromatase have been generated and provide complementary evidence to exogenous estrogen administration models. These mice have high circulating levels of estrogen and show Leydig cell hyperplasia and/or Leydig cell tumors. Like *in utero* exposure to high levels of estrogen, mice overexpressing aromatase have failed testicular descent; this cryptorchidism may at least in part explain the failure of spermatogenesis and infertility in these mice.

VII. CONCLUSIONS

Taking together the results from studies localizing aromatase and ERs in the testis and epididymis, and from estrogen administration and transgenic mice models, it is apparent that spermatogenesis is dependent on estrogen action. Various processes important for spermatogenesis are impaired by inappropriate exposure to estrogens during fetal and pubertal development, as well as in adulthood, highlighting the importance of a normal balance between androgens and estrogens for male fertility. Spermatogenesis is also impaired by a congenital deficiency of ERα or aromatase, providing clues as to the physiological roles for estrogen action. There are enough discrepancies between the phenotypes of ER- and aromatase-null mice to speculate on the existence of (1) undiscovered aromatase or ER genes, (2) estradiol-independent ER actions, and/or (3) estrogen actions independent of ERα or ERβ in the testis and male reproductive tract. Nevertheless, it is clear that normal spermatogenesis requires estrogen, and that the timing, amount, and duration of estrogen action must be tightly coordinated for the development and maintenance of normal sperm production.

Glossary

aromatase Enzyme that catalyzes the conversion of androgens to estrogens. A member of the cytochrome P450 superfamily, namely, aromatase cytochrome P450 (P450arom, product of the *CYP19* gene). In common with other microsomal P450 enzymes, aromatase requires NADPH-cytochrome P450 reductase to provide reducing equivalents.

efferent ductules Series of ductules connecting the testis to the head of the epididymis; their primary function is to resorb fluid leaving the testis in order to concentrate sperm on entry to the epididymis.

estrogen Substance that promotes development of female secondary sexual characteristics. The "traditional" estrogen is 17β-estradiol, although numerous substances have estrogenic activity.

estrogen receptor α The first identified receptor for estrogen; estrogen receptors are members of the nuclear receptor family.

estrogen receptor β A second receptor for estrogen that was identified more recently; encoded by a separate gene.

Leydig cells Steroidogenic cells of the testis; their main function is to secrete androgens.

Sertoli cells The "nurse" cells of the seminiferous epithelium; these cells provide nutritional and structural support for developing germ cells.

spermatids Haploid germ cells that undergo differentiation from an early, rounded form to a mature, elongated form.

spermatocytes Tetraploid germ cells undergoing meiosis.

spermatogenesis Process by which immature germ cells divide and differentiate into mature spermatozoa.

spermatogonia Proliferative and differentiating diploid cells that are the most immature germ cell type.

Estrogen in the Male: Nature, Sources, and Biological Effects

HANS-UDO SCHWEIKERT
University of Bonn

Estrogen is part of the male endocrine system. In healthy males the main source of estrogens is the conversion of circulating androgens in peripheral tissues. Data obtained from human mutations impairing either estrogen action or formation, and from corresponding knockout mouse models, demonstrate that in the male, estrogen plays an important biological role in the maturation and homeostasis of the skeleton. At present the impact of estrogen on other tissues or functions in the male, including the cardiovascular system, fertility, or glucose and lipid metabolism, is less clear.

I. INTRODUCTION

Recognition of estrogens as "male" hormones dates to 1934, when Zondek reported that the urine of stallions contained large quantities of estrogen, whereas the urine of mares contained lower quantities of estrogen. Zondek concluded from the observation that "the conversion of the male into the female hormone appeared to be quite possible." Three years later, Steinach and Kun provided supporting evidence for this assumption when they found that urinary excretion of estrogen increased after the administration of testosterone propionate to men. In 1979, MacDonald and co-workers demonstrated that the conversion of circulating testosterone and androstenedione by the enzyme aromatase in peripheral tissues is quantitatively the major source of estrogen in men. However, the biological role of estrogen in males remained largely unknown until 1994, when complete estrogen insensitivity (estrogen resistance) due to a nonfunctional mutated estrogen receptor (ER) had been recognized in a man who had a distinctive phenotype, mainly eunuchoid habitus and severe osteopenia, despite normal serum androgen and elevated estrogen levels. Thereafter, the importance of estrogen in males was further

Estrogen in the Male: Nature, Sources, and Biological Effects

HANS-UDO SCHWEIKERT
University of Bonn

Estrogen is part of the male endocrine system. In healthy males the main source of estrogens is the conversion of circulating androgens in peripheral tissues. Data obtained from human mutations impairing either estrogen action or formation, and from corresponding knockout mouse models, demonstrate that in the male, estrogen plays an important biological role in the maturation and homeostasis of the skeleton. At present the impact of estrogen on other tissues or functions in the male, including the cardiovascular system, fertility, or glucose and lipid metabolism, is less clear.

I. INTRODUCTION

Recognition of estrogens as "male" hormones dates to 1934, when Zondek reported that the urine of stallions contained large quantities of estrogen, whereas the urine of mares contained lower quantities of estrogen. Zondek concluded from the observation that "the conversion of the male into the female hormone appeared to be quite possible." Three years later, Steinach and Kun provided supporting evidence for this assumption when they found that urinary excretion of estrogen increased after the administration of testosterone propionate to men. In 1979, MacDonald and co-workers demonstrated that the conversion of circulating testosterone and androstenedione by the enzyme aromatase in peripheral tissues is quantitatively the major source of estrogen in men. However, the biological role of estrogen in males remained largely unknown until 1994, when complete estrogen insensitivity (estrogen resistance) due to a nonfunctional mutated estrogen receptor (ER) had been recognized in a man who had a distinctive phenotype, mainly eunuchoid habitus and severe osteopenia, despite normal serum androgen and elevated estrogen levels. Thereafter, the importance of estrogen in males was further

substantiated by the description of males with complete estrogen deficiency due to mutations of the aromatase gene. The two men with aromatase deficiency reported hitherto had a similar phenotype as in estrogen resistance but in contrast to the former showed significant bone maturation with estrogen therapy. These observations document the important role of normal estrogen formation and action in the male, notably bone. Two other findings have provided further insight into the complex mechanism(s) of action of estrogen in males. In 1996, the cloning of a second estrogen receptor, ER-β (as opposed to the classical ER, which is now designated ER-α), was reported. Moreover, knockout mouse models with disruption of the genes encoding the estrogen receptors (αERKO, βERKO, and αβERKO double knockout mice) and the enzyme aromatase (ARKO mouse) have been developed.

II. CHARACTERISTIC FEATURES OF ANDROGEN METABOLISM AND ACTION IN MALES

Although androgens act at the molecular level like other steroid hormones, i.e., by combining with the androgen receptor (AR), their mechanism of action is characterized by the fact that in many androgen target tissues, testosterone is converted to 5α-dihydrotestosterone (DHT) by steroid 5α-reductase (5α-R) activities before binding to the AR. Two 5α-R isozymes, designated types 1 and 2, have been identified and originate from different genes. 5α-R type 1, the predominant isozyme, has been identified in a variety of human tissues such as nongenital skin, kidney, and brain. In genital tissues such as the prostate and the external genitalia, 5α-R type 2 appears to be the predominant isozyme. DHT is biologically more potent than testosterone as an androgen because DHT binds more tightly to the androgen receptor and the DHT–receptor complex is more readily transferred to the DNA-binding state and activates a receptor reporter gene more efficiently than testosterone. Consequently, DHT serves as a local androgen amplification mechanism of testosterone and may also regulate specific genes.

Because of their chemical structure, testosterone and androstenedione (which is secreted mainly by the adrenal glands) not only can be reduced in a variety of peripheral tissues to 5α-reduced metabolites, to produce or lead to the formation of the biologically important DHT, but can also serve as substrates for aromatization to estrogen (to estradiol from testosterone and to estrone from androstenedione; Fig. 1). Both the 5α-reduction and the aromatization of testosterone and androstenedione are irreversible reactions under biological conditions.

The property of circulating testosterone and androstenedione serving as precursors for the synthesis of estrogen and for the formation of DHT makes it difficult to study the androgenic effects in their target organs, since every androgenic effect observed must be investigated with regard to the extent to which it is induced by either testosterone, DHT, or estradiol or, alternatively, by their synergistic action.

III. MUTATIONS THAT IMPAIR ANDROGEN ACTION IN THE HUMAN

Insight into the specific action of both testosterone and DHT has been obtained from two different single gene mutations in the human, namely, male pseudohermaphroditism due to complete resistance to androgens (the complete androgen insensitivity syndrome, CAIS; also known as testicular feminization) and that due to deficient 5α-reductase activity (5α-reductase deficiency). Both disorders impair androgen action and are natural models for studying the role of testosterone and DHT in males.

A. Complete Androgen Insensitivity Syndrome

A 46,XY karyotype, testes and an unambiguously female habitus and psychosexual orientation characterize individuals with CAIS. Axillary and pubic hair are sparse or absent (hairless women) and the external genitalia are female. The female internal genitalia, the uterus and the fallopian tubes, are absent; the vagina is thus blind-ending. The testes are located in the abdomen, the inguinal canal, or in the labia majora. They contain normal Leydig cells and seminiferous tubules without spermatogenesis. In the adult, gonadotropin secretion and testosterone production are in the upper normal range for men or are elevated and estrogen production is increased. Adults tend to be tall, and bone age is normal. Bone mass is within the female range, which indicates that estrogens alone do not fully compensate for the loss of androgen receptor function. The underlying defects of the disorder are various mutations in the androgen receptor gene.

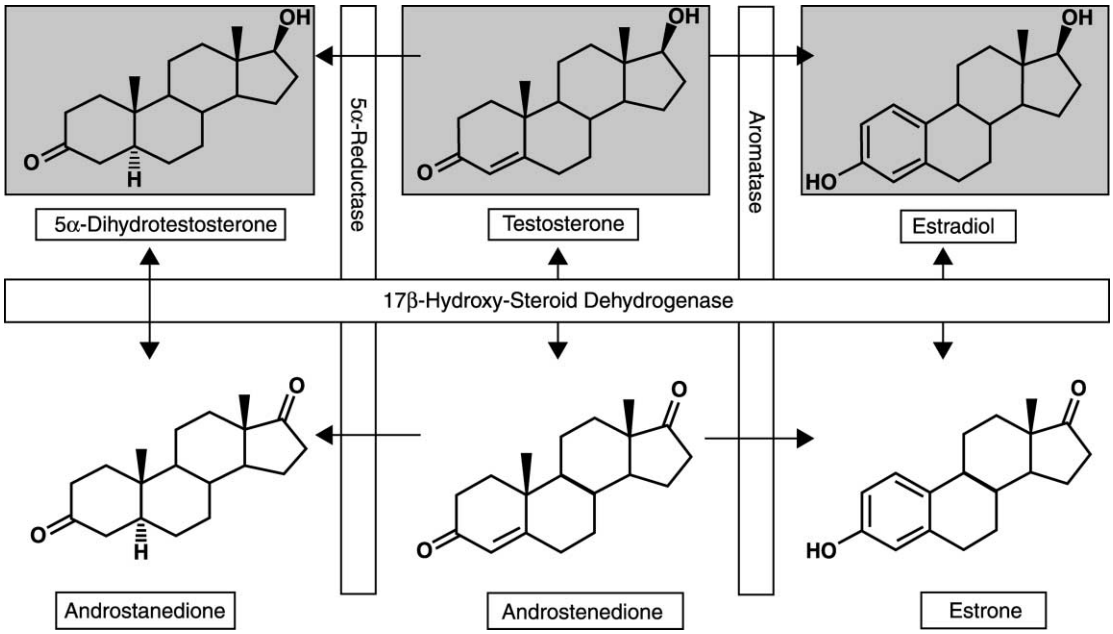

FIGURE 1 Major pathways for the synthesis of active androgens and estradiol (shaded boxes) in peripheral human tissues. Two isozymes of the 5α-reductase and six isozymes of the 17β-hydroxysteroid dehydrogenase family, of which isozyme types 1, 3, 5, and 7 catalyze the reduction and types 2 and 4 catalyze the oxidation of steroids, have been determined to be expressed in human peripheral tissues. Small amounts of androstenedione can also be synthesized from adrenal androgens such as DHEA and its sulfate via the sequence DHEAS → DHEA → androstenedione. The conversion is mediated by the sequential action of the enzymes steroid sulfatase and 3β-hydroxysteroid dehydrogenase (two isozymes).

B. 5α-Reductase Deficiency

This disorder is caused by mutations in the 5α-R type 2 gene. Affected individuals have a normal male karyotype, 46,XY, and testes, but incomplete virilization. The infant usually presents with undescended testes, ambiguous genitalia, such as a bifid scrotum, a severely hypoplastic penis, and hypospadias. However, the Wolffian duct derivates, the epidymidis, the vas deferens, and the seminal vesicle, are normally developed and open into a blind vaginal pouch. Female internal genitalia are absent. Virilization is observed at puberty (probably due to the conversion of testosterone to DHT by the 5α-R type 1) with phallic enlargement, descent of the testes, and deepening of the voice. Gynecomastia does not develop. Bone mineral content is in the low range for men. However, male-type facial and body hair commonly is scanty and the prostate remains rudimentary. Spermatogenesis is absent or impaired. Although most patients have been raised as girls, gender orientation in adulthood is usually unambiguously male. In the adult, serum gonadotropin levels are within the normal range or slightly elevated and testosterone production and estrogen production are those of normal men. Serum DHT levels are either subnormal or in the low normal range.

Since virilization in the disorder is defective only in the external genitalia and the prostate, where the 5α-R type 2 is normally expressed, it can be deduced that testosterone is the androgen responsible for the differentiation of the Wolffian duct into the epidymidis, the vas deferens, and the seminal vesicle, and it is DHT that mediates masculinization of the prostate and the external genitalia.

Taken together, the findings in individuals with single gene mutations that impair either DHT formation or testosterone and DHT action demonstrate that major effects of testosterone and DHT action include the development of the male sexual phenotype during embryogenesis (development of the internal and external genitalia as well as the prostate), the promotion of virilization at the time of puberty and its maintenance during adulthood, and gender orientation. In addition, the action of androgens is involved in the regulation of gonadotropin secretion,

in the initiation and maintenance of spermatogenesis, and at least to some extent in the accumulation of male bone mineral density.

IV. STEROID PATHWAYS IN PERIPHERAL TISSUES

The enzymes 5α-reductase, 17β-hydroxysteroid dehydrogenase (17β-HSD), and aromatase are the major metabolizing enzymes necessary for the formation of biologically active androgens (testosterone and DHT) and estrogens, mainly estradiol, from circulating precursors. Their activities are expressed to various extents in extraglandular tissues (Fig. 1). Androstenedione can also be formed from dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS), which are secretion products of the adrenal. The complexity of this system in human peripheral tissues is highlighted by the presence of two 5α-reductase isozymes and at least six 17β-HSD isozymes. The isozymes of the 17β-HSD family catalyze either the reduction or the oxidation of sex steroids and therefore represent important control elements for their activation (by reduction) or inactivation (by oxidation). The enzyme sulfatase mediates the conversion of DHEAS to DHEA, and the latter can be transformed to androstenedione by means of the 3β-hydroxysteroid dehydrogenase, of which two isozymes are expressed in peripheral tissues. It is clear that, by means of this enzymatic machinery, peripheral cells and tissues can modulate, i.e., activate or inactivate, the biological potencies of circulating steroids. The potent androgens and estrogen formed from biologically inactive circulating precursors in peripheral tissues can be utilized to act directly at the site of their biosynthesis, e.g., by binding to their specific receptors (intracrine mechanism); alternatively, the steroids can be released to act on neighboring cells (paracrine mechanism) or can be secreted into the circulation to act at distal sites (endocrine function).

V. ESTROGEN SYNTHESIS IN PERIPHERAL TISSUES

A variety of peripheral tissues have been identified to produce estrogen from circulating androstenedione and testosterone such as adipose tissue, brain, liver, skin (fibroblasts), hair roots, skeletal muscle, prostate, and bone.

A. Enzyme Aromatase

Estrogen formation from androstenedione and testosterone in peripheral and testicular tissues is synthesized by the catalytic action of the membrane-bound enzyme aromatase, a cytochrome P450-dependent enzyme. NADPH is the necessary coenzyme. Aromatase action involves oxidation, removal of the methyl group at the carbon 19 position of testosterone or androstenedione, and removal of the hydrogen at the carbon 1β-position (Fig. 1). For aromatase activity, three molecules of oxygen are required per molecule of steroid. Aromatase is encoded by the CYP19 gene, which encodes a protein that in many species consists of approximately 500 amino acids. The coding region of the gene spans nine exons beginning with exon II, and expression of the gene is determined by tissue-specific promoters, which lead to transcripts that are always the same regardless of the site of expression.

The overall rates of estrogen formation in the testis (estrogens are not formed in the adrenals) and in the peripheral tissues are much lower than those for other steroid hormones, a relationship that is reflected by the greater potency, lower secretory rates, and lower blood levels of estrogen (Table 1).

VI. ORIGIN OF ESTROGENS IN MALES

MacDonald and co-workers, using isotope infusion techniques, have assessed the daily production rate of estrogens and androgens in young healthy men. The mean daily plasma production rate of testosterone

TABLE 1 Serum Levels, Daily Production Rates, and Origin of Androgens and Estrogens in Men

Steroid	Serum levels	Daily production rates	Origin
Testosterone	3–10 ng/ml	5–10 mg	>95% secreted by the testes
Androstenedione	0.5–3.5 ng/ml	2–4 mg	Approximately 60% secreted by the adrenals, rest formed from DHEAS and testosterone in peripheral tissues
Estradiol	20–40 pg/ml	40–60 μg	Approximately 85% from peripheral conversion of testosterone, androstenedione, and estrone, 15% from testicular secretion
Estrone	20–40 pg/ml	50–70 μg	95–100% from peripheral conversion of androstenedione, testosterone, and estradiol

was approximately 6 mg and that of androstenedione was 3.0 mg. The mean daily production rate of estrone was approximately 60 μg and that of estradiol was 45 μg. Estrone formation was derived totally by peripheral aromatization of circulating androstenedione and testosterone, whereas of the 45 μg of estradiol produced, only approximately 10 μg was secreted by the testes. Weinstein and co-workers have obtained similar results; testicular daily estradiol secretion was approximately 10 μg, or approximately 25% of the total estradiol production, whereas estrone secretion accounted for approximately 5%. Taken together, these studies demonstrate that in healthy men approximately 95 to 100% of the total daily production of estrone and 85% of estradiol are derived from peripheral aromatization of circulating serum androstenedione and testosterone, whereas the testes secrete only small amounts of estrogen (Table 1).

VII. REGULATION OF PERIPHERAL ESTROGEN PRODUCTION

The factors that regulate estrogen formation are still not fully understood. Short-term administration of human chorionic gonadotropin in men before surgery resulted in a simultaneous increase of estradiol, estrone, and testosterone into spermatic vein blood. The rate of estrogen production is not influenced by castration or adrenalectomy, but is lowered due to the decreased concentrations of circulating androgen precursors, which serve as a substrate for aromatization.

VIII. INCREASED ESTROGEN PRODUCTION IN MALES

Estrogen formation is enhanced with increasing body weight and with age. With slowly decreasing testosterone levels with advancing age and in the presence of obesity, the development of signs of feminization, especially gynecomastia, is more likely since there is an increased conversion of the remaining precursors to their respective estrogenic products. A markedly increased conversion of androstenedione to estrone is observed in liver disease and in adrenal tumors secreting androgen precursors. An increase in estrogen production that results ultimately in a decreased testosterone:estrogen production ratio is also present in a number of clinical entities associated with gynecomastia. In cirrhosis, due to decreased clearance of testosterone by the liver, the extrahepatic conversion of testosterone to androstenedione is increased. Since androstenedione is a better substrate for peripheral aromatization than testosterone, its decreased hepatic clearance provides an increased testosterone availability for its oxidation to androstenedione in peripheral tissues. Because the hepatic clearance of androstenedione is also decreased, the availability of both androstenedione and testosterone is increased, which again favors peripheral estrogen formation.

Furthermore, increased testicular estrogen secretion occurs in men with disorders that are characterized by increased gonadotropin secretion such as in Klinefelter's syndrome (males with an additional X chromosome resulting in the 47,XXY karyotype), CAIS (see above), and hypergonadotropic hypogonadism.

IX. SERUM ESTROGEN LEVELS IN MALES

A. Childhood

When serum estradiol levels are determined with conventional immunoassays, levels are close to the detection limit of these assays and are similar in boys and girls. However, significant sex differences have been discovered with newly developed ultrasensitive recombinant cell bioassays. Mean serum estradiol levels (picograms per milliliter) in prepubertal children in one study were 0.08 in boys and 0.6 in girls (assay detection limit 0.02 pg/ml) and in a second study were somewhat higher (1.4 pg/ml in boys and 3.5 pg/ml in girls; assay detection limit <1.0 pg).

B. Puberty

Utilizing an ultrasensitive estradiol detection assay, it has been demonstrated that as normally growing boys progress into puberty, a significant rise in estradiol levels occurs simultaneously with the peak growth velocity, an average of 3 years after the onset of puberty. Thereafter, estrogen levels continue to increase until the end of puberty, and by that time reach an average serum level of approximately 12 pg/ml.

C. Adulthood

Estradiol and estrone levels as measured by immunoassays span a range from approximately 20 to 40 pg/ml (Table 1) and on average tend to increase with advancing age. However, because of increased sex hormone-binding globulin, free estradiol levels appear to be largely unchanged in aging.

X. BIOLOGICAL ACTIONS OF ESTROGEN IN MALES

The role of estrogen in development, growth, and other physiological functions in the human male has been thought to be relatively unimportant. Recent findings have challenged this view and have advanced our knowledge on the biological action of estrogen in males.

A. Estrogen Receptors

The biological effects of estradiol are predominantly mediated by two distinct intracellular receptors, the "classical" estrogen receptor (now designated ER-α), which was cloned approximately 15 years ago, and a second estrogen receptor, ER-β, which was cloned in the mid-1990s. Two different genes encode both ERs. They are ligand-inducible transcription factors that belong to the nuclear hormone superfamily. Since the DNA- and ligand-binding domains of both receptors exhibit a high degree of homology, both receptors can interact with the identical DNA-response elements and display similar *in vitro* binding profiles for endogenous and synthetic estrogens. In addition, there may be an interaction between the two ERs. In males, ER-α is predominantly expressed in the testis, pituitary, liver, heart, kidney, skeletal muscle, and osteoblasts, whereas ER-β transcripts predominate in the prostate. Transcripts for both receptors are present in approximately similar amounts in the epididymis, adrenals, bone, thyroid, and various regions of the brain.

XI. MUTATIONS THAT IMPAIR THE FUNCTION OF THE ESTROGEN RECEPTOR OR THE FORMATION OF THE ENZYME AROMATASE IN HUMAN MALES

In contrast to gene mutations that impair androgen action, only few cases of naturally occurring mutations of the genes encoding either the estrogen receptor (ER-α) or the enzyme aromatase have been identified.

A. Estrogen Resistance Syndrome

Resistance to estrogen action has been reported in a single case of a 28-year-old man with a premature stop codon, which resulted in a truncated, nonfunctional ER-α protein. The patient was tall (204 cm, >95 percentile; weight 127 kg) and had a bone age of 15 years with evidence of slow and continued linear growth during adulthood. The man had a normal onset of puberty, was normally virilized, and reported no history of gender identity disorder. He had normal male genitalia, normal testes, and a normal-sized prostate. Semen analysis revealed a normal sperm count with decreased viability. His serum estradiol and estrone, serum follicle-stimulating hormone (FSH), and serum luteinizing hormone (LH) concentrations were elevated, whereas serum testosterone concentrations were normal and serum DHT was borderline low. The patient did not respond to high-dose estrogen therapy; e.g., he did not develop gynecomastia or impotency. Neither gonadotropins nor estrogen-dependent proteins, such as sex hormone-binding globulin or serum prolactin, changed with treatment. Bone age and bone mineral content remained unaltered during estrogen administration. These observations demonstrate that estrogen plays an important biological role in the maturation and homeostasis of the male skeleton and indicate that estrogen action on bone is mediated predominantly by ER-α. A follow-up study of the patient at the age of 31 years provided evidence of premature coronary artery disease, and serum glucose and lipid analyses revealed abnormalities; however, at present it is unclear whether these disorders are related to the nonfunctional ER-α.

B. Aromatase Deficiency

Despite the size and complexity of the CYP19 gene, aromatase deficiency has been reported in only nine cases. Three of the cases were male (two men and one infant), and all had normal male genitalia at birth. The two adults had an unremarkable childhood, normal pubertal development, and normal gender identity. In one man, extremely low estrogen levels and markedly elevated serum testosterone, FSH, and LH concentrations were found. In the second man, whose CYP19 gene mutation was associated with a lesser degree of aromatase deficiency, serum estradiol was low, serum testosterone was normal, and the gonadotropin levels were slightly elevated. Testis size in the two men differed considerably, being large in one (25 ml volume) and subnormal (8 ml) in the other. The men were extremely tall (>3 standard deviations) with continued growth into adulthood and unfused epiphyses in their midtwenties. Both had osteopenia, and estrogen treatment resulted in epiphyseal closure and an increase in bone mass. These observations again support an essential role of estrogen in the maturation of the skeleton and the accrual of bone mass.

XII. MUTATIONS THAT IMPAIR THE FUNCTION OF THE ESTROGEN RECEPTOR OR THE FORMATION OF THE ENZYME AROMATASE IN RODENTS

A. Estrogen Receptor Knockout Mice

αERKO mice and αβERKO mice have reduced femoral length and significantly reduced bone mineralization. αERKO mice have cortical osteopenia and increased bone turnover, which is more pronounced in the male than in the female. In contrast, βERKO mice have a skeletal phenotype that is indistinguishable from that of wild-type males. The most striking phenotype in the male αERKO and αβERKO mice includes testicular degeneration and epididymal dysfunction combined with deficits of sexual behavior and infertility. In comparison, βERKO males are fertile and exhibit normal sexual behavior.

B. Aromatase Knockout Mice

Like αERKO mice, ARKO mice display significantly reduced femur length and have osteopenia. Other major phenotypic differences between wild-type and ARKO males are manifested mainly in the reproductive tissues. They cause infertility in aging males and severe deficits in sexual behavior.

Taken together, the knockout mouse models demonstrate that estrogen is important for bone mass accrual in the male. For hitherto unknown reasons, the knockout mice show less pronounced skeletal phenotypic differences than humans with the corresponding mutations. Furthermore, important species-related differences exist; for example, in the human, in contrast to mice, estrogen deficiency or estrogen resistance does not appear to affect male psychosexual development.

XIII. SUMMARY

The conversion of circulating testosterone and androstenedione by the enzyme aromatase in peripheral tissues is quantitatively the major source of estrogen in men. The current data obtained from human mutations impairing either estrogen action or formation and from corresponding knockout mouse models indicate that estrogen deficiency is not lethal for a conceptus (either male or female). They demonstrate that in the male, estrogen plays a major role in the control of bone growth as well as in the accumulation and maintenance of bone mass. Less clear at present is the impact of estrogen on other tissues or functions in the male, including the cardiovascular system, fertility, and glucose and lipid metabolism.

Glossary

androgen or estrogen resistance Unresponsiveness or insensitivity of tissues toward the action of androgens or estrogens, caused by a functional defective androgen or estrogen receptor.

knockout mouse Animal model involving targeted gene(s) disruption.

male pseudo-hermaphroditism Disorder of phenotypic sex, caused by defective masculinization of the male embryo. Can result from defects of testicular androgen synthesis or defects in androgen action (see androgen resistance).

peripheral tissues Extraglandular tissues, i.e., extratesticular and extra-adrenal tissues.

Estrogen Receptor (ER) Actions through Other Transcription Factor Sites

STEPHEN SAFE
Texas A&M University

Estrogen receptor-α (ER-α) and estrogen receptor-β (ER-β) are members of the nuclear receptor family of ligand-activated transcription factors that mediate tissue-specific responses to 17β-estradiol and other steroidal and nonsteroidal estrogens. Classical activation of genes through consensus (or nonconsensus) estrogen response elements requires interactions with ER-α or ER-β homo- or heterodimers and a host of other nuclear cofactors that are essential for ligand-activated gene expression. Nuclear estrogen receptors also activate genes through other DNA-dependent and -independent pathways, and there is increasing evidence that estrogen receptor interactions with other transcription factors and proteins may be important.

I. INTRODUCTION

The classical mechanism of estrogen action involves ligand-dependent formation of nuclear estrogen receptor (ER) homo- or heterodimers and interaction with consensus palindromic estrogen response elements (EREs) [i.e., $-GGTCA(N)_3TGACC-$] in target 17β-estradiol (E2)-responsive gene promoters (Fig. 1). The subsequent recruitment of other nuclear co-activator and coregulatory proteins and interactions with the basal transcription machinery result in transactivation. This DNA-dependent mechanism of ER-mediated responses has been characterized for several genes that contain consensus or nonconsensus EREs; however, it has also been shown that hormonal activation of many other genes may involve genomic (nuclear) pathways that are DNA dependent or independent and other mechanisms that do not require nuclear ERs (i.e., nongenomic).

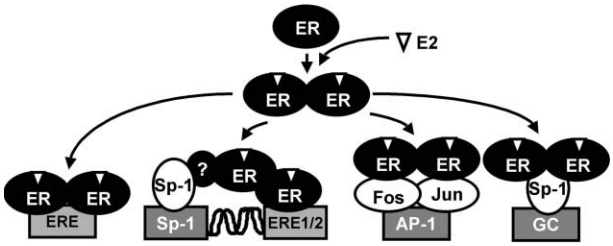

FIGURE 1 Pathways for nuclear estrogen receptor (ER) action through genomic DNA-dependent and -independent interactions. Estrogens and other ER agonists bind the receptor and activate genes through binding response elements or by direct interactions with other DNA-bound transcription factors. ERE, Estrogen response element; E2, 17β-estradiol; AP-1, activator protein 1.

ER subtype-selective ligand synthesized by the same group showed full ER-α agonism but pure ER-β antagonism.

The discovery of a second estrogen receptor will require that we revisit many biological and clinical studies and reinterpret them in the light of the presence of two receptors. Such studies are now being performed, generating interesting and sometimes unexpected findings.

Estrogen Receptor Biology and Lessons from Knockout Mice

DEBORAH L. SWOPE AND KENNETH S. KORACH

National Institute of Environmental Health Sciences, North Carolina

The steroid hormone estrogen induces a wide variety of physiological responses in mammalian tissues. Estrogen is found in both females and males, although at higher levels in females. Estrogen causes its multitude of effects through estrogen receptors that mediate the transcription of a number of genes involved in reproduction, metabolism, and growth and differentiation. The current understanding of estrogen action is rooted in a model in which the estrogen receptor is bound by ligand, homodimerizes, and interacts with high-affinity binding sites for estrogen receptors found in the promoters of target genes. The bound receptor activates transcription of the target gene. Estrogen receptors also modulate expression of genes that do not contain these binding sites, can be activated in a ligand-independent manner by growth factors, and can also function as repressors of transcription.

I. ESTROGEN RECEPTORS: STRUCTURE AND MECHANISM OF ACTION

Estrogen receptors (ERs) belong to the nuclear hormone receptor (NHR) superfamily of proteins, which includes over 200 members that share several homologous domains and functions. ERs are class I members of this superfamily. Class I receptors function as transcription factors; their activities are mediated by a variety of small ligands that interact with the ligand-binding domain (LBD) of the receptor to activate transcription. A majority of the receptors in this family bind as dimers through the DNA-binding domain (DBD) to specific sequences called hormone response elements (HREs); the HREs are found in the promoters of target genes, and through their interactions regulate the expression of target genes.

A. Structure of ERs

Two ER proteins have been identified: ER-α and ER-β. Each is a product of a separate gene located on separate chromosomes, although the proteins are highly related, suggesting a common evolutionary ancestry. Numerous splice variants of both ER-α and ER-β have been observed in normal tissues, in tumors, and in transformed cell lines, but Western blotting studies have identified the predominantly expressed 599-amino-acid protein for ER-α (mouse) and the 530-amino-acid protein for ER-β. ERs, like other NHRs, contain a variable amino-terminal A/B domain, which contains a ligand-independent activation function (AF-1); a highly conserved C domain, which contains two zinc fingers and is required for DNA binding; the hinge, or D domain, which contains nuclear localization signals; and a large hydrophobic E domain, which contains the dimerization domain, binds to ligands, and also contains the major ligand-dependent activation function, AF-2 (Fig. 1). ERs also contain a unique F domain at the C-terminus; domain F is not seen in other NHRs and is poorly conserved between ER-α and ER-β. The function of domain F is unclear, but deletion and mutagenesis of the F domain have suggested a role in influencing transcriptional activity of the ER.

The greatest degree of homology between receptors in the NHR superfamily lies in the DNA-binding domain, which is composed of two zinc fingers that bind DNA with high affinity. Due to the high degree of homology between the DBDs of ER-α and ER-β (97%; Fig. 1), these two receptors bind to the same estrogen response elements (EREs). The consensus

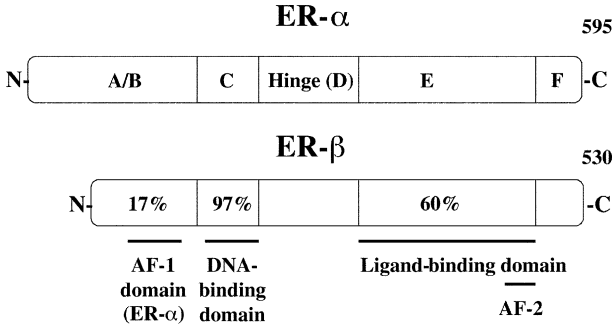

FIGURE 1 Major functional domains of the mouse estrogen receptors (ERs). This schematic depicts the six functional domains (A through F) found in ERs. Homology between ER-α and ER-β structural domains is also shown. Note that the greatest degree of homology lies between the DNA-binding domain (C domain) and the ligand-binding domain (E domain).

ERE is a 13-base-pair (bp) palindromic sequence (GGTCAnnnTGACC) consisting of two 5-bp inverted repeats with a 3-bp spacer; most genes contain nonconsensus EREs in their promoters. Each ER molecule in the dimer binds to one 5-bp repeat (also known as a half-site). *In vitro* studies have shown that the two estrogen receptors can homodimerize (α/α or β/β) or heterodimerize (α/β). However, only cells that express both receptors would be capable of forming heterodimers; to date, co-expression has been observed in a limited number of cell types *in vivo*, and it remains unknown whether heterodimers form productive complexes in these cells. The ERs also share a moderate degree of homology in the LBD (60%; Fig. 1), which likely accounts for the similar binding affinities of ER-α and ER-β for estradiol and other ligands, including diethyl stilbestrol (DES) and 4-hydroxytamoxifen.

B. Transcriptional Activation by ERs

ERs activate transcription of target genes in response to a number of stimuli, including estrogens, xenoestrogens, and growth factors. The classical mechanism by which the ER activates transcription is a ligand-dependent response mediated by a conformational change in the ER induced when estrogen (or another agonist) binds to the LBD, which promotes dimerization (Fig. 2). This conformational change also alters the position of helix 12, an α-helix that contains the AF-2 activation domain. This hydrophobic AF-2 motif interacts with LXXLL motifs [known as nuclear receptor (NR) boxes] found in co-activator/cofactor molecules such as steroid receptor co-activator-1 (SRC-1), glutamate receptor-interacting

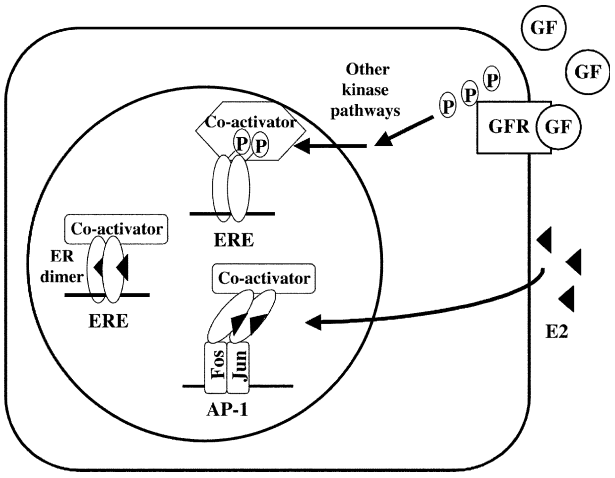

FIGURE 2 Mechanisms of estrogen receptor (ER) transcriptional activation. This diagram details several mechanisms by which the ERs activate transcription in response to a variety of signals on different types of promoters. Transcription regulated by estrogen response elements (EREs) is initiated following binding of estradiol (E2) to the ER, dimerization, and binding to the ERE. Activation from an ERE can also result from activation via the activation function-1 domain by growth factor (GF) signaling. Additionally, non-ERE-mediated activation can occur via an activator protein 1 (AP-1) site (or Sp-1 site; not shown). GFR, Growth factor receptor; P, progesterone.

protein 1 (GRIP1), and Ca^{2+}/cAMP response element-binding protein (CBP)/p300, as well as others. The repositioning of helix 12 forms a co-activator-binding surface on the ER that enables the AF-2 domain to interact with these molecules, enhancing the formation of a productive transcriptional complex.

Additionally, ERs activate transcription through ligand-independent pathways that involve signaling in the absence of estrogen (Fig. 2). A number of signaling pathways can modulate ER activation, including growth factors, protein kinase A (PKA), and protein kinase C (PKC). Growth factors such as epidermal growth factor (EGF) and insulin-like growth factor-I (IGF-I) can induce activation of genes regulated by EREs; this activity requires ERs, as shown by disruption of induction in *in vitro* studies as well as in studies in ER-α knockout mice or in studies involving treatment with the ER antagonist ICI 182,780. Activation requires the AF-1 domain of human ER-α, which can be phosphorylated at Ser-118 by the mitogen-activated protein kinase (MAPK) pathway following stimulation by EGF or IGF-I. This event potentiates interaction with the p68 RNA helicase, which functions as an AF-1-specific co-activator, and enhances expression of genes regulated by the ERE. In contrast, ER-β does not appear to have a functional AF-1 domain, although there are reports of phosphorylation events potentiating interaction of the A/B domain with the co-activator SRC-1 in the absence of ligand. These alternative mechanisms for activating the ERs may represent another means for mediating or enhancing transcription via the ERs in environments with low hormone levels.

ERs can also regulate gene expression in the absence of EREs. Expression of genes with AP-1 sites in their promoters can be stimulated by ER-α indirectly interacting with the AP-1 response element via the Fos and Jun heterodimer (Fig. 2). ER-α and ER-β display opposite effects at this promoter: ER-α can activate transcription from the AP-1 element under the influence of estradiol, but ER-β is unable to do so. However, ER-β can activate from AP-1 sites when exposed to antiestrogens. This effect can be explained by the differences in AF-1 function seen between ER-α and ER-β, because activation of the AP-1 element by ERs requires both AF-1 and AF-2. Likewise, ER-α can activate transcription via the GC-rich Sp-1 binding site [found, for example, in the retinoic acid receptor α (RAR α) gene promoter] indirectly by interacting with the Sp-1 transcription factor in the absence of ligand, or by binding as an ER-Sp-1 complex to ERE half-sites located near the Sp-1 binding site in gene promoters.

There are also many reports of ER-mediated rapid cytosolic responses that are nongenomic actions, i.e., they do not involve regulation of transcription. Membrane-associated estrogen-binding proteins have been described, and several studies suggest that the nuclear and membrane ERs are similar, if not the same. The rapid responses mediated by these proteins appear to be G-protein-mediated events, resulting in the activation of PKC, release of calcium, and other signaling pathways. ER-α also has been observed to associate with a number of cytosolic proteins involved in cell signaling, including SRC and Akt, a serine/threonine kinase. Future studies of these membrane-associated events will continue to broaden our understanding of the nongenomic roles of the ERs.

II. ESTROGEN RECEPTOR KNOCKOUT MODELS (α, β, AND α/β)

Until recently, mutations of ERs were unknown in humans, and so knockout models of the various estrogen receptors were developed in mice in order to

facilitate studies of estrogen action *in vivo*. Much of the early progress made in determining the role of estrogen and estrogen receptor was gained from pharmacological or surgical (castration) manipulations of laboratory animals, from cell culture models, and from *in vitro* studies. However, much of the current information is derived from studies conducted on the recently developed knockout models, which have provided invaluable insights into a number of aspects of the ERs in normal and disease states.

A. ER-α Knockout Mice

Disruption of the ER-α gene in mice using gene targeting techniques has resulted in the ER-α knockout (αERKO). This line of mice displays a complex phenotype detailed in Table 1. Development of the reproductive tracts of males and females appears normal in these knockouts, and the mice are healthy and have a normal life span. However, at the age of maturity a number of reproductive phenotypes become evident. The homozygous αERKO females are completely infertile; cannot ovulate, have numerous hemorrhagic ovarian cysts, and exhibit a "trapped follicle" phenotype after superovulation. No corpora lutea are evident. The αERKO female has an increased level of circulating luteinizing hormone (LH); if treated with gonadotropin-releasing hormone (GnRH) antagonists, the hemorrhagic cysts characteristic of αERKO ovaries do not develop, suggesting that the elevated level of LH is responsible for this ovarian phenotype. The αERKOs not only lack the ability to ovulate, but implantation studies using donor embryos have revealed that they also cannot support a pregnancy. They also do not show the classical responses to the administration of estradiol, i.e., there is no increase in uterine wet weight or in the expression of progesterone receptor (PR), and therefore the uterus is unable to prepare properly for pregnancy. αERKO females also do not undergo normal mammary gland development; no alveoli are evident and the ducts do not develop past the epithelial rudiment. Additionally, αERKO females have a high level of serum estradiol, most likely a result of the lack of negative feedback through ER-α that is required to regulate the levels of estradiol.

αERKO males are likewise infertile; prenatal development is normal, although testes are slightly smaller than those of wild-type males. Young males produce viable sperm, but this ability decreases with age. This may be due to atrophy of the epithelium of the seminiferous tubules and the severe dilation of the efferent ductules in the testes that causes a decreased ability to resorb fluid. However, studies have shown that αERKO sperm can develop normally if transplanted to a wild-type male, suggesting that expression of ER-α in the environment, but not in the germ cells, is required for proper sperm development. αERKO males, like the females, show an increased level of circulating LH.

B. ER-β Knockout Mice

As with the αERKO mice, the βERKO mice reproductive tracts appear to undergo normal development. βERKO males have normal fertility and appear to have no testicular phenotype. However, the female βERKO is subfertile, but the phenotype is distinct from that observed in the αERKO. A "trapped follicle" phenotype is also evident following superovulation as with the αERKO, but where complete anovulation is seen in the αERKO, βERKOs do spontaneously ovulate, but with decreased frequency, resulting in small litters. There is no increase in LH as seen in the αERKO mice; the hemorrhagic cysts that characterize the αERKO ovary due to increased LH are not seen in the βERKO ovary. Normal uterine responses to estradiol treatment (increase in uterine weight, normal implantation, and increased expression of PR) are present in the βERKO mice. The females have normal mammary gland development, lactate normally, and successfully nurse pups.

C. "Double" Knockout Mice

The double knockout displays an overt phenotype that resembles the αERKO mice in many ways (see Table 1). Both sexes have normal prenatal development of the reproductive tracts. A notable difference between the αERKO and α/βERKO lines is the progressive appearance in the adult ovary of abnormal follicles that resemble seminiferous tubules. Three types of follicles are observed: normal follicles, "intermediate" follicles that contain degenerating oocytes and granulosa cells, and follicles that have lost the germ cell and have no granulosa cells. Instead, cells lining the lumen of both of these abnormal follicle types resemble Sertoli cells; the "intermediate" follicle type contains both granulosa cells and these Sertoli-type cells. Markers of Sertoli cells, including Müllerian inhibiting substance (MIS) and Sox9, are detected in both of the abnormal follicle

TABLE 1 Phenotypes of ER Knockout Mouse Models

Tissue/system	αERKO	βERKO	α/βERKO
Fertility	Females and males infertile	Females subfertile, decreased litter size; males fertile	Both sexes infertile (resembles αERKO phenotype)
Female reproductive system			
Uterus	Hypoplastic uterus; no uterotropic response to estradiol; no implantation	Normal responses to estradiol; can support normal pregnancies	Resembles αERKO
Ovary	No ovulation; immature follicles and appearance of hemorrhagic cysts at puberty; "trapped follicle" phenotype after superovulation; elevated levels of estrogen and testosterone	Normal appearance; reduced ovulation	Granulosa cells undergo sex reversal, become Sertoli-like cells
Male reproductive system			
Testes	Normal development; testes decrease in weight with age; fluid resorption in efferent ducts decreases with age; sperm have poor motility, cannot fertilize oocytes *in vitro*	Normal	Resembles αERKO phenotype
Mammary gland	Immature; only a ductal rudiment present (development not stimulated by estradiol)	Normal development; normal lactation	Immature; resembles αERKO phenotype
Bone	Female: decreased bone diameter; male: decreased density; both sexes are shorter than wild type	Normal in males; increase in bone density in females	Both sexes shorter
Cardiovascular	Estradiol protection normal; decreased basal NO activity	Normal estradiol protection	Estradiol does not protect against increases in vascular medial area, but still protects against proliferation after injury
Gonadotropin/ hormone levels	Females and males: elevated levels of LH, estradiol, and testosterone; females: reduced prolactin levels	Normal	Elevated LH
Mating behavior	Decreased aggression; deficient mating behaviors	Normal sexual behavior	Males display no mounting behavior

types, suggesting that the granulosa cells have "redifferentiated" to a Sertoli cell type; this phenotype is most likely due to the loss of germ cells.

Other physiological systems are also affected by loss of one or both of the ERs. Effects have been noted in bone, the cardiovascular system, and behavior, all systems in which estrogen has been implicated for normal function. These effects are detailed in Table 1. All of the ERKO models demonstrate some defects in bone: αERKOs and α/βERKOs are shorter. However, there are some gender differences; the αERKO males have lower bone density and the females have smaller diameter bones. There is no apparent defect in the bones of βERKO males, but the females show an increased bone density. It is uncertain whether these effects are developmentally related or if the phenotypes are a result of the effects of abnormal steroid responses in the adults.

Estrogen has long been implicated in gender differences observed in the rates of heart disease seen in humans. Studies have indicated that ER-α is the main ER expressed in the aorta, but that ER-β is also expressed in the vasculature and has been linked with hypertension. Interestingly, the αERKO and βERKO models do not show a loss of estrogen protection from vascular injury, but the α/βERKO model shows an attenuated response, suggesting that the two ER types might compensate for one another or that another pathway may be involved in this effect. However, an effect on nitric oxide (NO) synthesis in male αERKOs has been noted; these mice have an impaired ability to synthesize basal levels of nitric oxide, but can respond normally to the effects of NO.

Mating behavior, not surprisingly, is also affected by disruption of ER expression. Disruption of ER-α expression severely affects mating behaviors in the αERKO males and females. Adult female αERKOs are not sexually receptive in the presence of males and may be attacked by males; both behaviors may reflect elevated levels of testosterone in αERKO females. The αERKO males display somewhat normal behavior toward females in that they will attempt to mount a female, although the frequency of this behavior is reduced. However, intromission and ejaculation are nearly completely absent in these males, suggesting that ER-α is critical to the consummation of mating. In contrast, βERKO males and females appear to have normal mating behaviors. Surprisingly, α/βERKO males lose all mounting responses, suggesting that either individual ER can compensate.

III. ESTROGEN RECEPTOR BIOLOGY

To date, only one mutation of the coding region of the ER-α gene has been identified in humans; prior to the identification of the patient in whom the gene was identified, it was assumed that mutations in ER-α were lethal. A 28-year-old adult male was observed to have tall stature with continued slow growth, delayed bone maturation, insulin resistance, and increased levels of luteinizing hormone and estradiol. Estrogen therapy had no effect on the patient's symptoms, and it was determined that he carried a mutation on both alleles of ER-α that resulted in a premature stop codon. Similar phenotypes have been described in other patients with defects in estrogen synthesis, many due to defects in aromatase, which is required for the synthesis of endogenous estrogens. However, the limited number of patients exhibiting such syndromes and difficulty in obtaining samples from them has made it difficult to study many aspects of estrogen action in humans. The difficulty in identifying humans with estrogen receptor mutations has led many researchers to postulate that ER-α mutations might be lethal. Successful generation of the different ERKO lines and the subsequent identification of the patient homozygous for a disrupting mutation disproved this theory and also demonstrated that ER-α was not required for proper prenatal development.

Development of mouse lines lacking either or both of the ERs has therefore given us invaluable tools for the *in vivo* study of the roles of estrogen and estrogen receptors. Many of the phenotypes observed in the ERKOs are consistent with those seen in the aromatase-deficient and the estrogen-mutant patient, suggesting that the various mouse lines represent good models for the study of estrogen action in mammals. Surprisingly, neither of the ERs is required for prenatal development of the reproductive tracts in males or females, as demonstrated by the normal development of these systems in all of the knockout models. However, ERs are required for normal reproductive function, as established by the various phenotypes that emerge at puberty in the ERKO models. Development of the double (α/βERKO) knockout line has allowed investigators to confirm the roles of ER-α and ER-β by studying the individual genes for these receptors. Continuing studies of the estrogen receptor knockout mice and generation of new mouse lines with modified estrogen receptors will allow investigators to add more details to the complex role of estrogen in normal physiology.

Glossary

activation function-1 The ligand-independent domain found in the N-terminus of ER-α that can be activated by non-estrogen-dependent signaling. ER-β lacks this function.

activation function-2 This major activation domain of ERs is located in the C-terminus of the proteins. It lies at the C-terminal end of the ligand-binding domain and is characterized by a hydrophobic α-helical structure with the invariant amino acid motif &phis;&phis; XE&phis;&phis; (where &phis; is any hydrophobic amino acid, X is any amino acid, and E is glutamic acid). This helix interacts with LXXLL motifs found in co-activators (L is leucine).

co-activator Accessory protein that interacts with nuclear receptors when the receptor is in an active conformation, enhancing transcriptional activation. Co-activators function as a "bridge" from the receptor to the general transcriptional apparatus; interact with receptors via LXXLL motifs.

DNA-binding domains Portions of the receptor proteins containing a double zinc finger motif that binds to the DNA sequence.

estrogen receptor Protein target for the steroid hormone estrogen. Two distinct forms of this nuclear receptor have been identified, ER-α and ER-β.

estrogen receptor knockouts Mouse lines developed using gene targeting strategies to disrupt expression of endogenous genes encoding ER-α (αERKO) or ER-β (αERKO).

estrogen response element Specific binding sequence for the estrogen receptor; located in the promoter of estrogen target genes. The consensus estrogen response element is a 13-base-pair inverted palindrome containing a 3-base-pair spacer (GGTCAnnnTGACC).

ligand-binding domains Large C-terminal domains that are well conserved among members of the nuclear hormone receptor superfamily. Composed of several α-helices, these domains are involved in hormone binding, dimerization, and activation of hormone-dependent transcription.

Estrogen Receptor Crosstalk with Cellular Signaling Pathways

CAROLYN L. SMITH

Baylor College of Medicine

Glossary

activation function-1 The ligand-independent domain found in the N-terminus of ER-α that can be activated by non-estrogen-dependent signaling. ER-β lacks this function.

activation function-2 This major activation domain of ERs is located in the C-terminus of the proteins. It lies at the C-terminal end of the ligand-binding domain and is characterized by a hydrophobic α-helical structure with the invariant amino acid motif &phis;&phis; XE&phis;&phis; (where &phis; is any hydrophobic amino acid, X is any amino acid, and E is glutamic acid). This helix interacts with LXXLL motifs found in co-activators (L is leucine).

co-activator Accessory protein that interacts with nuclear receptors when the receptor is in an active conformation, enhancing transcriptional activation. Co-activators function as a "bridge" from the receptor to the general transcriptional apparatus; interact with receptors via LXXLL motifs.

DNA-binding domains Portions of the receptor proteins containing a double zinc finger motif that binds to the DNA sequence.

estrogen receptor Protein target for the steroid hormone estrogen. Two distinct forms of this nuclear receptor have been identified, ER-α and ER-β.

estrogen receptor knockouts Mouse lines developed using gene targeting strategies to disrupt expression of endogenous genes encoding ER-α (αERKO) or ER-β (αERKO).

estrogen response element Specific binding sequence for the estrogen receptor; located in the promoter of estrogen target genes. The consensus estrogen response element is a 13-base-pair inverted palindrome containing a 3-base-pair spacer (GGTCAnnnTGACC).

ligand-binding domains Large C-terminal domains that are well conserved among members of the nuclear hormone receptor superfamily. Composed of several α-helices, these domains are involved in hormone binding, dimerization, and activation of hormone-dependent transcription.

Estrogen Receptor Crosstalk with Cellular Signaling Pathways

CAROLYN L. SMITH

Baylor College of Medicine

Estrogen receptors respond to a number of nonsteroidal molecules through the process of signal transduction pathway crosstalk. In this process, the signal transduction pathways affect the transcriptional activity of the receptor, which is typically regulated by other agents (e.g., estrogens). The activity of the estrogen receptor can be influenced by pathway crosstalk in the presence or absence of the receptor's cognate ligand.

I. INTRODUCTION

The two estrogen receptors, ER-α and ER-β, are predominantly nuclear proteins that mediate that biological effects of estrogens in their role as ligand-regulated transcription factors. Estrogens enter the cell by passive diffusion and bind to their nuclear receptors, whereupon the receptors dimerize, tightly bind specific DNA sequences termed estrogen-response elements, and undergo a conformational change that promotes their interaction with co-activator proteins. Although in this classical model, an extracellular signal (i.e., estrogen) enters the cell and thereby regulates ER function, there are a number of extracellular agents that still possess the ability to affect ER transcriptional activity. Indeed, communication between the extracellular environment and the nucleus is important for the regulation of gene expression and cellular function. Information can be transmitted between the two compartments via intracellular signal transduction pathways that utilize a variety of second messengers, protein kinases, and/or molecules able to translocate from the cytoplasm to the nucleus. Thus, in addition to the relatively well-characterized steroid-dependent activation of transcription, ERs are responsive to a variety of nonsteroidal molecules through a process of signal transduction pathway cross talk with the receptors and/or their associated proteins that can regulate the receptor's transcriptional activity (e.g., co-activators, co-repressors, and heat shock proteins). Pathway crosstalk can alter the activity of the receptor in the absence or presence of its cognate ligand.

II. ESTROGEN RECEPTOR PHOSPHORYLATION AND TRANSCRIPTIONAL ACTIVITY

Stimulation of ER transcriptional activity by its ligand, estrogen, is accompanied by increases in receptor phosphorylation, suggesting a correlation between receptor phosphorylation and transcriptional activity. To date, five *in vivo* phosphorylation sites (Ser-104, Ser-106, Ser-118, Ser-167, and Tyr-537) have been mapped for ER-α (see Fig. 1). The ER-α is hyperphosphorylated in response to hormone, and different studies suggest that either Ser-118 or Ser-167 is the major estrogen-induced phosphorylation site, perhaps reflecting cell type-specific differences (COS-1 versus MCF-7 cells) in ER phosphorylation or resulting from differences in the techniques used to map these residues. Detailed studies mapping *in vivo* estrogen-induced ER-β phosphorylation sites have not been reported, but the A/B/C/D region of the murine receptor is phosphorylated, and alanine mutation of Ser-106 and Ser-124 reduces the phosphorylation of this region of ER-β in response to epidermal growth factor (EGF) treatment.

Mutation of three of the amino-terminal phosphorylation sites of ER-α (Ser-104, Ser-106, and Ser-118) to alanine residues significantly reduces the estrogen-induced transcriptional activity of this receptor and highlights the importance of these amino acids for full receptor function. Although the basis by which these amino acids affect ER transcriptional activity has not been fully established, there is evidence that phosphorylation of these sites positively influences receptor interaction with the p68/p72 co-activators. Similarly, the putative phosphorylation sites in the A/B region of ER-β affect its interaction with steroid receptor co-activator-1 (SRC-1). The extent to which mutation of these phosphorylation sites affects estrogen-induced ER-α transcriptional activity varies with both cell type and promoter context. A likely explanation for these differences is that the relationships between phosphorylation and co-activator and possibly co-repressor interaction with ER vary in a cell- and/or promoter-specific manner.

III. ESTROGEN RECEPTOR CROSSTALK WITH THE CYCLIC AMP SIGNALING PATHWAY

The relationship between ER phosphorylation and transcriptional activity is consistent with the ability of several pharmacological agents able to increase

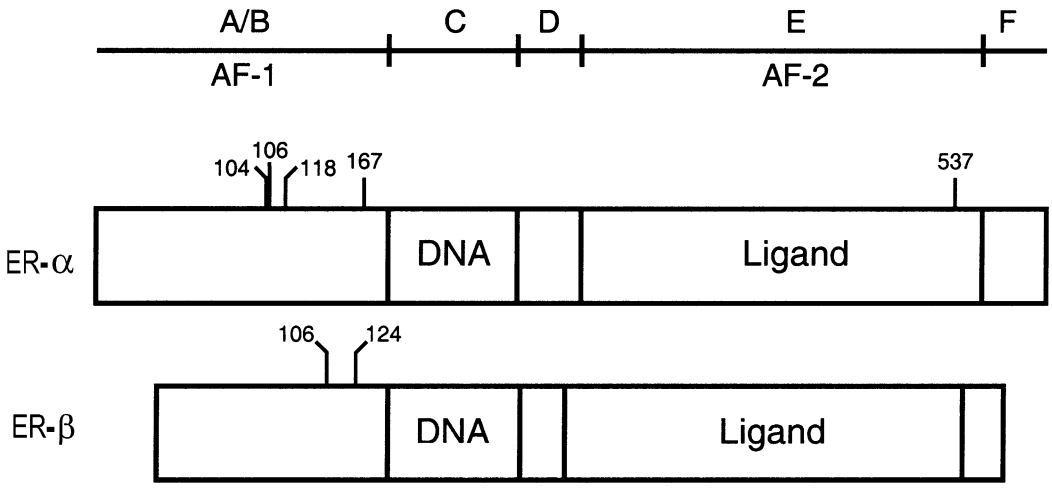

FIGURE 1 Schematic representation of ER-α and ER-β. The DNA- and ligand-binding domains are indicated for each receptor, and the numbers indicate the location of phosphorylation sites. The boundaries of regions A thru F and the positions of the two activation functions (AF-1 and AF-2) are shown at the top.

intracellular cyclic AMP (cAMP) levels and protein kinase A (PKA) activity to induce receptor phosphorylation and stimulate ER-α transcriptional activity. For instance, cholera toxin (CT; a G-protein activator) in combination with 3-isobutyl-1-methylxanthine (IBMX; a phosphodiesterase inhibitor) increases intracellular cAMP and thus activates PKA. Treatment of cultured uterine cells with these pharmacological agents results in increased progesterone receptor (PR) expression, a known ER target gene. Similarly, 8-bromo-cyclic AMP (8Br-cAMP), a cell-permeable cAMP analogue, induces PR gene expression, and the pure anti-estrogen ICI 164,384 was able to block this stimulation, thereby demonstrating that this response was ER-dependent. In addition, the neurotransmitter dopamine, apparently by activating a cAMP/PKA-dependent signaling pathway, has been shown to stimulate ER-α-dependent gene expression. Although CT/IBMX treatment results in increased phosphorylation of the receptor, transient transfection studies indicated that cAMP activation of ER-α does not require phosphorylation of any of the potential cAMP-dependent PKA phosphorylation sites located in the C-terminus of the receptor, even though it is this region that becomes phosphorylated in response to CT/IBMX treatment. Another study, which examined the ability of CT/IBMX to stimulate the transcription of several synthetic ER target genes in CHO and 3T3 cells, revealed that activation also depends on cell and promoter context and suggests that other factors (e.g., other transcription factors or co-activators) contribute to the ability of cAMP signaling pathways to regulate ER-dependent gene expression. In addition, the ability of some cAMP/PKA-mediated responses to be blocked by cycloheximide indicates that *de novo* synthesis of other cellular factors contributes to determining cell and promoter dependence. It should be noted that cAMP/PKA and estrogen signaling pathways can synergistically stimulate ER-α transcriptional activity, suggesting that these two pathways activate receptor function through distinct mechanisms.

The ability of the cAMP-dependent signaling pathway(s) to activate another member of the steroid receptor superfamily, the chicken progesterone receptor, without stimulating its phosphorylation suggested that receptor-associated proteins that contribute to nuclear receptor-dependent transcription might themselves be targets of signal transduction pathways. Indeed, it has been demonstrated that 8Br-cAMP enhances phosphorylation of the SRC-1 co-activator on amino acids Thr-1179 and Ser-1185, and mutating these residues to nonphosphorylatable alanines reduces co-activator-dependent enhancement of PR activity induced by either progesterone or 8Br-cAMP. These residues are thought to play a part in stabilizing SRC-1's interaction with another co-activator protein, pCAF (p300/CBP-associated factor). Similarly, a PKA-dependent signaling pathway enhances the intrinsic transcriptional activity of another ER co-activator, CBP (CREB-binding protein). Thus, cAMP signaling may increase ER-dependent gene expression by increasing the transcriptional activity of co-activators that bind to this receptor. In addition, the cell cycle regulator cyclin D1 has

been demonstrated to enhance ER-dependent transcription, possibly by enhancing SRC-1 recruitment to ER-α. The cAMP-mediated signaling pathway increases cyclin D1 association with ER, suggesting that the receptor's enhanced activity may also be the result of improved interaction with other co-activators. Thus, cAMP-mediated receptor-dependent transcription may depend on protein-protein interactions and also modulation of the intrinsic activity of co-activators.

IV. ESTROGEN RECEPTOR CROSSTALK WITH THE MITOGEN-ACTIVATED PROTEIN KINASE SIGNALING PATHWAY

Treatment of cells with either EGF or insulin-like growth factor-1 (IGF-1) results in the stimulation of ER-α and ER-β transcriptional activity. Importantly, these responses are blocked by the anti-estrogens ICI 164,384 or EM652, demonstrating that they are ER-dependent. In contrast to the activation function-2 (AF-2) domains of the ERs, the activity of the AF-1 domains is constitutive and in many contexts is dependent on serine phosphorylation. Moreover, growth factor activation of ER-α leads to phosphorylation of Ser-118, whereas ER-β appears to become phosphorylated at Ser-106 and Ser-124. Consequently, mutation of these residues to alanines results in the loss of EGF-induced activation of ER-α and ER-β. The phosphorylation of ER-α is likely mediated by mitogen-activated protein kinase (MAPK)/extracellular-signal regulated kinase (ERK) since overexpression of constitutively activated ras or constitutively active MAPK kinase (both are upstream activators of MAPK) results in enhanced AF-1 activity. Conversely, a dominant negative form of MAPK kinase decreases activity. Inhibition of EGF-induced ER-β transcriptional activity by the MEK1 (MAPK kinase-1) inhibitor PD98059 also indicates that EGF activation of ER-β is achieved via a MAPK signal transduction pathway. Taken together, EGF activation of both receptors appears to be mediated through MAPK/ERK. However, other studies suggest that EGF-mediated activation of ER-α might also occur through phosphorylation of Ser-167 by $pp90^{rsk1}$ or Akt (see below). It is unclear what determines the type of pathway that growth factors utilize to cross-talk with ERs. Signaling by the Src/JNK and p38 pathways, two other types of MAPKs, also stimulates ER-α transcriptional activity, although these kinases do not appear to require Ser-118 phosphorylation and JNK is unable to phosphorylate ER-α. Thus, multiple factors may mediate growth factor-dependent signaling to ER-α.

The ability of growth factors to activate ERs may arise in part by crosstalk with co-activators. The SRC/p160 family co-activators AIB1 (amplied in breast cancer-1) and GRIP1 (glucocorticoid receptor-interacting protein-1) can be phosphorylated by MAPK (ERK2) *in vitro*. Moreover, constitutively active MEK1 stimulated the intrinsic transcriptional activity of AIB1. In addition, the p300 general co-activator could be co-immunoprecipitated with AIB1 in a MEK1-dependent manner, suggesting that this signaling pathway enhanced p300-AIB1 protein–protein interaction. Similarly, the GRIP1 co-activator is phosphorylated by ERK2 on Ser-736 *in vitro* and mutating this residue to an alanine blunts the ability of EGF to induce the intrinsic transcriptional activity of GRIP1. Furthermore, the S736A mutant's ability to enhance the transcriptional activity of the CBP general co-activator was substantially impaired relative to the wild-type GRIP1. Taken together, these results suggest that MAPK phosphorylation of p160 co-activator family members serves to enhance their interactions with p300/CBP and can therefore lead to indirect regulation of receptor-dependent transcription.

Several *in vivo* EGF and IGF-1 responses have been attributed to the ability of these growth factors to stimulate ER activity. For instance, in ER-α knockout (ERKO) mice, EGF induction of PR gene expression is absent. Importantly, EGF receptor expression, autophosphorylation, and ability to stimulate c-fos activity in response to EGF stimulation were not altered in ERKO mice compared to wild type mice, indicating that the EGF signaling pathway is intact. Recently, it was demonstrated that EGF-mediated activation of ER-α is also involved in the lordosis behavioral response in rodents.

V. ESTROGEN RECEPTOR CROSSTALK WITH THE PROTEIN KINASE C SIGNALING PATHWAY

ER-α-dependent transcriptional responses can also be influenced by agents that stimulate the intracellular protein kinase C (PKC) signaling pathway. Interestingly, the gonadotropin-releasing hormone activation of ER reporter genes can be blocked by GF109203X, a PKC inhibitor. The phorbol ester, 12-*O*-tetradecanoylphorbol 13-acetate (TPA), which activates PKC, increases phosphorylation of the ER-α A/B domain, and this is at least partially attributed to Ser-118 phosphorylation. ER-α may be activated by TPA

alone or in a synergistic manner with TPA plus estrogen, but ER-α-dependent responses can also be inhibited by TPA in a promoter-dependent and cell type-dependent manner. However, TPA can also reduce ER-α expression levels and receptor binding to its estrogen-response element *in vitro*. The implications of these TPA-mediated effects relative to ER-α transcriptional activity are unclear.

VI. ESTROGEN RECEPTOR CROSSTALK WITH THE AKT SIGNALING PATHWAY

Although growth factors can signal to ER-α via MAPKs, they may also stimulate receptor transcriptional activity via the serine/threonine kinase Akt (also known as protein B kinase). Activation of Akt kinase activity is dependent on phosphatidylinositol 3-kinase (PI3-K), and the specific PI3-K inhibitor, LY294002, blocks activation of ER-α transcriptional activity in cells treated with either EGF or IGF-1. In addition, expression of a dominant negative form of Akt blocks growth factor activation of ER-α, whereas a constitutively active form is able to mimic growth factor activation of ER-α transcriptional activity and induction of PR gene expression. The ICI 182,780 anti-estrogen blocks Akt activation of ER-α. Moreover, ER-α can be phosphorylated by Akt *in vitro* and *in vivo*, and mutation of Ser-167 to an alanine blocks Akt stimulation of ER-α transcriptional activity, indicating that Akt signaling cross-talks directly with ER-α.

Glossary

co-activators Molecules, generally proteins, that stimulate the activity of transcription factors, such as the estrogen receptors.

crosstalk The ability of signal transduction pathways to influence the activity of molecules, such as the estrogen receptors, that are typically regulated by other agents.

signal transduction pathway A group of molecules that enable signals initiated at remote locations to communicate to the final target through intermediary steps.

Estrogen Receptor (ER) Actions through Other Transcription Factor Sites

STEPHEN SAFE
Texas A&M University

Estrogen receptor-α (ER-α) and estrogen receptor-β (ER-β) are members of the nuclear receptor family of ligand-activated transcription factors that mediate tissue-specific responses to 17β-estradiol and other steroidal and nonsteroidal estrogens. Classical activation of genes through consensus (or nonconsensus) estrogen response elements requires interactions with ER-α or ER-β homo- or heterodimers and a host of other nuclear cofactors that are essential for ligand-activated gene expression. Nuclear estrogen receptors also activate genes through other DNA-dependent and -independent pathways, and there is increasing evidence that estrogen receptor interactions with other transcription factors and proteins may be important.

I. INTRODUCTION

The classical mechanism of estrogen action involves ligand-dependent formation of nuclear estrogen receptor (ER) homo- or heterodimers and interaction with consensus palindromic estrogen response elements (EREs) [i.e., $-GGTCA(N)_3TGACC-$] in target 17β-estradiol (E2)-responsive gene promoters (Fig. 1). The subsequent recruitment of other nuclear co-activator and coregulatory proteins and interactions with the basal transcription machinery result in transactivation. This DNA-dependent mechanism of ER-mediated responses has been characterized for several genes that contain consensus or nonconsensus EREs; however, it has also been shown that hormonal activation of many other genes may involve genomic (nuclear) pathways that are DNA dependent or independent and other mechanisms that do not require nuclear ERs (i.e., nongenomic).

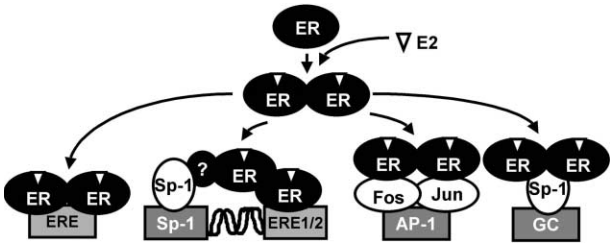

FIGURE 1 Pathways for nuclear estrogen receptor (ER) action through genomic DNA-dependent and -independent interactions. Estrogens and other ER agonists bind the receptor and activate genes through binding response elements or by direct interactions with other DNA-bound transcription factors. ERE, Estrogen response element; E2, 17β-estradiol; AP-1, activator protein 1.

II. OTHER ER-DEPENDENT GENOMIC PATHWAYS OF ESTROGEN ACTION

Transcriptional activation of E2-responsive genes through ER–ERE binding also requires interactions of ERs with co-activator/coregulatory proteins as well as other DNA-bound transcription factors. The importance of these interacting proteins as enhancers or inhibitors of E2-dependent gene expression is dependent on cell context, and this can be a critical factor that determines which ER-mediated pathways are functional. Several studies have identified E2-responsive gene promoters containing one or more ERE half-sites (ERE1/2) and GC-rich Sp protein binding sites, and research in our laboratory has characterized E2-responsive ERE1/2$(N)_x$Sp motifs (Fig. 1) in the cathepsin D, heat-shock protein 27, and transforming growth factor-α gene promoters, where $N = 23$, 10, and 31, respectively. Both GC-rich and ERE1/2 sites are required for transactivation, and formation of ER/Sp-1–DNA complexes is also dependent on other proteins that have not been identified (Fig. 1).

There is increasing evidence that ligand-dependent activation of many E2-responsive genes is promoter DNA independent and involves ER interactions with other DNA-bound transcription factors (Fig. 1). Estrogens down-regulate several erythroid cell-specific genes, and at least one pathway for this response involves ER-α interaction with GATA-1, an erythroid transcription factor. Interactions between ER-α and ER-β with the activator protein 1 (AP-1) complex has demonstrated a potentially important DNA-independent genomic pathway that modulates AP-1 promoters and the response is dependent on ER subtype, ligand structure, and cell/tissue context. For example, in HeLa cells transfected with an AP-1 promoter–reporter construct, both estrogens and antiestrogens (tamoxifen/ICI 182780) activate ER-α/AP-1, whereas antiestrogens, but not estrogens, activate ER-β/AP-1.

DNA-dependent interactions of ER-α/Sp-1 with ERE1/2$(N)_x$Sp-1 have been characterized in some gene promoters in breast cancer cell lines; however, more recent studies have demonstrated ER-α/Sp-1 interactions with GC-rich promoter elements may be a critical DNA-independent pathway for regulating hormone-responsive genes in breast cancer cell lines. For example, results of promoter analyses suggest that the following E2-responsive genes are up-regulated through ER-α/Sp-1 in breast cancer cells: c-*fos* and genes for retinoic acid receptor α1, insulin-like growth factor binding protein 4, thymidylate synthase, cyclin D1, E2F1, adenosine deaminase, cathepsin D, DNA polymerase α, and several other genes involved in hormone-induced DNA synthesis and cell cycle progression. In other cell lines, ER-α/Sp-1 activates genes for the vitamin D receptor, progesterone receptor, epidermal growth factor receptor, low-density lipoprotein receptor, and the receptor for advanced glycation end products, and a recent study suggests that ER-α/Sp-1 down-regulates insulin-like growth factor receptor in rat aortic smooth muscle cells. Sp-1 is only one member of an expanding family of zinc finger nuclear transcription factors and there is evidence that other Sp proteins bind ERs to modulate cell-specific expression of genes. For example, we have shown that ER-α/Sp-3 is necessary for E2-dependent decreased vascular endothelial growth factor (VEGF) expression in HEC1A endometrial cancer cells, whereas both ER-α/Sp-1 and ER-α/Sp-3 play a role in hormonal activation of VEGF in ZR-75 breast cancer cells. Thus, interactions of ER-α and possibly ER-β with Sp family proteins can modulate cell-specific expression of E2-regulated genes, and there are reports that other ligand-activated or orphan nuclear receptors also affect gene expression through binding Sp proteins.

III. ER-DEPENDENT NONGENOMIC PATHWAYS ACTIVATED BY E2

Research carried out in primary and transformed cell lines from multiple tissues/organs indicate that E2

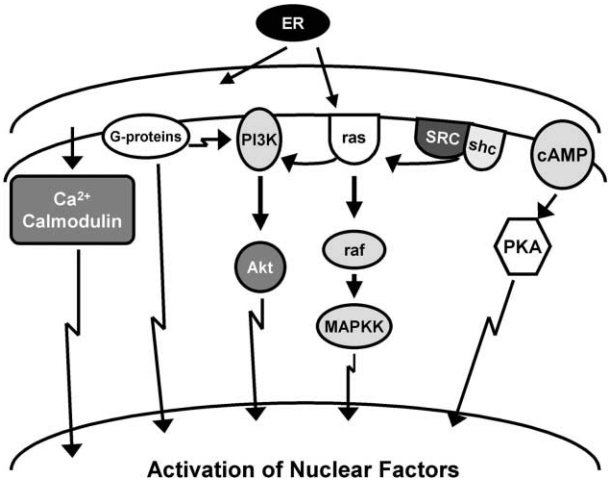

FIGURE 2 Estrogen receptor (ER)-dependent activation of multiple kinases by E2 through nongenomic pathways. Estrogen activates multiple kinase pathways through interactions with a membrane-bound or -associated ERs; multiple kinase activities can be induced and these are cell context dependent. PI3K, Phosphoinositide 3-kinase; MAPKK, mitogen-activated protein kinase kinase; PKA, protein kinase A.

induces rapid responses (< 5 min) that cannot be mediated by the nuclear ERs. Many of these nongenomic responses up-regulated by E2 resemble those induced by growth factors/cytokines through their corresponding cell membrane receptors, and this includes rapid activation of intracellular kinases and increased phosphorylation/activation of their downstream nuclear transcription factor substrates. For example, a recent study in this laboratory has reported that within 5–10 min after treatment of MCF-7 breast cancer cells with E2, there was a significant increase in phosphorylation of mitogen-activated protein kinase 1/2 (MAPK1/2), increased phosphorylation of the transcription factor Elk-1, and transactivation of a construct containing a serum response element from the c-*fos* gene linked to a luciferase reporter gene. Similar results were obtained after treatment of MCF-7 cells with insulin-like growth factor-I (IGF-I). Studies in several laboratories show that E2 rapidly activates multiple intracellular kinase pathways (Fig. 2), including SRC, ras, MAPK, phosphoinositide 3-kinase (PI3K), cAMP–protein kinase A (PKA), calcium ion/calmodulin, protein kinase C, and G-protein-coupled pathways (Fig. 2).

The ER has been identified in the cell membrane, and activation of kinases by E2 in ER-negative cell lines can be observed after transfection with ER-α or ER-β and incorporation of these proteins into the cell membrane. At present, the precise location, structure, and function of membrane ERs are unclear in most cell lines, and factors that control their cell context-dependent activation of one or more kinase pathways have not been determined. A further complication in understanding the diversity of ER-dependent nongenomic pathways has been the direct association of ER-α with multiple membrane-associated intracellular regulatory proteins. For example, ER-α binds directly to the SH2 domain of Src; ER-α also interacts with the PI3K p85 regulatory unit (but not the SH2 or SH3 domains of p85), the IGF-IR, calmodulin, and the $G_{\alpha i}$ subunit of the membrane G-protein complex (Fig. 3). The contributions of membrane or intracellular ERs on cell-context dependent interactions with these regulatory proteins and their activation of kinase pathways are unknown.

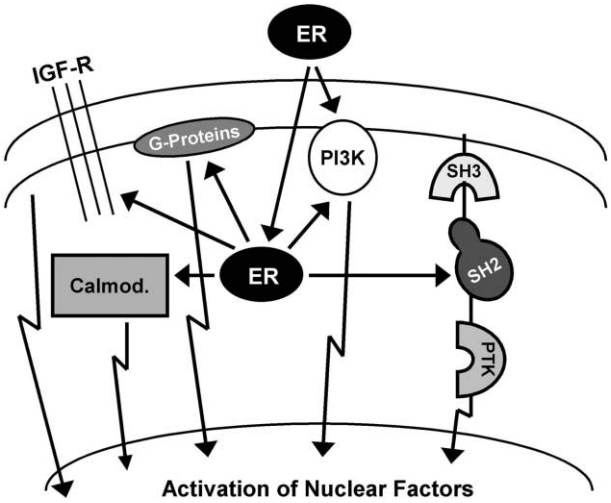

FIGURE 3 Examples of direct interactions of estrogen receptor-α (ER) with key intracellular proteins that regulate kinase pathways. There is evidence that ligand-bound ER-α also binds specific domains of intracellular kinases; however, the functional consequences of these interactions are dependent on cell context. PI3K, Phosphoinositide 3-kinase; IGF-R, insulin-like growth factor receptor; Calmod., calmodulin.

IV. SUMMARY

Regulation of E2-responsive genes is critical for normal physiology in multiple tissue/cell types; estrogens also contribute to various tissue-specific adverse responses, including breast cancer and other hormone-dependent cancers. Not surprisingly, our understanding of transcriptional modulation (increased/decreased) of E2-responsive genes has become increasingly complex. It is now understood that classical activation of genes through consensus (or nonconsensus) EREs requires interactions with ER-α or ER-β homo- or heterodimers, and a host of other nuclear cofactors that are essential for ligand-activated gene expression. Nuclear ERs also activate genes through other DNA-dependent and -independent pathways, and there is increasing evidence that ER interactions with AP-1, Sp family transcription factors, GATA, NF-κB, and other proteins may also be important for regulation of E2-responsive genes. Nongenomic ER-α-dependent activation of kinases by E2 has also been characterized in several cell types. The increasing complexity and multiplicity of E2-dependent regulatory pathways is consistent with the diverse functions of this hormone, which plays an essential role not only in development of the female and male reproductive tract but in many other organs/tissues, including the vascular system, bone, and brain.

Estrogen Receptor-α Structure and Function

ANN M. NARDULLI

University of Illinois, Urbana-Champaign

Estrogen receptor-α is a member of a large family of transcription factors that are activated by hormone binding and that interact directly with DNA to bring about changes in transcription. Estrogen receptor-α mediates the effects of estrogens and antiestrogens in target cells and is found in target cell nuclei. The activity of estrogen receptor-α is modulated by different ligands, estrogen response elements, transcription factors, co-activators, and corepressors, conferring versatility in hormone signal response and cell regulation.

I. OVERALL ESTROGEN RECEPTOR-α STRUCTURE

Estrogen receptor-α (ER-α) is a member of a large superfamily of ligand-activated transcription factors that includes steroid, thyroid, and retinoid receptors and numerous orphan receptors with ligands that

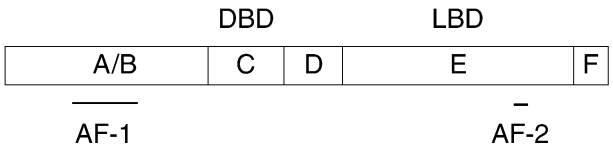

FIGURE 1 ER-α domain structure. ER-α is composed of six domains (A through F). The DNA-binding domain (DBD) is responsible for interacting specifically with the estrogen response element. The ligand-binding domain (LBD) interacts with numerous agonistic and antagonistic hormones. The positions of the amino-terminal (A/B), carboxy-terminal (F), and hinge (D) regions of the receptor are shown as well as the transcription activation functions AF-1 and AF-2.

have not been defined. Molecular and biochemical analyses have demonstrated that, like other members of the nuclear receptor superfamily, ER-α contains six domains (A through F; Fig. 1) that are structurally and functionally conserved. When the ER-α sequence from different species is compared, the most highly conserved region of the receptor is domain C, the DNA-binding domain (DBD), which contains two Cys_2Cys_2 zinc finger motifs. The DNA-binding domain is necessary and sufficient for binding of ER-α to a specific nucleotide sequence, the estrogen response element (ERE), which resides in estrogen-responsive genes. Domain E, the ligand-binding domain (LBD), is also highly conserved and is responsible for interaction of the receptor with various estrogens and antiestrogens. In addition to these two highly conserved domains are regions with considerable variation in amino acid sequence, including the amino-terminal A/B domain, the carboxy-terminal F domain, and the centrally located hinge region, domain D. Within receptor domains A–F are discrete amino acid sequences that are important in maintaining receptor function. Sequence analysis and functional studies of wild-type and mutant ER-α proteins have identified two receptor regions that are important in enhancing transcription of estrogen-responsive genes. Transcription activation function-1 (AF-1) is localized in the amino-terminal A/B domain of the receptor and serves as a ligand-independent transcription activation domain. Activation function-2 (AF-2) resides in the hormone-binding domain and acts as a ligand-inducible activation domain.

II. STRUCTURE OF THE DNA-BINDING DOMAIN

ER-α binds with high affinity and specificity to the ERE, which is typically located in the 5′ flanking region of estrogen-responsive genes. The consensus ERE comprises two inverted, palindromic half-sites separated by three intervening nucleotides that vary in nucleotide sequence (GGTCAnnnTGACC). Although it has not been possible at this point to examine the interaction of full-length ER-α with the ERE, X-ray crystallographic analysis has been used to examine the interaction of the ERE with the region of the receptor responsible for the specificity of this interaction, the DBD. These studies have demonstrated that the DBD binds to the two ERE half-sites as a homodimer (Fig. 2). Each of the DBD monomers is composed of two amphipathic α-helices that

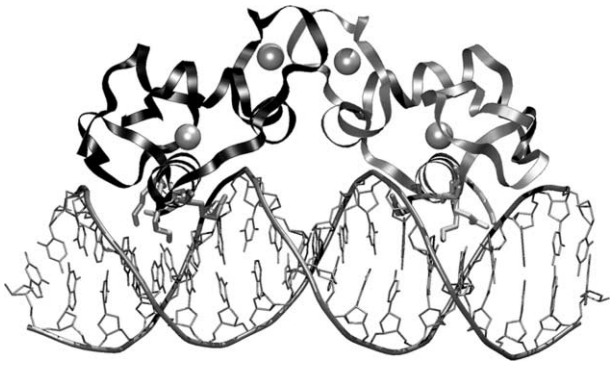

FIGURE 2 Structure of ER-α DBD bound to the consensus ERE. Two DBD monomers bind as a dimer to the major groove of the DNA helix, which contains the palindromic consensus ERE. Amino acids in the "recognition helix" of each DBD contact specific nucleotides in each ERE half-site. The two zinc atoms that coordinate four cysteine residues in each DBD monomer are shown as spheres. Figure provided by Dorina Kosztin and Klaus Schulten, University of Illinois, Urbana-Champaign.

interact at their midpoints and are oriented at right angles. The "recognition helix" of each monomer is seated in the major groove of the DNA helix and forms a network of hydrogen bonds with specific nucleotides in the ERE half-site. The second α-helix forms multiple hydrophobic interactions with the recognition helix, which helps to stabilize DBD structure. The two DBD monomers interact with each other through a dimerization domain, which is a discrete region located between the two α-helices. Together, these protein–protein and protein–DNA interactions contribute to stabilization of the DBD–ERE complex.

III. STRUCTURE OF THE LIGAND-BINDING DOMAIN

The ER-α LBD is a discrete multifunctional domain located near the carboxy terminus of the receptor (Fig. 1) and is the portion of the receptor responsible for interacting specifically with a variety of naturally occurring and synthetic estrogens and antiestrogens. The LBD is composed of 12 α-helices that form a wedge-shaped structure (Fig. 3). Three of the α-helices (H5/6, H9, and H10) form an antiparallel core that is sandwiched between two α-helical layers (H1-4 and H7, H8, and H11). Located in the narrow end of the wedge is a hydrophobic cavity that is excluded from the external environment and forms the ligand-binding pocket. Because of the relatively large size of

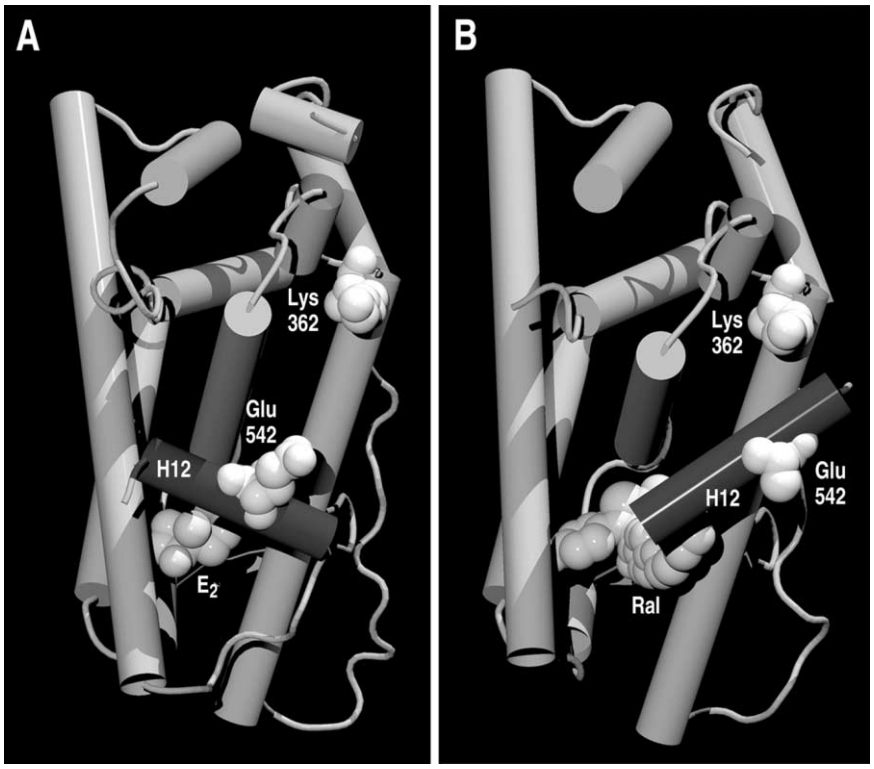

FIGURE 3 Structure of the ER-α LBD bound to estrogen or raloxifene. α-Helices 1–11 (light gray cylinders); and α-helix 12 (dark gray cylinder) comprise the wedge-shaped ER-α LBD. Binding of the LBD to 17β-estradiol (A) or raloxifene (B) causes a dramatic change in the position of helix 12 (H12). Lys-362 in helix 3, Glu-542 in helix 12, and the ligands 17β-estradiol (E2) and raloxifene (Ral) are represented as light-colored spheres. Figure provided by Dorina Kosztin and Klaus Schulten, University of Illinois, Urbana-Champaign.

this hydrophobic cavity, the ER-α LBD can accommodate a diverse range of estrogenic and antiestrogenic ligands.

Although biochemical studies have suggested for some time that ER-α conformation is different when bound to estrogens and antiestrogens, these differences have been most clearly delineated in X-ray crystallographic studies carried out with the ER-α LBD. Binding of an estrogen such as 17β-estradiol or diethyl stilbestrol to the ER-α LBD results in the positioning of helix 12 over the ligand-binding pocket (Fig. 3A). In contrast, when the LBD is bound to an antiestrogen such as raloxifene or 4-hydroxytamoxifen, the bulky side chains of these antiestrogens protrude out of the ligand-binding pocket and require the repositioning of helix 12 (Fig. 3B). Helix 12 is rotated 130° in the raloxifene-bound LBD compared to the estrogen-bound LBD. Thus, the conformation of the LBD is different when bound to estrogens and antiestrogens, most notably in the positioning of helix 12.

IV. ASSOCIATION OF ESTROGEN RECEPTOR-α WITH COREGULATORY PROTEINS

It has become increasingly clear that ER-α does not function in isolation, but that it requires the participation of coregulatory proteins to modulate transcription of estrogen-responsive genes effectively. A number of co-activator proteins that interact with ER-α and enhance estrogen-mediated transactivation have been identified, including steroid receptor co-activator-1 (SRC-1), transcription intermediary factor-2 (TIF2), and amplified in breast cancer 1 (AIB1). These co-activators contain receptor interaction domains with the amino acid sequence LXXLL, where L is a leucine and X is any amino acid. These co-activator LXXLL motifs bind to a shallow, hydrophobic groove that is formed in the LBD when it is bound to estrogen. A glutamic acid in helix 12 (Glu-542) and a lysine in helix 3 (Lys-362) of the ER-α LBD form a "charge clamp" that marks the boundaries of the co-activator binding surface and

that helps to anchor the co-activator LXXLL motif in the hydrophobic groove of the estrogen-bound receptor (Fig. 3A). When the LBD is occupied by an antiestrogen, helix 12 is reoriented and binds along the co-activator binding surface, thereby inhibiting contact between the receptor and the co-activator LXXLL motif (Fig. 3B). Corepressors, which bind to the antiestrogen-occupied ER-α and inhibit transcription, have also been identified. The recruitment of co-activator and corepressor proteins with histone acetylase and deacetylase activities, respectively, appears to be important in modulating chromatin structure and the accessibility of transcription factors to their respective DNA binding sites. Whereas acetylation of histones is associated with more open chromatin structure, increased accessibility of transcription factor binding sites, and increased transactivation, deacetylation of histones is associated with more compact chromatin structure, decreased accessibility of transcription factor binding sites, and decreased transactivation. The transcription of estrogen-responsive genes is most likely subject to the combined effects of co-activator and corepressor proteins.

V. MECHANISM OF ACTION

The most clearly defined mechanism by which ER-α alters cell function is through direct interaction with DNA. Circulating estrogen enters a cell and binds to the intracellular ER-α, which is present in the nucleus of target cells (Fig. 4). On binding hormone, ER-α undergoes a change in conformation and the estrogen-occupied receptor dimerizes and interacts with EREs residing in estrogen-responsive genes. Interaction of the estrogen-occupied ER-α with the ERE modulates transcription of ERE-containing genes and alters the levels of specific mRNA transcripts. Nuclear mRNA is processed and exported to the cytoplasm, where it is translated into protein. Thus, the ER-α–ERE interaction is a critical link in the chain of events that leads to changes in cellular function. Although the consensus ERE has been the most widely studied ER-α binding site, most of the estrogen-responsive genes identified to date have EREs that deviate from the consensus sequence by one or more nucleotides. This variation in nucleotide sequence influences receptor binding, transcription activation, and recruitment of co-activator proteins.

A number of genes have been identified that do not possess an ERE sequence but are clearly estrogen responsive. Recent evidence suggests that ER-α regulates transcription of some of these estrogen-responsive genes by interacting with DNA-bound proteins such as Sp-1 and activator protein 1 (AP-1) rather than binding directly to DNA. There is also accumulating evidence that nongenomic events, which include posttranslational modifications such as phosphorylation, may be involved in regulating rapid responses to hormone.

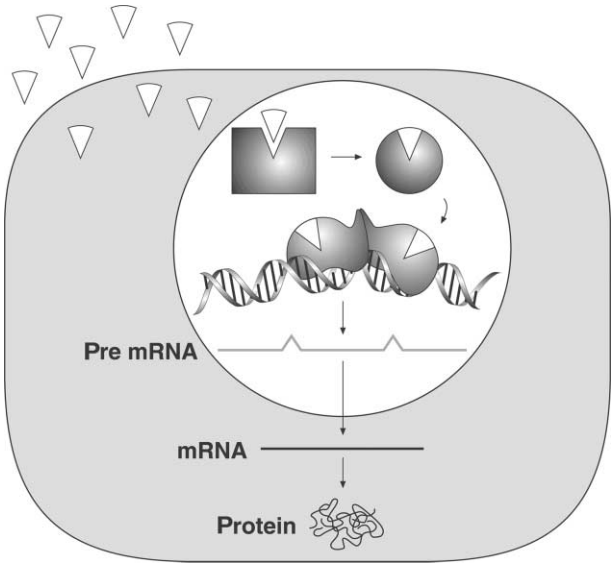

FIGURE 4 Mechanism of estrogen action. Circulating estrogen enters the cell and binds to ER-α located in the nucleus of target cells. Binding of hormone induces a conformational change in receptor structure and causes ER-α to dimerize and bind to estrogen response elements residing in estrogen-responsive genes. Interaction of ER-α with the estrogen response element alters transcription of estrogen-responsive genes. The newly synthesized mRNA transcripts are processed in the nucleus and transported to the cytoplasm, where they are translated into proteins.

VI. EFFECTS OF ESTROGENS

Estrogen treatment of target cells alters transcription of a wide variety of genes. Estrogen is a hormone of critical importance in the development and maintenance of reproductive function. Although circulating estrogen typically inhibits gonadotropin secretion from the anterior pituitary, the rising estrogen levels at midcycle initiate a luteinizing hormone (LH) surge from the anterior pituitary, which in turn induces ovulation. Thus, estrogen supplementation has been extensively used to regulate ovulation and fertility. Estrogen acts on the uterus to increase cell proliferation and is required for mammary gland development. Estrogen also appears to play a role in maintaining bone mineral density and neural and

cardiovascular physiology. Interestingly, it is now clear that estrogen plays a crucial role in the male reproductive tract and is required for concentration of sperm. Studies in ER-α-deficient mice indicate that estrogen may also influence behavior in both males and females.

VII. EFFECTS OF ANTIESTROGENS

Antiestrogens bind to ER-α and inhibit the actions of estrogens in target cells. Tamoxifen inhibits estrogen-induced tumor cell proliferation and has been the most widely used antiestrogen for breast cancer treatment and prevention. In contrast to its antagonistic effects in breast cancer cells, tamoxifen has agonistic effects in other tissues and, like estrogen, helps to maintain bone mineral density, improve lipid profiles, and stimulate uterine endometrial cell growth. Tamoxifen's agonistic effects in the uterus result in an increased incidence of endometrial cancer. Thus, tamoxifen acts as an antagonist in mammary tissue, but as an agonist in uterus and bone. On the basis of its mixed agonist/antagonist activity in different tissues, tamoxifen has been reclassified as a selective estrogen receptor modulator (SERM). Another SERM, raloxifene, functions as an antagonist in mammary tissue and decreases the incidence of breast cancer in women who are at increased risk of developing this disease. Unlike tamoxifen, raloxifene functions as an antagonist in the uterus and is not associated with an increased incidence of endometrial cancer. The development of new SERMs that function as agonists in bone, cardiovascular, and neural cells, but as antagonists in mammary and uterine cells, could provide new therapies for breast cancer treatment and prevention and for the treatment of postmenopausal symptoms.

VIII. SUMMARY

The estrogen receptor is a ligand-activated transcription factor that resides in the nucleus of target cells. Those regions of the receptor responsible for interacting with DNA and hormones have been defined in detail and have provided a greater understanding of how the receptor functions in target cells. The ability of different ligands, EREs, transcription factors, co-activators, and corepressors to interact with ER-α and to modulate its activity provides target cells with tremendous versatility in responding to hormonal signals and regulating cellular function.

Glossary

agonist Naturally occurring or synthetic compound that binds to a receptor and mimics a specific effect.

antagonist Naturally occurring or synthetic compound that binds to a receptor and opposes the actions of an agonist.

antiestrogen Steroidal or nonsteroidal compound that binds to the estrogen receptor and opposes the actions of estrogen when administered in combination with estrogen, but may also elicit estrogenic effects when administered alone.

co-activator Protein that interacts with the estrogen receptor and enhances transcription of estrogen-responsive genes.

corepressor Protein that interacts with the estrogen receptor and inhibits transcription of estrogen-responsive genes.

estrogen Naturally occurring or synthetic steroid that binds to the estrogen receptor and stimulates the development of female secondary sex characteristics and promotes growth and maintenance of the female reproductive system.

estrogen response element Specific nucleotide sequence located in an estrogen-responsive gene; the estrogen receptor binds to the sequence and thereby alters expression of the gene.

selective estrogen receptor modulator Ligand that binds to the estrogen receptor and has agonistic or antagonistic effects that are cell and promoter specific.

Estrogen Receptor-β Structure and Function

KARIN DAHLMAN-WRIGHT, KONRAD KOEHLER*, AND JAN-ÅKE GUSTAFFSON

Karolinska Institute, Sweden • **Karo Bio AB, Sweden*

For a long time estrogen receptor-α (ER-α) was thought to be the single mediator of the physiological effects of estrogen. However, in 1996, a novel ER was discovered in the rat prostate. This receptor was named ER-β, to distinguish it from the previously identified ER-α. ER-β homologues have subsequently been cloned from human, mouse and various other species including cow and goldfish. The discovery of ER-β has forced us to re-evaluate the biology of estrogen. ER-β is abundant in the male reproductive tract and considerable attention has been paid to the role of ER-β in the male reproductive tract.

I. INTRODUCTION

ER-β belongs to a family of ligand-activated transcription factors, the nuclear receptor family. Binding of ligand results in association with hormone-responsive DNA elements in the regulatory regions of target genes. Physical interaction of the DNA-bound receptor with co-activator proteins then leads to changes in the transcriptional rate of regulated genes.

The structure of the ER-β gene reveals how several transcripts and proteins with potentially important biological roles may be generated. The three-dimensional structure of the ER-β ligand-binding domain provides insight into how different ligands may lead to different biological end-points. Animals with eliminated expression of ER-β are instrumental in defining the role of this receptor in physiology and have already provided important information. Although the focus of this article is on ER-β, it is necessary to also discuss ER-α, since it is the coordinated and integrated activities of these two receptors that bring about the physiological effects of estrogen.

II. ER-β GENE STRUCTURE

The human ER-β gene is localized on chromosome 14q23–q24. The 59 kb gene includes eight coding exons (Fig. 1). In humans, there is an alternative last exon designated CX (Fig. 1).

ER-β has the same general primary structure as all nuclear receptors (NRs) (Fig. 2a). This structure includes an N-terminal domain termed the A/B domain. This domain harbors a transcriptional activation function (AF-1). Next to the A/B domain is the DNA-binding domain (DBD), also termed the C-domain. This is the most conserved region of the receptor protein, including two zinc-finger motifs, where eight strictly conserved cysteine residues coordinate two zinc atoms. This domain also includes

Estrogen Receptor-β Structure and Function

KARIN DAHLMAN-WRIGHT, KONRAD KOEHLER*, AND JAN-ÅKE GUSTAFSSON

Karolinska Institute, Sweden • **Karo Bio AB, Sweden*

For a long time estrogen receptor-α (ER-α) was thought to be the single mediator of the physiological effects of estrogen. However, in 1996, a novel ER was discovered in the rat prostate. This receptor was named ER-β, to distinguish it from the previously identified ER-α. ER-β homologues have subsequently been cloned from human, mouse and various other species including cow and goldfish. The discovery of ER-β has forced us to re-evaluate the biology of estrogen. ER-β is abundant in the male reproductive tract and considerable attention has been paid to the role of ER-β in the male reproductive tract.

I. INTRODUCTION

ER-β belongs to a family of ligand-activated transcription factors, the nuclear receptor family. Binding of ligand results in association with hormone-responsive DNA elements in the regulatory regions of target genes. Physical interaction of the DNA-bound receptor with co-activator proteins then leads to changes in the transcriptional rate of regulated genes.

The structure of the ER-β gene reveals how several transcripts and proteins with potentially important biological roles may be generated. The three-dimensional structure of the ER-β ligand-binding domain provides insight into how different ligands may lead to different biological end-points. Animals with eliminated expression of ER-β are instrumental in defining the role of this receptor in physiology and have already provided important information. Although the focus of this article is on ER-β, it is necessary to also discuss ER-α, since it is the coordinated and integrated activities of these two receptors that bring about the physiological effects of estrogen.

II. ER-β GENE STRUCTURE

The human ER-β gene is localized on chromosome 14q23–q24. The 59 kb gene includes eight coding exons (Fig. 1). In humans, there is an alternative last exon designated CX (Fig. 1).

ER-β has the same general primary structure as all nuclear receptors (NRs) (Fig. 2a). This structure includes an N-terminal domain termed the A/B domain. This domain harbors a transcriptional activation function (AF-1). Next to the A/B domain is the DNA-binding domain (DBD), also termed the C-domain. This is the most conserved region of the receptor protein, including two zinc-finger motifs, where eight strictly conserved cysteine residues coordinate two zinc atoms. This domain also includes

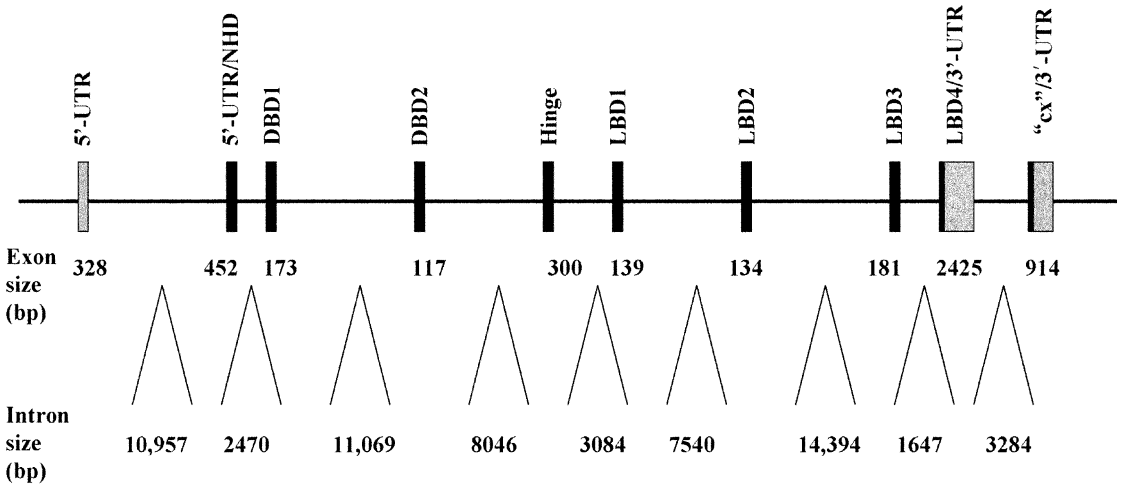

FIGURE 1 The gene structure of ER-β. Protein coding sequences are shown in black; untranslated regions (UTRs) are shown in gray.

a dimerization region. The DBD is linked to the ligand-binding domain (LBD) by the hinge domain (domain D). Domain D is poorly conserved. The LBD or the E/F domain includes multiple functions including binding of agonists or antagonists, dimerization, binding of co-factors, as well as transcriptional activation. The transactivation function at the C-terminus (AF-2) is in most cases dependent on the binding of ligand for activity.

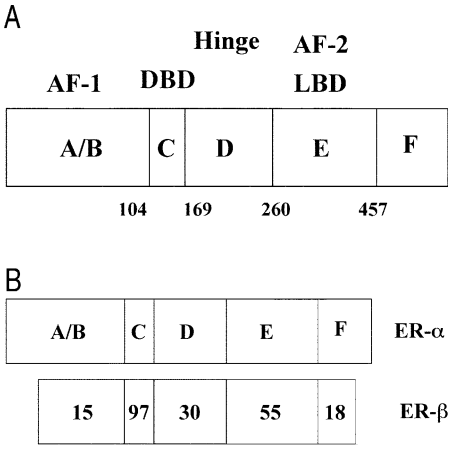

FIGURE 2 (A) Overall structural organization of the ER-β protein. Numbers below the schematic representation of the ER-β protein refer to the first and last amino acids of the human DBD and LBD, respectively. A/B, Transcriptional activation function; C, DNA-binding domain and dimerization region; E/F, ligand-binding domain, transcriptional activation function, and dimerization region. (B) Homology between ER-α and ER-β (%).

The amino acid sequence homology between ER-α and ER-β is approximately 97% in the DBD and approximately 55% in the LBD. Regions that are directly involved in ligand binding and transcriptional activation show a higher degree of conservation (Fig. 2b). Human ER-β has approximately 89% identity with rat ER-β and 88% identity with mouse ER-β.

A. ER-β Isoforms

1. Alternative Translational Initiation

Alternative translational initiation gives rise to proteins containing 530 and 548 amino acids, respectively, in addition to the 485-amino-acid protein originally cloned. Both of the longer receptor isoforms have been identified in rodents. Only the 530-amino-acid form has been observed in human. These isoforms have not yet been characterized with regard to specific physiological functions.

2. ER-βins

ER-βins, also called ER-β2, contains an extra 54 bp insertion in the reading frame, causing an 18-amino-acid insertion in the LBD between exons 5 and 6 (Fig. 3). This insertion occurs through alternative splicing. ER-βins shows severely impaired ligand binding and transcriptional activation. However, ER-βins binds to an estrogen-response element (ERE) and can heterodimerize with ER-β variants and ER-α. ER-βins acts as a dominant negative regulator of ER-β and ER-α and causes a dose-dependent inhibition of ER-β and ER-α transcriptional activity. ER-βins has been described for mouse and rat.

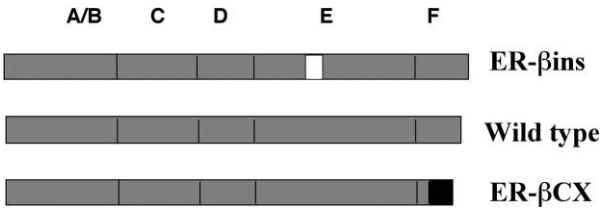

FIGURE 3 ER-β isoforms. The ins domain found in the variant ER-βins in rodents is indicated in white. The CX domain found in the variant ER-βCX in humans is indicated in black.

3. *ER-βCX*

Another splice variant occurring in the human, ER-βCX, has an alternative last exon and C-terminus (Fig. 3). The last 61 amino acids encoding parts of helix 11 and helix 12 in wild-type ER-β is replaced by 26 novel amino acids to produce ER-βCX. This isoform does not bind ligand or DNA. DNA binding by ER-α is inhibited by ER-βCX. This finding is in contrast to the lack of an influence on ER-β DNA complexes. When ER-βCX is co-transfected with ER-α or ER-β, it inhibits ligand-induced transactivation by ER-α but does not influence ER-β-mediated transactivation. Other ER-β splice variants have also been cloned. Interestingly, it has been shown that expression of ER-βCX is increased in several forms of cancer, including cancer of the breast, ovary, and prostate. Other isoforms have also been shown to be associated with disease.

B. ER-β Polymorphism

Analysis of a German population identified two common polymorphisms in the ER-β gene, one silent change in exon L1 and one change in the 3′-untranslated region (Fig. 4). Polymorphism refers to the existence of different base pairs at a given nucleotide position. It is evident that the ER-β gene contains very few polymorphic nucleotide positions. Several less common polymorphisms were also identified in the German population (Fig. 4). These polymorphisms change the amino acid sequence in the hinge region. The functional consequences of these mutations remain to be determined.

			Allele frequency
1	809 (del 21)	Δ Q238 to K244	< 0.01
2	846 G → A	G-250-S	< 0.01
3	1082 G → A	Silent	0.04
4	1421 T → C	Silent	< 0.01
5	1730 A → G	3'-UTR	0.60

FIGURE 4 ER-β genetic variants. Data from Rosenkranz, K., *et al.* (1998) *J. Clin. Endocrinol. Metab.* **83**, 4524.

Recently, a polymorphic dinucleotide CA repeat in the noncoding 3′-portion of the gene was identified. It has been suggested to be associated with bone mineral density in women. An additional study showed an association between the length of the CA repeat and androgen levels in women. Women with a short CA repeat region displayed higher levels of total and free testosterone than women with many CA repeats. However, the molecular mechanism by which the length of the CA repeat leads to changes in androgen levels remains obscure. It is unclear whether the CA repeat affects the activity and/or expression level of the ER-β protein. However, there are reasons to believe that repeat nucleotide sequences (micro/minisatellites), even when situated in untranslated regions, may influence the expression of a gene.

C. The ER-β Promoter

The promoters of the mouse and human ER-β genes have been cloned and preliminary functional analyses have been reported. A 2.1 kb fragment of the human promoter exhibited functional promoter activity in ER-β-positive cells but not in ER-β-negative cells, suggesting that it maintained the cell-restricted expression of the intact ER-β gene. Two transcription start sites were observed, which are located about 200 bp apart approximately 400 bp upstream from the ATG. The proximal promoter contains both TATA box and initiator (Inr) elements and is highly GC-rich. The Inr sequence is highly homologous to the preferred Inr sequence. Serial deletion analysis revealed that a 293 bp region encompassing the TATA box and Inr element possesses basal promoter activity. An *Alu* repeat sequence exists between −1416 and −1703. This *Alu* element belongs to a new class of *Alu* DNA repeats, which contain an imperfect ERE and function as ER-dependent transcriptional enhancers. The sequence of this DNA element is GGTCAnnnTGGTC. This element might be responsible for the observed 30-to 40-fold estradiol induction of ER-β expression in T47D cells. Consistent with this observation, deletion of this *Alu* element in the ER-β promoter resulted in decreased promoter activity in reporter assays. Several binding sites for transcription factors

including SP-1, AP-1, Oct-1, and N-myc were noted. Deletion analysis of the ER-β promoter using appropriate reporter assays identified enhancer and silencer elements. A negative regulatory element was identified at −425 using this analysis. This element has the sequence AGCCTCTCT and is referred to as the negative regulatory element. This sequence is the consensus sequence for a ubiquitous transcriptional silencer that represses transcription in the absence of steroids. The mouse ER-β promoter contains several putative *cis*-acting elements, many of which are also found in the mouse ER-α promoter. Therefore, the expression of both ERs may be partially regulated by a common mechanism.

III. ER-β PROTEIN STRUCTURE AND INTERACTING MOLECULES

A. The DNA-Binding Domain

The DNA-binding domain includes two so-called zinc fingers, in which four cysteines coordinate one zinc atom, and folds into a "finger-like" structure. The P-box refers to a sequence of three amino acids in the first zinc finger, which is involved in DNA sequence recognition. The D-box refers to a sequence of approximately 5 amino acids in the second zinc finger, which is responsible for protein–protein interactions in the dimer that binds to DNA.

The three-dimensional structure of the ER-β DBD has not been determined. However, since the identity between ER-α and ER-β is 97% in this domain, the structures must be very similar.

The three-dimensional structure of ER-α DBD bound to an ERE has been determined. The structure of the protein–DNA complex has revealed the exact mechanism of how amino acids in the so-called P-box recognize specific base pairs in the estrogen-response elements. The structure also revealed how the D-box is used for dimerization, thereby restricting the spacing between the two half-sites constituting the ERE.

B. The Ligand-Binding Domain

Crystal structures for various NR LBDs with or without bound ligand have shown that the binding of ligand leads to a conformational change in the receptor protein, resulting in a transcriptionally active protein. Furthermore, the architecture of the domain is conserved with 12 α-helices. The three-dimensional structures for the ER-β LBD bound to raloxifene (a cell- and tissue-specific agonist–antagonist) and the isoflavonoid genistein (an ER-β-specific agonist), respectively, have been reported (Figs. 5a and 5b). Three-dimensional structures for ER-α bound to various agonists and antagonists have also been reported.

The ER-α agonist structures show a central layer of three helices, packed between two additional layers of helices creating a molecular scaffold with the ligand-binding pocket close to the surface of one end. Helix 12 (H12) is positioned across the ligand-binding pocket. This configuration facilitates interaction between the receptor and co-activators. When anti-estrogens are bound, H12 translocates to a position that masks the co-activator-binding site. In the crystal structure of genistein-bound ER-β LBD,

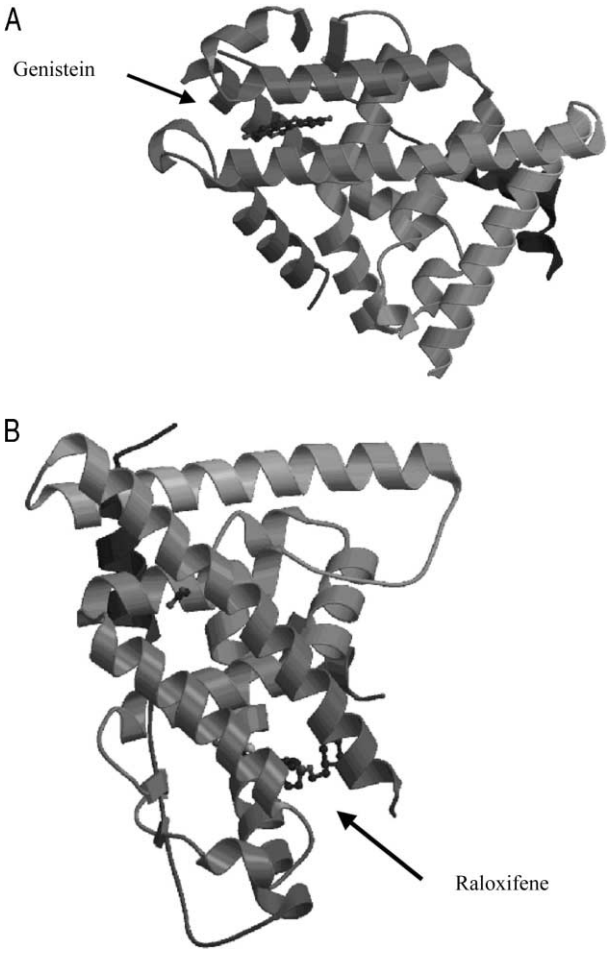

FIGURE 5 (A) Crystallographic structure of ER-β LBD complexed with genistein. (B) Crystallographic structure of ER-β LBD complexed with raloxifene. These figures were produced using MOLSCRIPT [Kraulis, P. J. (1991) *J. Appl. Crystallogr.* **24**, 946–950] and Raster3D [Merritt, E. A., and Bacon, D. J. (1997) *Methods Enzymol.* **277**, 505–524].

H12 does not adopt the typical agonist conformation but rather adopts the position of an antagonist–ER LBD complex. This particular positioning of H12 might explain why genistein is a partial agonist.

C. Dimerization

ER-β dimerization is required for transcriptional activation. *In vitro*, ER-β dimerization is independent of ligand. However, whether this is also the case *in vivo* needs to be established. ER-β and ER-α form functional heterodimers *in vitro* and *in vivo*. ER-β and ER-α are co-expressed in various cell types, suggesting that heterodimerization occurs *in vivo*.

D. Ligand Binding

ER-β and ER-α have similar ligand-binding specificities. The natural estrogen 17β-estradiol (E2) binds to both ER-α and ER-β with similar high affinity (dissociation constant, K_d, 0.1 nM for ER-α and 0.4 nM for ER-β). This is not surprising considering the particularly high sequence similarity in the region of the LBDs that is directly involved in ligand binding. However, there are major differences between the ER isoforms regarding affinities for several compounds as well as ligand-induced responses. For example, tamoxifen is a pure antagonist for ER-β but for ER-α its agonist and antagonist properties depend on the cellular context.

Phytoestrogens, like genistein, generally have higher affinities for ER-β than for ER-α. At low nanomolar concentrations, genistein-activated estrogen-specific transcription is ER-β specific. However, the maximal transcriptional activity achieved with ER-β is only half of the activity obtained with ER-α at higher concentrations of genistein. Fig. 6 shows the molecular structures of some agonists and antagonists with estrogenic activity. Several large pharmaceutical companies are involved in the development of ER-β-specific selective estrogen receptor modulators (SERMs). However, none of these drugs has yet reached the market. SERMs may have the potential to achieve the beneficial effects of estrogens but avoid the unwanted side effects. Indications for such compounds are menopausal symptoms, e.g., hot flashes, osteoporosis, and cardiovascular disease.

E. Are Phytoestrogens Natural SERMs?

Phytoestrogens are nonsteroidal polyphenolic compounds present in several edible plants. Phytoestrogens can be divided into four subclasses based on chemical structure: isoflavonoids, flavonoids, coumestans, and lignans. The major dietary source of isoflavonoids (e.g., genistein) is soybean. Flavonoids are widely distributed in the plant kingdom and are

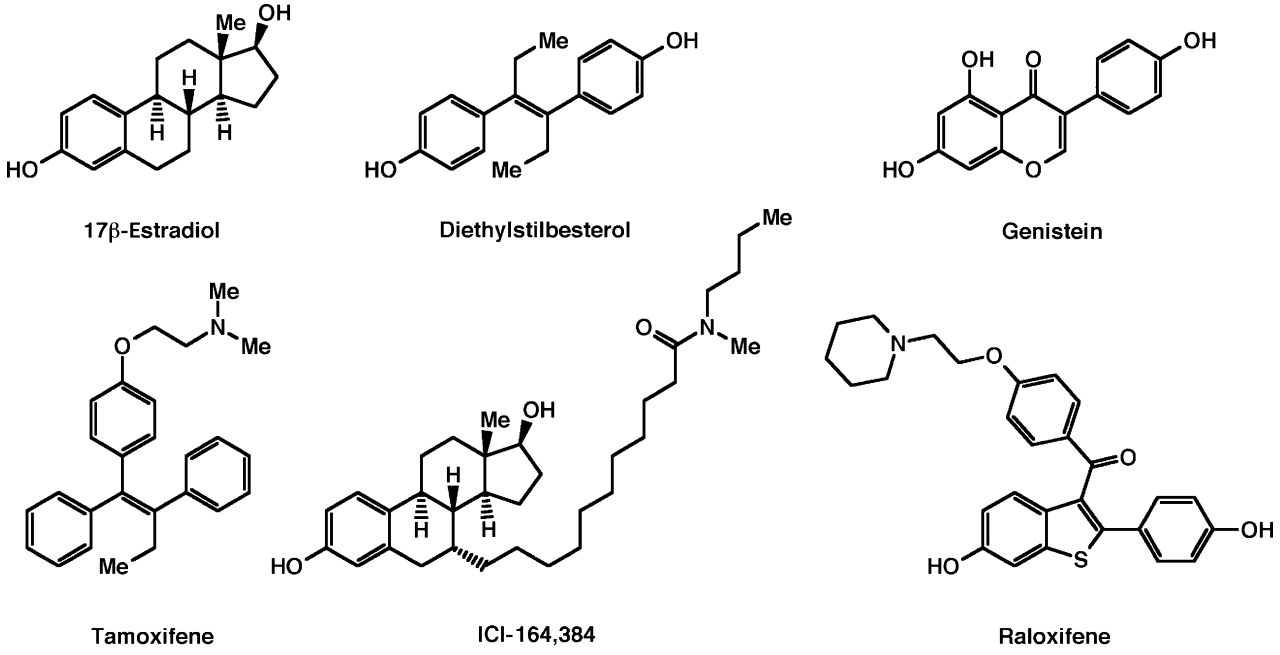

FIGURE 6 Molecular structures of selected estrogen receptor agonists and antagonists.

present in several edible plants. Coumestans, present in alfalfa sprouts, for example, are not common in the human diet. Isoflavones and coumestrol interact with ER *in vitro* but the binding affinities of different compounds with similar structures differ remarkably. Some flavonoids show modest estrogenic activity and others are completely inactive. Lignans have very weak estrogenic activity and require millimolar concentrations to demonstrate any ER-mediated activity.

F. Co-regulators

Co-regulators, i.e., co-activators and co-repressors, enhance or suppress the activity of NRs, respectively. These proteins usually exist in large complexes and some have enzymatic activities. Many co-regulators have the consensus amino acid sequence LXXLL for NR interaction. This sequence can be found in single or multiple copies in NR-interacting proteins. During the past 5 years, protein–protein interaction screenings and biochemical approaches have led to the identification of a large number of co-regulators that act at different functional levels of NR interaction. The majority of these co-regulators bind to the LBD. Co-regulators, in a simplified view, connect the ER with components of the basal transcriptional machinery and chromatin components.

Co-activators that have been shown to be relevant for ER function include the steroid receptor co-activator (SRC) family, CREB-binding protein (CBP)/p300, and the thyroid hormone receptor-associated protein (TRAP)/vitamin D-receptor interacting protein (DRIP) complex. SRC proteins are involved in recruiting chromatin and/or histone-modifying enzymatic activities to ligand-activated ERs bound at target genes. The histone acetylase activity of CBP has been shown to be required for efficient ER target gene activation *in vivo*. The TRAP/DRIP complex may mediate signals from ERs to the RNA polymerase multiprotein complex. A few differences between ER-α and ER-β with regard to co-activator recruitment have been reported. The interaction between ER-β and the TRAP/DRIP complex seems stronger than that of ER-α. On the other hand, ER-α interacts more strongly with SRC-3 than does ER-β.

Co-repressors that have been shown to affect ER function include N-CoR (nuclear receptor co-repressor) and SMRT (silencing mediator of retinoid and thyroid receptors). RIP140 (receptor-interacting protein-140) and SHP (short heterodimerization partner) bind to AF-2 of ERs and exhibit negative co-regulatory functions at least partially because they compete with SRC-1 binding and function. Interestingly, ER-β interaction with SRC-1 and SHP *in vitro* is ligand-independent, in contrast to the interaction of ER-α with these co-factors, which is ligand-dependent.

G. Phosphorylation

Phosphorylation of Ser-106 and Ser-124 (nomenclature refers to the 548-amino-acid mouse ER-β) of ER by MAPK results in ligand-independent recruitment of SRC-1 and transcriptional activation. Co-expression of components of the MAPK pathway also enhances estrogen-induced gene activation.

A conserved tyrosine amino acid residue in ER-β LBD can be mutated to produce a constitutively active receptor. This residue is phosphorylated by the Src family of protein kinases. Mutated receptors appear to be in an active conformation as judged by proteolytic digestion (and show ligand-independent interaction with the co-activator SRC-1). This ligand-independent event can be inhibited by antagonists. In wild-type ER, phosphorylation of this Tyr residue might increase the affinity of the receptor protein for the ligand.

IV. TRANSCRIPTIONAL ACTIVATION

Both ER-α and ER-β are capable of activating transcription from the classical EREs. However, ER-β demonstrates a weaker transactivating capacity and requires 10-fold higher concentrations of 17β-estradiol for full transactivating capacity in most cell types compared to ER-α (Fig. 7). In addition, as pointed out above, ER-β fails to show tamoxifen-induced agonist activity, due to a functional difference in the A/B domains of the ER isoforms. The isolated ER-β AF-1 domain fails to initiate transcription when fused to the GAL4 DBD. On conventional estrogen-responsive DNA elements, ER-β and ER-α show similar agonist and antagonistic profiles. However, this is not the case for all types of response elements. The estrogen agonists 17β-estradiol and diethylstilbestrol, in the presence of ER-β, inhibit transcription from an AP-1 element (Fig. 8). Moreover, the anti-estrogens raloxifene and ICI 164,384 induce transcription from an AP-1 element in the presence of ER-β in all cell systems tested (Fig. 8). Tamoxifen induces transcription from these elements in the presence of ER-α in some but not all cellular systems.

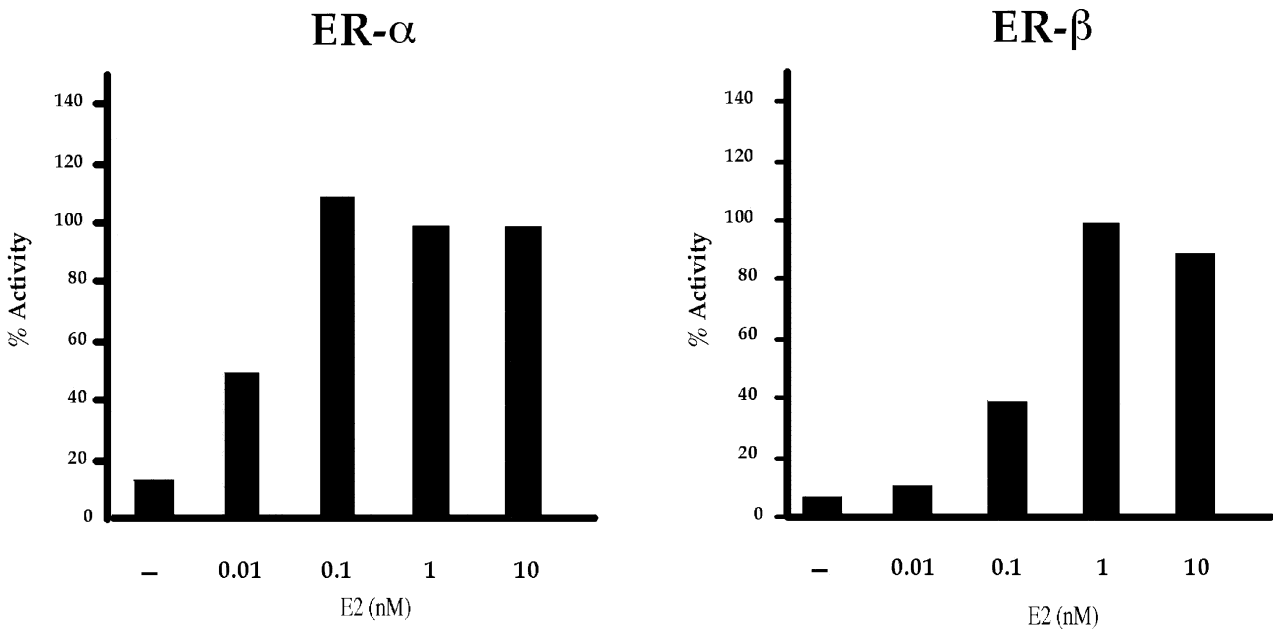

FIGURE 7 Estrogen-mediated transcriptional activity of ERE sequences. The ability of ER-α and ER-β to induce transcriptional activation from an ERE was tested in reporter assays. The concentration of E2 (17β-estradiol) is indicated. Reprinted from Pettersson, K., *et al.* (2000) *Oncogene* **19**, 4970–4978, with permission.

V. ANIMAL MODELS

A. ER-β Expression

Tissue-specific expression of ER-β is important to consider when one attempts to understand the phenotype of ER-β knockout animals. In rodents, the tissues with the highest level of expression of ER-β are prostate, ovary, and lungs. ER-β is also present in the mammary gland, bone, uterus, epididymis, ovary, kidney, bladder, intestine, central nervous system, and cardiovascular system.

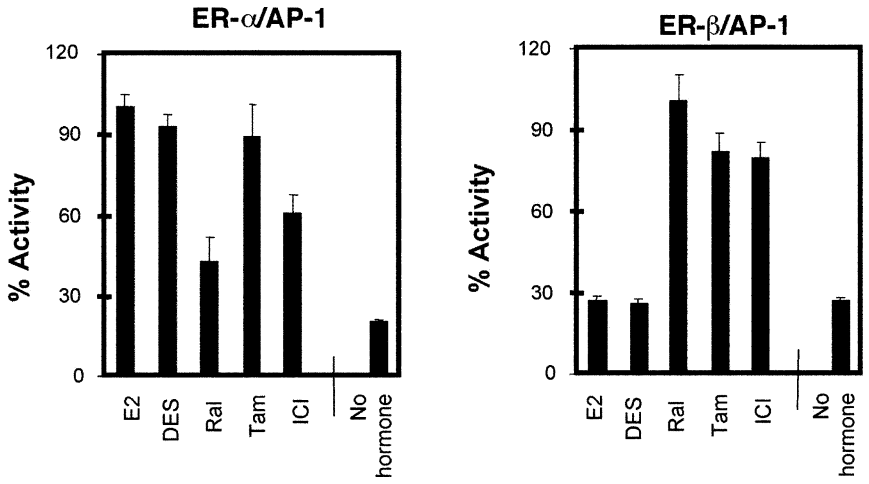

FIGURE 8 Estrogen-mediated transcriptional activity of AP-1 sequences. The ability of ER-α and ER-β to induce transcriptional activation from an AP-1 element was tested in a reporter assay. E2, 17β-estradiol; DES, diethylstilbestrol; Ral, raloxifene; Tam, tamoxifen; ICI, ICI 164,384. Reprinted from Paech *et al.* (1997) with permission.

B. ER-β Knockout Animals

Knockout animals are those in which production of a particular protein has been eliminated due to deletion of parts of the gene that are necessary for the production of a functional protein. ER-β knockout animals (BERKO) are viable.

1. The Reproductive Tissues

BERKO female mice have low fertility and disturbed ovarian function with almost no spontaneous ovulations and premature ovarian failure. There is a paucity of corpora lutea and an increase in the number of follicles with premature atresia. Follicles are actively recruited into the growth pool but they fail to mature. The oocytes are not released and they die within the preantral follicles. Uterine dysfunction probably contributes to the severe subfertility of BERKO female mice since fetuses are resorbed. The litter size is always small. ER-β knockout mice display abnormal epithelial growth in the breast and development of severe cystic breast disease. BERKO male mice show prostate hyperplasia and dysplasia reminiscent of what is sometimes seen in human. Studies have shown that decreased expression of ER-β is associated with increased expression of the androgen receptor and it is likely that this is relevant for the observed phenotype.

2. Bone

BERKO mice show no alterations in bone phenotype before puberty. Adult female BERKO mice have increased limb length and increased cortical bone mineral content. Trabecular bone is normal. No abnormalities have been seen in the bones of male BERKO mice.

3. Central Nervous System

We have found that the brains of BERKO mice show several morphological abnormalities. There is a regional neuronal hypocellularity in the brain, with a severe neuronal deficit in the somatosensory cortex and a remarkable proliferation of astroglial cells in the limbic system but not in the cortex. These abnormalities are evident at 2 months of age. As BERKO mice age, the neuronal deficit becomes more pronounced, and at 2 years of age, there is a degeneration of neuronal cell bodies throughout the brain.

4. Additional Phenotypes

BERKO female and male mice have elevated blood pressure. BERKO male mice have a tendency for reduced weight of retroperitoneal fat pads, suggesting a role for ER-β in white adipose tissue. There are also abnormalities in the immune system.

VI. ER-β IN PHYSIOLOGY

Below are some examples of the role of estrogen in physiology and what is known about the differing roles of the two estrogen receptors in these contexts. It is beyond the scope of this article to make a comprehensive review of the role of estrogen in physiology.

A. The Reproductive Tissues

1. Prostate

Estrogen has been widely used for the treatment of advanced prostatic cancer. However, the precise mechanisms of its effects on prostatic cancers remain uncertain. In addition to acting on the pituitary–testicular axis to effectively lower circulating levels of androgens and act as chemical castration agents, estrogens are believed to have direct growth inhibitory effects on prostatic cancer via induction of apoptosis or cell cycle arrest. Several investigations have demonstrated expression of ER-β in both normal and hyperplastic epithelia. In contrast, expression of the ER-α protein is restricted to stromal cells. These findings suggest that estrogens have direct effects on normal epithelium via ER-β signaling pathways.

In the human prostate, expression of ER-β was reported to be consistently expressed in normal prostate, but in many studies expression was decreased or absent in prostatic cancer, paralleling tumor grade. In contrast, one study demonstrated that the ER-β protein was expressed at a higher level in cancer than in normal epithelium. The expression of ER-β variants in prostate cancers was recently reported. It was shown that expression of the ER-βCX variant was inversely associated with wild-type ER-β expression. Furthermore, ER-βCX was expressed significantly more in the high-grade cancers than in the low-grade cancers, and expression of ER-βCX was a bad prognostic sign. These studies suggest that ER-β and ER-βCX may be good prognostic indicators for prostatic cancers and that ER-β-specific agonists will provide opportunities for improved therapeutic strategies.

2. Breast Tissue

It is believed that the ER-α protein plays a central role in the development and progression of most breast cancers. This is the basis for the use of anti-estrogens,

including tamoxifen, for the treatment of breast cancers. Moreover, the presence of ER-α protein in tumor tissue is an important prognostic factor that correlates with higher survival rates and lower risk of relapse.

Because ER-α-containing epithelial cells in the normal breast do not express proliferation markers, the mechanisms through which estrogen induces epithelial growth are not clear. The prevailing concept is that estrogen induces the secretion of growth factors from the stroma and that these agents stimulate epithelial cells to proliferate. ER-α has long been thought to be responsible for the secretion of growth factors in response to estradiol in the stroma. This appears to be the case, at least in rodents. In humans, several studies have failed to demonstrate the presence of ER-α in stroma from normal tissue and cancer tissue. Whether the distribution of ERs in different cellular compartments of breast tissue is different between rodents and humans or whether there are variations between individuals are questions that need further examination. In recent studies, ER-β was recently found to be the predominant ER in breast stroma. These findings indicate that ER-β may play a role in growth factor secretion.

Expression of ER-β mRNAs has been detected by reverse transcriptase-polymerase chain reaction in both normal and malignant human breast tissue, and ER-β protein has been identified in human breast tumors by Western blotting. It has been suggested that ER-β contributes to the initiation and progression of carcinogenesis, is expressed in breast cancers of higher grades, and is a marker for estrogen responsiveness.

We have recently investigated the correlation between estrogen receptors and proliferation markers in breast tissue samples. The presence of ER-α in breast cancer epithelium is associated with a decreased level of expression of the proliferation markers Ki67 and cyclin A, whereas ER-β expression is associated with elevated levels of these markers. The highest level of expression of either Ki67 or cyclin A is seen in cancers that are ER-α–ER-β. These results suggest that it might be ER-β and not ER-α that is related to proliferation in breast cancer.

In summary, much remains to be clarified regarding the role of ER-β in the breast.

B. Effects of Estrogen on the Cardiovascular System

Many published clinical studies have shown that postmenopausal estrogen replacement is associated with a decreased incidence of cardiovascular disease even though this notion has recently been challenged. Several studies suggest that estrogen plays an important role in the cardiovascular system. However, the mechanism of action of estrogen on the cardiovascular system is poorly understood. For instance, few studies have addressed whether sex hormones (estrogen and testosterone) could affect cardiac remodeling or mass.

Both ERs are expressed in the myocardial cells of rats, guinea pigs, and humans. Which ER plays an important role in the heart is, however, unclear. ER-β knockout mice, in which the gene for ER-β has been disrupted, show elevated blood pressure with left ventricular wall thickness. These data suggest that ER-β may play an important role in blood pressure control and cardiac function. However, the mechanisms behind these observations remain unclear.

C. Effects of Estrogen in the CNS

Estrogen exerts many functions in the central nervous system. It influences the development, plasticity, and survival of neurons with consequences for age-related neuronal degenerative diseases. Epidemiological studies suggest that E2 replacement therapy decreases the likelihood of developing Alzheimer's disease. However, estrogen replacement in older women did not affect the incidence or progression of Alzheimer's disease.

In situ hybridization and immunohistochemical studies in rodent and human brains have shown that there are neuronal populations that express both receptors and some that express only one of the two receptors. No morphological changes have been reported in mice lacking ER-α; however, as described above, striking morphological abnormalities have been observed in the brains of ER-β knockout mice.

VII. CONCLUSIONS

The discovery of a second ER subtype, ER-β, has revitalized the search for improved drugs for menopausal hormone therapy, which would provide the benefits of estrogen replacement therapy but with fewer side effects than currently used drugs.

Several large pharmaceutical companies are engaged in the development of ER-α- and ER-β-selective drugs but as yet there is no information as to how far this work has progressed. However, synthetic ER subtype-selective ligands have been reported. The most ER-α-selective ligand showed 120-fold higher agonist potency for ER-α than for ER-β. Another

ER subtype-selective ligand synthesized by the same group showed full ER-α agonism but pure ER-β antagonism.

The discovery of a second estrogen receptor will require that we revisit many biological and clinical studies and reinterpret them in the light of the presence of two receptors. Such studies are now being performed, generating interesting and sometimes unexpected findings.

Glossary

BERKO Mice with inactivated, knocked-out versions of estrogen receptor-β.

estrogen receptor-α (ER-α) The first cloned estrogen receptor, which displays differences compared to ER-β with regard to structure, ligand binding, expression profile, and physiological effects.

estrogen receptor-β (ER-β) A protein that, after binding its ligand, estrogen, activates the transcription of genes, resulting in specific physiological effects.

estrogen-response element The specific estrogen receptor-binding DNA sequence in the promoter region of genes that are regulated by estrogen.

Estrogen Receptor Biology and Lessons from Knockout Mice

DEBORAH L. SWOPE AND KENNETH S. KORACH

National Institute of Environmental Health Sciences, North Carolina

The steroid hormone estrogen induces a wide variety of physiological responses in mammalian tissues. Estrogen is found in both females and males, although at higher levels in females. Estrogen causes its multitude of effects through estrogen receptors that mediate the transcription of a number of genes involved in reproduction, metabolism, and growth and differentiation. The current understanding of estrogen action is rooted in a model in which the estrogen receptor is bound by ligand, homodimerizes, and interacts with high-affinity binding sites for estrogen receptors found in the promoters of target genes. The bound receptor activates transcription of the target gene. Estrogen receptors also modulate expression of genes that do not contain these binding sites, can be activated in a ligand-independent manner by growth factors, and can also function as repressors of transcription.

alone or in a synergistic manner with TPA plus estrogen, but ER-α-dependent responses can also be inhibited by TPA in a promoter-dependent and cell type-dependent manner. However, TPA can also reduce ER-α expression levels and receptor binding to its estrogen-response element *in vitro*. The implications of these TPA-mediated effects relative to ER-α transcriptional activity are unclear.

VI. ESTROGEN RECEPTOR CROSSTALK WITH THE AKT SIGNALING PATHWAY

Although growth factors can signal to ER-α via MAPKs, they may also stimulate receptor transcriptional activity via the serine/threonine kinase Akt (also known as protein B kinase). Activation of Akt kinase activity is dependent on phosphatidylinositol 3-kinase (PI3-K), and the specific PI3-K inhibitor, LY294002, blocks activation of ER-α transcriptional activity in cells treated with either EGF or IGF-1. In addition, expression of a dominant negative form of Akt blocks growth factor activation of ER-α, whereas a constitutively active form is able to mimic growth factor activation of ER-α transcriptional activity and induction of PR gene expression. The ICI 182,780 anti-estrogen blocks Akt activation of ER-α. Moreover, ER-α can be phosphorylated by Akt *in vitro* and *in vivo*, and mutation of Ser-167 to an alanine blocks Akt stimulation of ER-α transcriptional activity, indicating that Akt signaling cross-talks directly with ER-α.

Glossary

co-activators Molecules, generally proteins, that stimulate the activity of transcription factors, such as the estrogen receptors.

crosstalk The ability of signal transduction pathways to influence the activity of molecules, such as the estrogen receptors, that are typically regulated by other agents.

signal transduction pathway A group of molecules that enable signals initiated at remote locations to communicate to the final target through intermediary steps.

Ethylene

PAUL B. LARSEN

University of California, Riverside

Ethylene is a simple gaseous hydrocarbon that is responsible for regulating physiological processes at all stages of plant growth and development. Ethylene plays a crucial role in a number of physiological processes, including seed germination, growth, adaptation to environmental stress, induction of pathogen defense responses, fruit ripening, and tissue senescence.

I. INTRODUCTION

Ethylene is considered to be one of the five classic plant hormones, with its biological activity being described as early as 1901 by Dimitry Neljubov, who reported that a component of illuminating gas, which he determined to be ethylene, had profound effects on the growth of pea seedlings. Subsequent physiological analysis has linked ethylene to processes ranging from seed germination and growth to fruit ripening and tissue senescence. Significant progress toward understanding the mechanisms underlying both its biosynthesis and its perception has been made.

II. PHYSIOLOGICAL AND AGRICULTURAL RELEVANCE

Although ethylene plays a significant role in a wide range of physiological events, it is best known for mediating the induction of stress responses and senescence in plants. Ethylene has been implicated in processes throughout the life cycle of the plant, many of which have tremendous agricultural importance. These include seed germination and growth, adaptation to environmental stress, induction of pathogen defense responses, and promotion of both tissue senescence and fruit ripening.

The effects of ethylene on seed germination and seedling growth have been well documented. Ethylene promotes seedling emergence, giving the growing embryo the necessary mechanical strength to penetrate the seed coat. Perhaps the most scientifically important and at the same time agriculturally insignificant process is the seedling triple response. This response is limited to dark-grown seedlings (e.g., germinating seedlings in soil). Characteristics of the triple response include shortening and thickening of the hypocotyl and root, proliferation of root hairs, and most dramatically, formation of a pronounced apical hook. The triple-response adaptation provides the growing seedling with the mechanical strength necessary to penetrate the soil. Use of this response as a phenotype for identification of ethylene-related mutants has given the means to identify and characterize several components of the ethylene-signaling pathway, as will be reviewed in Section IV.

As mentioned, ethylene is responsible for mediating several adaptive responses in plants. Ethylene is critically important for controlling adaptation to growth in a low-oxygen environment (hypoxia), such as is found in a flooded field. Following flooding, ethylene production is stimulated in the roots, resulting in mechanisms that increase the availability of oxygen to root tissue. These mechanisms include formation of aerenchyma tissue, which consists of gas-filled channels in root tissue that develop from the senescence or separation of root cells. Aerenchyma tissue serves to create an internal gas exchange channel from the shoot, which is not in a hypoxic environment, to the root, thus supplying oxygen to the hypoxic root tissue. Persistence of low-oxygen conditions in root tissue promotes dramatic ethylene-mediated changes in leaves including triggering of epinasty (e.g., downward curvature) along with senescence and abscission, each of which is thought to reduce the level of stress imposed on the root.

Ethylene perception is an integral part of pathogen and pest responses in many plant species. Following infection or attack, ethylene production is greatly increased, resulting in the induction of a suite of genes responsible for defense and recovery. Genes include those that code for degradative enzymes such as glucanases and chitinases, both of which act to break down the cell walls of fungal invaders. In response to insect attack, ethylene induces the production of polypeptides that serve as proteinase inhibitors following ingestion. Ethylene is also responsible for stimulating the production of a class of compounds termed phytoalexins that have both antimicrobial and antifungal activity. Finally, ethylene acts to increase the total phenolic content in tissues following attack. This includes increased lignin biosynthesis, which is a cell wall component required for repair of damaged tissue.

Root development is dramatically affected by ethylene, including formation of root hairs and response to gravity. Ethylene is a positive regulator of root hair formation, causing proliferation of root hairs when it is present at high concentrations. Applications of compounds that block ethylene perception substantially reduce root hair number, which is consistent with ethylene's predicted role in stimulation of their production. In *Arabidopsis thaliana*, root hairs develop specifically from epidermal cells that overlap junctions between underlying cortical cells. This contextual development is believed

to result from apoplastic translocation of the ethylene precursor 1-aminocyclopropane-1-carboxylic acid (ACC) from the central portion of the root to the epidermal cell layer. Since epidermal cells that overlap the apoplastic junction between cortical cells receive higher levels of ACC, it is more likely that these cells will develop root hairs. Ethylene also plays a role in regulating the response of roots to gravity in some plant species, with ethylene treatment causing a 90° shift in the direction of growth and often causing roots to grow opposite to gravity.

In many monoecious plants (i.e., both male and female flowers on the same individual plant), flower sex is directly determined by ethylene. This is true for cucumbers, in which high ethylene production by the floral meristem results in female flowers. This is opposed by gibberellic acid, which promotes the production of male flowers. Ethylene is also critical for the death of the flower including abscission and senescence. Abscission is a controlled process that results in the breakdown of cells in an area called the abscission zone, leading to the detachment of leaves, fruit, and flowers from the body of the plant. Ethylene, working in conjunction with the plant hormone abscisic acid, causes increased expression of degradative enzymes that destroy this zone. Loss of cellular integrity in the region weakens the junction, causing the organ or tissue to fall off. In commercial orchards, application of ethylene is used as a method both to reduce fruit number (which allows for better development of the remaining fruit) and to loosen fruit prior to mechanical harvesting.

Of all the processes regulated by ethylene, senescence and fruit ripening are by far the most agriculturally significant. Senescence is a tightly controlled degradative process that leads to the death of leaves and flowers. Senescence represents the breakdown of tissue and remobilization of metabolites in response to environmental factors or as a result of tissue age. Senescence is promoted by ethylene and opposed by the plant hormone cytokinin. The progression of senescence is linked to substantial increases in ethylene production, which has a promotive effect on the rate of senescence, although elimination of ethylene perception does not prevent its onset. Senescence results from the induction of a tightly regulated subset of genes whose primary function is cellular degradation. Ultimately, senescence causes the breakdown of chlorophyll, proteins, DNA, RNA, and membranes as a means to free up nutrients for redistribution to other areas. A vivid example of senescence is the annual development of fall color found in deciduous forests, which represents the remobilization of nutrients from the senescing leaves to other nutrient sinks within the tree. Senescence is an important issue for the floral industry since ethylene generated following harvest causes the rapid senescence of many climacteric flowers including carnations. In general, flower senescence is commercially controlled by application of inhibitors of ethylene perception, which are supplied as additives dissolved in the vase solution.

Fruit ripening is probably the most commonly known response to ethylene, even having an old wives' tale associated with it. This tale, which happens to be true, asserts that if one places a ripe climacteric fruit (e.g., banana or avocado) into a paper bag with an immature climacteric fruit, the immature fruit will quickly be triggered to ripen. This is a function of ethylene perception and represents the stimulation of the ripening program by the high levels of ethylene released from the mature fruit. It should be noted that, although related, fruit ripening is distinct from senescence in that cellular integrity, including organellar structure, is maintained during the ripening process. As can be imagined, the process of fruit ripening has tremendous commercial relevance since this controls the development of the critical characteristics (e.g., texture, color, and taste) that consumers associate with fruit quality. Ethylene-dependent ripening is not a characteristic of all fruits but is found in many of the most commercially important fruits in the Western world. These include bananas, tomatoes, peaches, avocados, olives, pears, plums, and apples. In many cases, restriction of ethylene perception and/or production by these fruits results in incomplete or no ripening, which attests to the critical importance of ethylene in promoting this process. Ethylene-dependent ripening is correlated with the climacteric, which is a sustained burst in both aerobic respiration, presumably to produce the necessary energy for the progression of ripening, and ethylene production. As with ethylene production and perception, restriction of aerobic respiration by reducing the level of environmental oxygen or storage temperature is an effective means of limiting the progression of the ripening process.

Of the climacteric fruits, tomato has developed into the best-studied model system for the molecular and biochemical events that underlie the ripening process. One reason for this is the availability of several ripening-related tomato mutants that affect different aspects of this process including ethylene perception and ripening progression. Tomato fruit development can be divided into two distinct stages—the preclimacteric stage, which is a time of rapid cell

division and fruit growth, and the climacteric stage, during which the ripening program is initiated and carried out. The onset of the climacteric stage is marked by the induction of several molecular and biochemical processes that promote ripening. These include production of a suite of enzymes, such as polygalacturonase and pectin methylesterase, that cause fruit softening through the breakdown of cell walls and the middle lamella, which is a pectin-rich area between the walls of adjoining cells. Additionally, the climacteric initiates changes in pigmentation of the tomato fruit, with chlorophyll being degraded at the same time that there is an increase in lycopene biosynthesis, which gives the tomato fruit its characteristic red coloration. Flavor attributes begin to develop at this point with the induction of several enzymes that are responsible for the breakdown of complex polysaccharides. Finally, the ripening program induces the expression of components of the ethylene biosynthesis pathway in order to sustain the high level of ethylene that ripening climacteric fruits evolve.

Modern agricultural practices have struggled with the balance between a fully ripened fruit and a marketable commodity. With the progression of ripening, fruits and vegetables become more difficult to transport due to tissue softening, increasing the incidence of damage and pathogen attack. Fruits such as tomatoes and bananas are currently harvested at an immature stage in order to have a fruit that can withstand the hazards of travel. Prior to delivery to market, these fruits are exposed to high levels of ethylene to stimulate the ripening process. In effect, the old wives' tale about ethylene has become the industry standard for the initiation of ripening in climacteric fruits.

III. BIOSYNTHESIS

Ethylene is a simple unsaturated two-carbon molecule ($H_2C{=}CH_2$) that features a carbon–carbon double bond that is the basis for its biological activity. Ethylene biosynthesis was first elucidated in the late 1970s by Dr Shang Fa Yang at the University of California, Davis. The ethylene biosynthetic pathway consists of a simple three-step catalytic conversion of L-methionine into ethylene (see Fig. 1).

The first step is the combination of ATP and L-methionine into *S*-adenosylmethionine (SAM) by the enzyme methionine *S*-adenosyltransferase. Methionine *S*-adenosyltransferase is not considered to be the rate-limiting step of ethylene biosynthesis since SAM is required not only for ethylene production

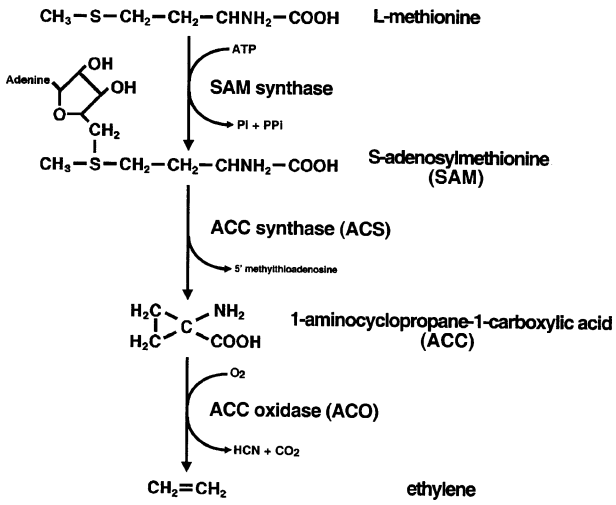

FIGURE 1 Ethylene biosynthesis pathway. Ethylene is produced through a simple two-step biochemical pathway that begins with the conversion of *S*-adenosylmethionine (SAM) to 1-aminocyclopropane-1-carboxylic acid (ACC) by the enzyme ACC synthase. Subsequently, ACC is converted to ethylene by ACC oxidase. In general, ACC synthase is considered to be the key regulatory step of this pathway since expression and activity of this enzyme are both highly controlled.

but also for the production of a diverse range of compounds including polyamines and lignin.

SAM is subsequently converted to (ACC), which represents the first unique step of ethylene biosynthesis. This conversion is mediated by ACC synthase (ACS), which requires pyridoxal phosphate for activity. This step is highly regulated with increased ethylene biosynthesis generally being dependent on increased expression of ACS since it is a highly unstable enzyme. Overexpression or increased stability of ACS has been shown to result in greatly increased levels of ethylene production. Several inhibitors of ACS activity have been defined, with the most commonly used being L-α-(2-aminoethoxyvinyl)-glycine (AVG), which is generally inhibitory to pyridoxal phosphate-requiring enzymes.

The final step of ethylene biosynthesis is the formation of ethylene from ACC, which is catalyzed by the enzyme ACC oxidase (ACO). ACO requires O_2 for its activity and releases both cyanide and CO_2 as by-products. ACO is membrane localized and its activity is inhibited by membrane disruption. Inhibitors of ACO include $CoCl_2$ and α-aminoisobutyric acid. Generally, ACO is not considered to be the regulated step of ethylene production since elicitors of ethylene biosynthesis usually do not induce ACO expression.

Since ethylene is a gas, ethylene production rates by plants are easily measured using a gas chromatography system.

IV. PERCEPTION

In the past 15 years, significant progress has been made toward elucidation of the molecular and biochemical mechanisms of ethylene perception. This progress has primarily been achieved through the use of *A. thaliana*, which has been adopted by plant science as a model system for molecular genetics and mutational analysis. By identifying mutants that have defects in ethylene perception, it has been possible to isolate many of the molecular components of the ethylene-signaling pathway, serving as a framework for plants in general since orthologues to these components have been found throughout the plant kingdom. This identification has been achieved through isolation of either mutants that cannot perceive ethylene (ethylene insensitive) or mutants that display ethylene responses even in the absence of added ethylene (constitutive ethylene response) (see Fig. 2).

The first ethylene-insensitive mutant was identified in 1986 when Drs Anthony Bleecker and Hans Kende at Michigan State University described an *Arabidopsis* mutant that did not display the seedling triple response following exposure to high levels of ethylene. This mutant, *etr1-1*, was the initial member of a group of *Arabidopsis* mutants with aberrant ethylene responses and was the first step toward defining this pathway. Subsequent efforts to identify the gene that was affected by this mutation led to the isolation and characterization of the first known ethylene receptor, *ETR1*. *ETR1* encodes a membrane-localized protein with three hydrophobic transmembrane regions along with a large cytoplasmic region (see Fig. 3). The transmembrane regions comprise an ethylene-binding pocket, which forms by dimerization of ETR1. Reconstitution of the transmembrane regions of ETR1 in a yeast system demonstrated that ETR1 is capable of binding ethylene, which is consistent with its role as an ethylene receptor.

It has long been speculated that a metal such as copper is required for ethylene binding, since copper is predicted to have an affinity for the carbon–carbon double bond of ethylene. Addition of copper to the yeast ethylene-binding system dramatically increased the efficiency of ethylene binding. Also, loss-of-function mutations in the *Arabidopsis* copper transporter *RAN1*, which block the delivery of copper to the ethylene receptors, disrupt normal receptor function and ethylene binding. Interestingly, one

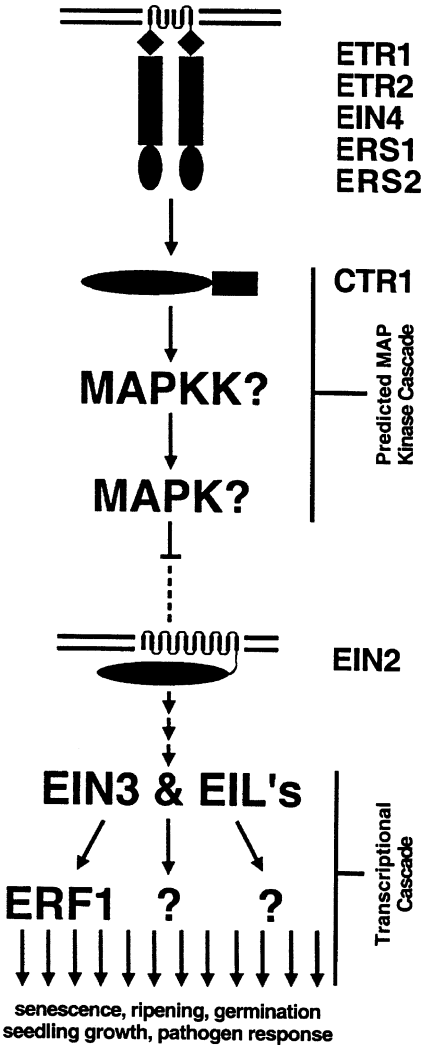

FIGURE 2 Schematic representation of the current understanding of the ethylene-signaling pathway. This includes a family of five ethylene receptors that regulate the activity of a predicted MAP kinase cascade. Ultimately, this pathway terminates in a transcriptional cascade that activates ethylene-dependent physiological changes.

method of ethylene control commonly used in the cut-flower industry is to provide silver nitrate to the flower. Silver is capable of substituting for the copper ion in the ethylene-binding pocket. Although still capable of binding ethylene, silver causes some unknown change in the ethylene receptors that blocks normal function and inhibits ethylene signaling, thus blocking the initiation of ethylene-dependent programs such as flower senescence.

ETR1 actually is a member of a family of five ethylene receptors in *Arabidopsis*, each with its own distinct structural characteristics (see Fig. 3). Families of ethylene receptors are also found in other

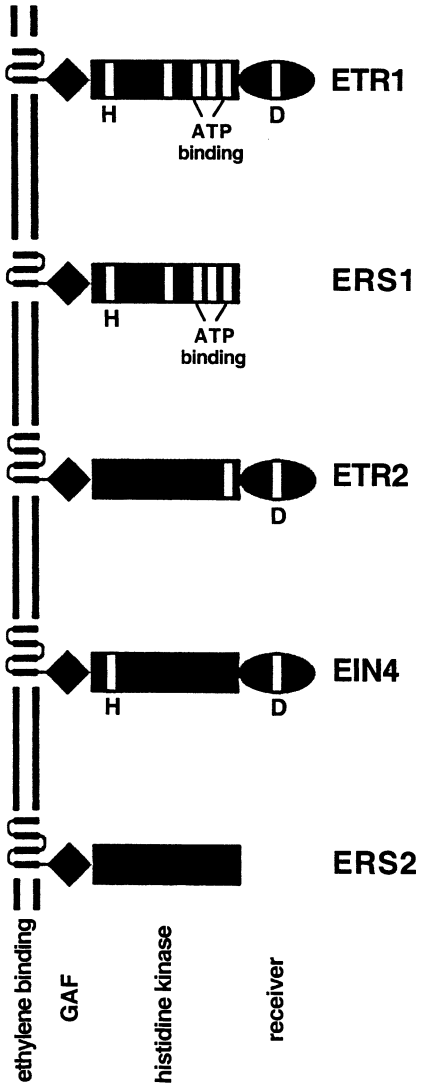

FIGURE 3 Architecture of the *Arabidopsis* ethylene receptor family. The *Arabidopsis* ethylene receptors can be divided into two classes based on whether or not they possess the requirements for histidine kinase activity. The subfamily 1 receptors ETR1 and ERS1 have all of the motifs (indicated as white bars) that are associated with functional bacterial two-component regulators. The subfamily 2 receptors (consisting of ETR2, EIN4, and ERS2) are missing some or all of these motifs, making it less clear as to their function in the regulation of downstream factors in ethylene signaling. All receptors have an ethylene-binding domain at their amino-terminus. Additionally, ETR1, ETR2, and EIN4 have a receiver domain at the carboxy-terminus. It is this domain that is predicted to directly control the activity of CTR1 or some other downstream factor.

plant species including tomato, carnation, melon, and maize. It is not known why there are multiple receptors in each species, but genetic evidence indicates that all five of the *Arabidopsis* receptors function to regulate the activity of a common downstream factor, CTR1. The ethylene receptors are related to a family of bacterial signaling proteins that are collectively called two-component regulators. Bacterial two-component regulators serve to "sniff" the environment, being responsible for detecting changes in the concentration of specific molecules and subsequently regulating gene expression to compensate for these changes. Two-component regulators generally consist of a combination of two proteins—a sensor protein and a response–regulator protein. The former has both an input domain, which is the point of binding for a specific ligand, and a histidine kinase domain, which initiates a signaling event in response to ligand binding. The response–regulator domain is most often composed of a receiver domain, which is the recipient of a phosphate from the histidine kinase, and an output domain, which regulates the activity of a downstream factor. In many cases, the bacterial output domain directly activates transcription. In general, ligand binding results in activation of the histidine kinase domain and autophosphorylation of a highly conserved histidine found in this domain. Subsequently, there is a phospho-transfer event, in which the phosphate attached to the histidine is transferred to a highly conserved aspartate in the receiver domain. It is the phosphorylation state of the receiver domain that determines the activity of the output domain.

The *Arabidopsis* ethylene receptors possess many of the features of bacterial two-component regulators. The family can be divided into two classes of receptors—one composed of *ETR1* and *ERS1* and the second consisting of *ETR2*, *EIN4*, and *ERS2*. Each receptor has a predicted ethylene-binding domain, which is characterized by a high level of conservation of the three hydrophobic transmembrane regions found in ETR1. Additionally, each protein has a soluble GAF domain of unknown function. Both ETR1 and ERS1 are different from the other receptors in that they possess all of the known requirements for having histidine kinase activity, with ETR1 exhibiting histidine autophosphorylation *in vitro*. In contrast, the subfamily 2 receptors possess histidine kinase-like domains but lack many or all of the motifs necessary for autophosphorylation. The ethylene receptors can also be divided based on whether or not they possess a receiver domain. Unlike many bacterial two-component regulator sensor proteins, ETR1, ETR2, and EIN4 all have receiver domains. In contrast, neither ERS1 nor ERS2 has this domain. In each case, the receiver domain possesses the conserved aspartate that serves as the phosphate acceptor in the bacterial two-component regulator scheme. This raises the

interesting possibility that the ethylene receptors function in a manner similar to bacterial two-component regulators in that they regulate the activity of a downstream factor as a function of the phosphorylation state of the receiver. It is not clear why the different receptors have different aspects of the two-component machinery, but it suggests that the receptors work synergistically to regulate the ethylene-signaling pathway since ETR1 is the only receptor that has all of the requirements to complete a histidine to aspartate phospho-transfer.

CTR1, a mitogen-activated protein kinase kinase kinase (MAPKKK) similar to the mammalian MAPKKK Raf, acts downstream of the ethylene receptors (see Fig. 2). *CTR1* is a negative regulator of ethylene signaling, since loss-of-function mutations in this gene result in a constitutive ethylene-response phenotype (i.e., constitutive triple response). In general, MAPKKKs regulate a mitogen-activated protein (MAP) kinase cascade that propagates a signal through phosphorylation. Identification of a MAPKKK in the ethylene-signaling pathway suggests that a MAP kinase cascade may participate in ethylene signal transduction, but to date no MAP kinase kinase or MAP kinase has been associated with ethylene perception. Little is known about how CTR1 is regulated except that it interacts strongly with the cytoplasmic portions of the ethylene receptors ETR1 and ERS1, both in the yeast two-hybrid assay and *in vitro*. It has been argued that this association is part of the mechanism of CTR1 regulation and is consistent with the role of two-component regulators in other systems, most notably the *Saccharomyces cerevisiae* HOG1 pathway. In this system, the activity of a downstream MAPKKK is directly determined by the phosphorylation state of a response regulator. Interestingly, loss-of-function mutations in three or more ethylene receptors result in a constitutive ethylene-response phenotype, most likely due to the loss of activators of CTR1. This supports the hypothesis that the ethylene receptors function to regulate the activity of CTR1 and are required to maintain CTR1 in an active state in the absence of ethylene.

Although significant progress has been made toward identifying the components of the ethylene-signaling pathway, large gaps in our understanding remain. The steps that immediately follow *CTR1* remain unknown. Genetic analysis indicates that *EIN2* (i.e., *ethylene insensitive 2*) functions downstream of *CTR1* in the ethylene-signaling pathway, yet it is not clear how many steps separate the two. *EIN2* was identified as a recessive mutation that causes ethylene insensitivity, indicating that it functions as a positive regulator of ethylene signaling. *EIN2* can be divided into two domains—a region of 12 transmembrane loops and a cytoplasmic domain. It is not clear what role *EIN2* plays in ethylene signal transduction, but genetic evidence has shown that it is required for ethylene perception.

Ultimately, the ethylene-signaling pathway terminates in a transcriptional cascade. Several factors have been identified that act as transcriptional activators in response to ethylene, subsequently inducing the expression of ethylene-responsive genes. *EIN3* (i.e., ethylene insensitive 3) was the first ethylene-related transcription factor isolated, with loss-of-function mutations in this gene causing partial ethylene insensitivity. Analysis of the *Arabidopsis* genome has identified several EIL (EIN3-like) proteins that also function as transcriptional activators. Downstream of *EIN3* is a transcription factor, *ERF1* (i.e., ethylene-response factor 1), that is up-regulated by *EIN3* following ethylene exposure. *ERF1*, which is a member of a family of *ERF*-like genes in *Arabidopsis*, is responsible for activating the transcription of a subset of ethylene-regulated genes by binding to a common gene promoter element called the ethylene-response element. Ultimately, the transcriptional cascade headed by *EIN3* and the *EIL*s alters the transcription of a suite of genes that are responsible for the manifestation of the previously described ethylene-mediated physiological changes.

V. CONTROL

As mentioned, there are several well-developed methods for controlling both ethylene biosynthesis and perception. Some of these have been adopted for commercial use to limit the progression of ethylene-dependent phenomena including senescence and ripening. Inhibitors have been identified for each of the unique steps of ethylene biosynthesis. These include AVG and (aminooxy)acetic acid, both of which inhibit the activity of ACC synthase. Although less effective, inhibitors of ACC oxidase have also been identified, including $CoCl_2$ and α-aminoisobutyric acid. Of all the inhibitors of ethylene production, AVG is probably the most widely used commercially, including being applied in orchards to reduce the incidence of fruit abscission and to concomitantly increase fruit size.

Ethylene perception can be controlled with either competitive or noncompetitive inhibitors of ethylene binding. Silver nitrate is a noncompetitive inhibitor, working to displace copper from the ethylene-binding pocket. The biochemical mechanism of silver-

mediated inhibition of ethylene perception is unclear since silver, like copper, has a high affinity for ethylene. It is likely that silver blocks some critical event that occurs between ethylene binding and initiation of signal transduction, forcing the receptor to maintain CTR1 in an active state regardless of the ethylene concentration in the environment. Silver is commercially important in the cut-flower industry but is not used in the fruit industry since it is a highly toxic heavy metal.

Competitive inhibitors vie with ethylene for binding to the copper moiety in the receptor pocket. All competitive inhibitors of ethylene binding have at least one carbon–carbon double bond, which is the point of association with the copper ion. Interestingly, some molecules that have this double bond actually can serve as ethylene agonists, in that they can stimulate weak ethylene responses. Propylene is an excellent example of an ethylene agonist, having three carbons with one carbon–carbon double bond. Propylene effectively competes with ethylene for binding and will elicit ethylene responses at a level that is 100–1000 times less effective than ethylene itself. With increasing molecular size, steric hindrance becomes an important issue, limiting the effectiveness of compounds as ethylene agonists but not necessarily their effectiveness as competitive inhibitors. This includes a class of cyclic carbon molecules, collectively referred to as cyclic olefins. These are large ring molecules that possess at least one carbon–carbon double bond. 2,5-Norbornadiene (NBD) and 1-methylcyclopropene (1-MCP) are the best competitive inhibitors described to date, with 1-MCP treatment causing irreversible inhibition of ethylene binding. Although there is great promise for these inhibitors, they have yet to be developed for commercial applications partly because of the noxious odor associated with many cyclic olefins, including NBD.

VI. SUMMARY

In summary, ethylene has profound implications for plant growth and development at all stages of the life cycle. These range from mediating adaptive responses to an ever-changing environment to development of the qualities that consumers expect in a ripened fruit. The former is especially important for plant survival since plants are sedentary. For this reason, plants are incapable of avoiding environmental challenges and have been forced to evolve complex adaptive strategies to cope with these stresses. Because of its commercial importance, ethylene has received an intense level of scrutiny by plant scientists in the past century in order to not only understand its relevance to plant physiology but to also begin to unravel the fundamental mechanisms underlying its perception. Any advance in our knowledge of ethylene perception and its subsequent physiological effects furthers efforts to control processes that are critical for agriculture and food quality.

Glossary

agonist A chemical compound capable of binding to a receptor and causing a reaction or activity.

apical hook A structure that forms at the uppermost portion of the hypocotyl that serves to reorient the cotyledons and apical meristem to prevent damage from soil-borne obstructions.

climacteric A substantial increase in aerobic respiration coupled with high levels of ethylene production associated with ripening of fruits such as tomatoes, avocados, and apples (which are therefore termed climacteric fruits).

cyclic olefin A member of a class of cyclic carbon structures that contain at least one carbon–carbon double bond that may competitively block ethylene binding.

hypocotyl The stem-like area between the cotyledons and primary root of the growing seedling.

mitogen-activated protein (MAP) kinase cascade A series of successive phosphorylation events responsible for the propagation of a signal; this cascade consists of three steps beginning with a MAP kinase kinase kinase that phosphorylates a MAP kinase kinase that subsequently phosphorylates a MAP kinase.

seedling triple response An ethylene-dependent phenotype found in dark-grown seedlings characterized by exaggerated apical hook formation, shortening and thickening of the hypocotyl and root, and proliferation of root hairs.

two-component regulator A protein–sensor system commonly found in bacteria, yeast, and plants that serves to detect changes in specific environmental stimuli.

Extracellular Matrix and Follicle Development

R. J. RODGERS AND H. F. IRVING-RODGERS
University of Adelaide, Australia

The endocrine units within the adult ovary—follicles and corpora lutea—continually develop and regress, thus giving rise to the day-to-day variation in hormone secretion by the ovary. The formation of follicles and corpora lutea requires tissue remodeling and cellular replication and specialization. Considerable research effort has been directed at how hormones and growth factors regulate processes. Research efforts are now being directed at the composition (summarized in Table 1) and roles of the extracellular matrix in these processes.

I. INTRODUCTION

The adult ovary contains a reserve of inactive primordial follicles. Each contains a small nongrowing oocyte and a layer of nondividing pregranulosa cells encapsulated by the follicular basal lamina. Each day, a number of primordial follicles become active, and the oocyte commences growing and the granulosa cells begin to divide (preantral stage). As the granulosa cells divide, the number of layers of granulosa cells (called the membrana granulosa or follicular epithelium) around the oocyte increases, and the basal lamina expands. Later in development, a fluid-filled cavity or antrum forms in the follicles (antral stage). As the follicle grows, a specialized zona pellucida develops around the oocyte, and specialized stromal layers—theca interna and externa—develop. Only follicles that reach the stage of having a large antrum ovulate their oocytes in response to the surge release of luteinizing hormone. On ovulation, the epithelial granulosa cells redifferentiate into the nonepithelial luteal cells of the corpus luteum. Nonovulating follicles undergo atresia and regression instead.

II. EXTRACELLULAR MATRIX IS IMPORTANT FOR FOLLICLE DEVELOPMENT

The extracellular matrix, more aptly termed the intercellular matrix, has many different roles. These include effects on cell behavior, such as migration, division, differentiation, cell death, and cell anchorage. Matrix can play a role in the fluid dynamics of a

II. EXTRACELLULAR MATRIX IS IMPORTANT FOR FOLLICLE DEVELOPMENT

The extracellular matrix, more aptly termed the intercellular matrix, has many different roles. These include effects on cell behavior, such as migration, division, differentiation, cell death, and cell anchorage. Matrix can play a role in the fluid dynamics of a

TABLE 1 Composition of Matrices in Ovarian Follicles

Matrix	Developmental stage	Laminins	Collagens	Other components
Follicular basal lamina	Primordial	α1, β2, γ1	Type IV α1, α2, α3, α4, α5, α6	
	Preantral	α1, β2, γ1	Type IV α1, α2, α3, α4, α5, α6	Nidogen, perlecan
	Antral	α1, β2, γ1	Type IV α1, α2,	Nidogen, perlecan
	Atretic, antral	α1, β2, γ1, +/− α2	Type IV α1, α2,	Nidogen, perlecan
Call-Enxer bodies	Preantal	α1, β2, γ1	Type IV α1, α2, α3, α4, α5, α6	Nidogen, perlecan
Theca interna in general	Antral		Type VI	Fibronectin, versican
Thecal matrix	Antral	γ1	Type IV α1, α2	
Thecal sub endothelial basal lamina	Antral	β1, β2	Type IV α1, α2	
Thecal arteriole smooth muscle basal lamina	Antral	β2	Type IV α1, α2	
Theca externa matrix	Antral		Types I and III	Versican, chrondroitin sulfate, dermatan sulfate

tissue, either providing osmotic forces or filtering soluble materials as they pass through the matrix. Matrix can provide mechanical support of tissues, either rigid or elastic. In addition, nutrients, hormones, and other extracellular signals are often required to traverse the matrix in order to reach target cells. Matrix has the ability to bind growth factors. Binding can be direct or indirect via the specific binding proteins for the growth factors, ensuring that they act locally. In essence, extracellular matrix really defines or rather provides microenvironments, thus enabling cells to specialize in the matrix. It is not surprising then that extracellular matrix is generally a diverse mixture of components and that the composition of the matrix is important.

III. EXTRACELLULAR MATRIX OF THE MEMBRANA GRANULOSA

In the ovary, the membrana granulosa of each ovarian follicle is enveloped by a follicular basal lamina, which separates it from the surrounding stromal elements in primordial follicles or from the theca interna in antral follicles. The follicular basal lamina is believed to play a role in influencing granulosa cell proliferation and differentiation. Additionally, in healthy follicles, it excludes capillaries, white blood cells, and nerve processes from the granulosa compartment until ovulation, at which time the basal lamina is degraded.

A. Basal Laminas

Basal laminas are specialized sheets of extracellular matrix that in epithelia underlie the epithelial cells and separate them from the adjoining stroma. They influence epithelial cell proliferation and differentiation and can selectively retard the passage of molecules from one side of a basal lamina to the other. Basal laminas are composed of a lattice-type network of type IV collagen intertwined with a network of laminin. This structure is stabilized by the binding of entactin/nidogen to the collagen and laminin. The heparan sulfate proteoglycan perlecan and other molecules are associated with the type IV collagen-laminin backbone. Importantly, basal laminas in different regions of the body differ in the ratio of all these components. Furthermore, each "component" is really a class of several components. Thus, each type IV collagen molecule is composed of three α chains, but to date, six different types of α chain (α1 to α6) have been discovered. Potentially, any combination of these might be present. Similarly, each laminin molecule is composed of one α (A in the old nomenclature), one β (B1 in the old nomenclature), and one γ (B2 in the old nomenclature) chain, yet five different α chains, three β chains, and three γ chains have been discovered. It is believed that the unique composition of each basal lamina contributes to its specific functional properties.

B. Selective Filtration by the Follicular Basal Lamina

Based upon the roles of basal laminas in other tissues and organs, it can be speculated that the follicular basal lamina is important for maintaining the polarity and the degree of specialization of granulosa cells that align the follicular basal lamina. The follicular basal

lamina probably has a role in retarding the entry of higher molecular weight plasma proteins and molecules (e.g., low-density lipoproteins) into the follicular antrum. Conversely, if the flow of material in the other direction is similarly retarded, the follicular basal lamina may trap large molecules (e.g., some proteoglycans) synthesized by granulosa cells and oocytes in the follicular fluid. The molecular mass cut-off is calculated to be 100 to 850 kDa, based upon comparisons of the composition of follicular fluid with that of plasma. This does not necessarily indicate the cut-off imposed by the follicular basal lamina only, since plasma proteins also must traverse the vascular subendothelial basal lamina before reaching the follicular antrum.

Size may not be the only determinant of movement across the follicular basal lamina. It has been shown that the blood–follicle barrier to movement of inter-α-trypsin inhibitor is due to its negative charge, suggesting that the follicular basal lamina may also exclude material on this basis. In addition, the follicular basal lamina contains perlecan, a heparan sulfate proteoglycan. Heparan sulfate proteoglycans can bind a number of growth factors [e.g., fibroblast growth factor 2 (FGF2)] or their binding proteins [e.g., follistatin, insulin-like growth factor-binding protein 2 (IGF-BP2), and IGF-BP5]. Thus, it is possible that the follicular basal lamina may act as a barrier to the movement of growth factors.

C. Matrix Interactions with Granulosa Cells

Studies of the effects of the components of basal laminas and other extracellular matrix components have been undertaken. One model that is ideal for studying the effects of the follicular basal lamina on granulosa cells is that of the chicken follicle. Methods for isolating the chicken follicle have been available since the mid-1970s but only recently has the chicken follicle been used for this purpose. In addition, other components of the basal lamina are available commercially: laminin 1, laminin 2, and even an assembled laminin 1 matrix (Matrigel); however, it is the components of laminin 3 that are present in the follicular basal lamina. Other matrix molecules (collagens, vitronectin, fibronectin, etc.) are available for culturing granulosa cells but none of these truly represent the appropriate matrix mimicing that found *in vivo*.

Cells interact with matrix via the cell surface adhesion receptors, the integrins. Integrins are heterodimeric glycoproteins composed of α- and β-subunits. Over 17 α- and 8 β-subunits are known, producing over 23 different heterodimeric combinations. Additional molecules within the cell associate with integrins in order for a cell–matrix junction to form. Thus, matrix provides the cells with anchorage. It is not simply a ligand–receptor interaction that determines the effects of the matrix on cells. Only a few integrins have been localized to granulosa cells in a number of species. These include α2, α3, α6, and α6β1. Tetraspanins interact with the integrins as part of the process by which the matrix links with intracellular signaling molecules, and indeed one of the most highly expressed proteins in granulosa cells from ovulating follicles was identified long ago (CD63, ME491).

D. Changing Composition of the Follicular Basal Lamina

In follicles, the follicular basal lamina expands in surface area during follicular development and its composition changes as it does so. In bovine follicles, expression of type IV collagen α3 to α6 declines during growth, whereas α1 and α2 continue to be expressed. Laminin β1 is transiently expressed at the preantral stage, and α1, β2, and γ1 appear to be more highly expressed. Nidogen and perlecan are not present in primordial follicles but are expressed later in follicular development. Laminin α2 is very unusual. It is expressed in only a few healthy antral follicles.

E. Cellular Origin of the Follicular Basal Lamina

Evidence is accumulating that the granulosa cells are the source of many components of the follicular basal lamina. The laminin γ1 chain is expressed by granulosa cells and other indirect evidence on the origins of follicular basal lamina stems from identifying the components of Call-Exner bodies (see below). These bodies are ultrastructurally similar to basal lamina and have been observed within the membrana granulosa of follicles *in vivo*, suggesting that they are synthesized by granulosa cells. Type IV collagen chains α1, α2, α3, α4, and α5, the laminin α1-, β2-, and γ1-subunits, perlecan, and nidogen/entactin have been localized to the Call-Exner bodies. Granulosa cells cultured under anchorage-independent conditions can also synthesize a basal lamina that contains at least type IV collagen and fibronectin. Whether there is a contribution from the theca in larger follicles, or indeed the stroma surrounding preantral follicles, to the production of the follicular basal lamina is not known. One candidate component is laminin α2. In other tissues where it is a

component of an epithelial basal lamina, it appears to originate from the stroma. In bovine follicles, laminin α2 is expressed in only a very small proportion of healthy follicles but more commonly in atretic follicles. The expression pattern of this laminin chain is also different from that of the other laminin molecules examined, and hence a different cellular origin could explain this observation.

F. Regulation of Synthesis of the Follicular Basal Lamina

Very few studies of the regulation of the synthesis of follicular basal lamina by follicles have been undertaken. With the advent of whole-follicle culture and the culture of granulosa cells without anchorage in which granulosa cells produce a basal lamina, opportunities now exist to study basal lamina regulation *in vitro*. Indeed, initial studies have identified ascorbate, known to be necessary for collagen synthesis, as being beneficial for follicle culture.

G. Atresia and the Follicular Basal Lamina

The event of atresia that occurs in follicles is unusual in the body as it involves the complete destruction of the epithelial layer by death of all the epithelial cells. In other epithelia, such as lumenal gut epithelium or involuting glands, cells undergo apoptosis as they age, but this is regional and involves only a few cells at any one time. Certainly the stem cells survive to regenerate the populations of cells. However, the stem cells of the membrana granulosa do not survive follicle atresia. Thus, the question as to what happens to the follicular basal lamina during atresia is an interesting one.

Histochemical observations of bovine and ovine follicles undergoing atresia have identified laminin chains, perlecan, nidogen, and type IV collagen chains. In these studies, the components identified in atretic follicles were the same as those present in the class of follicles from which they were derived, except for laminin α2. Laminin α2 was found to be more commonly expressed in atretic follicles than in the healthy follicles from which they arose. However, the expression of laminin α2 did not correlate with the type or severity of atresia. As follicles shrink during atresia, folding of the basal lamina occurs. Thus, the follicular basal lamina survives the early events of atresia.

Even if the basal lamina is not completely destroyed early in atresia, macrophages, endothelial cells, and fibroblasts can breach the follicular basal lamina as they migrate from the thecal layer of atretic follicles. However, the movement of cells from the thecal side across the basal lamina is restricted while the basal lamina is aligned with healthy granulosa cells.

H. Call-Exner Bodies

Call-Exner bodies of ovarian follicles have been described as "a ring of granulosa cells disposed radially around a central cavity filled with fluid and showing histochemical reactions similar to the liquor folliculi [follicular fluid]." They are present in follicles of many species and in ovarian tumors. The role, if any, of Call-Exner bodies is not known. The central extracellular region is lined by a basal lamina-like structure, which can be highly folded or unassembled. Bovine Call-Exner bodies of preantral follicles contain basal lamina components, including the α1 to α5 chains of type IV collagen, the α1, β2, and γ1 chains of laminin, perlecan, and nidogen, reflecting the composition of the follicular basal lamina at that stage of follicular development. On further follicular development, the basal lamina material of Call-Exner bodies changes in the apparent ratio of type IV collagen to laminin, similar to what occurs in the follicular basal lamina. In addition, laminin α2, which is believed to be derived from the thecal layer and not from granulosa cells, is not present in the Call-Exner bodies.

I. Turnover and Degradation of the Extracellular Matrix

During follicle development, continual remodeling of the follicular wall occurs as the follicle enlarges. In particular, the structural collagens of the theca externa and in nearby stroma and tunica must be turned over to allow for expansion of the follicle. The follicular basal lamina must also be expanded. The vasculature continually expands within the theca interna and so too its associated matrix. These processes require the turnover of the matrix to be discrete since the final result is an extension or growth of the matrix, not a total degradation. The precise mechanism by which this occurs is not well understood, but clearly it involves the simultaneous degradation and synthesis of matrix. Enzymes involved in matrix degradation, including matrix metalloproteinases 1, 2, 9, and 13, tissue inhibitor of metalloproteinases 1 and 2, tissue plasminogen activator, urokinase plasminogen activator, and plasminogen activator inhibitor 1, have been studied in the ovary and were reviewed in 1999 by Smith and associates. Many of these enzymes have been studied

for their role in ovulation, a process that involves dramatic changes in tissue structure as the follicle redevelops into a corpus luteum.

IV. FOLLICULAR FLUID

Proteoglycans consist of a core protein with attached glycosaminoglycans. Follicular fluid has been analyzed for its composition of glycosaminoglycans, and the biochemical production of the glycosaminoglycans by granulosa cells has been studied by Yanagishita, Hascall, and colleagues. Recently, two proteoglycans, versican and perlecan, were identified in human "follicular fluid." These two proteoglycans and decorin were also identified in bovine follicles but were found to be components of the follicular wall, which readily contaminates follicular fluid on aspiration. Hyaluronan is a glycosaminoglycan that lacks a core protein. It has also been identified in follicular fluid surrounding the most antral layer of granulosa cells using link protein as the ligand. The roles, if any, of these proteoglycans in follicular fluid remain to be determined.

V. EXTRACELLULAR MATRIX OF THE OOCYTE AND CUMULUS CELLS

The production of hyaluronan by cumulus cells has also been well studied for its role in expanding the cumulus–oocyte complex in ovulating follicles. Hyaluronan is assembled at the cell surface by a hyaluronan synthase. Three of these genes have been identified, and hyaluronan synthase 2 is expressed by cumulus cells. A number of hyaluronan-binding proteins have also been identified, which in follicles include versican, link protein, and members of the inter-α-trypsin inhibitor family. This family constitutes a complex set of molecules. Bikunin is produced in the liver by the proteolytic cleavage of a translational product that includes α2-microglobulin and bikunin. A number of additional proteins can attach via covalent bonds to the chondroitin sulfate side chain of bikunin. These include heavy chains 1, 2, or 3 (also known as SHAPs or serum-derived hyaluronan-associated proteins) and TNFα-stimulated gene-6 (TSG-6). These chains in turn can bind hyaluronan. These molecules are interesting as the SHAPs gain access to the follicular fluid of ovulating follicles from the circulation, whereas TSG-6 appears to be expressed by cumulus cells in response to the luteinizing hormone surge. The importance of these molecules is underscored by the loss of fertility associated with gene mutations.

The zona pellucida of the oocyte is a very specialized extracellular matrix composed of a number of oocyte-secreted glycoproteins [zona pellucida 1 (ZP1), ZP2, and ZP3]. The zona pellucida is important for fertilization and has been reviewed many times. Disruption of zona pellucida formation or its normal function either by gene "knockout" in mice or by immunization shows that the zona pellucida is required for normal follicular development and particularly for the formation of a proper cumulus complex.

VI. EXTRACELLULAR MATRIX OF THE THECA

Laminin γ1 chain, laminin 1 components (α1, β1, or γ1), and type IV collagen α1 and α2 are present in bovine follicles throughout the theca interna and are not associated with any conventional basal laminas, such as those of blood vessels. At the electron microscopic level, fragments of basal lamina-like, electron-dense material have been observed and this matrix been designated the "thecal matrix." In other species, such as mouse and rat, in theca and in the interstitial tissue of developing gonads, a similar matrix has been observed by localizing laminin 1 components. The origins and functions, if any, of the thecal matrix are not known.

A number of basal laminas exist in the theca-subendothelial basal laminas and those surrounding the smooth muscle cells of arterioles. In bovine follicles, no laminin α1, α2, or γ1 is present but both β1 and β2 are in the subendothelial basal laminas of the blood vessels (arterioles, capillaries, and venules). The laminin β2 chain is also present in the smooth muscle layers surrounding the arterioles, which are located principally in the theca externa. This is consistent with studies in other tissues, in which the β1 chain has been reported to be limited to subendothelial basal laminas, whereas the β2 chain is present surrounding smooth muscle cells. Type IV collagen α1 and α2, but not α3, α4, α5, or α6, are present in the subendothelial basal lamina of arterioles, venules, and capillaries in the theca and in the basal laminas of arteriolar smooth muscle cells. The presence of multiple basal laminas throughout the thecal layers makes it difficult to study the expression of basal lamina components when relying solely on RNA analyses or Western blot analyses.

Since theca interna and externa are stromal layers, other types of matrix components are present. Structural collagens have been observed in the theca externa of many species, and collagens I and III have been identified by immunohistochemistry and by RNA

analyses. Type VI collagen has also been identified in theca interna. One role of this molecule is in the organization of fibronectin, and fibronectin has been identified in the theca interna in some studies.

VII. FIBRONECTIN

At least 20 different isoforms of fibronectin exist, due to alternative splicing of mRNA at three separate sites (the EDA, EDB, and V regions). A number of these splice variants are expressed in follicles; the EDA domain of fibronectin has been shown to be mitogenic for granulosa cells *in vitro*, and fibronectin synthesis by granulosa cells can be regulated by FGF2. There are a number of reports in which fibronectin has been localized in ovaries; often these studies used antibodies that recognize all forms of fibronectin. There does not appear to be a consistent pattern across species, with reports of fibronectin, usually of an undefined type, being localized to different follicle compartments. All of these reports may be accurate but given that a circulating form of fibronectin exists, which many of the antibodies used would react with, considerably more effort is required to identify the precise expression patterns of fibronectin isoforms during follicle development.

VIII. SUMMARY

The study of the extracellular matrix is well advanced in other organs of the body. This has provided a vast body of knowledge and reagents with which to study the extracellular matrix in the ovary. The study of the extracellular matrix in the ovarian follicle is particularly interesting and challenging since the follicle has so many different and alternative phases of development. Recent years have seen a considerable increase in the knowledge of this subject and the next few years promise to produce results just as exciting.

Glossary

follicle A small, narrow cavity or sac in an organ or tissue, such as those in the ovaries that contain developing eggs.

luteinizing hormone A gonadotropic glycoprotein hormone produced by the gonadotropes of the anterior pituitary gland.

oocyte A developing egg cell.

Genetic mutations affecting ovulation rate are often referred to as fecundity genes (e.g., Fec), since the most noticeable effect is on the number of offspring produced by the animals that bear these mutations. Mechanisms by which animals with higher ovulation rates achieve these effects cannot be explained by currently understood interactions between the pituitary gland and ovary but recent results suggest that interactions within the ovary itself contribute significantly to this outcome.

I. INTRODUCTION

Ovulation rate in mammals is determined by a complex exchange of hormone signals between the pituitary gland and the ovary and by a localized exchange of hormones within ovarian follicles between the oocyte and its adjacent somatic cells. Many mammals, such as humans, cattle, sheep, goats, and deer, normally have an ovulation rate of 1 egg/cycle, whereas other mammals, such as rats, mice, hamsters, cats, dogs, and pigs, have ovulation rates that vary between 4 and 15 eggs/cycle. Thus, when asking fundamental questions as to why some humans or farmed livestock (e.g., sheep) have a natural predisposition to produce two or three rather than one offspring, it is useful to examine the results from animals with a low-ovulation-rate phenotype.

The hormonal interactions between the pituitary gland and the ovary have been studied in some detail in both multiple and single ovulating species. The temporal interrelationships among the pituitary hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH) and the ovarian hormones, such as estradiol, progesterone, and inhibin are well understood. However, these interactions by themselves do not explain why some species always ovulate many eggs and other species ovulate mainly one egg. In contrast to our understanding of the pituitary–ovarian axis, there is a paucity of information regarding the hormonal interactions within the ovary and how these events might influence ovulation rate. In this regard, the inheritance patterns of several, naturally occurring genetic mutations that cause anovulation (e.g., sterility) or either modest (i.e., 0.2–0.5) or large (i.e., ≥ 0.8) increases in ovulation rate (Table 1) have been identified in sheep. When the mean inherited increase in ovulation rate is less than a whole number, this indicates that only some animals within a flock, at any moment in time, are expressing an increase above that observed in the control animals.

II. OVARIAN FOLLICULAR DEVELOPMENT

A summary of the various stages of ovarian follicular growth in sheep, together with the stage of onset of expression of genes encoding hormones, hormone receptors, or binding proteins in oocytes, granulosa cells, and/or theca interna/externa is shown in Fig. 1. The list of genes expressed is by no means a complete summary of those currently known and many more are expected to be included in the future. Follicles may form as either a primordial (i.e., type 1) or a transitory (i.e., type 1a) structure. Oocytes of these so-called "nongrowing" follicles express genes encoding several hormone receptors [e.g., bone morphogenetic protein receptor type IB (BMPR-IB), also known as ALK6, BMPR-II, or c-kit] and also at least one known growth factor, growth differentiation factor 9. Although the essential growth-initiating signals are not known, ovarian follicles develop through the transitory and/or primary (i.e., type 2) stages without being receptive to the pituitary hormones (i.e., gonadotropins) FSH or LH. During the primary and preantral (i.e., types 3 and 4) stages of growth, an increasing number of hormones, hormone receptors, and/or binding proteins are synthesized by the oocyte, granulosa cells, or theca cells. Thus, the regulation of follicular development becomes increasingly complex. Current information indicates that many of the regulatory factors are members of the transforming growth factor-β (TGF-β) superfamily [e.g., bone morphogenetic

TABLE 1 Sheep with Single Genetic Mutations or Putative Major Gene Mutations Affecting Fecundity

Name (Allele)	Chromosome	Phenotype (mean ovulation rate)	Phenotype (mean litter size)	Gene identification
Inverdale ($FecX^I$)	X	++ (1.8) I+ (2.9) II (0)	++ (1.6) I+ (2.3) I (0)	BMP15

proteins (BMPs), TGF-$\beta_{1,2,3}$, anti-Müllerian hormone, inhibins, and activins], receptors for this family (e.g., BMPR), or hormones that may act as binding proteins for some TGF-β family members (e.g., follistatin). Other prominent regulatory factors are c-kit and kit ligand, also known as stem cell factor, and members of the insulin-like growth factor family.

As follicles develop through the preantral and early antral (i.e., type 5) stages, granulosa cells become increasingly responsive to FSH and theca cells to LH. The roles that other pituitary hormones, such as prolactin and growth hormone, may play in the sheep is obscure. Nevertheless, throughout these stages of follicular growth, there is no absolute requirement for pituitary hormones. In sheep, some 17 or 18 doublings of the granulosa cell population occur as a type 1/1a follicle develops into a preovulatory follicle. During this developmental period, neither FSH nor LH is essential for the first 14–16 doublings of the granulosa cell populations or for the formation of the theca interna. It has therefore been deduced that early follicular growth is regulated, in large part, by a localized exchange of hormonal signals within the ovary and specifically within the follicle itself. Nevertheless, during the final stages of follicular development, FSH and LH are critically important for the synthesis and secretion of follicular hormones (e.g., steroids) and for determining the number of follicles that ovulate. For example, pituitary LH secretion is episodic and the frequency of these episodic concentrations in plasma regulates the theca-derived follicular secretions of the steroids androstenedione and testosterone. In contrast, the pituitary release of FSH is more "wave-like" and these more gradual variations in plasma FSH determine the number of antral follicles (i.e., large type 5 follicles) with granulosa cells capable of: (1) metabolizing theca-derived androstenedione or testosterone to estradiol; (2) synthesizing inhibin; and (3) acquiring LH receptors. In turn, and as a consequence of increasing follicular estradiol and inhibin output, the plasma concentration of FSH, but not the episodic frequency of LH release, is suppressed. This ensures that only the steroid-secreting, large follicles containing granulosa cells with LH receptors remain viable and capable of going on to ovulate. During the type 4 and 5 developmental stages, granulosa cells become increasingly sensitive to FSH in terms of their ability to synthesize the intracellular messenger cyclic adenosine monophosphate (cAMP). The ability of granulosa cells to synthesize estradiol and acquire LH receptors is influenced markedly by the plasma concentrations of FSH and the sensitivity of the cells per se to FSH. For example, in mammals, it is known that the administration of exogenous FSH increases ovulation rate in a dose-responsive manner. However, recent studies of naturally occurring genetic mutations in sheep demonstrate that, in addition to FSH, at least one member of the TGF-β superfamily,

namely, BMP15, and also a receptor known as BMPR-IB have extremely important roles in determining ovulation rate.

III. FecX^{I} AND FecX^{H}

Both the Inverdale (FecX^{I}) and the Hanna (FecX^{H}) mutations have been mapped to the X chromosome and identified as separate point mutations in the coding region of BMP15 (Table 1). In FecX^{I} animals, a single T–A nucleotide substitution at nucleotide position 92 of the mature coding sequence results in an aspartic acid replacing a valine in a highly conserved region of the protein. In FecX^{H} animals, a single C–T nucleotide substitution at nucleotide position 67 results in a premature stop codon in place of glutamic acid at amino acid residue 23 of the mature protein. The effect of the Inverdale or Hanna mutation in heterozygous females is to increase ovulation rate by almost 1 egg/cycle, whereas homozygous females or females carrying one copy of Inverdale together with one copy of Hanna are sterile as follicular development is arrested at the primary (type 2) stage (Fig. 1). Gene expression studies of BMP15 in noncarriers, heterozygous carriers, and homozygous carriers indicate that within the ovary, only the oocytes in type 2 or larger follicles contain the mRNA for this gene. Studies using immunohistochemical techniques to localize BMP15 protein have identified its presence in the oocytes of noncarriers. Studies in rats with recombinant human BMP15 demonstrate that this factor can stimulate DNA synthesis in granulosa cells and therefore BMP15 can be considered a growth factor. At this time, the identity of the receptor for BMP15 in granulosa cells is unknown. Since the Inverdale, Hanna, and Inverdale × Hanna animals all display the same ovarian phenotype, it is clear that the presumptive modified BMP15 protein in Inverdale and the putative truncated BMP15 peptide in Hanna have little or no biological activity. Collectively, these findings establish that, in sheep, BMP15 is an oocyte-derived growth factor essential for stimulating the proliferation of granulosa cells from the type 2 stage of follicular development (Fig. 1). Of equal significance is the finding that animals that contain oocytes that produce half the amount of normal BMP15 have a higher ovulation rate. In heterozygous Inverdale animals, it is known that the plasma concentrations of FSH are not different from those in control (nonmutated) sheep. Thus, the question arises as to how an oocyte-derived growth factor can influence ovulation rate. It seems that the oocyte may achieve this effect by influencing the sensitivity of its adjacent granulosa cells to FSH. This interpretation is based on the following evidence from *in vitro* studies: (1) BMP15 inhibits FSH-induced differentiation of rat granulosa cells and (2) granulosa cells from heterozygous Inverdale ewes respond to FSH by producing higher levels of cAMP earlier in follicular development than cells from noncarrier ewes. Thus, the higher ovulation rate in heterozygous Inverdale or Hanna ewes is likely due to a higher proportion of follicles being more responsive to FSH than occurs in noncarrier animals.

IV. FecB^{B}

The mutation in Booroola ewes has been mapped to sheep chromosome 6 and was identified as a point mutation in the BMP type IB receptor (Table 1). A similar mutation has been identified in the highly fecund Garole and Javanese sheep (Table 1), suggesting that these animals have a common ancestry with Booroola sheep. In FecB animals, a single A to G substitution at nucleotide position 830 results in an arginine replacing a glutamine residue in a highly conserved region of this receptor. The ligand for this receptor is not known. The BMPR-IB mRNA, together with its companion BMPR-II mRNA, is present in oocytes from the type 1/1a stage of development. In granulosa cells, BMPR-II mRNA is present in type 1/1a follicles but BMPR-IB mRNA is not evident until the type 2 stage. BMPR-IB mRNA is also found in other tissues, such as the brain, pituitary gland, skeletal muscle, kidney, and uterus. Animals heterozygous for this mutation have a mean ovulation rate of approximately 3 eggs/cycle, whereas those that are homozygous have a mean ovulation rate of approximately 5 eggs/cycle (Table 1). The precise mechanism by which this mutation affects ovulation rate is not known. It seems likely that both the pituitary gland and the ovary are affected and that both interact to enhance ovulation rate. Homozygous carriers of FecB^{B} in Booroola ewes have higher plasma concentrations of FSH than noncarrier animals and have granulosa cells that become more responsive to FSH earlier in follicular development than noncarrier animals. In homozygous FecB^{B} females, both the oocyte and the granulosa cells differentiate and mature earlier in follicular development than in noncarrier animals. In FecB^{B} animals, the oocyte reaches its mature diameter in a type 4 follicle, whereas this does not occur in noncarriers until the type 5 stage of development.

In addition, granulosa cells in homozygous carriers are required to undergo only 16–17 doublings before ovulation instead of the 18–19 undertaken by noncarriers. This reduced number of doublings may be related to the earlier maturation of the oocyte, which in turn signals a greater proportion of granulosa cells to enter a differentiative pathway instead of a proliferative pathway. In addition to granulosa cells in $FecB^B$ carriers having a higher responsiveness to FSH earlier in development, these cells synthesize estradiol and acquire LH receptors at an earlier stage of follicular development than do noncarriers.

V. $FecX2^W$

Recently, the inheritance patterns of ovulation rate in Woodlands (Fec $X2^W$) sheep indicate that it is on the X chromosome and likely to be a single or dominant set of mutations in a single gene. The $FecX2^W$ mutation has been shown not to be a mutation in BMP15. It is worth noting that $FecX2^W$ is maternally imprinted as only females inheriting the gene from their sire have increased ovulation rates. Moreover, the $FecX2^W$ mutation is expressed only on paternal inheritance from carrier males that are the progeny of dams in which the gene is silenced. The Woodlands gene is the first imprinted gene known to increase ovulation rate. The reproductive endocrinology of Woodlands sheep has not been reported.

IV. $FecI^I$ AND $FecC^C$

Other sheep breeds with putative major genes are the Thoka ($FecI^I$) and Cambridge (Fec^C) breeds (Table 1). However, the chromosomal location, gene identity, and reproductive endocrinology of these animals are not known.

Glossary

allele One of two or more alternative forms of a gene, each of which possesses a unique nucleotide sequence.

fecundity Offspring produced per female. Combines fertility (ability to produce offspring) and prolificacy (number of offspring).

genotype The entire array of genes carried by an individual or the particular allele at a specified locus in an individual.

ovulation rate Number of mature eggs released from the ovaries during one reproductive cycle.

phenotype The observable characteristics of an individual as determined by the interaction of its genotype and its environment.

Flt3 Ligand

SHULI ZHANG AND HAL E. BROXMEYER
Indiana University School of Medicine and Walther Cancer Institute, Indianapolis

Flt3 ligand (FL) is a transmembrane protein that binds to Flt3, a fms-like tyrosine kinase 3 receptor, and triggers the intracellular signaling cascade that leads to the proliferation and development of hematopoietic stem cells and progenitor cells. For most activities, FL has modest effects by itself; however, FL manifests potent co-stimulating activity and actively synergizes with other cytokines for optimal biological effects.

I. INTRODUCTION

Blood cell production is a tightly controlled, kinetically active process. The mature blood cells in the body that are required to fight infection, provide humoral and cell-mediated immunity, allow us to breathe, and prevent bleeding are derived through a catenated system from immature subsets of rare cells, the hematopoietic stem and progenitor cells. In the adult, the stem and progenitor cells used for the formation of blood elements are produced and functional mainly in the bone marrow. However, ontologically, these cells are found first in the aorta–gonad–mesonephros region, in the yolk sac, and later in sequence in the fetal liver, fetal spleen, and fetal bone marrow. Adult blood has an extremely low frequency of these cells, unless they are inducibly mobilized from the marrow to blood through a variety of procedures, including the infusion of cytokines; in contrast, for as yet unknown reasons, the blood collected from the placenta and umbilical cord at the birth of a baby has a high frequency of hematopoietic stem and progenitor cells. For treatment of a number of malignant and nonmalignant disorders, the only hope for the patient is replacement of stem/progenitor cells from either allogeneic or autologous transplantation. For such transplants, stem and progenitor cells derived from adult bone marrow, placental and cord blood, and cytokine- and/or chemotherapy-mobilized peripheral blood have been used.

Under normal conditions, the production and differentiation of hematopoietic stem and progenitor cells are regulated by cell–cell and cytokine–cell interactions. In this context, cytokines can stimulate, augment, or suppress the growth of stem/progenitor cells. This article will focus on the growth factor and potent co-stimulating molecule Flt3 (fms-like tyrosine kinase 3) ligand (FL), which acts by binding to the Flt-3/Flk-2 tyrosine kinase receptor and triggering the intracellular signal transduction that determines the cellular actions regulating hematopoiesis.

II. Flt3 LIGAND

Reports on the cloning of the Flt3 receptor were published in 1991, but the cloning of FL was not reported until 1993. The cloning of FL was accomplished from a cDNA clone isolated from an expression library of the murine T-cell line P7B-0.3A4 and from mouse thymic stromal cells. The FL cDNA encoded a type 1 transmembrane protein that was shown to stimulate the proliferation of cells transfected with Flt3. The soluble form of FL acted on the proliferation of phenotypically defined early subsets of blood cells, and it also enhanced the response of mouse stem cells and primitive subsets of human cells to other growth factors. A fragment of murine FL was used as a probe to clone human FL from a T-cell cDNA library. The human and murine forms of FL are 72% identical at the amino acid level, although the homology is greater in the extracellular region than in the cytoplasmic region. FL appears to be relatively non-species-specific in that the soluble forms of the human and murine FL are comparable in proliferation-inducing/co-stimulating activities on human and murine target cells. In many cases, the effects of FL have been documented in the presence and in the absence of serum in the culture medium and with purified cells, single isolated purified cells, and relatively unpure target cell populations. FL is widely expressed in many different tissues, yet the expression of its receptor, Flt3, is much more limited. The selected tissue expression of Flt3 will be covered in Section VI.

III. BIOLOGICAL ACTIVITIES OF FL *IN VITRO*

Because tyrosine kinase receptors such as c-kit and c-fms have the respective ligands stem cell factor (SCF, also called c-kit ligand, steel factor, and mast cell growth factor) and macrophage colony-stimulating factor (M-CSF), which are potent but selective growth factors, and Flt-3 is expressed on primitive blood cells, it was assumed that once the ligand for Flt-3 was identified, it also would demonstrate growth factor activity.

A. FL Effects on Proliferation of Myeloid Progenitor Cells

By itself, FL has relatively weak proliferation-stimulating activity on hematopoietic stem cells and progenitor cells. However, similar to the action of SCF, the ligand for the c-kit-encoded receptor, when FL was used in combination with other growth factors it manifested potent co-stimulating activity. The action of FL with other growth factors was in many cases synergistic, and at the least, the effect of the combination of FL with another growth factor was additive. FL synergized with granulocyte/macrophage colony-stimulating factor (GM-CSF) or interleukin-3 (IL-3) to enhance the proliferation of granulocyte/macrophage progenitor cells (CFU-GM), with granulocyte (G)-CSF to enhance the proliferation of granulocyte progenitor cells (CFU-G), and with M-CSF to enhance the proliferation of macrophage progenitors (CFU-M). It also had additive to synergistic effects when added with GM-CSF, IL-3, G-CSF, or M-CSF in combination with SCF. This synergism was apparent in both the numbers of CFU-GM-, CFU-G-, and CFU-M-derived colonies formed *in vitro* and the number of cells per colony. The colonies formed from progenitors stimulated with the combination of FL and SCF plus other colony-stimulating factors or cytokines came from progenitor cells that were more immature than those colonies that formed from cells grown in the presence of only one or two cytokines. That FL acted on the more primitive subsets of progenitor cells was consistent with the effects of FL on progenitors known to occur earlier in maturation than CFU-GM, CFU-G, and CFU-M. FL enhanced the proliferation of high-proliferative-potential colony-forming cells (HPP-CFC) and long-term culture-initiating cells. FL also enhanced colony formation of early (BFU-MK) and more mature (CFU-MK)-subsets of megakaryocytic progenitors in the presence of thrombopoietin (TPO). FL had minimal effects on enhancing erythropoietin-responsive erythroid (BFU-E) and multipotential (CFU-GEMM) progenitors. Although there are reports that FL has an effect *in vitro* on BFU-E and CFU-GEMM, the effect was modest and abbreviated in that the erythroid cell-containing colonies that formed were small in size. FL also enhanced colony formation of CFU-GM, HPP-CFC, and other myeloid progenitor cells (MPCs) when used in combination with either P1XY321, a GM-CSF/IL-3 fusion protein, or the combination of IL-6 with the soluble IL-6 receptor. In fact, FL synergized with essentially all the colony-stimulating factors and those interleukins that had MPC growth-stimulating/enhancing activity. The effects of FL when used with other cytokines are enhanced even further when SCF is added to the mix.

The expansion of hematopoietic stem cells and MPCs *ex vivo* is a goal of clinical medicine, and FL has been found to be a critical component of the cytokine combinations used to expand MPCs and possibly stem cells *ex vivo*. The most potent combination of cytokines used for *ex vivo* expansion is currently believed to be FL, TPO, and SCF, although additional cytokines have been added to this three-factor combination, sometimes with enhanced effects. There is no question that these *ex vivo* conditions expand MPCs. However, whether or not these *ex vivo* expansion procedures actually result in expansion or even maintenance of human hematopoietic stem cells with long-term repopulating capability (e.g., the competitive long-term marrow repopulating stem cell) is still an open question. There is some evidence that the three-factor combination does *ex vivo* expand the human cell population capable of repopulating sublethally irradiated mice with severe combined immunodeficiency (SCID). At this time, the mouse SCID repopulating cell (SRC) assay is considered the best assay for detecting human hematopoietic stem cells, but it is not a perfect assay as it does not allow for rescuing a lethally irradiated animal, the hallmark for a stem cell assay and one that is used to define mouse stem cells. Also, there are large discrepancies in the literature as to the extent of *ex vivo* expansion of human SRC. In this context, the membrane-bound form of FL may be more potent than the soluble form of FL in enhancing the *ex vivo* expansion of human stem cells and more immature subsets of MPCs.

B. FL Effects on Proliferation of Lymphoid Progenitor Cells

FL has been found to act with IL-7 to support expansion of murine thymic B-cell progenitors, murine B-cell commitment and development from

uncommitted progenitors, promotion of stromal cell-independent expansion and differentiation of human fetal pro-B cells, and growth of $CD43^+$ $B220^{low}$ progenitor cells (very primitive B cells) but not of the more mature pro- or pre-B-cell compartments. In combination with transforming growth factor-β (TGF-β), FL potentiates the *in vitro* development of Langerhans-type dendritic cells.

C. FL-Responsive Progenitors as Targets for Negatively Acting Cytokines

Progenitor cells responsive to stimulation by a combination of growth factors are the more immature subsets of progenitors, those with enhanced expansive capabilities. A number of cytokines have been shown to suppress the proliferation of myeloid progenitors, especially the more immature subsets of these cells. Members of the chemokine family of cytokines and also TGF-β and tumor necrosis factor α (TNFα) have demonstrated suppressive activities on FL-responsive MPCs. Chemokines fall into four subfamilies denoted by their cysteine–cysteine (CC), CXC (where X is another amino acid), C, and CX_3C motifs. More than 20 members within the CC, CXC, and C subfamilies, of the more than 60 chemokines known to exist, can suppress the proliferation of immature subsets of human and murine MPCs, including those responsive to the co-stimulating effects of FL. TGF-β and TNFα have similar effects on the growth of murine $Sca1^+Lin^-$ cells. In the mouse system, the $Sca1^+Lin^-$ phenotype is usually a marker for murine hematopoietic stem cells. The effects of chemokines, TGF-β, and TNFα on suppression of the proliferation and growth of FL-responsive MPCs and murine $Sca1^+Lin^-$ cells has been confirmed at the level of single target cells. This strongly suggests that the suppressive effects on the FL-responsive target MPCs/stem cells are direct. The single-cell experiments are crucial to determining direct actions, since numerous cytokines have multiple actions, including the capacity to induce the production/release of cytokines from cell populations that can act in a paracrine fashion. Thus, unless studies such as this are performed at the level of the single isolated cell, it will not be possible to rule out an indirect effect mediated through the induced release of another cytokine or cytokines that are the final mediator of the biological effect noted.

D. FL Effects on Survival of Progenitor Cells

All primary cells will undergo programmed cell death (apoptosis) when removed from the presence of cytokines. In addition to its capacity to augment/co-stimulate the proliferation of progenitor cells, FL acts as a survival/anti-apoptosis factor. Survival/apoptosis can be evaluated *in vitro* by removing cells from growth factor (even in the presence of serum) and then subjecting the cells to delayed addition of the growth factors. Thus, cells can be plated in the absence or in the presence of the putative survival/anti-apoptotic cytokine (which should not have the capacity to stimulate or enhance proliferation of the target population by itself, either because it is not active in this context or because it is used at a concentration lower than the concentration at which it is active). By delaying the addition of the proliferation-stimulating cytokines (e.g., colony-stimulating factors), it is possible to evaluate the survival-enhancing activity of the test material. That this effect is actually anti-apoptotic requires verification by the use of apoptosis detection assays (e.g., annexin binding, caspase 3 activation). In the context of these types of studies, FL was found to act as a survival/anti-apoptotic activity for CFU-GM, BFU-E, and CFU-GEMM in $CD34^{+++}$ bone marrow and cord blood cells and for CFU-M. FL inhibits apoptosis of acute myelogenous leukemia (AML) cells and this effect is associated with enhanced expression of the anti-apoptotic genes coding for Bcl-2 and Bax. These anti-apoptotic effects of FL on myeloid and B-lymphoid progenitor cells could be counterbalanced by chemokines, TGF-β, and TNFα. FL has also been shown to protect the murine M1 leukemic cell line from leukemia inhibitory factor (LIF)-induced differentiation and suppression of "self-renewal."

It is of interest that up-regulation of Flt3 receptor expression on murine bone marrow $Sca1^+Lin^-$ $c\text{-}kit^+$ cells was accompanied by a loss of self-renewal capacity but sustained lymphoid-restricted reconstitution potential. How this finding relates to the proliferation- and/or survival-enhancing effects of FL remains to be determined.

IV. BIOLOGICAL EFFECTS OF FL *IN VIVO*

A. Effects on Hematopoiesis and MPC Mobilization

Mice with a targeted disruption of the FL receptor, Flt3, demonstrated normal mature hematopoietic cell populations, but they had decreased numbers of primitive B-lymphoid progenitors. Also, phenotypically defined stem cell populations from these mice had decreased T-cell and myeloid repopulation capability in lethally irradiated secondary recipient

mice in a competitive stem cell-repopulating assay, with the greatest decrease apparent in the lymphoid lineage.

Recombinant soluble FL has been administered to mice and primates to evaluate the effects on hematopoiesis in these animals. When administered to mice for 15 days at a dose of 10 μg/mouse, there was an increase in nucleated cellularity in the spleen and peripheral blood. This was coincident with increases in splenic B cells, myeloid cells, and nucleated erythrocytes. There were increased numbers of granulocytes, lymphocytes, and monocytes in the blood and increased numbers of CFU-GM, BFU-E, and CFU-GEMM in bone marrow, spleen, and blood. Increases were also noted in the numbers of CFU-spleen cells (a more mature member of the stem cell compartment that is assayed *in vivo*) and in phenotypically defined populations of stem cells. Administration of FL to mice and rabbits was radioprotective but was most effective in this activity if given prior to the irradiation.

The FL-induced mobilization of stem and progenitor cells to the blood is of clinical relevance as growth factor-mobilized stem and progenitor cells can and are being used for clinical transplantation. When administered to primates at 200 μg/kg/day, there was a slow increase over time in the numbers of peripheral blood MPCs that peaked 2 weeks after start of the injections. In addition, there were enhanced numbers of circulating lymphoid and osteoclast progenitors. FL synergized with G-CSF in primates to enhance mobilization to the blood of the different types of progenitors.

FL and G-CSF synergy in the mobilization of stem and progenitor cells was also seen in mice. Administration of 100 μg/kg/day FL in combination with G-CSF synergized to mobilize hematopoietic stem cells with a $Sca1^{+Lin^{-c}}$–kit^{+} phenotype and with both short- and long-term engrafting capability. These cells induced by FL alone or in combination with G-CSF could protect lethally irradiated mice and resulted in long-term multilineage engraftment. The synergy between FL and G-CSF for mobilization was apparent not only in the numbers of stem/progenitor cells mobilized but also in the speed with which the cells were mobilized.

B. Effects on Dendritic Cells and Natural Killer Cells

An interesting outcome of the studies evaluating the *in vivo* effects of FL in mice was the observation that FL enhanced the numbers of dendritic cells, potent antigen-presenting cells, and potential effector cells for immune therapy of tumor development.

FL administration resulted in enhanced numbers of functionally mature dendritic cells, with the markers MHC class II, CD11c, DEC205, and CD86, which were capable of presenting alloantigen or soluble antigen to T lymphocytes or in priming an antigen-specific T-cell response *in vivo*. Increased numbers of these dendritic cells were seen in bone marrow, gastrointestinal lymphoid tissue, liver, lymph node, lung, peripheral blood, peritoneal cavity, spleen, and thymus. Enhanced numbers of cells were also seen in mouse liver that had an immature dendritic cell phenotype with poor T-cell allostimulatory activity. However, propagation of these immature dendritic cells *in vitro* with GM-CSF and IL-4 induced a more mature dendritic cell phenotype and enhanced functional activity. When administered to mice with G-CSF, FL induced an increase in the numbers of plasmacytoid dendritic cells in bone marrow and spleen.

In vivo administration of FL to mice also resulted in increased numbers of functional natural killer (NK) cells in bone marrow, thymus, blood, spleen, and liver; this effect possibly occurs through the induced expansion of NK-cell progenitors (Pro-NK cells).

V. FL AND MALIGNANCY/THERAPY

It is not entirely clear what role the FL/Flt3 axis plays in malignancy or indeed whether it plays any role at all. However, in addition to stimulatory/co-stimulatory effects of FL on normal cells, FL stimulates the proliferation of blast cells from some patients with acute myelogenous leukemia *in vitro*, and this effect is synergized when FL is added with G-CSF, GM-CSF, IL-3, or SCF.

In humans, FL is predominately synthesized as a transmembrane protein that must undergo proteolytic cleavage to generate a soluble form of the molecule. When murine stem/progenitor cells were transduced with retroviral vectors encoding murine transmembrane FL, the increased expression of this gene resulted in predisposition of Flt3 receptor-positive progenitor cells to leukemic transformation. Also, retroviral-mediated gene transfer of human FL enhanced the proliferation and intracellular activity of mitogen-activated protein kinase (MAPK) in the Flt3-expressing human leukemia cell line AML-5. FL was detected on the surface of the transduced AML-5 cells and although there was some increase in the numbers of AML-5 colony-forming cells, the main effect was to enhance the proliferation of individual

AML-5 colony-forming cells to form much larger colonies. Information on intracellular signaling induced by FL as well as information on Flt3 mutations is presented in Section VI.

A. FL Therapy in Animal Models

FL has shown efficacy in modifying disease progression in a number of animal models of solid tumors. In a murine model of metastatic lung cancer (Lewis lung carcinoma), administration of FL delayed tumor growth, but this was a temporary effect. In a murine model of metastasis, FL reduced the number of hepatic metastases, and this was coincident with increased numbers of dendritic cells, $CD4^+$ T cells, and $CD8^+$ T cells. Depletion of NK cells in these mice reduced the anti-tumor effects of FL, indicating that NK cells are also mediators of the FL effects. Increased anti-tumor effects in this model were apparent when FL was used in combination with IL-12.

Mice challenged with syngeneic breast cancer cells were protected by administration of soluble FL, but this protective effect was transient. However, transducing the murine breast cancer cells with murine or human FL genes by retroviral-mediated gene transduction decreased tumor development and protected mice from a subsequent challenge with untransduced tumor cells. Genes for either the membrane-bound form or the soluble form of FL were protective in this context. It was believed that the protective effects might be exerted through an effect on antigen-presenting cells but might also be mediated in part by NK cells since immunodepletion of activated NK cells with anti-asiolo-GM_1 blocked the anti-tumor activity.

It remains to be determined how effective FL therapy might be for certain tumors and exactly how these anti-tumor effects are being mediated. It is not likely that FL treatment of tumors that express Flt3 would be helpful, and in fact this might be counterproductive since FL acts as a proliferation-/co-proliferation-inducing and/or survival-enhancing cytokine for normal and leukemic Flt3-expressing cells.

VI. Flt3 RECEPTOR

A. Structure of Flt3 Receptor

The human Flt3 has 993 amino acids and the murine Flt3 has 1000 amino acids. They are 86% identical at the amino acid level. The Flt3 receptor is a single transmembrane protein and has an extracellular region composed of five immunoglobulin-like domains, a single transmembrane region, a juxtamembrane (JM) domain, a conserved tyrosine kinase domain spaced by a kinase insert region, and a C-terminal region. The Flt3 receptor thus belongs to the type III receptor tyrosine kinase family, which also includes the receptors for M-CSF, SCF, and platelet-derived growth factor (PDGF).

The murine and human Flt3 receptors have 9 and 10 potential sites for N-linked glycosylation, respectively, in their extracellular domains. The protein is glycosylated at one or more of these sites and undergoes carbohydrate remodeling as it migrates from the endoplasmic reticulum to the cell surface. The Flt3 receptor protein immunoprecipitated from cells treated with tunicamycin (an inhibitor of N-linked glycosylation) has a molecular mass of 110 kDa, which is the predicted size of the protein backbone alone. Immunoprecipitation of cells transfected with the Flt3 receptor reveals two proteins of 130–143 and 155–160 kDa. Pulse–chase experiments showed that the larger protein arose from the smaller protein, presumably as a result of glycosylation processing. Consistent with this interpretation is the finding that only the 158 kDa species is found on the cell surface. There do not appear to be any O-linked sugars on the protein.

B. Expression of Flt3 Receptor in Normal Tissues

Murine Flt3 is expressed mainly in hematopoietic tissues, brain, gonads, and placenta. The significance of Flt3 expression in nervous tissues is not known, but the major site of expression and function appears to be hematopoietic tissues. In mouse bone marrow (BM), Flt3 expression is restricted to primitive stem/progenitor cells. In humans, Flt3 mRNA is expressed in most lymphohematopoietic organs including bone marrow, thymus, spleen, liver, and lymph nodes and weakly in placenta. No expression is seen in either B or T cells, but monocytes or granulocytes are weakly positive. In normal human bone marrow, expression of Flt3 is limited to $CD34^+$ cells, a population enriched for hematopoietic stem/progenitor cells. However, recent studies show that $CD34^-$ lineage negative BM cells also express Flt3. More than 60% of $Flt3^+$ human BM cells co-express CD33, a myeloid cell-surface antigen, suggesting that Flt3 may be expressed on subsets of myeloid progenitor and/or mature cells. Most human $CD34^+$ BM and cord blood cells express Flt3, and most GM progenitors express Flt3, whereas $CD34^+Flt3^+$ cells are depleted in erythroid progenitors. Flt3 appears to be shut off before

erythroid differentiation and gradually down-regulated during GM differentiation. Myeloid-derived and lymphoid-derived dendritic cell (DC) progenitors appear to express Flt3, because they respond to FL in combination with other cytokines. However, mature DCs do not seem to express Flt3.

C. Expression of Flt3 Receptor on Hematopoietic Cell Lines and Leukemia

Expression of Flt3 receptor has been extensively studied in mouse and human hematopoietic cell lines. No Flt3 expression is seen in any of the mouse T-cell, macrophage, erythroid, megakaryocyte, or mast-cell lines examined or most early mouse B-cell lines, but it has been reported in several mature B-cell lines. In contrast, human Flt3 is expressed in a high percentage of human myeloid and monocytic cell lines. All myeloma, erythroid, and erythroblastic cell lines are Flt3 negative, and only a few megakaryocytic cell lines are positive. Among lymphoid cell lines, pro-B- and pre-B-cell lines are Flt3 receptor positive, whereas all T-cell lines, NK-cell lines, and Hodgkin's cell lines are negative.

Interestingly, Flt3 receptors are frequently seen on most AML blasts and pre-B acute lymphoblastic leukemia (ALL) cells. The majority of adult AML samples from all French American British (FAB) classes are positive for Flt3 receptor expression, as are all B-lineage ALL samples. In contrast, both T-cell and B-cell lymphomas are negative for Flt3 receptor expression. Almost all chronic-phase or accelerated-phase CML samples are negative for Flt3 receptor expression. However, approximately two-thirds of the samples from chronic myelogenous leukemia (CML) patients in blast crisis are Flt3 receptor positive.

D. Mutation of Flt3 Gene

Mutations of receptor tyrosine kinases, including c-kit, PDGF receptor (PDGFR), and Flt3, have been found in human leukemia. In acute myeloid leukemia, an internal tandem duplication (ITD) mutation of the juxtamembrane domain of the Flt3 gene has been found in 20–30% of patients. In Flt3/ITD, a fragment of the juxtamembrane domain-coding sequence was arranged in direct head-to-tail succession. Its location and length vary from sample to sample, but the duplicated sequence is always in-frame. Thus, mutant Flt3 contained a long JM domain although other domains were not affected. All duplications involve sequences that contain one to four tyrosine residues. These additional tyrosines could potentially play a role in the autophosphorylation of the receptor. Flt3/ITD mutations result in constitutive activation of Flt3 and subsequent activation of downstream MAPK and Stat5 even without ligand stimulation. Flt3/ITD-transfected murine IL-3-dependent cell lines, such as Ba/F3, 32D, and FDC-P1, are able to proliferate without IL-3 and cause leukemia-like disease when injected into syngeneic mice. Clinically, in AML patients, these mutations appear to be associated with higher white blood cell counts and poorer survival. These results suggest that abnormal regulation of Flt3 may contribute to leukemic transformation and that the Flt3 receptor may represent a therapeutic target in AML.

Recently, a point mutation of D835 in the kinase domain of human Flt3 was found in some AML patients. The D835 residue is located in a region called the activation loop of receptor tyrosine kinases (RTKs), and mutations in D835 spontaneously activate tyrosine kinase activity and induce factor-independent proliferation of hematopoietic cell lines. A similar point mutation was found in the c-kit gene (D816). In contrast to Flt3/ITD mutations, D835 mutations were not associated with poor prognosis.

E. Signal Transduction through the Flt3 Receptor

Similar to other type III RTKs, Flt3 is activated by ligand-induced dimerization and transphosphorylation of tyrosine residues in the cytoplasmic domain. Subsequent signal transduction is mediated through the association and/or phosphorylation of cytoplasmic substrates that propagate the signal. Several groups have reported the intracellular signaling pathways activated by either wild-type Flt3 or constitutively active mutant Flt3 in different cell systems. Since the Flt3 receptor was cloned before the ligand was found, the early studies examined the putative signal components of wild-type Flt3 using chimeric receptors containing the extracellular domains of either c-kit or M-CSF receptor (c-fms) fused to the transmembrane and cytoplasmic domains of murine Flt3. The chimeric receptor transduces activation signals through association with and/or phosphorylation of a number of cytoplasmic proteins, including the p85 subunit of phosphatidylinositol 3-kinase (PI3-kinase), RAS GTPase-activating protein, phospholipase C-γ, Vav, growth factor receptor-binding protein 2 (Grb2), and Src homology and collagen protein (Shc). Recent studies using full-length wild-type Flt3 have

confirmed most of the above findings and identified several new signaling components.

F. PI3-Kinase/Akt Pathway

PI3-kinase is a heterodimeric protein containing an 85 kDa regulatory subunit (p85) and a 110 kDa catalytic subunit (p110). It was one of the first major signal molecules identified in Flt3 signaling. Activation of murine Flt3 induces tyrosine phosphorylation of p85, the association of p85 with Flt3 through the SH2 domain, and subsequent activation of PI3-kinase. Murine Flt3 has two potential p85-binding sites, Y^{922}FVM and Y^{958}QNM. It has been shown by phosphopeptide competition and mutagenesis studies that, in contrast to c-kit and CSF-1R, p85 binds to Y958 in the carboxy tail of the receptor. A mutant receptor in which Y958 had been changed to F958 could not bind p85 and did not activate PI3-kinase upon activation. Yet the mutant receptors, when expressed in fibroblasts or in the interleukin 3-dependent cell line Ba/F3, still provided a mitogenic signal comparable to that of wild-type receptors. The Y958F mutation had no effect on the internalization of the receptor.

Compared with murine Flt3, human Flt3 does not have a p85-binding motif at the carboxyl-terminus but does have one at the second kinase domain, Y^{919}IIM. PDGF receptor, CSF-1 receptor, and c-kit all have the p85-binding site in the kinase insert domain. Co-immunoprecipitation experiments failed to detect the association between human Flt3 and p85, suggesting that, in contrast to murine Flt3, p85 does not bind directly to human Flt3. Instead, p85 associated with Shp-2,SH2-domain-containing phosphatase (SHIP), Cbl (casitas B-lineage lymphoma), and Gab2 (Grb2-associated binder 2). Immunoblotting with anti-phosphotyrosine antibody failed to detect the phosphorylation of p85 in these studies. These results suggest that human Flt3 may use different mechanisms to activate PI3-kinase. In addition to PI3-kinase, activation of Flt3 induced the transient activation of Akt, a serine/threonine protein kinase downstream of PI3-kinase.

G. MAPK Pathway

Several studies have found that the stimulation of Flt3 ligand activates extracellular signal-related kinase (ERK). The activation of ERK is required for the mitogenic signaling of Flt3 ligand as PD98059, a specific MAPK kinase inhibitor, inhibited cell proliferation induced by FL in a dose-dependent manner. The activation of ERK is likely mediated by the adapter protein Grb2, which has been shown to bind directly to both murine and human Flt3. There are two putative Grb2-binding sites in the C-terminus of Flt3. It remains to be determined whether Grb2 binds to both sites or to either of them.

In addition to Grb2, Shc, SHIP, Shp-2, Cbl, and Cbl-b become prominent tyrosine-phosphorylated proteins after activation by Flt3. Interestingly, Shc does not bind directly with Flt3, and it associates with tyrosine-phosphorylated SHIP. In contrast to other members of the type III RTKs, Shp-2 does not bind directly to Flt3. Rather it associates with Grb2. In human myeloid cell lines and pro-B-cell lines, Cbl and Cbl-b are tyrosine phosphorylated and associate with p85 on ligand stimulation. Gab1 (Grb2-associated binder 1) and Gab2, two scaffolding adapter proteins, have recently been identified as new components of Flt3 signaling. Both Gab1 and Gab2 are transiently tyrosine phosphorylated and interact with Shp-2, Grb2, and p85.

H. Jak/Stat Pathway

The Janus kinase/signal transducer and activator of transcription (Jak/Stat) pathway represents an extremely rapid membrane-to-nucleus signaling system and is widely used by members of the cytokine receptor superfamily. Jaks are cytoplasmic tyrosine kinases with four mammalian members: Jak1, Jak2, Jak3, and Tyk2 (protein tyrosine kinase-2). Stats are latent cytoplasmic transcription factors that become activated after recruitment to an activated receptor complex. Subsequently, these active Stats translocate to the nucleus to affect gene expression. Seven Stat proteins have been identified in mammalian cells: Stats1 to 6, including Stat5a and Stat5b, which are encoded by distinct genes. In addition to the cytokine receptor superfamily, a number of RTKs, including c-kit, PDGFR, and M-CSF receptor, have been shown to activate the Jak/Stat pathway. Among Stat proteins, only Stat5 has been found to be involved in Flt3 signaling. It has been shown that Stat5 may mediate the proliferative effect of FL on hematopoietic progenitor cells. Thus far, Jak kinases have not been implicated in Flt3 signaling.

VII. FUTURE DIRECTIONS

Compared with other type III RTKs, little is known about the intracellular signaling pathways of Flt3. Considering the important role of FL/Flt3 in normal hematopoiesis, studies of Flt3 signaling mechanisms should shed light on how FL functions in normal hematopoiesis. More importantly, this knowledge

may provide insight into the pathogenesis of leukemia and thus help in designing strategies to slow the progression of and possibly cure certain forms of leukemia.

Glossary

Flt3 The fms-like tyrosine kinase 3 receptor that acts as the cell surface mediator of biological effects induced by its ligand upon specific receptor binding.

Flt3 ligand (FL) A type 1 transmembrane protein that in soluble or transmembrane form binds to Flt3 and elicits the intracellular signaling cascade that guides hematopoietic stem and progenitor cells to proliferate, survive, and develop. For most activities, FL has modest effects by itself, but it is a potent co-stimulating molecule and actively synergizes with other cytokines for optimal biological effects.

hematopoiesis The production of blood and immune cells. The mature end-stage blood and immune cells are generated from a rare population of hematopoietic stem cells that have the capacity to self-renew and/or differentiate into multilineage blood and immune cells. Stem cells give rise to rare populations of progenitor cells, which have little or no self-renewal capacity and are more restricted/committed to specific cell lineages. Progenitor cells give rise to precursor cells, which are the first morphologically recognized dividing cells within a specific blood/immune cell lineage. Stem/progenitor cell production is regulated by cytokines and cell–cell interactions that stimulate, enhance, and/or suppress the proliferation, self-renewal, differentiation, survival/apoptosis, and/or migration (homing/mobilization) of these cells.

Follicle-Stimulating Hormone (FSH)

WILLIAM L. MILLER
North Carolina State University

Follicle-stimulating hormone (FSH) is an α/β heterodimer produced only in pituitary gonadotropes, which constitute 3–8% of all pituitary cells. FSH acts on granulosa cells and Sertoli cells to ensure maturation of eggs and sperm in females and males, respectively.

I. INTRODUCTION

Follicle-stimulating hormone (FSH) is named for its ability to stimulate follicle growth in females, as depicted in Fig. 1. Follicle-stimulating hormone stimulates the division and function of granulosa cells that surround and nurture the developing oocyte (egg) in the follicle.

Spermatogenesis also relies heavily on FSH, which induces Sertoli cell division in early life. In later life, both FSH and testosterone stimulate Sertoli cells to nurture B spermatogonia as they develop into sperm. A number of hormones from the hypothalamus, the gonads, and the pituitary itself help regulate FSH. This article first deals with the effect(s) of FSH on sperm and egg maturation (including the use of FSH to solve infertility problems in the female) and then it outlines the complex nature of FSH regulation in mammals.

II. STRUCTURE OF FSH

A ribbon diagram of human FSH is shown in Fig. 2. Two different subunits (α/β) are held together tightly by noncovalent bonds. The human α-subunit, encoded by a single gene on chromosome 6q12.2, is 92 amino acids long, contains five cysteines that stabilize it by intrasubunit disulfide bonds, and is N-glycosylated on asparagines 52 and 78. Up to 30% of its final weight comes from carbohydrate. The α-subunit is found in other hormones, such as luteinizing hormone (also made in gonadotropes), thyroid-stimulating hormone (made in pituitary thyrotropes), and human chorionic gonadotropin (made in placental tissue).

The β-subunit of human FSH is encoded by a single gene on chromosome 11p13. It is 111 amino acids long, contains six cysteines that stabilize its conformation with disulfide bonds, and is N-glycosylated on asparagines 7 and 24. As with the α-subunit, approximately 30% of the β-subunit of FSH is carbohydrate by weight. Both FSHβ and luteinizing hormone β (LHβ) gonadotropin subunits are produced in pituitary gonadotropes and bind to the common α-subunit described above, which is produced in excess.

The carbohydrate content of FSH varies significantly throughout the estrous/menstrual cycle and has been thought to be important in FSH regulation. At the beginning of the cycle, the carbohydrate contains more sialic acid and is, therefore, more acidic, but more basic forms predominate at the end of the cycle. The more acidic forms have longer half-lives because they are protected longer from degradation, but they have less biological activity. Because of the trade-off in longevity versus potency, it has never been established clearly whether the changes in glycosylation are biologically significant.

Inactivating mutations for FSH are very rare so infertility is not likely to come from faulty FSH. Both the α- and β-subunits of FSH are encoded by single-copy genes and are vulnerable to a standard rate of mutation. However, there are no mutations of the α-subunit known to inactivate FSH, and there are very few individuals known, worldwide, to harbor inactivating mutations of the FSH-specific β-subunit. Women with homozygous inactivating mutations for FSH suffer from amenorrhea and are infertile. Men lacking functional FSH have normal or slightly delayed puberty, but have small testes and have low sperm count. Heterozygous mutations of FSH do not alter reproductive function.

III. FSH RECEPTOR

Follicle-stimulating hormone acts only by binding its receptor, shown in Fig. 3. This is a classical seven-transmembrane G-protein-coupled receptor

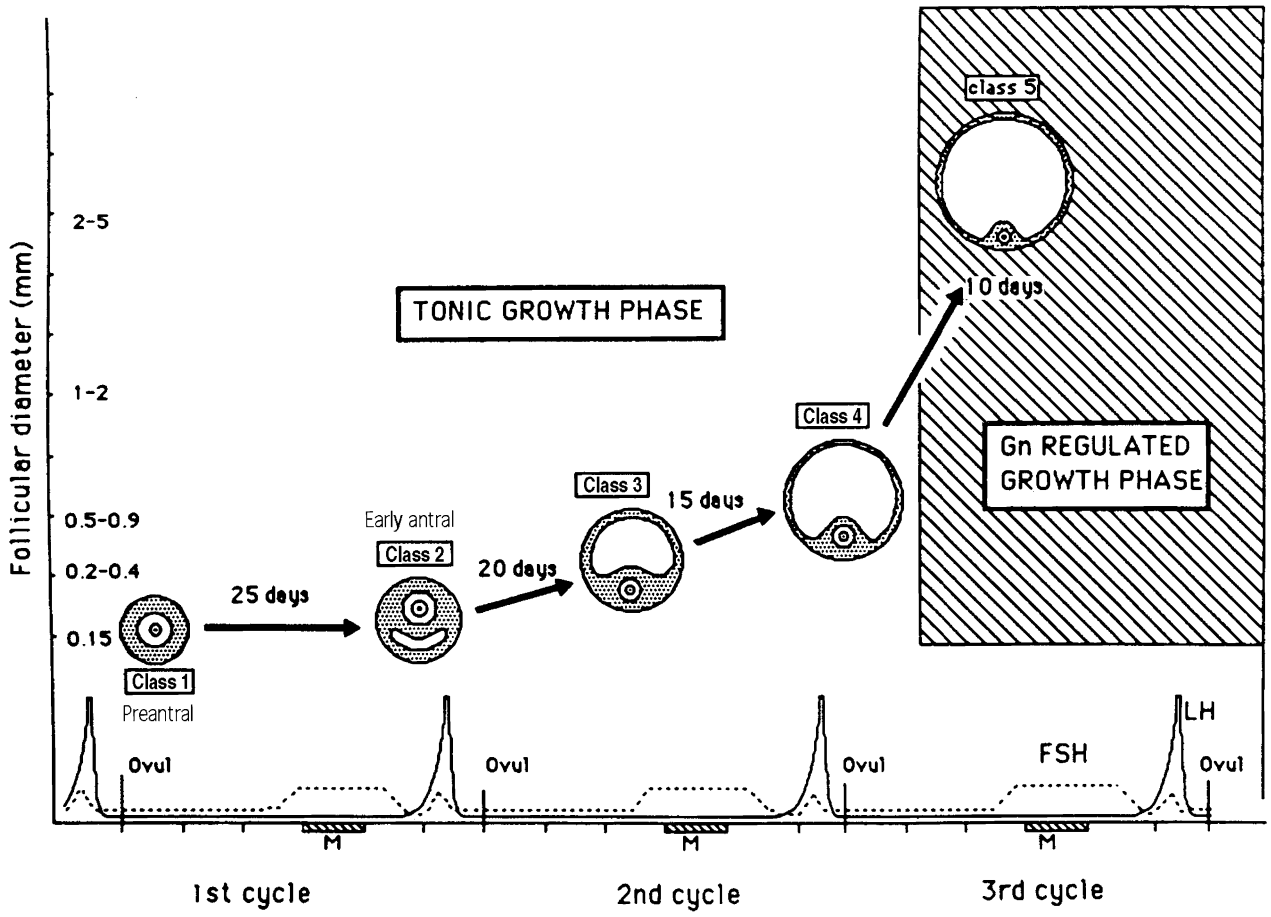

FIGURE 1 Schematic representation of human ovarian follicle development. Primordial follicles entering the growth phase form primary follicles (class 1). This is followed by gonadotropin-independent (tonic) growth (classes 1 to 4) and eventually gonadotropin (Gn)-dependent growth. Note that the overall development from a class 1 to a class 5 follicle takes three cycles. Modified from Gougeon, A. (1986) *Hum. Reprod.* **1**, 81–87, with permission.

that is found only on granulosa or Sertoli cells. The FSH receptor activates heterotrimeric G-proteins having $G\alpha_s$-subunits that stimulate production of the intracellular "second messenger" cyclic AMP, which, in turn, activates protein kinase A to phosphorylate a number of proteins such as enzymes and transcription factors that induce or inhibit the expression of many genes, some of which have been identified. Evidence also indicates that heterotrimeric G-proteins containing $G\alpha_i$- and G11/q-subunits are mobilized to activate protein kinase C and several map kinases and to increase intracellular calcium levels, but the physiological importance of these mechanisms is not clear. The complete array of genes and proteins affected by the FSH receptor in granulosa or Sertoli cells has not yet been determined, but the effects of FSH are widespread within granulosa and Sertoli cells.

Very few individuals have defective FSH receptors. The few known mutations of FSH receptors are shown in Fig. 3. Seven cases involve inactivating point mutations (open boxes) and one mutation causes the receptor to be hyperactive (filled circles). Defective FSH receptors give rise to the same infertility and developmental symptoms observed with defective FSH (see above).

IV. FSH ACTION IN THE TESTIS

Sertoli cells are the only cells with FSH receptors in males. As noted in Fig. 4, FSH stimulates Sertoli cells to nurture spermatogonia as they mature into spermatocytes. It is noteworthy that failure of FSH to stimulate Sertoli cells usually leads to reduced male fertility, but this is "clinically hidden" and not obvious by merely looking at a man since it causes

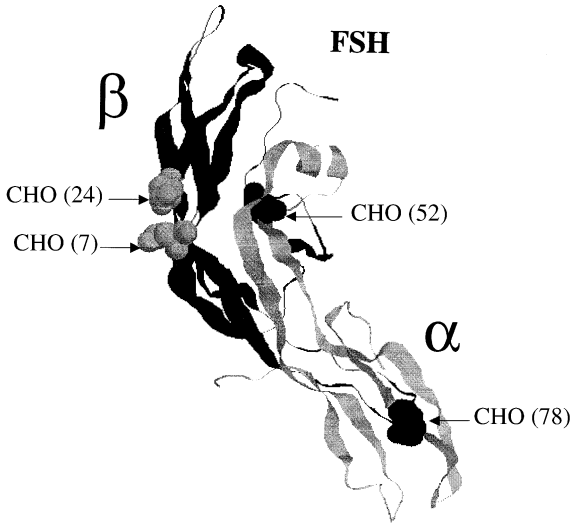

FIGURE 2 Ribbon diagram of FSH showing the noncovalently associated α-subunit (light gray) and β-subunit (black). Glycosylation sites are shown at specific amino acids on both subunits [indicated by CHO (carbohydrate) with the amino acid position number given in parentheses]. Reprinted from Fox, K. M., *et al.* (2001) *Mol. Endocrinol.* **15**, 378–389, with permission from The Endocrine Society.

no change in testosterone and associated secondary male characteristics. Thus, males may appear virile but have very few or no sperm.

Male contraception has long been an interest of reproductive biologists, and significant effort has been devoted toward disrupting FSH action to prevent spermatogenesis (a male contraceptive method). Indeed, interrupting FSH action by immunization against FSH has been shown to block spermatogenesis in adult monkeys. Recent data gathered from both mice and men have caused controversy about this approach to contraception, however, because males that have never been able to respond to FSH from birth are still fertile. They have only 25% of the Sertoli cells of normal males, have smaller testes, and have sperm counts that are 75% lower than those of normal males, but they still produce enough sperm to be fertile. The current hypothesis reconciling the effects of FSH loss during adulthood with those of FSH loss from birth suggests that alternate hormone pathways can develop *in utero* to permit sperm production in males lacking FSH or FSH receptors from birth, whereas removal of FSH in adults occurs after alternate pathways are able to develop. This hypothesis argues that specifically targeting FSH production in adult males may still be an effective means of blocking spermatogenesis.

Another approach to male contraception involves nonselectively depressing all pituitary gonadotrope function to decrease both FSH and LH. This approach, however, requires steroid hormone replacement (testosterone) to maintain masculine body characteristics and libido since LH maintains male sex drive and body characteristics by inducing Leydig cells to produce the male sex steroid, testosterone.

V. FOLLICULAR GROWTH AND REGULATION

The female granulosa cell is analogous to the male Sertoli cell. It is the only cell type in females that contains FSH receptors and its function is to nurture the developing gamete (oocyte) within the ovarian follicle (Fig. 1). Since granulosa cells also produce estrogens, which induce secondary female sex characteristics and maintain the menstrual cycle, a failure of FSH not only causes infertility, but also manifests itself "clinically" in women.

In Fig. 1, granulosa cells are shown directly contacting the oocyte. They comprise the gray area that surrounds the oocyte and provide it with growth factors such as epidermal growth factor and transforming growth factor-β (TGF-β) family members. There is a critical flow of hormone information between the oocyte and granulosa cells that is not well defined but is initiated and maintained by FSH. Since granulosa cells also produce estrogens, they are responsible for the increase in estrogens during the follicular phase that triggers the gonadotropin surge leading to the climactic act of ovulation (see Figs. 1 and 5).

Fig. 1 focuses on the maturation of a single "dominant" follicle as it develops over the course of several human menstrual cycles. It also highlights the very important period of FSH rise that influences follicular development (the dotted line in Fig. 1 represents increased FSH secretion during the "follicular phase"). This rise in FSH is thought to be the only physiologically important rise in FSH during the reproductive cycle although FSH also rises during the LH surge on day 0.

Women have approximately 400,000 primordial follicles at puberty, each containing a single egg that can develop into a mature oocyte, as shown in Fig. 1. Between puberty and age 27, women lose a majority of these eggs. Each month, more than 1000 follicles enter their final developmental stage (class 5) but only one becomes dominant and has the chance to release its mature egg following the LH surge. After age 27, the loss of eggs per month is significantly decreased, but the number of developing oocytes is decreased as well.

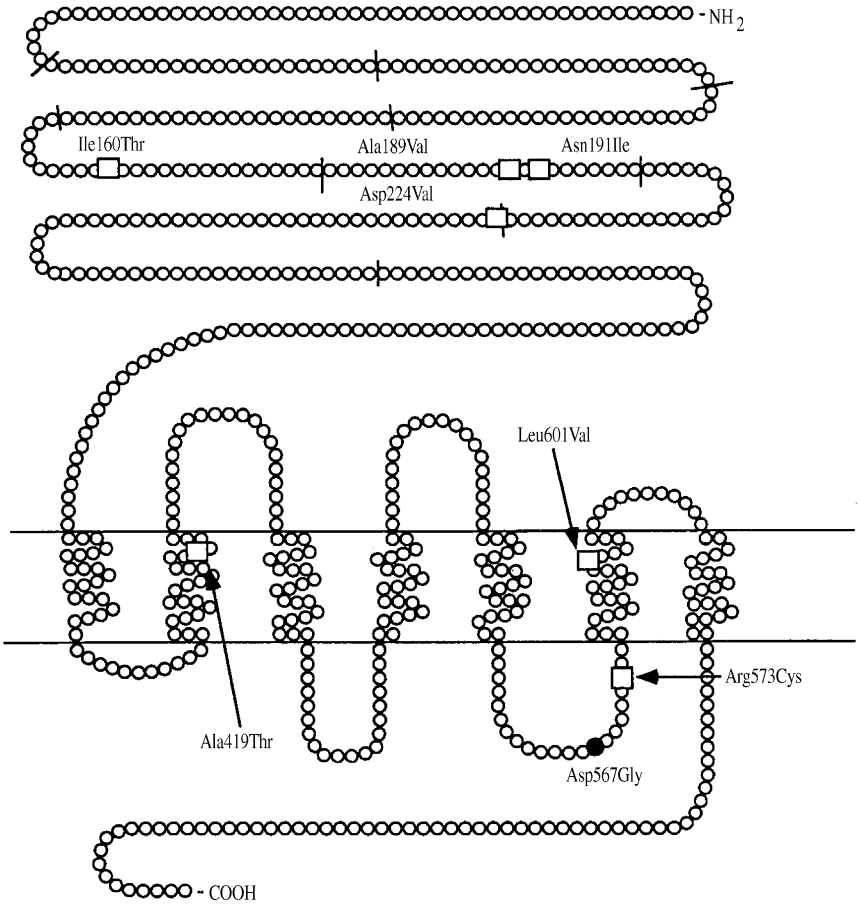

FIGURE 3 The amino acid sequence for the human FSH receptor. This schematic shows the locations of seven inactivating mutations (open squares) and one activating mutation (filled circle) known to occur in the human FSH receptor. The short lines across the amino acid chain show the combination sites for the 10 exons of the gene encoding the human FSH receptor. Reprinted from Themmen and Huhtaiemi (2000), with permission from The Endocrine Society.

The decline in FSH during the follicular phase of the cycle (see Fig. 5) plays a critical role in selecting the single dominant follicle that eventually releases its egg to the uterus. The dominant follicle becomes relatively independent of gonadotropin support after it reaches 10 mm in diameter and continues to grow and flourish as FSH declines during the latter part of the follicular phase (day −7 to day 0). This single dominant follicle synthesizes the estrogen needed to trigger the gonadotropin surge that causes the follicle to burst and release its fully mature oocyte on day 0 (Figs. 1 and 5). Only the most mature follicle eventually becomes independent of gonadotropin production; the others (>99.9% of the follicles!) stop developing as FSH falls below a "threshold level" that is required for their maintenance and they undergo atresia (apoptosis and self-absorption).

Fig. 5 shows that FSH reaches its highest level on day 0, but as noted above, this transient increase seems to have little impact on overall follicle development. The primary effect of FSH comes from its early and continuous rise during the follicular phase and menses in humans that constantly stimulates granulosa cells once it reaches a high enough threshold level to influence them. Finally, Fig. 5 shows an increase in progesterone produced by the corpus luteum, which forms from the spent dominant follicle. Progesterone dominates the reproductive cycle for 14–16 days during the "luteal phase." Declining levels of estrogens and progesterone in the absence of pregnancy elicit menstruation in the primate. This is followed by the follicular phase that matures and selects another dominant follicle for ovulation.

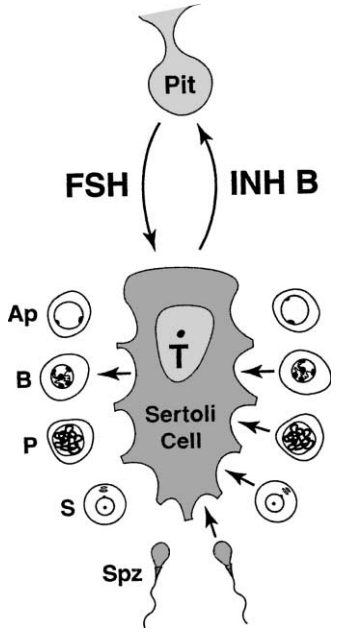

FIGURE 4 A model for the regulation of sperm production in primates. According to this model, FSH amplifies a basal level of spermatogenesis that is dependent on intratesticular testosterone (T). The degree of amplification is directly related to the circulating concentration of FSH, and FSH drive is relayed to the germinal epithelium via the production of a paracrine factor by the Sertoli cell. This paracrine factor favors the survival of differentiated B spermatogonia (B), which leads to an increase in the number of subsequent generations of germ cells. The FSH concentration is regulated by the rate of secretion of inhibin B (INH B) by the Sertoli cell. Inhibin B exerts a brake on FSH secretion by suppressing FSHβ gene expression. The mechanism that controls the rate of inhibin B secretion by the testis is controversial but in the present model a signal(s) from the differentiated germ cells is proposed to positively regulate inhibin B production by the Sertoli cell. The intensity of the putative germ cell signal is posited to be related to the number of differentiated germ cells. VI. INDUCTION OF OVULATION WITH FSH

Follicle-stimulating hormone is used to induce ovarian follicle development in women with hypothalamic amenorrhea (low gonadotropins), "unexplained infertility," or endometriosis. These women are treated with FSH to cause ovulation induction that is termed "controlled ovarian hyperstimulation." In these women, enough FSH is given to produce four to six ovulations since the success rate with only one ovulation is low (20%). A "step-down" procedure is usually used, starting with high doses to recruit a large number of follicles and using lower doses during the final maturation stage of the follicles to mimic the decrease in FSH and selection of one (or two) dominant follicles that occurs during the normal reproductive cycle. Development of dominant follicles is monitored with transvaginal ultrasound and the goal is to produce one or two fetuses, which is usually met.

Some women are afflicted with polycystic ovary syndrome. Many of these women are relatively insensitive to insulin and may ovulate on their own when given insulin sensitizers or they may need both insulin sensitizers and FSH. These women are at the highest risk for multiple births from FSH treatment.

Reaching the correct level of stimulation is difficult because women exhibit significant variability in their individual requirements for FSH during their cycles. Also, FSH preparations are variable (postmenopausal urine gonadotropins, purified recombinant FSH). These different preparations seem equally efficacious when used properly. As noted above, it has become the general practice to adjust FSH dose as deemed necessary while monitoring follicle growth by ultrasound to obtain the formation of several dominant follicles.

When there is a need for *in vitro* fertilization, FSH preparations are administered to women at very high levels so that FSH receptors on the granulosa cells are saturated. This permits many of the developing follicles to attain ovulatory size. The oocytes from these multiple ovulatory-size follicles are retrieved prior to the normal time of ovulation and fertilized *in vitro*. In this case, the number of embryos transferred back into the womb is highly controlled and the remaining embryos are cryopreserved for later transfer.

VII. REGULATION OF FSH

The production of FSH is regulated primarily at the transcriptional level of its β-subunit, which is the limiting subunit for FSH production in pituitary gonadotropes. Transcription of the FSHβ subunit is controlled by a number of hormones including hypothalamic gonadotropin-releasing hormone (GnRH), TGF-β family members, and follistatin, which is produced in the pituitary and gonads. Gonadal steroids are also important but often work indirectly through regulation of GnRH and/or TGF-β family members.

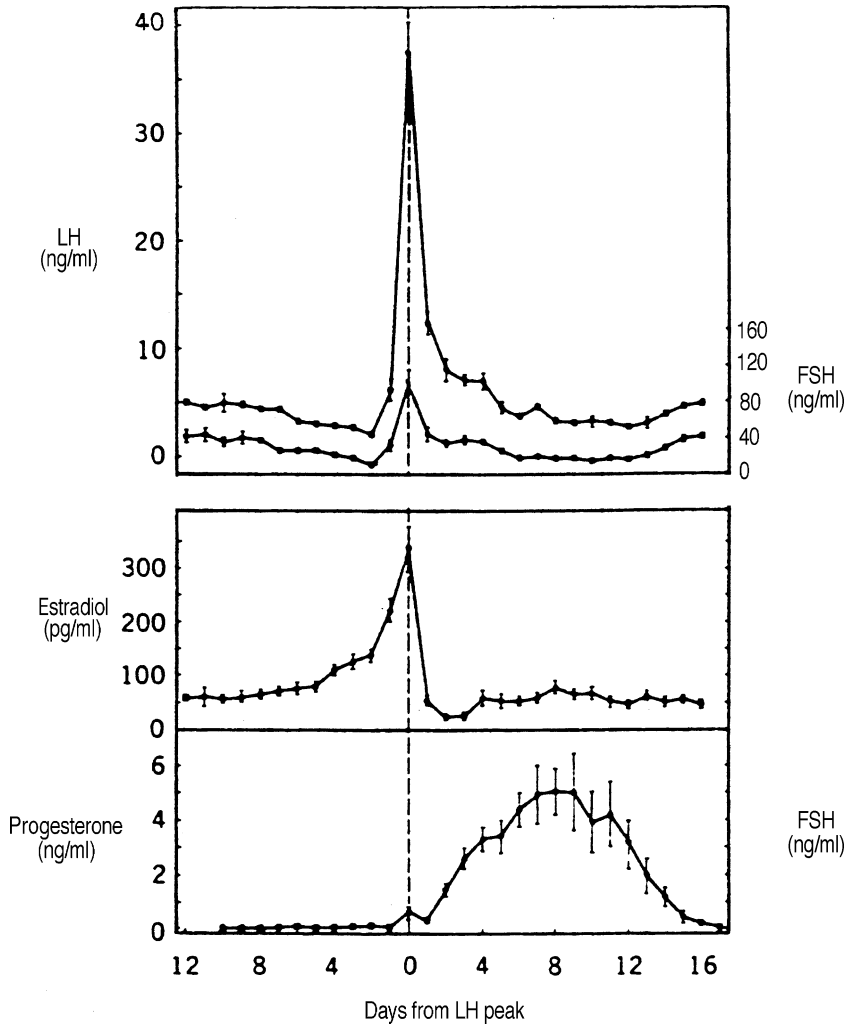

FIGURE 5 Profile of the concentrations of follicle-stimulating hormone, luteinizing hormone, estradiol, and progesterone throughout the rhesus monkey menstrual cycle. Reprinted from Knobil, E. (1974) *Rec. Prog. Horm. Res.* 30, 1–36, with permission.

A. Gonadotropin-Releasing Hormone

GnRH is a major inducer of FSHβ expression. When GnRH action is blocked in rats by GnRH antagonists or antibodies that bioneutralize GnRH, overall FSH levels fall 50–60%. When GnRH is absent from birth, as in hypogonadal mice (hgp mice), the females produce 60% less FSH than normal mice and hgp males produce only 17% of the normal FSH level. These hypogonadal mice have even less LH than FSH and are infertile. Correction of the defective GnRH gene in mice corrects all gonadal failure. A similar defect in GnRH secretion is found in humans with Kallmann's syndrome (olfactory–genital hypoplasia). Normal FSH production and normal reproductive function can be established in these individuals by providing GnRH pulses by pump at hourly intervals although the procedure is costly and cumbersome for the patient.

There is evidence (*in vitro* and *in vivo*) that GnRH can directly induce FSHβ transcription. Direct induction of FSHβ transcription is likely to be a small part of this GnRH effect, however, because GnRH also stimulates general protein translation and gene transcription in gonadotropes in a pleiotropic manner.

B. TGF-β Members: Induction of FSH

Although GnRH is a major inducer of FSH, TGF-β family members seem to have even more influence over FSH expression. As shown in Fig. 6, activins are

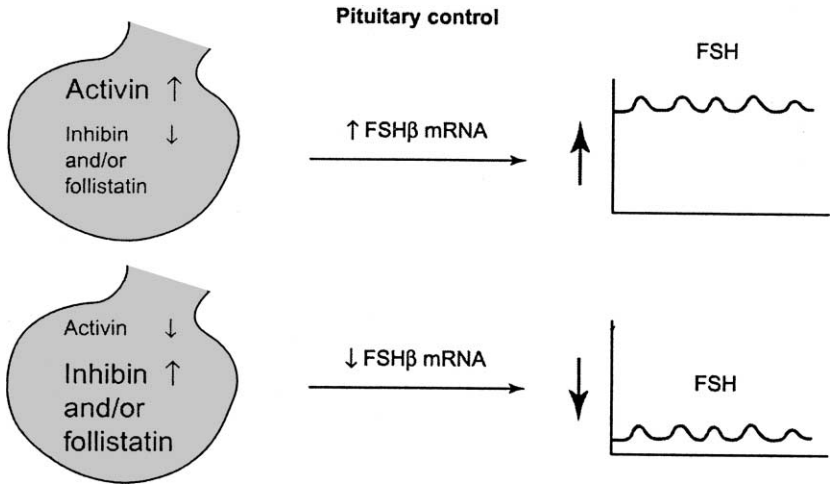

FIGURE 6 Schematic representation of the local pituitary loop involving activin, inhibin, and follistatin and their impact on FSH secretion. This model predicts that increases in pituitary activin or decreases in inhibin and follistatin will increase FSH secretion. In contrast, a decrease in activin or increases in follistatin–inhibin will lower FSH secretion. Reprinted from Padmanabhan, V., and McNeilly, A. S. (2001) *Reproduction* **121**, 21–30, with permission.

strong inducers of FSH and inhibins and follistatin (which blocks activin action) are powerful inhibitors of FSH.

It has been known for 15 years that activins A and B can induce FSHβ transcription, and it has recently been reported that three other TGF-β family members also induce FSHβ. These are bone morphogenetic proteins 6, 7, and 15 (BMP6, BMP7, and BMP15), which are less potent than the activins but may be more abundant. The mRNAs for all of these TGF-β family members are present in the pituitary either in gonadotropes or in other pituitary cells so they may all stimulate FSHβ transcription by autocrine and/or paracrine methods.

Although activin B can be induced by GnRH under certain defined conditions, it is not known whether this induction is central to FSH regulation *in vivo*. It is possible that these TGF-β inducers of FSHβ transcription are expressed in a constitutive manner to provide constant stimulation for FSH production or, perhaps, certain family members are regulated specifically to control FSH expression at discrete periods of time. This is an area of research that is ripe for exploration.

C. Inhibition of FSH

Inhibition of FSHβ transcription is accomplished by follistatin and inhibins. Follistatin is a molecule that binds and bioneutralizes activins and BMPs. Although it is produced at many locations in the body, it is secreted locally in the pituitary and is thought to work primarily in this local environment to control expression of FSH. Follistatin can be induced by GnRH under certain defined conditions and in certain species, but it is not certain how crucial this regulation is to overall control of FSH *in vivo*.

Inhibins A and B are α/β heterodimers of the TGF-β family that are strong inhibitors of FSHβ transcription (most TGF-β family members are like activins or BMPs, which are β/β homodimers or β/β heterodimers). The inhibins appear to bind their own receptors, which block FSH production by interfering with activin receptors. Inhibins are produced primarily in the ovaries and testes and exert considerable negative control over FSH production in the pituitary. Castration or ovariectomy leads to a large increase in FSH, which is generally attributed to the cessation of gonadal inhibin secretion. It is not clear, however, how much influence gonadal inhibins have over day-to-day regulation of FSH since there is little convincing evidence to show that blood levels fluctuate enough to cause the changes observed in Fig. 6.

D. Gonadal Steroids

Finally, gonadal steroids such as estradiol and progesterone alter production of FSH, but they generally act indirectly by changing GnRH secretion during the estrous period of the female cycle. It is clear that estrogens and progestins can act directly at the promoter of FSHβ to inhibit its transcription, but the importance of this inhibition has not been established *in vivo* in sheep and this type of inhibition

does not occur in rodents such as mice. Sometimes GnRH secretion is stimulated and sometimes it is inhibited by steroids, but this is somewhat variable among species except for the stimulation given by estrogens during the preovulatory surge of LH.

VIII. SUMMARY

Follicle-stimulating hormone is produced in pituitary gonadotropes and acts on Sertoli and granulosa cells to ensure maturation of sperm and eggs in males and females, respectively. It can be used to hyperstimulate ovarian function to produce follicles in women who have trouble ovulating naturally for a number of reasons. Whereas FSH is absolutely required for egg production, sperm production occurs without FSH, but is stimulated significantly by it. Regulation of FSH is controlled by hypothalamic GnRH, TGF-β family members made in the pituitary and gonads, and gonadal steroids such as estrogens and progestins.

Glossary

corpus luteum The progesterone-producing tissue in the ovary that is formed from dominant follicles under the influence of luteinizing hormone.

follistatin A molecule that binds and inactivates β/β transforming growth factor-β family members, thereby indirectly inhibiting follicle-stimulating hormone transcription.

gonadotropes Pituitary cells that make and secrete gonadotropins (follicle-stimulating hormone and luteinizing hormone).

gonadotropin-releasing hormone A hypothalamic decapeptide released in a pulsatile way that stimulates gonadotropes to produce and/or secrete follicle-stimulating hormone and luteinizing hormone.

gonadotropins Follicle-stimulating hormone and luteinizing hormone, which are made in the pituitary; they regulate the gonads (ovary and testis) in mammals.

granulosa cells Located in the ovarian follicle, these are the only female cells that respond to follicle-stimulating hormone. They nurture the developing oocyte and produce estrogens in the ovarian follicle.

Sertoli cells The only male cells that respond to follicle-stimulating hormone (FSH). They respond to FSH by dividing (early in life) and by supporting spermatogenesis in the adult.

transforming growth factor-β (TGF-β) family members β/β-type members are released from the pituitary and induce FSH; inhibitory TGF-β members (α/β type) are released by the gonads.

Folliculogenesis

JOCK K. FINDLAY
Prince Henry's Institute of Medical Research, Australia

The functions of the ovary are the production of fertilizable oocytes and hormones in a timely manner. To achieve this requires a complex interplay between the growth and development of the ovarian follicles that house the oocytes and the extra- and intraovarian hormones and growth factors that regulate these processes. This article gives a description of ovarian folliculogenesis and provides an overview of the hormonal regulation of folliculogenesis in the ovarian cycle.

I. FOLLICULOGENESIS

The adult ovary is a multifunctional, dynamic organ with compartments that vary according to its physiological status. Folliculogenesis is the process describing the growth and development or atresia of follicles, through a series of morphological and functional stages from primordial to ovulatory. Follicles in this growth trajectory can be divided into two morphological categories based on the presence or absence of a fluid-filled cavity, or antrum, in the granulosa compartment. Preantral follicles are primordial, primary, or secondary, whereas antral follicles are either tertiary or ovulatory (also called Graafian follicles). Primordial follicles can be defined as nongrowing, with all other types being committed to growth, differentiation, and ovulation or to atresia.

Primordial follicles consist of a primary oocyte arrested in meiotic prophase surrounded by a single layer of squamous pregranulosa cells and with no basal lamina or zona pellucida. These follicles can remain in this state for long periods, up to 40 years in women, and are found principally in the stromal cortex. Although said to be "quiescent", the primordial follicles are metabolically active. Some begin a very slow transformation into an intermediate stage before becoming primary follicles. These intermediate follicles contain a mixture of squamous and cuboidal granulosa cells but exhibit no change in oocyte or follicle size. In small primary follicles, the oocytes are surrounded by a single layer of cuboidal granulosa cells confined by an outer basal lamina and separated from the oocyte by the zona pellucida. The zona layer is traversed by cytoplasmic processes of the granulosa cells that form gap junctions with the oocyte. Growth in these primary follicles is recognized by an increase in oocyte diameter and an increase in granulosa cell number. Oocyte growth is not accompanied by the resumption of meiosis, which occurs after the preovulatory surge of gonadotropins.

Secondary follicles are larger than primary follicles and consist of the primary oocyte with its zona pellucida surrounded by several layers of granulosa cells, a basal lamina, and a theca layer that forms when there are two or three granulosa cell layers. The thecal cells are recruited from interstitial stromal cells. There is a marked rise in the mitotic rate of the somatic cells and formation of the blood and lymph networks in the theca layer. The granulosa/oocyte compartment of the follicle within the basal laminar remains avascular up to the time of ovulation and relies on gap junctions between these cells to form a syncytium to transport nutrients, intercellular regulators, and metabolic waste.

The appearance of the antrum heralds the formation of the tertiary follicle. The oocyte is surrounded by cumulus cells derived from the granulosa cells. Although the mitotic rate of the granulosa and theca cells begins to decline in tertiary follicles, follicles continue to increase in size because of an increase in antral fluid volume. Functional changes in the granulosa layer finally transform the follicle to be capable of releasing an oocyte at ovulation and luteinization of the somatic cells in response to the preovulatory surge of gonadotropin.

II. HORMONAL CONTROL OF FOLLICULOGENESIS

Primordial follicles leave the pool committed irreversibly to growth or atresia. The number making this commitment each day depends on the species and age and is small (up to 10 or 20) compared with the total number available. The mechanism by which a particular follicle is recruited for growth is not known, but no two recruited follicles will be functionally identical once they are in the growth trajectory. The commitment to leave the primordial pool is independent of the cyclic changes in the pituitary hormones, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and prolactin. This leads to the conclusion that local mechanisms may be involved. The location of the primordial follicle within the ovary,

or intrafollicular factors, perhaps originating from the oocyte, may be determining factors. Alternatively, the trigger may involve release from inhibition by some mechanism that is not yet understood. FSH may have an indirect influence through its action on larger follicles to produce paracrine factors that can modify the recruitment of primordial follicles.

Committed preantral primary and secondary follicles enter a slow tonic growth phase that is independent of gonadotropins but facilitated by them. In primary follicles, granulosa cell proliferation and atresia rates are low and are independent of the cyclic changes in pituitary hormones. Atresia is characterized by degeneration of the oocyte. The granulosa cells express FSH receptors, which facilitate proliferation through the action of FSH on cyclin D2, an essential component of the cell cycle machinery. They do not express the LH receptor (LHR), do express low levels of aromatase, and make very little estrogen. This phenotype of the granulosa cell is most likely regulated by the inhibitory actions of growth and differentiation factor 9 (GDF9) and/or bone morphogenic factor-15 (BMP-15) from the oocyte. In turn, GDF9 and/or BMP-15 production by the oocyte may be maintained in a positive feedback loop by kit ligand from the undifferentiated granulosa cells. The granulosa cells also express high levels of androgen receptor (AR) and increasing levels of estrogen receptor (ER), particularly ER-β. Theca cells form at this time and become LH responsive through the acquisition of LHR, a process that is influenced by the oocyte, most likely via GDF9. The thecal production of androgen is driven by LH, facilitated by insulin-like growth factor-I (IGF-I) and inhibin, and inhibited by activin, all granulosa cell paracrine regulators. Thecal androgen production, coupled with the low levels of aromatase in the granulosa cells, results in a high androgen to estrogen ratio in these follicles. Androgen action via the AR on granulosa cells facilitates their slow proliferation and eventually FSH-induced differentiation in late preantral follicles.

As the preantral follicles expand through the proliferation of granulosa cells, it is hypothesized that there is a gradient of influence of the oocyte on the granulosa cells by paracrine factors such as GDF9 and BMP-15. As a result, the more distal, mural granulosa cells of secondary follicles are under less influence from the oocyte and become more differentiated by acquiring more ER and IGF-I receptors. They also respond to FSH by increasing aromatase activity, thus increasing their capacity to produce 17β-estradiol (E2) from thecal androgen. This marks the shift from FSH independence to FSH dependence and coincides with the appearance of the antrum and the transformation to tertiary follicles. These follicles now require FSH to maintain their growth and viability or they succumb to atresia. The balance between growth and atresia is at the mercy of cyclical fluctuations in FSH and LH in the blood. There is also differentiation of the granulosa population into three layers related to the proximity to the oocyte. The layer closest to the oocyte comprises the cumulus cells, which remain under the influence of the oocyte until the time of ovulation, and has a phenotype distinct from the antral and mural layers. The mural layer closest to the basement membrane has the highest levels of expression of steroidogenic enzymes and gonadotropin receptors.

The follicle(s) selected for ovulation comes from these early antral, FSH-dependent tertiary follicles. Selection or cyclic recruitment is accomplished through a timely rise in the circulating levels of FSH such as occurs at menstruation in women or after exogenous gonadotropin treatment. This results in an increase in the mitotic index of the granulosa cells and increased capacity of the follicle to synthesize E2 due to an increase in the FSH-dependent aromatase activity. There is also an enhanced supply of androgen substrate as theca cells respond with increased sensitivity to LH. The androgen to estrogen ratio is now in favor of E2. Inhibin B production by the granulosa cells also increases in response to the rise in FSH. Inhibin B and E2 suppress the circulating levels of FSH below the threshold necessary to maintain viability of the remaining antral follicles, thereby establishing dominance. The dominance established over the other nonselected follicles persists until after ovulation when the corpus luteum is formed. Dominance is maintained by the selected follicle in the face of falling levels of FSH, through three mechanisms. The first is due to the actions of paracrine and autocrine regulators in the dominant follicle such as IGF-I, activin, transforming growth factor-β, and E2, which sensitize the follicular cells to the gonadotropins. The second mechanism is the acquisition of LHR on the granulosa cells so that they are driven by the increasing frequency of LH pulses as ovulation approaches, rather than depending on the falling levels of FSH. The third is the suppression of FSH levels by E2 and inhibin B, and subsequently by inhibin A, produced by the dominant follicle.

A short-loop positive feedback system operating within the dominant or Graafian follicle drives E2 production to a level sufficient to trigger the preovulatory gonadotropin surge by the pituitary

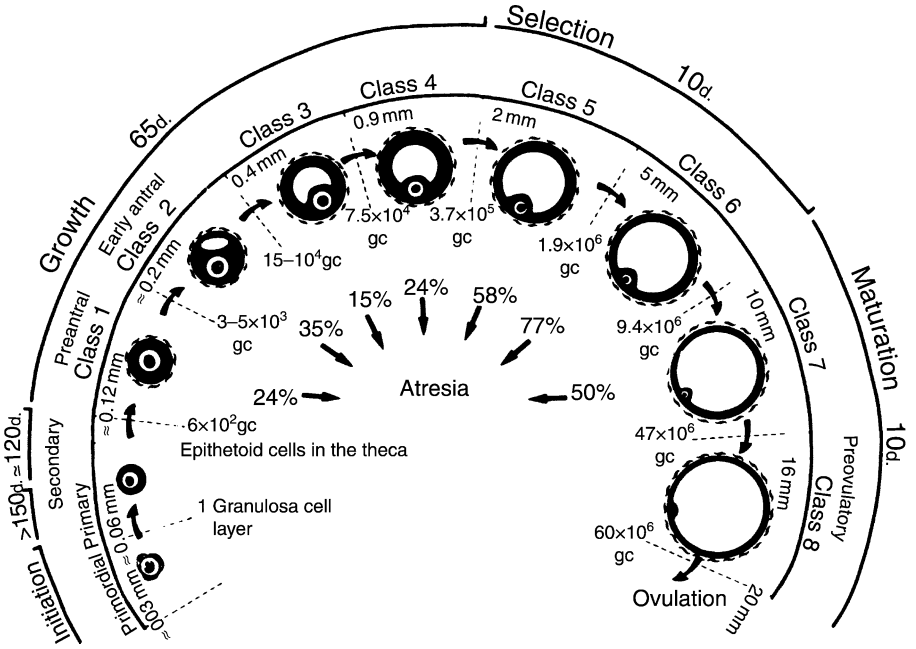

FIGURE 1 Classification of follicles in the human ovary. Reprinted from Gougeon, A. (1986). Dynamics of follicular growth in the human: A model from preliminary results. *Hum. Reprod.* **1**, 1–87, by permission of Oxford University Press.

gland and ovulation ensues. The LH surge triggers the resumption of meiosis of the oocyte, the expansion of the cumulus cells, and the cascade of inflammatory-like processes in the follicle wall to allow release of the oocyte–cumulus complex. It also triggers the onset of luteinization of the granulosa and theca cells and the formation of the corpus luteum.

Less than 1% of follicles that leave the primordial pool ever ovulate and it takes them 320 days to reach that point in the human ovary (Fig. 1). It is only during the last 15 days that the dominant follicle is gonadotropin-dependent. Intrafollicular regulators from the oocyte and somatic cells play a very important local role throughout folliculogenesis.

Glossary

antral follicles Are either tertiary or ovulatory, also called Graafian follicles, and are characterized by the presence of a fluid-filled antrum in the granulosa layer.

atresia The process whereby oocytes are lost from the ovary other than by ovulation.

cumulus cells The layer of granulosa cells surrounding the oocyte that make up the cumulus oophorus.

dominance The status of the follicle destined to ovulate, which has a regulatory influence over other antral follicles.

follicle Consists of a germ cell or oocyte surrounded by somatic cells and is the fundamental reproductive element of the ovary.

folliculogenesis The growth and development or atresia of follicles, through a series of morphological and functional stages from primordial to ovulatory.

gonadotropins The glycoprotein hormones follicle-stimulating hormone and luteinizing hormone, which are secreted by the pituitary gland and which stimulate ovarian cells.

granulosa cells Hormone-producing somatic cells that surround the oocyte and become differentiated into cumulus cells, which are closest to the oocyte, and antral and mural cells.

local regulation Autocrine, paracrine, or juxtacrine regulation of cells by growth factors or cytokines made locally within a tissue.

preantral follicles Are primordial, primary, or secondary, depending on the size of the oocyte, the number and type of granulosa cells, and the presence of theca cells.

primary oocyte An oocyte in the process of undergoing the first meiotic division, arrested in meiotic prophase.

recruitment The process whereby a primordial follicle leaves the resting pool and becomes committed to

growth, development, and ovulation or instead undergoes atresia.

selection The process whereby an antral follicle(s) is saved from atresia by a rise in follicle-stimulating hormone and develops as the dominant follicle.

steroidogenic enzymes A family of enzymes, many of which belong to the P450 gene family, that catalyze the synthesis and metabolism of the sex steroid hormones, estrogens, androgens, and progestogens.

theca cells Hormone-producing somatic cells differentiated into a vascularized interna and externa layer, recruited from the stroma to lie around the basal lamina outside the granulosa layer.

zona pellucida A layer of highly glycosylated proteins regulated by the oocyte Fig α gene; it forms the unique surface coat of the oocyte and is traversed by extensions of cumulus cells that form gap junctions with the oocyte.

Folliculogenesis, Early

URSULA A. VITT AND AARON J. W. HSUEH
Stanford University School of Medicine

Early folliculogenesis is the process by which ovarian follicles grow and develop from the primordial stage to the point at which the antral cavity is formed. This development is controlled by a number of paracrine factors that are derived from all three compartments of the follicle—the oocyte, granulosa cells, and theca cells.

I. INTRODUCTION

The development of the mammalian ovary is characterized by the division and differentiation of primordial germ cells into oogonia and the subsequent endowment of a fixed number of primordial follicles. This pool of primordial follicles is gradually depleted during reproductive life. The follicles develop through primordial, primary, and preantral stages before acquiring an antral cavity (see Fig. 1). Some primordial follicles begin to grow as soon as they are formed but most enter a state of suspended animation. Primordial follicles are characterized by the centrally located oocyte surrounded only by a thin layer of flattened granulosa cells. The primary follicle has cuboidal-shaped granulosa cells that proliferate during the formation of preantral follicles concomitant with an increase in oocyte size. Once follicles reach the small antral stage, most of them undergo atresia unless rescued by follicle-stimulating hormone (FSH). Under the influence of gonadotropins, the antrum is formed and the selected antral follicles further increase in size until they reach the preovulatory stage. Early folliculogenesis denotes the development of follicles up to the time of antral formation and has to date been believed to be largely independent of the influence of endocrine hormones and regulated mainly by paracrine factors. All three compartments of ovarian follicles (oocyte, granulosa cells, and theca cells) have been shown to produce paracrine hormones determining the development of the other cellular compartments. This article examines the role of paracrine factors expressed during early follicle stages whose function is at least partially understood. A summary of these factors and the follicle stages affected is given in Table 1.

II. PRIMORDIAL FOLLICLE DEVELOPMENT

A. Formation and Maintenance of the Primordial Follicle Pool

The processes that lead to the initial endowment of a fixed number of primordial follicles at the onset of

growth, development, and ovulation or instead undergoes atresia.

selection The process whereby an antral follicle(s) is saved from atresia by a rise in follicle-stimulating hormone and develops as the dominant follicle.

steroidogenic enzymes A family of enzymes, many of which belong to the P450 gene family, that catalyze the synthesis and metabolism of the sex steroid hormones, estrogens, androgens, and progestogens.

theca cells Hormone-producing somatic cells differentiated into a vascularized interna and externa layer, recruited from the stroma to lie around the basal lamina outside the granulosa layer.

zona pellucida A layer of highly glycosylated proteins regulated by the oocyte Fig α gene; it forms the unique surface coat of the oocyte and is traversed by extensions of cumulus cells that form gap junctions with the oocyte.

Folliculogenesis, Early

URSULA A. VITT AND AARON J. W. HSUEH
Stanford University School of Medicine

Early folliculogenesis is the process by which ovarian follicles grow and develop from the primordial stage to the point at which the antral cavity is formed. This development is controlled by a number of paracrine factors that are derived from all three compartments of the follicle—the oocyte, granulosa cells, and theca cells.

I. INTRODUCTION

The development of the mammalian ovary is characterized by the division and differentiation of primordial germ cells into oogonia and the subsequent endowment of a fixed number of primordial follicles. This pool of primordial follicles is gradually depleted during reproductive life. The follicles develop through primordial, primary, and preantral stages before acquiring an antral cavity (see Fig. 1). Some primordial follicles begin to grow as soon as they are formed but most enter a state of suspended animation. Primordial follicles are characterized by the centrally located oocyte surrounded only by a thin layer of flattened granulosa cells. The primary follicle has cuboidal-shaped granulosa cells that proliferate during the formation of preantral follicles concomitant with an increase in oocyte size. Once follicles reach the small antral stage, most of them undergo atresia unless rescued by follicle-stimulating hormone (FSH). Under the influence of gonadotropins, the antrum is formed and the selected antral follicles further increase in size until they reach the preovulatory stage. Early folliculogenesis denotes the development of follicles up to the time of antral formation and has to date been believed to be largely independent of the influence of endocrine hormones and regulated mainly by paracrine factors. All three compartments of ovarian follicles (oocyte, granulosa cells, and theca cells) have been shown to produce paracrine hormones determining the development of the other cellular compartments. This article examines the role of paracrine factors expressed during early follicle stages whose function is at least partially understood. A summary of these factors and the follicle stages affected is given in Table 1.

II. PRIMORDIAL FOLLICLE DEVELOPMENT

A. Formation and Maintenance of the Primordial Follicle Pool

The processes that lead to the initial endowment of a fixed number of primordial follicles at the onset of

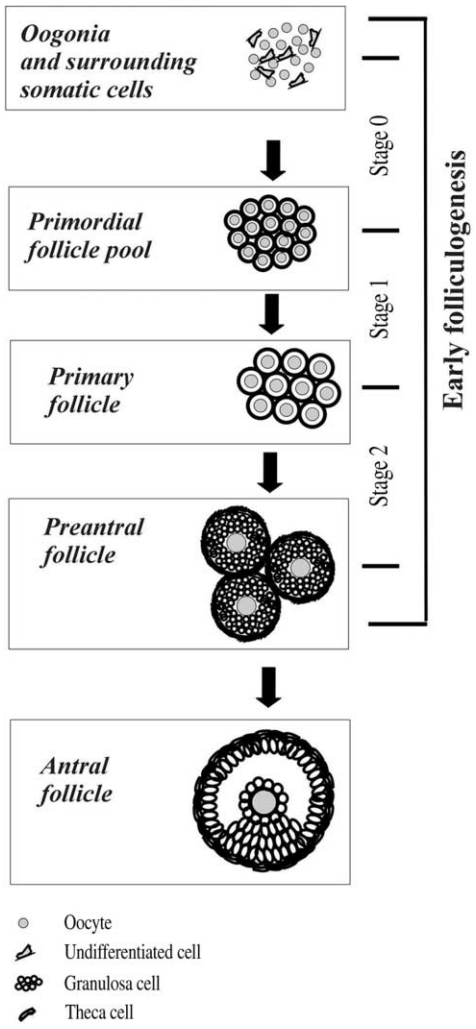

FIGURE 1 Folliculogenesis starts with the endowment of primordial follicles by the association of oocytes with surrounding somatic cells. The formed primordial follicles grow and develop through primary and preantral stages characterized by granulosa cell and theca cell proliferation concomitant with oocyte growth.

folliculogenesis are poorly understood. Of several paracrine factors that have been found to be expressed during follicular endowment, only nerve growth factor (NGF) has been shown to be essential for the incorporation of oocytes into follicular structures. This is revealed in the phenotypes of NGF null mice, which have a small number of follicles due to a reduction of somatic cell proliferation associated with follicle formation. NGF is secreted by the oocyte and thus represents a control of somatic cell proliferation by the germ cell before the formation of the primordial follicle.

In addition to NGF, other paracrine factors that have been found to be expressed during follicle endowment include Kit ligand (KL) and transforming growth factor-β (TGF-β). KL (also known as stem cell factor) is expressed during follicle endowment and is believed to play a key role in the maintenance of the primordial follicle pool. KL is expressed in a soluble form and a membrane-bound form by somatic cells and signals through the c-kit receptor, a proto-oncogene expressed primarily by the oocyte. Even though KL has been shown to be essential for primordial germ cell migration in some mice with KL mutations, it is not an essential factor for primordial follicle endowment as follicle development can progress up to primary stages in mice lacking KL. The role of TGF-β in primordial follicle formation is unknown as TGF-β1 null mice are embryonic lethal.

TABLE 1 Factors Involved in Early Folliculogenesis

		Stage[b]		
Ligand	**Expression cell type[a]**	**0**	**1**	**2**

[b]Stage 0, primordial follicle; Stage 1, primary follicle; Stage 2, preantral follicle.
[c]Expressed and function studied.
[d]Expressed but function unclear.

Its function in later follicular stages is the enhancement of mitogenic effects induced by other factors such as FSH, which stands in contrast to the anti-mitogenic effects of TGF-β in other cell types.

Once the primordial follicle pool is established, a gradual depletion of this pool occurs throughout life. Several factors have been described to control, directly or indirectly, this depletion. In addition to the protective action of KL, both leukemia inhibitory factor (LIF) and insulin-like growth factor-I (IGF-I) have additive effects on the preservation of primordial follicles via inhibition of oocyte apoptosis. LIF is a pleiotropic cytokine of the interleukin-6 family and was named for its ability to inhibit the proliferation of a myeloid leukemic cell line. To date, its function in the primordial follicle other than inhibition of apoptosis is unknown but it represents, like KL, a germ cell protection signal derived from somatic cells. Similarly, the protective effect of granulosa cell-derived IGF-I is transmitted to IGF-I receptors on the oocyte.

Another factor involved in the maintenance of primordial follicles is anti-Müllerian hormone (AMH). The specific cellular function of AMH in primordial follicles is unknown but the phenotype of AMH null mice shows an increase in primordial follicle recruitment leading to early depletion of the primordial follicle pool. As both the AMH ligand and its receptor are expressed in somatic cells, it represents an autocrine as well as a paracrine control mechanism of primordial follicle preservation. Furthermore, factors such as parathyroid hormone-related hormone (PTHRP) are present in both oocytes and granulosa cells of primordial follicles and are known to have an anti-proliferative effect but neither their specific function in primordial folliculogenesis nor their mutant phenotypes are known.

B. Initiation of Primordial Follicle Growth

To date, the mechanisms leading to the initiation of primordial follicle growth are unknown. Some authors believe that some primordial follicles start to grow as soon as they are formed and that a constant feedback loop between growing follicles and nongrowing follicles determines the number of follicles starting to grow at any given point in time. One of the main changes occurring during the transition from the primordial to the primary follicle stage is the formation of an outer layer of theca cells. Thus, the association of the germ cell with epithelial granulosa cells in the primordial follicle is followed by the interaction of the follicular structure with the surrounding mesenchyme. Paracrine factors such as activin A, which interacts with extracellular matrix proteins, could play a key role in this interaction and have a stimulatory effect on the initiation of follicle growth. In addition, theca cell differentiation has been shown to be controlled by KL, which promotes primordial follicular growth.

Furthermore, other factors such as growth differentiation factor 9 (GDF9) have been shown to lead to a decrease in the number of primordial follicles and a subsequent increase in the number of growing follicles, suggesting that they might play a role in the initiation of primordial follicle growth. In all studies completed thus far, however, the increase in follicle progression to preantral and larger follicles might lead to an enhancement of primordial follicle growth, and thus, these results may be secondary and not represent a direct action of a given factor on primordial follicle growth. This is especially true for GDF9 as its expression in primordial follicles is unknown. In contrast to stimulatory factors, changes in the secretion of growth-inhibiting factors could also affect the initiation of primordial follicle growth.

III. PRIMARY FOLLICLE GROWTH

After initiation of growth, primordial follicles progress to primary follicles with distinct layers of granulosa and theca cells closely associated with the centrally located oocyte. The growth of the primary follicle is characterized by the proliferation of both granulosa and theca cells, leading to the formation of the preantral follicle with several layers of both cell types. Several of the paracrine factors mentioned above that affect primordial follicle growth are also expressed during this stage and could control primary follicle growth.

GDF9 plays a key role in the control of primary follicle growth as reflected by the infertile phenotype of GDF9 null mice. Ovaries lacking GDF9 exhibit a complete block in follicle development at the primary stage. Thus, the oocyte largely controls primary follicle growth via secretion of GDF9, which has been shown to be a potent mitogenic agent of granulosa cells. In addition to GDF9, GDF9B, its closest paralogue, is co-expressed with GDF9 by the oocyte. The phenotype of homozygous GDF9B mutant Inverdale sheep revealed striking similarities with GDF9 mutant mice. This observation and the fact that GDF9B stimulates granulosa cell proliferation *in vitro* indicate that GDF9B shares functional

similarities with GDF9 even though primary follicle growth is largely unaffected in GDF9B mutant mice. The species differences in GDF9B function are of interest as GDF9B could represent a potential factor leading to the vast differences in ovarian follicle development between different species.

At the primary follicle stage, KL also has essential effects on follicle growth. The naturally occurring Steel Panda mutant mice as well as KL null mutant mice display ovarian phenotypes similar to that of GDF9 null mice. At this stage of folliculogenesis, receptors for KL are present on the oocyte as well as on theca cells. Thus, primary follicle growth is controlled by oocyte-derived GDF9 as well as by granulosa cell-derived KL, which controls both oocyte and theca cell development.

Furthermore, TGF-β and IGF-I as well as their receptors are expressed in primary follicles. Their influence on primary follicle development is, however, not well studied. The same applies to angiogenin, a potent mediator of blood vessel formation, which is expressed in granulosa cells of primary follicles. Even though blood vessel formation in the ovary is an essential requirement for folliculogenesis, the specific roles of angiogenin in follicle growth are unclear.

IV. PREANTRAL FOLLICLE GROWTH

As more layers of somatic cells surround the oocyte, mainly as the result of granulosa cell proliferation, the preantral follicle is formed. Most of the paracrine factors involved in primordial and primary growth continue to be secreted and could influence preantral follicle development. In addition, a large number of other paracrine factors were found to be expressed during preantral follicle development. This increased number of secreted factors could be due to the fact that preantral follicle stages are easier to retrieve and a much larger number of studies were performed using preantral and larger follicles than were performed using follicles from earlier stages.

The first step of preantral follicle development includes mainly granulosa cell proliferation promoted by mitogenic agents. Again, GDF9 and KL have been shown to promote follicle growth at this stage. Another mitogenic agent, epidermal growth factor (EGF), which is also expressed in primary follicles, stimulates preantral follicle growth. GDF9 enhances the number of growing preantral follicles, probably due to its proliferative action. In contrast, KL and EGF contribute to the growth of the preantral follicle via suppression of apoptosis. Furthermore, KL induces theca cell proliferation and secretion of hepatocyte growth factor (HGF). The latter, via stimulation of KL expression, leads to a positive feedback loop that promotes the growth of both granulosa cells and theca cells. Thus, in addition to the ongoing paracrine communication between granulosa cells and the oocyte, another level of communication is introduced by further growth and development of theca cells. *In vitro* studies suggest that the two somatic cell types modulate each other by affecting proliferation, differentiation, and responsiveness to gonadotropins in a reciprocal manner. The example of KL and HGF mentioned above is only one of these paracrine interactions. Another very well-studied interaction is the theca cell-derived secretion of androgens, which promote granulosa cell responsiveness to FSH and serve as substrates for the estrogen-producing granulosa cells.

In addition to several paracrine factors present in the preantral follicle, inhibins, activins, estradiol, and progesterone represent the most important hormones secreted by the ovary and are responsible for both endocrine feedback regulation of the anterior pituitary and paracrine regulation of local ovarian functions. FSH stimulates inhibin secretion by granulosa cells, and inhibins, in turn, suppress FSH secretion by the pituitary, thus forming a negative feedback loop. Furthermore, inhibin null mice display sex cord stromal tumors, showing that inhibins function as tumor suppressors. In contrast, activins stimulate the release of FSH from the pituitary. In addition, activins are the first paracrine factors secreted by preantral follicles that have been reported to suppress primary follicle growth.

Ovarian estrogens suppress pituitary gonadotropin secretion. In addition to endocrine effects, estrogens are autocrine factors because estrogen receptors are localized in granulosa cells and treatment with estrogens has been shown to promote follicle growth and granulosa cell differentiation.

In addition to ovarian secretion of endocrine hormones, pituitary control of preantral follicle development is established by the synergistic effects of FSH and luteinizing hormone (LH) on preantral follicle growth. Although the best known effect of FSH is its stimulation of estradiol production by granulosa cells, the main function of FSH in the preantral follicle is to drive the formation of the antrum. The growth-promoting effect of FSH is probably due to its differentiative action and subsequent follicle antrum formation. Concomitant with the formation of the antral cavity and thus termination of preantral follicle growth is the differentiation

of two subsets of granulosa cells. The mural granulosa cells have a higher level of LH receptor expression and a greater steroidogenic capacity than the cumulus granulosa cells located adjacent to the oocyte. GDF9, secreted by the oocyte, is known to inhibit FSH-induced differentiation. A gradient of oocyte-derived GDF9 in combination with FSH has been reported to support the formation of these two subsets of granulosa cells.

Several paracrine factors secreted by granulosa cells in the follicle modulate the effects of FSH. Both IGFs and fibroblast growth factors are believed to modulate FSH-induced steroidogenesis. Many more factors have been described to be present in the preantral follicle, such as propioomelanocortin and granulocyte/macrophage colony-stimulating factor. However, their specific functions in preantral follicle development are not well studied.

V. SUMMARY

The early development of the ovarian follicle is controlled by a variety of paracrine factors that are derived from all three compartments of the follicle. The secretion of growth-promoting and unidentified inhibiting factors by the oocyte is essential for the onset of follicle growth and different stages of follicle development. However, the oocyte itself is again influenced by paracrine factors secreted by surrounding granulosa cells. The granulosa cells communicate with feedback loops with the outer theca cells and both cell types are controlled by pituitary-derived hormones. During the early stages of ovarian development, folliculogenesis can commence without pituitary control. At later stages, granulosa cells and the anterior pituitary communicate via different hormonal feedback loops to ensure successful follicle development.

Glossary

antrum Extracellular matrix-containing cavity that divides the oocyte from granulosa cells in the antral follicle.
apoptosis Programmed cell death.
atresia Follicle degeneration.
endowment The first step of follicle formation in which the oocyte is associated with surrounding somatic cells to form a primordial follicle.
folliculogenesis The process by which follicles grow and mature from primordial to preovulatory stages.
preantral follicle Oocyte surrounded by several layers of granulosa and theca cells. Includes all growing follicle stages after the primary follicle stage up to the formation of the antrum.
primary follicle Oocyte surrounded by one clearly visible cuboidal-shaped layer of granulosa cells and a thin layer of theca cells.
primordial follicle First stage of follicle development, consisting of the oocyte surrounded by a thin layer of granulosa cells.
steroidogenesis The production and secretion of steroids (in the ovary, mainly progesterone, androstenedione, and estradiol) by differentiated somatic cells.

Follitropin (Follicle-Stimulating Hormone) Receptor Signaling

JAMES A. DIAS

New York State Department of Health and State University of New York

Gonadotrope cells of the anterior pituitary produce follicle-stimulating hormone (follitropin) in response to tropic signals from the hypothalamus and the gonads. Follitropin is a glycoprotein hormone. All of the glycoprotein hormones have an α-subunit that is identical in primary sequence but that may vary in the extent of glycosylation. The specificity of binding is conveyed by the β-subunit, which is unique for each hormone.

I. INTRODUCTION

Secretion of follitropin into the blood is under control of the hypothalamus. Hypothalamic neurons release gonadotropin-releasing hormone into the portal system, and—despite its small size (decapeptide) and rapid clearance kinetics—the releasing hormone reaches high concentrations in the pituitary portal system due to a retrograde blood flow. Gonadal (testicular or ovarian) steroids also regulate the expression of gonadotropin genes in gonadotropes. Estrogens can up-regulate secretion and testosterone and progesterone can decrease expression. Inhibins and activins, nonsteroidal hormones produced by the gonads, also control follitropin secretion. Inhibin and activin can suppress or increase, respectively, gonadotropin secretion.

When follitropin is secreted into the blood from anterior pituitary gonadotropes, it binds to and activates follitropin receptors in the Sertoli cells of the testis or the granulosa cells of the ovary. In females, development of ovarian follicles and production of mature viable oocytes are thus under control of follitropin. In the absence of follitropin signaling, ovarian follicular development is arrested at a stage prior to antrum formation. In males, follitropin is essential for maintaining the production of many high-quality gametes. The following discussions describe the molecular mechanisms underlying formation of the follitropin–follitropin receptor complex, as well as how binding leads to the activation process and how the activation process is regulated.

II. FOLLITROPIN

The pituitary glycoprotein hormone follitropin consists of two subunits, an α-subunit of 92 amino acids and a β-subunit of 114 amino acids (see Fig. 1). Each subunit is a product of a different gene from different chromosomes. There are four glycoprotein hormones, and each of the four β-subunits of these glycoprotein hormones is from a unique gene. Thus, there are four β-subunit genes, but there is only one α-subunit gene. Following synthesis on the ribosome and translocation into the endoplasmic reticulum, each subunit folds into domains (see schematic in Fig. 1). The α-subunit folds much more rapidly than the β-subunit and may serve as a scaffold on which the β-subunit is assembled. Each subunit has the same tertiary conformation, although the subunits differ in primary sequence. This conformation, or protein fold, is characteristic of a family of proteins called cystine knot proteins. Cystine knot proteins have many different functions despite a similar pattern of folding. One additional difference between cystine knot proteins is that some are heterodimeric, like follitropin, and others are homodimeric. In order for follitropin to have activity, it must form the heterodimer. In the endoplasmic reticulum, disulfide bonds of the cystine knot are formed within the α- and β-subunits and then follitropin is assembled by a combination of the two subunits (Fig. 1).

Depending on the species, each follitropin subunit has one or two sites that allow a process of carbohydrate attachment (glycosylation) that is linked to asparagine residues (Fig. 1, panel AB2). The signal for asparagine-linked glycosylation in proteins can be predicted if the primary sequence contains the motif Asn-X-Ser/Thr, where X can be any amino acid. Folding, assembly, secretion, and circulatory half-life of follitropin are affected by glycosylation of the subunits. In the blood, many glycosylation variants of follitropin exist, all having the same primary sequence but with different degrees of carbohydrate complexity. The physiological and analytical significance of this heterogeneity

is considerable. Assembly of the subunits into a heterodimeric protein in the endoplasmic reticulumx is necessary for proper glycosylation and full activity.

The biological activity of any hormone is usually measured in a bioassay. Historically, bioassays were carried out by measuring effects of hormone treatments in animals (*in vivo*). Now, bioassays are commonly carried out in the laboratory using isolated cells or cellular components (*in vitro*). However, because of considerations of metabolic clearance, final activity of any hormone must still be measured *in vivo*. The activity of follitropin is measured by its ability to bind to the follitropin receptor and to induce signal transduction *in vitro*, and by its ability to stimulate ovarian weight gain *in vivo*. Follitropin levels are measured in blood using sensitive immunoassays. Generally, the quality of an immunoassay is measured by the ratio of bioassay activity and immunoactivity (B/I ratio; optimum ratio = 1.0). Because follitropin is glycosylated and has many glycosylation variants (glycoforms) in blood, the B/I ratios of follitropin change with various physiological states, thus making its measurement problematic.

Incomplete glycosylation of follitropin can lead to altered clearance kinetics. It has been noted that desialylated follitropin is cleared more rapidly from the blood than is native follitropin. Because the glycoform profile can change in blood depending on physiological state as well as during pharmacological intervention, it has been of interest to determine what role carbohydrate plays in follitropin function, beyond prolonging clearance. In this regard, it has been noted that removal of carbohydrate from follitropin α-subunit site N76 has dramatic effects on the thermal stability of the hormone, which could affect its storage properties. Importantly, removal of carbohydrate from site N52 results in increased affinity of binding to receptor with a concomitant decrease in signal transduction. The etiology of these effects likely rests in the stabilizing effect that carbohydrate has on protein.

Because only heterodimeric follitropin is active in the body, it has been recognized for some time that both subunits must participate in formation of the active complex with the follitropin receptor. Notably, two residues, which are conserved in follitropin from humans to fish, have been found to be essential for follitropin binding to its receptor. These are Asp-93 on the β-subunit and Lys-52 on the α-subunit. The crystal structure of human follitropin shows that a distance of about 6 Å separates the side chains of these two residues. In addition, several residues in the carboxyl-terminal tail of the α-subunit, juxtaposed with these two essential residues, are also critical for high-affinity binding. Thus, the most critical residues, which are essential for follitropin binding to its receptor, are brought together not only by protein folding but also by the assembly of the two subunits. However, until the crystal structure of the follitropin–follitropin receptor complex is determined, it cannot be predicted how many other residues contribute in important, yet not critical, ways to formation of the stable complex.

In summary, follitropin is modular, with each subunit folding into higher order domains to form a tertiary structure, and finally associating, one α-subunit and one β-subunit, to form an active principal. The most critical residues for binding to receptor are brought together in three-dimensional space as a result of the association of the two subunits. The formation of this glycosylated, active complex, which contains 206 amino acids and four glycosylation sites and has a molecular mass in excess of 35,000 Da, and its secretion into the blood are the first steps in follitropin action. Contact with the follitropin receptor is the next step.

III. FOLLITROPIN RECEPTOR

Follitropin receptor is a single-subunit protein of 678 amino acids. Unlike follitropin, which is composed of two subunits, the follitropin receptor is a single polypeptide chain. However, the receptor can be

FIGURE 1 Biosynthesis of follitropin. The primary structure of human follitropin (follicle-stimulating hormone) subunits, α-FSH (A1) and β-FSH (B1), predisposes a set of secondary structure elements, β-sheets (indicated by arrows). Following synthesis and transfer across the endoplasmic reticulum, each subunit folds into a tertiary structure and disulfide bonds form (indicated by ball-and-stick models in A2 and B2). Assembly is required to form the active heterodimeric protein (AB1; for clarity, the β-subunit is darker). During assembly, FSH is glycosylated [AB2; carbohydrate shown in the space-filling model in Corey–Pauling–Kultun (CPK) colors], thereby prolonging its half-life in blood (for an explanation of CPK colors, see, e.g., http://beta.rcsb.org/pdb/pe/shared/cpk-rgb.htm). All structural models prepared using Web Lab Viewer Pro, M.S.I., Inc.

thought of as a modular protein with several domains. For example, it contains a large extracellular domain that is necessary and sufficient to bind heterodimeric follitropin. The extracellular domain is 345 amino acids, roughly 1.5 times the size of follitropin heterodimer. The extracellular domain is also glycosylated. A second module of the receptor, the transmembrane domain, is composed of 273 amino acids. This part of the receptor is predicted to traverse the membrane seven times, giving rise to a heptahelical module that is the signal transducer of the receptor. An interesting aspect of this second module is that it forms three small extracellular loops that are 18, 20, and 11 amino acids long and three small intracellular loops that are 9, 20, and 24 amino acids long. These loops are likely to play important roles in the consummation of a signal transduction event following hormone binding. Finally, a third domain of the receptor is its cytoplasmic tail, which is composed of 65 amino acids. One can readily appreciate that each module of the receptor has complexity, and that the environment surrounding each module will play a key role in its functionality, especially with regard to signal transduction.

IV. FOLLITROPIN RECEPTOR SIGNALING

It is generally accepted that follitropin signals through the follitropin receptor via a guanosine nucleotide binding protein (G-protein)-coupled pathway. The G-proteins are heterotrimers that bind to the cytoplasmic domains of G-protein-coupled receptors. On activation, the G-proteins bind guanosine triphosphate (GTP), and then they dissociate into an α-subunit ($G_{s\alpha}$) and a stable heterodimeric $\beta\gamma$ subunit complex ($G_{\beta\gamma}$). The $G_{s\alpha}$ subunit binds to and activates adenylate cyclase. There are 12 different forms of G_{α}. Some are stimulatory ($G_{s\alpha}$), some are inhibitory ($G_{i\alpha}$), and others have specific ion-channel or enzymatic activation properties. The $G_{\beta\gamma}$ subunit binds to and activates phospholipase C, which in turn hydrolyzes phospholipids to inositol triphosphates and prostaglandin.

Follitropin activates the adenylate cyclase pathway indirectly by acting as a guanine nucleotide exchange factor. When follitropin binds to its receptor, a conformation of the receptor is stabilized, which predisposes the stimulatory subunit of heterotrimeric G-protein to release guanosine diphosphate (GDP) and to bind GTP. The binding of GTP to the G-protein α-subunit causes dissociation of the G-protein α-subunit from the G-protein $\beta\gamma$ -subunit complex. The G-protein α-subunit can now activate adenylate cyclase. Adenylate cyclase is thus activated by the G-protein α-subunit, which has guanosine triphosphate bound. The activation of adenylate cyclase leads to catalysis of adenosine triphosphate (ATP) to form cyclic adenosine monophosphate (cAMP).

An elevation of intracellular cAMP leads to activation of protein kinase A. This kinase thereby regulates the activity of its substrate proteins. Protein kinase A is activated by the binding of cAMP to its regulatory subunit. The activation of this kinase leads to pleiotropic effects. Most notably, the phosphorylation of cAMP response element binding proteins and their subsequent effects as transcriptional regulators have been extensively studied. More recently, it has been appreciated that cross talk between signaling pathways can occur with follitropin treatment. Thus, the mitogen-activated protein kinase pathway can be activated by protein kinase A, an indirect effect of follitropin stimulation.

Follitropin has also been shown to stimulate phosphorylation and activation of protein kinase B in granulosa cells. This kinase is involved in cell survival. Because follitropin plays a role in selection of follicles and prevention of atresia, this particular relationship is an attractive mechanism by which to explain how follitropin prevents apoptosis.

V. FOLLITROPIN SIGNAL ATTENUATION

Follitropin receptor signaling is attenuated in four ways. First, phosphorylation of the receptor appears to be associated with decreased sensitivity to agonist-mediated stimulation (desensitization). This mechanism is rapid (minutes) and does not require a change in concentration of receptor at the cell surface. Desensitization occurs by phosphorylation of the receptor on its intracellular loops.

On occupancy by follitropin, the follitropin receptor becomes susceptible to phosphorylation. Phosphorylation of the follitropin receptor occurs on the first and third intracellular loops of the receptor. A specific kinase that interacts with the follitropin receptor has not been identified. However, it is possible to phosphorylate the receptor by treatment of cells with nonspecific stimulator of protein kinase C. Protein kinase C can thereby regulate the activity of substrate proteins such as the follitropin receptor. These enzymes are activated and regulated by a variety of factors, including calcium, inositol triphosphates, ceramide, and phosphorylation and adapter proteins. Also, overexpression of G-protein receptor kinase in

cells can enhance phosphorylation of the follitropin receptor. An important distinction between these two kinases is that the G-protein receptor kinase can phosphorylate the receptor efficiently only if follitropin is bound. Thus, ligand-induced phosphorylation by the G-protein receptor kinase family is one mechanism for attenuation of follitropin signaling.

The second mechanism of follitropin receptor signal attenuation is via removal of occupied receptor from the cell surface, a process called down-regulation. The process of movement of receptor from the cell surface into clathrin-coated pits is referred to as internalization. Although receptor turnover occurs to some extent without ligand occupancy, ligand-induced internalization is faster. When follitropin binds the follitropin receptor and phosphorylation of the receptor occurs, the phosphorylated receptor is bound by β-arrestin. Binding of the receptor by β-arrestin greatly enhances the rate of internalization of the receptor via clathrin-coated pits. Mutation of phosphorylation sites in the first intracellular loop of the follitropin receptor results in a decrease in internalization, demonstrating that this loop in particular is important for internalization through an arrestin-mediated pathway.

Additional mechanisms lead to attenuation of follitropin-mediated signaling. A family of enzymes called phosphodiesterases accomplishes the conversion of cAMP to AMP. The catalysis of this second messenger provides a third level of control of the cellular response to follitropin by decreasing levels of this activator of protein kinase A. The actions of phosphodiesterases are neither spatially nor temporally restricted. Their broad role in all signaling pathways cannot be understated. However, one specific role related to follitropin receptor signaling is that of attenuating the follitropin-mediated signal. Likewise, it is important to remember that although follitropin has a spatial constraint, the second messenger cAMP has few boundaries. Its inactivation in particular cellular compartments must be appreciated to understand fully how follitropin signaling is not necessarily a linear phenomenon. Moreover, follitropin can regulate the expression levels of phosphodiesterase. Thus, prolonged exposure of Sertoli cells to follicle-stimulating hormone can lead to multilog increases of phosphodiesterase isoform four mRNA and log increases in activity. Surprisingly, when phosphodiesterase 4 knockout mice were examined, they exhibited decreased ovulation, suggesting that this isoenzyme may also play a role in preventing desensitization of the ovary to gonadotropin signaling. In fact, treatment of ovarian follicles with an inhibitor of this isoform causes ovulation, mimicking a gonadotropin (LH) effect, suggesting that inhibitors of phosphodiesterase might be used to treat gonadotropin resistance.

A recently discovered protein family functions as regulators of G-protein signaling (RGS). These proteins contain an RGS domain, which is necessary for negatively regulating G_α protein subunits. This diverse protein family provides a fourth mechanism of desensitization; RGS proteins terminate signaling of G-proteins that have already been activated. In this sense, they are not like kinases that inactivate receptors. They act to dampen a G-protein activity at the level of the activated G-protein by accelerating the hydrolysis of GTP. Although these proteins have not been directly studied in the follitropin receptor system, their ubiquitous nature assures that they will be found to play a key role in regulation of follitropin signaling.

VI. GENETIC ABNORMALITIES

It might be expected that mutations of the genes encoding either follitropin or the follitropin receptor will lead to disorders in reproduction. Indeed, several mutations identified in the follitropin β and follitropin receptor genes are associated with fertility disorders. Not surprisingly, mutations in follitropin genes that change codons for those cysteine residues necessary for disulfide bond formation (C51G, C82R), as well as premature stop codons, result in infertility. No mutations in the α-subunit have been reported in patients with infertility, probably because of the absolute requirement for the α-subunit for formation of the active thyrotropin heterodimer and for normal thyroid function.

Several mutations reported for the follitropin receptor do diminish follitropin-mediated signal transduction. When the codon for Ala-172 is mutated to the codon for valine, females present with ovarian dysgenesis and arrested follicular development. High follitropin levels in serum are indicative of a lack of ovarian feedback inhibition at the pituitary. Males are less affected, but they show decreased testicular volume. Arrested follicular development is noted when mutation occurs in the codons for Ile-143, Arg-556, Asp-207, and Leu-584.

Mutations in the extracellular domain of follitropin receptor (I143T, D207V, A172V, and N174I) cause a defect in signaling due to a dramatic decrease of receptors on the cell surface. The decrease in

receptors at the cell surface leads to a decrease in follitropin-mediated signal transduction and to lowered maximal levels of cAMP, as compared to wild-type receptor. Mutations that affect binding only slightly but that do affect signal transduction have been reported. These are at codons in the intracellular loop 3 (R556C) or in the sixth (L584V) or second (A402T) transmembrane domains. Only one activating mutation of follitropin receptor has been found, in the third intracellular loop (D550G). This is in direct contrast to the lutropin receptor, in which many inactivating and activating mutations have been discovered. The lack of activating mutations in the follitropin receptor has suggested to some that the conformational stability of the follitropin receptor differs from that of the lutropin receptor.

Glossary

adenylate cyclase Nucleotidase that converts adenosine triphosphate to cAMP.
desensitization Transient loss of cellular responsiveness to tropic hormone.
down-regulation Transient loss of cell surface receptors following exposure to tropic hormone.
glycoprotein hormones Family of heterodimeric (two dissimilar subunits) glycosylated proteins in vertebrates that includes thyrotropin, follitropin, lutropin, and choriogonadotropin.
G-protein Heterotrimeric (containing three dissimilar subunits) guanosine triphosphate hydrolase enzyme.
MAP kinase Family of mitogen-activated protein kinases that phosphorylate proteins on serine or threonine residues.
phosphodiesterases Cyclic nucleotidases that hydrolyze cAMP and cGMP.
protein kinase C Family of enzymes that phosphorylate serine or threonine residues in proteins.
protein kinase A Family of tetrameric (R_2C_2) enzymes that phosphorylate tyrosine residues in proteins.
RGS proteins Newly discovered family of proteins that are regulators of G-protein signaling.

Gastrin

JENS F. REHFELD
University of Copenhagen

This article describes the biology of gastrin, an important gastrointestinal hormone that regulates gastric acid secretion and mucosal growth in the stomach. After a historical introduction, the article focuses on the structure of gastrin peptides, structure–function relationships, gastrin biogenesis and expression, and cellular release. The biology of the gastrin receptor is also described. In addition, the article alludes to the phylogenesis, ontogenesis, and oncogenesis of gastrin peptides and concludes by discussing the perspectives of recent gastrin research.

I. HISTORICAL INTRODUCTION

Gastrin is the master hormone of the gastrointestinal tract, just as insulin is the master hormone of the pancreas. Gastrin was discovered in 1905 in the wake of Bayliss' and Starling's breakthrough discovery of secretin in 1902. It was John Edkins from London who found that the antral mucosa of the stomach released a gastric acid-stimulating factor into the blood. He named the factor gastrin, an abbreviation for "gastric secretin." Hence, secretin and gastrin were the first peptide hormones to be discovered.

In 1964, gastrin was purified and identified as a peptide of 17 amino acids (Fig. 1). The C-terminal sequence of gastrin-17 and that of another gastrointestinal hormone, cholecystokinin (CCK), were subsequently shown to be identical and to constitute the active site of both hormones. Thus, biologically active gastrin and CCK peptides have the same C-terminal pentapeptide sequence, and this sequence has been exceedingly well conserved throughout evolution over the past 500 million years. The homology of the active site, as well as other structural similarities, defines gastrin and CCK as members of the same hormone family.

During the past three decades, the concept of gastrin as a simple peptide hormone from the upper

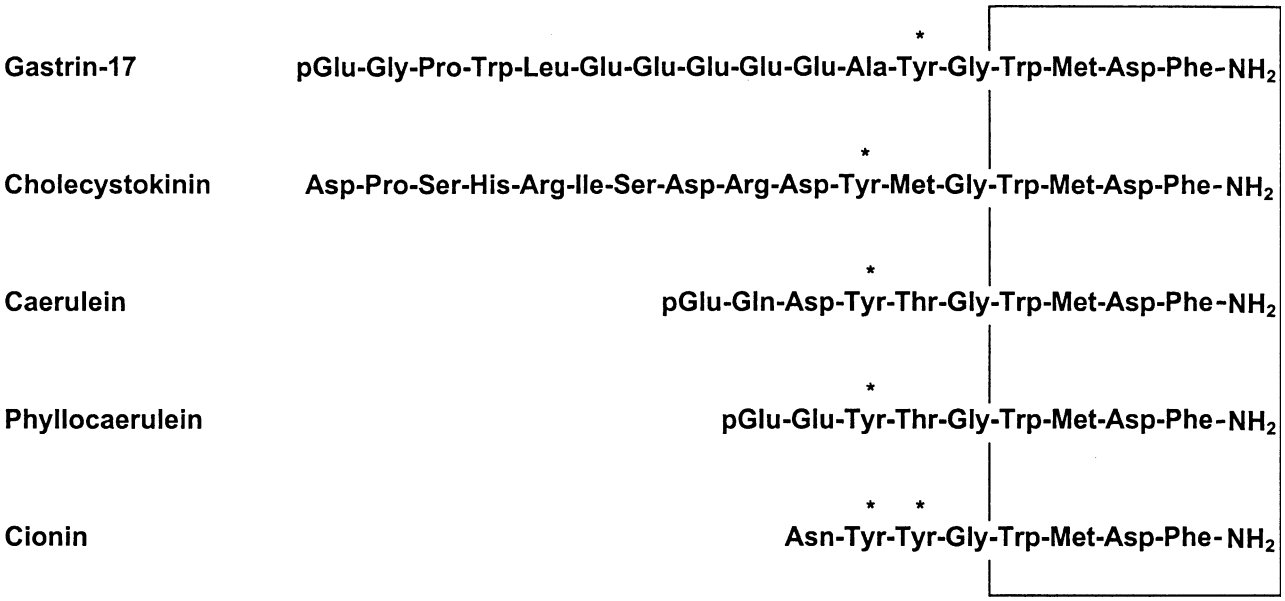

FIGURE 1 The C-terminal amino acid sequences of members of the gastrin–cholecystokinin family. The asterisks over the tyrosine residues indicate O-sulfation.

digestive tract has changed considerably. Now gastrin is known to occur in multiple molecular forms in plasma and tissue. Moreover, the gastrin gene is expressed in a cell-specific manner in a variety of neurons, endocrine cells, and other epithelial cells outside the gastrointestinal tract. Moreover, gastrin has been shown to stimulate growth in the stomach and perhaps elsewhere. Today, the view is favored that growth stimulation is a major function of gastrin.

Along with an increased focus on growth effects, clinical interest in gastrin has expanded from its role in duodenal ulcer disease to its significance in diabetes mellitus and in tumor development in the stomach, pancreas, and colorectal mucosa. However, gastrin may, in accordance with its widespread expression, also be involved in growth and neoplasias elsewhere.

II. STRUCTURE—FUNCTION RELATIONSHIPS

Most biologically active peptides occur in families whose members display structural homology. The occurrence of peptide families is believed to reflect evolution from a single ancestral gene by duplication and subsequent mutations. Also, gastrin and CCK are, as mentioned, members of the same family, and it is possible that the putative common ancestor resembles a dityrosyl-sulfated peptide, cionin, which has been isolated from neurons in protochordates. The frog skin peptides caerulein and phyllocaerulein are also members of the gastrin–CCK family (Fig. 1). At our present state of knowledge, however, CCK and gastrin are the only members of the family in mammals.

All known biological effects of gastrin and CCK peptides reside in the conserved common C-terminal tetrapeptide amide sequence (Fig. 1). Modification of this sequence grossly reduces or abolishes its receptor binding and biological effects in terms of gastric acid secretion and gastric mucosal growth. The different N-terminal extensions of the common C-terminal pentapeptide amide sequence increase the biological potency and the specificity of gastrin/CCK-B receptor binding. Of particular importance for receptor specificity is the tyrosine residue at position 6 of mammalian gastrin and at position 7 of CCK peptides, as counted from the C-terminal phenylalanine (Fig. 1). The gastrins are consequently defined as peptides that stimulate gastric acid secretion and have the C-terminal sequence Tyr-X-Trp-Met-Asp-Phe-NH_2 (where X in most mammalian species is a glycine residue). The tyrosine residue is partly sulfated in gastrins, and the gastrin/CCK-B receptor binds sulfated and unsulfated ligands equally well.

The active-site homology of gastrin with CCK has posed large problems in the study of these peptides, because the active site is strongly immunogenic and because the gastrin/CCK-B receptor binds peptides having the shared C-terminal sequence with almost equal affinity. Human gastrin peptides display extensive homology with corresponding peptides from other species. The extent of the species differences has been elucidated by cDNA deduction of the preprogastrin structures for various mammals. Comparison of the sequences shows that the active site and structures around major processing sites are well preserved (Fig. 2).

III. THE GASTRIN GENE AND mRNA

The single-copy gene for human gastrin is located on chromosome 17q. The cloning of mammalian gastrin and CCK genes shows that the genes are structurally similar, both in the overall exon–intron organization and in certain peptide-coding sequences. The gastrin gene spans 4.1 kb of chromosomal DNA and contains two introns of 3041 and 130 bp, respectively (Fig. 3). Antral G cells generate a single mRNA of 0.7 kb, which encodes the 101-amino-acid preprogastrin in human and mouse, whereas other mammalian preprogastrins have 104 amino acids due to a prolonged C-terminal flanking peptide (Fig. 2). The first exon encodes the 5′-untranslated region (5′-UTR) (Fig. 3). Gastrin cDNAs derived from tumor mRNA are identical to those isolated from mRNA in normal tissues.

Several studies have identified important regulatory domains in the human gastrin gene promoter using rodent cell systems. Hence, a cell-specific regulatory element has been located in the cap–exon 1 region of the human gastrin gene, and a pancreatic islet cell-specific regulatory domain in the gastrin promoter, containing adjacent positive and negative DNA elements, has also been identified. This regulatory domain may be a switch controlling the transient transcription of the gastrin gene in the pancreatic islet cells during fetal and neonatal development. The transcription of the gastrin gene is stimulated by epidermal growth factor (EGF) and inhibited by somatostatin. The EGF-responsive element is of interest for the elucidation of the growth-promoting and oncological significance of gastrin, since EGF/transforming growth factor-α (TGF-α) is expressed in a variety of carcinoma cell lines derived from the colorectal mucosa, ovary, pancreas, and stomach.

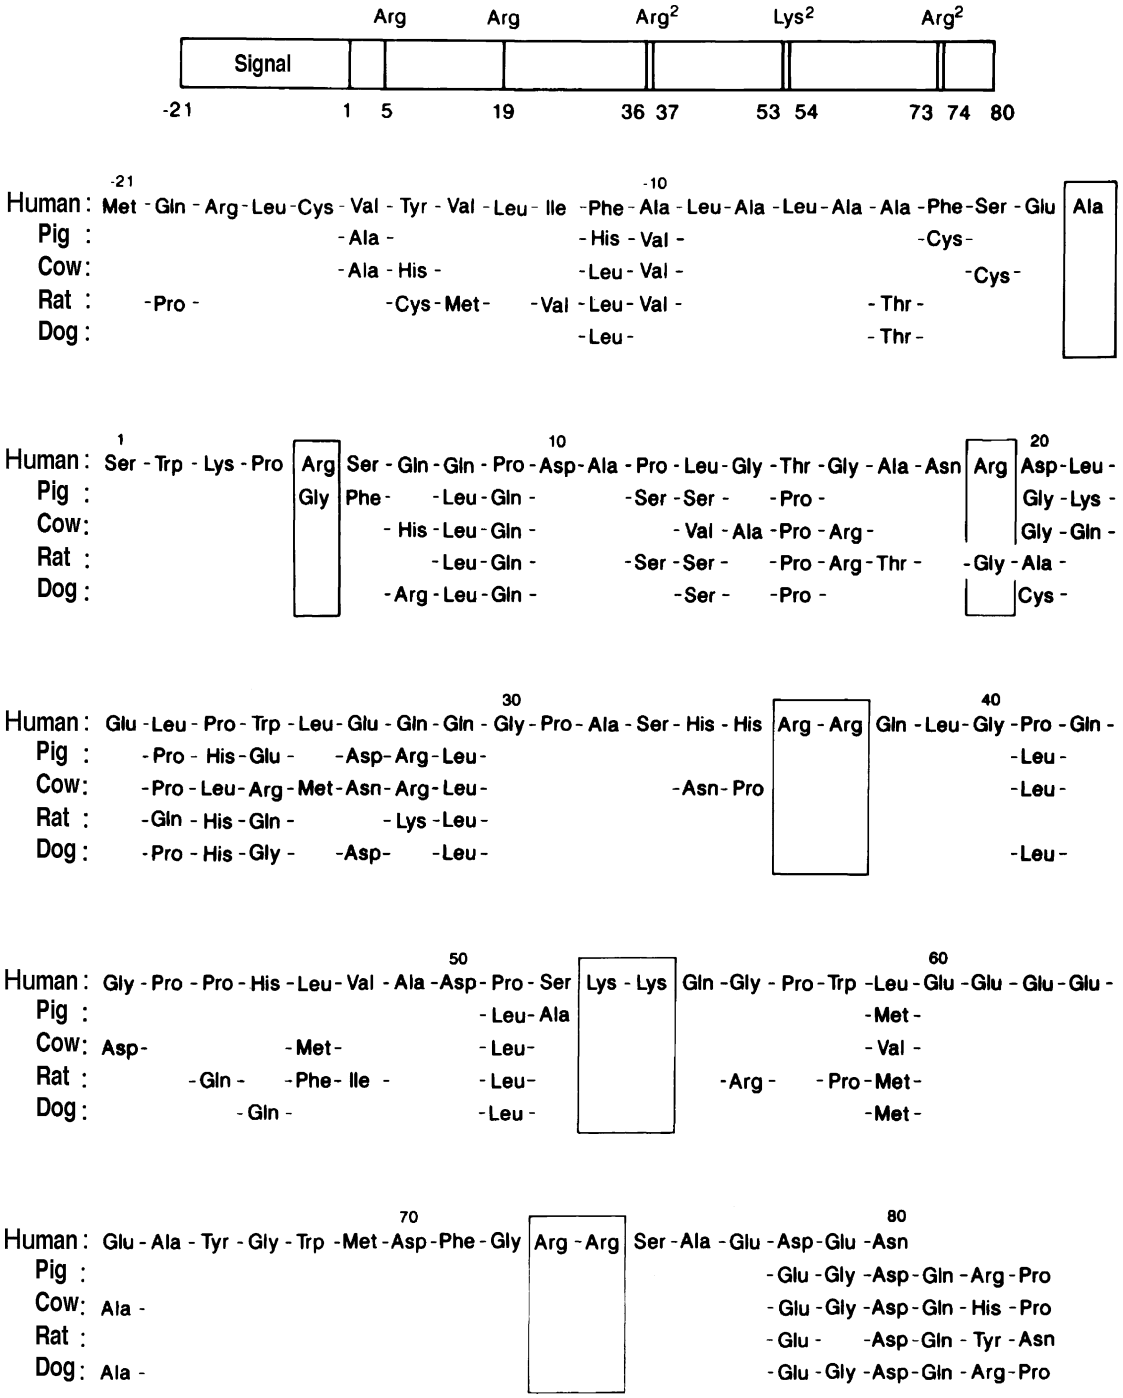

FIGURE 2 The cDNA-deduced amino acid sequences of preprogastrins from five mammalian species. Boxes indicate established proteolytic processing sites, mainly at di- and monobasic sites. Note the preserved sequences around the active site (residues 68–71) and around major processing sites.

Therefore, neoplastic expression of the gastrin gene may be due to transcriptional stimulation by EGF and/or TGF-α.

Thus far, no tissue-specific splicing or use of alternative promoters has been reported. Therefore, the tissue-specific molecular pattern of gastrin peptides is due to differences in posttranslational processing, rather than to alternative RNA splicing.

In the developing rat colon, gastrin mRNA concentrations increase from birth to adulthood,

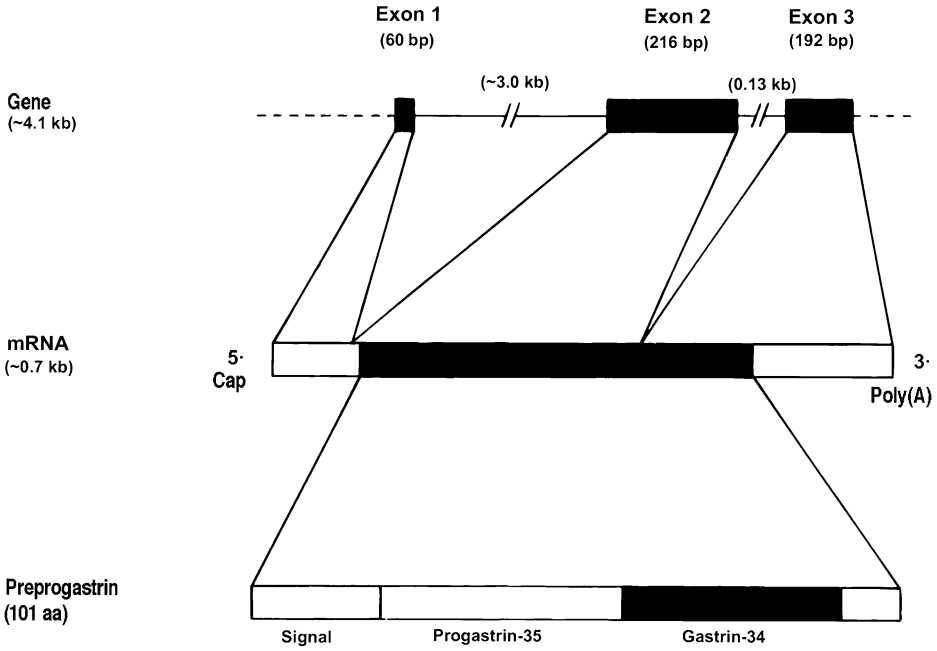

FIGURE 3 Structure of the human gastrin gene, mRNA, and prepropeptide. Exons are shown as boxes, and introns are shown as straight lines. The black area of the mRNA indicates the coding region. Numbers indicate the number of base pairs or kilobase pairs in each section of the gene. In preprogastrin, the position of gastrin-34 is shown.

apparently without a corresponding increase in peptide synthesis. Therefore, expression of the gastrin gene also appears to be regulated at the translational level. Comparison of rat, pig, and human cDNA sequences shows remarkably conserved nucleotide sequences in the 5′- and 3′-untranslated regions. It is therefore possible that such a sequence in the 5′-UTR may determine the translational efficiency of the expression cascade. The 3′-UTR may be involved in regulation of polyadenylation, termination of transcription, or message stability. Further studies on gastrin mRNA are necessary to explain these observations. The expression of the gastrin gene is ontogenetically regulated. Consequently, expression of the gastrin gene in tumors may involve factors that normally are expressed only in fetal life.

IV. PROGASTRIN MATURATION

The antral G cells are the main site of gastrin synthesis. A small number of G cells are also present in the proximal duodenum. After antrectomy, however, the duodenal G cells "antralize" and increase their synthesis considerably. Gastrin biosynthesis studies have thus far focused on antral tissue. Combining the results of these studies with general knowledge about peptide hormone synthesis provides a clear picture of the processing pathway of antral progastrin (Fig. 4).

After translation of gastrin mRNA in the endoplasmic reticulum and co-translational removal of the N-terminal signal peptide from preprogastrin, intact progastrin is transported to the Golgi apparatus. In the *trans*-Golgi network, the first posttranslational modifications occur. These are O-sulfation of the Tyr-66 residue neighboring the active site, and the first endoproteolytic convertase cleavage at two monobasic processing sites. From the *trans*-Golgi network, vesicles carry the processing intermediates toward the basal part of the G cells, where the gastrin peptides are stored in characteristic secretory granules. The cleavage by prohormone convertases 1 and 2 (PC1/3 and PC2), the exoproteolytic carboxypeptidase E trimming, and the subsequent glutamine cyclization, corresponding to the N-termini of gastrin-34 and gastrin-17 (Figs. 2 and 4), continue during the transport from the Golgi to the immature secretory granules. The last, decisive processing step in the synthesis of gastrin then occurs during storage in the secretory granules. The secretory granules contain the amidation enzyme, which removes glyoxylate from the immediate precursors, the glycine-extended

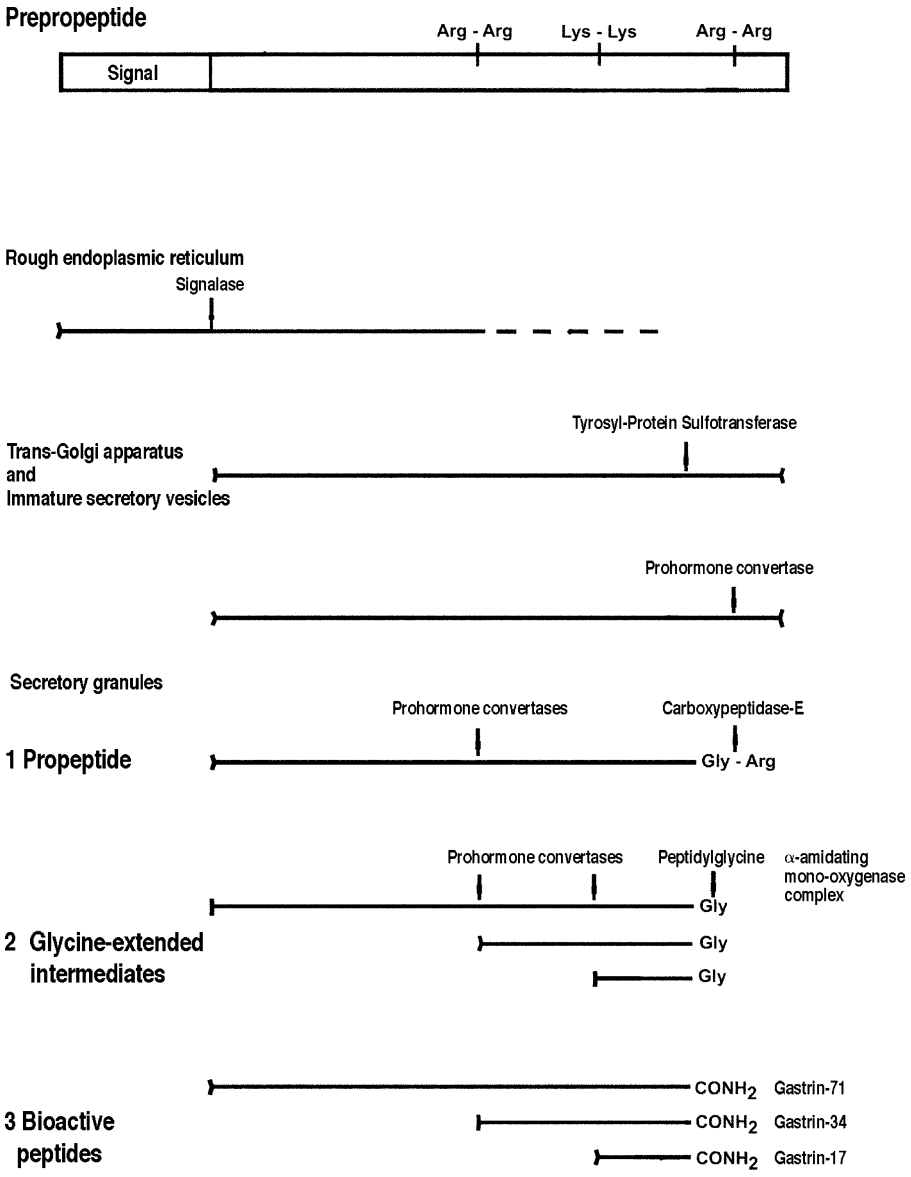

FIGURE 4 Schematic illustration of the posttranslational processing of preprogastrin in the antral G cell.

gastrins, to complete the synthesis of bioactive carboxyamidated peptides (Fig. 4). Amidation of gastrin is an all-or-none activation process that is carefully controlled. Activation of the enzymatic amidation process requires copper, oxygen, and ascorbic acid as co-factors and a pH of approximately 5. Carboxyamidiation of peptides is known to require two sequentially acting enzymes: a peptidylglycine α-hydroxylating monooxygenase, derived from the N-terminal part of the enzyme precursor, and a peptidyl-α-hydroxyglycine α-amidating lyase, derived from the remaining intragranular region of the precursor.

V. CELLULAR GASTRIN RELEASE

As a result of the elaborate biosynthesis process, the antral G cells release a heterogeneous mixture of progastrin products from the mature secretory granules into the blood. In human, a small percentage of these products are nonamidated precursors, mainly glycine-extended gastrins, whereas more than 95% are α-amidated bioactive gastrins. Of these, 85% are gastrin-17, 5–10% are gastrin-34, and the rest is a mixture of gastrin-71, gastrin-14, and the short gastrin-6 (Fig. 4). Approximately half of the amidated gastrins are tyrosine-sulfated. Due to gross differences

in metabolic clearance rates, the distribution pattern of gastrins in peripheral plasma changes, so that larger gastrins with their long half-lives predominate over gastrin-17 and shorter gastrins. Hence, in peripheral blood, gastrin-34 is the predominant form of gastrin.

Increased gastrin synthesis changes the molecular pattern in plasma further. Abnormally increased antral synthesis occurs in human by achlorhydria, as seen in pernicious anemia. In antrum-sparing pernicious anemia, the translational activity of gastrin mRNA in G cells seems to be so high that the enzymes responsible for the processing of progastrin cannot keep up with the maturation of the peptide. Consequently, G cells release more unprocessed and incompletely processed nonamidated progastrin products when the rate of synthesis is increased. Also, the carboxyamidated gastrins are less sulfated and the N-terminus of progastrin is cleaved to a lesser degree. Precursors, processing intermediates, and long-chained carboxyamidated gastrins, such as gastrin-71 and gastrin-34, are, as mentioned, cleared at a relatively slow rate from the circulation and therefore accumulate in plasma when the rates of synthesis and release are increased.

Gastrin peptides are also released from cell types other than the antroduodenal G cells. Quantitatively, these other cells contribute only a little to circulating gastrin, partly because the secretion seems to serve local purposes and partly because the biosynthetic processing is cell-specific. Thus far, expression of progastrin and its products has been encountered outside the antroduodenal mucosa in endocrine cells] in the ileum and the colon, in endocrine cells in the fetal and neonatal pancreas, in pituitary corticotrophs and melanotrophs, in oxytocinergic hypothalamo-pituitary neurons, in a few cerebellar and vagal neurons, in the adrenal medulla of some species, in the bronchial mucosa, in postmenopausal ovaries, and in human spermatogenic cells. As shown in Table 1, the concentrations and presumably also the synthesis in the extra-antal tissues are far below those of the antral "main factory."

The function of gastrin synthesized outside the antroduodenal mucosa is not yet fully known, but an obvious possibility is paracrine or autocrine regulation of growth. Second, it is possible that the low concentration of peptides is without significant function in the adult, but is a relic of a more comprehensive fetal synthesis for local stimulation of growth. A third possibility is that the low cellular concentration and, hence, low tissue concentration are due to constitutive rather than regulated secretion. With constitutive secretion, there is no storage of peptides in the cells despite a considerable amount being released per unit of time.

TABLE 1 Expression of the Gastrin Gene at the Peptide Level in Normal Adult Mammalian Tissue

Tissue	Total translation product (pmol/g tissue)	Precursor percentage
Gastrointestinal tract		
Antral mucosa	10,000	5
Duodenal mucosa	400	20
Jejunal mucosa	40	30
Ileal mucosa	20	85
Colonic mucosa	0.2	100
Neuroendocrine tissue		
Cerebellum	5	20
Vagal nerve	8	10
Adenohypophysis	200	98
Neurohypophysis	30	5
Adrenal medulla	2	100
Pancreas	2	95
Genital tract		
Ovaries	0.5	100
Testicles	6	100
Spermatozoa	2	55
Respiratory tract		
Bronchial mucosa	0.3	100

Note. Orders of magnitude based on examination of different mammalian species.

Although it is possible that the extra-antral synthesis of gastrin is without function in the adult organism, recognition of the phenomenon has considerable biomedical interest. Hence, tumors originating from cells that express the gastrin gene at low levels in adult organisms may produce significant amounts of gastrin in tumors. Well-known examples are pancreatic, duodenal, and ovarian gastrinomas that give rise to the Zollinger–Ellison syndrome.

VI. THE GASTRIN RECEPTOR

The gastrin/CCK-B receptor is the predominant receptor for gastrin and CCK peptides in the central nervous system. It is expressed with particularly high density in the cerebral cortex. The gastrin/CCK-B receptor is less selective than the CCK-A receptor, which binds only sulfated CCK peptides. In contrast, the gastrin/CCK-B receptor binds both sulfated and nonsulfated gastrin and CCK peptides as well as short C-terminal fragments of CCK and gastrin, all with

similar high affinity. The gastrin/CCK-B receptor is abundantly expressed in the brain, in ECL (enterochromaffin-like) cells in the stomach, and also at a lower level in the exocrine and endocrine pancreas of human. The canine gastrin receptor is a 453-amino-acid protein that also contains seven transmembrane domains and belongs to the G-protein-coupled receptor superfamily (Fig. 5). Like the CCK-A receptor, it has a number of N-terminal glycosylation sites and several serine and threonine residues for phosphorylation but no tyrosine phosphorylation site. The gastrin receptor also activates phospholipase C, degrades inositol-phospholipids, mobilizes intracellular calcium, and activates protein kinase C. Valine-319 in the sixth transmembrane domain of the human gastrin/CCK-B receptor determines the binding specificity of the nonpeptide receptor antagonists. This receptor site for antagonist binding differs from that of agonist binding, as shown also for other peptide receptors. Hence, allosteric binding of nonpeptide antagonists is a common feature of the G-protein-coupled, seven-transmembrane-spanning family of peptide receptors. Alternative splicing of gastrin/CCK-B receptor mRNA has been observed. The significance of the splicing in terms of receptor specificity is still unknown.

VII. SUMMARY AND PERSPECTIVE

Gastrin is an important regulatory peptide system. Although originally discovered and named as a simple gastrointestinal hormone, gastrin peptides are now recognized as widespread intercellular messengers in many compartments of the body. In addition to their classical blood-borne hormonal activity as regulators of gastric acid secretion via ECL-cell release of histamine, gastrin peptides are neurotransmitters and growth factors. In addition, the far-reaching phylogeny indicates a vital role for gastrin and gastrin-like peptides in the evolution of multicellular life for more than 500 million years.

The gastrin system of peptides continues to be a subject of extensive interest and research. In recent years, it has been suggested that the progastrin molecule itself as well as intermediate processing products such as the glycine-extended gastrins may have specific growth-promoting effects. Accordingly, it has been suggested that target cells in normal and neoplastic tissue express specific receptors for these precursors and processing intermediates. The suggestions are interesting, but they are still hypothetical ideas that require further and substantial evidence. A necessary milestone that remains to be reached

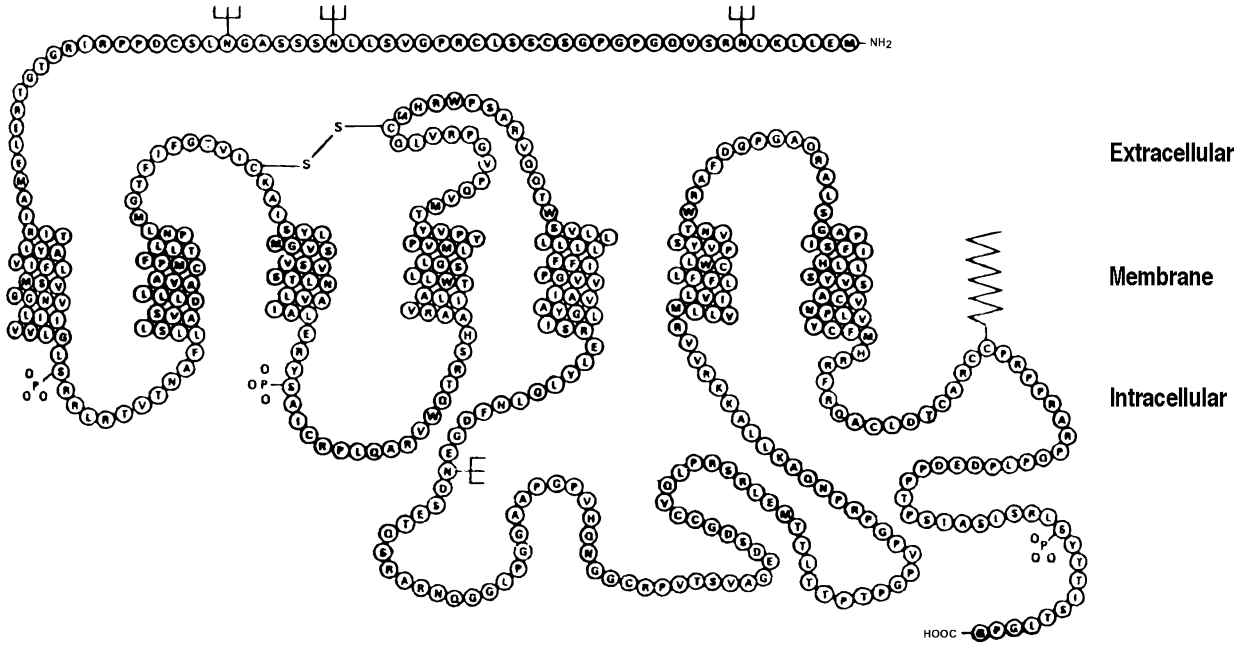

FIGURE 5 Schematic model of the rat gastrin/CCK-B receptor. The cDNA-deduced amino acid sequence (single-letter code) shows putative transmembrane helices, consensus sites for N-linked glycosylation (tridents), serine and threonine phosphorylation ($-PO_3$), disulfide bridge ($-S-S$), and cysteine palmitoylation (jagged line). Gastrointestinal Hormone (GI) Regulated Signal Transduction

MARK R. HELLMICH

University of Texas Medical Branch, Galveston

Gastrointestinal hormones, peptide messengers that are released from endocrine cells, are distributed throughout the gastric mucosa, small intestine, and colon in response to nervous activity, physical stress, and chemical stimulation coincident with the intake of food. Acting in an endocrine, paracrine, or neurocrine manner, gastrointestinal hormones regulate a variety of specific biological responses by the stomach, small intestine, pancreas, liver, and gallbladder to optimize the physiological conditions necessary to permit efficient digestion and absorption of protein, carbohydrates, and fat from the lumen of the intestine.

I. INTRODUCTION

Gastrointestinal (GI) hormones act in concert with the nervous system to regulate exocrine and endocrine GI secretion, cell proliferation, differentiation, and motility. The GI tract produces many different peptide hormones and GI-active neuropeptides, some of which are listed in Tables 1 and 2, respectively. There are myriad GI peptides that activate signal transduction pathways; the following discussion presents a summary of the current knowledge of the intracellular signal transduction pathways involved in normal physiological actions of a select few GI hormones (gastrin, cholecystokinin, and secretin) on specific GI tract target cells: gastric parietal cells, enterochromaffin-like cells, and pancreatic acinar cells.

II. GI HORMONE SIGNALING: AN OVERVIEW

All GI hormones are polypeptides that bind to receptors belonging to the superfamily of guanine nucleotide-binding protein (G-protein)-coupled receptors (GPCRs). GI hormone-stimulated signal transduction begins with the binding of the peptide hormone to its cognate cell surface receptor. Highly specific interactions between individual amino acid residues of the peptide hormone and amino acids of the receptor cause a conformational change in the receptor, which transduces the informational content of the peptide hormone across the plasma membrane to intracellular signal transduction networks. These networks consist of second-messenger-producing enzymes, protein kinases, phosphatases, scaffold and adapter proteins, transcription factors, and other regulatory proteins, which act in a synergistic and combinatorial manner to elicit specific cellular responses to the hormone stimulus.

As members of the GPCR superfamily, all GI hormone receptors share common structural motifs, including seven transmembrane-spanning α-helical domains, and all function as ligand-regulated guanine nucleotide exchange factors for intracellular heterotrimeric G-proteins. Heterotrimeric G-proteins are composed of the products of three gene families encoding α, β, and γ subunits. The agonist-activated GPCR catalyzes the exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) bound to the G_α subunit, as well as the dissociation of GTP-G_α from its cognate $G_{\beta\gamma}$ dimer. The activated GTP-G_α and $G_{\beta\gamma}$ subunits, in turn, regulate the activity of various intracellular effector proteins, such as phospholipases, adenylyl cyclases, protein kinases, membrane ion channels, and members of the Ras family of GTP-binding proteins. Approximately 20 mammalian G_α subunits have been identified and, based on structural similarities, are divided into four distinct subfamilies: the cholera-toxin-sensitive αs subunits, which stimulate adenylyl cyclase and thus increase levels of intracellular cAMP; the pertussis-toxin-sensitive αi/o subunits, which inhibit adenylyl cyclase activity; the pertussis-toxin-insensitive αq/11/14 subunits, which stimulate membrane phospholipases; and the α12/13 subfamily, which appear to provide

TABLE 1 Gastrointestinal Hormones

Hormone	Major actions
Gastrin	↑ Acid and pepsin secretion from gastric mucosa; ↑ ECL proliferation
CCK	↑ Pancreatic enzyme secretion and gallbladder contraction
Secretin	↑ Pancreatic bicarbonate and H_2O secretion
Motilin	↑ Intestinal motility
Enteroglucagon	↑ Enterocyte proliferation
Somatostatin	↓ Gastric acid secretion and gastric motor activity
Gastric inhibitory peptide	↑ Glucose-stimulated insulin secretion and ↓ gastric acid secretion
Pancreatic polypeptide	↓ Pancreatic bicarbonate secretion
Peptide YY	↓ Gastric motor activity and acid secretion

TABLE 2 GI Active Neuropeptides

Neuropeptide	Major actions
Bombesin (gastrin-releasing peptide)	↑ Gastrin release
Substance P	↑ Smooth muscle contraction mediates inflammatory response
Vasoactive intestinal peptide	↑ Smooth muscle relaxation and pancreatic bicarbonate secretion
Calcitonin gene-related peptide	↑ Somatostatin release and smooth muscle contraction

a link between GPCRs and the activation of the Ras-related GTP-binding protein, Rho.

In addition to the G_α subunits, 12 G_γ subunits and 6 G_β subunits have been cloned. When released from the activated GTP-α subunit following receptor stimulation, $G_{\beta\gamma}$ dimers activate intracellular signaling molecules such as phosphatidylinositol 3-kinases (PI3-kinases), select isoforms of adenylyl cyclase, and receptor kinases, which play an important role in attenuating agonist-induced receptor activation. The mechanisms of GI hormone-stimulated intracellular signal transduction have been extensively characterized in a number of experimental models. Several excellent reviews have recently been published and are listed in the bibliography at the end of this article.

III. MAJOR GI HORMONES AND RECEPTORS

Classical hormones are secreted from endocrine glands or cells into the bloodstream and are distributed to their targets through the general circulation. GI hormones are a subset of hormones produced by and released from endocrine cells of the gut in response to a meal that have other gut cells as their primary targets. Not all GI hormones function in a truly endocrine fashion—that is, many GI peptides are not discharged into blood vessels to act at a distant (target) site, but rather they act in either a paracrine or neurocrine manner. Of the many regulatory peptides found in the GI tract, five peptides can be considered "true" GI hormones. There is ample evidence showing they are released into the blood from one site of the GI tract in response to a meal and act at a distant target site to regulate the processes of nutrient digestion, absorption, and transit. The five major GI hormones that act predominantly in an endocrine manner are gastrin, cholecystokinin (CCK), secretin, gastric inhibitory peptide (GIP), and motilin. Currently, little is known about the intracellular signaling pathways mediating the actions of GIP and motilin, thus this review focuses on the signaling pathways regulated by gastrin, CCK, and secretin (Fig. 1).

A. Gastrin

In the GI tract, gastrin regulates gastric acid secretion from parietal cells, histamine release from enterochromaffin-like (ECL) cells, and normal and neoplastic cell proliferation. Gastrin is released from G cells located in the gastric antrum and duodenum. The major circulating forms of gastrin are the amidated gastrin 1–17 (G-17) and big gastrin, gastrin 1–34 (G-34). During the interdigestive (basal) state, most of the gastrin detected in human serum is G-34. Unlike other species, in humans the duodenal mucosa produces significant amounts of G-34. After a meal,

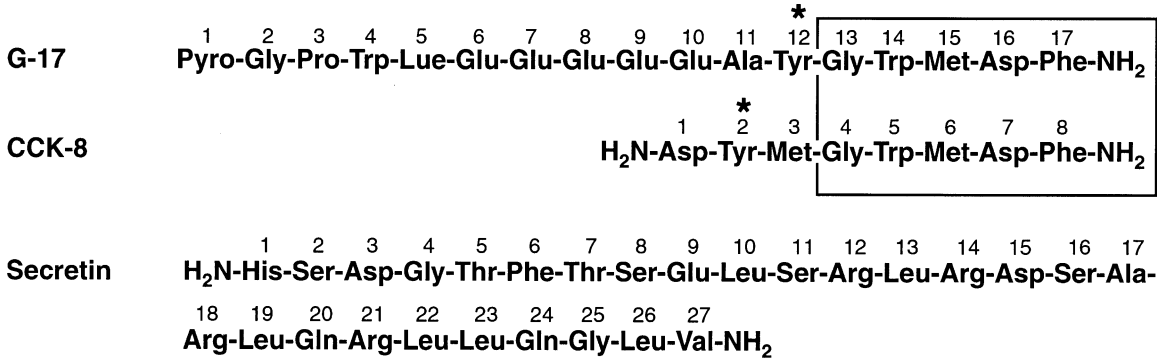

FIGURE 1 Amino acid sequences of gastrin 1–17 (G-17), cholecystokinin 1–8 (CCK-8), and secretin. The last five amino acid residues of G-17 and CCK are identical (box). The sites of sulfation are indicated (*). Pyro, Pyroglutamyl.

however, large quantities of antral gastrin, primarily G-17, are released and provide most of the stimulus for gastric acid secretion. Gastrin regulates acid release directly by stimulating HCl-producing parietal cells and indirectly by stimulating ECL cells to increase production and release of the biogenic amine, histamine, which binds to H_2 histamine receptors on the parietal cell and enhances gastrin-stimulated acid secretion.

B. Gastrin/CCK-B Receptor

The gastrin receptor was originally cloned from an expression cDNA library constructed with canine parietal cell messenger RNA (mRNA) and was found to be identical to the cholecystokinin-B (CCK-B) receptor (CCK-BR) cloned at about the same time by other laboratories from rat brain and the rat pancreatic acinar carcinoma cell line, AR42J. To date, cDNA for CCK-BR has been cloned from rat brain and stomach, rat pancreatic tumor cells, human brain, calf pancreas, guinea pig gallbladder and stomach, and from ECL and parietal cells from the rodent *Mastomys natalensis*. A comparison of cDNA sequences from these various species indicates that the structure of CCK-BR is highly conserved, with an overall predicted amino acid sequence identity of 72% and pairwise amino acid sequence identities of 84–93%. Within the same species, CCK-BR shares approximately 50% sequence identity with the CCK-A receptor (CCK-AR), which is the primary physiological receptor for the gastrin-related peptide, CCK (Fig. 1).

Translation of the rat and canine CCK-BR cDNAs predicts proteins composed of 452 and 453 amino acid residues, respectively. Hydropathy analysis indicates that CCK-BR has a structure common to GPCRs, i.e., the seven transmembrane-spanning segments. In addition, CCK-BR contains at least three consensus sites for N-linked glycosylation (Asn-X-Ser/Thr), which is consistent with the 74- and 78-kDa glycoproteins identified by affinity cross-linking studies using ^{125}I-labeled [Leu or NorLeu^{15}]-gastrin-2–17 and gastric mucosal extracts enriched for parietal cells. Also, CCK-BR has in the first and second extracellular loops two conserved cysteine residues, which may form a disulfide bridge required for stabilization of its tertiary structure, and a cysteine in the COOH-terminal tail domain, which may serve as a membrane-anchoring palmitoylation site.

C. CCK

Although CCK is structurally related to gastrin, its major targets are the pancreas and gallbladder. In the pancreas, CCK is an important regulator of digestive enzyme secretion and acinar cell growth. In the gallbladder, CCK is a potent stimulus of gallbladder wall contractions and plays a role in relaxation of the sphincter of Oddi, which guards the exit of the common bile duct into the duodenum. CCK also plays a role in potentiating the effects of secretin and the related peptide, vasoactive intestinal peptide (VIP), on pancreatic bicarbonate secretion and growth regulation of the exocrine pancreas.

CCK is expressed in intestinal I cells, located in the duodenum and jejunum, as well as in neurons of the enteric, peripheral, and central nervous systems. It is released from I cells into the bloodstream in response to the presence of fatty acids longer than eight carbon atoms and proteins in the form of short peptides and single aromatic amino acids in the lumen of the duodenum.

In humans, CCK occurs predominantly as COOH-terminal amidated 58- and 8-amino-acid peptides that arise from the posttranslational processing of a 115-amino-acid preprohormone. Additional forms of CCK (CCK-39 and CCK-33) have been described in various species, including humans. All of these forms of CCK have similar molar potencies for the stimulation of pancreatic enzyme secretion from *in vitro* preparations of rat pancreatic acini. CCK-8 is the shortest peptide that exhibits biological activity. However, to achieve full potency, the tyrosine seven residues from the COOH-terminus must be sulfated (Fig. 1).

D. CCK-A Receptor

The first receptor for CCK (CCK-AR) was cloned from a rat pancreatic acinar cell cDNA library using degenerate oligonucleotide primers as probes. Hydropathy analysis of the CCK-AR cDNA indicated seven putative transmembrane-spanning domains. The deduced sequence of the rat CCK-AR predicts a 429-amino-acid protein with a calculated molecular mass of 48 kDa. Consistent with ligand affinity cross-linking experiments, which identified a CCK binding protein with a molecular mass of approximately 90 kDa in pancreatic acini, three potential sites for N-linked glycosylation have been identified on the CCK-AR extracellular domains. Other structural features of potential functional importance include three consensus sites for protein kinase C (PKC)

phosphorylation in the third intracellular loop and a cysteine residue in the COOH-terminal tail domain that may serve as a membrane-anchoring palmitoylation site.

To date, CCK-AR cDNA clones have been characterized from guinea pig gallbladder, pancreas, and gastric chief cells; human gallbladder; and rabbit gastric mucosa. The CCK-AR is highly conserved among these different species, with an overall amino acid sequence homology of 80% and a pairwise amino acid sequence identity of 87–92%. Unlike the CCK-BR, which binds sulfated-CCK and gastrin with similar affinities, CCK-AR is highly selective for sulfated-CCK and binds gastrin poorly.

E. Secretin

Secretin was the first peptide hormone discovered. The principal biological action of secretin is to stimulate the release of bicarbonate and water from pancreatic acinar cells. Secretin is secreted from S cells located in the duodenum and, to a lesser extent, from the jejunum, when the acidity of the duodenal contents fall below a pH of 4.5.

Unlike other peptide hormones, only a single form of secretin has been identified. Biologically active secretin is 27 amino acids long (Fig. 1) and is derived from the posttranslational processing of a 104-amino-acid residue peptide preprohormone. Secretin has structural homology with glucagon, gastric inhibitory peptide (GIP), and vasoactive inhibitory peptide.

F. Secretin Receptor

The first secretin receptor cDNA was isolated using an expression cloning strategy and mRNA from the cell line NG108-15. The secretin receptor cDNA encodes a GPCR containing 449 amino acids with a mass of approximately 49 kDa. In addition, the secretin receptor contains five potential sites of N-glycosylation, 10 extracellular cysteine residues, and three intracellular consensus sites for protein kinase C-mediated phosphorylation. The predicted amino acid sequences of the rat and human secretin receptors are 81% identical.

Following cloning of the secretin, VIP, calcitonin, and parathyroid hormone receptors, it became apparent that, although these receptors shared common structural and functional characteristics with the superfamily of GPCRs, they were sufficiently different from the rhodopsin/β-adrenergic family of GPCRs to warrant assigning them to a new branch of the phylogenetic tree. Currently, five classes (A–E) of GPCRs are recognized. The secretin receptor defines class B GPCRs and, in addition to those listed above, includes receptors for glucagon, glucagon-like peptide-1 (GLP-1), GIP, and pituitary adenylate cyclase-activating polypeptide (PACAP). Gastrin/CCK-BR and CCK-AR are members of the class A rhodopsin-like receptors.

Secretin is the preferred ligand of the secretin receptor and binds with relatively high affinity. Competition binding studies found that 50% of bound [^{125}I]-labeled secretin was displaced by 1 n*M* of unlabeled secretin. In addition to secretin, the secretin receptor will bind VIP and glucagon but with much lower affinity. A concentration of 1 μ*M* of unlabeled VIP was required to displace 50% of the labeled secretin bound to the secretin receptor.

IV. GASTRIN REGULATION OF GASTRIC ACID SECRETION

The stimulation of gastric acid secretion from the parietal cell in response to a meal is a complex process involving the integration of signals from the nervous systems, GI hormones, and the biogenic amine histamine. The parietal cells receive input from the neurotransmitter acetylcholine, released from neurons of the vagus nerve, from the GI hormone gastrin, released by G cells of the gastric antrum, and from ECL cells, which produce and release histamine (Fig. 2). Gastrin plays a central role in the regulation of acid secretion from parietal cells by both direct and indirect mechanisms.

A. Parietal Cells

The parietal cells, located in the fundus of the stomach, secrete a solution of 0.15 *M* HCl and 7 m*M* KCl, with traces of other electrolytes. The concentration of hydrogen ion in parietal cell secretions is greater than 1 million times the concentration in the plasma. The low pH of gastric secretions initiates denaturation of ingested proteins and converts the inactive protease pepsinogen, released from gastric chief cells, into the active enzyme pepsin. The acid also kills many of the bacteria that enter the stomach, thereby reducing the number of potentially pathogenic organisms that reach the intestines.

The final step in acid secretion from parietal cells involves translocation of gastric H^+,K^+-ATPase from its intracellular vesicular compartment to the apical plasma membrane. H^+,K^+-ATPase is related to the family of P-type cation pumps, which includes

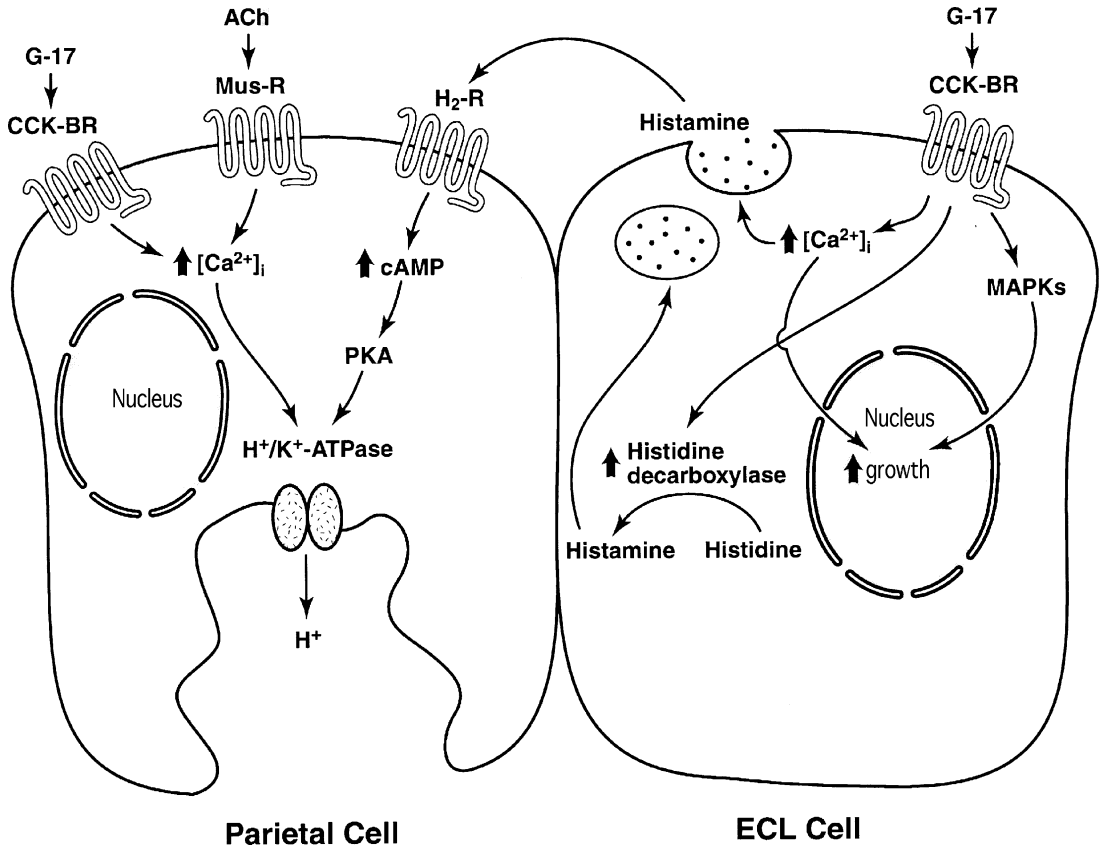

FIGURE 2 Summary of intercellular regulation of gastric acid secretion from a gastric parietal cell and an enterochromaffin-like (ECL) cell. CCK-BR, Cholecystokinin-B receptor; ACh, acetylcholine; H_2-R, histamine receptor; PKA, protein kinase A; MAPKs, mitogen-activated protein kinases.

Na^+,K^+-ATPase. H^+,K^+-ATPase consists of a catalytic α-subunit and a highly glycosylated β-subunit. It uses the energy from ATP hydrolysis for the electroneutral countertransport of H^+ for K^+. In unstimulated parietal cells, H^+,K^+-ATPase is sequestered within a population of cytoplasmic vesicles called tubulovesicles, which are spatially insulating from the gastric lumen. Also, the tubulovesicle membrane has a very low permeability to KCl, limiting the activity of the pump even though there is ample ATP around the enzyme. Activation of acid secretion is achieved when (1) the tubulovesicles fuse with the apical secretory membrane, thus recruiting functional H^+,K^+-ATPase to the expanding microvillar surface, and (2) the apical membrane becomes permeable to KCl.

B. Gastrin Stimulates H^+,K^+-ATPase Translocation

Gastrin stimulates the translocation of tubulovesicles containing H^+,K^+-ATPase to the apical membrane in a process involving membrane docking and fusion. Studies of classical secretory systems, from those of budding yeast to those of the mammalian nervous system, have revealed an evolutionarily conserved multimeric complex of proteins that regulate secretory vesicle docking and fusion. Integral membrane proteins called soluble N-ethylmaleimide-sensitive factor attachment protein receptors (SNAREs) and Ras-related GTP-binding proteins of the Rab subfamily are essential components of the docking and fusion machinery. Vesicle docking and membrane fusion require the highly regulated interaction of the vesicle membrane proteins known as synaptobrevins [also called vesicle (v)-SNAREs or vesicle-associated membrane proteins (VAMPs)] and the plasma membrane proteins, i.e., syntaxins, and synaptosomal-associated proteins (SNAPs), collectively referred to as t-SNAREs. All SNAREs are associated with the membrane via a single transmembrane domain or acylation, and all possess one or more α-helices capable of forming coiled-coiled structures.

Vesicle docking and fusion to the plasma membrane involve, in part, the formation of a complex between v-SNAREs and t-SNAREs, as well as regulation by additional factors, including Rabs. Rabs are a large family of evolutionarily conserved small GTP-binding proteins; over 40 members have been identified in mammalian cells. Different Rabs are found on vesicular elements of secretory and endosomal pathways and are required for vesicle docking and fusion to target membranes. Several proteins and their isoforms that function in vesicle docking and fusion have been identified in parietal cells. These include syntaxin isoforms 1 through 4, VAMP-2 (synaptobrevin), SNAP-25, Rab2, Rab11, Rab25, and secretory carrier membrane proteins (SCAMPs).

C. Gastrin Stimulates an Increase in $[Ca^{2+}]_i$

The precise signaling pathways linking CCK-BR activation with tubulovesicle docking and fusion have not been defined. However, it is known that gastrin stimulation of parietal cells activates phospholipase C (PLC), leading to the generation of the second messengers inositol 1,4,5-triphosphate ($InsP_3$) and 1,2-diacylglycerol (DAG) from the hydrolysis of plasma membrane phosphatidylinositol 4,5-bisphosphate (PIP_2). Soluble $InsP_3$ activates ligand-gated Ca^{2+} channels that are located in the endoplasmic reticulum, resulting in a rapid and transient elevation in the concentration of free cytoplasmic Ca^{2+} ($[Ca^{2+}]_i$). Elevated levels of $[Ca^{2+}]_i$ and DAG activate PKC in a number of cell types and, presumably, in parietal cells, although currently there is no direct evidence for a role of PKC in gastrin-stimulated acid secretion. Gastrin-stimulated increases in $[Ca^{2+}]_i$ could, however, (1) promote vesicular motor activity through the activation of downstream Ca^{2+}/calmodulin-dependent myosin light chain kinase, (2) regulate actin filament turnover, or (3) promote interactions between SNAREs and the Ca^{2+}-dependent phospholipid-binding protein annexin (Fig. 3). Further studies are necessary to examine the potential role of these pathways in gastrin-stimulated H^+,K^+-ATPase translocation and acid secretion.

D. Gastrin Potentiates Histamine-Stimulated Acid Secretion

Gastrin regulates acid secretion, in part, by binding to CCK-BR on parietal cells to stimulate acid release; however, in most species this direct effect of gastrin is relatively weak. More significant to the overall acid production by parietal cells are the indirect effects of

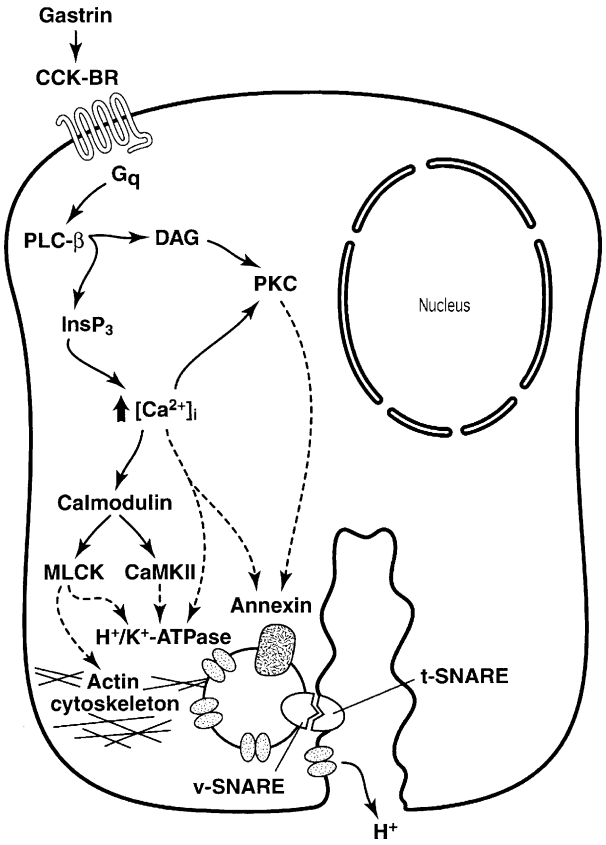

FIGURE 3 Parietal cell. Summary of pathways mediating gastrin-stimulated acid secretion from the gastric parietal cell (dashed lines indicate proposed pathways). CCK-BR, Cholecystokinin-B receptor; PLC-β, phospholipase C-β; DAG, diacylglycerol; PKC, protein kinase C; $InsP_3$, inositol 1,4,5-trisphosphate; MLCK, myosin light chain kinase; CaMKII, calmodulin kinase II; v-SNARE, vesicle soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor; t-SNARE, target membrane SNARE.

gastrin on ECL cell histamine release. Gastrin binds to CCK-BR on the ECL cells, where it stimulates both production and release of histamine. Gastrin increases histamine production by stimulating histidine decarboxylase activity (Fig. 4). Treatment of ECL cells with pertussis toxin inhibits the effects of gastrin on histidine decarboxylase activity, suggesting the involvement of $G_{i/o}$ in this process. Once released from ECL cells, histamine, acting in a paracrine fashion, binds to H_2-type histamine receptors on the parietal cell to greatly enhance acid secretion through a cAMP- and protein kinase A (PKA)-dependent pathway (Fig. 2). Where gastrin- and histamine-stimulated signaling pathways converge to potentiate acid secretion is currently unknown.

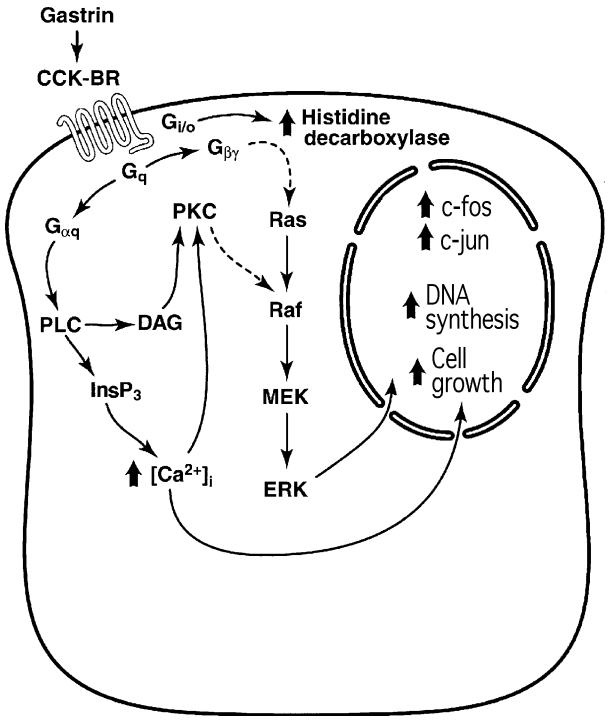

FIGURE 4 Enterochromaffin-like cell. Summary of pathways mediating gastrin-stimulated growth in the enterochromaffin-like cell (dashed lines indicate proposed pathways). CCK-BR, Cholecystokinin-B receptor; PKC, protein kinase C; PLC, phospholipase C; DAG, diacylglycerol; MEK, mitogen-activated protein kinase kinase; ERK, extracellular signal-regulated kinase.

V. GASTRIN REGULATION OF CELL GROWTH

In addition to its role in gastric acid secretion, gastrin also acts as a potent growth factor and has been implicated in a variety of normal and abnormal biological processes, including maintenance of the gastric mucosa, proliferation of ECL cells, and neoplastic transformation. It is well established that in rats and humans, hypergastrinemia (higher than normal concentration of gastrin in the blood) is associated with ECL cell proliferation and occasionally with the development of gastric carcinoid tumors. Also, there is epidemiological evidence implicating hypergastrinemia as a risk factor for the development of colorectal cancer, and studies using genetically altered mice have demonstrated the proliferative effects of gastrin on the normal stomach and colonic mucosa. Many cell lines have been used to study the signal transduction pathways associated with the proliferative effects of gastrin. Some of these cell lines express an endogenous CCK-BR and others have been transfected with expression plasmids containing the CCK-BR cDNA. Accumulating evidence indicates that mitogen-activated protein kinases (MAPKs) play a central role in gastrin-stimulated cell proliferation.

A. Mitogen-Activated Protein Kinases

MAPKs are serine/threonine-directed kinases that are activated by a variety of stimuli, including growth factors, cytokines, neurotransmitters, hormones, extracellular matrix proteins, and cell stress. MAPKs regulate a number of cellular processes, including gene transcription, protein translation, metabolism, and the function of the cytoskeleton. As a result, MAPKs are involved in the control of cell growth, differentiation, and apoptosis. These actions are carried out by phosphorylating downstream target proteins and by carrying information to the nucleus or cytoskeleton through translocation within the cell. Currently, five MAPK pathway subfamilies have been identified, including the extracellular signal-regulated kinases (ERK1 and ERK2), the c-Jun N-terminal kinases (JNKs), the 38-kDa MAPKs (p38 MAPKs), ERK5, and ERK3/ERK4.

MAPKs are activated by a kinase cascade composed of three families of protein kinases acting in series. Each MAPK is activated by an upstream MAPK kinase (MAPKK), which is, in turn, activated by a MAPK kinase kinase (MAPKKK). All MAPKKs are dual-specificity kinases that activate MAPKs by phosphorylating both the tyrosine and threonine residues present in the consensus sequence (T-X-Y). Six MAPKK family members have been identified and are designated MEK1–MEK5 and ERK3 kinase. Upstream of MAPKKs are the MAPKKKs, which include protein kinases such as Raf-1, Raf-A, and Raf-B, transforming growth factor-β (TGF-β)-activated kinase (TAK), and thousand-and-one-amino acid kinase (TAO). MAPKKKs receive information from cell surface receptors, usually through a small GTP-binding protein of the Ras superfamily. The Ras superfamily members include Ras, Rho, Rac, and Cdc42, all of which, like the Gα subunits of heterotrimeric G-protein, are activated when bound with GTP.

B. MAPK Activation through PKC- and Ca^{2+}-Dependent Pathways

Gastrin-stimulated ERK activation has been reported in a variety of cells, including the human gastric cancer cell line AGS-B, Rat1 fibroblasts, Chinese hamster ovary (CHO) cells, NIH 3T3 cells, and in

the rat pancreatic cell line AR42J. In AR42J cells, gastrin activates PKC, stimulates MAPK pathways, activates the Ras-related protein Rho, and induces c-*fos* gene expression. Inhibition of either PKC or the agonist-stimulated increase in $[Ca^{2+}]_i$ blocks gastrin-stimulated ERK activation in AR42J cells, indicating that MAPK activation requires PKC activity. Another indication of the critical role of PKC in gastrin-stimulated signal transduction is the observation that inhibitors of PKC block ERK-mediated phosphorylation and activation of the transcription factors Elk1 and Sap-1a, which regulate the activity of the serum response element (SRE) located in the c-*fos* promoter. The precise mechanism by which gastrin-stimulated PKC activates ERK is unknown. However, there is evidence in AR42J cells that gastrin stimulates rapid tyrosine phosphorylation of a complex of proteins composed of the adapter protein Shc (Src homology and collagen), Grb2 (growth factor receptor-bound protein 2), and the guanine nucleotide exchange factor Sos (son-of-sevenless), which, in turn, leads to the activation of Ras and Raf. However, in other cells, gastrin apparently regulates MAPK through a Ras-independent activation of Raf.

Gastrin stimulates both a rapid release of Ca^{2+} from intracellular stores and an influx of Ca^{2+} across the plasma membrane from the extracellular fluid. Depending on cell type and gastrin concentration, CCK-BR stimulation induces either a rapid and sustained increase in $[Ca^{2+}]_i$ or oscillatory increases in $[Ca^{2+}]_i$. Ca^{2+} oscillations have been linked to CCK-BR regulation of cell growth because gastrin-stimulated increases in DNA synthesis are blocked when the C-terminal 44 amino acids of CCK-BR are removed. Although agonist stimulation of the truncation mutant of CCK-BR causes an elevation in $[Ca^{2+}]_i$, Ca^{2+} oscillations are not induced. These data demonstrate the importance of the pattern of change in $[Ca^{2+}]_i$ in defining the specific cellular response to a particular signal. The idea that the pattern of change in $[Ca^{2+}]_i$ can encode specific cellular responses is supported by recent data showing that altering both the amplitude and the duration of intracellular Ca^{2+} oscillation affects the patterns of expression of specific genes. Neither the mechanism by which gastrin induces Ca^{2+} oscillations nor the molecular events linking Ca^{2+} oscillation to gastrin-stimulated cell growth have been discovered.

C. Gastrin Stimulates ECL Cell DNA Synthesis

Unlike parietal cells, ECL cells are capable of proliferation and are stimulated to do so by gastrin. Gastrin increases the number of isolated rat ECL cells in culture, suggesting a direct mitogenic effect, and stimulates replication of ECL cells *in vivo* as measured by [^{3}H]thymidine incorporation. Moreover, hypergastrinemia is associated with an increase in ECL cell numbers in humans and rats and with the occurrence of gastric ECL cell carcinoid tumors. Using ECL cells isolated from the small sub-Saharan rodent, *Mastomys natalensis*, it was found that gastrin stimulated a dose-dependent increase in DNA synthesis measured by an increase in the incorporation of [^{3}H]thymidine. The gastrin-induced increase in DNA synthesis was blocked by the selective MAPKK inhibitor, PD98059. These results contrast those seen with parietal cells from the same animal, which showed that gastrin had no effect on either MAPK activity or [^{3}H]thymidine incorporation.

VI. CCK REGULATION OF PANCREATIC ENZYME RELEASE AND CELL GROWTH

In the pancreas, CCK is a major regulator of digestive enzyme secretion in response to a meal. The pancreatic acini are the functional units for pancreatic exocrine secretion. The primary function of the pancreatic acinar cell is to synthesize, package, and secrete a variety of digestive enzymes, including trypsinogen, chymotrypsinogen, lipases, and pancreatic amylase. In addition to stimulating secretion, it has recently become clear that CCK also is an important factor in the regulation of acinar cell growth, energy product, gene expression, and protein synthesis. All of these responses are initiated on binding of CCK to the CCK-AR located on the basolateral membrane surface of pancreatic acinar cells (Fig. 5).

A. CCK Stimulates Phospholipase Activity and an Increase in $[Ca^{2+}]_i$

CCK-stimulated amylase release from pancreatic acinar cells requires an agonist-induced increase in $[Ca^{2+}]_i$. It appears that the G-proteins involved in CCK-mediated increases in $[Ca^{2+}]_i$ belong to the G_q subfamily of heterotrimeric G-proteins, which, through the activation of PLC, stimulate an $InsP_3$-dependent increase in $[Ca^{2+}]_i$. Pancreatic acinar cells contain all three G_q family members, which include G_q, G_{11}, and G_{14}. Studies using G-protein α-subunit-specific antibodies have demonstrated that CCK activation of PLC is inhibited by antibodies directed against the COOH-terminal domains of

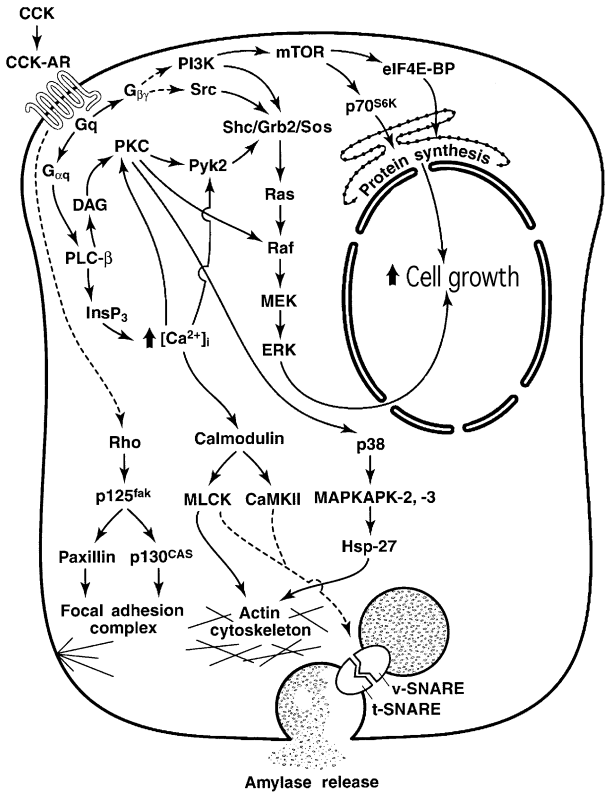

FIGURE 5 Pancreatic acinar cell. Summary of signal transduction pathways mediating cholecystokinin (CCK)-stimulated pancreatic acinar cell growth and amylase secretion (dashed lines indicate proposed pathways). PI3-K, Phosphatidylinositol 3-kinase; mTOR, mammalian target of rapamycin (protein); eIF4E-BP, elongation initiation factor binding protein; MAPKAPK, mitogen-activated protein kinase-activated protein kinase (see Figs. 3 and 4 for other abbreviations).

$G_{\alpha q}$ and $G_{\alpha 11}$, indicating the involvement of these G proteins in CCK stimulation of PLC activity.

In addition to G_{α} subunits, the $G_{\beta\gamma}$ subunits of G-proteins also activate some isoforms of PLC. Rat pancreatic acinar cells express several PLC phosphatidylinositol-specific isoforms, including PLC-β1, -β3, -γ1, and -δ1. Treatment of acinar cells with a low concentration of CCK induces an oscillating Ca^{2+}-activated chloride current across the plasma membrane. The activation of this chloride channel requires an increase in $[Ca^{2+}]_i$ and, therefore, its activity is frequently used as an experimental indicator of elevated levels of $[Ca^{2+}]_i$. Addition of purified $G_{\beta\gamma}$ subunits, via a micropipette, induced intracellular Ca^{2+} oscillations, mimicking the effect of CCK on the Ca^{2+}-activated chloride current, whereas addition of a $G_{\beta\gamma}$ scavenger blocked the Ca^{2+}-activated chloride current induced by CCK. These data suggest that $G_{\beta\gamma}$ plays a role in mediating the effects of CCK on the regulation of $[Ca^{2+}]_i$, perhaps through the regulation of specific $G_{\beta\gamma}$-sensitive PLC isoforms. However, studies using specific anti-PLC antibodies have found that only an anti-PLC-β1 antibody blocked CCK-stimulated PLC activity. PLC-β1 is generally believed to be regulated by $G_{\alpha q}$ and not $G_{\beta\gamma}$, suggesting that the effects of $G_{\beta\gamma}$ on $[Ca^{2+}]_i$ are not mediated by PLC.

In addition to $InsP_3$ and DAG, a third product of PLC activity, arachidonic acid, is involved in CCK-stimulated amylase secretion from rat pancreatic acinar cells. Several laboratories have found that CCK-induced intracellular Ca^{2+} oscillation and amylase release are mediated by arachidonic acid. Increased arachidonic acid production in response to CCK can occur through two distinct pathways. One pathway involves the action of PLC and diglyceride lipase on phosphoinositides and another involves phospholipase A_2-mediated hydrolysis of phosphatidylcholine. Both pathways appear to be involved in CCK stimulation of amylase release from acinar cells.

B. CCK Activates Ca^{2+}-Dependent Protein Kinases

The elevation in $[Ca^{2+}]_i$ induced by CCK initiates the activation of various Ca^{2+}-dependent protein kinase cascades, including Ca^{2+}-dependent isoforms of PKC and Ca^{2+}-activated calmodulin (CaM)-dependent kinases. Calmodulin is a ubiquitous 19-kDa Ca^{2+}-binding protein that is responsible for activating several acinar cell enzymes, including multiple protein kinases, in a Ca^{2+}-dependent manner. Seven distinct CaM kinases have been characterized. Four of these have been identified and/or purified from pancreatic tissue, including myosin light chain kinase (MLCK), CaM kinase I, CaM kinase II, and CaM kinase III. MLCK is believed to mediate the increased phosphorylation of myosin light chains observed in pancreatic acinar cells following stimulation with CCK. Furthermore, an inhibitor of MLCK, ML-9, blocks amylase release from acini, indicating an important role for this kinase in CCK-stimulated secretion.

Another important family of protein kinases activated, in part, by Ca^{2+} is the PKC family. The PKC enzymes are widely distributed in many tissues and phosphorylate a wide variety of substrates on serine and threonine residues. Three groups or subfamilies of PKC isoforms have been characterized based on similarities of their biochemical properties and amino acid sequences. The three subfamilies are the conventional (sometimes referred to as classical),

novel, and atypical protein kinases. The conventional PKC enzymes, which include PKC α-I, β-I, β-II, and γ, are activated by phorbol esters, such as 12-*O*-tetradecanoylphorbol-13-acetate (TPA), DAG, and Ca^{2+}. The novel PKC isoforms (δ, ϵ, η, θ), on the other hand, are activated by phorbol esters and DAG but not by Ca^{2+}. Following treatment of cells with phorbol esters, there is a translocation (activation) of PKC from the cytosol to the membranes, as defined by cell fraction experiments. CCK stimulation of pancreatic acinar cells causes the translocation of PKC enzyme activity to the membrane fraction. Also, a considerable amount of evidence supports a role for PKC in the regulation of CCK-stimulated amylase secretion. Prolonged incubation of cells with either TPA or other phorbol esters will down-regulate PKC activity within the cells. Down-regulation of PKC in guinea pig acini decreases both the magnitude and the sensitivity of CCK-stimulated amylase release without affecting the response to Ca^{2+} ionophore or VIP. Several recent studies have focused on identifying the isoforms of PKC present in acini. Western blotting using subtype-specific antibodies shows the presence of PKC α, β, δ, ϵ, and ξ. However, only the novel PKC δ and ϵ are translocated to a membrane fraction on CCK stimulation, suggesting that these Ca^{2+}-independent subtypes may mediate the stimulatory effects of CCK on amylase secretion.

C. ERKs Mediate CCK-Stimulated Acinar Cell Growth

Of the six MAPK pathways identified, three are involved in CCK-stimulated signal transduction—the ERK, JNK, and p38 MAPK cascades. In isolated rat pancreatic acini and in the rat pancreas *in vivo*, CCK stimulates a rapid and transient increase in the level of phosphorylation and kinase activity of two isoforms of ERK, ERK1 and ERK2 (also known as p44 and p42 MAPK, respectively). The activating phosphorylation of ERK1 and ERK2 results from the activation of the upstream, dual-specificity MAPK kinases, MEK1 and MEK2. Several pathways leading to MEK activation have been identified. In pancreatic acinar cells, epidermal growth factor (EGF) receptor, a tyrosine kinase receptor, activates MEKs and hence ERKs via the Shc/Grb2/Sos protein complex, as well as Ras and Raf. In contrast to EGF, CCK only weakly affects Shc/Grb2/Sos complex formation and has no measurable effect on Ras activity. However, CCK stimulation of ERK activity is blocked by inhibitors of PKC, suggesting that the major mechanism for CCK activation involves PKC-mediated, Ras-independent activation of Raf. Further support for a Ras-independent activation of ERK by CCK in acinar cells is provided by experiments using an adenoviral vector expressing a dominant-negative N17Ras. Expression of N17Ras in rat acinar cells did not affect CCK-stimulated amylase release, intracellular Ca^{2+} mobilization, or ERK activation, but completely blocked EGF-stimulated ERK activation. These data support the conclusion that, in contrast to EGF, CCK stimulates ERK activity through a Ras-independent mechanism.

D. CCK Activation of JNK: A Possible Role in Pancreatitis

Although JNKs may play a role in cell proliferation, their major role appears to be in the regulation of apoptosis, or programmed cell death, in response to stress stimuli. CCK activates two isoforms of JNK (p46 and p55) in pancreatic acini both *in vitro* and *in vivo*; however, the activation is slower than that of ERKs and also requires higher concentrations of hormone. It is well established that high concentrations of CCK can induce pancreatitis in rats and mice and that activation of JNK is one of the earliest events associated with pancreatitis. Interestingly, inhibition of JNK with a selective inhibitor blocks the edema associated with pancreatitis, suggesting a possible beneficial role for JNK in mediating the stress response. However, a role for CCK in the regulation of pancreatic JNK activity under normal conditions has not been established.

E. p38 MAPK Regulates Actin Cytoskeleton Organization

The p38 MAPKs are activated both by stresses (UV irradiation, heat, and osmotic stress) and by growth stimuli (hematopoietic growth factors). CCK rapidly activates p38 MAPK in rat pancreatic acinar cells in a time- and dose-dependent manner. In contrast to JNK activation, which requires higher (superphysiological) concentrations of CCK, maximal activation of p38 MAPK occurs between 0.3 and 1.0 n*M*. Interestingly, treatment of rat acini with higher concentrations of CCK (10 n*M*) leads to a decrease in p38 MAPK activity, suggesting that agonist concentration may be an important determinant in the selective activation of different MAPK pathways. CCK stimulation of rat acinar cells causes disruption of the actin cytoskeleton, which may be important for SNARE-mediated docking and fusion of zymogen granules with the plasma membrane. Inhibition of p38 MAPK

with the selective inhibitor SB203580 blocks the effects of CCK on actin organization. Several downstream targets of CCK-activated p38 MAPK have been identified, including MAP kinase-activated protein (MAPKAP)-2 kinase and -3, and heat-shock protein (Hsp)-27; however, the functions of these proteins in acinar cell physiology remain largely unknown.

F. CCK Regulates Protein Synthesis through the PI3-K–mTOR–p70^{S6K} Pathway

CCK regulation of digestive enzyme secretion and acinar cell growth requires new protein synthesis. The PI3-K–mTOR–p70^{S6K} pathway is the primary regulator of protein synthesis. The p70^{S6K} protein is one of two kinases that phosphorylate the small ribosomal subunit protein S6, thereby regulating the synthesis of mRNA with 5′-polypyrimidine tracts. The mammalian target of rapamycin (mTOR) protein stimulates protein synthesis by phosphorylating the elongation initiation factor binding protein eIF4E-BP (also called PHAS-1), which is the binding protein for the translation initiation factor, eIF4E. In a nonphosphorylated state, eIF4E-BP is bound to eIF4E. After phosphorylation by mTOR, eIF4E-BP dissociates from eIF4E; eIF4E then forms a complex with the scaffolding protein eIF4A and the RNA helicase eIF4G, and initiates translation. CCK stimulates phosphorylation of p70^{S6K} and eIF4E-BP in rat pancreatic acini. CCK-stimulated phosphorylation of p70^{S6K} is blocked by rapamycin, which, on binding to its intracellular receptor FKBP-12, inhibits mTOR, and by wortmannin, an inhibitor of PI3-K. Phosphorylation of eIF4E-BP and release of eIF4E are inhibited by wortmannin. The net result of treating pancreatic acinar cells with either rapamycin or wortmannin is inhibition of CCK-stimulated protein synthesis. The mechanism by which CCK activates PI3-K in acinar cells is currently unknown. However, in other cell types, $G_{\beta\gamma}$ mediates GPCR activation of the PI3-K pathway. Further studies are required to determine if a similar pathway is utilized in acinar cells.

G. CCK Regulation of Tyrosine Kinase Activity and Rho GTPase

CCK stimulation of rat pancreatic acini causes a rapid and dose-dependent phosphorylation of tyrosine residues on p125^{Fak}, p130 Crk-associated substrate (p130^{CAS}), and paxillin. The phosphorylation of these proteins does not require activation of PKC or an increase in $[Ca^{2+}]_i$ and is associated with profound alterations in the organization of the actin cytoskeleton and the assembly of focal adhesions. Treating the cells with *Clostridium botulinum* C3 toxin, an ADP-ribosyltransferase that inhibits Rho GTPase activity, blocks the CCK-stimulated tyrosine phosphorylation of p125^{Fak} and paxillin, suggesting a role for Rho in the tyrosine phosphorylation of these proteins. Elucidation of the signaling mechanisms coupling CCK to Rho-mediated changes in cytoskeleton organization will, however, require additional investigations.

Recently, Pyk2, a Ca^{2+}-dependent kinase related to p125^{Fak}, was found to be activated on CCK stimulation of acinar cells. In other cell types, Pyk2 activates ERKs through an Shc/Grb2/Sos complex. Whether a similar mechanism regulates CCK activation of ERKs in pancreatic acinar cells is not known.

VII. SECRETIN-STIMULATED SIGNALING TRANSDUCTION

Secretin is a member of a larger family of related peptides that includes GIP, VIP, parathyroid hormone (PTH), growth hormone-releasing hormone (GHRH), and exedens. All of these peptides share a high degree of amino acid sequence homology, are widely distributed in the body, and exert pleiotropic physiological effects, in many instances by acting in a paracrine manner. Secretin is the principal hormonal stimulant of pancreatic and biliary bicarbonate (HCO_3^-) and water secretion and it may contribute to pancreatic enzyme secretion. High concentrations of secretin may also contribute to gastric secretion of pepsinogen, inhibit gastric acid secretion and postprandial gastric emptying, and stimulate secretion of bicarbonate and epidermal growth factor from Bunner's glands.

The effects of secretin on target tissues result from activation of adenylyl cyclase and the subsequent generation of 3′, 5′-cyclic adenosine monophosphate (cAMP) and the activation of cAMP-dependent PKA. Studies assessing the presence of $G_{\alpha s}$ in secretin receptor-expressing cells and the ability of guanosine triphosphate (GTP) analogues to diminish radiolabeled secretin binding support the idea that secretin stimulates cAMP production through the $G_{\alpha s}$-mediated activation of adenylyl cyclase.

Additional molecular targets of secretin stimulation include cAMP-dependent activation of the cystic fibrosis transmembrane regulator Cl^-channels and translocation of the water channel, aquaporin-1, from subcellular organelles to the cell surface of rat

cholangiocytes. The latter response to secretin stimulation is inhibited by treating the cholangiocytes with colchicine, an inhibitor of microtubule polymerization. Finally, secretin-stimulated increases in cAMP result in activation of the slowly activating K^+ current (I_{Ks}) in rat pancreatic acinar cells. The signaling pathways linking cAMP to activation of these various channels are not known. Presumably, the activation of PKA is required, but further investigations are needed to confirm this mechanism.

VIII. FUTURE DIRECTIONS

Application of modern molecular biology to the study of GI hormone-regulated signal transduction has revealed complex webs of interrelated signaling pathways that regulate diverse and sometime overlapping and competing biological responses. The challenge for future investigation is to unravel the webs of signaling pathways, with the goal of understanding how specific cellular responses are generated. It is generally accepted that an important determinant of signaling specificity is the cellular context in which it occurs. One way to study signaling pathways in the appropriate physiology and cellular context is with genetically altered animal models. Transgenic and gene "knockout" animals provide a powerful tool for examining the effects of defined genetic changes in the context of the whole animal. One needs only to consider possible species differences when extrapolating the results from experimental animal models to humans. Other areas that warrant future effort are the development of human transgenic and gene-disrupted gastrointestinal cell lines, and improved methodologies for quantitative kinetic analyses of signaling pathways. After all, the real challenge to unraveling the complex signaling networks is to distinguish between what is functionally possible and what is biologically important.

Glossary

cholera toxin An A-B-type bacterial toxin produced by the bacterium *Vibrio cholerae*; catalyzes transfer of the ADP-ribose moiety of nicotinamide dinucleotide to the α-subunit of G-proteins of the G_s subfamily, resulting in their constitutive activation.

enterochromaffin-like cells Histamine-producing cells located in the gastric glands of the stomach.

mitogen Substance that induces an increase in cell proliferation, usually by stimulating DNA, RNA, and protein synthesis.

pancreatitis Acute or chronic inflammation of the pancreas.

paracrine Describes the relationship between a hormone-releasing cell and its target cell. Hormones that act in a paracrine manner are released from a cell into the extracellular space and act on adjacent target cells without reaching the general circulation.

parietal cells Acid-producing cells located in the gastric glands of the stomach.

pertussis toxin An A-B-type bacterial toxin produced by the bacterium Bordetella pertussis; catalyzes transfer of the ADP-ribose moiety of nicotinamide dinucleotide to the α-subunit of G-proteins of the $G_{i/o}$ subfamily, resulting in their inactivation.

protein kinases Class of enzymes that catalyze the transfer of the γ phosphate from ATP to the amino acid side chains of substrate proteins. Typically, the phosphate is transferred to serine, threonine, or tyrosine residues within a protein. Generally, the activity of a protein kinase is directed to a specific consensus site, consisting of several amino acids in a defined sequence.

Gastrointestinal Hormone-Releasing Peptides

JAN-MICHEL OTTE*, JAROSLAW WALKOWIAK†, AND KARL-HEINZ HERZIG*,‡

*Christian-Albrechts-Universität, Germany • †Karol Marcinkowski University of Medical Sciences, Poland • ‡University of Kuopio, Finland

Since the discovery and isolation of the first gastrointestinal hormones, secretin, gastrin, and cholecystokinin, more than 100 different biologically active gut peptides have been discovered. These peptides regulate gut motility, secretion, digestion, and adsorption of nutrients. In the past decade, much interest has been generated regarding the hypothesis that the secretion of gastrointestinal hormones is regulated, in part, by releasing factors produced in the gut. The purpose of this article is to describe these releasing factors.

I. CHOLECYSTOKININ/SECRETIN-RELEASING FACTORS

A. Lumenal Cholecystokinin-Releasing Factor

Lumenal cholecystokinin (CCK)-releasing factor (LCRF) was isolated originally from a jejunal perfusate of conscious rats. The peptide has a molecular mass of 8136 Da and is composed of 70–75 amino acids. LCRF exhibits a unique amino acid composition with no sequence homology. Microsequence analysis revealed only a partial N-terminal sequence of 41 residues; the remainder of the LCRF sequence structure has not been described. LCRF-like immunoreactivity has been found throughout the gut, including the pancreas, with the highest levels in the small intestine. Immunohistochemistry showed strong staining of the epithelium of intestinal villi, Brunner's glands, myenteric plexus, gastric pits, and pancreatic ductules and islets. The natural endogenous peptide and different synthetic fragments ($LCRF_{1-41}$, $LCRF_{1-35}$, and $LCRF_{11-25}$, but not $LCRF_{1-6}$) have significant CCK-releasing activity.

The N-terminal fragment of LCRF, $LCRF_{1-35}$, significantly stimulated CCK release in a dose-dependent manner (5–200 n*M*) from dispersed human intestinal mucosa cells. In the rat, diversion-stimulated pancreatic exocrine secretion is inhibited by somatostatin, peptide YY (PYY), and the bile acid taurocholate. One report shows that in conscious rats, somatostatin does not affect lumenal LCRF levels but inhibits diversion-stimulated CCK release and pancreatic enzyme secretion, suggesting that LCRF secretion is not regulated by somatostatin. The effect of PYY or bile acids on LCRF-stimulated CCK release has not been described. Another report shows that a diversion-stimulated increase of LCRF in the duodenal lumen was not inhibited by atropine and that intraduodenal and intravenous administration of the synthetic somatostatin analogue octreotide inhibited CCK release and lowered LCRF and pancreatic secretion stimulated by bile and pancreatic juice diversion in rats, indicating that somatostatin may have a role in the regulation of LCRF secretion. Further work needs to be done to examine the role of endogenous LCRF in nutrient-induced CCK secretion and its interaction with other CCK-releasing factors.

B. Diazepam-Binding Inhibitor

In the search for a CCK-releasing factor, another peptide, diazepam-binding inhibitor (DBI), was isolated and sequenced from porcine intestinal mucosa; the peptide consists of 86 amino acids and has a molecular mass of 9810 Da. DBI was first isolated from rat brain and was named for its ability to displace diazepam from the γ-aminobutyric acid type A receptor. DBI has been detected in a number of organs outside the central nervous system, with the highest concentration in the liver, duodenum, testis, kidney, and adrenals. DBI_{1-86} and DBI_{32-86} have been found in the porcine duodenum. The primary structure of this protein is highly conserved. In agreement with its wide distribution, multiple biological functions have been described for this protein. In addition, DBI has been reported to function as a high-affinity acetyl coenzyme A-binding protein in the liver, to stimulate steroidogenesis in adrenal cells, to act as an autocrine/paracrine regulator of Leydig cell function, and to inhibit glucose-stimulated insulin release. DBI immunoreactivity is detected in the endocrine pancreas and in the secretory epithelial cells of the gut. Intraduodenal infusion of synthetic porcine DBI in rats significantly stimulates pancreatic amylase output and CCK release, which is completely blocked by the CCK antagonist MK326. In anesthetized rats with pancreaticobiliary and intestinal cannula, a 2-fold increase in pancreatic protein secretion accompanied by a 10-fold increase in CCK

plasma levels has been observed. These increases were paralleled by a 4-fold increase in lumenal DBI levels. Furthermore, after 5 h of bile–pancreatic diversion and return of CCK levels to baseline, intraduodenal infusion of peptone significantly stimulated DBI release, which was blocked by a DBI antibody. Previously, it has been shown that peptone, but not casein, maltose, or L-amino acids, stimulated the secretion of CCK-releasing peptide into the lumen. 5-HT_3 and substance P antagonists blocked peptone-stimulated secretion. Based on these findings, Li and Owyang suggested that peptone stimulates serotonin release, which activates the sensory substance P neurons in the submucosal plexus. Signals are then transmitted to cholinergic interneurons and epithelial CCK-releasing peptide (CCK-RP)-containing cells via cholinergic secretomotor neurons (Fig. 1).

Regulation of DBI-induced CCK release has been shown *in vitro* in isolated intestinal mucosal cells. Somatostatin inhibited DBI-stimulated CCK release in a dose-dependent manner. This inhibition could be reversed by pertussis toxin, indicating that somatostatin acts via its receptor on CCK cells (I cells) coupled to an inhibitory guanine nucleotide-binding protein of adenylate cyclase. In contrast to somatostatin, neither PYY nor taurocholate affects DBI-stimulated CCK release, suggesting that these substances act through other mechanisms to inhibit feedback-stimulated exocrine pancreatic secretion.

C. Secretin-Releasing Peptide

Intestinal secretin regulates pancreatic water and bicarbonate secretion. Secretin is released from S cells in the upper small intestine by various stimuli such as gastric acid, fatty acids, and bile salts. In addition, several neuropeptides such as pituitary adenylate cyclase-activating polypeptide (PACAP), gastrin-releasing peptide (GRP), and serotonin via 5-$HT_{2/3}$ receptors stimulate the release of secretin. Diversion of pancreatic juice from the duodenum increases plasma levels of secretin in addition to CCK,

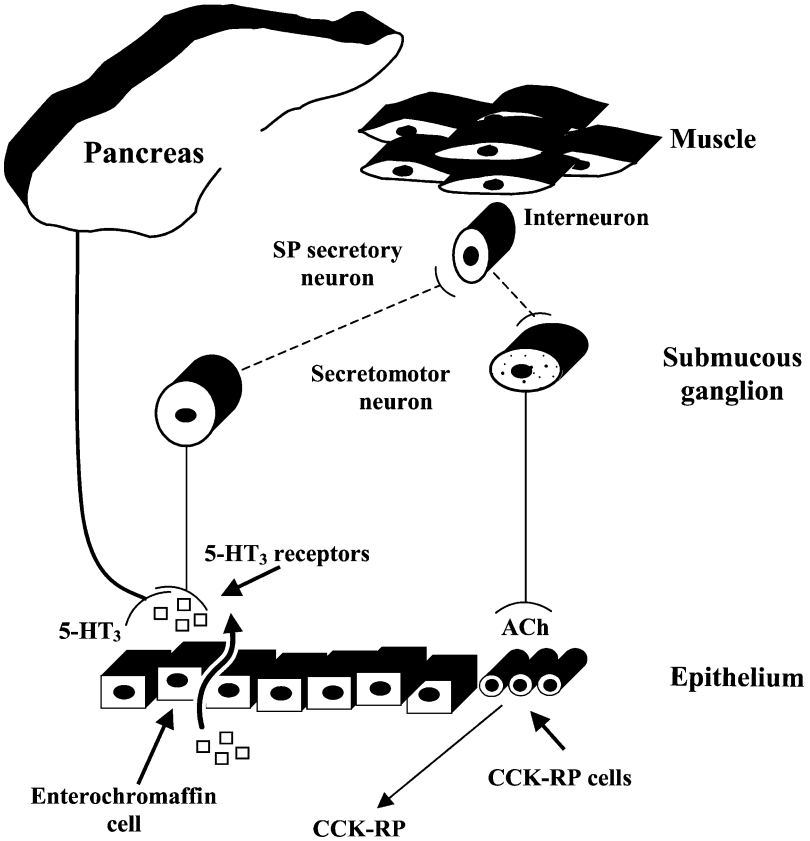

FIGURE 1 Model of the neuroendocrine control of the secretion of CCK-releasing peptide (CCK-RP). Peptone stimulates CCK-RP secretion by activating intestinal submucosal cholinergic neurons. Ach, acetylcholine. Adapted from Li, Y., and Owyang, C. (1996). Peptone stimulates CCK-releasing peptide secretion by activating intestinal submucosa cholinergic neurons. *J. Clin. Invest.* **97**, 1463–1470.

indicating a regulatory feedback control mechanism for secretin release. To further investigate the mechanism of this feedback regulation, donor rats were intraduodenally perfused with 0.01% hydrochloric acid. Reinfusion of the adjusted pH and threefold concentrated perfusate into a recipient rat significantly stimulated volume flow, bicarbonate output, and plasma secretin levels. These effects were completely blocked by intravenous infusion of rabbit anti-secretin serum 15 min prior to the intraduodenal perfusion of the concentrated perfusate from the donor rats. Treatment of the perfusate with trypsin also abolished the effect, suggesting that acid-stimulated secretin release is mediated by a peptide produced in the upper small intestine. The release and action of this peptide have been shown to be neuromodulated. Recently, a secretin-releasing peptide has been demonstrated in canine pancreatic juice. Two peptides of 14,061 and 14,053 Da have been isolated and sequenced with identical or substantial sequence homology to the canine pancreatic phospholipase A2. Testing commercially available porcine pancreatic phospholipase A2 revealed a dose-dependent stimulation of secretin release from murine intestinal CCK cells (STC-1 cells) and from isolated rat duodenal mucosa. Preincubation of the concentrated intestinal perfusate from donor rats with polyclonal rabbit porcine phospholipase A2 antibodies significantly suppressed secretin-releasing activity in recipient rats. The physiological relevance of duodenal and pancreatic phospholipase A2 still needs to be investigated and defined.

D. Monitor Peptide

Diversion of pancreatic juice or the intraduodenal instillation of protease inhibitors results in a reduced tryptic activity in the duodenal lumen and enhances CCK-stimulated pancreatic enzyme secretion. Intraduodenal trypsin infusion, on the other hand, inhibits pancreatic exocrine secretion. In addition to this negative feedback mechanism in the absence of pancreatic secretion entering the duodenum, a "positive feedback" mechanism has been demonstrated in which a secreted product in the pancreatic juice itself stimulates further secretion by CCK release. Funakoshi and co-workers isolated a novel peptide from pancreatic juice and named it "monitor peptide" for its putative function of monitoring the intraduodenal environment. Purification and sequencing of monitor peptide revealed 61 amino acids exhibiting substantial homology to the family of pancreatic secretory trypsin inhibitors. The human form of monitor peptide has not been characterized. Despite being a member of the family of protease inhibitors, monitor peptide directly stimulates CCK release during vascular perfusion of the intestine devoid of intralumenal proteases and from isolated, perfused intestinal mucosal cells. Monitor peptide directly increased intracellular calcium concentrations in an enriched population of intestinal CCK cells. In addition, a reversible, temperature- and pH-dependent binding to dispersed intestinal mucosal cells has been shown. Monitor peptide-binding sites exist throughout the small intestine, corresponding to the distribution of CCK cells. ^{125}I-monitor peptide-binding sites have been found only on the villi and not in the crypts of the small intestine. CCK stimulated the transcription of monitor peptide in a Ca^{2+}-dependent and protein kinase C-independent manner. In chronically ethanol-fed rats, monitor peptide mRNA levels were elevated more than four times in the pancreas, indicating that monitor peptide may contribute to the observed hypersecretion during chronic alcohol consumption.

II. FUTURE PERSPECTIVES

Another process, apart from pancreatic secretion, that is also regulated by a complex interaction of neural, paracrine, and endocrine signals from the brain and gastrointestinal tract involving different releasing peptides, is gastric acid secretion (Fig. 2). Gastric acid secretion reflects a balance between histamine-induced stimulation and somatostatin-induced

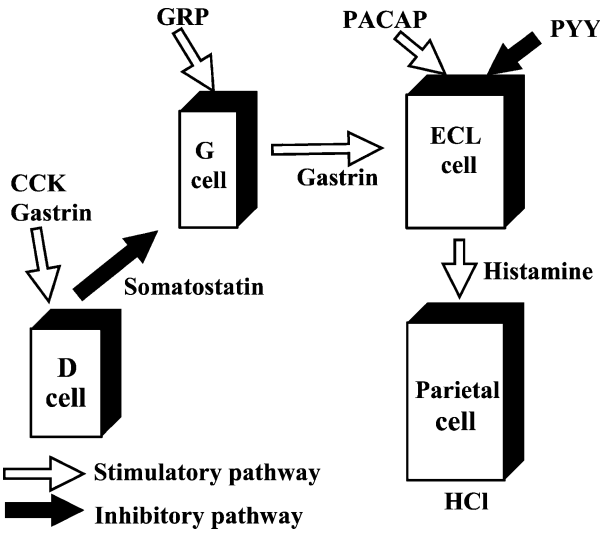

FIGURE 2 Gastric acid secretion regulated by releasing factors influencing gastrin and histamine release.

inhibition, with gastrin acting as a "histamine-releasing peptide" and CCK and CGRP acting as "somatostatin-releasing peptides." In a recent animal study, endothelin, met-enkephalin, PYY, PACAP, and vasoactive intestinal peptide (VIP) were also shown to have strong stimulatory, concentration-dependent effects on ECL-cell histamine mobilization.

Gastrointestinal hormone-releasing peptides also have an important role in nutrient-mediated insulin secretion. These releasing peptides, the incretins, functionally link the intestine and pancreatic beta cells, thereby generating the "entero-insular axis" (Fig. 3). Incretins contributing to the entero-insular axis in a paracrine or neuronal fashion include gastric inhibitory polypeptide (GIP), glucagon-like polypeptide-1 [GLP-1 (7–36) amide], islet amyloid peptide (Amylin), CCK, GRP, and VIP. To date, the most physiologically relevant incretins are GIP and GLP-1 (7–36) amide.

In addition, peptides that play a role in the regulation of gastrointestinal function either by their own actions or by the release of other peptides have recently been identified. These include leptin, ghrelin, orexin, and apelin. Ghrelin can be regarded as an important regulatory peptide that potentially links enteric nutrition with growth hormone secretion, growth, and food intake. Orexin has been proposed to stimulate the secretion of insulin, leptin, and serotonin. Finally, apelin is the newest member of the growing family of CCK-releasing peptides. The physiological significance of apelin in protease-mediated feedback regulation of CCK and pancreatic exocrine secretion and its interaction with DBI and LCRF still needs to be investigated.

Glossary

cholecystokinin A peptide hormone that is secreted by mucosa endocrine cells (I cells) of the upper small intestine and that stimulates pancreatic exocrine secretion, stimulates gallbladder contraction, and inhibits gastric emptying.

diazepam-binding inhibitor One of the putative releasing factors for cholecystokinin.

lumenal Facing the interior of a cell or the interior cavity (lumen) of an organ; e.g., a releasing factor may be secreted directly into the intestinal lumen where it acts on the lumenal side of gut hormone cells localized in the intestinal epithelium.

negative feedback A type of feedback regulation in which the final product of a pathway acts to inhibit the first reactions in the pathway.

releasing factor A small peptide/protein produced in the gastrointestinal tract and/or pancreas that stimulates the secretion of gut hormones; levels of these releasing factors in the gut lumen may be regulated, in part, by degradation from pancreatic enzymes.

Ghrelin

GUIYUN WANG, HEUNG-MAN LEE, ELLA W. ENGLANDER, AND GEORGE H. GREELEY JR.
Shriners Hospitals for Children and University of Texas Medical Branch, Galveston

Ghrelin is a recently discovered ligand for the growth hormone secretagogue receptor. Ghrelin is expressed primarily in stomach endocrine cells; administration of ghrelin to animals stimulates growth hormone secretion, food intake, and weight gain. Overall, present findings suggest that ghrelin has a role in regulation of energy balance and expenditure and serves as an endocrine link between the stomach, pituitary, and hypothalamus.

I. INTRODUCTION

Growth hormone (GH) secretion from the pituitary gland is under the regulation of two hypothalamic hormones, GH-releasing hormone (GHRH) and somatotropin release-inhibiting factor (SRIF; somatostatin). GHRH stimulates GH release whereas SRIF inhibits GH secretion. Development of synthetic GH-releasing peptides (GHRPs) (i.e., GHRP-6, hexarelin) that stimulate GH secretion through a non-GHRH receptor has led to the hypothesis that there are unique, endogenous GH-releasing peptides distinct from GHRH. This non-GHRH receptor has been determined to be a growth hormone secretagogue receptor. Cloning of a novel G-protein-coupled receptor for the GH-releasing peptides bolstered the hypothesis of unique GH-releasing peptides, and, more recently, the endogenous ligand for the growth hormone secretagogue receptor was cloned. Two separate groups concurrently characterized and named the native ligand, one group calling the peptide ghrelin and the other group naming it motilin-related peptide. Ghrelin is the name used in this article.

II. STRUCTURE

Ghrelin is a 28-amino-acid peptide (Fig. 1) with an n-octanoylated Ser-3 residue. The n-octanoylation is essential for biological activity. Although present data show that only the first five amino acid residues are necessary to maintain the biological activity of ghrelin, additional work must be done to show that the pentamer retains all of the biological activities of ghrelin (1–28). The cDNAs for rat, mouse, dog, and human ghrelin have been cloned. Human ghrelin is homologous to rat ghrelin with the exception of two residues. A second endogenous ghrelin variant from a missing rat stomach extract has been described; this

Shriners Hospitals for Children and University of Texas Medical Branch, Galveston

Ghrelin is a recently discovered ligand for the growth hormone secretagogue receptor. Ghrelin is expressed primarily in stomach endocrine cells; administration of ghrelin to animals stimulates growth hormone secretion, food intake, and weight gain. Overall, present findings suggest that ghrelin has a role in regulation of energy balance and expenditure and serves as an endocrine link between the stomach, pituitary, and hypothalamus.

I. INTRODUCTION

Growth hormone (GH) secretion from the pituitary gland is under the regulation of two hypothalamic hormones, GH-releasing hormone (GHRH) and somatotropin release-inhibiting factor (SRIF; somatostatin). GHRH stimulates GH release whereas SRIF inhibits GH secretion. Development of synthetic GH-releasing peptides (GHRPs) (i.e., GHRP-6, hexarelin) that stimulate GH secretion through a non-GHRH receptor has led to the hypothesis that there are unique, endogenous GH-releasing peptides distinct from GHRH. This non-GHRH receptor has been determined to be a growth hormone secretagogue receptor. Cloning of a novel G-protein-coupled receptor for the GH-releasing peptides bolstered the hypothesis of unique GH-releasing peptides, and, more recently, the endogenous ligand for the growth hormone secretagogue receptor was cloned. Two separate groups concurrently characterized and named the native ligand, one group calling the peptide ghrelin and the other group naming it motilin-related peptide. Ghrelin is the name used in this article.

II. STRUCTURE

Ghrelin is a 28-amino-acid peptide (Fig. 1) with an n-octanoylated Ser-3 residue. The n-octanoylation is essential for biological activity. Although present data show that only the first five amino acid residues are necessary to maintain the biological activity of ghrelin, additional work must be done to show that the pentamer retains all of the biological activities of ghrelin (1–28). The cDNAs for rat, mouse, dog, and human ghrelin have been cloned. Human ghrelin is homologous to rat ghrelin with the exception of two residues. A second endogenous ghrelin variant from a missing rat stomach extract has been described; this

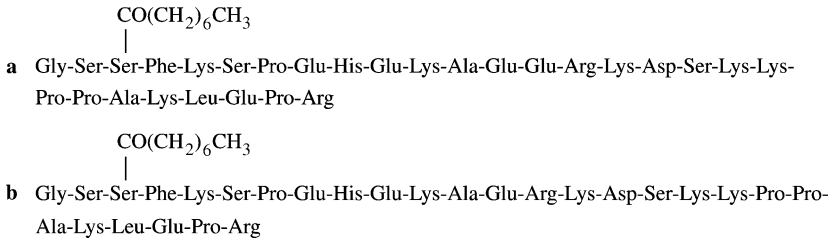

FIGURE 1 Amino acid sequences of (a) rat ghrelin-28 and (b) *des*-Gln^{14}-ghrelin.

ligand, called *des*-Gln^{14}-ghrelin, is a 27-residue peptide and its sequence is identical to that of ghrelin except for a glutamine. *Des*-Gln^{14}-ghrelin has an n-octanoyl modification at Ser-3, like ghrelin, which is essential for biological activity. Genomic sequencing and cDNA analysis indicate that *des*-Gln^{14}-ghrelin is not encoded by a gene distinct from the ghrelin gene but is encoded by an mRNA created by alternative splicing of the ghrelin gene, making this the first described example of a novel mechanism that produces peptide multiplicity.

III. DISTRIBUTION

Reports on the endocrine cell types expressing ghrelin in the stomach are conflicting. A mouse study demonstrates that ghrelin is expressed in stomach enteroendocrine cells that also express either chromogranin A (CGA) (a marker of endocrine cells), serotonin, or somatostatin. The same report shows that ghrelin is also expressed in stomach cells that do not express CGA or serotonin. Additionally, the mouse study reports that ghrelin expression is detected in the testis but not in various brain regions (including the olfactory bulb, hippocampus, cerebellum, cortex, and striatum) nor in mammary glands, uterus, ovary, kidney, thymus, liver, and spleen. Immunohistochemical localization of ghrelin shows a few ghrelin-containing cells in mouse crypts and villi of the duodenum and among the mucous cells of Brunner's glands. A separate rat/human study shows that stomach ghrelin is not co-expressed with somatostatin, serotonin, or histamine and is strictly localized in the X/A-like endocrine cell of the oxyntic mucosa, which accounts for approximately 20% of the endocrine cells in the oxyntic gland. The rat study shows that ghrelin-immunoreactive cells are abundant from the neck to the base of the rat oxyntic gland and rare in the pyloric gland. Ghrelin-immunoreactive cells are also found in the upper small intestine and are marginally dispersed in the distal small intestine and colon.

Radioimmunoassay (RIA) studies show a gradient of ghrelin expression in the rat gastrointestinal tract, with the mucosal layer of the stomach fundus expressing the highest concentration and lower levels in the antrum of the stomach, duodenum, jejunum, ileum, and colon. Ghrelin is not expressed in the fetal rat stomach, although its expression increases dramatically during the second and third postnatal weeks.

There are conflicting reports on the expression of ghrelin in the rat pancreas, kidney, and liver. Ghrelin and its receptor are reported to exist in the mouse kidney. Ghrelin is also expressed in other, nonenteric sites, including the placenta and hypothalamus. The ghrelin receptor shows a widespread distribution, suggesting multiple paracrine, autocrine, and endocrine roles for ghrelin. The ghrelin receptor is found in the pituitary gland, hypothalamus, stomach, heart, lung, pancreas, intestine, and adipose tissue.

IV. ACTIONS

The biological activities of ghrelin indicate that ghrelin has a global role in the regulation of body metabolism and energy expenditure. Ghrelin administered systemically and intracerebroventricularly (ICV) stimulates GH secretion in rats, and systemically administered ghrelin stimulates GH secretion in humans (Table 1). In humans, ghrelin is more potent than GHRH and hexarelin and causes an approximately 15-fold elevation in plasma GH levels. The rise in plasma GH levels persists for longer than 60 min. In rats, the stimulatory effect of ghrelin on GH secretion is both rapid and transient because plasma GH values peak within 10 min after its administration and return to basal values within 40–60 min. The plasma GH responses to ghrelin, when expressed as a percentage of basal values, are similar during troughs and peaks of the spontaneous

pulsatile GH secretion in rats. Ghrelin will also stimulate GH secretion when given to rat pituitary cells in culture. In rodents, ghrelin given systemically stimulates release of gastrin and insulin. In rats, ICV-administered ghrelin stimulates ACTH and prolactin secretion and inhibits TSH secretion (Table 1). Leptin and prolactin are unchanged by ghrelin administration in rats. In humans, systemic ghrelin stimulates ACTH, prolactin, cortisol, aldosterone, epinephrine, and GH secretion. Changes in luteinizing hormone (LH), follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH) secretion are not observed in response to ghrelin administration in humans. The prolactin, ACTH, and cortisol-releasing actions of ghrelin are consistent with the stimulatory effects of hexarelin, a synthetic GH-releasing peptide. The releasing action of ghrelin on GH, ACTH, and prolactin are probably mediated at the pituitary and hypothalamic levels. Because the cortisol-releasing effect of hexarelin is absent when the pituitary is separated from the hypothalamus, the stimulatory action of ghrelin on cortisol secretion is most likely mediated by ACTH. The epinephrine-releasing action of ghrelin is probably a direct action on the adrenals because binding sites for ghrelin are present on the adrenal glands.

Another intriguing biological activity of ghrelin is its ability to stimulate food intake and weight gain when given to rodents either ICV or systemically. This is not surprising, however, because synthetic GHRPs stimulate food intake and growth in rats. Ghrelin also reduces fat utilization in rats. Ghrelin was found to be more potent than any other orexigenic peptide except neuropeptide Y (NPY). In mice, the rank order of potency for increasing ingestive behavior was NPY > ghrelin > agouti-related protein (AGRP) > orexin A > orexin B > melanin-concentrating hormone (MCH). The orexigenic activity of systemically administered ghrelin is dependent on vagal afferent pathways and is consistent with earlier reports that central administration of GHRP-6 and KP-102, two synthetic GH secretagogues, stimulates food intake and weight gain in rats. Mechanistically, the orexigenic actions of ICV-administered ghrelin are apparently mediated by brain circuits for NPY and AGRP, two peptides with potent orexigenic actions in the rodent brain. The orexigenic action of ghrelin is blocked by ICV injection of an NPY/Y1 receptor antagonist and ghrelin antagonizes the leptin-induced reduction in food intake through the activation of hypothalamic NPY/Y1 receptor pathway.

In terms of stomach effects, ghrelin, given systemically or ICV, stimulates gastric acid secretion in rats. Systemic ghrelin also stimulates gastric motility in rats and either centrally or systemically administered ghrelin stimulates gastric emptying in mice. The stimulatory action of ghrelin on acid secretion is mediated via a vagus-dependent cholinergic pathway based on the fact that its effects are blocked by atropine or bilateral cervical vagotomy but not by a histamine H_2 receptor antagonist. Because intravenous ghrelin stimulates gastrin secretion in rats, the stimulatory action of ghrelin on acid secretion may be mediated partly by gastrin. Ghrelin administered ICV induces expression of c-*fos* in neurons of the nucleus of the solitary tract and the dorsal motor nucleus of the vagus nerve. These are regulatory sites for gastric secretion in the brain. Together, these findings suggest that ghrelin has a role in the vagal-mediated control of gastric function.

V. REGULATION OF GHRELIN EXPRESSION AND SECRETION

Because ghrelin is postulated to be involved in regulation of metabolism and energy expenditure, we would anticipate that ghrelin expression and secretion are influenced by metabolic hormones. Stomach ghrelin expression is up-regulated under conditions of negative energy balance and down-regulated with a positive energy balance. In fasted rats, stomach ghrelin expression and secretion increase significantly, and with refeeding ghrelin expression and secretion decrease. Insulin and leptin, given acutely, up-regulate ghrelin expression in rodents. Interestingly, plasma ghrelin levels are reduced in obese humans, which is thought to reflect excess caloric intake. This human study suggests that the decrease in plasma ghrelin levels is due to elevated insulin or leptin levels. The human study also concluded that the decreased plasma ghrelin levels are a physiological adaptation to the positive energy balance associated with obesity.

Glossary

antrum of the stomach Gastrin-producing portion of stomach.

ghrelin A stomach peptide hormone that stimulates growth hormone secretion and food intake.

growth hormone-releasing hormone Hypothalamic hormone that stimulates growth hormone release.

growth hormone-releasing peptide Peptide that stimulates growth hormone secretion through a receptor other than a growth hormone-releasing hormone receptor.

growth hormone secretagogue receptor The unique receptor for a growth hormone-releasing peptide.

oxyntic mucosa Acid-secreting portion of stomach.

somatostatin Hypothalamic somatotropin release-inhibiting factor that inhibits growth hormone secretion.

Gibberellins

VALERIE M. SPONSEL
University of Texas, San Antonio

Gibberellins are tetracyclic diterpenes that are found in plants and fungi. A few of the 126 gibberellins identified to date are known to be active hormones that are involved in seed germination, seedling emergence, stem elongation, and flower and fruit development. The gibberellin receptor has not yet been conclusively identified.

I. INTRODUCTION

To date, 126 gibberellin A (GA) compounds from plants and fungi have been characterized. They have been named in chronological order of their discovery (GA_1 to GA_n). All GAs are diterpenes with the same tetracyclic skeleton, but they differ in the types and positions of functional groups. Although individual plant species may contain >20 different GAs, probably only one GA in each species has intrinsic biological activity and is the active hormone. The others are either precursors or deactivation products of the active hormone. GAs are present in vegetative tissues at concentrations ranging from 0.1 to 100.0 ng g^{-1} fresh weight. The concentrations may be several orders of magnitude higher in developing seeds, which historically have been an excellent source of GAs for characterization. Developing seeds have also been useful sources of biosynthetic enzymes for determining metabolic pathways. Moreover, germinating cereal grains have been a model system for studying GA action because of the role GAs play in inducing synthesis and secretion of α-amylase. Another notable action of GAs is on stem growth. Some plants treated with biologically active GAs in excess of their natural levels can be made to grow exceedingly tall. In contrast, plants treated with growth retardants that inhibit GA biosynthesis and plants in which GA biosynthesis is genetically blocked are dwarfs. GAs act in stem growth via an enhancement of both cell division and cell elongation. GAs also promote flowering, male fertility, and fruit development.

II. HISTORY

Gibberellins get their unusual name from the fungus *Gibberella fujikuroi*, from which they were first isolated. *Gibberella fujikuroi*, a pathogen of rice, causes severe stem overgrowth, commonly known as "foolish seedling disease." Early work on the characterization of growth-promoting factors produced by the fungus led to the first isolation of GAs. It became apparent in the 1950s that plants contain similar GAs to those in *Gibberella*, although at much lower levels than in the fungus. Application of GAs to a variety of dwarf or nonflorally induced plants led to striking effects on growth and flowering, paving the way for the designation of GAs as a new class of plant hormone.

III. STRUCTURE

Gibberellins are tetracyclic diterpenes with an *ent*-gibberellane ring structure (Fig. 1). They contain either 20 or 19 carbon atoms. The C_{20} GAs, e.g., GA_{12} (Fig. 1), which have the full complement of 20 carbons, are precursors of the C_{19} GAs. The C_{20} GAs do not have bioactivity per se. Although there are large numbers of C_{19} GAs, many of these do not have all the structural requirements for bioactivity, which include the presence of a 3β-hydroxyl group and absence of a 2β-substituent. Of the C_{19} GAs that fulfill these criteria, GA_1 (Fig. 1), GA_3, GA_4, and GA_7 are the most active. Their high biological activity

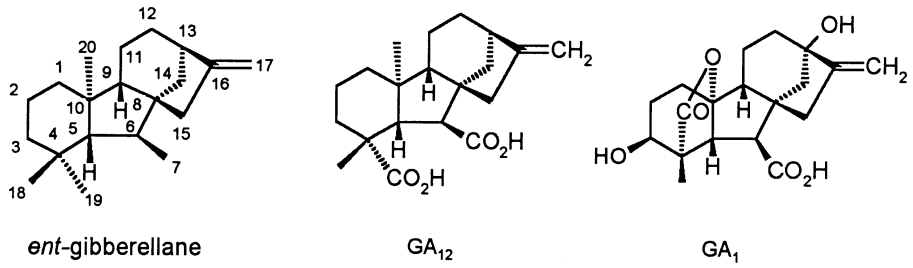

FIGURE 1 The *ent*-gibberellane skeleton, which is common to all gibberellins (GAs); GA_{12} is a C_{20} GA with the full diterpenoid complement of 20 carbons, and bioactive GA_1 is a C_{19} GA that has lost carbon 20.

undoubtedly explains why these GAs were among the very first to be isolated. In most species, GA_1 is considered to be the active hormone. However, in *Arabidopsis thaliana*, GA_4 (13-deoxyGA_1) appears to be more bioactive than GA_1, and is suggested to be the active hormone. There is also evidence that additional GAs may have activity in the control of flowering. GA_3, also known as gibberellic acid, is the major GA in *G. fujikuroi* and is produced commercially from fungal fermentations. GA_3 has many commercial uses in horticulture, agronomy, and brewing.

IV. BIOSYNTHESIS AND METABOLISM

Biosynthesis of GAs in plants can be divided into three parts. The first part occurs in plastids and involves biosynthesis of a tetracyclic hydrocarbon, *ent*-kaurene (Fig. 2). In the second part of the pathway, which occurs in the endoplasmic reticulum, *ent*-kaurene is oxidized sequentially and is converted to the first-formed GA, GA_{12} (Fig. 3). The third part of the pathway occurs in the cytosol and it can produce the multiplicity of C_{20} and C_{19} GAs known to be present in most plants.

The diterpenoid nature of GAs indicates that they are synthesized from isopentenyl diphosphate (IPP), which is the universal 5-carbon building block for all terpenoids. The classical route to IPP is the acetate/mevalonate (MVA) pathway. This pathway is located in the cytosol and leads to sesquiterpenoids (containing 15 carbon atoms) and triterpenoids (30 carbons). In the past 10 years, a second biosynthetic route to IPP has been discovered in bacteria, algae, some protozoa, and plants. This is the 1-deoxy-D-xylulose 5-phosphate (DOXP) pathway (Fig. 2), and in eukaryotes this new pathway occurs only in plastids. IPP formed in chloroplasts and other types of plastids is further converted to monoterpenes (10 carbons), diterpenes (20 carbons), and tetraterpenes (40 carbons). Therefore, DOXP-derived IPP might be expected to be the precursor of GAs, because they are diterpenes. Although the synthesis of GAs by this route has not been demonstrated unequivocally, it is generally assumed that the DOXP pathway will be the major biosynthetic route to GA precursors.

Briefly, in the DOXP pathway, a two-carbon unit (derived by decarboxylation of pyruvate) is added to glyceraldehyde 3-phosphate to give DOXP. The reaction is catalyzed by DOXP synthase and seems to be a point of regulation in the pathway. The gene encoding DOXP synthase in several plants is expressed in a developmental and tissue-specific manner. The next reaction, catalyzed by DOXP reductoisomerase, involves the reduction and intramolecular rearrangement of the linear DOXP to give a branched structure, 2-C-methyl-D-erythritol 4-phosphate (MEP). The route from MEP to IPP is only partially defined (Fig. 2), but all reactions so far elucidated take place in plastid stroma.

Subsequent condensation of IPP and its isomer, dimethylallyl diphosphate, gives the monoterpene, geranyl diphosphate (GPP). Two molecules of GPP combine to give the linear diterpene, geranylgeranyl diphosphate (GGPP). At GGPP the pathway branches in several directions, with separate branch pathways leading to the carotenoids, to the phytoene side chain of chlorophyll, to the nonaprenyl side chain of plastoquinone, and to the *ent*-kaurenoids and GAs. Only the branch to the *ent*-kaurenoids and GAs is considered here.

En route to GAs, cyclization of the linear GGPP to the tetracyclic *ent*-kaurene occurs in two stages (Fig. 2). GGPP is converted first to a bicyclic compound, *ent*-copalyl diphosphate, by *ent*-copalyl diphosphate synthase (CPS). *ent*-Copalyl diphosphate is converted to the tetracyclic compound *ent*-kaurene in a reaction catalyzed by *ent*-kaurene synthase (KS). CPS is present at much lower levels than KS, and so CPS is thought to have an important "gatekeeper"

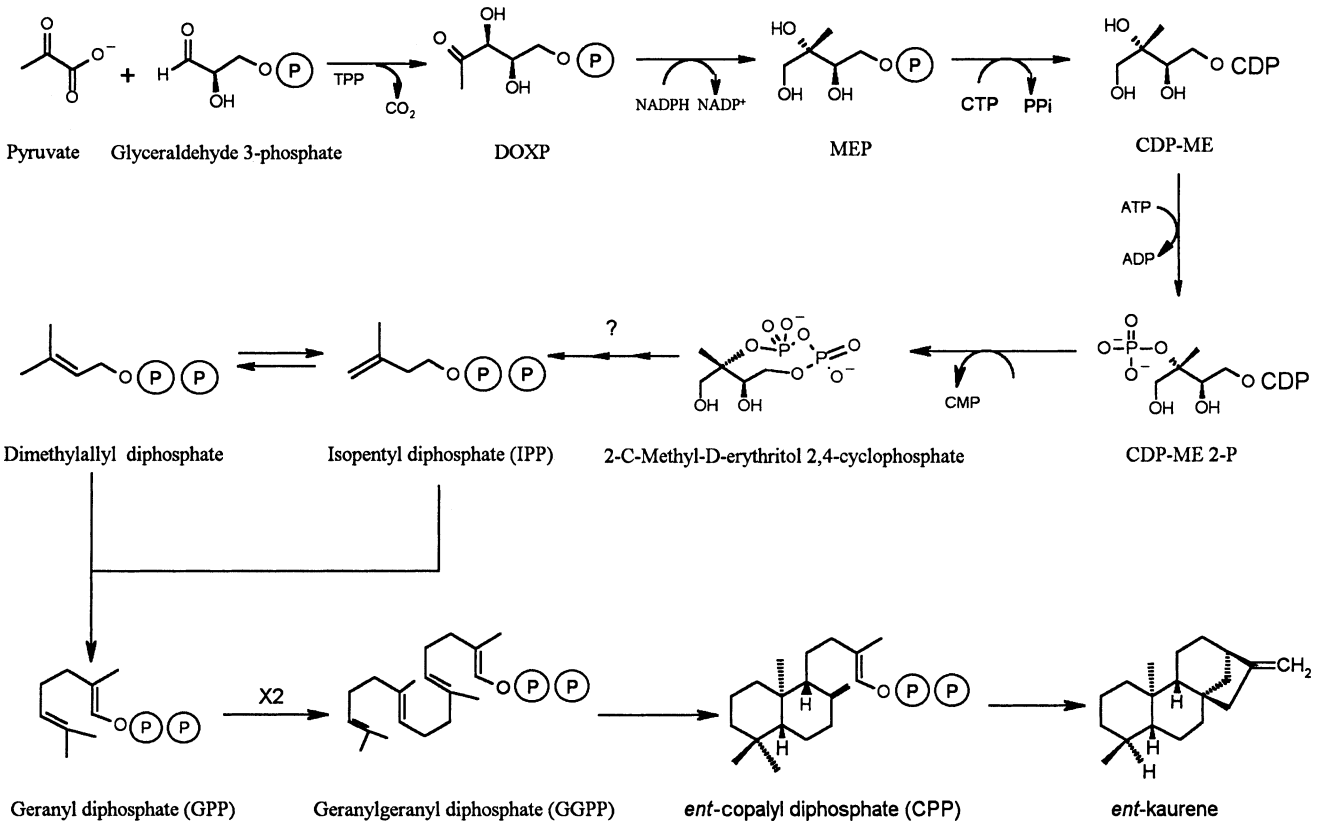

FIGURE 2 The 1-deoxy-D-xylulose 5-phosphate (DOXP) pathway to isopentenyl diphosphate, and subsequent formation of the diterpene, *ent*-kaurene. CDP-ME, 4-diphosphocytidyl-2-C-methylerythritol; CDP-ME 2-P, 4-diphosphocytidyl-2-C-methyl-D-erythritol 2-phosphate; MEP, 2-C-methyl-D-erythritol 4-phosphate.

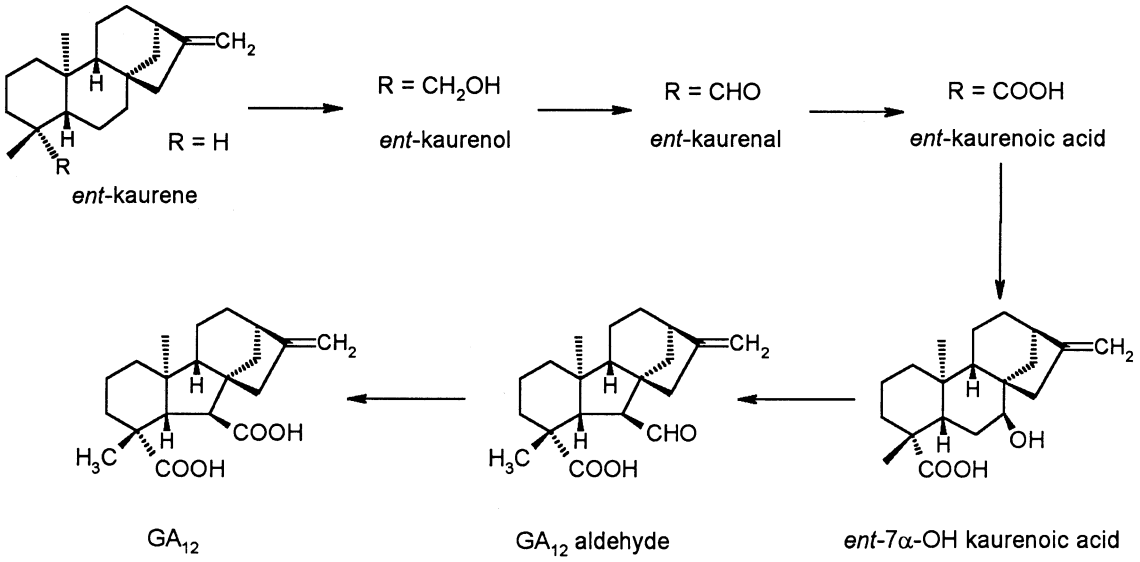

FIGURE 3 The multistep conversion of *ent*-kaurene to GA_{12}.

function on the branch of the terpenoid pathway that is committed to *ent*-kaurenoids and GAs.

The next part of the pathway (Fig. 3) involves the sequential oxidation of *ent*-kaurene at carbon 19 and is catalyzed by a membrane-bound, cytochrome P450 enzyme, *ent*-kaurene oxidase. This catalytic activity has been thought for some time to be associated with the endoplasmic reticulum, although recently *ent*-kaurene oxidase from *Arabidopsis* was reported to be localized to the chloroplast outer envelope. *ent*-Kaurene oxidase is multifunctional and can catalyze three oxidations: *ent*-kaurene → *ent*-kaurenal → *ent*-kaurenol → *ent*-kaurenoic acid (Fig. 3). The next enzyme in the pathway, *ent*-kaurenoic acid oxidase, is also a multifunctional P450 monooxygenase and is associated with the endoplasmic reticulum in *Arabidopsis* and many other species. It can catalyze the sequence: *ent*-kaurenoic acid → 7β-hydroxykaurenoic acid → GA_{12}-aldehyde → GA_{12} (Fig. 3). These reactions involve the conversion of a 6-membered B ring to a 5-membered B-ring and the formation of a carboxylic acid at carbon 7. The biosynthetic pathway leading to GA_{12} appears to be the same in all plants examined to date, but it can diverge from there on. The next reactions, comprising the last part of the pathway, occur in the cytosol.

There are multiple positions in the GA molecule for subsequent oxidation. The enzymes that catalyze these reactions are soluble 2-oxoglutarate-dependent dioxygenases. The sequential oxidation of carbon 20, until it is eventually lost as CO_2, yields a GA containing 19, instead of 20, carbon atoms (Fig. 4). The carboxyl at C-4 forms a lactone at C-10, and this γ-lactone is essential for bioactivity. Also necessary for bioactivity is the presence of a 3β-hydroxyl group or some other functionalization of carbon 3, including a 2,3 double bond. The introduction of hydroxyl groups can occur "early" or "late" in the pathway, and because the dioxygenases do not have absolute substrate specificity, parallel and interconnecting pathways may occur.

Because several of the enzymes in the pathway are multifunctional, as few as four enzymes can catalyze the 10 reactions needed to convert *ent*-kaurene to a bioactive GA. This is a much smaller number than expected. However, despite the small number of different enzymes that are needed, it is now known that some of the enzymes, particularly the dioxygenases, are encoded by small gene families. This means that there are multiple isoenzymes of some of the enzymes. In *Arabidopsis*, for instance, there are as many as five different 20-oxidases. The expression of individual members of a gene family can be tissue specific and developmentally regulated. Moreover, regulation by intrinsic and/or extrinsic factors may operate on selective isoenzymes only.

With regard to sites of synthesis, there is incontrovertible evidence that GA biosynthesis occurs in the developing seeds of many species. The stages of GA biosynthesis from GGPP have been demonstrated repeatedly in cell-free systems from endosperm preparations and other seed parts. Other sites of GA biosynthesis include actively growing tissues such as shoot tips, expanding leaves, and floral organs.

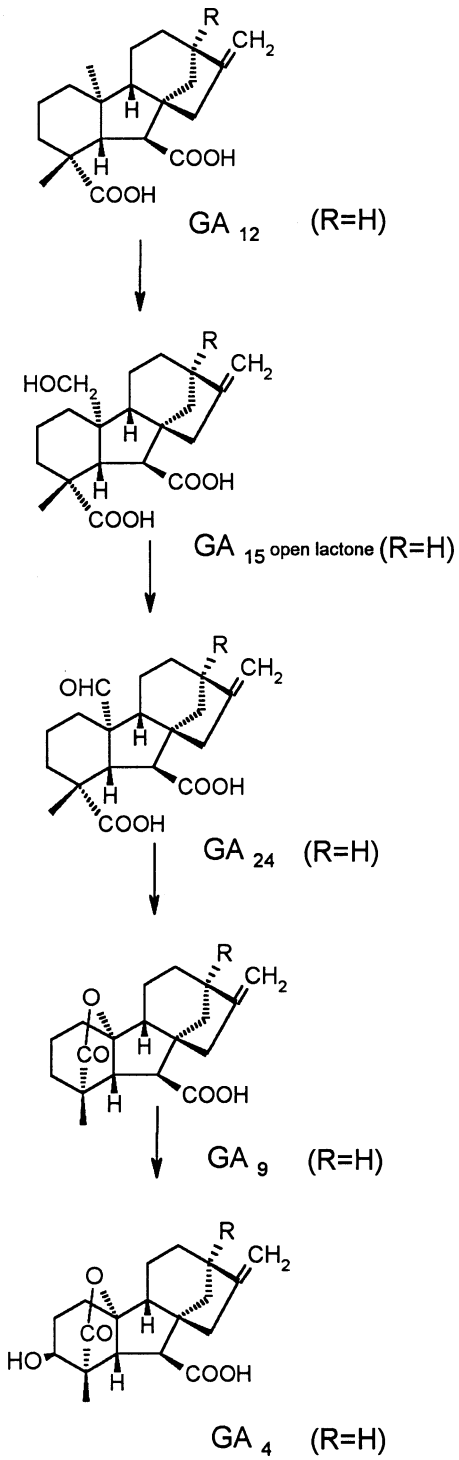

FIGURE 4 The three-step conversion of GA_{12} to GA_9 is catalyzed by a multifunctional GA 20-oxidase and results in the formation of the C_{19} GA, GA_9. Hydroxylation at carbon 3 is required to form a bioactive GA, GA_4. Any of these GAs can be a substrate for a 13-oxidase, potentially giving the following sequence: GA_{53}, GA_{44}-open lactone, GA_{36}, GA_{20}, and GA_1, in all of which R = OH.

The evidence for GA biosynthesis in these tissues comes from studying the expression of genes that encode key enzymes in the GA biosynthetic pathway. The use of reporter genes for these studies has been particularly instructive. In many cases, the site of GA synthesis correlates with the site of GA action. Although localized movement of GAs may occur—for instance, within regions of the shoot apex or between different seed parts—there is little evidence that long-distance transport is required.

Alteration in GA biosynthesis in response to environmental factors is one important way that light, for example, can have an impact on plant growth and development. GA biosynthesis is affected by both light quantity and quality. In *Arabidopsis* and spinach a stem-expressed 20-oxidase is up-regulated in shoots after exposure to long days, coincident with stem elongation and prior to flowering. 3-Oxidation in lettuce and *Arabidopsis* seeds is enhanced in red illumination and is important for germination. In both of these examples, up-regulation of an enzyme catalyzing a rate-limiting step in the biosynthetic pathway leads to an increase in the level of bioactive GA.

V. USE OF MUTANTS

In the past, there have been concerted efforts to identify all GAs in a given plant species, to determine the GA metabolic pathways within the plant, and to characterize a comprehensive series of mutants. The GA-responsive stem length mutants of corn, pea, and *Arabidopsis* have been particularly useful. For each of these species a series of mutants that showed a graded severity of phenotype, from extreme dwarf to semidwarf, were either generated or obtained from natural sources (e.g., *Arabidopsis*; Fig. 5). Each of these mutants was shown to be blocked at a specific stage in GA biosynthesis between *ent*-kaurene and the active hormone. Treatment of a particular mutant with an *ent*-kaurenoid or GA beyond the metabolic block can restore normal growth. If a mutant is blocked for 3β-hydroxylation (*ga4* in *Arabidopsis*, *d1* in corn, *le* in pea,), 3-deoxy GAs cannot restore growth, whereas GA_4 or GA_1 can, providing evidence that the active GA must be 3β-hydroxylated.

In addition to having an extreme dwarf phenotype, the *ga1*, *ga2*, and *ga3* mutants of *Arabidopsis* are also male-sterile. Flower buds fail to open and no seeds are set (Fig. 5). Treating these mutant plants with GA not only restores normal stem elongation but also restores fertility. Moreover, seeds of these

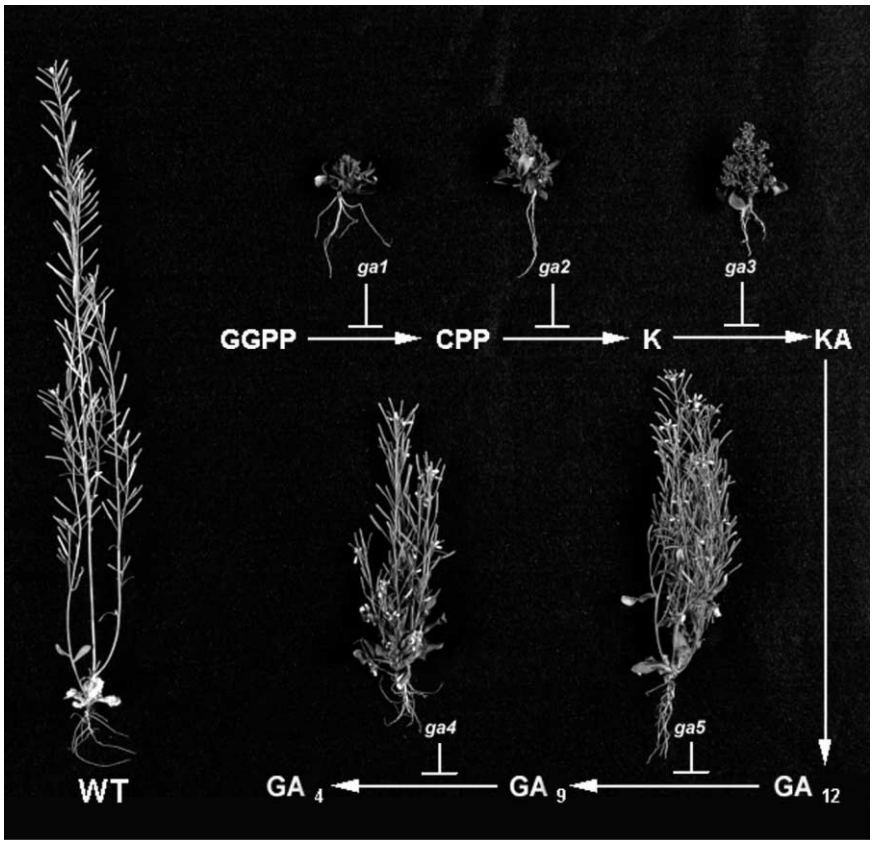

FIGURE 5 *Arabidopsis thaliana*. The Landsberg *erecta* ecotype (wild type) and five mutants, *ga1–ga5*. The position of the metabolic block in the GA biosynthetic pathway is shown for each mutant. All plants are photographed at 7 weeks. Only wild-type, *ga4*, and *ga5* plants have flowered and set seed. The *ga1*, *ga2*, and *ga3* mutants are male-sterile dwarf plants.

three GA-deficient mutants of *Arabidopsis* cannot germinate unless they are treated with GA, underscoring the requirement for GAs in several different phases of a plant's life cycle.

Using GA biosynthesis mutants, it has been shown that stem length is proportional to the content of bioactive GA. This has been clearly demonstrated for pea stem length and GA_1 content. Thus, factors that control the pool size of GA_1 or other active GA in the target tissue will be important for determining growth. Control points include the regulation both of biosynthesis of the active hormone and of its subsequent deactivation. In *Arabidopsis*, the 20-oxidases and 3-oxidases are regulated by feedback. The action of GA in promoting growth down-regulates transcription of genes that encode enzymes occurring earlier in the GA pathway. The precise mechanism whereby this regulation occurs is not known. Deactivation involves 2β-hydroxylation and may also involve conjugation to glucose. The 2β-hydroxylase is regulated by a feedforward mechanism.

Other mutants that have been characterized have altered responses to GAs. These mutants, which can be identified by their short or very tall phenotypes, are unlike the previously described mutants because their stem height often bears no direct correlation to their level of endogenous GA_1 (or GA_4). This is because the feedback control of the biosynthetic pathway requires GA-induced growth. In the absence of growth and the consequent absence of feedback regulation, the transcription of genes encoding 3-oxidase and 20-oxidase enzymes is up-regulated, which results in very high GA levels in severely dwarfed individuals. In contrast, other mutants can be unusually tall, even if the levels of endogenous GAs are reduced to almost zero by chemical or genetic means. Both of these types of mutants are useful tools with which to dissect the signal transduction pathway, and are discussed later.

VI. MODE OF ACTION IN CEREAL GRAIN

The cereal aleurone system has been the most well-investigated site of GA action. During germination, GA_1 from the embryo moves to the aleurone, which is a layer or layers of cells that envelope the starchy endosperm (Fig. 6). Within the aleurone layer, GA from the embryo induces the synthesis and secretion of hydrolytic enzymes, including several isoforms of α-amylase. α-Amylase catalyzes the breakdown of starch in the nonliving starchy endosperm, yielding usable forms of fixed carbon to nourish the growing seedling (Fig. 6). Cereal grains would therefore appear to be excellent material from which to isolate a GA receptor, and attempts to do so are ongoing.

The site of GA perception appears to be the plasma membrane of aleurone cells. The evidence for this is twofold. First, GA_4 that has been covalently linked to agarose beads to prevent its uptake into the cell can still induce α-amylase production. Second, GA injected directly into aleurone cells has no bioactivity. Two GA-binding proteins that specifically bind bioactive GAs have been isolated from aleurone cells, but unequivocal evidence that either or perhaps both (as a dimer) are the GA receptor is not yet available. Despite this serious gap in our understanding of GA perception, there is now a considerable amount of evidence for downstream signaling events that transduce the GA signal into the well-defined responses of α-amylase production and secretion. There are some small differences in GA signaling in grains of different genera (barley, rice, wheat, and wild oats are all used extensively), and the following description draws together experimental data from several different systems.

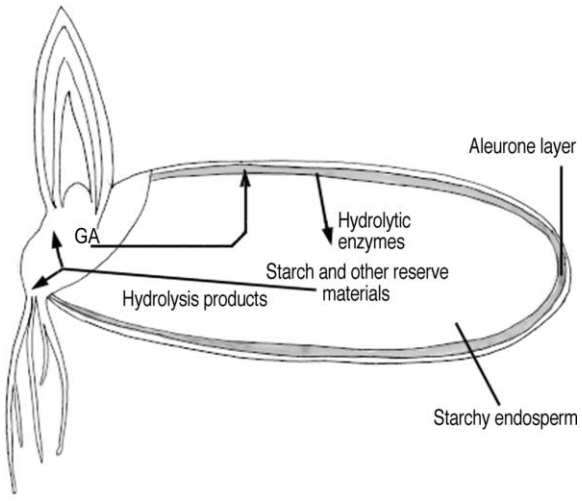

FIGURE 6 Cereal grain showing that GA from the embryo moves to the aleurone. *De novo* synthesis of amylase and other hydrolytic enzymes occurs in the aleurone. These enzymes break down reserve materials in the starchy endosperm in order to nourish the growing seedling.

Components of the GA signal transduction chain have been identified in the plasma membrane, cytosol, and nucleus (Fig. 7). Several lines of evidence indicate that bioactive GA, perceived at the plasma membrane and bound to a hypothetical receptor protein, interacts with a membrane-localized heterotrimeric G-protein. G-protein agonists can induce α-amylase gene expression in wild oat protoplasts in the absence of GA. Moreover, guanosine triphosphate (GTP)-γ-S, which binds G_α subunits and holds them in an activated form, stimulates α-amylase expression, whereas guanosine diphosphate (GDP)-β-S, which holds the subunits in an inactivated form, prevents GA induction of α-amylase gene expression. Additional evidence linking a putative heterotrimeric G-protein with GA signal transduction comes from the observation that the *dwarf1* (*d1*) mutant of rice, which has impaired sensitivity to GA, has a defective G_α subunit.

Based on identification of both Ca^{2+}-dependent and -independent events, there appears to be a dichotomy in the GA signal transduction pathway within the cytoplasm of barley aleurone cells (Fig. 7). One branch of the signaling pathway leads to rapid increases in intracellular calcium concentration, particularly in the peripheral cytoplasm, whereas the other branch leads to induction of α-amylase gene expression. Sustained lowering of Ca^{2+} levels for several hours does not affect α-amylase gene expression but inhibits α-amylase secretion. On the other hand, syntide 2 (an inhibitor of phosphorylation) inhibits GA induction of α-amylase but does not inhibit the rapid increase in Ca^{2+} concentration that is observed with GA treatment. These results show that effects of GA on α-amylase gene expression are independent of the Ca^{2+} effects, although intracellular Ca^{2+} concentration is important in α-amylase secretion. In the *d1* mutant of rice, previously mentioned because it defines a mutation in a G_α subunit of a heterotrimeric G-protein, both Ca^{2+}-dependent and -independent responses to GA_3 are perturbed at all but the highest dose of GA_3. This global disruption of GA responses would reinforce the position of a G_α-protein early in the GA signal transduction pathway (Fig. 7).

The mechanism for elevating intracellular Ca^{2+} concentration is presently unknown, but it has been suggested to involve increased flux of Ca^{2+}

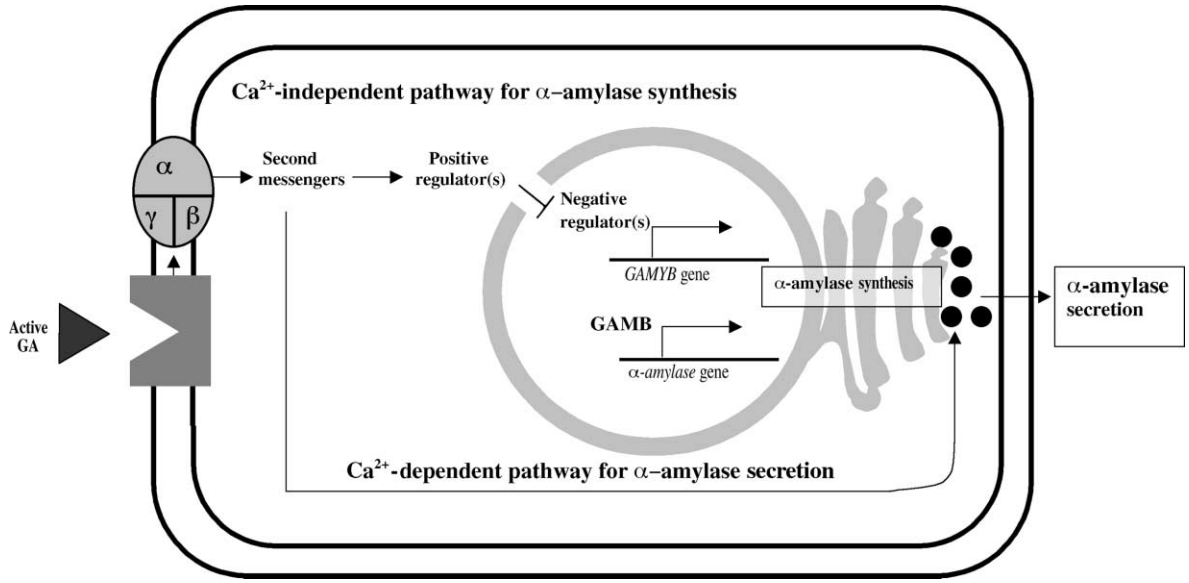

FIGURE 7 Simplified scheme to show some putative players in GA signal transduction in a generic cereal aleurone cell. The GA receptor is thought to be membrane localized, and the signal may be transduced through a heterotrimeric G-protein, the α-subunit of which is encoded by the *D1* locus in rice. The transduction pathway bifurcates into Ca^{2+}-dependent and Ca^{2+}-independent branches. The latter branch is under the control of both positive (GID1 in rice, GSE in barley) and negative (SLR in rice, SPY and SLN in barley, Rht1 in wheat) regulators. In the presence of a GA signal the negative regulation is removed, allowing GAMYB transcription factors to be formed, α-amylase genes to be transcribed, and α-amylase protein to be synthesized and secreted.

from the apoplast and/or a release of Ca^{2+} from an intracellular storage pool. GA also causes an elevation of calmodulin (CaM) levels in the aleurone. Targets for the elevated levels of Ca^{2+} and CaM in the cytoplasm may be transporters, channels, or other membrane proteins at several cellular locations, some of which may be directly involved in the secretory process.

Use of guanylyl cyclase inhibitors prevents a transient increase in cyclic GMP (cGMP) normally seen in barley aleurone layers 2 h after GA treatment. These inhibitors also reduce the accumulation of α-amylase mRNA and that of the gibberellin-associated MYB transcription factor, GAMYB. For this and other reasons, it has been suggested that cGMP may be a component of the transduction chain, provisionally placed downstream of the G-proteins and upstream of MYB. Interestingly, there is evidence in tomato for phytochrome A activation of a heterotrimeric G-protein, which in turn uses cGMP and Ca^{2+} in separate transduction chains to bring about anthocyanin production and chloroplast development.

Reversible phosphorylation is also involved in the GA signal transduction chain. The aforementioned syntide 2, which essentially blocks phosphorylation by competing with natural substrates, inhibits GA induction of gene expression. In contrast, okadaic acid, which is a phosphatase inhibitor, negates the effects of GA on Ca^{2+} accumulation, on gene expression, and on α-amylase secretion. This inhibitor therefore must act early (i.e. before the transduction chain branches) or, if it acts later it, it must act at two sites to inhibit both branches of the signal transduction chain.

The induction of gene expression by GA has been studied in detail. Within their promoter regions, amylase genes contain a GA response element (GARE) to which GA-inducible nuclear proteins bind. The GAMYB proteins have been identified as GA-inducible transcription factors that bind to the conserved sequence TAACA/GA of GAREs and transactivate amylase genes. The same transcription factors may also transactivate other GA-inducible genes. Because the expression of *GAMYB* precedes the expression of amylase genes and does not require protein synthesis, it is suggested that *GAMYB* represent primary response genes. There is a possibility that GA acts to repress a repressor of GAMYB (this is discussed again briefly in the next section). Additional nuclear proteins can bind other sequences adjacent to the GARE that comprise a so-called GARC (GA response complex). The TATCCAC box

in the promoter of amylase 1 is a suspected site of interaction. The identity of these cis-acting elements is as yet unknown, but they are envisaged to act as enhancers.

In summary, GA signaling in aleurone cells (represented schematically in Fig. 7) involves a putative membrane-bound receptor that may interact with a heterotrimeric G-protein to bring about a cascade of events within the cytoplasm. These may include, but are not limited to, an enhancement of guanylyl cyclase and an increase in cGMP, an elevation of intracellular Ca^{2+}, and the induction of transcription factors that facilitate α-amylase gene expression. α-Amylase is one of several hydrolytic enzymes that move to the starchy endosperm and catalyze the mobilization of reserve materials. The resulting breakdown products are essential for nourishment of the emerging seedling. Cereal grains in which amylase production is perturbed have impaired seedling emergence. Because cereals provide the world's population with a majority of its caloric needs and over half its protein, the importance of GA-induced amylase production in cereal aleurone cannot be overstated.

VII. REGULATION OF STEM GROWTH BY GAs

One of the most easily recognized effects of GA is on stem elongation, and a number of stem length mutants with altered sensitivity to GA have been characterized. The mutants fall into two broad phenotypic categories: those that are dwarf and have reduced responsiveness to applied GAs and those that are as tall or taller than wild-type plants, irrespective of how much GA they contain. Biochemically, the mutants also fall into two main categories: those that have a mutation in a negative regulator of GA signaling and those that have a mutation in a positive regulator of GA signaling. The exact nature of a mutation (i.e. whether it is a loss- or gain-of-function mutation) will have an impact on the phenotype. The mutant loci discussed here are listed in Table 1.

It is now apparent that many plants contain a mutated form of a gene initially defined by the *GAI* (*gibberellin insensitive*) locus in *Arabidopsis*. *GAI* encodes a putative transcription factor that is a negative regulator of GA signaling. In wild-type plants, GA can derepress this regulator, allowing GA responsiveness. If a deletion occurs in a particular region of the *GAI* gene, identified by a DELLA motif in the amino acid sequence, then the alteration causes a semidominant gain-of-function mutation. This type of mutation (designated as the *gai1-1* allele) prevents GA from being able to derepress the negative regulator, or, to put it in other words, a mutation in the DELLA region makes *GAI* a constitutive repressor of the GA response. The resulting phenotype is a very dwarf plant that is GA insensitive.

GAI orthologues present in maize (*dwarf8*, *D8*), wheat (*reduced height1*, *RHT1*), barley (*slender*, *SLN*), and rice (*slender rice*, *SLR*) all encode a similar protein. So too does the *RGA* (*repressor of ga1-3*) gene in *Arabidopsis*, which was isolated as a suppressor of the GA-deficient phenotype of *ga1-3* mutants. The *d8* and *Rht1* semidominant mutations, like *gai1-1*, have a deletion in the DELLA region and are dwarf nonresponders to GA. Historically, this mutation has had a profound effect on the well-being of millions of people, because it is the mutation responsible for the development of semidwarf cereals adapted to the semitropics by Dr. Norman Borlaug in the Green Revolution of the 1960s. Interestingly, it has been shown that mutations in *GAI* and its orthologues in barley (*SLN*) and rice (*SLR1*) can give either slender or dwarf phenotypes, depending on the locations of the mutations. For example, in rice the slender phenotype is exhibited by plants in which a mutation occurs in the nuclear localization sequence of *SLR1*. In these recessive loss-of-function mutants, the GA response is constitutively derepressed, giving a very tall phenotype. Alternatively, a truncation in the DELLA region of *SLR1* (produced by transforming wild-type plants with *pSLRtr*) results in a semidominant gain-of-function mutation, which gives a GA-insensitive dwarf phenotype. This unusual situation in which the two mutations in the same gene can lead to opposite phenotypes has been demonstrated for *sln* and *gai* mutants too. An intragenic suppressor of *GAI* gives a recessive mutation, and these plants (*gai*) have a nondwarf phenotype that is in direct contrast to the severely dwarf phenotype of the *gai1-1* mutants (Table 1). It is assumed that this *gai* loss-of-function mutant does not have a slender phenotype because of the presence of a functional repressor of gibberellin (RGA) protein.

Recessive mutations at another locus, involving *Spindly* (*SPY*), which was first defined in *Arabidopsis*, partly suppress the *gai* phenotype. This indicates that *SPY* may also be a negative regulator of GA signal transduction. It has been proposed that in the absence of GA, SPY activates GAI and RGA. In the presence of GA, SPY would be inactivated, or GAI and RGA might be modified to prevent interaction with SPY. The outcome would be the removal of negative

TABLE 1 Genetic Loci Known, from Mutant Analysis, to Affect GA Response

Species	Locus[a]	Mutant	Type	Phenotype	Proposed action of wild-type gene product
Arabidopsis	*Spindly*	*spy*	Recessive	Tall	Negative regulator of GA signaling
Barley	*Spindly*	*Hvspy*	Recessive	Tall	Negative regulator of GA signaling
Arabidopsis	*RGA*	*rga*	Recessive	Semidwarf	Negative regulator of GA signaling
Arabidopsis	*GAI*	*gai1-1*	Semidominant	Dwarf	Negative regulator of GA signaling
Arabidopsis	*GAI*	*gai*	Recessive	Wild type	Negative regulator of GA signaling
Maize	*Dwarf8*	*d8*	Semidominant	Dwarf	GAI orthologue
Wheat	*Reduced ht1*	*Rht1*	Semidominant	Dwarf	GAI orthologue
Barley	*Slender*	*sln1*	Recessive	Tall	GAI orthologue
Rice	*Slender rice*	*slr1-1*	Recessive	Tall	GAI orthologue
Rice	*Slender rice*	*pSLRtr*	Semidominant	Dwarf	GAI orthologue
Rice	*Dwarf1*	*d1*	Recessive	Dwarf	Positive regulator of GA signaling
Rice	*GID*	*gid*	Recessive	Dwarf	Positive regulator of GA signaling
Barley	*GSE*	*gse*	Recessive	Dwarf	Positive regulator

[a]Abbreviations: *RGA*, *repressor of ga1-3*; *GAI*, *gibberellin insensitive*; *GID*, *gibberellin-insensitive dwarf*; *GSE*, *gibberellin sensitive*.

regulation of the signaling pathway, allowing a GA response. It has recently been shown that SPY also affects plant development in addition to, but separate from, being involved in GA signaling. These additional roles for SPY have yet to be defined.

Studies utilizing green fluorescent protein (GFP) have shown that RGA is localized in the nucleus. However, given that neither RGA nor GAI possesses DNA-binding domains, it is likely that they interact with an additional factor (possibly a GAMYB transcription factor) that can bind to DNA. In barley, the gene product of *SLN*, which is the barley orthologue of *GAI* and thus a negative regulator of GA signaling, appears to be degraded in the presence of GA. This degradation of SLN is required before the expression of GAMYB in aleurone cells can be enhanced by GA. This result ties in a negative regulator of GA signaling (SLN), which was first defined through a mutant phenotype in stems with a known transcription factor (GAMYB) in the signaling pathway in aleurone. The GA-induced disappearance of RGA from *Arabidopsis* nuclei has also been reported, and again is consistent with the direct or indirect removal of a negative regulator by GA.

Compared to negative regulation, less is known about positive regulation of GA response pathways. Two loss-of-function (recessive) mutations, *d1* and *gid1* (*gibberellin-insensitive dwarf1*) in rice have been described. The mutant phenotypes are dwarf or semidwarf. As mentioned earlier, *D1* encodes a G_{α}-subunit, implicating it early in signal transduction in aleurone cells. The function of *GID* has been examined in double mutants. Plants with an *slr1 gid1* genotype are phenotypically slender, indicating that *slr1* is epistatic to *gid1*. This is consistent with a role for SLR1 downstream of GID1. In preliminary results it has been shown that in wild-type plants SLR1, visualized by fusion of the gene to one encoding GFP, is localized to nuclei and disappears with GA treatment. In *gid1 SLR1-GFP* plants, the GFP signal is retained in the nucleus, implying that a functional GID1 protein is required for the GA-dependent removal of the negative regulation imposed by SLR1.

A putative positive regulator, encoded by the *GSE* (*gibberellin sensitivity*) locus, has been described in barley. A recessive loss-of-function mutation gives a dwarf phenotype with some reduction in sensitivity to GAs for both leaf elongation and amylase synthesis. In double mutants, *sln1* is epistatic to *gse*, implying that SLN1 is located downstream of GSE in the signal transduction chain.

Overall, the picture that is emerging for GA signaling in both stems and aleurone is of a series of negative regulators (e.g., SPY, and GAI and its orthologues, namely, RGA, SLR, SLN, Rht1, D8,) that keep the GA response pathway repressed in the absence of GA. GA removes the repression, either by acting directly or though one or more positive regulators (e.g., GID1) to inactivate or degrade the negative regulator(s) (Fig. 7).

A GA-binding protein has not been unequivocally identified in vegetative tissue, nor have many ultimate target genes of the GA signal been identified. Compared to the downstream events in the aleurone system, stem elongation and flowering responses are more complex to analyze. Nevertheless, progress has been made with several systems, notably one

employing deep-water rice and its response to flooding. Deep-water rice is grown in Southeast Asia, where severe flooding can occur during the monsoon season. Rapid stem extension of up to 25 cm day^{-1} after submergence is a consequence of an increased ratio of GA to abscisic acid. Applied GA, in the absence of flooding, can mimic the increases in cell division and the enhanced cell extension normally seen after submergence. Rice genes that are regulated by GA include those encoding proteins that function in the cell cycle and those involved in "loosening" the cell wall to allow elongation to occur. Expansins are a class of proteins that are closely correlated with the walls of elongating cells, but as yet have an unknown function. Other genes that might encode components in the transduction pathway have been sought in rice using a variety of approaches. The expression of a gene that codes for a leucine-rich repeat receptor-like protein kinase is up-regulated by GA in actively dividing and elongating cells. Also rapidly up-regulated in meristematic cells by GA treatment is the gene *Growth Regulating Factor1*, which encodes a putative transcription factor or activator. Further progress in elucidating the function of this and other GA-regulated genes in deep-water rice can be expected in the near future, and it will enhance greatly our understanding of the mode of action of GAs in stem growth.

VIII. SUMMARY

The GA group is a daunting array of 126 individual compounds known to be present in plants and fungi. Much is known about their biosynthesis and metabolism, and structure/activity considerations lead us to believe that only a handful of GAs are active hormones in their own right. Their repertoire of activities includes promotion of signal events in the life cycle of a plant such as seed germination, seedling emergence, stem growth, flowering, and fruit development. Despite our inability to identify conclusively a GA receptor, much is now known about how the GA signal is transduced into the well-defined responses of amylase production and secretion in germinating cereal grains, and into less well-defined responses such as cell elongation.

Glossary

aleurone Layers of cells surrounding the starchy endosperm in cereal grains; on stimulation by gibberellins during germination, the cells synthesize hydrolytic enzymes to break down starch and other storage materials in the starchy endosperm.

C_{20} gibberellins Diterpenes with the full diterpenoid complement of 20 carbon atoms; the first of the products formed in the GA biosynthetic pathway.

C_{19} gibberellins Diterpenes that, through metabolism, have lost carbon 20 and so contain only 19 carbon atoms.

GA-insensitive dwarf mutants Plants in which there is a defect in the ability to detect or respond to bioactive GA; cannot be normalized by application of GA.

GA-sensitive dwarf mutants (GA biosynthesis mutants) Plants in which one of the enzymatic steps in the GA biosynthetic pathway is blocked, resulting in reduced levels of GA; can be normalized by application of a GA normally produced in the pathway after the metabolic block.

Glucagon Action

MARK L. EVANS AND ROBERT S. SHERWIN
Yale University School of Medicine

Glucagon is a 29-amino-acid peptide hormone secreted from the alpha cells of the pancreas. The main target organ for glucagon is the liver, where it increases hepatic glucose production and release. Glucagon achieves this by having coordinated actions to increase gluconeogenesis and glycogenolysis and to inhibit glycolysis and glycogen synthesis, with the net effect of directing hepatic flux toward synthesis and release of glucose. These actions are opposed by insulin. In health, glucagon and insulin secretion and action are carefully coordinated to provide an integrated control of hepatic glucose metabolism.

I. INTRODUCTION

The mechanisms of glucagon action are outlined in this article; the focus is on the established hepatic effects of glucagon, but there is also discussion of some of the putative actions of glucagon on nonhepatic organs. Some of the conditions in which the physiology of glucagon action is disturbed are described. Several biological actions of glucagon have been exploited therapeutically and therefore some possible diagnostic and therapeutic uses for exogenous glucagon in clinical practice are detailed.

II. GLUCAGON RECEPTOR

Like other peptide hormones, the intracellular actions of glucagon are initiated by binding to a cell surface receptor, which triggers a series of intracellular events mediated by second-messenger pathways. The glucagon receptor (GR) was first cloned in 1993 and is encoded on chromosome 17q25. The GR is a member of a large family of guanosine triphosphate (GTP)-binding protein-coupled receptors, all with seven transmembrane domains. Within this larger family of receptors, the glucagon receptor belongs to a subset of highly homologous receptors that includes receptors for peptides closely related to glucagon, i.e., glucagon-like peptide-1 (GLP-1), gastric inhibitory peptide (GIP), vasoactive intestinal peptide (VIP), pituitary adenylate cyclase-activating peptide (PACAP), secretin, and growth hormone-releasing hormone (GRH). The subset also includes receptors for peptides unrelated to glucagon, such as corticotropin-releasing hormone (CRH), parathyroid hormone (PTH), and calcitonin.

III. SIGNAL TRANSDUCTION

Glucagon binding to the cell surface GR triggers two complementary second-messenger pathways that act intracellularly to mediate the downstream actions of glucagon, the cyclic AMP (cAMP) pathway and the calcium-mediated pathway.

A. cAMP Pathway

The best characterized mechanism for the transduction of glucagon binding to the GR into intracellular actions of glucagon involves formation of the second messenger, cAMP. Activation of the cAMP pathway is mediated by a GTP-dependent regulatory protein (G-protein) mechanism. Binding of glucagon to the GR results in an interaction with the stimulatory G-protein complex (GS). GS is a complex composed of α-, β-, and γ-subunits. In its trimeric state, the GS complex has the nucleotide guanosine diphosphate (GDP) bound to its α-subunit and is inactive. Glucagon binding to the GR acts to release the α-subunit of the GS by a process involving exchange of GDP for guanosine triphosphate. The liberated α-subunit is then active and able to stimulate the enzyme adenylyl cyclase, which converts ATP into the second messenger, cAMP. This process is limited by the endogenous GTPase activity of the α-protein, which will break down GTP to GDP, allowing reassociation of the inactive trimer.

Degradation of cAMP is catalyzed by the enzyme phosphodiesterase. Glucagon also acts to inhibit phosphodiesterase, probably by an inhibitory (GI) G-protein-mediated mechanism, to further increase cAMP signaling. The cascade of glucagon action continues with cAMP activation of cAMP-dependent protein kinase A (PKA). PKA is a heterotetrameric protein complex and, analogous to the activation of the GS, the process involves dissociation of the tetramer to free the catalytic subunits. The liberated catalytic (C) subunits of PKA catalyze the phosphorylation of serine or threonine residues in regulatory sites of key metabolic enzymes (to be described later). In addition to these rapid actions, PKA also alters gene expression through Ser-133 phosphorylation of the cAMP response element binding protein (CREB). CREB is a nuclear transcription factor that binds directly to DNA that contains a specific 8-base-pair sequence—the cAMP response element (CRE)—to alter gene expression.

In recent years, the importance of co-activators that enhance the actions of transcription factors has been recognized. For actions mediated by the cAMP/CREB pathway, two co-activators have been characterized—CREB-binding protein (CBP-1) and peroxisome proliferator-activated receptor-γ co-activator (PGC-1). CBP-1 is a co-activator for a number of transcriptional factors, including, but not limited to, CREB. Co-activators do not directly alter gene expression but do so by facilitating the actions of transcription factors. In the case of CBP, this probably involves a number of different mechanisms, including the acetylation of nuclear histones and the recruitment of other co-activators. PGC-1 is a recently described nuclear co-activator that facilitates the hepatic cAMP/CREB-mediated actions of glucagon to increase expression of key gluconeogenic enzymes such as phosphoenolpyruvate carboxykinase (PEPCK). It seems likely that over the coming years, other co-activators and co-repressors acting on CREB-mediated gene expression will be described.

The cAMP pathway is a common effector mechanism for a number of hormones acting at cell surface receptors. For example, many of the hepatic effects of glucagon (see later) are also stimulated by β-adrenergic receptor-mediated activation of the cAMP pathway.

B. Calcium Pathway

Although the cAMP pathway is the better characterized second-messenger pathway, glucagon also stimulates the complementary calcium/phospholipid pathway. Glucagon binding to GR results in the breakdown of cell membrane phospholipid, phosphatidylinositol 4,5-bisphosphate (PIP_2), by phospholipase C to two active compounds, inositol 1,4,5-trisphosphate ($InsP_3$) and 1,2-diacylglycerol (DAG). A rise in intracellular $InsP_3$ results in calcium release, initially from the endoplasmic reticulum but also from an influx of extracellular calcium into cells. Both calcium and the elevated levels of DAG activate protein kinase C (PKC), which is then able to alter activity by phosphorylating other intracellular enzymes (described later).

Although the cAMP and calcium pathways are described separately here, there are areas of overlap between the downstream effects (see later). There is also a synergism, so activation of one pathway will increase signaling through the other. For example, probably acting at multiple sites, cAMP amplifies signaling through the calcium pathway, from increased receptor affinity to amplification of the InsP3-mediated rise in intracellular calcium. Calcium is also able to stimulate CREB binding and thus alter gene expression, probably acting both by direct calmodulin-mediated and by indirect cAMP-mediated mechanisms.

IV. HEPATIC ACTIONS

A. Liver

Although glucagon actions in other tissues have been reported (and will be discussed later), the main target organ of glucagon action is undoubtedly the liver, where glucagon acts to increase glucose production and output. The portal anatomy is ideally designed so that glucagon (and insulin) secreted from the pancreas can bathe the liver in relatively high concentrations, compared with systemic levels, allowing changes in glucagon (and insulin) secretion to exert relatively rapid effects on hepatic metabolism.

In general, hepatic metabolism is characterized by the existence of opposing metabolic pathways —for example, glycogen synthesis and breakdown —with maintenance of homeostasis depending on an integrated balance between antagonistic pathways. Glucagon exerts its actions by having a coordinated action on these pathways, tending, for example, to increase glycogenolysis and simultaneously decrease glycogen synthesis. This fine control of hepatic metabolism is further increased by the opposing actions of insulin. Secretions of insulin and glucagon from the pancreas are, in general, inversely correlated in health, thus creating an exquisitely

sensitive mechanism for controlling hepatic glucose homeostasis.

B. Glycogenolysis/Glycogen Synthesis

The rapid effects of a rise in glucagon, i.e., increased hepatic glucose output, are mediated predominantly by increased glycogen breakdown. Glucagon enhances glycogen breakdown and inhibits glycogen synthesis by a series of coordinated changes in the activities of key enzymes controlling glycogen flux. The actions of glucagon on these regulatory enzymes are mediated by phosphorylation of key enzymes controlling glycogen synthesis/breakdown.

Glucagon increases glycogenolysis by activating the key enzyme, glycogen phosphorylase (Fig. 1). Glycogen phosphorylase is a key rate-limiting enzyme that is necessary for the breakdown of glycogen; it exists as a homodimer of subunits of about 100 kDa. Phosphorylation of glycogen phosphorylase on Ser-14 converts the enzyme from inactive phosphorylase b to active phosphorylase a. This phosphorylation is mediated by a regulatory enzyme, phosphorylase kinase, which in turn is also activated by phosphorylation. Phosphorylase kinase is a 1300-kDa protein complex made up of four different subunit types (α_4, β_4, γ_4, and δ_4) arranged as a hexadecamer. Phosphorylation of glycogen phosphorylase is catalyzed by the γ-subunit. Glucagon activates phosphorylase kinase by calcium-mediated activation (mediated by the δ-subunit) or by cAMP-dependent protein kinase phosphorylation of sites on the α- and β-subunits. This action of glucagon will be limited by the actions of glycogen-associated protein phosphatases (PP-1Gs), which will tend to convert active glycogen phosphorylase a back into inactive glycogen phosphorylase b.

This enhancement of glycogenolysis by glucagon is complemented by actions to inhibit glycogen synthesis. Again, this is mediated by phosphorylation of a key enzyme, glycogen synthase. Glycogen synthase is an 85-kDa protein with a number of potential phosphorylation sites at both N and C termini. Phosphorylation of serine residues of glycogen synthase converts it from the active "a" form into the inactive "b" form. Glucagon-induced phosphorylation (and thus inactivation) of glycogen synthase is probably mediated by a number of different kinases, including cAMP-dependent protein kinase. Glycogen synthase is reactivated by a specific glycogen-associated protein phosphatase (PP-$1G_L$). PP-$1G_L$ is also a site of glucagon action in that it is inhibited by the glucagon-driven rise in intracellular calcium and by inhibition by phosphorylase a.

In summary, glucagon will thus tend to promote a net glycogenolysis within liver parenchymal cells, resulting in increased flux of glucosyl units into glucose 6-phosphate. Glucose 6-phosphate may then be hydrolyzed by glucose 6-phosphatase, releasing glucose for hepatic export into the hepatic vein.

C. Glycolysis/Gluconeogenesis

Glucagon also exerts coordinated actions on the opposing pathways of glycolysis and gluconeogenesis, inhibiting the former and increasing the latter

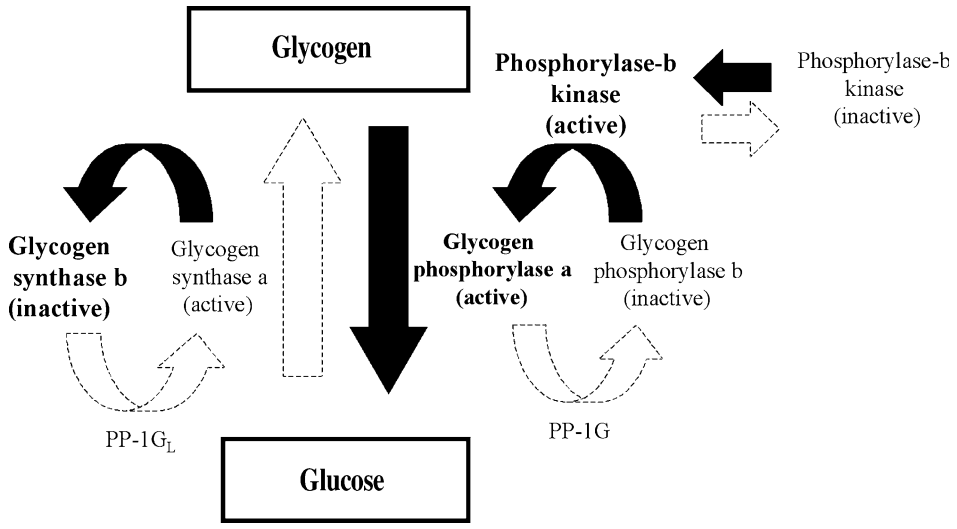

FIGURE 1 Glucagon acts to promote glycogenolysis (actions shown by filled arrows). PP-1G, Glycogen-associated protein phosphatase.

in order to stimulate hepatic glucose production. The key regulatory step in glycolysis is the phosphorylation of fructose 6-phosphate to fructose 1,6-bisphosphate by the enzyme phosphofructo-1-kinase (PFK-1) (Fig. 2). In contrast to many other enzymes in glycolysis, the actions of PFK-1 are unidirectional, i.e., irreversible by PFK-1. During gluconeogenesis, fructose 1,6-bisphosphate is converted back into fructose 6-phosphate by the action of fructose 1,6-bisphosphatase. Thus the metabolic balance between glucose breakdown and formation depends on the balance between the activity of PFK-1 and fructose 1,6-bisphosphatase. This balance is controlled with the aid of the enzyme phosphofructo-2-kinase/fructose 2,6-bisphosphate (PFK-2), which is the site of action of glucagon on glycolysis/gluconeogenesis. PFK-2 acts to convert fructose 6-phosphate into fructose 2,6-bisphosphate, but, in contrast to the PFK-1 and fructose 1,6-bisphosphatase, the action of PFK-2 is reversible. The direction of action of PFK-2 is determined by its phosphorylation state: when phosphorylated it acts as a phosphatase and when dephosphorylated it acts as a kinase. Fructose 2,6-bisphosphate, the product of PFK-2 when dephosphorylated, is an allosteric activator of PFK-1.

Like the effects on glycogen metabolism, the short-term effects of glucagon on glycolysis/gluconeogenesis are exerted by phosphorylation of a key enzyme. Glucagon acts via protein kinase A to increase phosphorylation of PFK-2, thus converting it into a phosphatase and decreasing levels of fructose 2,6-bisphosphate. This will tend to decrease activity of PFK-1 and thus reduce flux through glycolytic pathways.

Glucagon also acts via CREB to alter gene expression, increasing levels of key gluconeogenic enzymes such as phosphoenolpyruvate carboxykinase, fructose 1,6-bisphosphatase, and glucose 6-phosphatase. Glucagon also decreases levels of the glucose transporter GLUT 2 and the hexokinase glucokinase, thus reducing liver glucose uptake and flux into glycolytic pathways. One important difference between the actions of glucagon on glycogenolysis/glycogen synthesis and actions on glycolysis/gluconeogenesis is that the latter is slower to reverse. This is probably of functional importance, because resynthesis of glycogen during refeeding after a fast, for example, will occur via gluconeogenesis and glycogen synthesis.

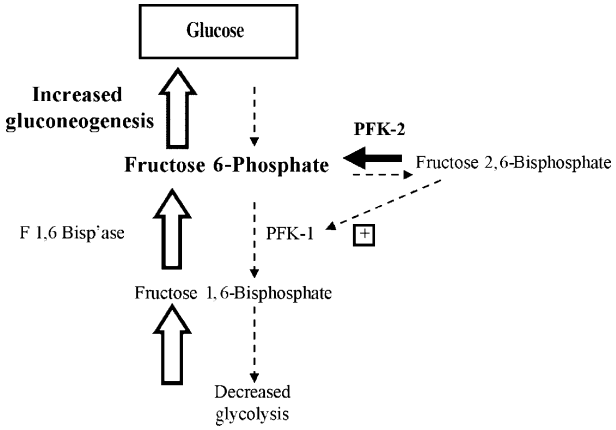

FIGURE 2 Glucagon acts to increase gluconeogenesis by inhibiting PFK1 (actions shown by large arrows). F1,6 bisp'ase, Fructose 1,6-bisphospatase; PFK-1, phosphofructokinase-1; PFK-2, phosphofructokinase-2/fructose 2,6-bisphospatase.

D. Ketogenesis/Lipogenesis

Glucagon induces ketone formation and inhibits lipid synthesis in the liver. Lipid synthesis is inhibited by glucagon by phosphorylation of acetyl coenzyme A (coA) carboxylase, the first step in lipid synthesis. This effect is further enhanced by glucagon's actions to decrease glycolysis, which results in a decrease in acetyl coA, the substrate for acetyl coA carboxylase.

The net result is a decrease in levels of malonyl coA, the product of acetyl coA carboxylase. As well as being the first intermediate in the fatty acid synthesis pathway, malonyl coA has a key controlling influence on lipid metabolism. Increased levels of malonyl coA inhibit carnitine palmitoyltransferase I (CPT I), which transfers fatty acids across the mitochondrial membrane to undergo β-oxidation, resulting in formation of the ketones β-hydroxybutyrate and acetoacetate. A reduction in malonyl coA levels as a consequence of glucagon action thus results in increased β-oxidation of lipids and enhanced hepatic ketone formation. Insulin has opposite actions by decreasing levels of cAMP and thus decreasing protein kinase A phosphorylation of acetyl coA carboxylase.

E. Physiological Role of Glucagon

In health, blood glucose levels are usually maintained within a remarkably tight range. In particular, glucose from the bloodstream is the main, if not the exclusive, fuel for the brain. If blood glucose falls, cognitive performance and brain functioning decrease. If blood glucose rises, as in diabetes, body tissues may be damaged. Glucose homeostasis is achieved largely by interplay between glucagon and insulin actions, although other hormones, the autonomic nervous

system, and the hormone-independent effects of glucose per se also contribute. Mice in which the GR has been knocked out have a lower set point for glucose maintenance, with fed and fasted blood glucose levels about 30 mg/dl lower than in controls, suggesting that glucagon action plays an important, but not critical, role in maintaining euglycemia under normal conditions.

During exercise or stress, such as sepsis, hepatic glucose output rises. Human studies with somatostatin infusion to suppress glucagon secretion (and with replacement of insulin) suggest that the rise in glucagon seen during such stresses plays an important role.

V. NONHEPATIC SITES

Although the classical target organ for glucagon action is the liver, as described above, glucagon receptors are known to exist in tissues in a number of other organs, suggesting putative actions of glucagon in some of these organs. Nevertheless, the main target of glucagon action is the liver.

A. Adipose Tissue

Glucagon receptor mRNA is present in adipose tissue. Glucagon has been shown to have lipolytic actions *in vitro*. A number of *in vivo* studies have also demonstrated an augmentation of lipolysis by glucagon. However, the doses of glucagon used were supraphysiological and studies using more physiological doses, and more sensitive measurements of local tissue metabolism such as microdialysis, have failed to show any effect.

B. Pancreas

Glucagon receptor mRNA has been detected in islets. *In vitro*/*ex vivo* studies suggest that glucagon potentiates insulin secretion from isolated islets, although the potency is considerably less than that of the insulin secretagogue GLP-1. Although the full significance of this remains to be determined, it is possible that local glucagon release from pancreatic alpha cells may exert a paracrine regulation on insulin secretion from beta cells.

It is also conceivable that GR on alpha cells may contribute to the feedback control of insulin secretion. In keeping with this, the GR knockout mice have markedly elevated circulating glucagon levels—two orders of magnitude higher than in wild-type animals and considerably higher than would be expected from their modestly lowered blood glucose. This suggests that there may be a blood glucose-independent feedback loop controlling glucagon secretion, with alpha cells monitoring bioactive glucagon by a GR-mediated process.

C. Other Organs

Glucagon receptor mRNA has been identified by Northern blotting in rat heart, gastrointestinal tract, kidney, brain, spleen, ovary, and thymus, and in lesser amounts in adrenal gland, thyroid, and skeletal muscle. Glucagon has been demonstrated to have both inotropic and chronotropic effects on myocardium, and to be a vasodilator. In the kidney, glucagon has been shown to increase renal blood flow, glomerular filtration rate, and electrolyte excretion, although pharmacological doses are required. The kidney is also a gluconeogenic organ but, in contrast to its effects on the liver, glucagon has no actions on renal glucose production. In summary, the action of glucagon on these nonclassical target tissues is uncertain, with many of the effects being demonstrable only when pharmacological doses of glucagon are used. On the other hand, the presence of glucagon receptors suggests that there may be other, as yet unidentified, actions of glucagon in these organs.

VI. MINIGLUCAGON

Miniglucagon was first discovered in 1990 as the product of the proteolytic cleavage of glucagon by a protease named the miniglucagon-generating endopeptidase (MGE). Miniglucagon is the COOH-terminal (19–29) fragment of glucagon cleaved by MGE at the Arg^{17}-Arg^{18} doublet. Although first described in hepatic cells, MGE has been identified in pancreatic islets and other putative target tissues of glucagon, including heart, gastric mucosa, kidney, and spleen.

Miniglucagon has been demonstrated to be biologically active. Indeed, it is two orders of magnitude more potent than the intact glucagon molecule, which may more than compensate for the lower concentrations compared to full-length glucagon. In pancreatic islets, for example, miniglucagon colocalizes with glucagon in alpha cell secretory granules, with levels at about 3–4% of intact glucagon levels.

A number of putative actions have been suggested for miniglucagon, most notably in nonhepatic tissues. *In vitro* studies on insulin secretion from islets and/or isolated pancreata have shown that miniglucagon inhibits, and miniglucagon antiserum increases, insulin secretion. Similarly, in heart muscle there is

some *in vitro* evidence that cleavage of glucagon into miniglucagon may be necessary, at least in part, for the inotropic effects of glucagon. However, the exact physiological role of miniglucagon and its interplay with glucagon action remain to be determined.

VII. ABNORMAL GLUCAGON ACTION

A. Glucagon in Diabetes

Abnormal glucagon secretion has long been recognized in type 1 diabetes. Circulating glucagon levels are elevated in absolute or relative terms and may not suppress normally with eating. This has lead to the suggestion that diabetes is a bihormonal disease, with hyperglucagonemia contributing to the development of hyperglycemia and possibly even the catabolic state that may be present at diagnosis of type 1 diabetes. As previously discussed, the actions of insulin and glucagon are closely coordinated so that the insulin deficiency that coexists in undertreated diabetes makes it difficult to disentangle the effects of elevated glucagon from those of hypoinsulinemia. It seems likely that the dominant influence is the lack of insulin. The exact contribution of hyperglucagonemia to remains to be determined.

At the other extreme, glucagon secretion may fail to rise during hypoglycemia in type 1 diabetes This reduction in defensive glucagon responses, particularly if then combined with secondary deficiencies in catecholamine and symptomatic responses to hypoglycemia, will significantly increase the risk of suffering from severe hypoglycemic episodes. The cause for this is uncertain.

B. Glucagon Receptor Mutations

In epidemiological studies, a polymorphism of the glucagon receptor (glycine at codon 40 is substituted by serine, indicated by the notation G40S) has been associated with an increased risk of type 2 diabetes mellitus, central obesity, and hypertension. Other population studies have failed to show an association. The mechanism by which G40S may result in diabetes or obesity is uncertain given that *in vitro* mutagenesis studies suggest that the G40S polymorphism results in a decreased affinity of the GR for glucagon, which might be expected, at least at face value, to protect against hyperglycemia. For the association with hypertension, a decreased natriuretic effect of glucagon in the G40S kidney has been suggested as a mechanism, although, as previously discussed, the physiological effects of glucagon in the kidney are not clearly established.

C. Glucagonomas

Glucagonomas are glucagon-secreting tumors of the pancreas (or rarely extrapancreatic) that may occur either in isolation or as part of a multiple endocrine neoplasia syndrome. Excessive secretion of glucagon leads to a glucagonoma syndrome characterized by the pathognomonic rash of necrolytic migratory erythema together with weight loss, glossitis, anemia, thromboembolism, gastrointestinal disturbances, and diabetes or impaired glucose intolerance.

VIII. DIAGNOSTIC USE/THERAPEUTIC USE

A. Diagnostic Use of Glucagon

Glucagon given as a 1-mg bolus by intravenous, intramuscular, or subcutaneous routes has been sparingly used as a diagnostic test in three areas of clinical practice. Although the tests are largely safe, about 20% of recipients suffer side effects, mostly nausea, dizziness, flushing, and transient syncope.

Glucagon has been used to measure the C-peptide response and thus, by inference, the insulin secretory reserve of diabetic patients. Although often assumed to distinguish between type 1 and type 2 diabetes without beta cell failure, in practice this is often complicated by type 1 patients with a persisting beta cell secretory reserve. For example, some patients may develop a "honeymoon" period, with minimal requirement for insulin lasting for several months after the onset of type 1 diabetes and a persistent C-peptide response to glucagon. Some type 1 patients may have an insidious onset of diabetes, i.e., the latent autoimmune diabetes of adult onset (LADA) with persisting C-peptide response during progression. Even in type 2 diabetes, C-peptide response has been in general an unreliable predictor of the need for insulin treatment.

In endocrinology clinics, glucagon has been used as a dynamic pituitary function test to measure growth hormone (GH) and adrenocorticotropic hormone (ACTH) secretory capacity, particularly in situations when insulin stress testing is desired but is contraindicated for medical reasons such as ischemic heart disease or epilepsy. The mechanism by which glucagon stimulates GH and ACTH release is poorly understood, but it may be a secondary effect mediated by catecholamine release. The latter effect has been employed by using a bolus of glucagon with measurement of plasma catecholamines in the diagnosis of phaeochromocytomas, although the test is not without risk and may not increase diagnostic

sensitivity above that of simple nondynamic measurement of plasma and urine catecholamines.

Finally, the 1-mg bolus glucagon test has also been used in oncology clinics to distinguish different types of tumor hypoglycemia, with a blood glucose rise of at least 30 mg/dl suggesting that hypoglycemia is a result of hypersecretion of insulin or insulin-like growth factor-II (IGF-II), rather than other neoplastic causes such as hepatic failure. A glycemic response to glucagon may also indicate that glucagon infusion is a useful palliative therapeutic option for such patients if other treatments are ineffective.

B. Therapeutic Use of Glucagon

Glucagon administered by subcutaneous, intramuscular, or intravenous routes is a rapid and effective treatment for insulin-induced hypoglycemia. Many patients with type 1 diabetes or their caregivers thus choose to have prefilled glucagon syringes at home for emergency rescue from severe hypoglycemia. An important caveat is that liver glycogen stores must be adequate for glucagon to be effective. The effects will also wear off relatively quickly, so that a successful rescue must be followed up by ingestion of carbohydrate to prevent a subsequent relapse (and, importantly, a critical review of the precipitating causes of the episode).

Glucagon has also been useful in rare cases of noniatrogenic hypoglycemia, either in cases of insulinoma or IGF-II-induced tumor hypoglycemia or in familial hyperinsulinemia. In these situations, glucagon must be given continuously, usually as a subcutaneous infusion.

The positive inotropic and chronotropic actions of pharmacological doses of glucagon have been utilized to treat drug-induced bradycardia, which can occur, for example, after overdoses of beta blockers, digoxin, or calcium blockers such as nifedipine or diltiazem. Although a role for glucagon in the treatment of bronchospasm, cardiogenic shock, and systolic/electromechanical cardiac arrest has even been suggested, the relative benefits of glucagon when compared with more conventional therapies remain to be determined and it seems unlikely that glucagon will replace more conventional therapies.

Glossary

cAMP response element binding protein Nuclear transcription factor that mediates effects of cAMP to alter gene expression.

cyclic adenosine monophosphate Second messenger formed inside cells in response to glucagon binding to its cell surface receptor, triggering a cascade of intracellular actions.

glycogenolysis Glucagon-stimulated breakdown of glycogen stores in the liver.

glycogen phosphorylase The main rate-limiting enzyme in glucagon-stimulated breakdown of glycogen.

glycogen synthase The main rate-limiting enzyme in glycogen synthesis; inhibited by glucagon.

miniglucagon Product of proteolytic cleavage of glucagon by endopeptidase; of uncertain physiological significance, despite its greater biological potency.

phosphorylase kinase Regulatory enzyme that modifies the action of glycogen phosphorylase by phosphorylation.

mice develop mild hypoglycemia due to glucagon deficiency. In contrast, the liberation of an intestinal profile of PGDPs, including glicentin, oxyntomodulin, and glucagon-like peptides (GLP-1 and GLP-2), derives from expression of the enzyme PC1/2 in enteroendocrine cells of the small and large intestines.

II. PROGLUCAGON GENE EXPRESSION IN THE PANCREAS

The level of blood glucose is a major determinant of secretory activity from the islet A cell, with hyperglycemia inhibiting, and hypoglycemia stimulating, the release of glucagon into the circulation. Consistent with these findings, rats subjected to chronic hyperglycemic infusion for 5 days exhibit a significant reduction in islet proglucagon mRNA transcripts as assessed by *in situ* hybridization. Because hyperglycemia is frequently associated with enhanced insulin secretion, it is difficult to isolate the effects of glucose versus insulin on the islet A cell. Insulin administration inhibits proglucagon gene expression in normal and diabetic rodents; insulin-induced hypoglycemia, however, is associated with increased pancreatic proglucagon gene expression in the rat. Similarly, food deprivation leading to mild hypoglycemia is associated with induction of rat proglucagon gene expression. Studies of streptozotocin-induced diabetes in rats demonstrate increased levels of pancreatic proglucagon mRNA transcripts in

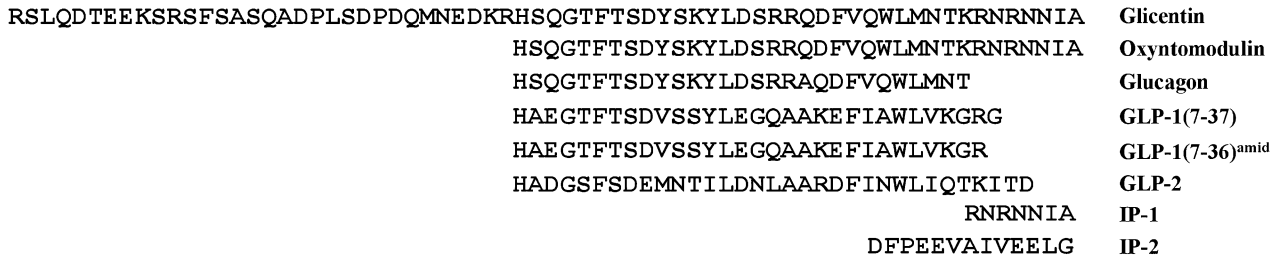

FIGURE 2 Amino acid sequence of the proglucagon-derived peptides liberated from proglucagon.

insulin-deficient diabetic rats, whereas the levels of proglucagon mRNA transcripts are reduced following correction of hyperglycemia following insulin administration. Whether changes in glucose alone, independent of insulin, regulate pancreatic proglucagon gene expression remains unclear, because correction of the hyperglycemia of experimental rodent diabetes with phlorizin is not associated with significant changes in the levels of pancreatic proglucagon mRNA. Despite the dominant inhibitory effect of insulin in the regulation of islet proglucagon gene expression, mice with targeted disruption of the insulin receptor gene exhibit no abnormalities in the levels of pancreatic proglucagon mRNA transcripts.

III. PROGLUCAGON GENE TRANSCRIPTION IN ISLET CELL LINES

Proglucagon gene expression has been studied predominantly in immortalized rodent islet A cell lines, including rat RIN1056A, hamster InR1-G9 or HIT T15-G, and mouse αTC-1 cells. Incubation of RIN1056A cells with sodium butyrate induces cell cycle arrest, cell differentiation, and increased levels of proglucagon mRNA transcripts due to induction of proglucagon gene transcription. Similarly, phorbol esters activate proglucagon gene transcription in RIN1056A cells whereas the arginine-induction of rat islet proglucagon gene expression is abrogated by treatment of islets with the protein kinase C inhibitor H-7. Although cyclic adenosine monophosphate (cAMP), acting through protein kinase A (PKA), up-regulates levels of proglucagon mRNA transcripts in primary cultures of rat islets, glucagon-producing rodent islet cell lines frequently exhibit defects in cAMP-dependent signaling and fail to increase levels of proglucagon mRNA transcripts following treatment with dibutyryl cAMP or forskolin. In contrast, transfection of islet cell lines with the catalytic subunit of PKA bypasses the cAMP signaling defect and activates proglucagon gene transcription. Consistent with data from studies of mice and rats *in vivo*, insulin reduces the levels of proglucagon gene expression in islet cell lines via inhibition of gene transcription. Paradoxically, despite the lack of evidence implicating a direct role for glucose in rodent proglucagon gene expression *in vivo* or in cultures of rat islets *in vitro*, chronic incubation (1–5 weeks) of islet InR1-G9 cells with glucose-supplemented medium (11 m*M* glucose) resulted in up-regulation of proglucagon mRNA transcripts, compared to cells incubated in 5 m*M* glucose for comparable time periods. The glucose-stimulated induction of proglucagon mRNA transcripts was due to enhanced gene transcription, and was inhibited by cotreatment with insulin. Analysis of proglucagon mRNA decay following incubation with actinomycin reveals an estimated $t_{1/2}$ of ~12 h in RIN1056A rat islet cells; however, factors that regulate islet proglucagon mRNA stability *in vivo* remain poorly understood.

IV. DELINEATION OF FUNCTIONAL DOMAINS WITHIN THE RAT PROGLUCAGON GENE PROMOTER

A majority of studies of proglucagon gene transcription have predominantly utilized the rat proglucagon gene promoter fused to heterologous reporter genes (e.g., genes encoding chloramphenicol acetyltransferase, luciferase, or growth hormone), followed by analysis of transcriptional activity in transfected islet cell lines. A majority of experiments have focused on the proximal sequences within the first 300 bp of the rat proglucagon promoter, because experiments in islet cell lines demonstrated that proglucagon promoter fusion genes containing additional 5′ flanking sequences extending to −2.3 kb exhibit levels of transcriptional activity comparable to that seen with sequences extending to −300 bp. Structural and functional characterizations of the rat promoter through deletional and mutagenesis studies have identified distinct cis-acting domains within the proximal 300 bp of the rat proglucagon promoter (Fig. 3). These domains, designated G1 through G5, bind transcription factors present in islet cell nuclear extracts and exhibit enhancer-like properties (G2–G5) or function as an islet A cell-specific promoter (G1) *in vitro*. The first three domains to be identified extend from −292 to −256 (G3), −192 to −179 (G2), and −114 to −74 (G1). Subsequent experiments subdivided the G3 sequence into an upstream domain A (5′-CGCCTGA) and a downstream domain B (5′-GATTGAAGGGTGTA-3), and an element partially overlapping original G1 sequences, designated G4, was identified spanning −140 to −100. More recently, DNA sequences located between G4 and G2, from −169 to −140, have been designated as the G5 element. A cAMP response element (CRE), 5′-TGACGTCA-3′, is located upstream of G3 from −300 to −292, and a phorbol ester response element has been mapped to sequences within G2. The finding that potassium-induced membrane depolarization activates glucagon gene

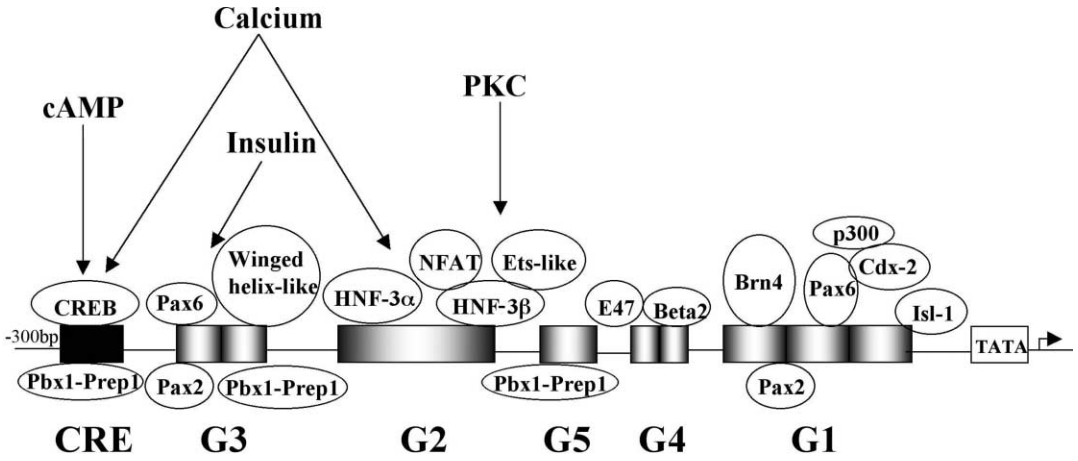

FIGURE 3 The proximal rat proglucagon gene promoter and its interaction with specific transcription factors. Specific functional subdomains, G1–G5, are located within the first 300 bp of the proximal rat proglucagon gene 5′ flanking region. cAMP, Cyclic adenosine monophosphate; PKC, protein kinase C; CREB, cAMP response element binding protein; HNF-3, hepatocyte nuclear factor-3 (see text for discussion of other factors).

transcription in a calcium-dependent manner has resulted in the mapping of the "depolarization response element" to sequences within the rat glucagon gene CRE. Mutational studies of the proximal rat proglucagon promoter have identified a second calcium response element within the region spanned by G2. Similarly, the inhibitory effect of insulin on rat proglucagon gene transcription has been mapped to the more distal domain A of the G3 element, and the available data suggest that insulin also exerts its effects through mechanisms converging on more proximal sequences located within the G1 element.

V. MECHANISMS MEDIATING ISLET A CELL-SPECIFIC PROGLUCAGON GENE TRANSCRIPTION

The observation that pancreatic proglucagon gene transcription is restricted to islet A cells has focused attention on identification of DNA sequences and transcription factors that both activate transcription in the A cell and restrict proglucagon gene transcription to the A cell. The difficulty in obtaining purified populations of nonimmortalized A cells for gene transfer studies has necessitated use of immortalized islet cell lines derived from insulinomas (beta cells) or glucagonomas (A cells) for comparative studies of islet cell-specific proglucagon gene transcription. Indeed, some degree of transcriptional activation is observed following transfection of rat proglucagon promoter sequences into islet beta cell lines. The G2 and G3 elements display weak enhancer-like activity in islet, but not nonislet, cell lines, whereas the more proximal G1 element is required for restriction of transcriptional activation to the islet alpha cell lineage. Nevertheless, the results of electrophoretic mobility-shift assays or footprinting experiments using these DNA elements in conjunction with nuclear extracts from islet cell lines exhibiting different hormonal phenotypes produce comparable patterns of DNA–protein interaction, providing evidence for considerable complexity in the transcriptional specification of A cell-specific gene transcription. Furthermore, insulin and somatostatin gene enhancer sequences placed upstream of the proximal rat proglucagon promoter can activate transcription in islet cells when linked to the G1 element. Moreover DNA sequences within the proglucagon gene G3 element bind nuclear factors that also recognize related sequences within the somatostatin upstream enhancer element and the insulin gene E-1 promoter region, leading to the designation of the G3 domain A region as the pancreatic islet cell-specific enhancer sequence (PISCES) element. Given the common embryological origin of hormonally distinct yet related islet cell lineages, it is not surprising that islet hormone genes have evolved both common and unique mechanisms for specifying islet subtype-specific gene transcription.

Within the G1 proximal promoter element, at least four distinct patterns of DNA–protein complex formation, with varying binding specificity, can be identified using nucleotide sequences from −100 to −52 as probes interacting with islet A cell nuclear extracts. The formation of several G1 complexes

appears to be relatively islet cell specific, and mutations within G1 that disrupt these DNA–protein interactions also result in diminished transcriptional activity in transfected islet A cells. Within the core G1 domain, the sequence CAGATG from −83 to −78 corresponds to E-1, an "E box-related" subdomain known to be important for expression of the somatostatin, insulin, and gastrin genes in islet cells. Two additional E box motifs are located within the adjacent G4 element, E-2, from −108 to −103, and E3, from −135 to −130. Functional studies using dominant negative helix–loop–helix (HLH) proteins suggest that the E-3 box likely represents the more functionally important sequence for transcriptional regulation. Although the insulin gene E boxes function as positive regulatory elements, the HLH protein E47 represses glucagon gene transcription mediated by E box binding sites, whereas the combination of E47 and Beta2 transcription factors activated glucagon promoter activity in InR1-G9 islet cells. Although Beta2-deficient mice develop diabetes and exhibit defects in formation of enteroendocrine cell lineages, whether Beta2 plays an essential role in control of glucagon gene expression independent of A cell lineage formation remains uncertain. Although the first 75 bp of the rat proglucagon gene promoter, comprising a portion of the proximal G1 element, imparts a degree of A cell specificity to transfected reporter genes, inclusion of the entire G1 domain extending to ∼ −100 is required for optimal specificity in alpha versus beta cell lines. Sequences within the G5 element may also function to restrict proglucagon gene transcription to A cells, because sequential deletion of the G5 element modestly increases transcriptional activity of proglucagon promoter reporter genes in nonislet cell lines.

VI. ISLET PROGLUCAGON GENE TRANSCRIPTION FACTORS

The observation that the proximal rat proglucagon promoter G1 element contains several TAAT nucleotide motifs corresponding to recognition sites for homeodomain transcription factors has provided impetus for assessment of the potential role of islet homeodomain proteins in the control of proglucagon gene transcription. The first islet transcription factor cloned using TAAT element DNA probes was Isl-1 (islet 1), a LIM domain homeobox protein that binds DNA sequences in the rat insulin gene E2 region. (The acronym LIM derives from the names of proteins Lin-11, Isl-1, and Mec-3.) Isl-1 also binds to TAAT motifs within the rat proglucagon gene G1 region and is a weak transactivator of proglucagon promoter activity in cell transfection studies. Nevertheless, mice with targeted disruption of the Isl-1 gene contain insulin mRNA transcripts yet exhibit defective islet A cell formation, implicating a role for Isl-1 in islet A cell development. Furthermore, inhibition of Isl-1 expression using antisense expression vectors in hamster islet InR1-G9 cells results in reduced levels of endogenous proglucagon mRNA transcripts. Whether Isl-1 is important for proglucagon gene expression in normal islet A cells awaits loss-of-function studies in human mutations or experiments designed to inactivate Isl-1 specifically in normal alpha cells *in vivo*. The beta cell transcription factor Pdx-1 also binds to the G1 element and is a potent repressor of proglucagon gene transcriptional activity and proglucagon mRNA transcripts, likely via DNA binding-independent mechanisms, in islet cell lines.

The *caudal* family homeobox protein Cdx-2/3, also cloned as an insulin gene enhancer binding protein, binds with high affinity to AT-rich motifs within the proglucagon gene G1 element and activates the proglucagon promoter *in vitro*. Increased expression of Cdx-2/3 also activates expression of the endogenous rodent proglucagon gene in transfected InR1-G9 cells. Two Cdx-2/3 isoforms are detected in rodent islet cells, including full-length bioactive Cdx-2/3, and an amino-terminally truncated protein that binds to the G1 element but does not exhibit transactivation potential. Determination of whether Cdx-2/3 is essential for islet proglucagon gene transcription in normal A cells *in vivo* is hampered by the early embryonic lethality of mice harboring inactivating mutations in the Cdx-2/3 gene.

Both Pax6 and Pax4 are expressed in the endocrine pancreas and play divergent roles in the control of cell lineage formation and proglucagon gene transcription. The paired homeodomain protein Pax6 binds to AT-rich motifs within both the G1 and G3 proximal promoter elements. The Pax6 protein activates G1- and G3-dependent transcription and is capable of synergistic transcriptional activation through heterodimer formation with Cdx-2/3, primarily through binding to the G1 element. The Pax-6:Cdx-2/3 transcriptional activation via G1 is further enhanced through interaction with the transcriptional co-activator p300. Mice with a targeted inactivation of the Pax6 gene, or mice expressing the dominant negative Pax6 SEY^{NEU} allele exhibit marked abnormalities in the formation of islet cell lineages, reduced numbers of islet A cells, and decreased levels of

proglucagon mRNA transcripts. Whether Pax6 is essential for proglucagon gene transcription in the adult A cell independent of its role in islet A cell development has not yet been determined.

The Pax4 gene is also essential for islet lineage development in that inactivation of the mouse Pax4 gene results in failure to form beta and delta cells, yet increased numbers of A cells. Also, Pax4 does not appear to be expressed in mature adult islet A cells, yet it is capable of acting as a transcriptional repressor of proglucagon gene expression when ectopically expressed in islet A cell lines. Intriguingly, the repression of transcription exerted by Pax4 may be independent of DNA binding, because Pax4 isoforms function as transcriptional repressors even in the absence of a DNA-binding domain. The integrated roles of Pax6 and Pax4 in islet cell development have led to a model whereby islet lineage allocation and phenotype may be dictated by both positive (Pax6) and negative (Pax4) control of cell development and hormone gene expression. The related homeobox transcription factor Pax2 is also expressed in islet alpha cells, binds to both the G3 and G1 promoter elements, and functions as a positive regulator of proglucagon gene transcription.

Brain 4 (Brn4), a POU domain transcription factor originally isolated from a rat hypothalamic cDNA library, binds to and transactivates promoters containing a DNA octamer motif recognized by related POU domain proteins. (POU is an acronym derived from the names of three transcription factors, Pit-1, Oct-1, and Unc-86, which are all characterized by a specific DNA-binding domain.) Brain 4 is also expressed in islet A cells, binds to AT-rich sequences within the 5′ end of the G1 element, and activates rat proglucagon gene transcription. Induction of Brn4 expression in beta cell lines is associated with activation of endogenous glucagon gene expression *in vitro*. Whether Brn4 is essential for proglucagon gene transcription in normal islets *in vivo* remains unclear; mice with targeted disruption of the Brn4 gene do not exhibit defects in islet glucagon gene expression. Members of the Maf transcription factor family also bind to G1 and enhance proglucagon gene transcription. Maf factors are capable of enhancing Pax6 transcriptional activity via increased Pax6 binding to G1 or though protein–protein interaction with Pax6 independent of DNA binding. Although c-Maf −/− mice have been generated via homologous recombination, a majority of c-Maf knockout embryos die on days E17.5–18.5, and the surviving mice exhibit microphthalmia; however, the status of endocrine pancreas and islet A cells in Maf −/− mice has not yet been reported.

Members of the hepatocyte nuclear factor-3 gene family (HNF-3), currently known as the Fox (forkhead box) transcription factors, bind to the rat proglucagon gene G2 element. HNF-3β (FoxA2) is expressed in islet A cell lines and overexpression of HNF-3β results in repression of proglucagon promoter activity in islet cell lines *in vitro*. Multiple HNF-3β isoforms can be detected in islet A cell lines that bind G2 with similar affinity, but only the full-length HNF-3β1 isoform represses transcriptional activity. HNF-3β also binds to the G3 element and transfection of a dominant negative mutant HNF-3β represses G3-dependent transcriptional activity in islet A cells. Targeted disruption of HNF-3β results in early embryonic lethality, precluding assessment of A cell formation and glucagon gene expression in the adult mouse, whereas beta-cell-specific inactivation of HNF-3β results in mice with hyperinsulinemic hypoglycemia, likely due to defective control of K_{ATP} channel function.

The HNF-3 (FoxA) proteins exhibit similar patterns of DNA-binding specificity, and both HNF-3α (FoxA1) and HNF-3γ (FoxA3) also bind to the glucagon gene G2 promoter element. Although a functional role for HNF-3γ in control of proglucagon gene transcription remains to be established, HNF-3α activates G2-dependent proglucagon gene transcription in heterologous fibroblasts and in islet cell lines. Furthermore, HNF-3α −/− mice exhibit reduced levels of pancreatic proglucagon gene expression and a defective glucagon secretory response to hypoglycemia, implicating an essential role for HNF-3α in islet proglucagon gene transcription.

VII. INTESTINAL PROGLUCAGON GENE EXPRESSION

Nutrient ingestion represents a primary determinant of proglucagon gene expression in enteroendocrine cells of the small and large intestines. Fasting reduces and feeding stimulates proglucagon gene expression in the rodent small bowel. High-fiber diets lead to up-regulation of proglucagon mRNA transcripts in the distal small bowel and colon, possibly due in part to a direct effect of fatty acids on induction of proglucagon gene expression. Indeed, lumenal infusion of long-chain triglycerides into the rat jejunum or intravenous infusion of fatty acids in parenterally fed rats stimulates intestinal proglucagon gene expression. Intestinal proglucagon gene expression is also up-regulated following major small bowel

resection or induction of experimental diabetes in rodents. The mechanisms regulating intestinal proglucagon gene expression are poorly understood, although incubation of intestinal cell lines with specific nutrients such as peptones or fatty acids upregulates proglucagon gene expression, likely through effects on proglucagon gene transcription. Peptide hormones such as gastrin-releasing peptide also stimulate intestinal proglucagon expression via activation of proglucagon gene transcription.

VIII. PROGLUCAGON GENE ENTEROENDOCRINE TRANSCRIPTION FACTORS

Compared to our understanding of islet proglucagon gene transcription, much less is known about control of proglucagon gene promoter activity in gut endocrine cells. Although the functional properties of the G1–G5 elements have been carefully defined in studies of islet-cell-specific proglucagon gene transcription, the potential importance of these proximal promoter elements in specifying intestine-specific gene transcription is less well understood. Evidence derived from analysis of proglucagon promoter activity following transfection of islet versus intestinal cell lines suggests important differences in the functional organization of proglucagon promoter elements in islet versus enteroendocrine cells. Transfection studies have identified a series of distal enhancer-like elements located between −2253 and −1292 bp upstream of the rat proglucagon gene transcription start site. This broad region of proglucagon gene 5′ flanking sequences, designated the glucagon gene upstream enhancer (GUE), appears to be functionally important for intestine-specific proglucagon gene transcription. Specific subdomains within the GUE exhibit positive and negative effects on reporter gene transcription, and GUE-derived probes bind proteins present specifically in GLUTag cell nuclear extracts. Nevertheless, proglucagon gene transcription factors that activate proglucagon gene expression specifically in gut endocrine cells have not yet been identified.

Both Cdx2/3 and Pax6 are expressed in enteroendocrine L cells, bind the G1 promoter element in electrophoretic mobility-shift assay (EMSA) experiments, and activate proglucagon gene transcription in transfected GLUTag mouse enteroendocrine cells. Mice expressing the dominant negative Pax6 SEY^{NEU} allele exhibit markedly reduced levels of intestinal proglucagon mRNA transcripts in the small and large intestines. Whether this phenotype is principally due to the importance of Pax6 for enteroendocrine cell lineage formation or reflects an essential role for Pax6 in control of intestinal proglucagon gene expression remains unclear. In contrast to the central importance of HNF-3α for islet proglucagon gene expression, intestinal proglucagon gene expression appears normal in HNF-3α −/− mice.

IX. ANALYSIS OF ISLET AND INTESTINAL PROGLUCAGON GENE TRANSCRIPTION IN TRANSGENIC MICE

The proglucagon promoter sequences required for expression of a reporter gene in murine islets and enteroendocrine cells have been broadly identified in a limited number of transgenic mouse studies. A 1252-bp fragment of the rat proglucagon gene promoter and 5′ flanking region extending from the Kpn I site and including 57 bp of exon 1 sequences directed expression of a cDNA encoding SV40 T antigen to islet A cells, resulting in the formation of glucagonomas in mice that were several months old. Transgene expression was also detected in the brain, but not in enteroendocrine cells of the gut. These findings imply that DNA sequences sufficient for islet-specific expression are distinct from those required to target correct enteroendocrine-specific expression. Furthermore, transgene expression under the control of the 1252-bp rat promoter was highly restricted to islet alpha cells, indicating that sequences within this promoter region were sufficient for specification of cell-specific transgene expression. Similarly, a comparable fragment of the rat proglucagon gene promoter extending from the Xho I site to exon 1 was sufficient for directing expression of a modified transforming growth factor-β_1 (TGF-β_1) cDNA to islet A cells *in vivo*. A larger rat proglucagon promoter fragment extending to −2252 bp containing the first 58 bp of exon was also expressed in islet A cells and in brain cells. Furthermore, transgene expression was detected in enteroendocrine cells of the small and large intestines, and these mice developed glucagon-producing endocrine tumors of the colon after weeks of transgene expression. Islet hyperplasia and endocrine tumor formation were also observed in the pancreas after several weeks, suggesting that the −2252 bp of rat proglucagon gene 5′ flanking sequences contained additional information, compared to the smaller 1252-bp promoter fragment, resulting in a greater degree of transgene expression compared to that observed with

the −1252-bp promoter sequence. Transgene expression was also detected in the brain stem and hypothalamus of −2252-bp rat proglucagon promoter transgenic mice.

X. HUMAN PROGLUCAGON GENE TRANSCRIPTION AND PROMOTER STUDIES IN MICE

Although a majority of studies of proglucagon gene transcription have utilized the rat promoter in transfection and transgenic experiments, there is little information available about the functional organization and activity of the human proglucagon gene promoter. Comparison of the human and rat proximal promoter sequences reveals a reasonable degree of sequence conservation within the G1–G5 promoter subdomains. Nevertheless, human proglucagon promoter and 5′ flanking sequences extending to −600 bp are transcriptionally inactive following transfection of rodent islet or intestinal cell lines. Furthermore, in contrast to the data obtained with reporter genes under the control of rat proglucagon promoter sequences, several kilobases of human proglucagon gene 5′ flanking sequences are not sufficient for activation of reporter gene expression in rodent islet cell lines, and human glucagon-producing islet or enteroendocrine cells have not yet been characterized and transfected with these reporter genes. The current findings indicate considerable species-specific differences in the structural and functional organization of the rat versus the human proglucagon gene promoter. Additional experimental data in support of the unique functional organization of the human proglucagon gene promoter derive from transgenic mice studies. A transgene containing the human growth hormone gene under the transcriptional control of ~1.6 kb of the human proglucagon gene promoter was expressed in the brain stem and in enteroendocrine cells, but not in mouse pancreatic islets. These results, interpreted within the experimental limitations of using murine cells for analysis of human promoter expression, provide further evidence suggesting that the human proglucagon gene promoter has evolved distinct functional mechanisms for regulation of islet-specific proglucagon gene transcription.

XI. SUMMARY OF CURRENT KNOWLEDGE

Analyses of islet proglucagon gene expression, based on transfection experiments of rodent cell lines, transgenic mice, and physiological studies of glucoregulation in mice and rats, have delineated specific cis-acting domains and transcription factors that coordinately regulate rat proglucagon gene transcription specifically in islet A cells. Our knowledge of the DNA sequences and transcription factors important for control of proglucagon gene expression in enteroendocrine cells or neurons is considerably more limited. Furthermore, the available data from analysis of the human proglucagon promoter imply important functional species-specific differences, suggesting that the data obtained from analysis of the rat promoter may not necessarily be applicable to our understanding of human proglucagon gene expression. It seems likely that the development of additional experimental models using newly derived human endocrine cell lines, taken together with more detailed analysis of the factors regulating human proglucagon gene transcription, will be required to reconcile the differences observed in results from studies of rat and human proglucagon promoter control.

Glossary

diabetes Metabolic syndrome characterized by an elevated blood glucose that results from a combination of insufficient insulin production and/or deficient insulin action.

enteroendocrine cells Specialized, phenotypically distinct endocrine cells; found within the mucosa of the gastrointestinal tract, they produce one or more peptide hormones.

glucagon-like peptides Two small peptides, glucagon-like peptide-1 and glucagon-like peptide-2, derived from posttranslational processing of proglucagon; exhibit sequence similarity to glucagon.

intestine The gastrointestinal tract, including the stomach and the small and large bowel tracts.

islets The islets of Langerhans; include four distinct highly specialized endocrine cell types that produce insulin beta cells), glucagon (alpha cells), somatostatin delta cells), or pancreatic polypeptide (PP cells).

Glucagon-like Peptides: GLP-1 and GLP-2

YOUNES ANINI AND PATRICIA L. BRUBAKER
University of Toronto

Glucagon-like peptides, produced in the intestine, are hormones that participate in the regulatory processes of insulin secretion and intestinal growth. Mechanisms controlling their synthesis and secretion, the nature of their receptors, and their biological and potential therapeutic effects are of great interest because of their potential in treating diabetes and intestinal insufficiency.

I. INTRODUCTION

Glucagon-like peptide-1 [GLP-1(7–36 NH_2)] and glucagon-like peptide-2 [GLP-2(1–33)] are intestinal peptide hormones that play important roles in the regulation of insulin secretion and intestinal growth, respectively. The physiology of these peptides and their potential roles in the treatment of diabetes and intestinal insufficiency, respectively, have been the subject of a number of recent studies. The gene encoding proglucagon, the precursor of GLP-1 and GLP-2, is expressed in pancreatic alpha cells and in endocrine L cells that are localized in the distal intestine and colonic mucosa. Mammalian proglucagon protein contains three homologous hormonal sequences: glucagon, GLP-1, and GLP-2. These sequences appear in this order in proglucagon, but are separated by two intervening peptides (IPs), IP-1 and IP-2, and are preceded by an N-terminal extension called glicentin-related pancreatic polypeptide (GRPP) (Fig. 1). Present at either end of each peptide are pairs of basic amino acids (Lys-Arg or Arg-Arg), representing sites of cleavage by the prohormone convertases (PCs), PC2 and PC1/PC3, in islet A cells and intestinal L cells, respectively.

In pancreatic alpha cells, proglucagon is processed to glucagon, GRPP, IP-1, and the major proglucagon-derived fragment (MPGF), which contains the unprocessed GLP-1, IP-2, and GLP-2 sequences. Although very low levels of GLP-1 are generated in alpha cells, GLP-1 and GLP-2 are major products of proglucagon processing in L cells, along with glicentin and oxyntomodulin, which contain unprocessed glucagon. The enteroendocrine cells producing the proglucagon-derived peptides (PGDPs), classified as L cells, are one of the most abundant endocrine cell types in the mucosa of the mammalian ileum, colon, and rectum. They are one of the so-called open-type endocrine cells (e.g., an elongated cell with apical microvilli reaching into the intestinal lumen and a base rich in endocrine granules near the basal lamina), which suggests that these cells can directly sense the lumenal contents. Most of the L cells reside

exerted mainly in the liver, where glucagon receptors are abundant. Activation of these G-protein-coupled receptors by the hormone activates signal transduction pathways, leading to glycogenolysis and stimulation of gluconeogenesis. These actions elevate the blood sugar level, opposing the hypoglycemic action of insulin and thus helping maintain normal blood glucose levels during fasting and in the postprandial period. The main stimulus to glucagon secretion is hypoglycemia, but amino acids, other hormones such as insulin, and autonomic activity also appear to regulate its release.

The pancreatic alpha cells are one of four distinct endocrine cell types that occur in the pancreatic islets. They contribute 15–20% of the islet cell mass, being second in abundance to the beta cells, which make up 65–70% of the islet cell population. Endocrine cell secretory products (e.g., insulin) are carried first to the liver via the portal vein and then into the periphery, a factor that enhances the direct action of glucagon on the liver to regulate blood glucose levels.

II. BIOSYNTHESIS OF GLUCAGON

Early studies indicated that, like insulin, glucagon might be derived from a larger precursor. However, the prohormone was not identified until 1979 when Patzelt *et al.*, in pulse-chase labeling studies with isolated islets of Langerhans, demonstrated the existence of an 18-kDa protein that contained glucagon (Fig. 2). The 18-kDa proglucagon molecule was labeled after a very short pulse of radioactive amino acids and within 10 min underwent a slight shift toward a higher molecular weight, apparently due to O-glycosylation, thought to occur downstream of the glucagon moiety in the sequence. During the ensuing 2-h period, most of the proglucagon was converted via larger intermediate forms into the major products, consisting of glucagon and a ~10-kDa peptide termed the major proglucagon-derived fragment (MPGF).

The subsequent molecular cloning of glucagon cDNAs in several species confirmed these findings and provided the predicted amino acid sequence of preproglucagon, the encoded glucagon gene product (Fig. 3). Preproglucagon contains an N-terminal signal peptide in addition to the 18-kDa proglucagon sequence. However, besides glucagon, two additional glucagon-related sequences were found in proglucagon, within the C-terminal MPGF. These, like glucagon, were demarcated on either side by pairs of basic amino acids, suggesting that they could be released by proteolytic processing. Subsequent studies confirmed that these peptides, designated glucagon-like peptides (GLP-1 and GLP-2), are normally secreted from the proglucagon-expressing endocrine L cells in the intestinal mucosa. The L cells process proglucagon differently so as to liberate these two peptides, whereas the glucagon-containing N-terminal half of the proglucagon molecule is mainly released as a single intact entity known as glicentin

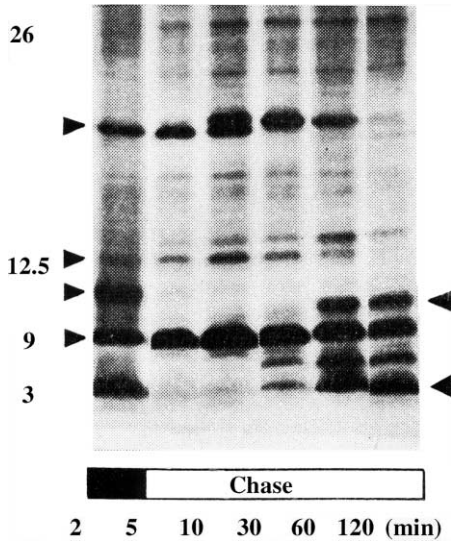

FIGURE 2 Biosynthesis of glucagon in rat islets of Langerhans. Pulse-chase labeling of rat islet proteins using [^{35}S]methionine as the tracer amino acid. After a 2-min pulse-labeling period, radioactivity was chased by dilution with a large volume of buffer containing an excess of unlabeled methionine. The glucose concentration was kept low (2.5 m*M*) to suppress insulin biosynthesis as much as possible. Proteins were resolved by sodium dodecyl sulfate/polyacrylamide gel electrophoresis and bands were identified by autoradiography. Numbers on the left represent molecular weights of marker proteins. Arrowheads on the left (from top down) indicate proglucagon (18 kDa), prosomatostatin (12.5 kDa), preproinsulin (11.5 kDa), and proinsulin (9 kDa). Arrowheads on the right indicate the major proglucagon fragment (10 kDa) and glucagon and the insulin B chain (3 kDa). Modified from Patzelt *et al.* (1979).

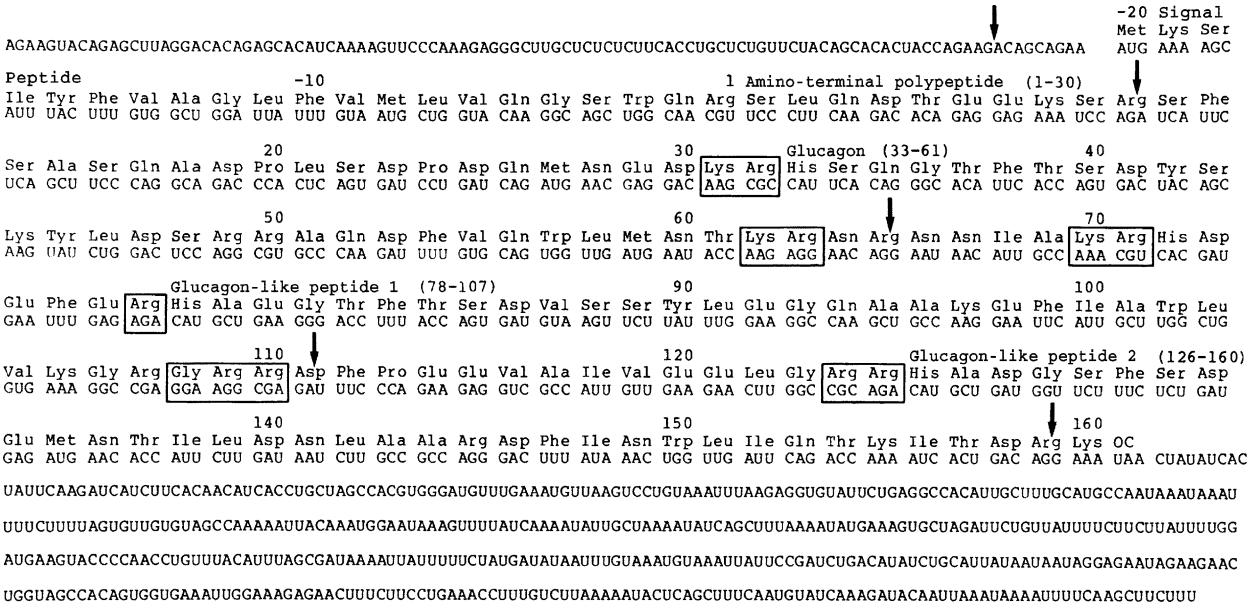

FIGURE 3 Structure of human preproglucagon mRNA and its encoded amino acid sequence. The mRNA encodes a 20-residue signal peptide (−20 to −1) followed by the 160-amino acid proglucagon sequence. The cleavage sites are boxed and vertical arrows indicate the positions of introns in the corresponding genomic sequence on chromosome 2 in humans. From Bell (1989) in *Endocrinology*, 2nd ed. (L. DeGroot, ed.) pp. 1263–1289, with permission.

(Fig. 4). The 69-residue glicentin peptide had been described originally as "gut glucagon" and had been isolated and characterized from intestinal mucosa.

GLP-1(1–37) is further processed at a single arginine residue in the L cells, giving rise to GLP-1(7–37), the major secreted GLP-1 bioactive form. It functions as a powerful "incretin," increasing insulin secretion in response to orally ingested food. The L cell secretory activity is regulated by other gut endocrine factors [such as glucose-dependent insulinotropic polypeptide (GIP)] that are released in response to feeding. GLP-1(7–37) acts on specific G-protein-coupled receptors in the beta cell that are distinct from the glucagon receptors, augmenting insulin secretion in response to the elevated blood glucose levels of the postprandial state.

Sequences near each cleavage site are shown above or below the sequence. GLP, Glucagon-like peptide; GRPP, glicentin-related polypeptide; IP, intervening peptide.

III. THE PROHORMONE CONVERTASES

Since 1990, with the identification of furin and PC2, a seven-member family of proprotein-processing endoproteases that act within the secretory pathway has gradually emerged (Fig. 5). These proteases are all homologues of the yeast-processing protease (kexin) but are more diverse in their functional adaptations and localization within the secretory pathway. The catalytic domain of the convertases is a serine protease that is related to the subtilisin family of proteases, known as subtilases, and this subfamily is therefore known as the subtilisin-like proprotein convertases (SPCs). Most of the subtilases are nonspecific degradative endoproteases. However, special adaptations in the SPCs, including an additional ~150-residue well-conserved downstream domain, the P domain, have increased their specificity and introduced a special regulatory feature-a

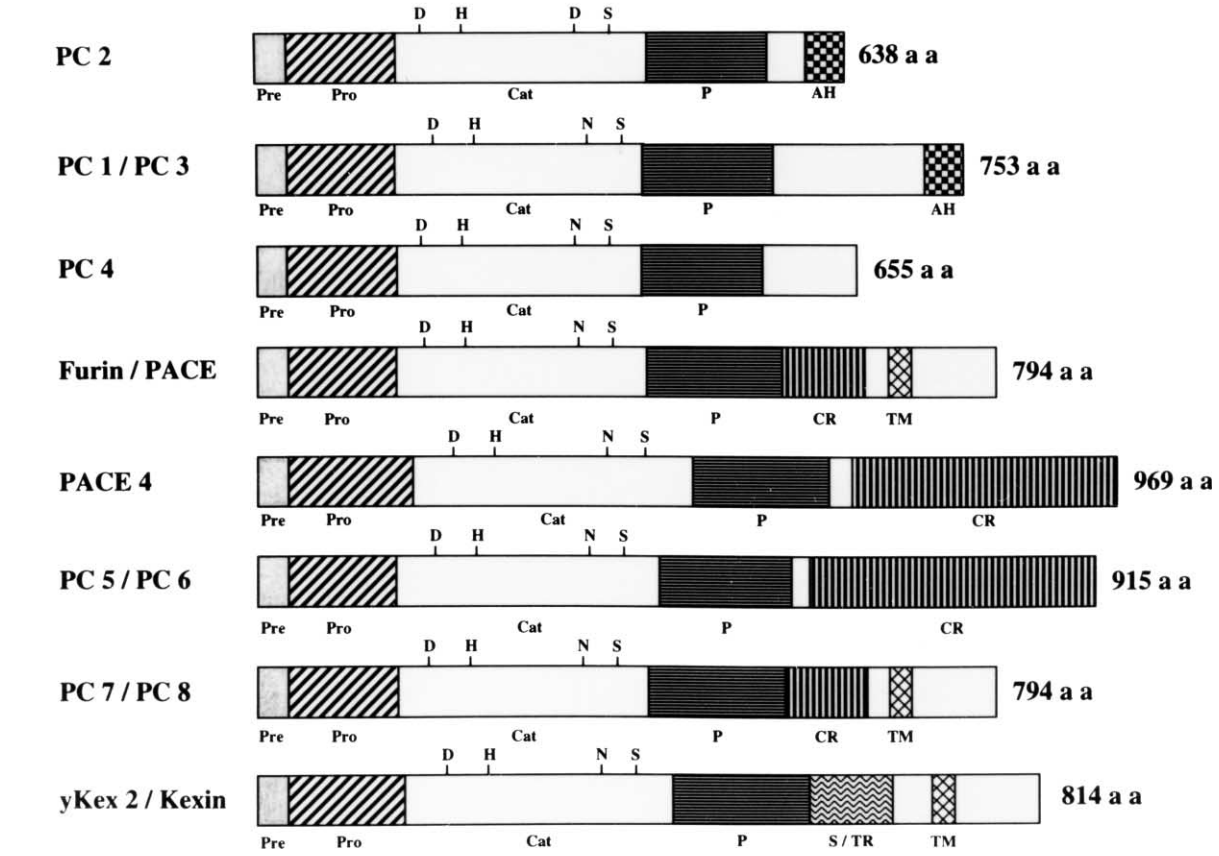

FIGURE 5 Schematic representation of the structural features (A) and sequence organization (B) of the mammalian subtilisin-like proprotein convertases (SPCs). All seven family members have well-conserved signal peptides, proregions (Pro), catalytic domains (CAT), and P domains (P), but differ in their carboxyl-terminal domains (VAR), as indicated. Autocatalytic cleavage and release of the prodomain results in activation. Modeling studies predict that the P domain

requirement for micro- to millimolar calcium for activity.

All of the convertases have an inhibitory prodomain that immediately follows the signal peptide at the N-terminus and that must be removed to activate the proenzyme. Evidence has indicated that this cleavage is autocatalytic and in most cases occurs during the transport of the proprotease from the endoplasmic reticulum (ER) to the Golgi region where the prodomain dissociates and is degraded or inactivated. The cleavage sites for activation reflect the cleavage specificity and consist of polybasic sequences having the following motif: Arg·X·Lys/Arg·Arg. PC2 differs from the other convertases in that its activation occurs in the distal secretory pathway, most likely in the trans Golgi network (TGN) or early secretory granules (progranules). PC2 also requires the neuroendocrine protein 7B2 for activation. After proPC2 folds in the ER, it binds to 7B2, which facilitates its transport to the secretory granules and subsequent autocatalytic cleavage to yield the active form. The molecular basis for this effect of 7B2 on PC2 activation is not completely understood, but it may act through stabilization or alteration of proPC2 structure in a manner that facilitates the achievement of an active conformation following cleavage of the prosegment.

PC2 and PC1/PC3 are two members of the convertase family that are widely distributed within the brain and neuroendocrine system and thus are the major players in the processing of both neuropeptide and hormone precursors. PC4 is also similar to PC2 and PC3 in size and overall structure, but appears to be confined in its expression to the gonads, where it plays a role in fertility. In the intestine and perhaps also in brain, PC5A/PC6A may also play a role in maturing some hormone precursors. These convertase family members all have the appropriate characteristics and structural features that allow them to be sorted into regulated secretory vesicles/granules and to function in their acidic interiors. In contrast, furin, PC7/PC8, and PC5/PC6B all have transmembrane domains with cytosolic extensions that interact with factors that target them to the TGN and constitutive cargo vesicles, where they process proreceptors and the precursors of growth factors and/or plasma membrane proteins during their unregulated transfer to the cell surface or exterior. The pH optima of this latter group are mildly acidic (pH ~ 6.0–6.5), whereas the pH optima of the secretory granule convertases range from ~5.0 for PC2 to ~5.5 for PC3. Because of its earlier activation during intracellular transit, PC3 is believed to begin to act as early as the stage of secretory granule assembly in the TGN, whereas PC2 begins to act only in the secretory granules. Most prohormone processing, however, is believed to occur within early secretory granules after their formation. In the maturing secretory granules, PC3 undergoes further cleavages in its C-terminal region, truncating it from the full-length 753-residue active form to a ~616-residue form that appears to have increased activity, thus contributing to enhanced prohormone processing activity within the acidic maturing secretory granules.

Proinsulin was the touchstone for much of our knowledge on prohormone biosynthesis and processing. Early research on proinsulin conversion showed that a combination of trypsin-like (trypsin is a basic residue-specific serine endoprotease) and carboxypeptidase B (CPB)-like (CPB is a basic residue-specific exopeptidase that removes C-terminal basic residues) activities rapidly and quantitatively generated the major natural products of proinsulin conversion in the islet beta cell, i.e., native insulin and C-peptide, the entire proinsulin connecting segment without N- or C-terminal basic residues. This model system using pancreatic trypsin and CPB is currently being used commercially with great success to convert biosynthetic human proinsulin to insulin in the manufacture of insulin for treatment of diabetes. However, the natural process of conversion is catalyzed by the SPCs, PC2, and PC3, working together along with carboxypeptidase E (CPE), a homologue of the exocrine pancreatic CPB in the beta cell secretory granules, as illustrated in Fig. 6. PC3 acts first, selectively cleaving the B chain/C-peptide junction in proinsulin and thereby generating an intermediate (split 32,33 and/or *des*-31,32 proinsulin) that is a better substrate for PC2. PC2 in turn cleaves preferentially at the C-peptide/A chain junction to complete the liberation of insulin. CPE normally removes the newly exposed basic residues from the B chain of insulin and the C-peptide so rapidly that such

folds to form an eight-stranded β-barrel that interacts with the catalytic domain through a hydrophobic patch. A note on alternative terminology of SPC, prohormone convertase (PC), and paired basic amino-acid-cleaving enzyme (PACE): furin = SPC1/PACE; PC2 = SPC2; PC1/PC3 = SPC3; PACE4 = SPC4; PC4 = SPC5; PC6 = SPC6; PC7 = SPC7/PC8/LPC.

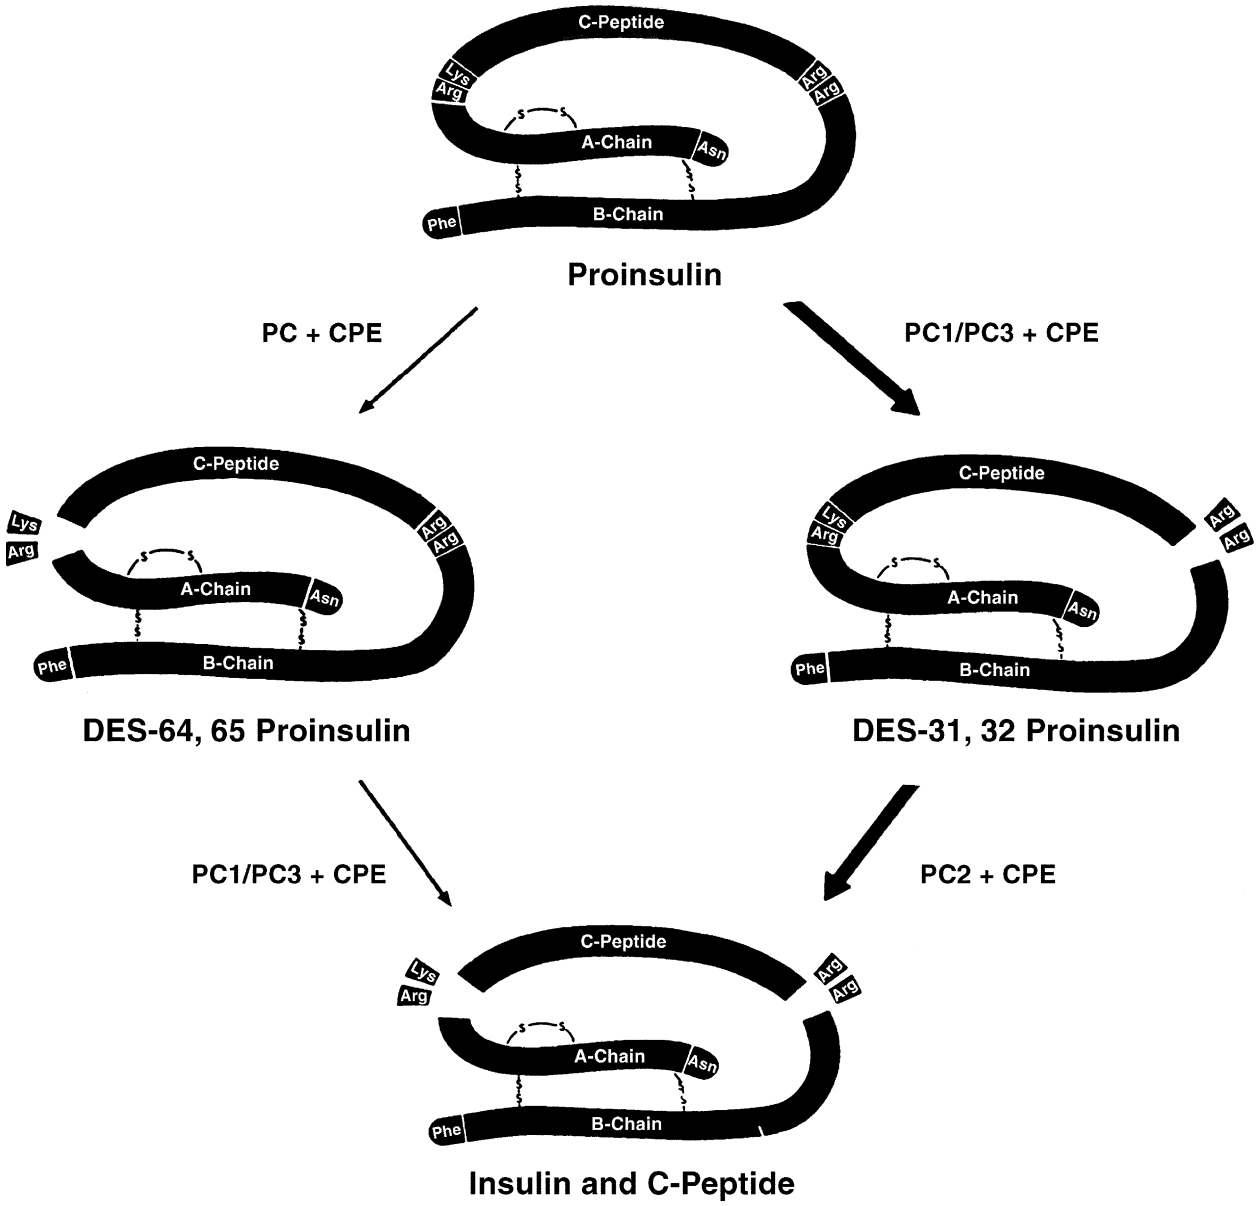

FIGURE 6 Processing of proinsulin to insulin and C-peptide by the prohormone convertases PC1/PC3 and PC2. Scheme depicts the preferential pathway on the right.

C-terminally extended intermediates are difficult to detect. Recent studies with PC2 null mice have demonstrated that proinsulin levels are elevated significantly (~30% vs <5%) and that *des*-31,32 proinsulin intermediates are also elevated, as expected. PC1/PC3 null mice, however, have a much more severe block in proinsulin processing, with levels as high as 85–90% and with significant accumulation of only *des*-64,65 proinsulin intermediates. These findings fully support the scheme shown in Fig. 6.

IV. DIFFERENTIAL PROCESSING OF PROGLUCAGON BY PC2 AND PC1/3

In studies on glucagon biosynthesis in a T antigen-transformed alpha cell line, TCI-6, Rouillé and co-workers have demonstrated that PC2 acting

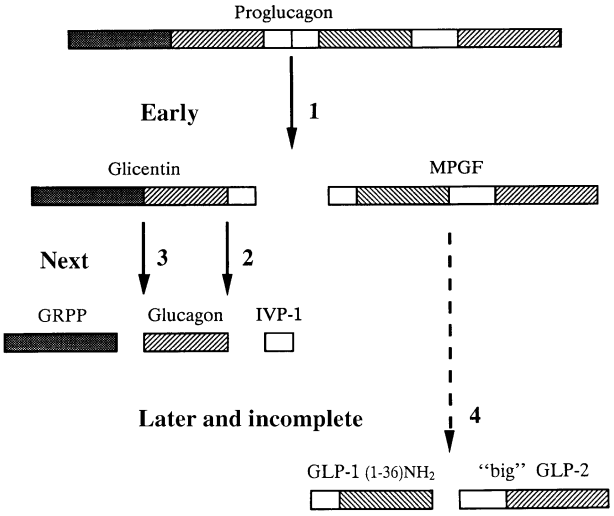

FIGURE 7 Proglucagon processing steps by prohormone convertase 2 in a pancreatic alpha cell-derived cell line, TCI-6. The cleavage at the interdomain site clearly precedes the further cleavage of glicentin to release glucagon. MPGF, Major proglucagon-derived fragment; GRPP, glicentin-related polypeptide; IVP-1, intervening peptide-1; GLP, glucagon-like peptide. Reproduced from Rouillé *et al.* (1994), with permission.

alone in these cells is able to reproduce the normal pattern of glucagon processing as seen in islets of Langerhans. Proglucagon is first cleaved at the interdomain site to release glicentin and MPGF. The glicentin is then further cleaved to glucagon, the C-terminal MPGF remains intact, and these products are secreted (Fig. 7). Further studies have fully elucidated the basis for the differential processing of proglucagon in the alpha cells versus the intestinal L cells, as shown in Fig. 8. The alpha cell pattern of processing of proglucagon is due to the presence of high levels of PC2 and the absence of significant levels of PC1/PC3 or other convertases. The importance of PC2 for the entire series of cleavages that release glucagon from proglucagon has now been confirmed by studies with isolated islets from PC2 and 7B2 null mice, which show a marked inhibition in proglucagon processing. These mice exhibit chronic hypoglycemia and flattened glucose tolerance curves, as expected if glucagon is lacking. Indeed, no active glucagon can be detected, despite the presence of marked alpha cell hyperplasia and large amounts of circulating higher molecular weight glucagon-like immunoreactive material. However, chronic treatment of these mice with glucagon via intraperitoneal osmotic minipumps for several weeks reverses the hypoglycemia and the alpha cell hyperplasia. A similar phenotype is seen in 7B2 null mice, which also lack active PC2.

By contrast, endocrine cells that express high levels of PC1/PC3 can be shown to process proglucagon efficiently to release glicentin and GLP-1, and probably GLP-2 as well. Efforts to identify conclusively the major intestinal L cell convertase as PC1/PC3 in canine intestine have not fully supported this notion, though, because immunoreactivity of both PC2 and PC1/PC3 appears to be present in the L cells. The reason for this discrepancy is not clear, but may be due to species differences between dogs and other mammals. Experiments using various endocrine cell lines that express both PC2 and PC1/PC3 indicate that these cells can process transfected proglucagon completely to all products-glucagon, GLP-1, and GLP-2. PC1/PC3 is also capable of cleaving at the single basic residue site in GLP-1 (proglucagon 72–107) to release active GLP-1(7–37). The proposed role of PC1/PC3 in the *in vivo* generation of GLP-1 in intestine has recently been confirmed by studies with PC1/PC3 null mice. These mice have markedly reduced levels of intestinal GLP-1 (J. Holst, personal communication).

Both PC2 and PC1/PC3 are able to rapidly perform the initial cleavage of proglucagon at the interdomain site between glicentin and the major proglucagon fragment (Fig. 8). These findings suggest that initial cleavage at this site may be required for the further, more specialized processing steps that follow. Recent protein modeling studies of have suggested a plausible explanation for the enhanced cleavage susceptibility of this site, as illustrated in Fig. 9. Further studies support the notion that proproteins such as proglucagon, proinsulin, proopiomelanocortin (POMC), and many others must have defined three-dimensional structures that serve to facilitate their relatively rapid intracellular transport, as well as their specific processing. Cell-specific proglucagon processing thus provides an excellent example of the regulation of specific hormone production from multifunctional precursors via differential tissue expression of prohormone convertases PC1/PC3 and PC2. The molecular basis for the sharply defined specificity of the various convertase cleavage sites within proglucagon, however, remains a mystery at this time.

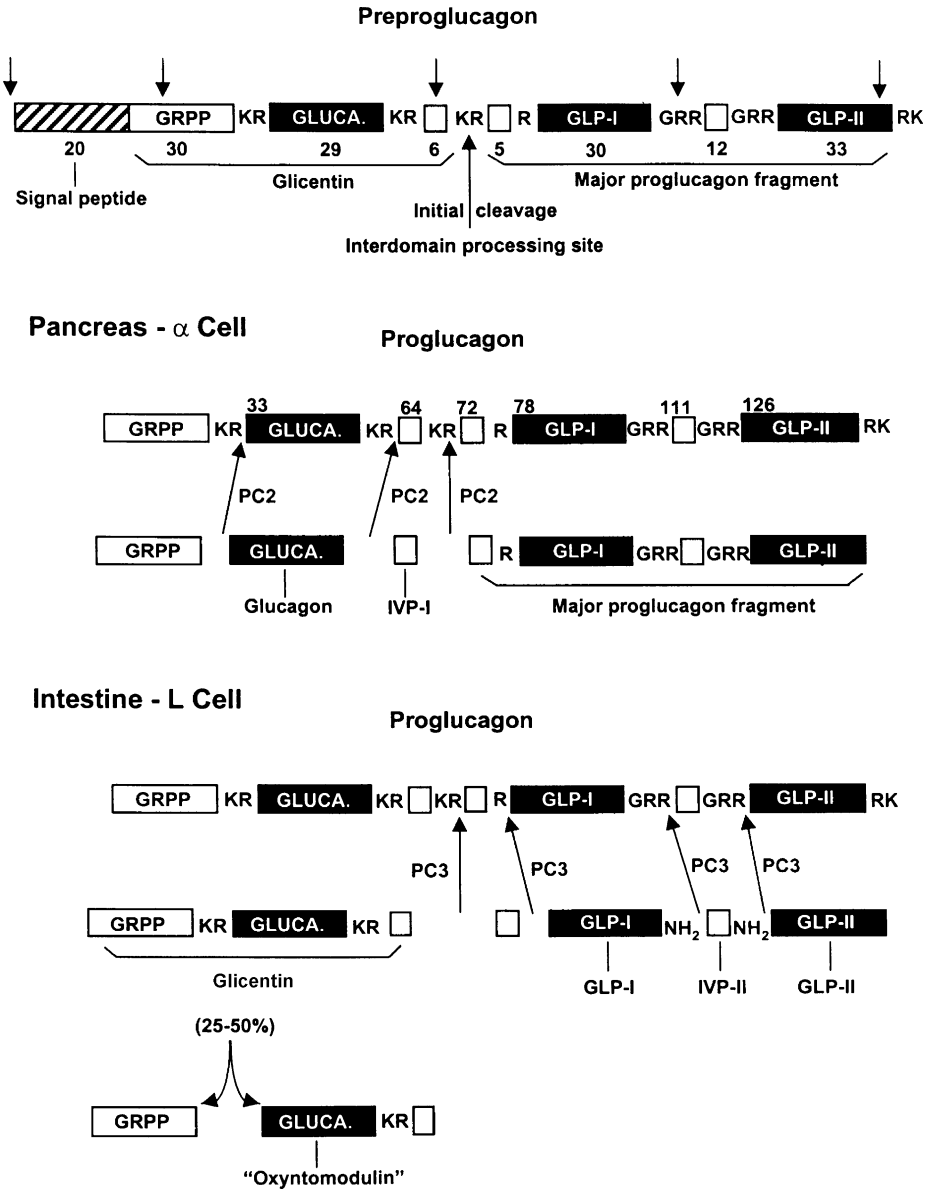

FIGURE 8 Differential processing of proglucagon by prohormone convertases (PC2 and PC1/PC3) in islet alpha vs intestinal L cells. Initial cleavage at the interdomain site by either convertase precedes the further specific processing of the right or left halves of the peptide. Abbreviations as in Fig. 7.

Glossary

glicentin The N-terminal glucagon-containing half of the proglucagon molecule.

gluconeogenesis Production in the liver of glucose from noncarbohydrate precursors to support the blood sugar during fasting.

hyperglycemia Circulating blood glucose levels above normal values.

hypoglycemia Circulating blood glucose levels significantly below normal values.

islets of Langerhans Small clusters of neuroendocrine cells scattered throughout the pancreas, consisting of alpha, beta, delta, and gamma cells that produce the hormones glucagon, insulin, somatostatin, and pancreatic polypeptide, respectively.

major proglucagon-derived fragment The C-terminal half of the proglucagon molecule containing the glucagon-like hormones glucagon-like polypeptide-1 and glucagon-like polypeptide-2.

precursor processing The specific proteolytic cleavage of larger precursor proteins to release biologically

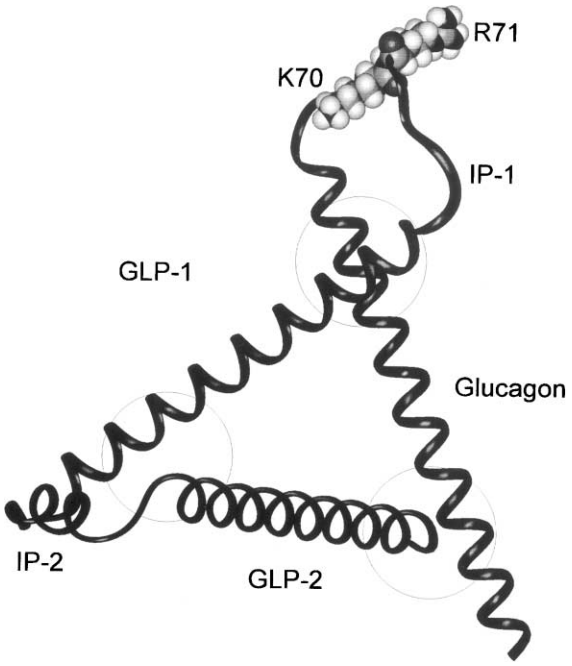

FIGURE 9 Computer-generated model of the structure of proglucagon based on the structure of glucagon in crystalline glucagon. In this model, the three glucagon-related sequences in proglucagon form a triangular structure similar to the stacking of glucagon observed in crystals, in which central alpha-helical regions interact at either end through conserved hydrophobic patches (depicted by the circles). The interdomain cleavage site is in the loop at the top, where it is readily accessible to PC1/PC3 or PC2 in the first step of processing. Courtesy of G. Lipkind.

active peptides or proteins, e.g., insulin from proinsulin.

preprohormone The initial protein precursor, e.g., preproglucagon, of a peptide hormone, as encoded in its chromosomal gene; it contains additional information (signal peptide) specifying its intracellular routing via the secretory pathway.

prohormone The precursor, e.g., proglucagon, of an active peptide hormone or set of functionally and/or structurally related hormones; it is processed into its various active products within secretory granules in its cells of origin.

signal peptide An additional peptide sequence of 12–30 amino acids, having a hydrophobic central stretch of 8–12 strongly hydrophobic amino acids, usually located at or near the N-terminus of a nascent secreted protein, that serves as a signal for its segregative transfer into the secretory pathway. The signal peptide is then removed by the signal peptidase when this function has been completed.

subtilisin-like proprotein convertases The seven-member family (in mammals) of precursor-processing endoproteolytic enzymes that are all derived in evolution from the bacterial serine protease subtilisin; function in the secretory pathway of most of the body's cells to process a wide variety of protein precursors.

Glucagon Secretion, Regulation of

TAMAR SMITH AND JOHN E. GERICH
University of Rochester School of Medicine

Glucagon is a single-chain 29-amino-acid 3.5 kDa peptide hormone encoded on chromosome 2. It is synthesized and secreted by alpha cells of the pancreatic islets of Langerhans following proteolytic cleavage of a prohormone precursor (proglucagon).

I. INTRODUCTION

Proglucagon is encoded by a single gene that contains six exons corresponding to six functional peptide domains. Alpha cell-specific transcription, translation, and modification lead to a 29-amino-acid final product that is formed into granules within the alpha-cell cytoplasm. The L-cells of the small intestine produce a similar precursor, which is processed differently than that of the pancreatic alpha cells so that different peptides are released. Once secreted from the pancreas, glucagon has a half-life of 3–6 min in plasma and is cleared from the circulation mainly by the liver and kidneys. Since pancreatic venous effluent directly enters the portal vein, portal venous glucagon concentration may be many times higher than that in the peripheral circulation.

Glucagon promotes the availability of endogenous fuels (primarily glucose) to maintain normoglycemia and protect against hypoglycemia. Glucagon's primary target organ is the liver but it may also act on adipocytes. Binding of glucagon to receptors in these tissues activates adenylate cyclase. The resulting increase in intracellular cyclic adenosine monophosphate (cAMP) levels alters the phosphorylation/dephosphorylation of enzymes that regulate glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis (Table 1).

Glucagon synthesis involves a typical series of intracellular events including synthesis in the endoplasmic reticulum, transport of the prohormone to the Golgi apparatus for modification and packaging into granules, and the subsequent secretion of glucagon following migration of granules to the plasma membrane.

Recent advances in methodology (cytoplasmic Ca^{2+} monitoring, patch clamp technique, availability of pure islet preparations) have led to a better understanding of the mechanisms involved in glucagon secretion. Changes in hormonally regulated cyclic nucleotides and calcium, in tandem with a nutrient-induced signal, have been implicated in the macromolecular events associated with glucagon secretion. It appears that nutrient-induced alterations in glucagon release are not mediated through changes in cellular cAMP levels since increased cAMP formation in alpha cells per se is insufficient to activate the glucagon secretory process by itself. Nutrient-induced glucagon release can be abolished by somatostatin, which inhibits cAMP formation and blocks cytosolic calcium increases. Somatostatin also inhibits phosphoinositide turnover and stimulates

TABLE 1 Key Enzymes Regulated by Glucagon

p-Enolpyruvate carboxykinase	Up-regulated by glucagon; stimulation of gluconeogenesis (slow action)
Cyclic AMP-dependent protein kinase	Up-regulated by glucagon; phosphorylates several enzymes that regulate fuel metabolism
Phosphorylase b kinase	Activated by cyclic AMP-dependent protein kinase; stimulation of glycogenolysis
Glycogen synthase	Inactivated by cyclic AMP-dependent protein kinase; inhibition of glycogen synthesis
L-type pyruvate kinase	Inactivated by cyclic AMP-dependent protein kinase; stimulation of gluconeogenesis
Acetyl CoA carboxylase	Inactivated by cyclic AMP-dependent protein kinase; inhibition of lipogenesis and stimulation of ketogenesis
Hormone-sensitive lipase	Activated by glucagon in adipocytes via increase in cAMP

phosphodiesterase, thereby augmenting the inhibition of cyclase production. Glucagon release can be amplified by exogenous cAMP (dibutyryl cAMP) and by agents such as epinephrine, which stimulate endogenous cAMP production in alpha cells. It has therefore been suggested that physiologic regulation of glucagon secretion entails the combined action of a nutrient-dependent signal and a cAMP-dependent signal. These most likely involve changes in intraislet calcium levels since glucagon release depends on the presence of extracellular Ca^{2+}, removal of which abolishes the secretory response of alpha cells to nutrients. Various factors including metabolic intermediates, nutrients, hormones, neuropeptides, and the autonomic nervous system can affect glucagon secretion (Table 2).

II. EFFECTS OF SUBSTRATES ON GLUCAGON SECRETION

A. Glucose

The primary regulator of insulin secretion *in vivo* is the plasma glucose concentration: increases suppress secretion and decreases stimulate it. Increases in the extracellular glucose concentration inhibit glucagon secretion. The threshold for glucose-induced inhibition of glucagon *in vitro* is 2–3 m*M*. Half-maximum inhibition and maximum inhibition of glucagon secretion *in vitro* occur at approximately 5.0 and 10.0 m*M* glucose, respectively (Fig. 1). On the other hand, a decrease in extracellular glucose concentration ($\leq$3 m*M*) stimulates glucagon release (Fig. 2). In humans, a decrease in plasma glucose from $\sim$90 to 70 mg/dl is sufficient to stimulate glucagon secretion. The ability of hexoses other than glucose to inhibit glucagon secretion is proportional to the alpha cell's capacity to metabolize the sugar, indicating that the provision of energy/generation of ATP is an important factor. Changes in glucose concentration also modulate the response of the alpha cell to various stimuli such as amino acids; e.g., infusion of glucose diminishes glucagon responses to arginine. This is a paradigm for the general process of integration of nutrient signals and other signals at the level of the alpha cells to modulate glucagon secretion.

The mechanism by which glucose affects glucagon secretion may result in part from the direct effects of glucose, the interrelationship between the alpha and beta cells (insulin), and other factors influenced by changes in glucose concentrations. Glucose probably has a direct effect since alpha-cell suppression can

TABLE 2 Classification of Major Factors Influencing Glucagon Secretion

Substrates	Neural	Local	Hormonal	Ionic
Glucose	Sympathetic	Somatostatin	Insulin	Calcium
Amino acids	Parasympathetic	Serotonin	Growth hormone	Potassium
Free fatty acids		Dopamine	Cortisol	
Ketone bodies		Prostaglandins	Thyroid hormones	
β-Hydroxybutyrate		γ-Amino butyric acid	Estrogens	
Acetoacetate			Androgens	
			Gastrointestinal hormones	
			Gastrin	
			Secretin	
			Pancreozymin (GIP,VIP)	

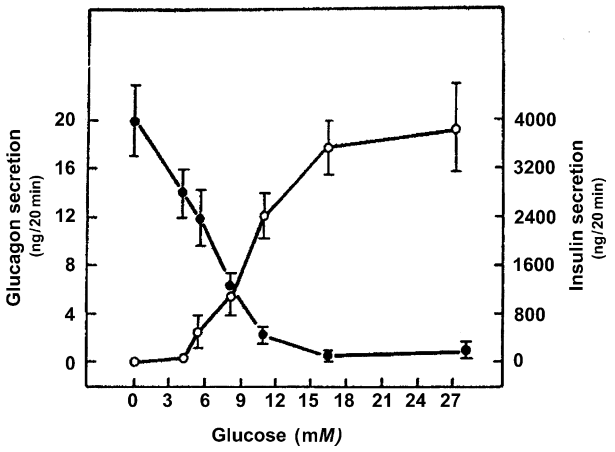

FIGURE 1 Dose–response relationships of the effect of glucose on the suppression of glucagon release and stimulation of insulin release in the perfused rat pancreas. Reprinted from Gerich *et al.* (1974) *J. Clin. Invest.* **54**, 833–841, with permission.

occur at glucose levels too low to stimulate insulin release. Glucose-mediated inhibition of glucagon secretion is thought to be effected via the lowering of intracellular calcium, a positive mediator of glucagon secretion. Exposure of islets to glucose decreases cytoplasmic calcium. There is considerable evidence that an indirect effect of glucose, the stimulation of insulin secretion, also contributes to the rapidity and magnitude of inhibition in alpha-cell secretory activity.

Glucagon release is enhanced by inhibitors of ATP synthesis and is inhibited by fatty acids and ketones, which are presumed to be acting as metabolic fuels. Because most secretory systems require energy, the energy within the alpha cell must be compartmentalized. It should be noted, however, that glucose may act through mechanisms independent of energy production, since the α-glucose anomer is more effective than the β-glucose anomer at suppressing glucagon release. Another possible mediator for glucose-induced suppression is the stimulation of γ-aminobutyric acid (GABA) release from pancreatic beta cells. GABA is co-localized with insulin within beta cells at concentrations comparable to those in the central nervous system. Enzymes responsible for the synthesis and degradation of GABA are present in the beta cell. GABA is released from the beta cell in concert with insulin. There is evidence that GABA subsequently interacts with the $GABA_A$ receptor to open membrane chloride channels, resulting in alpha-cell hyperpolarization and a net decrease in the frequency of action potentials in alpha cells. Thus,

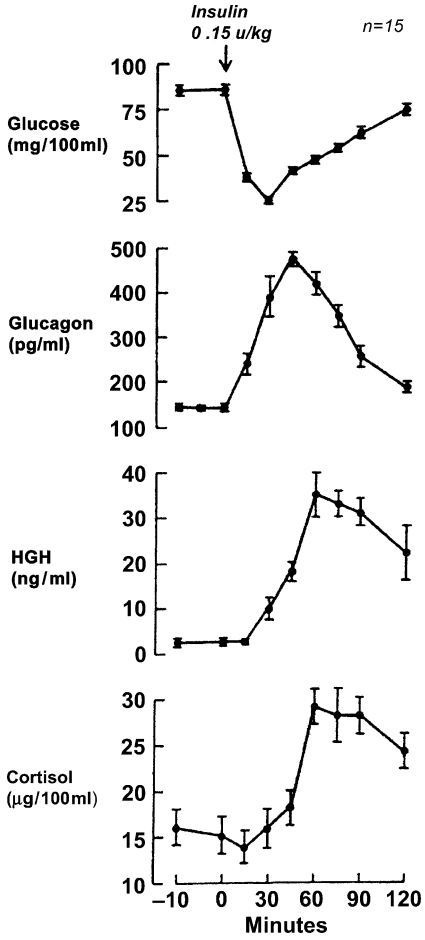

FIGURE 2 Effect of insulin-induced hypoglycemia on plasma glucagon levels in normal human volunteers. Reprinted from Gerich, J. E., Schneider, V., Dippe, S. E., Langlois, M., Noacco, C., Karam, J. H., and Forsham, P. H. Characterization of the glucagon response to hypoglycemia in man. *J. Clin. Endocrinol. Metab.* **38**, 77–82 (1974), with permission. Copyright The Endocrine Society.

GABA may exert a suppressive effect on the alpha cell that is independent of glucose.

B. Amino Acids

Amino acids induce biphasic glucagon release in human and other species (Fig. 3) and are probably as important in stimulating glucagon secretion as hypoglycemia. This effect is glucose dependent and is best observed at low glucose concentrations. The stimulatory effect of amino acids on glucagon secretion appears to be mediated, at least in part, by a direct interaction with the alpha cell, as indicated by studies measuring glucagon release from purified alpha-cell preparations. Current evidence suggests

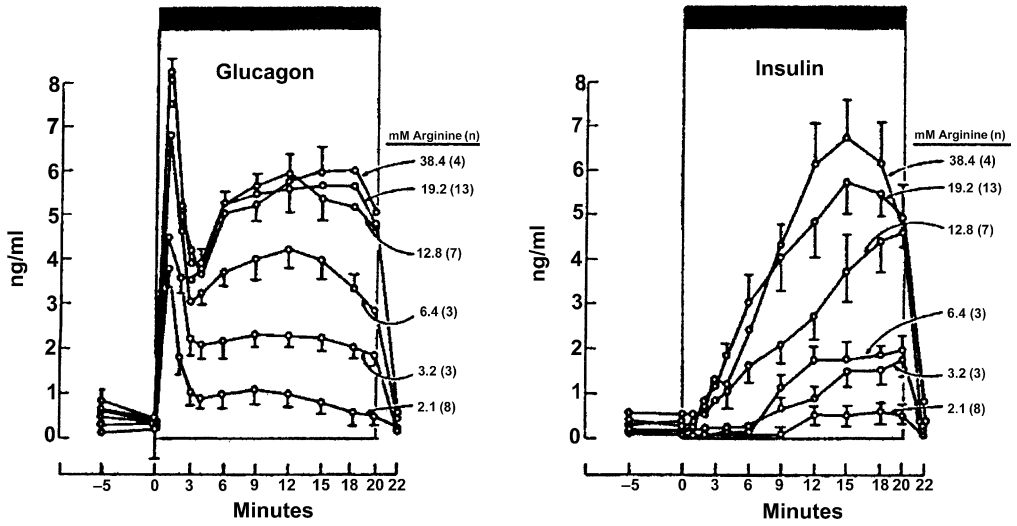

FIGURE 3 Release of glucagon and insulin from the *in vitro* perfused rat pancreas at various arginine concentrations. Reprinted from Gerich *et al.* (1974) *J. Clin. Invest.* **54,** 833–841, with permission.

that the release of glucagon is triggered by the binding of amino acids to membrane receptors, a process that is Ca^{2+} dependent. Changes in second messengers, such as diacylglycerol, Ca^{2+}, and cAMP, may also be involved.

Arginine is the most potent amino acid stimulator of glucagon and insulin secretion and has proven useful for the experimental study of hormonal relationships in the endocrine pancreas. Arginine increases the frequency of action potentials in alpha cells by a direct effect. Glutamine stimulates glucagon release and is readily metabolized by alpha cells. Regulation of glucagon secretion by glutamine appears to be reciprocally related to factors affecting glucose metabolism and ATP levels in the alpha cell. Leucine, although an effective stimulator of insulin release, does not stimulate glucagon secretion. Other amino acids effective in stimulating the release of glucagon are glycine, homoserine, serine, asparagine, valine, alanine, and glutamic acid. It is noteworthy that amino acids, which themselves have little or no activity in stimulating glucagon secretion, are able to potentiate secretion induced by another amino acid, so that ingestion of a mixture of amino acids produces a stimulatory effect that is greater than would be expected from summation of the separate amino acids' stimulatory capacities. Chronic ingestion of a high-protein diet reportedly results in chronically elevated fasting glucagon levels.

Stimulation of glucagon release during ingestion of a mixed meal—presumably the result of amino acids from the digested protein in the meal—would act to balance the actions of concomitantly released insulin (e.g., suppression of hepatic glucose release) to prevent postprandial hypoglycemia.

C. Free Fatty Acids and Ketone Bodies

Free fatty acids (FFA) and ketone bodies (β-hydroxybutyrate and acetoacetate), the predominant fuels in human, inhibit glucagon secretion *in vivo* and *in vitro*. It has been suggested that pancreatic alpha-cell function may in fact be more sensitive to changes in FFA than to glucose. Glucagon is an important stimulator of hepatic ketogenesis, and increases in FFA availability augment ketone body production not only by a mass effect but also by the diversion of hepatic fatty acid metabolism away from triglyceride formation and toward ketogenesis. Thus, suppression of glucagon release by FFA and ketone bodies may act as a possible negative feedback system to limit lipolysis and ketogenesis. Free fatty acids may also participate in the feedback regulation of lipolysis in the starvation state by permitting insulin secretion to occur despite a fall in the plasma glucose level, and this feedback system may involve limitation of glucagon secretion by rising plasma FFA levels.

FFA differ in their ability to affect glucagon secretion. Short-chain fatty acids (octanoate, valerate, butyrate, and propionate), long-chain fatty acids (oleate and palmitate), and ketone bodies inhibit glucagon release as a function of their degree of metabolism. Diminution of FFA oxidation by means

of various metabolic inhibitors augments glucagon release from intact guinea pig islets.

Polyunsaturated fatty acids (PUFA) are precursors for eicosanoids including prostaglandins, leukotrienes, and thromboxanes, which have hormone-like activities. Thus, certain FFA may indirectly influence glucagon release. For example, PUFA increase insulin release.

III. NEURAL EFFECTS ON GLUCAGON SECRETION

The sympathetic and parasympathetic nervous systems are important modulators of both islet alpha- and beta-cell function and therefore their effects on glucagon secretion are complex. The abundant nervous innervation of the islets has long been recognized. Nerves to the pancreas contain fibers from the greater and middle splanchnic nerves (originating in the celiac and superior mesenteric plexuses), visceral afferent fibers (which mediate pain due to distention), and parasympathetic fibers from the vagus nerve. There is reportedly no obvious relationship between the type of neuronal terminal and the type of islet cell innervated (alpha, beta, and delta cells are all associated with each neuron type) and there may be three or more neuron types innervating a single islet cell.

A. Sympathetic Nervous System

There is considerable evidence that the sympathetic nervous system may modulate islet hormone secretion both neurally (norepinephrine) and by release of adrenomedullary catecholamines. Epinephrine has been shown to stimulate glucagon secretion *in vivo* and *in vitro*. In dogs, electrical stimulation of mixed pancreatic nerves containing cholinergic and adrenergic fibers enhances glucagon secretion while suppressing insulin secretion. Stimulation of splanchnic nerves or the administration of catecholamines increases both insulin and glucagon release.

In humans, epinephrine, a mixed α- and β-adrenergic agonist, affects pancreatic alpha- and beta-cell function reciprocally, augmenting glucagon secretion via its β-adrenergic effects while inhibiting insulin release via its α-adrenergic effects. These actions probably reflect different sensitivities of α- and β-adrenergic receptors on human islet cells. α-Adrenergic receptor antagonists have no effect on basal glucagon release, but exert a potentiating effect (thought to be mediated by an increase in cAMP) on epinephrine-induced glucagon secretion. However, species differences exist; in the rat, for example, epinephrine-induced glucagon secretion may be completely inhibited by an alpha nonselective blocker or an α2 selective blocker (but not an α1 selective blocker), indicating that α modulation may be α2 specific.

Glucagon release is increased during exercise or various stresses. Activation of sympathetic innervation of the pancreas could account for the increased glucagon secretion and decreased insulin secretion during stress. Diabetic patients, having compromised beta-cell function, are prone to exaggerated hyperglycemic episodes during stress because of the inability to counteract the effects of catecholamines and glucagon with additional insulin release.

B. Parasympathetic Nervous System

The effects of the parasympathetic nervous system on glucagon secretion are purely stimulatory. Stimulation of the vagus nerve at various levels or administration of cholinergic drugs increases insulin and glucagon secretion in human and other species. Stimulation of glucagon and insulin release appears to be mediated by muscarinic receptors since atropine blocks the release of glucagon *in vitro* and lowers basal glucagon levels as well as glucagon responses to intravenous arginine in human.

C. Central Nervous System Control Sites

Stimulation of the ventromedial hypothalamus (VMH), a sympathetic center, augments glucagon secretion and suppresses basal insulin release, resulting in hyperglycemia due to increased glycogenolysis and plasma FFA levels due to increased lipolysis. The increase in plasma glucagon is not prevented by adrenalectomy, which suggests that glucagon release is due to direct innervation; however, adrenalectomy increases plasma insulin in these circumstances, indicating that insulin release had been under tonic inhibition by adrenomedullary catecholamines. Conversely, lesion of the ventromedial hypothalamus leads to increased plasma insulin and glucagon. It is therefore generally thought that the VMH represents a sympathetic center and the ventrolateral hypothalamus a parasympathetic center. It has been further proposed that the lateral and medial hypothalamus, splanchnic and vagus nerves, and the endocrine pancreas constitute a circuit that mediates the above-mentioned physiological responses.

In rats, intraventricular injection of 2-deoxyglucose, which causes central nervous system neuroglycopenia, leads to hyperglycemia associated with diminished insulin release and increased glucagon release. The latter is augmented by β-adrenergic receptor activation and inhibited by α-adrenergic receptor stimulation.

IV. HORMONAL EFFECTS ON GLUCAGON SECRETION

A. Insulin

Insulin suppresses glucagon. Acute withdrawal of insulin from patients with type 1 diabetes rapidly results in hyperglucagonemia, which is readily reversed by reinfusion of physiological amounts of insulin (Fig. 4). Excessive glucagon responses to arginine and after ingestion of balanced meals found in patients with diabetes can be reduced by physiologic quantities of insulin. Permissive low levels of insulin appear to be important for optimization of the response of alpha cells to glucose. The hyperglucagonemia seen in diabetic ketoacidosis, despite the hyperglycemia characteristic of the state, is consistent with this theory. One must consider, however, the relative influence of arterial insulin versus intraislet insulin, which is still poorly understood. The suppressive effects of insulin on glucagon secretion are mediated at least in part by increased intracellular ATP resulting from increased glucose metabolism. As discussed earlier, increased energy directed (portioned) to compartments limiting glucagon release could be involved.

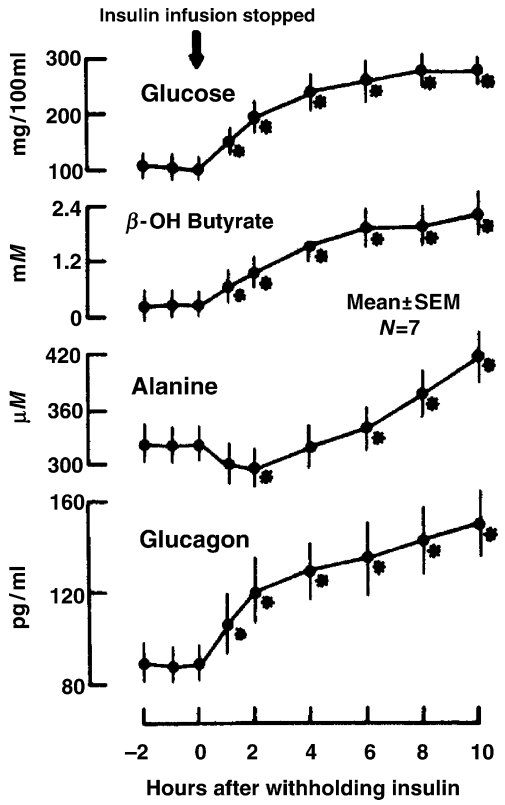

FIGURE 4 Effect of acute withdrawal of on plasma glucagon levels insulin in patients with type 1 diabetes. $^*P \leq 0.01$. Reprinted from Gerich, J. E., Tsalikian, E., Lorenzi, M., Karam, J. H., and Bier, D. M. Plasma glucagon and alanine responses to acute insulin deficiency in man. *J. Clin. Endocrinol. Metab.* **40**, 526–529 (1975), with permission. Copyright The Endocrine Society.

B. Somatostatin

Somatostatin is a 14-amino-acid polypeptide synthesized and released from pancreatic islet delta cells; it inhibits insulin and glucagon. Studies in rats in which administration of anti-somatostatin gamma globulin was observed to augment insulin and glucagon secretion indicate that somatostatin acts as a physiologic local regulator of both insulin and glucagon secretion. Its mode of action remains speculative.

There are five known somatostatin receptor subtypes, and inhibition of glucagon release is mediated via the sst1 subtype. The mechanism of transduction of the somatostatin signal has not been entirely elucidated. There is evidence that somatostatin, after binding to an external membrane receptor, is internalized via a calmodulin-dependent process. This interaction was further postulated to result in inhibition of adenylate cyclase, calcium channel opening, and phosphoinositide turnover. The inhibitory effect on the cyclase is reinforced by concomitant stimulation of soluble phosphodiesterase. The net effect is a reduction of cytosolic Ca^{2+} and inhibition of adenylate cyclase (and hence cAMP production). The inhibition produced by somatostatin is noncompetitive and therefore independent of the strength of stimulation for glucagon secretion.

C. Growth Hormone

The effects of growth hormone (GH) on glucagon secretion appear to be indirect, in that it increases the sensitivity of alpha cells to other primary regulators. When administered in pharmacological doses over the course of several days, GH elevates both basal and evoked levels of glucagon.

D. Glucocorticoids

In Cushing's syndrome and during glucocorticoid treatment, basal levels of glucagon and insulin are increased. This may be at least partially due to islet adaptation to insulin resistance and also to elevated plasma amino acid levels accompanying glucocorticoid excess. Glucocorticoids exert a direct inhibitory effect on insulin release that could secondarily increase glucagon release.

E. Catecholamines

The effects of catecholamines on glucagon secretion were discussed in Section III. A.

V. OTHER REGULATORY FACTORS

A. Pituitary Adenylate Cyclase-Activating Polypeptide

Pituitary adenylate-cyclase activating polypeptide (PACAP), originally isolated from ovine hypothalamus, exists in two forms: PACAP38, a 39-amino-acid peptide, and PACAP27, which is composed of the first 27 amino acids found in PACAP38. The peptide derives its name from its effectiveness in stimulating adenylate cyclase activity in the rat anterior pituitary. PACAP has been localized to nerves of the exocrine parenchyma, perivascular nerves, intrapancreatic nerve ganglia, and the nerve endings associated with islets (indicating neurotransmitter-like activity). PACAP shares considerable homology with various peptides from the secretin/glucagon/vasoactive intestinal peptide (VIP) family. PACAP has been shown to stimulate the secretion of glucagon from the rat pancreas *in vivo* and *in vitro* and more recently to stimulate both insulin and glucagon secretion in humans, indicating a role for this peptide in the regulation of islet cell function. The actions of PACAP are believed to be mediated through two receptor types: (1) a type 1 receptor with a relatively higher affinity for PACAP38 and PACAP27 than for VIP and (2) a VIP–PACAP common receptor that shows similar affinities for VIP, PACAP38, and PACAP27.

B. Serotonin and Dopamine

Islets of several species contain serotonin and dopamine, suggesting that these amines may influence islet function. Conflicting results, which may be due to different intra- and extracellular actions of these agents, leave their precise roles unclear. Serotonin diminishes the insulin response to glucose in the golden hamster, mouse, and rabbit, but increases it or has no effect in the rat, dog, and human. Serotonin antagonists (e.g., methysergide maleate) increase insulin release. Reserpine, which depletes catecholamine stores, reverses serotonin inhibition of insulin release, suggesting that serotonin may act indirectly by releasing catecholamines. Dopamine—or the administration of $<$E5$>$L$<$/E5$>$-3,4-dihydroxyphenylalanine, which is subsequently converted to dopamine—has been reported to diminish insulin release *in vitro* and to stimulate glucagon release *in vivo*. Whether dopamine acts by releasing catecholamines from local nerve endings, by a central nervous system action, or by a direct dopaminergic effect or other effect on islets is unresolved.

C. Gamma-aminobutyric Acid

GABA has recently been co-localized with insulin (in beta cells) and may mediate part of the inhibitory action of glucose on glucagon secretion by activating $GABA_A$-receptor Cl^- channels in alpha 2 cells.

VI. DEVELOPMENTAL AND NUTRITIONAL ASPECTS OF GLUCAGON SECRETION

Alpha cells are present early in fetal development, but functional maturity does not occur until after birth. Fetal islets are responsive to amino acids and to certain neurotransmitters (e.g., epinephrine and acetylcholine) but not to changes in glucose concentration. The large number of amino acids that can influence glucagon and insulin release from the pancreas of fetal and newborn lambs suggests that physiological changes in plasma amino acid concentration may be the primary regulators of glucagon and insulin release *in utero*. Plasma glucagon levels rise in the rat and human coincident with a fall in blood glucose levels at birth; however, this response is impaired in children of diabetic mothers. This may be due to hyperglycemia and hyperinsulinemia occurring *in utero* as a result of poor glycemic control in the mother.

Changes in glucagon secretion occur during pregnancy, including a reduced glucagon response to protein ingestion, which may contribute to the facilitated anabolism of late pregnancy. Changes in glucagon secretion also occur with the estrous cycle and after the administration of oral contraceptives.

A. Obese State

Islets in obese animals are frequently hypertrophied and hyperplastic. Basal glucagon levels are generally normal in obesity, but responses to arginine and hypoglycemia are excessive. There is evidence, however, that glucagon levels are elevated in grossly obese persons, particularly in persons with impaired glucose tolerance.

VII. GLUCAGON SECRETION IN DIABETES MELLITUS

Diabetes mellitus is the most common condition associated with abnormal glucagon secretion. In both type 1 and type 2 diabetes, fasting plasma glucagon levels are elevated in an absolute sense or are clearly inappropriate for the prevailing hyperglycemia. Since the withdrawal of insulin in euglycemic type 1 diabetic patients is associated with an increase in plasma glucagon that can be reversed by infusion of insulin, this hyperglucagonemia is at least in part secondary to insulin deficiency and/or insulin resistance. Responses to arginine infusion and to meal ingestion are also increased in both forms of diabetes. Since insulin responses are reduced in such individuals, the resultant increased glucagon:insulin ratio would contribute to hyperglycemia.

Curiously, although glucagon responses to nonglucose stimuli are increased in patients with diabetes, their responses to increases (suppression) and decreases (stimulation) of plasma glucose levels are impaired. This has led to the hypothesis that diabetes mellitus may be a bihormonal disorder due to a primary effect on "blindness" to glucose in both alpha and beta cells. Certainly this cannot be the case for patients with type 1 diabetes, in which defects in glucagon secretion appear to be primarily due to the lack of insulin release but the situation is less clear for patients with type 2 diabetes.

The diminished increase in glucagon release during hypoglycemia in people with type 1 and type 2 diabetes has been identified as a risk factor for severe hypoglycemia. To some extent this is secondary to repetitive episodes of hypoglycemia, which will reduce glucagon responses as demonstrated by patients with insulin-producing tumors of the pancreas. The mechanism for this phenomenon is unclear. It has been suggested that the glucagon response to hypoglycemia is dependent on a reduction in insulin release, which results in the deinhibition of glucagon release.

At the present time, the abnormal glucagon secretion in patients with type 1 diabetes, which is due to autoimmune destruction of islet beta cells, can be best explained on the basis of insulin deficiency. In patients with type 2 diabetes, the situation may be more complex and may involve resistance to insulin as well as a genetic defect in the alpha and beta cells of the pancreas.

VIII. SUMMARY AND CONCLUSIONS

Over the past 3 decades, much has been learned about the regulation of glucagon secretion. Like the regulation of insulin, it is complex and involves numerous factors, the most important of which are the prevailing plasma glucose concentration, the intraislet insulin concentration, and the sympathetic nervous system. However, much more needs to be known regarding the molecular mechanisms by which these regulators affect pancreatic alpha-cell function and its abnormalities in diabetes mellitus.

Glossary

adipocytes Large cells that are specialized for fat storage.

Golgi apparatus A complex cytoplasmic organelle consisting of a series of layered cisternae and associated small vesicles; it is involved in terminal glycosylation, membrane flow, secretion, and delivery of cellular products either to the cell surface or to the appropriate intracellular destination.

islets of Langerhans The irregular microscopic masses of cells that constitute the endocrine pancreas. Of the three cell types that form the islets, the alpha cells produce glucagon, the beta cells produce insulin, and the delta cells produce somatostatin.

ketone bodies Any of three compounds that arise from acetyl coenzyme A and that may accumulate in excess amounts as a result of starvation, diabetes mellitus, or other defects in carbohydrate metabolism.

Steroid hormones make up a very important class of cholesterol-derived regulatory molecules that are synthesized mainly in the adrenal glands, ovary, placenta, testis, and brain. Steroids of one class, the glucocorticoids, are synthesized specifically in the fasciculata cells of the adrenal cortex. The mechanisms of steroidogenesis, the series of reactions leading to production of a steroid hormone, have long been of interest. The steroidogenic acute regulatory protein is a key regulator in glucocorticoid synthesis.

I. INTRODUCTION

In most cases, steroids are synthesized in response to steroidogenic stimuli. All of the steroid hormones are of great physiological importance. Glucocorticoids, produced in the adrenal glands, regulate carbohydrate metabolism and stress responses; the adrenal glands also synthesize the mineralocorticoids, which are necessary to regulate salt balance and maintain blood pressure. The sex steroid hormones, estrogen and progesterone, synthesized in the ovary and placenta in the female, are essential for reproductive function and for maintaining secondary sex characteristics. These same functions are mediated in the male by androgens synthesized in testicular Leydig cells. Neurosteroids, another class of steroids, are synthesized in the brain and their functions include both stimulation and inhibition of γ-aminobutyric acid (GABA)ergic responses, modulation of the response of specific brain cells to excitatory amino acids, and enhancement of memory function. Thus, the steroid hormones have very diverse and important physiological functions within the body. This article focuses on the synthesis of a specific class of steroids, the glucocorticoids, and primarily on how this synthesis is regulated.

The process by which steroids are synthesized is referred to as steroidogenesis, which comprises a series of reactions that are identical in the initial stages. Steroidogenesis occurs in specialized cells in specialized tissues within an organism and results in the production of tissue- and cell-specific steroids. In all steroidogenic tissues, regardless of the final steroid hormones synthesized, the initial step in steroidogenesis is the conversion of the nonsteroid, cholesterol, to the first steroid formed, pregnenolone. This conversion occurs via the action of the cytochrome P450 side chain cleavage enzyme (P450scc), which resides in the inner mitochondrial membrane in all steroidogenic cells. Pregnenolone then exits

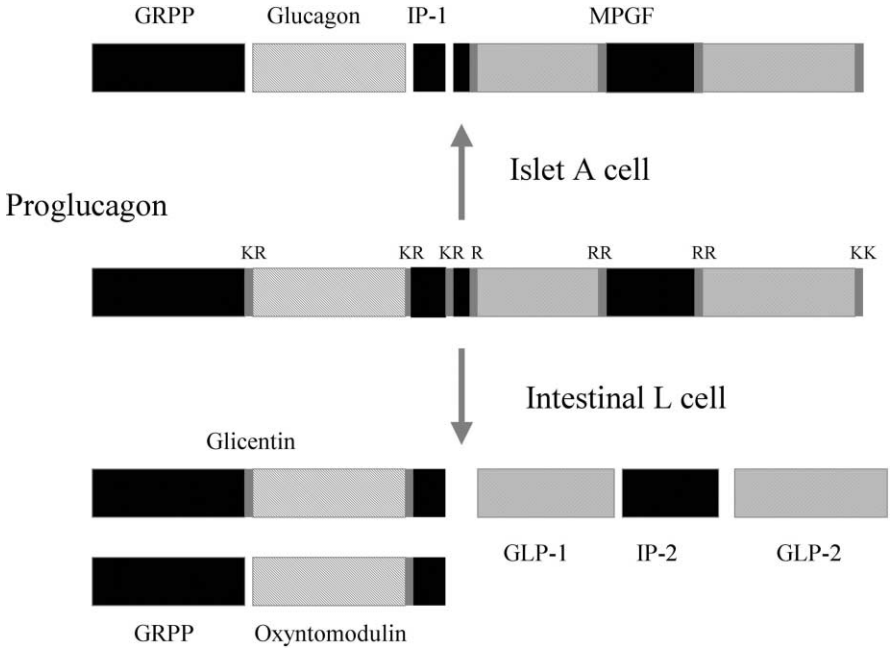

FIGURE 1 Schematic representation of the structure and tissue-specific processing of the proglucagon molecule in islet alpha cells and intestinal L cells. In the alpha cell, proglucagon processing leads to glicentin-related pancreatic polypeptide (GRPP, proglucagon 1–30), glucagon (proglucagon 33–61), the intervening peptide-1 (IP-1, proglucagon 64–69), and the major proglucagon-derived fragment (MPGF, proglucagon 72–158); in intestinal L cells, proglucagon processing liberates glicentin (proglucagon 1–69), glucagon-like peptide-1 (GLP-1, proglucagon 78–107), IP-2 (proglucagon 111–122), and GLP-2 (proglucagon 126–158). Glicentin is also partially processed to GRPP and oxyntomodulin (proglucagon 33–69).

in the crypts but a few can also be observed in the intestinal villi.

II. REGULATION OF GLP SECRETION

The GLPs are synthesized and secreted in a nutrient-dependent manner. Before the development of specific GLP-1 and GLP-2 radioimmunoassays, L cell secretion was quantified as gut glucagon-like immunoreactivity (GLI), which measured the levels of oxyntomodulin and glicentin. Because the production of GLI is correlated with that of GLP-1 and GLP-2, studies reporting secretion of GLI are assumed to reflect that of GLP-1 and GLP-2.

To investigate the direct effects of nutrients and endocrine, paracrine, and neural mediators at the level of the L cell, models consisting of primary cultures of fetal rat intestinal cells (FRICs) or canine ileal mucosal cells have been successfully developed. The limited number and viability of cells obtained by these techniques in addition to the heterogeneity of the isolated cells prevent extensive analysis of proglucagon gene regulation. However, the development of tumor-derived cell lines that express the proglucagon gene has aided in this regard. The GLUTag cell line was developed from intestinal tumors in proglucagon–SV40 large T antigen transgenic mice, whereas the STC-1 cell line was derived from a proximal intestinal endocrine tumor that developed in mice carrying the transgene for the rat insulin promoter linked to SV40 large T antigen and the polyoma virus small T antigen. Recently, a human L cell line (NCI-H716) has also been developed from a cecal tumor. The development of *in vitro* models of the L cell has facilitated investigation into the intracellular mechanisms underlying proglucagon gene expression and GLP secretion. Studies using FRIC cultures and the GLUTag cell line have shown that activation of protein kinase A (PKA) stimulates both synthesis and release of the GLPs, whereas activation of protein kinase C (PKC) results in increased secretion of the GLPs without affecting proglucagon gene expression. Calcium has also been shown to play an important role in basal L cell secretion; secretion is abolished when FRIC cultures are incubated with a calcium blocker ($CoCl_2$) and is stimulated by increasing the intracellular calcium concentration.

The release of GLP-1 and GLP-2 after nutrient ingestion is biphasic; an early peak occurs after 15–30 min and a second peak is seen 60 min later. The first peak occurs before the nutrients reach L cells in the distal ileum and colon, through an indirect neural and hormonal mechanism. The later peak is mainly due to direct contact of the nutrients with the L cells. Several studies have identified the mechanisms underlying the rapid release of GLP after food ingestion. Administration of the ganglionic blocker hexamethonium inhibits the release of GLP-1 stimulated by intraduodenal mixed meal or oleic acid *in vivo* in rats, showing the involvement of the nervous system in the control of distal L cell secretion. It has also been shown that bilateral subdiaphragmatic vagotomy completely abolishes duodenal fat-induced GLP-1 release in rats. Interestingly, glucose-dependent insulinotropic polypeptide (GIP), a hormone secreted by endocrine K cells of the upper small intestine, was also shown to stimulate GLP-1 secretion *in vivo* in rats. However, the effect of GIP is abolished by selective hepatic branch vagotomy, suggesting that GIP acts through vagal afferent pathways to stimulate L cells indirectly. This stimulation appears to be transmitted to L cells by the efferent pathway in the celiac branch of the vagus nerve.

Gastrin-releasing peptide (GRP), a neuropeptide, was also shown to stimulate GLP-1 secretion *in vitro* as well as *in vivo* in humans and several animal species. Mice lacking the GRP receptor have reduced GLP-1 and insulin responses as well as oral glucose intolerance, showing that intact GRP receptors are required for normal GLP-1 release. However, whether GRP is involved in the vagal regulation of the L cell is not known.

Acetylcholine and muscarinic receptors appear to be involved in the regulation of L cell secretion in both rats and humans, and they likely mediate the effect of the vagus on GLP secretion. Cholinergic muscarinic agonists stimulate GLI and GLP-1 release from the NCI-H716, STC-1, and GLUTag cell lines, as well as from FRIC cultures. In humans, the infusion of atropine (a nonspecific muscarinic antagonist) reduces the secretion of GLP-1 in response to oral glucose, indicating the involvement of muscarinic receptors in GLP-1 secretion. Recent data implicate the muscarinic m1 receptor subtype in this phenomenon in the rat. Epinephrine and the β-adrenergic agonist isopropanol stimulate GLP-1 secretion in isolated rat ileum or colon but have no effect on GLP-1 secretion by GLUTag and FRIC cells. Thus, the role of the sympathetic nervous system in the regulation of the L cell remains unclear.

Finally, the neuropeptide galanin was shown to inhibit both basal and GRP-stimulated GLP-1 secretion from isolated rat ileal L cells, and insulin and somatostatin-28 have been reported to inhibit GLP-1 release both *in vivo* and *in vitro*. Collectively, these findings underscore the complexity of the neural and endocrine mechanisms regulating GLP release from distal L cells in response to nutrients in the proximal duodenum (Fig. 2).

In humans and different animal species, food ingestion promotes secretion of GLP-1 and GLP-2 into the circulation; the most important nutrients inducing GLP secretion are carbohydrate and fat. Oral glucose administration stimulates GLP-1 and GLP-2 release in humans, rats, and pigs, but systemic administration of glucose has no effect on GLP-1 release, indicating that the glucose sensors are localized on the intestinal lumen. These observations are consistent with the role of GLP-1 as an important incretin hormone acting on the pancreatic beta cells to stimulate insulin release after glucose absorption. However, the majority of glucose ingested is absorbed into the jejunum, and the rapid release of GLP-1 after an oral glucose dose indicates that glucose does not directly stimulate the L cell. Although high concentrations of glucose (28 m*M*) have been shown to

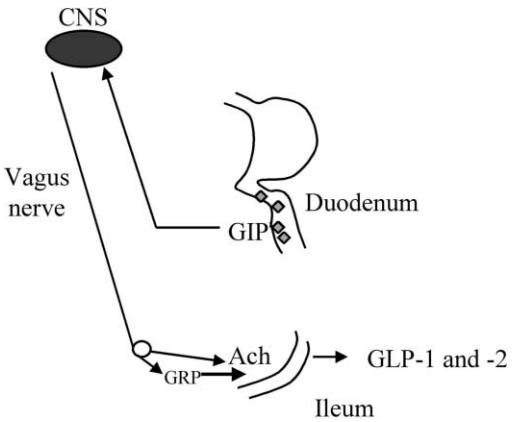

FIGURE 2 Model of the indirect mechanism underlying glucagon-like peptide-1 (GLP-1) and GLP-2 secretion from L cells after food ingestion. Entry of chyme into the duodenum induces the release of glucose-dependent insulinotropic polypeptide (GIP) from duodenal endocrine K cells. GIP stimulates the afferent branch of the vagus nerve to the vagus center, which sends a stimulatory signal via the efferent branch of the vagus nerve to L cells through muscarinic receptors and/or by stimulating the release of gastrin-releasing peptide (GRP) by myenteric neurons to stimulate GLP secretion by the L cell. Ach, Acetylcholine; CNS, central nervous system.

stimulate GLI secretion from FRIC cultures, the consensus opinion is that glucose has little direct effect on the L cell *in vivo*. By contrast, fat appears to be the most important nutrient inducing GLP secretion. Ingestion of mixed fat or triglycerides stimulates GLP-1 and GLP-2 release in humans and pigs. Intraduodenal fat stimulates GLP-1 secretion independently of contact with L cells, suggesting an indirect effect of fat to stimulate GLP-1 release. However, fatty acids can also stimulate GLP secretion from FRIC cultures and GLUTag cells, suggesting that fatty acids can act directly on L cells. Both the length and the degree of saturation of the fatty acids affect the ability of fats to stimulate GLP secretion; monounsaturated long-chain fatty acids are more potent stimulators of GLP release than are short- or medium-chain, saturated or polyunsaturated fatty acids.

Neither amino acids nor protein alone consistently increase GLP-1 release in humans, dogs, and rats. In contrast, peptone (a protein hydrolysate) has been shown to stimulate GLP-1 secretion from the isolated vascularly perfused rat intestine. Peptone also stimulates proglucagon mRNA expression in the STC-1 cell line. However, although peptone is more representative of the proteins found in the lumen, compared to simple amino acids or intact protein, most proteins are digested and absorbed in the jejunum. Thus, the role of proteins in modulating the L cell remains unclear.

III. GLP METABOLISM

Degradation of both GLP-1 and GLP-2 in the circulation appears to occur initially through the actions of dipeptidyl peptidase IV (DPP IV), which cleaves the amino terminus (His^1-Ala^2) of both peptides, resulting in GLP-1(9–36 NH_2) and GLP-2(3–33). These two fragments are the major metabolites of GLP-1 and GLP-2 in the circulation, and both are biologically inactive.

In normal rats, 50% of a bolus of GLP-1 is cleaved within 2 min, whereas GLP-1 remains intact for at least 10 min in DPP IV-deficient rats. Similarly, the half-life of GLP-2 in normal rats is approximately 6 min, but greater than 60 min in DPP IV-deficient animals. A recent study has shown high levels of DPP IV in the capillaries surrounding the L cells, and DPP IV is also present in the circulation. These findings have opened new avenues for developing GLP analogues that are resistant to DPP IV degradation, thereby enhancing the half-lives of these peptides. An alternative approach is the oral administration of a DPP IV inhibitor that, in rats, potentiates the actions of GLP-1 and GLP-2. These findings also indicate that the intact N-terminus of these peptides is important to their biological activity.

IV. GLP RECEPTORS

The receptors for GLP-1 and GLP-2 are both members of the glucagon receptor subfamily of the G-protein-coupled superfamily of receptors. The gene encoding the human GLP-1 receptor is localized to chromosome 6p21. The encoded 463-amino-acid protein has a high affinity for GLP-1 but can also bind glucagon with a 100- to 1000-fold reduced affinity. Interestingly a 39-amino-acid peptide (exendin4) isolated from the venom of the lizard *Heloderma suspectum* (gila monster) exhibits high sequence homology with GLP-1 and was shown to act as a full GLP-1 agonist at the GLP-1 receptor. The amino-terminally truncated form of exendin4 [exendin4(9–39)] is a potent antagonist of the GLP-1 receptor *in vitro* and *in vivo*. GLP-1 acts through its receptor by activating the adenylyl cyclase pathway. GLP-1 may also increase intracellular calcium concentrations by mobilizing Ca^{2+} from intracellular stores, both by activation of a phospholipase C pathway and through cAMP-dependent Ca^{2+}-induced Ca^{2+} release from ryanodine-sensitive Ca^{2+} stores. Finally, GLP-1 can also exert a direct stimulatory influence on voltage-dependent calcium channels in the pancreatic beta cell and stimulates the opening of Ca^{2+}-activated nonselective cation channels that are permeable to Ca^{2+} and Na^{+}.

The GLP-1 receptor is widely distributed in different tissues in the body, including the pancreas (primarily the beta and delta cells), brain, lung, stomach, kidney, and intestine. Biological activities of GLP-1 have also been detected in liver, muscle, and adipose tissue, but the presence of the GLP-1 receptor in these tissues remains controversial. *In vitro* studies show that the GLP-1 receptor is susceptible to rapid desensitization after 5 min of ligand binding and this is reversed within 10–20 min after removal of the ligand. GLP-1 receptor desensitization is correlated with the phosphorylation of serine residues in the C-terminal tail of the receptor. The GLP-1 receptor has also been shown to internalize. However, no tachyphylaxis to GLP-1 administration has been observed *in vivo*, thus the significance of this finding remains unclear.

It was only in 1999 that the rat and human GLP-2 receptors were cloned. The GLP-2 receptor is a 550-amino-acid protein, and the gene is localized on

chromosome 17p33.3 in humans. Like the related GLP-1 receptor, the GLP-2 receptor is coupled to the adenylyl cyclase pathway and is highly expressed throughout the gastrointestinal tract and the brain. Interestingly, recent studies have shown that the GLP-2 receptor is expressed in endocrine cells of the human gut, which suggests that some of the effects of GLP-2 are mediated through other intestinal hormones, growth factors, and/or neurotransmitters.

V. PHYSIOLOGICAL ACTIVITIES OF GLPs

A. Physiological Activities of GLP-1

The biological actions of GLP-1 are reflected by the functions of the organs expressing the GLP-1 receptor.

1. Effect of GLP-1 on Pancreatic Islets

The first biological effect of GLP-1 described was its ability to stimulate insulin secretion from pancreatic beta cells. GLP-1 was shown to increase levels of beta cell cAMP and insulin gene transcription, and to stimulate glucose-dependent insulin release. *In vivo* studies using exendin4(9–39), the GLP-1 receptor antagonist, have clearly shown that GLP-1 is an incretin hormone, mediating postprandial release of insulin from pancreatic beta cells. Consistent with these findings, elimination of GLP-1 receptor signaling in beta cells is associated with reduced intracellular cAMP and defective glucose-stimulated calcium influx. Mice with a null mutation in the GLP-1 receptor are also glucose intolerant.

Entry of glucose into beta cells induces generation of ATP, increasing the ATP/ADP ratio and closing the ATP-sensitive potassium channels. The closure of these channels results in a rise in resting potential (depolarization) of the beta cell, leading to opening of voltage-dependent calcium channels (L-type VDCCs). The influx of Ca^{2+} through these channels then triggers vesicular insulin secretion through the process of exocytosis. Repolarization of the beta cell is achieved by opening of delayed-rectifyer and calcium-sensitive potassium channels. Binding of GLP-1 to its receptor triggers signaling pathways that can affect each of these steps of glucose-dependent insulin secretion, including enhancement of the sensitivity of the K-ATP channel to ATP, and increased flux of Ca^{2+} through the VDCCs. Phosphorylation of secretion granule proteins by PKA may also trigger insulin secretion. It is believed that these actions are mediated through GLP-1-induced activation of PKA-dependent or related pathways (Fig. 3).

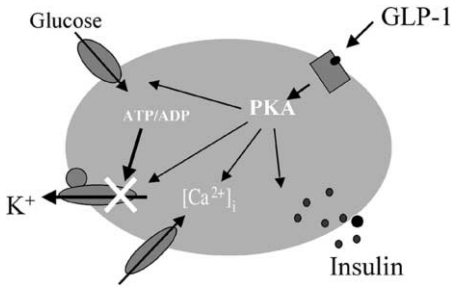

FIGURE 3 Model of the signal transduction pathways involved in the mechanism of insulin secretion in response to glucose and glucagon-like peptide-1 (GLP-1) in the beta cell. Glucose entry into the beta cell increases the ATP/ADP ratio, inducing closure of the potassium channels. This causes depolarization of the beta cell, leading to the opening of voltage-dependent calcium channels. The influx of Ca^{2+} triggers vesicular insulin secretion by exocytosis. Binding of GLP-1 to its receptor activates a protein kinase A (PKA)-dependent pathway, and, likely, other signaling pathways that can enhance each step of glucose-dependent insulin secretion.

Excitingly, recent studies have shown that GLP-1 can also stimulate islet cell proliferation *in vitro* and *in vivo*. Administration of GLP-1 or exendin4 for 10 days to neonatal diabetic rats following partial pancreatectomy or to prediabetic db/db mice stimulates expansion of the beta cell mass via induction of islet proliferation and neogenesis. GLP-1 has also been shown to induce differentiation of the acinar-like AR42J cells to endocrine cells containing immunoreactive insulin and glucagon. These effects are believed to occur through enhancement of ductal pdx-1 expression, a beta cell transcription factor. When taken together, these finding indicate that GLP-1 acts as a growth factor for the pancreatic islets.

2. Extrapancreatic Effects of GLP-1

GLP-1 is part of the so-called ileal brake, i.e., factors secreted by the distal intestine that inhibit gastric emptying and upper intestinal motility. GLP-1 has been shown to inhibit pentagastrin and meal-induced gastric acid secretion, and gastric emptying at physiological concentrations. In humans, the effect of GLP-1 on gastric emptying is mediated by the nervous system (e.g., requires intact vagal innervation). A recent study has further shown that the effect of GLP-1 on gastric emptying occurs before its effect on beta cells to stimulate insulin secretion, and it is hypothesized that the early peak of GLP-1 secretion may be responsible for inhibiting gastric emptying and the later peak may be involved in the regulation of insulin secretion.

GLP-1 has also been shown to inhibit food intake *in vivo* in rodents after intracerebroventricular administration. However, mice lacking GLP-1 receptor signaling are lean with normal food intake even after several months of high-fat feeding. These data show that GLP-1 is not essential for physiological control of nutrient intake and body weight regulation *in vivo*. However, one explanation for the anorexic effects of GLP-1 derives from studies demonstrating that neurons expressing the GLP-1 receptor are activated as part of the stress response, such as following lithium chloride administration.

Finally, as described earlier, GLP-1 is rapidly inactivated by the enzyme DPP IV, which is highly expressed in the capillaries surrounding the L cells. The inactivation of GLP-1 by DPP IV is very rapid, leading to a 1- to 1.5-min half-life for GLP-1(7–36) amide. Furthermore, it has recently been demonstrated that 50% of the GLP-1(7–36) amide that is released from the intestinal L cells is degraded in the surrounding capillaries; thus, biologically active GLP-1(7–36) amide may never reach the pancreas. However, a recent study has shown that co-infusion of GLP-1 and glucose into the portal vein increases insulin secretion through activation of a neural mechanism. Other studies show that portal vein infusion of glucose in mice lacking the GLP-1 receptor fails to increase the glucose clearance rate. These findings indicate that the GLP-1 receptor is part of the hepatoportal glucose sensor and suggest that basal fasting GLP-1 levels are sufficient to confer maximum glucose competence to the sensor. The hepatoportal system therefore constitutes an important extrapancreatic target for GLP-1 in the control of glucose homeostasis.

3. GLP-1 and Treatment of Type 2 Diabetes

In many patients with type 2 diabetes, insulin resistance ultimately compromises the ability of the beta cell to maintain an adequate level of insulin biosynthesis and secretion over a prolonged time. GLP-1 has emerged as a promising therapeutic for type 2 diabetes, because GLP-1 stimulates insulin secretion and insulin gene expression in a glucose-dependent manner; GLP-1 also lowers glucagon secretion, delays gastric emptying, reduces food intake, and may enhance insulin sensitivity and stimulate beta cell neogenesis. These combined effects of GLP-1 thereby improve glucose tolerance. Indeed, long-term infusion of GLP-1 into diabetic patients reduces fasting and fed plasma glucose levels, as well as body weight. The ideal mode and frequency of GLP-1 (or GLP-1 analogue) administration are still under investigation. Nonetheless, GLP-1 remains a promising therapeutic approach for the treatment of hyperglycemia in patients with type 2 diabetes.

B. Biological Activities of GLP-2

Although it has been suspected for many years that one of the proglucagon-derived peptides plays a role in adaptive bowel growth, it was only in 1996 that GLP-2 was shown to act as an intestinal growth factor. Exogenous GLP-2 induces crypt cell proliferation and inhibits villus tip apoptosis, thereby increasing villus height and small and large bowel weights within 6 days of twice-daily administration. Furthermore, GLP-2 also increases bowel function, increasing enzyme activity and enhancing nutrient absorption via stimulation of apical sodium-dependent glucose transporter (SGLT-1) and of basolateral glucose transporter-2 in rats. GLP-2 also enhances barrier function in the murine intestinal epithelium via effects on both the transcellular and paracellular pathways.

GLP-2, like GLP-1, also seems to be part of the so-called ileal brake, because GLP-2 can inhibit meal-induced gastric acid secretion and gastric motility. GLP-2 also appears to be involved in the central regulation of feeding behavior, although the physiological relevance of these findings remains unclear. Although all of the studies have been conducted in normal rodents, GLP-2 has also been shown to enhance bowel mass and function in several models of intestinal damage. These include atrophy caused by total parenteral nutrition and intestinal damage such as in dextran sulfate-induced colitis and both indomethacin- and chemotherapy-induced enteritis. In several of these models, GLP-2 has been shown to suppress the inflammatory response, possibly due to enhancement of intestinal barrier functions.

The intestinotropic effect of GLP-2 in the small and large bowels has paved the way for the use of GLP-2 as a treatment for intestinal insufficiency in humans. Indeed, administration of GLP-2 to patients with short bowel syndrome for 35 days produces increases in villus height concomitant with enhanced energy retention and weight gain. Whether GLP-2 can also be used to reduce inflammation in inflammatory bowel disease remains to be established.

VI. SUMMARY

GLP-1 and GLP-2 are intestinal peptide hormones with strong therapeutic potential for the treatment of patients with type 2 diabetes and intestinal

insufficiency, respectively. Future studies into the physiology and pathophysiology of these peptides will further establish the potential of both GLP-1 and GLP-2 for the treatment of human disease.

Glossary

glucagon-like peptide-1 A 30-amino-acid antidiabetic hormone that is found in endocrine cells of the gastrointestinal tract and in the brain.

glucagon-like peptide-2 A 33-amino-acid intestinotropic hormone that is found in endocrine cells of the gastrointestinal tract and in the brain.

G-protein-coupled receptor A type of receptor that contains seven transmembrane domains and that is noncovalently linked to signalling pathways via G proteins.

L cells Endocrine cells localized in the intestine; produce and secrete GLP-1 and GLP-2 and are categorized as "open" cells because the apical microvilli are in contact with the intestinal lumen.

proglucagon A 160-amino-acid peptide processed in a tissue-specific manner. In the pancreatic alpha cells, proglucagon is processed to glucagon, whereas in intestinal endocrine L cells, proglucagon is processed to several biologically active peptides, including glucagon-like peptide-1 and glucagon-like peptide-2.

Glucagonoma Syndrome

NICHOLAS CLARKE AND UDAYA M. KABADI
University of Iowa

Glucagonoma syndrome is a rare disorder characterized by necrolytic migratory erythema, cheilosis, diabetes mellitus or impaired glucose tolerance, normocytic normochromic anemia, venous thrombosis, and psychiatric symptoms.

I. OVERVIEW

The incidence of glucagonoma syndrome is one in 20 million and there are 200 reported cases in the literature. Glucagonoma, a tumor of the pancreatic alpha cell, is frequently malignant. Hepatic metastases are seen in two-thirds of patients at presentation. An elevated plasma glucagon in the setting of other findings associated with the syndrome is diagnostic. Most tumors are detected by computer tomography (CT) images of the abdomen or with selective arteriography of the pancreatic bed. Benign disease is curable through resection of the primary tumor. Tumor debulking in patients with metastatic disease often improves symptoms. Hepatic embolization may induce symptomatic relief, although almost half the patients manifest recurrent symptoms by 6 months. Somatostatin analogues may provide successful remission of the initial stage of the disease, although a progressive increase in dosage is often required to maintain efficacy.

II. CLINICAL FEATURES

Necrolytic migratory erythema (NME) is the characteristic cutaneous rash seen in patients with glucagonoma syndrome (Fig. 1). The rash starts as small erythematous macules and papules in the lower extremity, perineum, and perioral areas. The lesions blister, leaving central erosions and necrosis in the upper third of the epidermis. The lesions coalesce as they heal and become hyperpigmented. They are very pruritic and painful. Frequently the course of the dermopathy waxes and wanes, with exacerbations and spontaneous remissions occurring without treatment. The lesions often become secondarily infected with *Candida* or *Staphylococcus* species, leading to much of the morbidity and mortality of this disease. Diagnosis is difficult, often requiring multiple biopsies from an edge of a characteristic lesion. A characteristic lesion shows dermal perivascular lymphocytic infiltrate with associated edema, pallor, necrosis, and bullous disruption of the upper third of the epidermis. Other diseases associated with NME include liver disease, pellagra, kwashiorkor, and epidermal necrolysis.

The pathophysiology of NME remains elusive and controversial. Amino acid deficiency, zinc deficiency, and liver impairment have all been postulated as causes for NME. Some patients with glucagonoma syndrome and NME showed improvement in the rash on amino acid supplementation with total parenteral nutrition. In these patients, glucagon levels remained elevated, suggesting that glucagon is not a causative factor for the rash. However, not all patients receiving amino acid supplementation manifested an improvement of their rash.

Another major feature of glucagonoma syndrome is impaired glucose tolerance or diabetes mellitus. Diabetes in most patients is mild to moderate if it occurs. The patients are not prone to ketoacidosis and do not manifest microvascular complications of diabetes, but often require insulin for corrections of their hyperglycemia. Weight loss, noted frequently, occurs because of anorexia from the tumor burden and increased caloric expenditure caused by gluconeogenesis, resulting in the loss of both adipose tissue and muscle mass. Diarrhea is the most frequent gastrointestinal symptom, occurring in 15–29% of patients. Patients may also present with a sore mouth and a smooth and shiny beefy red tongue tender to palpation. Painful oral erosions and angular stomatitis may also be present.

Neurological and psychiatric symptoms are highly variable in patients with glucagonoma syndrome.

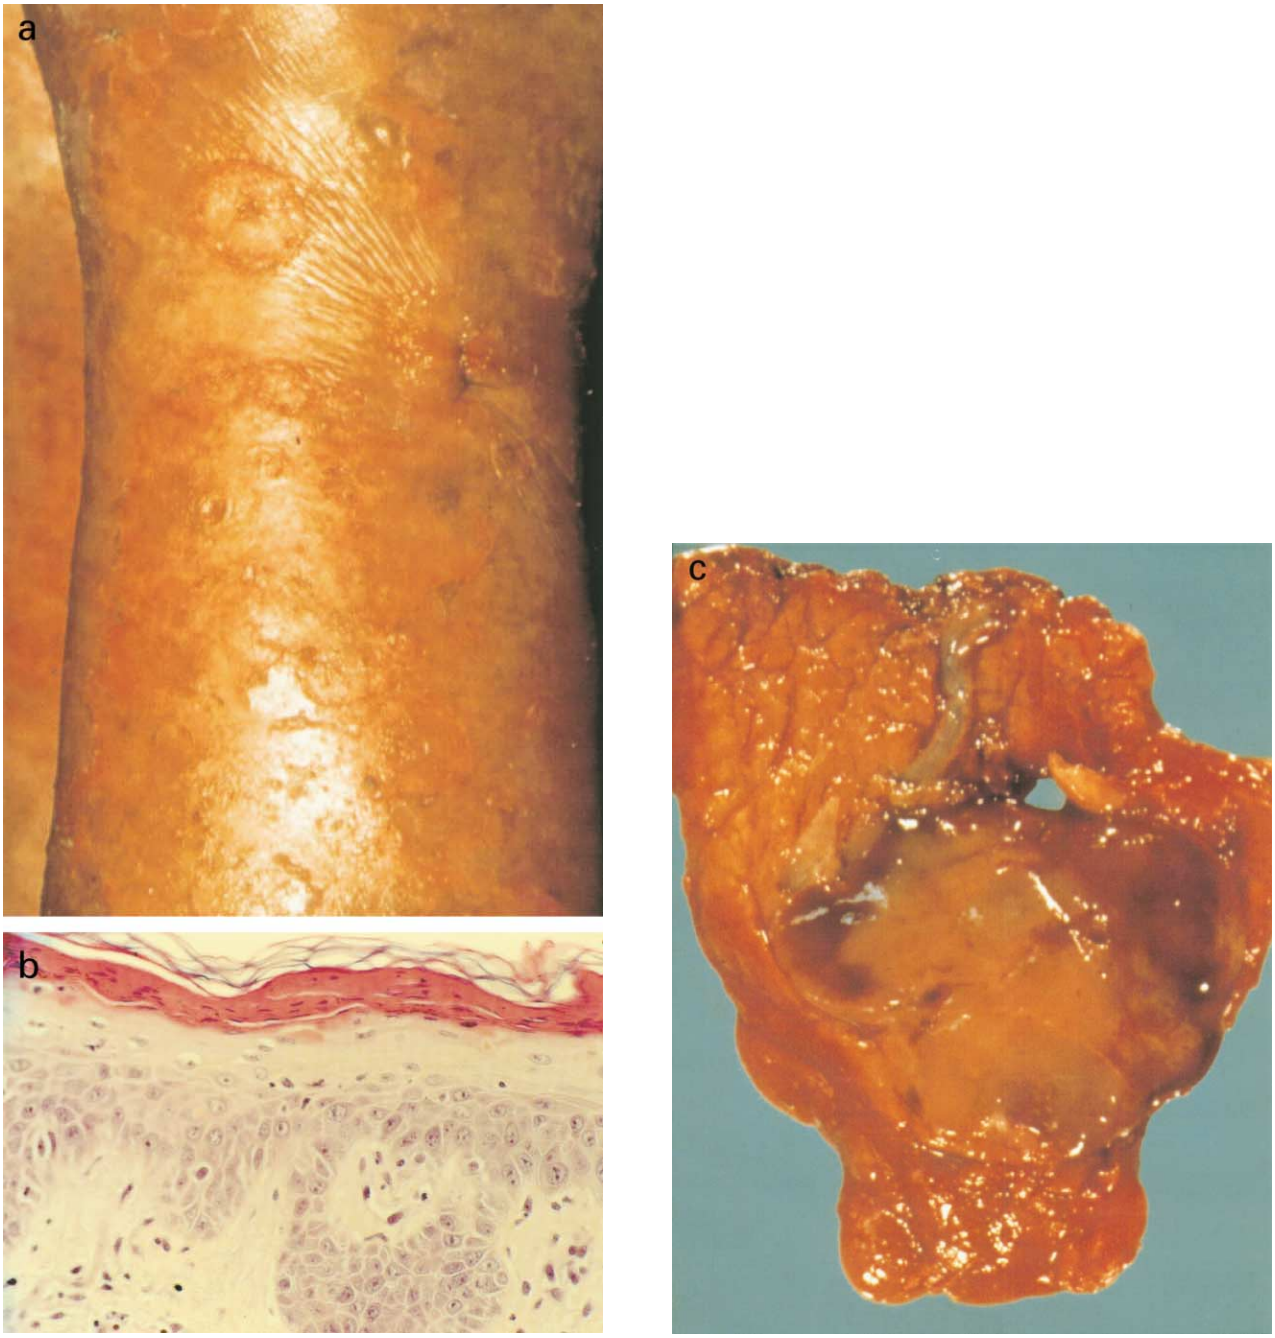

FIGURE 1 Characteristic rash on upper "necrolytic erythema" (a) with skin biopsy (b) and excised tumor (c).

These symptoms include depression, dementia, psychosis, decreased cognitive function, agitation, nervousness, insomnia, ataxia, muscle weakness, hyperreflexia, and fecal and urinary incontinence.

Thromboembolic events occur frequently in patients with glucagonoma syndrome, with 11–14% of patients manifesting these events at diagnosis and up to 30% being observed during the course of the disease. These events consist of deep venous thromboses and pulmonary emboli and account for half of all deaths attributed to glucagonoma syndrome. Other common causes of death include secondary infections of the skin lesions and gastrointestinal bleeding.

III. LABORATORY FINDINGS

All patients with glucagonoma syndrome have elevated plasma glucagon levels, usually between 1000 and 5000 pg/ml. Hyperglucagonemia has been seen in other conditions, including uncontrolled diabetes mellitus, with the highest levels being noted in diabetic ketoacidosis and hyperglycemic nonketotic hyperosmolar coma, strenuous exercise, burns, acute trauma, bacteremia, cirrhosis, starvation, renal failure, and Cushing's syndrome. However, in these conditions, fasting glucagon levels rarely rise above 500 pg/ml. A normocytic normochromic anemia is seen in patients with glucagonoma syndrome, possibly due to chronic disease. Serum iron, vitamin B12, folic acid, and bone marrow studies are usually normal. Panhypoaminoacidemia is a universal finding in patients with glucagonoma syndrome. Glucagon stimulates hepatic gluconeogenesis, leading to a decrease in plasma amino acid levels, especially alanine and glutamine. Therefore, in patients with glucagonoma syndrome, hepatic amino acid extraction is increased in response to elevated glucagon levels, causing gluconeogenesis with a decrease in protein synthesis, leading to hypoaminoacidemia. Once glucagon levels are lowered in patients with glucagonoma syndrome by medical or surgical means, a prompt increase in amino acid levels ensues. Hypoproteinemia, hypoalbuminemia, and hypocholesterolemia are frequently found in these patients as well. Elevated glucagon levels also promotes lipolysis, causing a rise in free fatty acids. Liver enzymes are usually normal, even in the presence of liver metastasis.

IV. TUMOR LOCALIZATION

The glucagonoma tumor is usually single and large with the presence of metastasis, usually in the liver in 50% of the subjects, at the time of diagnosis. Multiple imaging modalities assist in localizing the tumor, including CT or magnetic resonance imaging (MRI) of the abdomen as well as pancreatic arteriography and ultrasound. CT scanning is the most reliable initial test for localizing the tumor as well as metastatic lesions. Usually, the tumor is greater than 3 cm in diameter and may be located in any part of the pancreas, the tail being the most frequent pancreatic site. If a tumor is not detected by abdominal CT or MRI and the clinical suspicion is high, selective pancreatic angiography may be effective in the detection with the finding of the characteristic tumor "blush" because of high vascularity associated with the tumor.

V. TREATMENT

Treatment options include surgical excision, tumor debulking, hepatic artery embolization, somatostatin analogues, and anti-tumor chemotherapy. If the tumor is located exclusively in the pancreas, surgical excision may result in a cure. With a rapid fall in serum glucagon levels, improvement in the rash occurs within 24–48 h and resolution of the anemia, diabetes, and hypoproteinemia follows. Unfortunately, in two-thirds of patients, the tumors are malignant with the presence of hepatic metastases at the time of diagnosis. Nevertheless, surgical intervention in these patients may be a reasonable approach since it may alleviate the symptoms because of the lowering of the glucagon level. Procedures include a distal localized pancreatectomy or subtotal or 95% pancreatectomy and occasionally a Whipple's procedure, depending on the extent of the disease involvement.

These patients are high operative risks because of their weight loss, hypoproteinemia, skin rash, and tendency to develop venous thromboses. Perioperative management therefore includes transfusions, hyperalimentation or nasogastric feeding with amino acid supplements, topical and oral zinc supplements, administration of subcutaneous somatostatin analogues, and low-dose heparin for several weeks.

Somatostatin inhibits glucagon release. A long-acting analogue of somatostatin (octreotide acetate) has provided symptom relief for days to a month. It is most effective in amelioration of the skin rash with a lesser efficacy in preventing or reversing weight loss and lowering hyperglycemia. It is most useful in controlling symptoms at an early stage of disease. However, the dosage rises progressively in order to be effective in maintaining symptomatic relief.

Hepatic metastases are supplied mainly by the hepatic artery, whereas the blood supply to the surrounding liver tissue derives from both the hepatic artery and the portal vein. Therefore, hepatic artery embolization may be effective at inducing a regression of these metastases with the blood supply to normal liver tissue remaining adequate if the portal vein is patent. Therefore, prior to embolization of the hepatic artery, the patency of the portal vein is demonstrated by ultrasound and confirmed by angiography. Eighty percent of embolizations result in symptom relief, associated with lowering or normalization of glucagon levels. Unfortunately, in 50% of subjects, symptoms recur within 6 months either from revascularization of the tumor or from

natural progression of the disease, requiring further embolizations if surgery is contraindicated. Treatment with streptozotocin and 5-fluorouracil has neither yielded symptom relief nor induced normalization of glucagon levels.

Zinc therapy, applied topically or administered orally (e.g., 200 mg zinc sulfate daily), as well as amino acid infusions may alleviate cutaneous manifestations. Hyperglycemia may be controlled with a high-protein diet and insulin. However, despite several therapeutic approaches, weight loss frequently persists and the prognosis remains grave with a 5-year survival rate of 25–30% and a mean survival period of between 3 and 7 years.

Glossary

glucagonoma syndrome A disorder caused by elevated glucagon levels from a pancreatic alpha-cell tumor, leading to necrolytic migratory erythema, cheilosis, diabetes mellitus, impaired glucose tolerance, anemia, venous thrombosis, and psychiatric symptoms.

impaired glucose tolerance An early aspect of diabetes mellitus when the subject is unable to secrete sufficient insulin for a given carbohydrate load and leading to higher than normal plasma glucagon levels.

necrolytic migratory erythema The characteristic rash seen in glucogonoma syndrome, consisting of macules and papules in the lower extremities, perineum, and perioral areas, which blister, leaving central erosions and necrosis. They are often pruritic and painful.

somatostatin A peptide that inhibits glucagon release. A long-acting analogue of somatostatin is octreotide acetate, which is most effective with the skin rash in the early stages of the disease.

thromboembolic events Blood clots in the venous system leading to pulmonary embolism and possibly death.

Glucagon Processing

DONALD F. STEINER

University of Chicago, Illinois

Glucagon processing refers to the proteolytic cleavage of proglucagon, a large glucagon-containing precursor protein, by specific neuroendocrine prohormone convertases (PC2 and/or PC1/PC3); this processing releases glucagon and/or other biologically active peptides also contained within the proglucagon molecule, i.e., the glucagon-like peptides GLP-1 and GLP-2. Proglucagon is expressed in the body in several locations, including the alpha cells of the pancreatic islets, where proglucagon is processed to release only glucagon, and in the L cells of the intestinal tract, where proglucagon is processed differently to release mainly GLP-1 and GLP-2. This "differential processing" of the proglucagon molecule provides an example of the regulation of specific hormone production from multifunctional precursors via differential tissue expression of prohormone convertases PC1/PC3 and PC2.

I. INTRODUCTION

The existence of a pancreatic hypoglycemic factor was first postulated in the early 1920s, but it was not isolated and sequenced until the mid-1950s. Glucagon, the hyperglycemic hormone, is a 29-amino-acid peptide (Fig. 1) that is secreted primarily by the alpha cells of the islets of Langerhans, but in some species it is also secreted in small amounts from cells in the stomach and intestine. Its actions are

the mitochondria and is converted to progesterone by the enzyme 3β-hydroxysteroid dehydrogenase (3β-HSD) in the microsomal compartment and subsequently to a variety of other steroids, the final product resulting from the specific complement of steroidogenic enzymes present within those tissues.

In glucocorticoid biosynthesis, cholesterol is first converted to pregnenolone in the mitochondria by P450scc in adrenal fasciculata cells. The next step in the major pathway for the further metabolism of pregnenolone is the hydroxylation of pregnenolone by 17α-hydroxylase to form 17α-hydroxypregnenolone. 17α-Hydroxypregnenolone is then converted to 17α-hydroxyprogesterone by the 3β-HSD enzyme in a manner analogous to the conversion of pregnenolone to progesterone. Then, two subsequent hydroxylations of 17α-hydroxyprogesterone occur, yielding cortisol. The first hydroxylation occurs at position 21 as a result of the action of the microsomal enzyme cytochrome P450 21-hydroxylase, yielding 11-deoxycortisol. This compound then re-enters the mitochondria, where, by the action of the mitochondrial enzyme cytochrome P450 11β-hydroxylase, which hydroxylates the molecule at the 11 position, it is converted to cortisol. The pathways involved in the synthesis of glucocorticoids in the adrenal cortex and the enzymes utilized within these pathway are illustrated in Fig. 1.

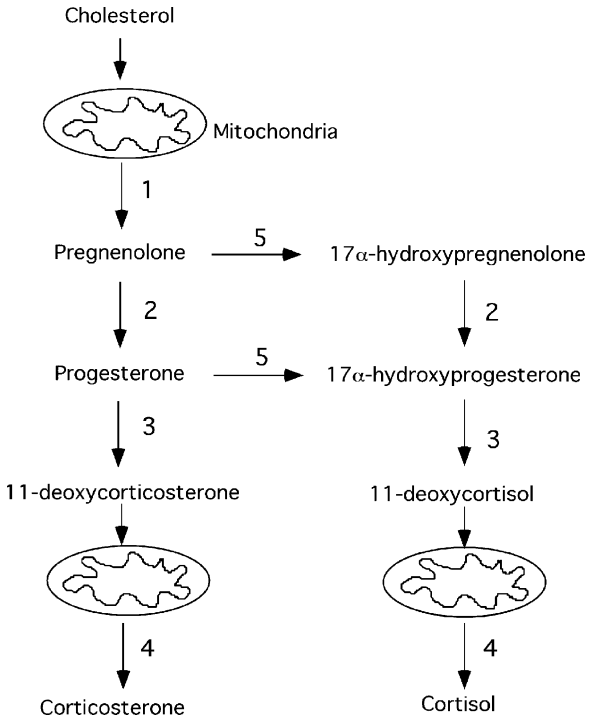

FIGURE 1 The biosynthetic pathway of glucocorticoids. Biosynthetic pathways lead from cholesterol to the major glucocorticoid hormones produced in the adrenal glands, cortisol and corticosterone. Conversions of cholesterol to pregnenolone, and 11-deoxycortisol to cortisol, occur in the mitochondria; the remaining reactions occur in the microsomal compartment. The numbers represent the enzymes involved in synthesis of the glucocorticoids: (1) cytochrome P450 side chain cleavage (mitochondrial); (2) 3β-hydroxysteroid dehydrogenase/Δ^5, Δ^4-isomerase (microsomal); (3) cytochrome P450 21-hydroxylase (microsomal); (4) cytochrome P450 11β-hydroxylase (mitochondrial); (5) cytochrome P450 17α-hydroxylase/C17-20 lyase (microsomal).

II. REGULATION OF GLUCOCORTICOID SYNTHESIS

The biosynthesis of glucocorticoids is regulated mainly by the pituitary tropic hormone, adrenocorticotropic hormone (ACTH), and usually occurs in two phases. The acute phase occurs on the order of minutes and is responsible for the rapid production of steroids in response to immediate need. The rapid biosynthesis of glucocorticoids to combat stressful situations comes to mind in this type of regulation. A more chronic form of regulation also occurs and encompasses the longer term expression of the mRNAs and proteins for the steroidogenic pathway enzymes to assure long-term steroidogenic capacity in the cells. The events involved in the chronic regulation of steroid hormone biosynthesis are not discussed further here; the focus here is on those events that result in the rapid biosynthesis of glucocorticoids in response to steroidogenic stimuli, i.e., the acute phase.

Like most biosynthetic pathways, the steroidogenic pathway has a rate-limiting step. For a long period of time, the rate-limiting step in this pathway was believed to be the activation of the P450scc enzyme, the first enzyme in the pathway, which converts cholesterol to pregnenolone. However, it soon became clear that this was not the case and it was demonstrated that the P450scc enzyme was active even in unstimulated cells. The search for the true rate-limiting step in steroid hormone biosynthesis was ongoing for many years and culminated in the finding that the regulated and rate-limiting step was the delivery of the substrate cholesterol from the outer mitochondrial membrane to the inner mitochondrial membrane, where the P450scc enzyme is located. This step was rate limiting because the hydrophobic nature of cholesterol would not allow it to traverse the aqueous intermembrane space of the mitochondria by simple diffusion and reach

the P450scc enzyme within the time frame observed for acute synthesis. Therefore, the acute synthesis of glucocorticoids is regulated by events that rapidly mediate the transfer of cholesterol from the outer to the inner mitochondrial membrane in response to ACTH.

With this knowledge came a great deal of investigation to determine the nature of the acutely regulated step. Initial studies were performed in the adrenal gland, because it had been observed that ACTH could stimulate the biosynthesis of steroids in incubated adrenal tissue slices. One of the first, and perhaps most important, observations concerning steroidogenesis was that acutely stimulated steroid production had an absolute requirement for the synthesis of new proteins. This was determined in studies that demonstrated that ACTH-stimulated corticoid synthesis in adrenal glands was sensitive to inhibitors of protein synthesis, an observation that has been corroborated many times since then. The importance of these observations can be seen when it is considered that the search for the putative regulator then had a potential target on which to focus, namely, a hormone-induced newly synthesized protein.

An important observation indicated that the protein-sensitive step was located in the mitochondria but had no effect on the activity of the P450scc. In similar studies, it was determined that inhibition of protein synthesis had no effect on the increased delivery of cholesterol to the outer mitochondrial membrane, but that the transfer of this substrate from the outer to the inner membrane was completely inhibited by cycloheximide. These observations indicated that the unknown protein(s) functioned at the level of the delivery of cholesterol to the P450scc enzyme, and thus the precise site of the cycloheximide-inhibited regulation had been determined. Powerful proof of this hypothesis was added when it was demonstrated that incubation of intact cells or isolated mitochondria with hydroxylated, and thus hydrophilic, cholesterol analogues that could freely diffuse to the P450scc enzyme resulted in full steroid biosynthesis.

In summary, many observations resulted in the characterization of the acute regulation of steroidogenesis and indicated that the production of steroids was dependent on a hormone-stimulated, rapidly synthesized, cycloheximide-sensitive protein, the function of which was to mediate the transfer of the hydrophobic substrate, cholesterol, from the outer to the inner mitochondrial membrane and the P450scc enzyme. The effort to identify and characterize this acute regulatory protein has been ongoing for approximately four decades. Although several candidates have emerged from these efforts, only the observations made for the steroidogenic acute regulatory (StAR) protein will be summarized here.

III. THE STEROIDOGENIC ACUTE REGULATORY PROTEIN

A candidate protein for the acute regulator of steroidogenesis was first described in the mid-1980s as an ACTH-induced, 30-kDa phosphoprotein in hormone-treated rat and mouse adrenocortical cells, and as a luteinizing hormone-induced protein in rat corpus luteum cells and mouse Leydig cells. These studies indicated that a close relationship between the 30-kDa proteins and steroid hormone biosynthesis existed in these tissues and that their synthesis, as was steroidogenesis, was sensitive to cycloheximide. Our laboratory was engaged in similar studies and described, in hormone-stimulated MA-10 mouse Leydig tumor cells, a protein family that was identical to proteins that had been previously described. In both laboratories, these proteins were found localized to the mitochondria and consisted of several forms of a newly synthesized 30-kDa protein. Later studies determined that the 30-kDa mitochondrial proteins were processed from a 37-kDa precursor form with an N-terminus containing a mitochondrial signaling sequence. Subsequent to those initial observations, many studies then went on to document tight correlations between the synthesis of steroids and the synthesis of the 30-kDa mitochondrial proteins. However, even as the correlations grew, a direct cause-and-effect relationship between 30-kDa protein expression and steroidogenesis was lacking, and it became necessary to clone the 30-kDa protein to prove or disprove unequivocally its function in steroidogenesis.

The 30-kDa protein was purified from hormone-stimulated MA-10 Leydig tumor cells, a cell line that is highly steroidogenic in response to stimulation. Peptide sequence information was obtained from the purified protein and this sequence was utilized to design degenerate oligonucleotides that were in turn used to screen a cDNA library generated from hormone-stimulated MA-10 cells. A full-length 1456-bp cDNA that had an open reading frame of 852 nucleotides was subsequently obtained for the precursor 37-kDa protein. This open reading frame coded for a protein that was 284 amino acids long. The nucleic acid sequence of the cDNA and the amino acid sequence of the 37-kDa protein were analyzed

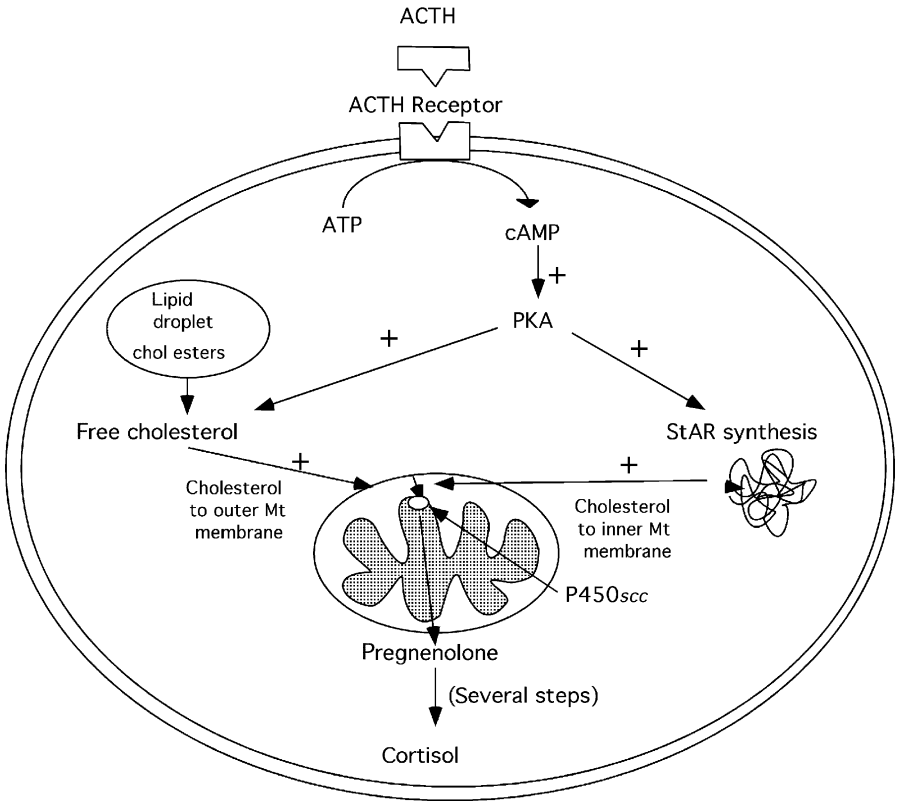

FIGURE 2 Regulation of glucocorticoid synthesis: cellular response to adrenocorticotropic hormone (ACTH) stimulation in adrenal cells. Tropic hormone stimulation of adrenal cells results in an increase in intracellular cAMP. Free cholesterol is mobilized to the outer mitochondrial membrane by mechanisms still not well understood. These steps are necessary to assure an adequate supply of this precursor for sustained steroid biosynthesis. Precursors for steroid biosynthesis can be supplied from *de novo* synthesis of cholesterol, from uptake of low-density and/or high-density lipoprotein cholesterol, or from plasma membrane cholesterol, as occurs in some cell types. In addition, the *de novo* synthesis of the steroidogenic acute regulatory (StAR) protein is also required to obtain full steroidogenic capacity in response to hormone stimulation. The function of StAR is to mediate the transfer of cholesterol from the outer mitochondrial (Mt) membrane to the inner mitochondrial membrane, where the cytochrome P450 side chain cleavage enzyme system (P450scc)resides. Although the exact mechanism of action of StAR has thus far escaped characterization, in its absence normal steroidogenesis is not possible. Cholesterol is converted to pregnenolone by P450scc, and then to glucocorticoids by microsomal and mitochondrial enzymes. PKA, Protein kinase A.

and found to be unique, indicating that the cDNA represented a novel protein. Most importantly, expression of the cDNA-derived protein in both a steroidogenic cell line (in the absence of stimulation) and in a nonsteroidogenic cell line (rendered steroidogenic by transfection with the appropriate enzymes) resulted in significant increases in steroid production, indicating a direct role for the 37- to 30-kDa proteins in steroid production. As a result of these studies, the newly characterized protein was named the steroidogenic acute regulatory (StAR) protein. Many studies rapidly followed the initial cloning of StAR and demonstrated that the StAR protein was acutely regulated by tropic hormone stimulation in many steroidogenic tissues and that its localization was essentially confined to steroidogenic tissues. To date, many observations have been recorded for the StAR protein and all indications are that it satisfies all of the criteria listed for the acute regulator. A summary of the cellular events that regulate hormone-stimulated glucocorticoid synthesis is shown in Fig. 2.

IV. CONSEQUENCES OF MUTATIONS IN THE StAR GENE

Closely following the cloning of the StAR cDNA, a series of investigations were conducted, the results of which would emphatically underscore the importance of StAR in the regulation of steroid hormone

biosynthesis. Congenital lipoid adrenal hyperplasia (lipoid CAH) is a rare, autosomal recessive, and potentially lethal condition in humans resulting from an almost complete inability of the newborn child to synthesize steroids. Due to the lack of testosterone biosynthesis *in utero*, individuals with this condition are born with female external genitalia regardless of genotype. This condition is manifested by the presence of large adrenals containing very high levels of cholesterol and cholesterol esters and also by a lesser, but increased amount of, lipid accumulation in the steroidogenic cells of the testis, the Leydig cells. Unless timely diagnosis of lipoid CAH is made and appropriate mineralocorticoid and glucocorticoid hormone replacement therapy is administered, death will result in days to weeks as a result of adrenocortical hormone deficiency, the most critical steroid required being the mineralocorticoid, aldosterone. Observations from nearly three decades ago demonstrated that tissue or isolated mitochondria from afflicted patients were unable to convert cholesterol to pregnenolone, and thus this disease was originally thought to be due to mutations in the P450scc gene. This belief had persisted until relatively recent times, when studies on P450scc genes, amplified from lipoid CAH patients, were shown to be normal. Further studies deduced that the defect was upstream of P450scc at the point of cholesterol delivery to the enzyme. In fact, it was subsequently, and correctly, argued that embryonic homozygous mutations in the P450scc enzyme would be incompatible with life in humans because the placenta is required to produce progesterone after the first trimester, and the placenta is derived from embryonic tissue. In addition to the P450scc gene and its accompanying electron transfer proteins, other proteins that had been reported to be involved in cholesterol transfer in the mitochondria were also found to be normal in lipoid CAH patients.

When StAR was cloned in 1994, it immediately became an excellent candidate for the causative agent in lipoid CAH. In studies designed to determine if StAR may be involved in lipoid CAH, StAR cDNA was prepared by reverse transcription and polymerase chain reaction (RT-PCR) using RNA isolated from the tissue of patients who had this disease. Careful examination of the PCR products revealed mutations in the StAR cDNA sequences of the first four patients examined, and these mutations were confirmed in the genomic DNA. Importantly, whereas expression of the normal human StAR protein in COS-1 cells (again rendered steroidogenic by transfection) resulted in significant increases in steroid production, expression of the mutant StAR cDNAs from these patients indicated that although the proteins were indeed expressed, they were completely inactive in promoting steroidogenesis. The results of these studies indicated that expression of normal StAR protein was an indispensable requirement in promoting cholesterol transfer to the P450scc enzyme, that lipoid CAH represented a natural knockout of StAR, and that the consequences of this knockout were totally in keeping with the hypothesized function of StAR. In addition to the original report indicating that StAR mutations caused lipoid CAH, many additional examples of mutations in StAR resulting in this disease have now been documented. To date, there have been 28 different mutations in the StAR gene that have been shown to result in lipoid CAH. It also appears that the greatest prevalence of this disease occurs in Japanese and Korean individuals. In summary, the potentially lethal condition in humans known as lipoid CAH can be considered as a naturally occurring knockout of the StAR gene, and its consequences have dramatically demonstrated the indispensable role of StAR in hormone-stimulated steroidogenesis. Indeed, the absence of its activity in the adrenal results in the loss of steroid hormones that are essential for life.

That mutations in the StAR gene resulted in lipoid CAH produced compelling evidence for the essential role of this protein in the acute regulation of adrenal steroidogenesis. Therefore, with the goal of having a model system to study its role in steroidogenic tissues and the effects of its loss on other tissues, a knockout of the StAR gene was produced in mice. All pups appeared normal at birth but all had female external genitalia regardless of genotype, as seen in the human condition. Following birth, all animals failed to grow normally and death occurred within a short period of time, presumably as a result of adrenocortical insufficiency. This was confirmed by the observation that serum levels of corticosterone and aldosterone were depressed but that levels of ACTH and corticotropin-releasing hormone (CRH) were elevated. These observations indicated an impairment in the production of adrenal steroids with an accompanying loss of feedback regulation at the level of the hypothalamus or pituitary. Inspection of the adrenal gland revealed a normal medulla but an abnormal cortex, having a disrupted fascicular zone replete with vacuolated areas. Specific staining procedures revealed that the vacuoles observed in the adrenal cortex region of the StAR knockout mouse contained highly elevated levels of lipid. This lipid consisted of cholesterol and cholesterol esters that accumulated as

a result of the inability of the cells to metabolize cholesterol. Subsequent studies extended the original findings in the newborn StAR knockout mice to include observations in animals that were kept alive with corticosteroid replacement therapy. The temporal effects of the StAR knockout on the adrenals were assessed. At birth, the adrenal glands were profoundly affected and contained high levels of lipid deposits within the cortical region. With progressing time after birth, the adrenals demonstrated increasing elevation in lipid deposition, particularly in the zona glomerulosa and zona fasciculata. Eventually, the entire cortical layer appeared to be filled with lipid, thus obliterating the cellular architecture of the cortex. In summary, StAR knockout mice demonstrated a phenotype that is essentially identical to lipoid CAH in humans. With specific regard to the adrenal gland, the inability to deliver cholesterol to the mitochondrial P450scc enzyme for synthesis of adrenocortical steroids was manifested by greatly increased lipid deposits in this gland and ultimately in death. Therefore, using observations obtained from both the human disease and the mouse knockout, the indispensable role of StAR in supporting normal adrenal steroidogenesis can readily be seen.

V. SUMMARY

The acute regulation of hormone-stimulated glucocorticoid synthesis in the fasciculata cells of the adrenal cortex, as in all steroid-synthesizing cells, requires the transfer of cholesterol from cellular stores and the outer mitochondrial membrane to the inner mitochondrial membrane. This cholesterol is utilized as substrate by the P450scc enzyme and is converted to pregnenolone, the first steroid synthesized in this pathway. This is the rate-limiting step in hormone-regulated steroidogenesis. An early observation demonstrated that hormonally regulated steroid biosynthesis required the synthesis of new proteins. The search for the putative regulatory protein has been ongoing for almost four decades and has resulted in several candidates. The steroidogenic acute regulatory protein appears to satisfy all of the criteria for the acute regulator. It is rapidly synthesized in steroidogenic cells in response to tropic hormone stimulation and appears to be specifically located in those cells. Its expression in both steroidogenic and nonsteroidogenic cells can result in the induction of steroid biosynthesis in the absence of tropic hormone treatment. Perhaps the most compelling example of the indispensable role of StAR in regulating steroid biosynthesis comes from the observation that mutations in its gene that render it inactive result in the disease congenital lipoid adrenal hyperplasia, a disease in which the afflicted patient can synthesize virtually no steroids. StAR knockout mice display a phenotype that is essentially identical to the human condition.

Glossary

cholesterol side chain cleavage enzyme A P450 enzyme (P450scc) located on the matrix side of the inner mitochondrial membrane in all steroidogenic cells studied to date. It is the rate-limiting enzymatic step in steroidogenesis and utilizes the substrate cholesterol to form pregnenolone, the first steroid synthesized in the steroidogenesis pathway.

cholesterol transfer The transfer of cholesterol to the inner mitochondrial membrane and to the P450scc enzyme constitutes the true regulated and rate-limiting step in the process of steroid hormone biosynthesis. Therefore, the mechanism of transferring cholesterol to P450scc is of critical importance.

glucocorticoids Steroids (cortisol and corticosterone) synthesized in the fasciculata cells of the adrenal cortex. Regulation of glucocorticoid synthesis utilizes mechanisms that are similar to those used for the synthesis of all steroids. Functions of the glucocorticoids include fostering vascular sensitivity to catecholamines, modulating immune responses, and promoting gluconeogenesis to maintain blood glucose levels and thus to preserve brain function.

mitochondria Intracellular organelles usually associated with energy production. In the steroidogenic cell, they are also the sites of the cytochrome P450 side chain cleavage enzyme system, which catalyzes the first step in the steroid biosynthetic cascade and is essential for the biosynthesis of steroids.

steroidogenic acute regulatory protein A protein that, to date, appears to possess all of the characteristics of the putative regulator protein. Hormone-stimulated steroid biosynthesis requires *de novo* protein synthesis, thus it is of critical importance to determine which proteins are involved in this regulation.

Glucocorticoid Drugs, Evolution of

CHRISTOPHER J. LARSON, JON ROSEN, AND JEFFREY N. MINER

Ligand Pharmaceuticals, San Diego, California

Glucocorticoids have broad clinical applications due to the anti-inflammatory, immunosuppressive, and cytostatic effects they elicit. Therapies for rheumatoid arthritis, collagen diseases, lymphatic leukemias and lymphomas, and asthma rely on the actions of glucocorticoids, making them one of the most widely employed classes of drugs.

I. INTRODUCTION

Glucocorticoids have a wide range of clinical applications, but unfortunately, their importance and utility are limited by serious side effects. Surprisingly, given their long history of use in the clinic, the molecular mechanisms of their therapeutic and adverse effects are poorly understood. This article will review the present understanding of glucocorticoid action in the body, summarize the historical evolution of glucocorticoid drugs to date, and then speculate as to how current research into the molecular mechanisms that generate the effects of glucocorticoids could drive the development of a future generation of drugs that mimic the therapeutic efficacy of glucocorticoids while minimizing some of their more serious side effects.

II. PHYSIOLOGY OF GLUCOCORTICOIDS

Human physiology is controlled by the four major classes of hormones: amines, prostaglandins, polypeptides, and steroids. Glucocorticoid steroid hormones such as cortisol are synthesized from

cholesterol in the adrenal cortex and target most cell types to regulate the basic functions of homeostasis and metabolism. Glucocorticoids stimulate mobilization of amino acids from muscle, mobilization of free fatty acids from adipose tissue, and deamination of amino acids and gluconeogenesis in the liver, all of which produce elevated blood glucose. Other physiologic actions of these steroid hormones include retarding inflammation, immunosuppression, and alteration of mood and cognition. Given their broad range of functions in many tissues, glucocorticoid levels are tightly regulated by a hormonal cascade within the hypothalamic–pituitary–adrenal (HPA) axis. Physiological stress also induces glucocorticoid production. Stress or circadian rhythms generate neural stimuli that induce corticotropin-releasing hormone (CRH) release by hypothalamic secretory cells. CRH and another factor, arginine vasopressin, cause the release of corticotropin (ACTH) by the anterior pituitary, which stimulates the secretion of glucocorticoids by the adrenal cortex. Glucocorticoids decrease the production of CRH in the hypothalamus and ACTH in the pituitary in a negative feedback loop.

III. PHARMACOLOGY OF GLUCOCORTICOIDS

Glucocorticoids govern carbohydrate, lipid, and protein metabolism to effect homeostasis. They induce the production of glucose in the liver by increasing the levels of a number of gluconeogenic enzymes and by providing substrates for those enzymes through catabolic action in skeletal muscle and adipose tissue. Glucose uptake in muscle and adipose is inhibited by glucocorticoids, resulting in increased circulating glucose, which in turn blocks protein synthesis and lipogenesis, so ongoing proteolysis and lipolysis lead to increased levels of amino and free fatty acids that become available for further gluconeogenesis. These permissive actions on gluconeogenesis and adipose tissue metabolism contribute to the maintenance of body temperature. Glucocorticoids inhibit the synthesis of collagen, fibronectin, and glycosaminoglycan and prevent normal function of the intercellular matrix; thus, glucocorticoid excess contributes to poor wound healing and facile bruising. Glucocorticoids modulate the inorganic as well as organic aspects of bone metabolism by various mechanisms, thereby contributing to osteoporosis under conditions of long-term excess. Glucocorticoids affect the cardiovascular and renal systems directly through their actions on heart and smooth muscle, enhancement of catecholamine synthesis, antagonism of vasodilators such as prostaglandins, activation of the angiotensin system, and regulation of epithelial sodium channel expression in kidney and colon. Glucocorticoids not only act directly on the kidney to affect sodium retention and volume control, they also act indirectly through their crossover effects in the mineralocorticoid receptor pathway. Glucocorticoids also modulate inflammatory and allergic reactions and probably decrease the immune response to prevent autoimmune diseases. Glucocorticoids also show effects in central nervous system (CNS) imprinting and general CNS function.

IV. MECHANISM OF ACTION OF GLUCOCORTICOIDS

Hormones such as glucocorticoids cause their effects in the body by binding to and activating intracellular receptors that in turn modulate gene expression. There is evidence that the steroids themselves or, more recently, the liganded receptors are capable of having very rapid nongenomic effects on the membrane of specific cell types (neural-derived cells in particular). These signaling pathways are only now being elucidated. The glucocorticoid receptor protein itself has separate domains dedicated to transcriptional activation, DNA binding, nuclear localization, and hormone binding. Compounds that bind and induce the activities of the natural hormone are termed agonists; compounds that bind but do not induce the activities of the natural hormone are termed antagonists. Compounds that fully induce or fully inhibit the activities of the natural hormone are considered full agonists and full antagonists, respectively. These classes lie at two ends of a continuum of partial or selective agonists, some of which may bind efficiently yet fail to induce all activities of the natural hormone, resulting in the regulation of a subset of the normal cadre of glucocorticoid-regulated genes.

The glucocorticoid receptor (GR) not only activates gene transcription when bound by glucocorticoid hormone, it represses the expression of a number of genes (Fig. 1). Gene activation by the GR proceeds by a widely accepted mechanism in which hormone diffuses across the cell membrane into the cytoplasm to where the receptor is held in an inactive complex by heat-shock proteins. Hormone binding induces a conformational change in the receptor that releases the heat-shock proteins and permits translocation of the receptor into the nucleus. The conformational changes induced upon hormone binding also allow dimerization of GR monomers, DNA binding at

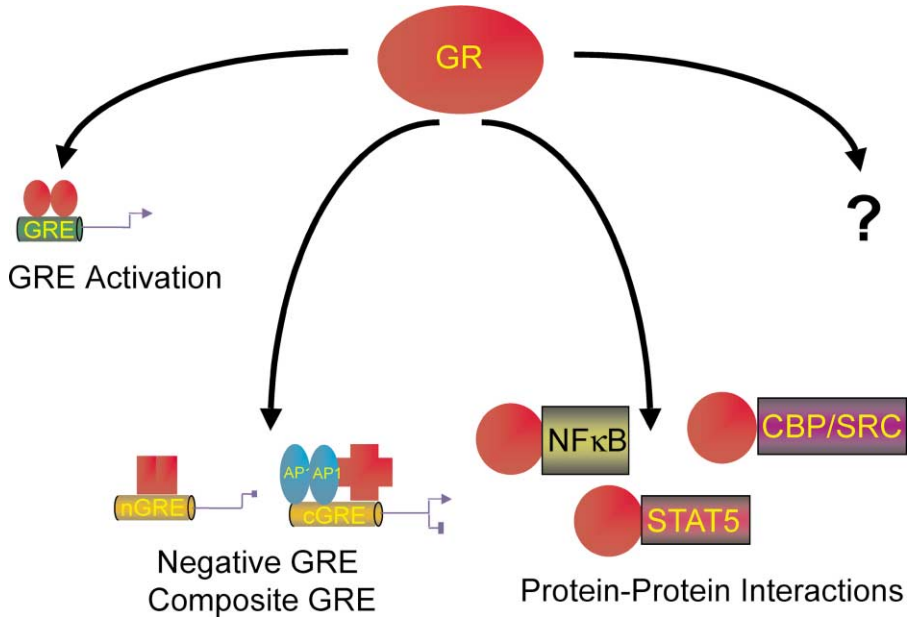

FIGURE 1 Gene regulation by the GR occurs by several mechanisms. The GR is depicted as the oval. From left to right, a series of possible receptor interactions is shown. The receptor can bind to GREs and activate transcription or it can bind to negative GREs (nGREs) and repress transcription. It can also bind to so-called "composite" GREs (cGREs), where its transcriptional activity can be increased or decreased by other nonreceptor factors bound in the same region. The GR can also regulate transcription by interacting with specific transcription factors [nuclear factor κB (NF-κB); signal transducers and activators of transcription 5 (STAT5)] and co-activators [CREB-binding protein (CBP); steroid receptor co-activator (SRC)]. These interactions can indirectly regulate gene expression by either reducing or enhancing the activity of the associated proteins. There are likely other potential interactions as yet undiscovered, depicted by the question mark.

glucocorticoid-response elements (GREs) by GR dimers, and interaction of GR dimers with various ancillary proteins that regulate transcription, all of which lead to activation of gene transcription. Genes activated by GR include gluconeogenic enzymes such as phosphosenolpyruvate carboxykinase, glucose-6-phosphatase, serine dehydratase, and tyrosine aminotransferase.

The mechanisms by which the GR represses gene transcription are less clearly understood, although again they probably involve protein–protein interactions. The two cases in which the actions of the GR have been the most extensively studied are the AP-1 and nuclear factor κB (NF-κB) transcription factor systems, although the GR also interferes with the transcriptional activities of Sp-1, Ca^{2+}/cAMP-response element-binding protein (CREB), GATA-1, and Oct-1. Glucocorticoids probably repress NF-κB transcriptional activation through some combination of (1) up-regulation of the inhibitor κB protein that sequesters NF-κB in the cytoplasm, thereby abrogating NF-κB-dependent gene transcription, (2) indirect or direct protein–protein interactions between the GR and NF-κB that either mask the transactivation domains of NF-κB or disrupt its interactions with the basal transcription machinery, and (3) squelching or competing for interactions with critical transcriptional co-activator proteins. Glucocorticoid repression of AP-1 transcriptional activation does not appear to involve inhibition of DNA binding by AP-1 due to direct protein–protein interactions but may include GR inhibition of a phosphorylation event required for AP-1 activation. Genes repressed by glucocorticoids acting through the GR include prolactin, proliferin, proopiomelancortin, chorionic gonadotropin α-subunit, collagenase type I, collagenase-3, *POMC*, and phorbol ester induction of stromelysin and collagenase. Interestingly, a protein normally thought to be involved in transcriptional activation by GR (glucocorticoid receptor-interacting protein 1) was recently shown to be involved in transcriptional repression. Clearly, more work is needed to understand the process of repression. Glucocorticoids also inhibit the production of a range of proinflammatory cytokines, including interleukin-1α (IL-1α), IL-1β, IL-2, IL-3, IL-5, IL-6, IL-8,

IL-12, interferon-γ, tumor necrosis factor α, and granulocyte/macrophage colony-stimulating factor.

V. GLUCOCORTICOID THERAPY

Abnormal levels of glucocorticoid production by the body can lead to several pathophysiologies. Overproduction of glucocorticoids driven by adrenocortical adenoma or carcinoma leads to excess cortisol and the condition known as Cushing's syndrome. In addition to Cushing's disease of primary origin in which excess cortisol secretion is due to overproduction, a defect in the control of cortisol secretion, typically caused by bilateral adrenal hyperplasia, can secondarily produce cortisol hypersecretion and manifest as Cushing's disease. Clinical symptoms of cortisol excess include hypertension, glucose intolerance, hirsutism, trunkal obesity, and osteoporosis. Additionally, the prolonged hyperglycemia generated by excess cortisol can exhaust insulin-producing pancreatic beta cells, converting mere insulin resistance to outright diabetes mellitus. At the other end of the spectrum, glucocorticoid insufficiency causes Addison's disease, in which outright destruction of the adrenal glands, glandular atrophy, or reduced adrenocortical secretion due to secondary causes produces cortical insufficiency and results in weakness, weight loss, hypoglycemia, and other symptoms.

Exogenous glucocorticoid therapy is therapeutically efficacious for numerous indications (Fig. 2), the majority of which follow from the strong anti-inflammatory actions of glucocorticoid-liganded glucocorticoid receptor. Asthma and allergies are inflammatory conditions in which treatment with glucocorticoids has proven useful. The immunosuppressive activity of glucocorticoids has proven useful in the treatment of rheumatoid arthritis and inflammatory bowel disease and also in reducing the chances of implant rejection after organ transplantation. The combined anti-inflammatory and immunosuppressive actions of glucocorticoids presumably underlie the effectiveness of glucocorticoids in the treatment of a variety of autoimmune- and allergen-mediated skin diseases such as psoriasis, atopic dermatitis, and seborrheic dermatitis. In addition, glucocorticoids inhibit proliferation and induce apoptosis in lymphocytes, which underlies their widespread application in the treatment of malignant proliferative disorders of the lymphatic system.

Glucocorticoids have broad physiological effects across many systems. The side effects of glucocorticoid therapy are extensive. They occur in both acute and chronic dosing regimens, are dosage-dependent, and ultimately limit the clinical utility of glucocorticoids as drugs (Fig. 3). The most common side effects of glucocorticoid treatment include osteoporosis, diabetes, myopathy, impaired wound healing, fat redistribution, suppression of the HPA axis, disease flare upon withdrawal, and behavioral changes.

Glucocorticoids cause bone loss by at least three mechanisms. First, they increase calcium excretion and inhibit calcium absorption, leading to lower serum calcium levels. Second, glucocorticoids decrease the activity of osteoblasts, the cells responsible for laying down new bone. Finally, glucocorticoids decrease testosterone and estrogen levels, hormones that maintain bone density. The result of these various molecular effects is increased risk of fracture and aseptic necrosis of the femoral head, increased risk of degradation of trabecular bone, and increased fracture rate. Several bone-protective

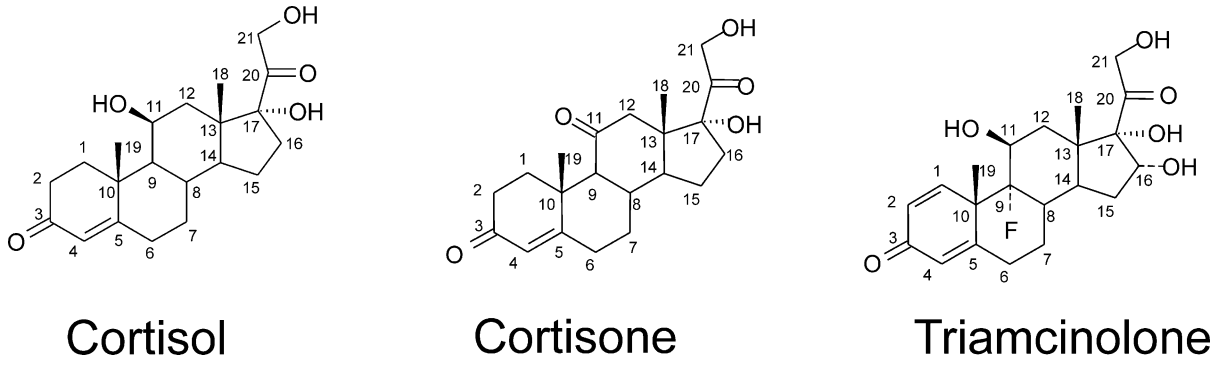

FIGURE 2 The structures of three glucocorticoids are shown together with the numbering system identifying carbons in the molecule. Cortisol, the endogenous glucocorticoid, is characterized by a hydroxyl at the 11 position. Cortisone has a double-bond oxygen at the same position. Triamcinolone is cortisol with a fluorine at the 9 position and a hydroxyl at the 16 position.

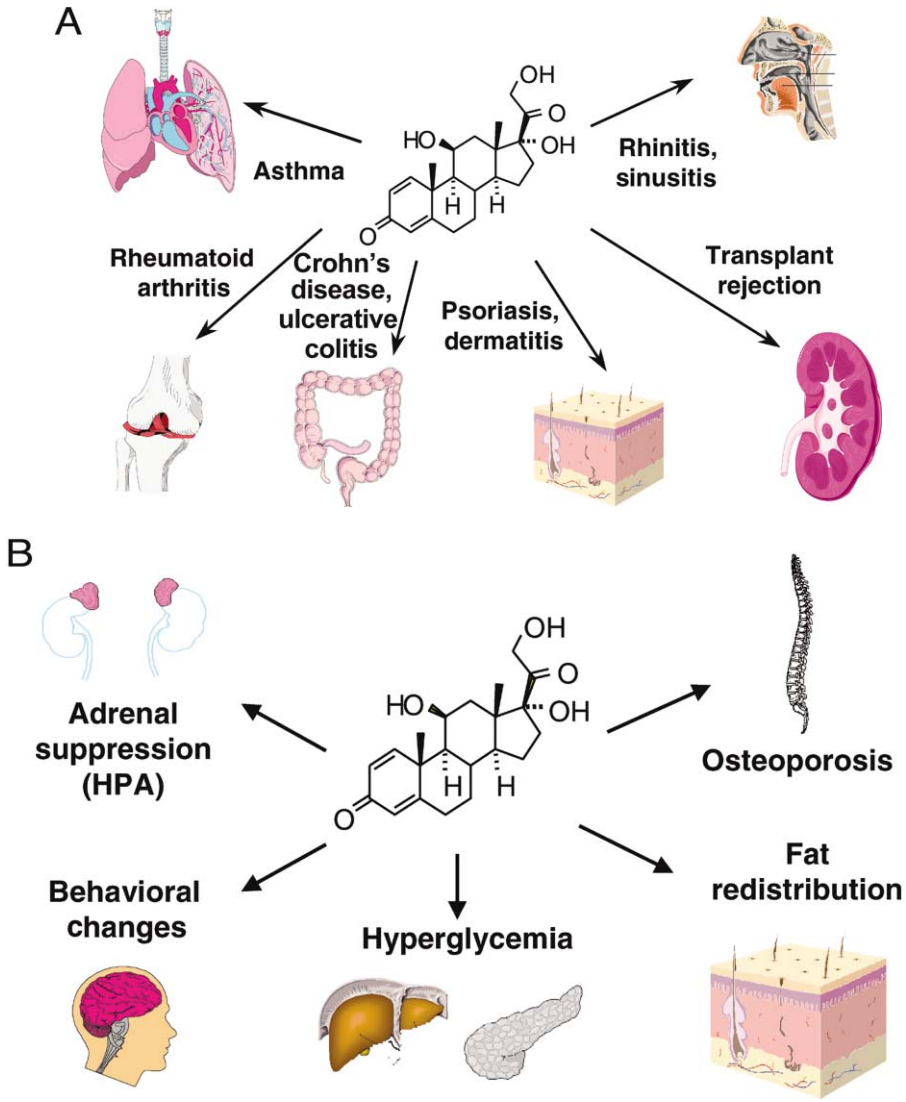

FIGURE 3 (A and B) Glucocorticoid therapy is both effective and destructive to patients. (A) Anti-inflammatory therapy with glucocorticoids is effective against a wide variety of inflammatory conditions. The steroid prednisolone is shown in the center. (B) The side effects of steroids are problematic and include adrenal suppression, behavioral changes, hyperglycemia, fat redistribution, and osteoporosis.

therapies such as reduced duration and dosage of glucocorticoids, anabolic steroids in men, hormone replacement therapy in women, and bisphosphonate treatment can mitigate these effects. Additionally, inhaled steroids have a reduced though detectable effect on bone. Administration of anti-osteoporosis agents from the bisphosphonate class (Alendronate) will likely reduce the negative effects of glucocorticoids on bone.

Glucocorticoids (GCs) can induce insulin resistance and even outright diabetes through long-term and/or high-dose application. This adverse consequence of glucocorticoid therapy probably results from three facets of glucocorticoid action that together increase circulating glucose levels. First, GCs suppress the levels of important insulin receptor signaling molecules, thus dampening the uptake of glucose from serum in response to elevated glucose levels. Second, GCs raise hepatic levels of phosphoenolpyruvate carboxykinase, the rate-limiting enzyme in gluconeogenesis, thereby increasing liver glucose output and further elevating glucose levels in the blood. Third, GCs inhibit insulin stimulation of blood flow to skeletal muscle, the major site of insulin-mediated glucose uptake in the body, reducing the opportunity to reduce glucose levels in

the bloodstream through normal physiological mechanisms. Combination therapy with insulin-sensitizing agents potentially could reduce this side effect.

High-dose glucorticoid treatment induces various states of myopathy, disorders of muscle tissue or muscle. Atrophy of fast-twitch muscle fibers has been observed histologically in several studies of human and animal tissues. GCs repress gonadal production of testosterone, a hormone that acts to maintain muscle tissue, highlighting the problem of loss of muscle mass and ensuing increased risk of dangerous falls in patients who are already at risk for fractures from GC-induced osteoporosis. These effects are the result of the normal catabolic action of GCs: they induce the breakdown of fats and muscle proteins to generate substrates for gluconeogenesis in the liver.

Glucocorticoids impair wound healing by several mechanisms. First, the anti-inflammatory effects of GCs inhibit the inflammation required for the wound healing process. Second, epithelialization and wound contracture are diminished, perhaps due to inhibition by GCs of growth factor secretion and keratinocyte proliferation. Third, GCs inhibit collagen synthesis and cross-linking, which reduces the extent and strength of regenerative tissue at the wound site. Thus, glucocorticoids can impair wound healing and increase the risk of infection several fold.

High-dose and/or long-term glucocorticoid treatment can induce a distinctive accumulation and redistribution of fat in which fat is depleted in limbs and deposited in visceral and trunkal areas. In particular, glucocorticoid treatment stimulates fat accumulation in depots in the face, supraclavical, and visceral areas, leading to the moon face and buffalo hump phenotypes characteristic of long-term glucocorticoid therapy. Additionally, individuals on long-term GCs can experience weight gain and loss of lean body mass, although the former may be due to an improvement in the underlying disease condition. These actions of glucocortiocoids are probably due to effects on lipid metabolism and insulin resistance.

Prolonged glucocorticoid therapy may lead to suppression of the HPA axis and thereby increase the risk of developing adrenal insufficiency during periods of stress. Until recovery of the axis is total, patients may need regular physiologic replacement doses administered in a tapering format; high-dose supplemental therapy may be required during a major illness or surgery.

The disease condition of some patients will flare upon the withdrawal of glucocorticoid therapy. This has been observed during treatments for inflammatory bowel diseases such as moderate to severe Crohn's disease, severe ulcerative colitis, and moderate ulcerative colitis.

High doses of glucocorticoid have been shown to induce euphoria or psychosis in a small fraction of patients, perhaps driven by cross-reactivity of GCs with the mineralocorticoid receptor (MR). The MR has been shown in rodents to be involved in a number of behaviors associated with exogenous treatment by glucocorticoids, and MR and GR levels are particularly high in the hippocampus, a region of the brain that is critical for the regulation of behavior.

VI. HISTORY OF SELECTIVE GLUCOCORTICOID RECEPTOR MODULATORS

Limited amounts of cortisone were first purified from animal adrenals in 1935–1936. A route of production was developed, involving synthesis from a bile acid, and in 1949, cortisone was first offered commercially. In 1948, at the Mayo Clinic, daily injections of a corticosteroid were administered to a cohort of arthritis patients. The results were so dramatic and the improvement was so significant that it was originally held that the cure for arthritis had been discovered. As the use of corticosteroids increased over subsequent years, side effects appeared and it was realized that large doses, given over prolonged periods of time, yielded significant adverse effects. Patients began to decline treatment because of the potential problems, and the use of corticosteroids became more conservative. Since that time organic chemists have synthesized a vast array of modified corticosteroids, with the goal of maintaining efficacy while reducing side effects.

Early approaches concentrated on finding compounds with greater anti-inflammatory activity than the natural steroid, cortisol. Introduction of a double bond at the 1,2 position of cortisol yields the well-known anti-inflammatory drugs prednisone and prednisolone. Prednisolone is the active form and is formed from prednisone by first-pass enzymatic conversion in the liver to the 11-hydroxyl form. These compounds have a four- to fivefold increase in anti-inflammatory activity with somewhat reduced sodium retention relative to cortisol. In addition, prednisolone has an increased duration of action relative to cortisone due to its slower metabolism. Combining the 1,2 double bond with the introduction of fluorines at the 6,6-methyl or 9 positions further potentiated anti-inflammatory activity. These compounds, however, led to much greater increases in sodium and water retention than cortisol relative to

anti-inflammatory activity due to increased mineralocorticoid activity. Further introduction of a methyl group at the 16 position combined with the 1,2 double bond and 9-fluoro substitution forming, for example, the potent anti-inflammatory dexamethasone led to further increases in anti-inflammatory activity while greatly reducing the mineralocorticoid activity. Hydroxylation at the 16 position had an effect similar to that of methylation (triamcinolone). For all of the systemic steroids in current use, although the anti-inflammatory potency is high and problems with sodium and water retention are somewhat lower, all of the other systemic problems caused by cortisol remain.

In order to use these glucocorticoids as topical agents, it was highly desirable to increase lipophilicity to improve penetration. For example, masking the 16- and 17-hydroxyls of triamcinolone as acetonides proved very effective. Numerous other strategies also proved very effective, especially for use on the skin. However, in the treatment of asthma, even the small amount of systemic activity seen with a variety of potent compounds could be problematic. In order to further reduce the systemic effects, several strategies were used. For example, fluticasone propionate has the same activating substitutions previously used (1,2 double bond, 6-fluoro, 9-fluoro, 16-methyl) but also two substitutions at the 17 position to enhance topical activity, a 17β-fluoromethyl carbothioate and 17α-propionate. This yields not only an exceedingly potent compound but also one that is likely to be highly metabolized at the 17β position to the inactive carboxylic acid. This is clearly a potential improvement in topical steroids for asthma, but for systemic administration there is clearly room for significant improvement in the development of more useful anti-inflammatory agents. Along these lines, the steroid deflazacort was originally believed to have less impact on bone while maintaining efficacy as an anti-inflammatory agent. This compound is a D-ring-substituted steroid that is otherwise similar to cortisol. The initial clinical data on deflazacort were quite encouraging, suggesting a decreased impact on both bone and glucose metabolism. Multiple randomized clinical trials appeared to indicate that deflazacort indeed has less severe side effects. The difficulty lies in demonstrating equivalent anti-inflammatory efficacy between prednisone and deflazacort. As described above, clear equivalence trials require large numbers of patients to ensure that a small but significant difference could be detected. Many of these clinical trials relied on the original determination of a 1:1.2 relative potency ratio described by the manufacturer (5 mg of prednisone = 6 mg of deflazacort). Subsequent trials that adjusted the steroid dose to maintain equivalent anti-inflammatory efficacy usually needed higher levels of deflazacort than the ratio of 1.2. Thus, trials comparing side effects may not have used biologically equivalent doses of deflazacort. Unfortunately, at these higher doses, the advantages of deflazacort vanished. In 1997, a group from Roussell Uclaf published the second attempt at a selective glucocorticoid receptor modulator after deflazacort. These compounds were again steroids, but these authors had used the molecular hypothesis described above and found several steroidal structures that were capable of separating transcriptional activation from repression (RU24858, RU40066, and RU24782). This group was able to show significant differences between their compounds and commonly used steroids. These molecules were very efficient inhibitors of both AP-1- and NF-κB-mediated gene induction and were strong anti-inflammatory agents *in vivo*. They also appeared to have reduced ability to activate gene expression in some contexts. Subsequent *in vivo* experiments from another group have not shown a therapeutic advantage of these types of molecules for body weight, thymic involution, and inhibitory effects at the growth plate of the femoral head, but the jury is still out. The results with these molecules have been utilized to suggest that the transcriptional repression/activation hypothesis fails to translate into therapeutic benefit; this view remains controversial.

VII. CURRENT AND FUTURE RESEARCH AND DEVELOPMENT

Since current formulations of glucocorticoids provide clear therapeutic value at existing levels of efficacy, new drug discovery in the area of selective glucocorticoid receptor modulators is and will be aimed at reducing the side effects that currently limit the clinical application of glucocorticoids. Although the specific side effects that could be targeted may vary depending on the disease target and patient population, a decrease in the rate and/or amount of bone loss induced by glucocorticoid therapy would represent a very significant improvement in the treatments available to patients on both anti-cancer and anti-inflammatory courses. Reduction in behavioral side effects and dysfunctional fat metabolism also would provide major clinical benefits. The therapeutic efficacy and side effects of glucocorticoids are

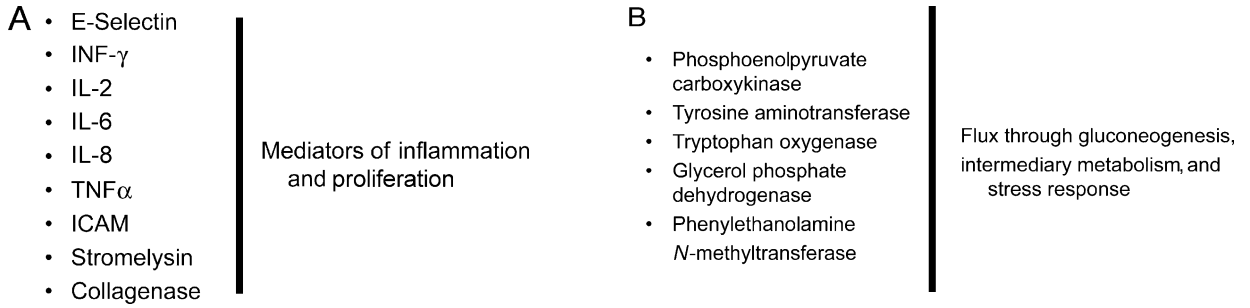

FIGURE 4 (A and B) Glucocorticoid receptor gene targets. (A) GC-mediated transcriptional repression; a large number of genes are involved in mediating inflammation and proliferation. mediated by the glucocorticoid receptor liganded to the glucocorticoid agent, and thus current and future work in pharmaceutical and academic laboratories is focused on identifying receptor modulators, compounds that possess only a portion of the activities of the natural steroids when bound to the receptor. With the publication of the crystal structures of the steroid- or ligand-binding domains of several steroid receptors, it has become apparent that the ligand-binding domain of intracellular receptors such as the glucocorticoid receptor transmits information from the ligand buried in its binding pocket out to the surface of the receptor. This information transfer allosterically contributes to the structure of the protein–protein interaction surfaces of the receptor, and changes in the structure of these surfaces lead to altered interactions with the panoply of proteins with which the glucocorticoid receptor cooperates to effect changes in gene expression. There are at least two general strategies for drug discovery that exploit these ligand-driven changes in the structure of interaction surfaces of the receptor. One approach is to ascribe the beneficial effects of glucocorticoids to one set of molecular functions of the glucocorticoid receptor and the side effects to another, distinct set molecular functions of the receptor and then attempt to discover ligands for the receptor that cause the receptor to retain the molecular functions leading to the beneficial actions but not the functions leading to the side effects. A separate approach follows the experience of the estrogen receptor field and the discovery of selective estrogen receptor modulators (SERMs), in which the beneficial effects of the steroid are assigned to receptor action in certain tissues in the body and the side effects are assigned to the actions of the receptor in other tissues; then, attempts are undertaken to discover ligands for the receptor that cause the receptor to be active in the tissues leading to the beneficial actions but not in the tissues leading to the side effects.

The first approach, based on the hypothesis that certain cellular functions of the glucocorticoid receptor are associated with the beneficial effects of a ligand and that other functions are associated with side effects, derives partially from the body of work demonstrating that transcriptional repression of specific pro-inflammatory genes by the glucocorticoid receptor may be involved in the anti-inflammatory efficacy of glucocorticoids (Fig. 4). Another body of work supports the argument that at least some of the side effects can be associated with transcriptional activation of certain metabolic genes in liver and fat (Fig. 5). In particular, genetic experiments in mice have provided powerful evidence for the separation of transcriptional activation from repression. Mutations in the dimerization domain of the glucocorticoid receptor that abrogate its DNA-binding ability and thus eliminate its transcriptional activation from some GREs have been created. Importantly, these mutations had little or no effect on transcriptional repression, which generally does not require association with canonical GREs, yet glucocorticoids retain their anti-inflammatory activity in these animals and can still down-regulate various pro-inflammatory cytokines. However, in response to glucocorticoids, these mice do not activate the transcription of liver enzymes that mediate glucose production. Following this hypothesis, selection of compounds that demonstrate an enhanced repression:activation ratio over steroids should yield a more beneficial therapeutic ratio than current glucocorticoids. However, the activation/repression hypothesis is debatable. For example, Lipocortin, a protein that supposedly mediates some anti-inflammatory

activity, is up-regulated by the transcriptional activation of glucocorticoids. Thus, compounds that retain their transcriptional repression abilities but lose the transcriptional activation that induces Lipocortin may have reduced anti-inflammatory properties. Furthermore, both osteocalcin and osteoprotegerin, important molecules in bone remodeling, are repressed by glucocorticoids; this repression could contribute to the osteoporosis associated with steroid use, and accordingly any compound that represses transcription may cause negative side effects in bone. Obviously, then, it will be difficult to predict the *in vivo* activities of compounds that favor transcriptional repression over activation, and only their synthesis and testing will determine whether the activation/repression hypothesis is useful for drug discovery.

The second approach follows the experience of the estrogen receptor field and the discovery of SERMs, in which beneficial effects of the steroid are assigned to receptor action in certain tissues in the body and the side effects are assigned to the actions of the receptor in other tissues, and then one attempts to discover ligands for the receptor that cause the receptor to be active in the tissues leading to the beneficial actions but not in the tissues leading to the side effects. One possibility in this model would be to use molecular and cellular assays to screen for compounds with reduced activity on the receptor in liver, fat, bone, and muscle—tissues in which glucocorticoid receptor-mediated side effects predominate—but that retain the desired anti-inflammatory activity. This strategy has been successfully employed in the estrogen receptor field to find selective estrogen receptor modulators that have reduced side effects in breast and uterus compared to estrogen but retain therapeutic efficacy in bone and heart.

A "third way" that combines tissue selectivity and selectivity with respect to the molecular functions activated in the glucocorticoid receptor by its ligands relies on the fact that there are individual promoters and tissues that require and express different sets of transcriptional co-activators and co-repressors for the function of the glucocorticoid and other steroid receptors. This approach relies on the accepted wisdom in the field that ligand binding determines steroid receptor conformation, steroid receptor conformation determines what subset of the set of transcriptional co-activators and co-repressors present in any given tissue is recruited to the steroid receptor in the presence of the ligand, and the set of transcriptional co-activators and co-repressors recruited determines the level and gene selectivity of transcriptional activation that is called the agonism, partial agonism, or antagonism of the ligand. Theoretically, a drug discovery program could be organized through this paradigm to develop novel glucocorticoid receptor modulators. The effort could be based on identifying ligands of the glucocorticoid receptor that alter the set of co-activators and co-repressors with which the liganded receptor interacts. In general, a ligand that permits only a subset of co-factor interactions should induce only a subset of the activities of the steroidal glucocorticoid ligands, and when combined with the differential representation of co-factors in various tissues in the body, this restricted co-factor recruitment profile should predict restricted *in vivo* activities in terms of both molecular functional specificity and tissue specificity (Fig. 5).

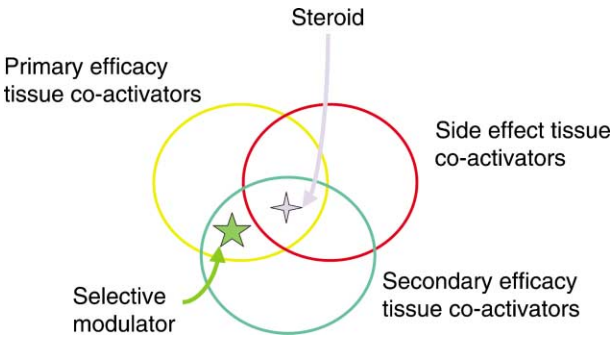

FIGURE 5 Selective co-activator interactions. Individual promoters and tissues are known that require and express different sets of transcriptional co-activators and co-repressors for the function of the glucocorticoid and other steroid receptors. It has been well established for numerous nuclear receptors that ligand binding determines steroid receptor conformation, steroid receptor conformation determines what subset of the set of transcriptional co-activators and co-repressors present in any given tissue is recruited to the steroid receptor in the presence of the ligand, and the set of transcriptional co-activators and co-repressors recruited determines the level and gene selectivity of transcription. Gene activation by glucocorticoids in various tissues in the body results in both therapeutic efficacy and detrimental side effects. Glucocorticoids and other steroids recruit distinct sets of co-factors in each of the tissues in which therapeutic effects and side effects emerge. A novel drug discovery paradigm for the identification of selective glucocorticoid receptor modulators would be to select for ligands that recruit to the receptor the same co-factors as glucocorticoids in the tissues in which efficacious results are desired, yet do not recruit to the receptor the same co-factors as glucocorticoids in the tissues in which side effects would be generated. This should generate full gene activation leading to therapeutic efficacy and reduced gene activation leading to side effects.

VIII. CONCLUSIONS

The identification of a tissue- or a function-selective glucocorticoid modulator has yet to be achieved, and though compounds with suggestive *in vitro* activities have been found, it is not yet clear that these compounds have the necessary profile *in vivo* to continue to provide the anti-inflammatory and anti-cancer activities of existing glucocorticoids while avoiding their most serious side effects. However, recent and ongoing research into the molecular and cellular actions of the glucocorticoid receptor when bound by glucocorticoids and their synthetic analogues provides both starting points for further research and hope that new drugs will be developed to address this large and unmet medical need.

Glossary

glucocorticoid Any of a group of hormones having the characteristic ring structure of steroids (such as hydrocortisone or dexamethasone) that are involved in carbohydrate, protein, and fat metabolism, that tend to increase liver glycogen and blood sugar, that are anti-inflammatory and immunosuppressive, and that are used widely in medicine (as in the alleviation of the symptoms of rheumatoid arthritis).

intracellular receptors A family of related transcription factors, some of which have affinity for specific hormones. These proteins mediate a wide range of physiological processes and are directly responsible for the effect of retinoids, estrogens, glucocorticoids, progestins, androgens, and thiazolidinediones, among others.

modulators Small-molecule drugs that mimic endogenous steroids by binding to intracellular steroid hormone receptors, but on binding allow only a subset of the molecular, cellular, and physiological responses that would be induced by the native steroid hormone to occur, thus effecting a desired pharmaceutical outcome.

Glucocorticoid Effects on Physiology and Gene Expression

IAN M. ADCOCK

Imperial College of Science, Technology, and Medicine, London

The major glucocorticoid in most mammals is cortisol. Cortisol secretion increases in response to any stress in the body, whether physical (such as illness, trauma, surgery, or temperature extremes) or psychological. However, this hormone is more than a simple marker of stress levels—it is necessary for the correct

functioning of almost every part of the body. Excesses or deficiencies of this crucial hormone also lead to various physical symptoms and disease states.

I. INTRODUCTION

The vast majority of glucocorticoid activity in most mammals is from cortisol, also known as hydrocortisone. Corticosterone is the major glucocorticoid in rodents. Although cortisol is not essential for life per se, it helps an organism to cope more efficiently with its environment. Nevertheless, loss or profound diminishment of cortisol secretion leads to a state of abnormal metabolism and an inability to deal with stressors, which, if untreated, may be fatal.

Cortisol is made in the zona fasciculata of the adrenal glands (Fig. 1). Its important functions in the body include roles in the regulation of blood pressure and cardiovascular function as well as regulation of the body's use of proteins, carbohydrates, and fats. Ninety percent of the secreted cortisol in circulation is bound to protein, mainly to cortisol-binding globulin. This protein binding probably decreases the metabolic clearance rate of glucocorticoids and, because the bound steroid is not biologically active, tends to act as a buffer and blunts wild fluctuations in cortisol concentration.

The body's level of cortisol in the bloodstream displays a diurnal variation; that is, normal concentrations of cortisol vary throughout a 24 h period. Cortisol levels in normal individuals are highest in the early morning at approximately 8 AM and are lowest just after midnight. This early morning dip in cortisol level often corresponds to increased symptoms of inflammatory disease in human.

II. EFFECTS ON CARBOHYDRATE AND PROTEIN METABOLISM

The name glucocorticoid derives from early observations that these hormones were involved in glucose metabolism. This role is most apparent in the fasted state, in which cortisol stimulates several processes that collectively serve to increase and maintain normal concentrations of glucose in blood. When cortisol is secreted, it causes a net reduction of extrahepatic protein stores, including skeletal muscle, leading to the release of amino acids into the bloodstream. This is due to both protein catabolism and reduced protein synthesis, possibly as a result of reduced amino acid transport into muscle cells. These amino acids are then transported to the liver, where they are used to synthesize glucose, which is required for energy production, in a process called gluconeogenesis (Fig. 2). Enhancing the expression of key

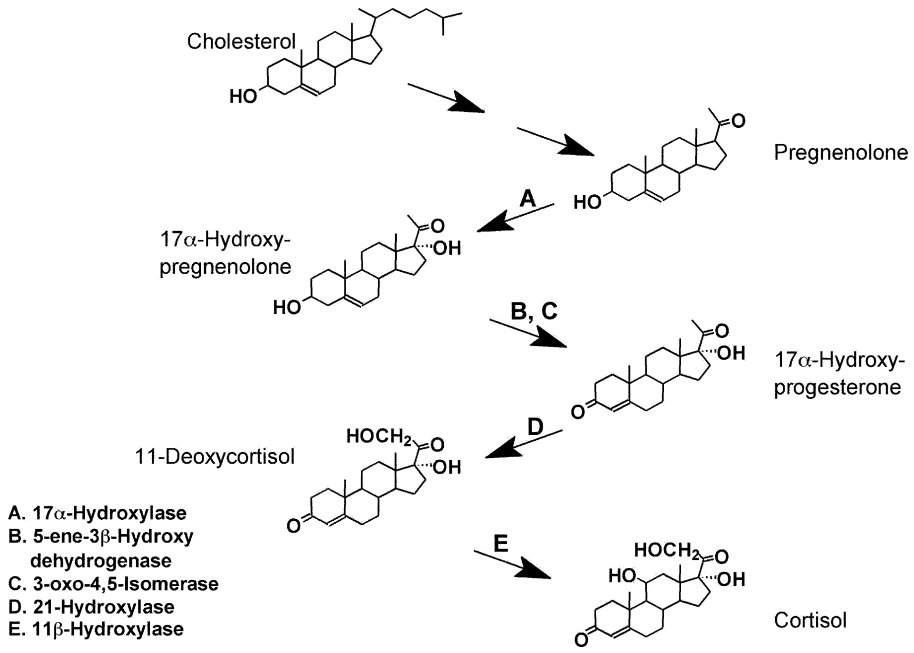

FIGURE 1 Pathway of cortisol synthesis from cholesterol in the liver. Pregnenolone is converted to 17α-hydroxyprogesterone before subsequent conversion to cortisol.

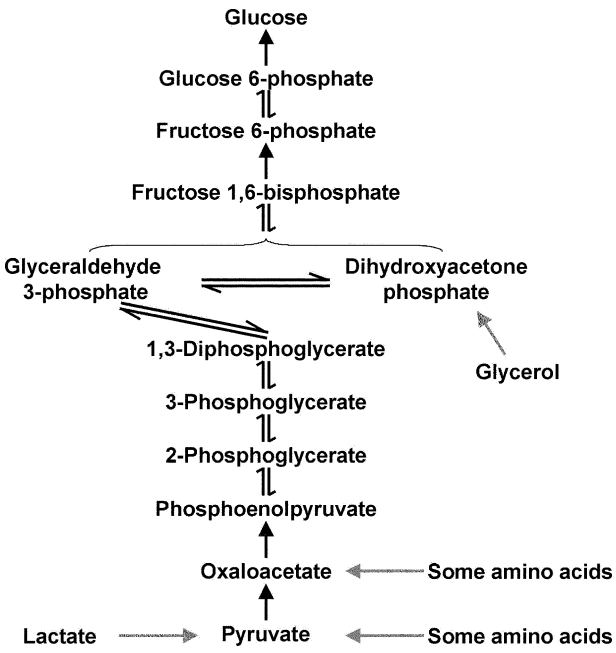

FIGURE 2 Pathway of gluconeogenesis. The distinctive reactions are the conversion of pyruvate to oxaloacetate and oxaloacetate conversion to phosphoenolpyruvate. The other reactions are common to glycolysis. The entry points for lactate, glycerol, and amino acids are shown.

enzymes, such as phosphoenolpyruvate carboxykinase (PEPCK), fructose 1,6-bisphosphate, and glycogen synthase, involved in gluconeogenesis is probably the best known metabolic function of glucocorticoids. The gene for PEPCK is acutely upregulated by cortisol in the liver and kidney, whereas insulin inhibits this process. PEPCK is absent in fetal liver but appears at birth, concomitant with the capacity for gluconeogenesis.

Gluconeogenesis is crucially important since the brain uses glucose as its primary energy source. Typically, the brain requires 120 g glucose per day and the body has reserves of 190 g available from glycogen stores. Therefore, during fasting and extreme exercise, glucose must be formed from noncarbohydrate sources to supplement cortisol-induced glycogen breakdown. At the same time, the other tissues of the body, including muscle and adipose tissue, but not the brain, decrease their use of glucose as fuel. As such, the actions of cortisol are to oppose those of insulin, generally by reversing the effects of insulin on enzyme expression.

Cortisol also stimulates the breakdown of fat in adipose tissue. The lipolytic activity of cortisol itself is not high but it enhances the actions of other lipolytic agents such as adrenaline and growth hormone. The fatty acids released by lipolysis are used for production of energy in tissues such as muscle, and the released glycerol provides another substrate for gluconeogenesis. Cortisol, in addition, moderately enhances the oxidation of cellular fatty acids secondary to reduced availability of glycolytic products. This process becomes increasingly important in times of starvation. Taken together, these energy-directing processes prepare the individual to deal with stressors and ensure that the brain receives adequate energy sources.

III. ANTI-INFLAMMATORY/ IMMUNOSUPPRESSIVE EFFECTS

Separate from its metabolic function, increased levels of glucocorticoids serve as potent suppressors of the immune and inflammatory systems. This is particularly evident when they are administered at pharmacologic doses but also is important in normal immune responses. As a consequence, glucocorticoids are widely used as drugs to treat inflammatory conditions such as arthritis, asthma, or dermatitis and as adjunct therapy for conditions such as autoimmune diseases. Synthetic glucocorticoids may also be used in organ transplantation to reduce the chance of rejection. Thus, although the early effects of cortisol are to stimulate the immune system, cortisol and synthetic glucocorticoids predominantly repress the inflammatory response by decreasing the activity and production of immunomodulatory and inflammatory cells.

The usefulness of glucocorticoids in treating inflammatory diseases was exemplified by the early work of Kendall and Hench. In a classic experiment, 100 mg of cortisone was injected into the muscle of a patient (Mrs. G.) suffering from chronic rheumatoid arthritis on September 21, 1948. Seven days later, the patient was able to walk to the shops for the first time in years. Kendall and Hench were awarded the Nobel prize for this work in 1950 and it represented a new approach to therapy with natural hormones by utilizing pharmacological, rather than physiological, doses.

There are five main aspects of inflammation: (1) the release of inflammatory mediators, such as histamine, prostaglandins, leukotrienes, cytokines, and chemokines; (2) increased blood flow in the inflamed area (erythema) caused by some of the released factors; (3) leakage of plasma from the vasculature into the damaged area (edema) due to increased capillary permeability; (4) cellular infiltration signaled by

chemoattractants; and (5) repair processes such as fibrosis. Glucocorticoids can modify all of these processes.

Glucocorticoids act on numerous inflammatory and immunomodulatory cells, including leukocytes, leading to a reduction in their localization at inflammatory sites. This is achieved by reducing the expression of adhesion molecules, such as intracellular adhesion molecule 1 (ICAM-1), particularly on endothelial cells, and consequently decreasing the movement of cells (T cells, monocytes, macrophages, and eosinophils) from the vasculature to the inflamed tissue. Glucocorticoids can also affect cell survival and death; as such, they can induce eosinophil and T-cell apoptosis and promote neutrophil survival. Inflammatory cells release a host of chemical mediators that enhance and perpetuate the inflammatory response. These mediators include cytokines, such as interleukin-1β (IL-1β) and tumor necrosis factor α (TNFα), and chemokines, such as eotaxin and IL-8. Glucocorticoids inhibit leukocyte function and responsiveness to inflammatory signals by suppressing the expression and release of all these factors. In addition, glucocorticoids reduce the expression of the receptors for these mediators along with the products of arachadonic acid metabolism (prostaglandins and leukotrienes).

IV. OTHER ACTIONS

The loss of the placenta at birth importantly deprives the fetus of a source of oxygen, glucose, and heat. In anticipation of these requirements, several organs, including the lungs, the gastrointestinal tract, the skin, the retina, and the central nervous system, undergo maturational changes in late pregnancy aimed at meeting these needs. For example, the lungs mature structurally and functionally, becoming distensible and capable of coping with high surface tension when air enters the alveoli with the first breath. Cortisol increases the rate of alveolar development, flattening of the lining cells, and thinning of the lung septa. In addition, cortisol stimulates the production of the phospholipid surfactant protein A. Mice with homozygous disruptions in the corticotropin-releasing hormone gene (CRH; see below) die at birth due to pulmonary immaturity. In addition, just before birth, cortisol induces a number of enzymes that are essential for survival postpartum. Thus, cortisol also increases the production of triiodothyronine and catecholamines in preparation for the sharp increase in metabolic rate and thermogenesis associated with breathing and the cold environment encountered by the newborn. In human, if birth is expected before 34 weeks gestation, maternal glucocorticoid supplementation reduces the likelihood of respiratory distress syndrome.

Cortisol maintains the contractility and work performance of skeletal and cardiac muscle (Fig. 3). This inotropic action may result from increased acetylcholine release or induction of the Na^+,K^+-ATPase and β-adrenergic receptors. However, to counterbalance this effect, cortisol decreases muscle protein synthesis, increases catabolism, and reduces muscle mass. This process accounts for the peripheral muscle loss seen in Cushing's disease (see below).

Another important role of cortisol is in the maintenance of normal blood pressure, an effect due primarily to modulating arteriole responsiveness to catecholamines and angiotensin II. Cortisol also

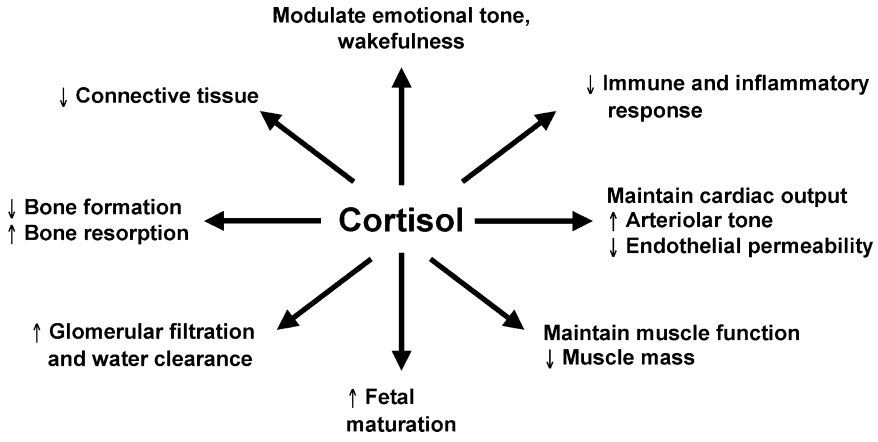

FIGURE 3 Overview of the major actions of cortisol on various tissues, organs, and systems other than its effects on carbohydrate metabolism.

decreases the synthesis of prostaglandins, which are important vasodilators and decrease endothelial cell permeability.

Cortisol also has important actions on bone formation. Cortisol reduces type 1 collagen synthesis, the fundamental component of bone matrix, and decreases osteoblast activity as detected by reduced osteocalcin release. Exacerbating these effects, cortisol also decreases the absorption of calcium from the intestinal tract by antagonizing 1,25-$(OH)_2$-vitamin D_3 synthesis and actions. These effects, in concert with an increase in the rate of bone resorption, promote an overall reduction in bone mass (osteoporosis). Cortisol also inhibits the synthesis of other collagens, resulting in skin thinning and capillary fragility.

Without adequate cortisol in the body, renal function is impaired, suggesting an important role in kidney function. Cortisol increases glomerular filtration by a combination of enhanced glomerular plasma flow and decreased preglomerular resistance. An additional action of cortisol is to inhibit antidiuretic hormone release from the hypothalamus by feedback inhibition, thereby further increasing kidney function.

Receptors for cortisol are fairly abundant in the brain, particularly within the limbic system and the hippocampus, and not surprisingly, cortisol is also known to alter mood, behavior, and sleeping patterns although the mechanisms for these effects are unknown. Long-term high-dose glucocorticoid therapy for immune and inflammatory diseases has a number of well-known side effects on the central nervous system.

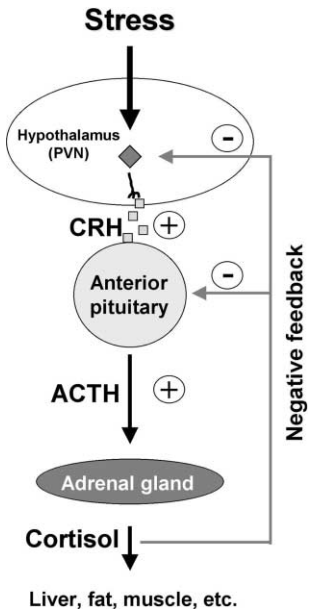

FIGURE 4 Feedback inhibition of stress-induced corticotropin-releasing hormone (CRH)- and adrenocorticotropic hormone (ACTH)-mediated production of cortisol. CRH released by the paraventricular nucleus (PVN) within the hypothalamus travels via the portal vessel to the anterior pituitary, where it stimulates ACTH production. ACTH, in turn, is released and stimulates adrenal cortisol synthesis and release. To maintain homeostasis, cortisol feeds back on this pathway to attenuate cortisol release.

V. CONTROL OF CORTISOL RELEASE

The body possesses an elaborate feedback system for controlling cortisol secretion and regulating the amount of cortisol in the bloodstream (Fig. 4). Cortisol is secreted in response to a single stimulator, ACTH, which is synthesized and released from the anterior pituitary gland, a small organ at the base of the brain, and is derived from the precursor molecule proopiomelanocortin (POMC). ACTH binds to receptors in the plasma membrane of cells in the zona fasciculata and reticularis of the adrenal. ACTH-receptor engagement stimulates G-protein activation, leading to enhanced adenyl cyclase activity and elevated intracellular levels of cyclic AMP. This ultimately leads to activation of the enzyme systems involved in the biosynthesis of cortisol from cholesterol (Fig. 1). ACTH is itself secreted under the control of the hypothalamic peptide CRH. The central nervous system thus controls glucocorticoid responses, providing an excellent example of close integration between the nervous system and the endocrine system.

Almost immediately after a stressful event, the levels of the regulatory hormones ACTH and CRH increase, causing an immediate rise in cortisol levels. When cortisol is present in adequate (or excess) amounts, a negative feedback system operates on the pituitary gland and hypothalamus, alerting these areas to reduce the output of ACTH and CRH, respectively, in order to reduce cortisol secretion to normal homeostatic levels. This is mediated by cortisol acting on glucocorticoid receptors (GRs) within the hypothalamus and pituitary gland that act to suppress the expression and release of both ACTH and CRH. This combination of positive and negative control on CRH secretion results in pulsatile secretion of cortisol. Typically, pulse amplitude and frequency are highest in the morning and lowest at night, accounting for the diurnal rhythm of cortisol.

FIGURE 5 Modular structure of the human 777-amino-acid glucocorticoid receptor.

VI. MECHANISM OF CORTISOL ACTION

Cortisol and other synthetic glucocorticoids exert their effects by binding to a single 777-amino-acid GR that is predominantly localized to the cytoplasm of target cells. GRs are expressed in almost all cell types and the density of GRs varies from 200 to 30,000 binding sites per cell. The affinity of the GR for cortisol is approximately 30 nM, which falls within the normal range for plasma concentrations of free hormone.

The GR has several functional domains (Fig. 5). The glucocorticoid ligand-binding domain is at the carboxyl-terminus of the molecule and is separated from the DNA-binding domain by a hinge region. There is an N-terminal transactivation domain that is involved in the activation of genes once binding to DNA has occurred. This region may also be involved in binding to other transcription factors. The inactive GR is part of a large protein complex (~300 kDa) that includes two subunits of the heat-shock protein Hsp 90, which blocks the nuclear localization of GR.

Cortisol can freely diffuse from the circulation into cells across the cell membrane and bind to the GR (Fig. 6A). Once cortisol binds to the GR, Hsp 90 dissociates, allowing the nuclear localization of the activated GR–cortisol complex and its binding to DNA. The GR combines with another GR to form a dimer at consensus DNA sites, termed glucocorticoid-response elements (GREs), in the regulating regions of steroid-responsive genes. The GRE is composed of two palindromic half-sites (AGAACA) separated by three nucleotides. This interaction allows the GR to associate with a complex of DNA-modifying and -remodeling proteins including steroid receptor co-activator-1 (SRC-1) and CREB-binding protein (CBP), which produce a DNA–protein structure that allows enhanced gene transcription. The number of GREs and their position relative to the transcriptional start site may be an important determinant of the magnitude of the transcriptional response to steroids.

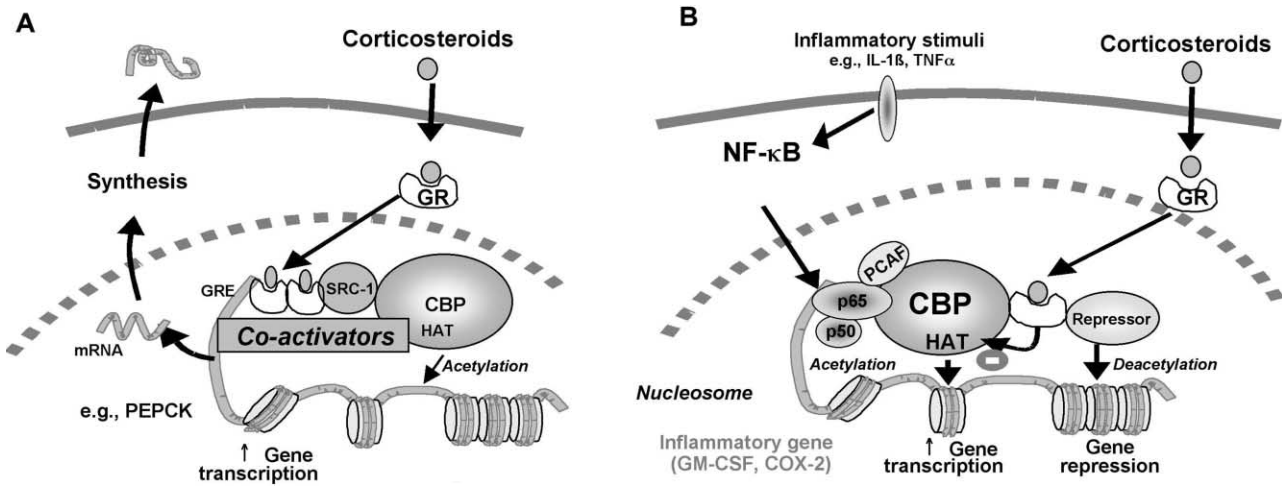

FIGURE 6 Molecular mechanism of glucocorticoid actions. Glucocorticoids freely diffuse across the plasma membrane and bind to a glucocorticoid receptor (GR). This complex translocates to the nucleus and, acting as a dimer (A), binds to a glucocorticoid-response element (GRE), resulting in binding to CREB-binding protein (CBP) and other co-activators, such as steroid receptor co-activator-1 (SRC-1). This activates the histone acetyl transferase (HAT) activity in CBP, resulting in histone acetylation and increased gene transcription of genes, such as phosphoenolpyruvate kinase (PEPCK). (B) Inflammatory mediators can stimulate granulocyte/macrophage colony-stimulating factor (GM-CSF) and cyclooxygenase 2 (COX-2) gene expression via nuclear factor κB (NF-κB) activation, leading to CBP and p300/CBP-associated factor (PCAF)-regulated chromatin remodeling. GR monomers can associate with CBP-associated HATs and reverse the histone acetylation induced by inflammatory stimuli by a direct effect and by recruiting repressor proteins such as histone deacetylases, thus leading to repression (silencing) of inflammatory genes, such as GM-CSF and COX-2, induced by NF-κB.

The PEPCK gene has two potential GRE half-sites within its promoter region (−395 to −349) but it must also associate with tissue-specific factors since glucocorticoids are positive regulators of PEPCK in the liver and negative regulators within adipose tissue. Accessory factor 1 (AF1) and AF2, binding to adjacent sites, act with the GR to form a glucocorticoid-response unit, and it is this unit that ultimately mediates cortisol stimulation of PEPCK gene transcription.

The mechanisms involved in gene repression are less well understood since most genes that are switched off by cortisol or synthetic glucocorticoids do not possess negative GREs (nGREs). One gene that does possess a nGRE is that for POMC. The GR binding to the nGRE blocks the action of Nur77, a transcription factor that mediates CRH stimulation of POMC expression.

GRs may form complexes with other transcription factors, such as activator protein 1 (AP-1) and nuclear factor κB (NF-κB), and co-factors within the nucleus that are involved in activating inflammatory gene expression without the requirement for DNA binding (Fig. 6B). This was first demonstrated by an inhibitory action of corticosteroids on the collagenase gene and shown to be due to a protein–protein interaction between the activated GR and AP-1. This has subsequently been demonstrated for other transcription factors, including NF-κB and nuclear factor of activated T-cells (NF-AT). NF-κB is an attractive target for corticosteroids since it regulates the expression of many inflammatory genes including granulocyte/macrophage colony-stimulating factor (GM-CSF), eotaxin, RANTES, IL-1β, TNFα, inducible nitric oxide synthase, cyclooxygenase 2, and ICAM-1. However, this cannot account for all of the anti-inflammatory effects of corticosteroids, since some inflammatory genes that are potently repressed by corticosteroids, such as IL-5, are not regulated by NF-κB. This suggests that reduction of gene expression by the GR may involve interference with transactivation mediated by recruitment of co-factors such as CBP and p300/CBP-associated factor (PCAF) and modulation of the nucleosomal structure.

Due to the differential effects of various ligands on GR gene induction and repression, it was postulated that the GR could recruit distinct sets of co-factors depending upon the context in which the GR was acting. One possible explanation for this effect proposed that the GR acts as a dimer bound to DNA or as a monomer when repressing AP-1 or NF-κB. In a series of recent experiments using mice expressing mutated GRs unable to dimerize and subsequently bind to DNA, Schutz and colleagues confirmed a role for GR DNA binding in the control of POMC expression but not in corticotropin-releasing factor expression or in that of inflammatory genes regulated by AP-1 or NF-κB.

VII. DISEASE STATES

The action of cortisol has many significant medical implications. For diabetics, more insulin may be required when they are under stress to cope with the increased blood glucose levels. Surgeons need to be aware that the protein catabolism of their patients may increase due to the stressfulness of their situation.

The most prevalent disorder involving glucocorticoids in humans and animals is Cushing's disease or hyperadrenocorticism. Excessive levels of endogenous glucocorticoids are generally seen as a result of a primary adrenal defect (adrenal neoplasm) or from excessive secretion of ACTH (pituitary adenoma). Alternatively, administration of excessive glucocorticoids for therapeutic purposes may lead to cushingoid symptoms. This condition generally affects adults, and approximately 10–15 people per million will develop this condition each year. Signs and symptoms of Cushing's syndrome include elevated blood pressure, development of diabetes, pink-to-purple stretch marks on the abdominal skin, fatigue, depression, moodiness, and accentuated fatty tissue on the face and upper back (buffalo hump). Women with Cushing's syndrome often have irregular menstrual periods and develop new facial hair growth. Men may show a decrease in sex drive. Treatment options are varied and depend on the cause of the excess cortisol.

Insufficient production of cortisol, often accompanied by an aldosterone deficiency, is called Addison's disease or hypoadrenocorticism. Most commonly, this disease is a result of infectious disease (e.g., tuberculosis in humans) or autoimmune destruction of the adrenal cortex. Usually more than 90% of the adrenal cortex must be destroyed before symptoms of adrenal insufficiency appear. This condition occurs in persons of all ages and affects approximately 1 in 100,000 people per year, affecting both sexes equally. Symptoms include fatigue, low blood pressure, weight loss, weakness, loss of appetite, moodiness, nausea, vomiting, and diarrhea. The production of other hormones by the adrenal is also often affected, with reduced levels of the hormone aldosterone, which is important for body salt and water balance, often accompanying the reduction

in cortisol. This condition can be treated by the administration of synthetic steroid hormone preparations.

Glossary

adrenocorticotropic hormone A hormone released by the anterior pituitary that stimulates the production of glucocorticoids and catecholamines by the adrenal gland.

cortisol The major glucocorticoid that is produced by the adrenal cortex in humans.

glucocorticoid-response element The DNA sequence to which the glucocorticoid receptor binds, thereby regulating gene expression.

glucose $C_6H_{12}O_6$, a 6-carbon aldose that is the major sugar in the blood and a key intermediate in metabolism. Used as a fluid and nutrient replenisher, usually given intravenously. The major energy source for the brain.

inflammatory mediators The endogenous compounds that mediate inflammation (autocoids) and related exogenous compounds including the synthetic prostaglandins.

nuclear co-factor A protein that enables a transcription factor to modify nucleosomal structure and/or gene transcription.

nuclear factor κB A pro-inflammatory transcription factor that is responsible for the activation of many inflammatory genes.

Glucocorticoid Receptor, Natural Mutations of

JEFFREY M. HARMON

Uniformed Services University of the Health Sciences, Maryland

The glucocorticoid receptor (GR) is a ligand-dependent transcription factor essential for the proper function of the hypothalamic–pituitary–adrenal axis and a host of other homeostatic processes. It also mediates the pharmacologic actions of therapeutic corticosteroids. Naturally occurring mutations in the GR can result in clinically important phenotypes.

I. INTRODUCTION

The glucocorticoid receptor (GR) mediates the physiologic action of endogenous corticosteroids and the pharmacologic action of therapeutic corticosteroids. Given its physiologic significance, it is not surprising that receptor knockouts in mice result in nonviable offspring and that relatively few

II. GLUCOCORTICOID RECEPTOR α AND β

There are two highly homologous human GR isoforms, hGRα and hGRβ. The hGR gene, which is located on chromosome 5, consists of nine exons (Fig. 1). Exon 1 and the first part of exon 2 contain 5′-untranslated region (5′-UTR), and exon 2 contains the translation start site. Exon 9 contains the translation stop site and a large 3′-untranslated region (3′-UTR). The GR gene is transcribed into multiple GRα mRNA messages. The two predominant GRα transcripts observed on Northern blots of human, rat, and mouse tissues are 7.0 and 5.5 kb mRNAs that are produced by alternative polyadenylation in the 3′-UTR. The 7.0 kb mRNA contains the full-length 3′-UTR (approximately 4.0 kb), and the 5.5 kb mRNA contains only about 2.4 kb 3′-UTR. Alternative splicing in exon 9 of the human GR primary transcript produces two variants, hGRα and hGRβ. In the default splicing pathway, the end of exon 8 is linked to the beginning of exon 9, resulting in the hGRα mRNA transcripts. The hGRβ mRNA transcript is generated by the alternative splicing pathway, which links the end of exon 8 to downstream sequences in exon 9. Thus, translation of hGRα and hGRβ mRNAs produces two proteins that are identical through amino acid 727, but diverge in the carboxy-terminus, with hGRα having an additional 50 amino acids and hGRβ having an additional, nonhomologous 15 amino acids. The difference in the carboxy-terminal sequences of hGRα and hGRβ results in different ligand-binding patterns. hGRα binds glucocorticoids with high affinity and regulates the transcription of glucocorticoid-response genes. However, hGRβ does not bind glucocorticoid and is transcriptionally inactive. No potential ligands for hGRβ have been identified.

Recently, the co-existence of two forms of GRα, GR-A (molecular mass = 94 kDa) and GR-B (molecular mass = 91 kDa), has been demonstrated in various mammalian tissues and cell lines. GR-A and GR-B are products of alternative translation initiation with the longer form, GR-A, initiated from the normal start codon ATG corresponding to methionine 1 and the shorter protein, GR-B, initiated from a downstream ATG codon corresponding to methionine 27 in hGRα. Interestingly, the Kozak sequence adjacent to the upstream ATG is weak and mutagenesis studies indicate that the GR-A and GR-B forms are generated by a "leaky" ribosomal scanning mechanism. Both GR-A and GR-B exhibit similar subcellular localization and nuclear translocation after ligand activation and are transcriptionally active upon hormone binding. GR-B appears to be more effective than the GR-A form in glucocorticoid-induced reporter gene transactivation assays.

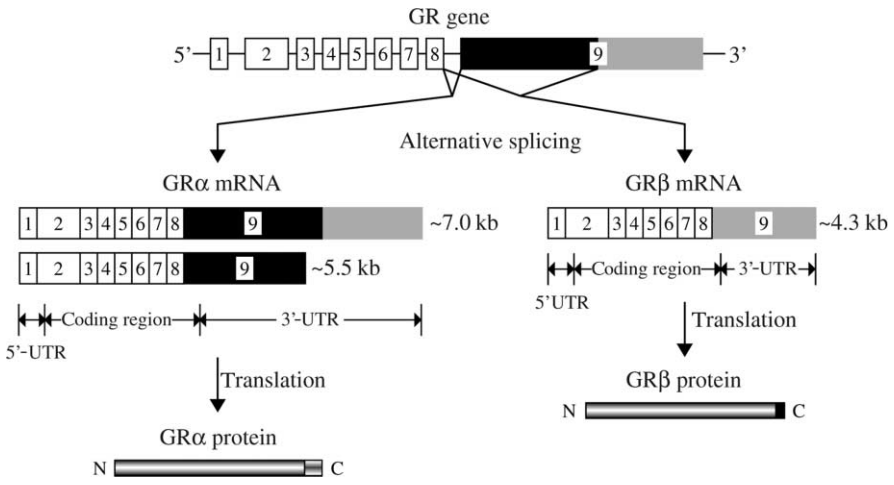

FIGURE 1 Expression of human GRα and GRβ. The top of the figure shows the DNA structure of the human GR gene. The exons are shown as boxes and numbered 1 to 9; the introns are shown as lines. A pre-mRNA is transcribed from this DNA and spliced in two different ways. On the left, the default splicing pathway includes exons 1 to 8 and links the end of exon 8 to the beginning of exon 9, generating different sizes of GRα mRNAs due to alternative polyadenylation. The default splicing pathway generates the GRα protein. On the right is shown the alternative splicing pathway, which includes exons 1 to 8 and links the end of exon 8 to downstream exon 9. This form of mRNA is translated into GRβ protein. Reproduced with permission, from The glucocorticoid receptor: Expression, function, and regulation of glucocorticoid responsiveness. R. H. Oakley and J. A. Cidlowski, "Glucocorticoids (Milestones in Drug Therapy)" (N. J. Goulding and R. J. Flower, eds.), pp. 55–80, ©2001 by Birkhäuser, Basel.

The expression regulation, tissue distributions, and physiological significance of these two GRα isoforms remain to be elucidated. Preliminary findings suggest that hGRβ also has A and B isoforms.

III. STRUCTURAL FEATURES OF GLUCOCORTICOID RECEPTOR α

In common with other nuclear receptors, the GR has a modular structure of three functionally separable domains (Fig. 2): (1) the amino-terminal domain, which has a constitutively active transcriptional activation function (AF-1); (2) the central DNA-binding domain (DBD), which contains two zinc-fingers responsible for interacting with DNA as well as forming homodimers; and (3) the carboxy-terminal ligand-binding domain (LBD), which is involved in hormone binding and contains a ligand-dependent transcriptional activation function (AF-2). There is a linker between the DNA-binding domain and the ligand-binding domain called the hinge region, which appears to be structurally flexible. As with other nuclear receptors, the structures of the three different domains of GR have been studied separately. It is poorly understood how these domains are organized and interact with one another within the context of a full-length receptor.

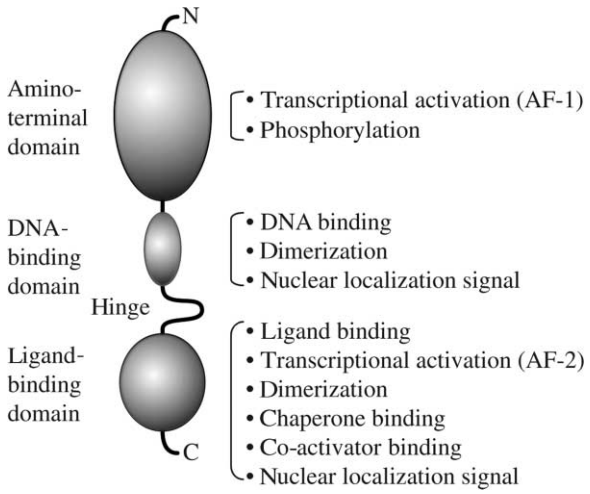

FIGURE 2 Modular structure of GRα. The GRα is composed of three functional domains. The amino-terminal domain contains a constitutive transcriptional activation function (AF-1) and all known amino acid phosphorylation sites. The central DNA-binding domain is involved in binding to a specific DNA-response element, the GRE, and also contains a dimerization surface and nuclear localization signal. The carboxy-terminal ligand-binding domain has multiple activities that include a ligand-binding activity, a ligand-dependent transcriptional activation function (AF-2), and a nuclear localization signal. In addition, it contains surfaces for dimerization and the binding of co-activators and molecular chaperones. A hinge region is shown between the DNA-binding domain and the ligand-binding domain.

A. The Amino-Terminal Domain

The amino-terminal domain of GR is the least conserved portion of the protein among different species and contains an amino acid sequence important for constitutive transactivation, called tau1 (τ1) or AF-1 (residues 77–262 in human GR). A smaller fragment that represents the activation core of the τ1, called τ1c, has been localized to residues 187–244 in hGR. The τ1c is almost as active as the intact τ1 and represents the only autonomous transactivation activity within the larger fragment.

The three-dimensional structure is not available for the amino-terminal domain of GR. It has been determined that purified τ1 and τ1c, which are enriched in acidic amino acid residues, are poorly structured in aqueous solution by circular dichroism and nuclear magnetic resonance (NMR) spectroscopy studies. In more hydrophobic solvents, three segments display a propensity to form α-helical conformations. There is a correlation between transcriptional activity and the propensity for α-helix formation, as suggested by proline substitution studies within these segments, indicating that the putative helices may be important for the GR function *in vivo*. It has also been reported that τ1 interacts with basal transcriptional machinery and other transcriptional co-factors. However, the mechanism by which the amino-terminal domain is involved in the constitutive transcriptional activity of the receptor is not clear.

Like other members of nuclear receptor family, GR is a phosphoprotein. The identified phosphorylated sites are located in the amino-terminal domain. Upon hormone binding, basally phosphorylated GR becomes hyperphosphorylated. Although the exact role of GR phosphorylation is not completely clear, it is generally believed that phosphorylation status plays an important role in receptor turnover and may account for the short half-life of the protein in the presence of ligand.

B. The DNA-Binding Domain

The glucocorticoid receptor can homodimerize and bind to the cognate glucocorticoid-response element (GRE) in the promoter region of target genes with a high affinity. The consensus sequence

of the GRE is the palindromic 15 bp sequence 5′GGTACAnnnTGTTC- T 3′ (where n is any nucleotide). The GR DBD contains eight cysteines, which can coordinate Zn^{2+} ions to form characteristic DNA-binding zinc-fingers. The GR DBD contains protein motifs that allow the receptor to bind to DNA and homodimerize.

The crystal structure of rat GR DBD in complex with DNA has been solved by X-ray diffraction analysis. The DBD contains two zinc-finger motifs that fold together into a globular domain. Each zinc-finger is formed by four cysteines chelated to a single Zn^{2+} ion (Fig. 3). The DBD can be divided into two modules, each consisting of a zinc-finger followed by an amphipathic α-helix. The two modules differ both structurally and functionally and fold together mainly through the interaction of the aromatic side chains of their amphipathic helices. The main loop of the amino-terminal zinc-finger has a short segment of anti-parallel β-sheet, and the carboxy-terminal zinc-finger has a distorted α-helix. The amino-terminal zinc-finger controls the DNA-binding specificity through amino acid residues in the P-box that contact bases in the major groove of the GRE. The carboxy-terminal zinc-finger provides the homodimerization interface, which is composed of amino acids in the D-box, to form a head-to-head symmetric dimer. Two structures of DBD–GRE complexes were determined by crystallographic analysis using the DBD in complex with different GRE sequences; one had a consensus GRE with three bases between two half-sites, and the other had a modified GRE with four bases between the two half-sites. The results suggested that the receptor adjusts to interaction with different GRE sequences by making different types of DNA contacts instead of by changing its homodimeric structure. The structure of the GR DBD in solution has been determined by NMR studies. It indicates that the GR DBD is a monomer in the absence of GRE.

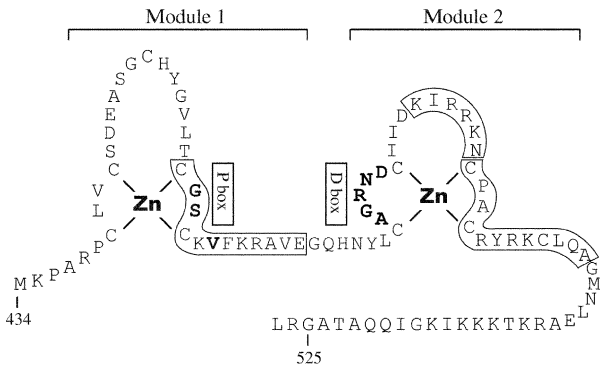

FIGURE 3 Zinc-finger motifs in the DNA-binding domain of GRα. Amino acid sequence from rat GRα is shown as in the crystallographic analysis and is numbered based on the full-length receptor. Three α-helical segments are shown in the boxes. Each of the structurally and functionally different modules, 1 and 2, contains a zinc-finger followed by an α-helix. The highlighted amino acids in module 1 form the P-box, which is involved in DNA binding. The highlighted amino acids in module 2 form the D-box, which provides the dimerization interface to form a symmetric homodimer. Both X-ray and NMR studies have shown that the amino acid residues of the carboxy-terminus of the DBD, residues 512 to 525 in rat GR, are poorly structured. This region is rich in basic amino acids and is partially responsible for the nuclear localization of the receptor, called the nuclear localization signal (NLS).

C. The Ligand-Binding Domain

The ability of GR to activate transcription of target genes requires the binding of glucocorticoids to its LBD. In addition to ligand binding, the GR LBD is required for nuclear translocation, the binding of heat shock proteins and co-activators, and homodimerization, and most importantly, it harbors a ligand-dependent transcriptional activation function (AF-2). The X-ray structure of the GR LBD has not been reported. Information has resulted from studies of LBD deletions and mutations. Most mutations of the GR LBD have led to a decrease or loss of ligand binding. The liganded structures of thyroid receptor α (TRα), retinoic acid receptor γ (RARγ), estrogen receptor α (ERα), progesterone receptor (PR), androgen receptor (AR), and peroxisome proliferator-activated receptor γ (PPARγ) have been solved. Unliganded structures have also been determined for LBDs of retinoid X receptor α and PPARγ. Despite substantial sequence divergence, the three-dimensional structures of these LBDs display a conserved helical arrangement and a similar overall protein folding. The LBDs determined contain 11 or 12 α-helices (H1–H12) and two short β-strands (s1, s2). The α-helices are arranged into a three-layer, anti-parallel sandwich structure forming a compact globular domain. A general arrangement of the α helical sandwich fold of nuclear receptors' LBD is illustrated in Fig. 4. It has been suggested that the apo-receptor undergoes conformational changes

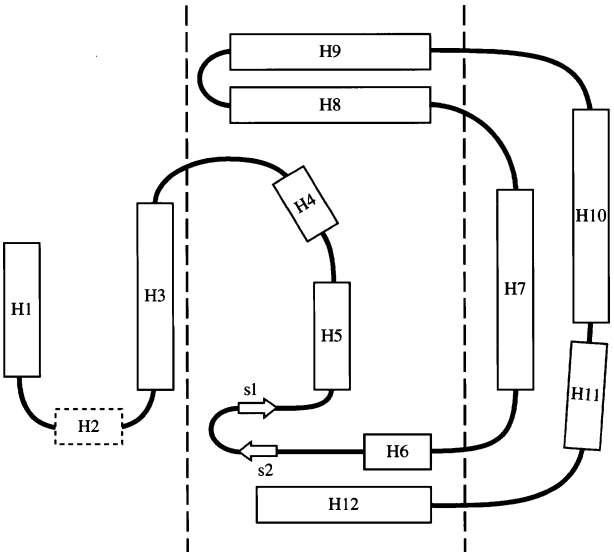

FIGURE 4 Topology scheme of the ligand-binding domain of nuclear receptors. A general helical arrangement and protein folding of solved nuclear receptor LBDs are shown. Boxed H1–H12 are α-helices; H2 is not in all LBDs. Arrowed s1 and s2 are β-sheets. Some LBDs have more than two β-sheets. Dashed lines separate the overall LBD into three layers. Reproduced with permission, from Steinmetz, A. C. U., Renaud, J.-P., and Moras, D. (2001). Binding of ligands and activation of transcription by nuclear receptors. *Annual Review of Biophysics and Biomolecular Structure* **30**, 329–359. ©2001 by Annual Reviews: www.AnnualReviews.org.

upon ligand binding, resulting in a more compact structure. Ligand binding may induce a major rearrangement of helix 12, which contains the core of ligand-dependent AF-2, holding back against the body of the receptor to close the entrance of ligand-binding pocket and generating the binding site for the co-activators.

A homology model of liganded hGR LBD can be developed based on known liganded hPR LBD crystal structure since among previously solved nuclear receptor LBDs, it shares the best pairwise sequence identity (54.183%) with hPR LBD. The secondary structure of holo-hPR LBD contains 10 α-helices without helix 2, and helices 10 and 11 are contiguous. Helix 12 in the hPR LBD is longer than in RAR, TR, and ER and spans all three layers of the "sandwich" enclosing the hormone-binding pocket. Following helix 12, the PR LBD has a 12-residue carboxy-terminal extension that is also present in GR and AR. This 12 amino acid residues form a β-sheet (s4) that is stabilized by an anti-parallel β-sheet interaction with another β-sheet (s3), between helix 8 and helix 9, located in the middle layer of the overall three-layered sandwich. This structure is thought to be important for ligand binding. The bound hormone contacts amino acids from helices 3, 5, 7, 11, and 12 and the β-turn (s1) between helices 5 and 6. In the crystal structure, the liganded PR LBD forms a dyad-symmetric homodimer in the asymmetric unit, with an interface that includes helix 12.

The amino acid sequence of hGRβ is identical to that of hGRα through amino acid 727. Thus, hGRβ does not contain helix 12. The last 15 nonhomologous amino acids in hGRβ, which correspond to the carboxy-terminus of helix 10 and the entire helix 11 in hGRα, are not helical as analyzed by several different secondary structure prediction schemes. These structural differences in hGRα and hGRβ may determine the functional differences between them.

The ligand binding domain of GR has recently been crystalized. It has an overall structure similar to other nuclear receptors although its dimerization interface may vary.

IV. THE FUNCTIONS OF GLUCOCORTICOID RECEPTOR α

In the absence of hormone, GRα is inactive and exists as a large protein complex that includes the receptor, two molecules of hsp90, and other associated proteins in the cytoplasm (Fig. 5). The association of GRα with hsp90, which functions as a molecular chaperone, is necessary for high-affinity hormone binding to the receptor. Hsp90 also keeps GRα in a conformation masking the NLSs, thus maintaining cytoplasmic localization. The GRα ligand-binding domain is involved in the interaction between GRα and hsp90 molecules. Two regions of GRα contain a NLS; the first NLS is identified in the carboxy-terminus of the DNA-binding domain and the second is located in the ligand-binding domain. Once lipophilic glucocorticoid molecules diffuse across the plasma membrane into the cytoplasm, they bind to the ligand-binding domain of GRα, resulting in a conformational change of the receptor and dissociation of hsp90 and other associated proteins. This process is referred to as receptor activation. Upon receptor activation, GRα becomes hyperphosphorylated. The sites of both basal phosphorylation and hormone-induced hyperphosphorylation have been identified in the amino-terminal domain of GRα. It has been suggested that receptor phosphorylation may regulate the interaction of GRα with other transcription factors important for gene transactivation and the stability of the receptor.

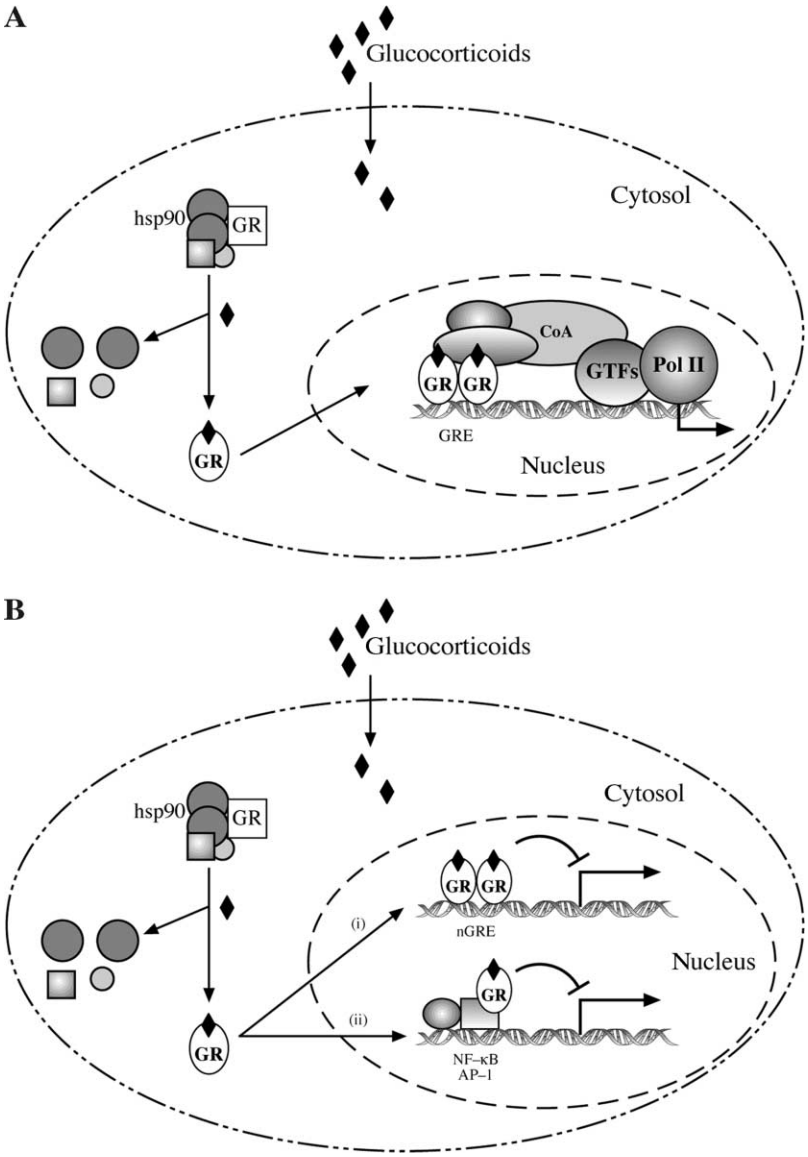

FIGURE 5 Regulation of gene expression by glucocorticoid receptor α. Lipophilic glucocorticoid molecules are able to diffuse easily across the cell membrane into the cytoplasm. Upon ligand binding, the glucocorticoid receptor (GR) is activated by releasing the inhibitory hsp90 and other associated proteins. (A) Activation of gene expression by GRα. Activated GR translocates into the nucleus and binds to the glucocorticoid-response element (GRE) as a homodimer where it interacts with co-activators (CoA). Co-activators bridge the GR with general transcription factors (GTFs) and RNA polymerase II (Pol II) and stimulate the transcription of GR target genes. (B) Repression of gene expression by GRα. Glucocorticoids induce GR dissociation from hsp90 and its translocation into the nucleus where GR can repress gene expression by (i) binding to the negative GRE (nGRE) or (ii) interacting with other transcription factors such as AP-1 and NF-κB.

Liganded GRα rapidly translocates into the nucleus, where it binds its cognate GRE in the regulatory region of the target gene as a homodimer. Regions participating in homodimerization include the D-box in the DNA-binding domain and a region within the ligand-binding domain that has not been precisely determined. The formation of GRα homodimers is required for both high-affinity binding to the GRE and modulation of target gene transcription by GRα. This type of action has been shown to regulate many genes such as the gluconeogenic enzymes phosphoenolpyruvate carboxykinase and tyrosine aminotransferase. Once bound to the GRE, GR stimulates the transcription of target genes by interacting directly

or indirectly through intermediary proteins, known as co-activators, with the basal transcription machinery (Fig. 5A). The mechanisms of co-activator action have been studied extensively. It has been revealed that co-activators regulate nuclear receptor-induced transactivation by remodeling chromatin or by facilitating the recruitment of basal transcriptional machinery. For example, the p160 family co-activator SRC-1 (steroid receptor co-activator-1) and p300/CBP [CREB (cyclic AMP-response element-binding protein) binding protein] are histone acetyltransferases (HATs), which stimulate transcription by modifying and destabilizing chromatin structure. The co-activator p/CAF (p300/CBP-associated factor) contains HAT activity, as well as TATA-box-binding protein (TBP)-associated factors, which facilitate the recruitment of the basal transcriptional machinery in order to initiate transcription. At least two regions in the GR are required for transcriptional activation function including ligand-independent AF-1 in the amino-terminal domain and ligand-dependent AF-2 in the carboxy-terminus of the ligand-binding domain. Most known co-activators primarily interact with the AF-2 surface in the presence of ligand.

Glucocorticoids can also inhibit gene expression via GRα binding to a negative response element, termed nGRE [Fig. 5B, (i)]. The nGRE has a more variable sequence and is different from the classic GRE. Examples of GRα-mediated transcription repression through an nGRE include genes encoding pro-opiomelanocortin, osteocalcin, and α-fetoprotein. The exact mechanisms involved in the repression are unclear. It is generally suggested that binding of GR to the nGRE may prevent the binding of essential transcription factors to their DNA cognate sites. For example, in the osteocalcin promoter, an nGRE site overlaps the TATA-box. Therefore, GRα and the basal transcription factor, TBP, may compete for the binding of the same site.

In addition to direct DNA binding, GRα can also repress gene transcription by negative cross talk with other transcription factors, such as activator protein-1 (AP-1) and nuclear factor-κB (NF-κB) [Fig. 5B, (ii)]. GRα directly interacts with these transcription factors and inhibits their transcriptional activities. However, the mechanisms of transrepression of AP-1 and NF-κB by GRα remain to be determined. The interaction surfaces between GRα and AP-1 or NF-κB have not been clearly localized. NF-κB and AP-1 are important regulators in mediating the transcriptional activation of many genes involved in the immune system. The negative cross talk between GRα and these transcription factors appears to be the potential mechanism underlying the important anti-inflammatory and immunosuppressive functions of glucocorticoids. Interestingly, in contrast to GR knockout mice, which die shortly after birth, knock-in mice containing a mutant GR that fails to homodimerize and subsequently does not bind DNA survive to adulthood. This suggests that transrepression is a critical function of the GR and that transactivation is dispensable, but these results have not yet been confirmed.

V. THE FUNCTIONS OF GLUCOCORTICOID RECEPTOR β

Both mRNA transcripts encoding the hGRα and hGRβ proteins have been detected in many human tissues, with hGRβ expressed at a considerably lower level than hGRα. In contrast to hGRα, hGRβ does not bind glucocorticoids or anti-glucocorticoids and does not transactivate glucocorticoid-responsive genes. In addition, hGRβ does not repress the transcriptional activity of other transcription factors, such as NF-κB. The biological function of hGRβ is not understood as yet; however, experimental evidence has shown that hGRβ can exert a dominant negative effect on transactivation by hGRα. Several possible mechanisms responsible for this dominant negative effect have been suggested, including the following: (1) hGRβ competes with hGRα for GRE binding, (2) hGRβ forms transcriptionally inactive heterodimers with hGRα, and (3) hGRβ competes to bind to co-activators needed by hGRα for transcriptional activity. In addition, an abnormal level of hGRβ, or the hGRα to hGRβ ratio, has been found in glucocorticoid-resistant patients. Interestingly, mice totally lack GRβ. Nevertheless, the biological significance of the GRβ isoform is still controversial.

VI. SUMMARY AND FUTURE PERSPECTIVES

The GR modulates gene expression by a number of different molecular mechanisms. There are two main modes of gene regulation, including transactivation by direct binding of the receptor to its cognate DNA-response elements and repression of gene expression through binding to nGRE or via cross talk with other transcription factors such as AP-1 and NF-κB. However, the mechanisms of both transactivation and transrepression are not completely understood. Future studies on the GR structure in the amino-terminal domain and the ligand-binding domain, as well as the interactions of each structural domain

within the context of the full-length protein, will aid in the elucidation of the function of this important nuclear receptor. Furthermore, knowledge of the relationship between the structure and the transcriptional regulation of GR may eventually lead to the development of new therapeutic strategies that selectively retain the potent anti-inflammatory and immunosuppressive effects of glucocorticoids while minimizing their negative side effects.

Glossary

alternative splicing A pre-mRNA processing pathway in which a single gene gives rise to different versions of the mRNA and, ultimately, to different proteins.

glucocorticoid receptor An intracellular protein that specifically binds glucocorticoids and functions as a transcription factor by activating or repressing the transcription of target genes. This receptor is a member of the nuclear hormone receptor family of ligand-inducible transcription factors.

glucocorticoid-response element A specific gluococorticoid receptor-binding DNA element that is located in the promoter regions of glucocorticoid target genes.

glucocorticoids Steroid hormones that are produced predominantly in the adrenal cortex from cholesterol; they regulate protein and carbohydrate metabolism and also inhibit the inflammatory response.

heat shock proteins Proteins that are synthesized by cells in response to increased temperature and function mainly as molecular chaperones protecting cellular proteins by aiding in protein folding.

nuclear receptors Ligand-inducible transcription factors that modulate target gene expression by binding to specific DNA sequences, termed hormone-response elements.

transactivation Stimulation of transcription by a transcription factor binding to DNA.

transcription factors Proteins that either are required for initiating RNA synthesis from gene promoters and together with RNA polymerase constitute the basal transcription machinery or recognize specific short consensus elements located upstream of the transcription starting point and regulate the transcription.

transrepression Inhibition of the transcriptional activity of a transcription factor.

zinc-finger A motif of amino acids with a characteristic spacing of cysteines that may be involved in binding zinc and that is also characteristic of some proteins that bind DNA.

naturally occurring mutations in the GR-coding region have been described. This article is intended to introduce the structure and function of the GR and to provide an overview of those naturally occurring genetic alterations in the GR gene that have significant effects on receptor function and/or result in a clinically relevant phenotype (see Table 1). Those readers interested in an in-depth review of all mutations in the GR gene are referred to the Glucocorticoid Receptor Resource (http://biochem1.basic-sci.georgetown.edu/grr/grr.html).

II. GLUCOCORTICOID RECEPTOR STRUCTURE AND ORGANIZATION

The GR (NR3C1) is a member of the nuclear receptor family of ligand-regulated transcription factors. In the absence of ligand, the receptor resides in the cytoplasm in a high-molecular-weight complex that includes heat-shock protein 90 (hsp90) and which maintains the receptor in a form able to bind ligand with high affinity. Ligand binding promotes dissociation of this complex and movement of the GR into the nucleus, where it regulates the transcriptional activity of hormonally responsive genes. Depending on the specific gene, this regulation can be positive or negative and is accomplished through a variety of mechanisms. Positive transcriptional regulation most often involves binding of a receptor homodimer to a glucocorticoid-response element (GRE) and the recruitment of transcriptional coactivators whose activities alter chromatin structure and activate the basal transcription apparatus. Negative regulation of gene expression can also involve the binding of the receptor to *cis*-acting promoter regulatory elements (negative GREs). However, negative regulation can be the result of protein–protein interactions with other transcription factors, such as activator protein-1 (AP-1), nuclear factor κB (NF-κB), and Oct-1, that can inhibit their ability to bind to DNA or to activate the basal transcription apparatus.

The GR, like all other members of the nuclear receptor family, is composed of distinct structural and functional domains. The N-terminal domain contains at least one transactivating function (AF-1) that interacts with a variety of co-regulatory and transcription factors, resulting in a complex network of communication between multiple signaling pathways. The centrally located DNA-binding domain contains two zinc-fingers. The distal knuckle of the N-terminal finger is part of an α-helix that binds in the major groove of the DNA and determines

the specificity of binding to the GRE. The C-terminal finger stabilizes the interaction of the receptor with DNA and its proximal portion participates in the formation of the receptor homodimers necessary for transcriptional activation from a canonical GRE. The C-terminally located ligand-binding domain (LBD) is composed of 11 α-helices and 4 short β-strands. In addition to forming a three-dimensional structure for selective, high-affinity binding of ligand, the LBD contains the region that binds to hsp90 as well as a transactivation function (AF-2) located in the C-terminal most α-helix that binds the p160 coactivator protein TIF (or GRIP-1). It is noteworthy that, unlike other members of the nuclear receptor superfamily and, in particular, other steroid hormone receptors, when co-crystallized with ligand and a co-activator peptide, the GR LBD is configured as a homodimer, whose formation appears to be required for efficient nuclear translocation and transcriptional transactivation.

The organization of the human GR gene is highly complex, with multiple promoters controlling transcription, and both alternative splicing and alternative use of translation initiation codons resulting in at least three physiologically relevant isoforms. GRα is a 777-amino-acid protein. It is the most abundant GR isoform and is capable of both transactivation and transrepression. The mRNA encoding GRα contains nine exons, a 5′-noncoding exon that can be derived from any of at least three promoters, and eight coding exons. The entire N-terminal domain is encoded within exon 2. The DNA-binding domain is encoded by exons 3 and 4, each of which codes for a single zinc-finger, and the ligand-binding domain is encoded by exons 5–9α. A shorter form of this protein (GR-B), presumably resulting from translation initiation at a downstream AUG in exon 2 and therefore lacking the N-terminal 26 amino acids, has also been routinely observed in immunoblots. This form of the receptor is more effective in transactivation than its full-length counterpart, but appears to be no more effective in transrepression.

Use of an alternative splice site in exon 9 results in the synthesis of the GRβ isoform, a 742-amino-acid protein whose C-terminal 15 amino acids are GRβ-specific. This isoform does not bind ligand. In addition, it appears to have dominant negative activity in some cells, and it has been proposed that an elevated ratio of the β/α isoform is responsible for the steroid resistance seen in some asthmatic patients. Alternative splicing generates two other GR isoforms, GRδ; and GRγ. GRδ is the result of failure to correctly remove intron G, resulting in the introduction of a premature stop codon. However, since the GR mRNA is subject to nonsense-mediated decay, it is unclear whether a truncated protein is actually synthesized. The GRγ isoform results from the use of an alternative splice site, leading to an additional arginine codon in the GR mRNA between exons 3 and 4 and the insertion of an arginine residue between G451 and Q452 in the interfinger region of the DNA-binding domain. GRγ proteins containing this additional residue are less potent activators of transcription than is the GRα isoform.

III. GERM-LINE MUTATIONS IN THE GR-CODING REGION

The GR is expressed in virtually all tissues and cells, and its proper function is required to support a large number of homeostatic processes. It is therefore not surprising that viable germ-line mutations in the coding region are quite rare. Nevertheless, a limited number of such mutations have been observed, most often associated with the clinical syndrome of primary cortisol resistance. This inherited disorder is characterized by inappropriately high levels of circulating cortisol, without the accompanying cushingoid body habitus that such levels would normally elicit. Mutations responsible for primary cortisol resistance have been described in the DNA-binding domain of the GR as well as at several positions in the LBD. Although the limited number of mutations makes it difficult to generalize, it appears that all such mutations result in decreased receptor transactivating activity and/or decreased affinity for ligand. It also seems probable that at least part of the variation in the clinical manifestation seen among patients with this disorder is a consequence of subtle differences in receptor phenotype associated with each specific mutation. However, with a single exception, all of the affected individuals are heterozygous. Thus, in individuals functionally hemizygous for the GR gene, there appears to be no compensatory increase in expression of the wild-type allele.

Only one mutation in the DNA-binding domain that can unambiguously be associated with primary cortisol resistance has been identified. This mutation in exon 4, R477H, results in the complete loss of transactivating activity, presumably as a result of the loss of DNA-binding activity to a canonical GRE. Mutations in the LBD responsible for primary cortisol resistance have been identified in exons 5, 7, 8, and 9α. The mutation in exon 5, I559N, results in the complete loss of ligand-binding

activity, and consequently this GR mutant lacks both transactivation and transrepression activity. Since I559 is involved in hydrophobic interactions within the LBD, and since the adjacent residue M560 has hydrophobic interactions with both the C-17 and the C-21 hydroxyl groups of the ligand, it is probable that the I559N mutation disrupts the internal structure of the LBD. This mutant also behaves as a dominant negative inhibitor of nuclear translocation of the wild-type GR. Thus, the phenotype associated with the I559N mutation is likely to reflect more than simple reduction of hormone-binding activity. However, primary cortisol resistance is observed even when a heterozygous mutation is not dominant negative. Patients with a 4 bp deletion resulting in the loss of a splice donor site at the 3′-end of exon 6 fail to express mRNA from the mutant allele, presumably as a result of the fact that GR mRNAs containing premature translation stop codons are subject to nonsense-mediated decay. Thus, simple reduction of GR expression is sufficient to cause primary cortisol resistance.

A D641V mutation in exon 7, a G679S mutation in exon 8, and V729I and I747M mutations in exon 9α are all associated with cortisol resistance. In contrast to receptors containing the I559N mutation, all of these mutants bind ligand, albeit with reduced affinity. All four mutants have substantially reduced transactivating activity but retain varying abilities to repress the activities of promoters regulated by negative GREs or which are NF-κB or AP-1 responsive. In addition, the I747M mutation, which disrupts a hydrophobic interaction of the LBD with the C-21 hydroxyl of the ligand and which fails to interact with the p160 coactivator GRIP-1, behaves as a dominant negative inhibitor of wild-type receptor transactivation.

IV. SOMATIC MUTATIONS IN THE GR-CODING REGION

The mutations responsible for primary cortisol resistance are inherited by the affected individuals. Somatic mutations in the coding region of the GR can also result in clinically important phenotypes. A single base insertion in GR exon 2 was identified in genomic DNA isolated from the pituitary adenomas of one of four patients examined. This mutation, which like the 4 bp deletion described above would probably result in nonsense-mediated decay of the mutant GR mRNA and loss of expression of the mutant allele, was not seen in DNA isolated from leukocytes obtained from the same patient, indicating that the origin of the mutation was somatic. However, since neither this nor any other mutation was identified in the tumor DNA of three other patients with such adenomas, the role of this insertion in the etiology and/or phenotype of the disease is unclear.

A missense mutation in exon 9α of the GR (L753F), originally identified in the human leukemic cell line CCRF-CEM, has also been shown to be present in archival biopsy material obtained from the patient from whom the cell line was established. This mutation results in an increased rate of ligand dissociation, consistent with the hydrophobic interaction between L753 and the C-11 carbonyl of the steroid molecule. In addition, this mutation results in substantial loss of transactivating activity as well as loss of the ability to repress the activity of NF-κB. However, repression of AP-1 activity is unaffected, reinforcing the observation that individual mutations in the GR gene can result in dissociation of various receptor functions. It is unlikely that the L753F mutation was responsible for the occurrence of the leukemia from which the CCRF-CEM cell line was established, since it was identified in only a fraction of the biopsy samples examined. Nevertheless, it is possible that the L753F mutation decreased the sensitivity of leukemic cells to glucocorticoid therapy, since even a twofold increase in GR concentration is sufficient to render otherwise steroid-resistant cells sensitive to the cytolytic activity of corticosteroids.

Using single-nucleotide polymorphisms (SNPs) in the GR-coding region (see below), loss of heterozygosity (LOH) at the GR locus has been detected in a significant fraction of corticotropinomas obtained from patients with pituitary-dependent Cushing's disease. In three of the six patients whose tumors exhibited LOH at the GR locus, at least two GR exons were undetectable, providing evidence for extensive deletion in the GR gene and presumably loss of expression of the mutated allele. Nevertheless, since more than half of the corticotropinomas examined had no apparent GR defect, the relationship between loss of GR expression and the clinical presentation of the disease is uncertain.

V. GENETIC POLYMORPHISMS

A rapidly increasing number of SNPs are being identified in the GR gene. For a current compilation of GR SNPs, the reader is referred to the National Center for Biotechnology Information SNP database at http://www.ncbi.nlm.nih.gov/SNP. Most of the

reported polymorphisms are in introns or are synonymous and therefore have no effect on the receptor protein. Nonsynonymous polymorphisms in exon 2 result in the amino acid substitutions R23K, F29L F65V, L112F, D233N, and N363S. With the exception of the N363S variant, which has been associated with a modest increase in steroid sensitivity, and for which an association with obesity in men has been proposed, none of these appears to result in a physiologically or clinically relevant phenotype. There is also a nonsynonymous polymorphism in exon 5, resulting in the substitution of lysine for asparagine at residue 517 in the portion of the GR between the nuclear localization sequence and the LBD. No alteration of receptor function has yet been associated with this polymorphism.

Among the SNPs outside of the GR-coding region, a polymorphism in the 3′-untranslated region of exon 9β that increases the stability of the GRβ mRNA has been described and was present in increased frequency in patients with rheumatoid arthritis. In addition, a *Tth* III1 restriction fragment length polymorphism (RFLP) in the GR promoter has been reported to be associated with elevated basal cortisol secretion in men. A *Bcl* I RFLP, also in a noncoding region of the GR gene, has been statistically associated with a variety of clinical phenotypes, including central obesity and dysregulation of the hypothalamic–pituitary–adrenal axis. Given the increasing pace with which SNPs and other polymorphisms are being identified and mapped in the human genome, and the level of interest in the association between such polymorphisms and human disease, it is certain that a substantial number of additional polymorphisms with clinically relevant phenotypes will be identified in the GR gene.

Glossary

genetic polymorphism A heritable genetic difference between two individuals at a specific location in the genome that is present in the general population.

germ-line mutation A heritable genetic alteration not present in the general population.

glucocorticoid receptor The intracellular receptor that mediates the response to the physiologic adrenal steroid cortisol and to pharmacologic corticosteroids, such as dexamethasone.

nonsense-mediated decay The process whereby cells degrade mRNAs containing premature stop codons to prevent the synthesis of truncated proteins.

somatic mutation An induced or spontaneous genetic alteration in a differentiated cell that is not transmitted to the next generation.

Glucocorticoid Receptor Structure and Function

DIANE DONG AND JOHN A. CIDLOWSKI

National Institute of Environmental Health Sciences, North Carolina

The glucocorticoid receptor (GR) is an intracellular protein that specifically binds glucocorticoids, steroid hormones produced primarily in the adrenal cortex and necessary for many physiological processes. The GR functions as a transcription factor by activating or repressing the transcription of target genes. It is a member of the nuclear hormone receptor family of ligand-inducible transcription factors and, like other members of this family, is a phosphoprotein. Two splicing variants of a single gene have been described, GRα and GRβ. These two isoforms are highly homologous. The GRα isoform is the primary receptor in the glucocorticoid signal transduction pathway. GRα is crucial for survival and is found in almost all human cells. The biological function of human GRβ has not yet been elucidated, but experimental results indicate that human GRβ can exert a dominant negative effect on transactivation by human GRα.

I. INTRODUCTION

Glucocorticoids are steroid hormones derived from the metabolic conversion of cholesterol in the adrenal cortex. They are required for many different physiological processes, including the development of organs, carbohydrate homeostasis, protein and fat metabolism, stress adaptation, and immune surveillance. These diverse actions have made glucocorticoids attractive for therapeutic development, and, as a class of compounds, they are among the most prescribed drugs in the world. Clinically, because of their immunosuppressive and anti-inflammatory activity, glucocorticoids are widely used in the treatment of chronic autoimmune/inflammatory and allergic diseases such as asthma, rheumatoid arthritis, inflammatory bowel disease, and skin disorders. At the cellular level, glucocorticoids exert most of their known effects by binding to an intracellular protein, termed the glucocorticoid receptor (GR), which, upon activation by glucocorticoids, activates or represses the transcription of certain target genes.

Glucocorticoid receptors belong to the nuclear receptor superfamily, members of which are ligand-inducible transcription factors that modulate transcription through binding to specific DNA sequences. This family consists of receptors with identified ligands, including receptors for small hydrophobic molecules such as steroid hormones, thyroid hormone, vitamin D, retinoic acids, and metabolites of long-chain fatty acid, as well as a number of orphan receptors, for which no endogenous ligands have been identified.

The glucocorticoid receptor was one of the first nuclear receptors cloned from mammalian cells. The human, rat, and mouse GR cDNAs were isolated in the mid-1980s. Two alternative splicing variants of a single gene have been described, GRα and GRβ, where GRα is the primary receptor in the glucocorticoid signal transduction pathway. Thus, the GRα isoform is commonly referred to as the GR. Consistent with the widespread physiological functions of glucocorticoids, GRα is distributed in almost all human cells and tissues with an expression level on the order of 3000–30,000 receptor molecules per cell. GRα is essential for survival. Transgenic mice devoid of GRα exhibit impaired lung development, reduced liver gluconeogenic enzyme expression, impaired proliferation, and elevated adrenocorticotropic hormone and corticosterone levels. The newborn mice died minutes after birth due to respiratory failure.

and function as ligand-activated transcription factors. Within this superfamily of intracellular receptors, there is a distinct subfamily consisting of the intracellular receptors for steroid hormones including glucocorticoids, mineralocorticoids, progesterone, and androgens. These related receptor proteins share some striking homologies within their DNA-binding domains and regulate the expression of specific target genes and gene networks.

The glucocorticoid receptor, which is shown schematically in Fig. 1, has three basic domains similar to the other members of this subfamily. It contains a variable and poorly conserved amino-terminal domain that is sometimes referred to as the immunogenic domain, since several monoclonal antibodies recognize epitopes located within this region of the protein. This domain is quite long (roughly the amino-terminal half of the polypeptide) and contains a strong independent transactivation domain (AF1) that is important for adding specificity to GR action. In the mouse GR protein, seven phosphorylation sites have been identified in the AF1-transactivating domain. This posttranslational modification increases the acidity of this region and by so doing may modulate the transactivation function. The GR protein also contains a highly conserved and more centrally located DNA-binding domain (DBD). Of a total of 9 cysteine residues in this domain, 8 are involved in complexing two zinc ions in tetrahedral arrangements. These "zinc-fingers" contribute to the folding of this domain as it interacts with DNA sequences and contacts specific nucleotides in the glucocorticoid-response elements (GREs). This DBD also contains a dimerization subdomain and a nuclear localization subdomain (NLS1). The carboxy-terminal ligand-binding domain comprises approximately 250 amino acids and contains a number of subdomains specifying not only the steroid-binding region, but also other functions including heat shock protein 90 (hsp90) binding, a second transactivation subdomain (AF2), a second nuclear localization subdomain (NLS2), and subdomains that interact with other transcription factors such as c-jun or c-fos and the nuclear NF-κB heterodimer. This domain seems to have a fairly complex structure, since some essential residues are quite remote from one another in the primary sequence. Alternative splicing of the primary GR gene transcript can generate a polypeptide in which the carboxy-terminal 50 amino acid residues are exchanged for an unrelated 15-amino-acid sequence originating from an alternative exon encoded by the same gene. This GR variant, which is referred to as GR-β to differentiate it from wild-type GR-α, is thus unable to bind ligand. Despite its inability to bind steroid, GR-β has been shown in transfection studies to block the transcriptional response mediated by hormone-bound GR-α. Whether endogenous GR-β levels are high enough to render a target cell glucocorticoid resistant by functioning as a dominant-negative inhibitor of GR-α is not currently known.

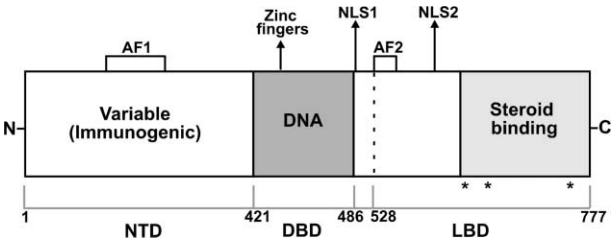

FIGURE 1 Domain structure of the human glucocorticoid receptor. Although not depicted, two dimerization domains have been identified. One dimerization domain is located in the DNA-binding domain (DBD) within the second zinc-finger; the other is located near the carboxy-terminal end of the ligand-binding domain (LBD). The location of the second nuclear localization signal (NLS2) has not been precisely mapped but does appear to involve a large portion of the carboxy-terminal domain. This suggests that NLS2 may actually be "assembled" from nonadjacent amino acid residues that are juxtaposed only after the conformational change induced by hormone binding. Binding of the hsp90 dimer requires a specific 7-amino-acid sequence at the amino-terminus of the LBD. The asterisks indicate 3 amino acid residues (604, 638, and 736) affinity-labeled by covalent binding of a glucocorticoid analogue. NTD, amino-terminal domain, AF1 (77–262) and AF2 (526–556), sequences important for transactivation of gene transcription; NLS1, nuclear localization signal 1.

To fully appreciate the molecular basis for the potential mechanisms underlying glucocorticoid resistance, it is important to understand the basic model that details the interaction of glucocorticoid hormones with their target cells found throughout the body. This model is depicted in Fig. 2 and will be briefly reviewed here. Clearly a defect or abnormality in any one of the steps depicted in this diagram could result in glucocorticoid resistance. As shown in this figure, cortisol (the primary glucocorticoid in humans) circulates in the plasma loosely bound to a transport protein called corticosteroid-binding globulin or CBG. Once delivered to the target cell, the lipid-soluble cortisol dissociates from the CBG and diffuses across the plasma membrane. Once inside the target cell, cortisol binds with high affinity and specificity to the unactivated/untransformed (non-DNA-binding form) GR protein. This unactivated

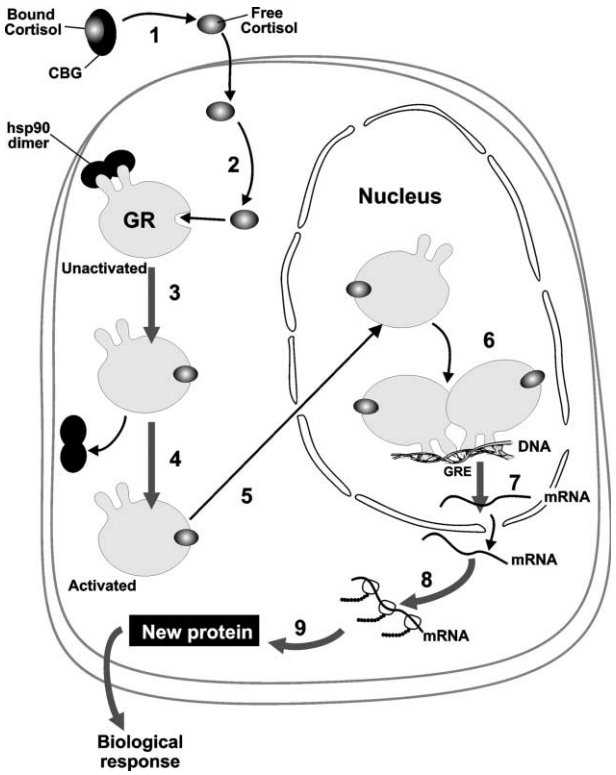

FIGURE 2 Steps involved in the interaction of cortisol with a glucocorticoid target cell. (Step 1) Cortisol molecule dissociates from its transport protein, CBG. (Step 2) After diffusing across the plasma membrane, cortisol binds to its unactivated, cytoplasmic GR with high affinity and specificity. (Step 3) Binding of cortisol to the GR induces a conformational change and dissociation of the hsp90 dimer. (Step 4) The DNA-binding domain (zinc-finger) is uncovered in the activated GR complex. (Step 5) The activated GR complex is translocated into the nucleus. (Step 6) The activated GR complex dimerizes and binds reversibly to GRE sequences. (Step 7) Gene transcription is enhanced, and mature messenger RNA species are generated. (Step 8) Translation of induced messenger RNAs occurs in the cytoplasm. (Step 9) Translated proteins mediate specific biological responses.

cytoplasmic GR is heteromeric and has a molecular weight of approximately 300 kDa because it is associated in a complex with other non-hormone-binding proteins. A dimer of the 90 kDa heat shock protein, which is induced when cells are stressed but is also expressed constitutively in nonstressed cells, is associated with the ligand-binding domain of the unactivated GR. In the properly folded GR, this hsp90 dimer occludes, or masks, the DNA-binding domain (zinc-fingers) of the receptor. Thus, in the absence of ligand, the unactivated GR is incapable of binding to DNA. In addition to blocking the DNA-binding domain, hsp90 also ensures that the 94 kDa GR protein will be in the proper conformation for subsequent ligand binding. Other non-hormone-binding proteins are also included in this heteromeric complex. For example, another heat shock protein, designated hsp56, is also located in this complex. This heat shock protein also functions as an immunophilin, since it binds a number of potent immunosuppressive drugs. The chaperone heat shock protein designated hsp70 also appears to associate with the GR and promote the assembly of this heteromeric complex. Binding of cortisol to the 94 kDa GR induces a conformational change in the protein and dissociation of the hsp90 dimer. Following this activation/transformation step and the exposure of the DNA-binding domain, the receptor translocates into the nucleus and binds to specific DNA sequences termed GREs. The GR binds as a homodimer to these GREs and either induces (increases) or represses (decreases) the rate of transcription of glucocorticoid-response genes. The induced messenger RNA molecules are then translocated into the cytoplasm and assembled into translation complexes for the synthesis of new proteins that alter the metabolism and/or function of the target cell.

The model presented in Fig. 2 is clearly an oversimplification of how activated GR complexes transactivate gene expression. For example, this model does not show how other proteins, referred to as co-activators and co-repressors, regulate the transactivational functions of the nuclear GR complexes. Binding of co-repressors to DNA appears to cause deacetylation of histones, producing condensation of chromatin and repression of transcription. Binding of activated GRs to GREs may displace such co-repressor molecules and recruit co-activator molecules. The co-activators then catalyze the acetylation of histones and decondensation of DNA. This allows for the further recruitment of other proteins required for the activation of RNA polymerase II and a subsequent increase in the rate of transcription. A family of steroid receptor co-activators has been described and these transcription-activating proteins appear to interact with these receptors through a conserved 5-amino-acid motif within the AF2 site and possibly within the AF1 site. The first functional co-activator cloned and identified was SRC-1 (steroid receptor co-activator-1). This co-activator was shown to interact with, and stimulate the activity of, both Type I receptors (estrogen, progesterone, androgen, mineralocorticoid, and glucocorticoid) and Type II receptors (thyroid hormone, Vitamin D3, retinoic acid, and orphan receptors). This molecule has been shown to be functional *in vivo*, since SRC-1 knockout mice exhibit

partial resistance to several hormones. Finally, SRC-1 has been shown to belong to a family of three co-activators that also includes TIF-2 and PCIP.

III. CLASSES OF GLUCOCORTICOID RESISTANCE SYNDROME

As summarized in Table 1, glucocorticoid resistance can be classified into four major subtypes including generalized inherited glucocorticoid resistance, pharmacologically induced glucocorticoid resistance, acquired or tissue-specific glucocorticoid resistance, and physiological resistance to glucocorticoids including genetic variations in sensitivity. It has been known for many years that within the normal population there is wide variability in the sensitivity to glucocorticoid hormones. This variability is clearly reflected in the wide range of responses to the same relative dose of exogenous glucocorticoids used in the treatment of various diseases. Published studies demonstrate that primary or hereditary abnormalities in the glucocorticoid receptor gene make 6.6% of the normal population relatively hypersensitive to glucocorticoids, whereas 2.3% are relatively resistant. This variability helps to explain why some individuals develop severe adverse effects during hormonal therapy with a low dose of glucocorticoids, yet others do not develop side effects even during long-term therapy with a much higher dose of glucocorticoids.

In the primary or hereditary abnormalities just mentioned, mutations in the GR gene have been shown to make individuals resistant or hypersensitive to the feedback effects of synthetic glucocorticoids such as dexamethasone. These mutations result in elevated (glucocorticoid resistance) or lowered (glucocorticoid hypersensitivity) circulating cortisol levels. These altered cortisol levels usually do not result in any specific signs or symptoms because they represent an adaptation or resetting of the hypothalamic–pituitary–adrenal axis at a higher (resistance) or lower (hypersensitivity) level in order to overcome the function of abnormal GRs in the target tissues. The symptoms associated with glucocorticoid resistance are the consequence of overstimulation of

TABLE 1 Classification of Human Glucocorticoid Resistance Syndromes

Type of resistance	Underlying mechanism
I. Generalized inherited (familial) glucocorticoid resistance (GIGR)	Mutations in GR gene
II. Pharmacologically induced glucocorticoid resistance	
A. Administration of GR antagonist RU486	Blocks ligand binding to GR protein and activates HPA by preventing negative feedback mediated by glucocorticoids
B. Treatment of leukemic cell line with chemotherapeutic drugs	Deletion of GR gene
C. Treatment of leukemic cell line with chemical mutagens	Deletion of GR gene
III. Acquired glucocorticoid resistance	
A. Neoplastic	
1. Ectopic ACTH syndrome	Decreased GR number, truncated GR, aberrant splicing and mutation of GR
2. Pituitary tumors (Nelson's syndrome)	Mutation of GR
3. Hematological malignancies	Mutations and aberrant splicing of GR
B. Transient	
1. Depression	Decreased number of GR
2. AIDS	Increased number of GR and reduced ligand affinity
3. Steroid-resistant asthma, rheumatoid arthritis, systemic lupus erythematosus	Number of GR abnormalities reported
IV. Physiological resistance to glucocorticoids and variations in sensitivity	
A. Receptor down-regulation	Glucocorticoids decrease rate of transcription of GR gene and decrease sensitivity
B. Distal nephron of kidney	11β-Hydroxysteroid dehydrogenase catalyzes conversion of cortisol to cortisone, which is an inactive glucocorticoid
C. Individual differences in glucocorticoid sensitivity	Genetic variation in control of cortisol secretion, regulation of HPA axis, and GR expression

Reprinted from *Steroids* **61**, S. Werner and M. Bronnegard, Molecular basis of glucocorticoid-resistant syndromes, pp. 216–221, copyright 1996, with permission from Elsevier Science.

the synthesis and secretion of ACTH by the anterior pituitary gland. Elevated ACTH secretion in turn stimulates increased production of adrenocortical androgens, which can cause acne and hirsutism, and mineralocorticoids, which can cause hypokalemia and hypertension. Several different GR abnormalities have been reported for primary glucocorticoid resistance. Missense mutations in the ligand-binding domain of the GR resulting in a decrease in ligand-binding affinity have been reported in two different families. A deletion of 4 bp in the intron close to exon 6 of the GR has been shown to result in a splice site deletion. This deletion results in the expression of only one allele and a 50% decrease in the GR protein level in the affected members of another family. Finally, a third GR gene mutation in the proximal region of the ligand-binding domain (in exon 5) has been shown to result in a functional loss of the mutant GR protein in other patients.

IV. GLUCOCORTICOID RESISTANCE IN DISEASES AND SPECIFIC PHYSIOLOGICAL STATES

As already mentioned, two major forms of glucocorticoid resistance include generalized inherited glucocorticoid resistance, in which all tissues are partially glucocorticoid resistant, and local (tissue-specific) or acquired glucocorticoid resistance, in which only the affected tissues are resistant to glucocorticoids. Generalized glucocorticoid resistance, in which most patients appear to be basically asymptomatic despite elevated cortisol levels, has been reported in some families. In this situation, the high cortisol levels are due to the glucocorticoid resistance of the anterior pituitary gland to cortisol-mediated negative feedback, leading to an elevation of ACTH levels. In patients with generalized glucocorticoid resistance, the elevated cortisol level exists without the signs and symptoms of hypercortisolism detected in Cushing's syndrome, where the patient is glucocorticoid sensitive. Clearly, complete or absolute glucocorticoid resistance would not be compatible with life, and therefore patients with generalized glucocorticoid resistance do develop some signs of Cushing's syndrome. As mentioned previously, an aberrant GR gene appears to be the cause of this syndrome.

What about glucocorticoid resistance that occurs in a tissue-specific manner? Nelson's syndrome is caused by an aggressive fast-growing ACTH-producing tumor that is highly resistant to inhibition by synthetic glucocorticoids. This syndrome occurs in approximately 10–30% of Cushing's patients who have had both of their adrenal glands removed. Nelson's syndrome in one patient has been shown to be associated with a heterozygous frameshift mutation in the GR gene. This frameshift results in premature termination of translation and low levels of the GR protein, which accounted for the decreased glucocorticoid sensitivity of the tumor. This specific mutation was not detected in the GR gene obtained from the patient's leukocyte DNA, demonstrating that it was of somatic origin.

In addition to GR defects resulting from GR gene mutations, glucocorticoid resistance is actually very dynamic and can vary in relation to a variety of physiological situations. For example, following physical exercise, a decreased ability of dexamethasone to inhibit interleukin-6 production by leukocytes has been reported. However, the precise mechanism underlying this acute glucocorticoid resistance is not known. More prolonged acquired glucocorticoid resistance may also play an important role in the origin of several diseases. For example, in rheumatoid arthritis and systemic lupus erythematosus, a decreased number of systemic lymphocyte GRs have been reported. In systemic lupus erythematosus, this decreased number of lymphocyte GRs was correlated with poor response to glucocorticoid therapy and, importantly, with a poor prognosis. Asthma is another interesting example of a disease in which a small percentage of patients are insensitive to glucocorticoid treatment. Studies indicate that steroid-resistant asthma is associated with a failure of glucocorticoids to inhibit the *in vitro* proliferation and cytokine secretion from T-lymphocytes obtained from these patients. In these resistant patients, both a reduced ligand-binding affinity of the GR and a reduced binding of the ligand–GR complex to specific DNA sequences (GREs) on the genome have been reported. This resistance to glucocorticoids could affect the immune system in two distinct ways. First, it could directly result in reduced control of inflammatory processes. Second, it could also result in altered cytokine patterns. Resistance to glucocorticoid treatment would probably slow the recovery of the patient in both of these situations.

Acquired glucocorticoid resistance can be induced by a number of mechanisms. Published data suggest that cytokines released during immune activation can actually alter the characteristics of the GR. For example, interleukin-1 alters GR function in cultured hepatoma cells, as evidenced by a decrease in GR-binding levels. Data such as these suggest that during acute inflammation, cytokines may alter metabolic

pathways in the liver by interfering with glucocorticoid action. A combination of interleukin-2 and interleukin-4 *in vitro* renders lymphocytes relatively resistant to dexamethasone-mediated inhibition and lowers the GR-binding affinity for ligand. Therefore, during any prolonged immune activation resulting in elevated concentrations of local or circulating cytokines, glucocorticoid resistance in other tissues and cell types could very well be induced.

Several specific cell types are rendered relatively resistant to endogenous glucocorticoids as a consequence of their metabolism in that tissue. Cells such as those lining the renal cortical collecting duct are targets for mineralocorticoids such as aldosterone and hence express intracellular mineralocorticoid receptors (MRs). These MRs share structural homologies with the GRs, especially when one compares the DNA- and ligand-binding domains. The endogenous glucocorticoid in humans, which is cortisol, actually binds to the MR with the same relative affinity as aldosterone. However, the normal circulating cortisol level is approximately 100-fold higher than the circulating aldosterone level. Despite this situation, these cells actually respond to aldosterone because they express an enzyme, Type II 11-β-hydroxysteroid dehydrogenase, which catalyzes the metabolism of cortisol to inactive cortisone. Since cortisone fails to bind to the MR, this mineralocorticoid receptor can now respond to the much lower circulating levels of aldosterone. This metabolism of cortisol to cortisone thus renders these mineralocorticoid target tissues less responsive, or partially resistant, to cortisol. It is important to note that this generated cortisone is then transported to the liver, where it can be converted back into active cortisol via the activity of Type I 11-β-hydroxysteroid dehydrogenase.

The possibility that glucocorticoid resistance may be associated with obesity has also received considerable attention. For several years, it was speculated that defects in hypothalamic–pituitary–adrenal (HPA) axis function might result in changes in energy metabolism, which could contribute to changes in total body fat. Altered HPA axis activity in obesity has in fact been reported, but the precise effect of this alteration on circulating cortisol levels was unclear. Deficiencies in GR feedback regulation in obesity were proposed based on resistance to administered dexamethasone, a potent glucocorticoid agonist. Recent studies have focused on the mechanism(s) underlying this resistance to glucocorticoid feedback in obesity. Obese subjects were found to have significantly higher basal ACTH levels but lower cortisol levels, suggesting that their adrenal glands are relatively insensitive to ACTH. When physiological doses of hydrocortisone (the same as cortisol) were infused into obese individuals, basal ACTH levels were decreased during the day, but not during the night as they were in control subjects. These data thus showed that obesity is associated with a relative insensitivity to glucocorticoid feedback and that this defect is most pronounced at night. The relatively low doses of hydrocortisone that were administered to these obese individuals would partially saturate their brain MRs and not GRs, since cortisol binds to MRs with an affinity that is 10-fold higher than its affinity for GRs. Thus, it was concluded that this insensitivity to glucocorticoids results from defects in the MR, rather than in the GR. This conclusion is consistent with the facts that MRs are expressed at high concentrations in the hippocampus and that this region of the brain has been strongly implicated in the negative feedback control of the HPA axis. Thus, this tissue-specific glucocorticoid resistance associated with obesity does not appear to be a consequence of GR defects like those reported in other types of glucocorticoid resistance.

V. GLUCOCORTICOID RESISTANCE IN HEMATOLOGIC MALIGNANCIES

The ability of glucocorticoids to inhibit the growth of, and subsequently lyse, immature lymphoid cells provides the rationale for their therapeutic utilization in the treatment of various human leukemias, lymphomas, and multiple myelomas. However, prolonged treatment with glucocorticoids often results in the emergence of resistant clones. Understanding the mechanism(s) underlying this resistance has been aided by the availability of a number of glucocorticoid-sensitive human cell lines. Analysis of numerous glucocorticoid-resistant clones isolated from these sensitive cell lines has revealed that mutations in the human GR gene are the principal cause of steroid resistance *in vitro*. Analysis of glucocorticoid resistance in the human leukemic CEM-C7 cell line suggests that these leukemic cells escape the cytolytic effects of glucocorticoids by mutating their GR genes at functionally important sites. Data demonstrate that the wild-type, glucocorticoid-sensitive CEM-C7 cells express two alleles of GR, the normal GR and an abnormal GR, which has a $Leu^{753} \rightarrow Phe^{753}$ mutation in the ligand-binding domain. In a spontaneously arising glucocorticoid-resistant clone, only this abnormal GR is expressed, and the normal GR gene is deleted. This abnormal GR has been

characterized as an "activation-labile" receptor. Although this mutated GR binds dexamethasone with the same relative affinity as the wild-type GR, activation or transformation of this dexamethasone–receptor complex to a DNA-binding form results in the dissociation of ligand (hence, the designation as activation-labile) and loss of transactivation capacity. Clearly, mechanisms other than mutations in the GR gene can contribute to *in vitro* glucocorticoid resistance in this human leukemic cell line. For instance, an endogenous modulator molecule appears to inhibit both nuclear translocation of the GR and glucocorticoid-induced apoptosis in this human leukemic cell line. Treatment of this sensitive CEM-C7 clone with glucocorticoid hormones also results in suppression of c-Myc and this response may play a key role in the hormone-induced apoptosis of these cells. This conclusion is demonstrated by the fact that sustained expression of c-Myc blocks glucocorticoid-induced apoptosis and antisense c-Myc oligomers induce cell lysis. These data are thus consistent with the theory that the lytic effects of glucocorticoids in CEM-C7 cells may involve reduction of c-Myc below the minimum levels required to maintain normal growth and viability. In multiple myeloma, it has been shown that aberrant GRs with deletions in their hormone-binding domains are generated by alternative splicing and that these abnormal GRs may contribute to glucocorticoid resistance in this hematological cancer. Whether these same mechanisms also occur *in vivo* during the development of glucocorticoid resistance in leukemias and multiple myeloma, and at what frequency, is not known. However, it is interesting to note that receptor-negative cell lines with GR gene deletions have been detected after exposure of CEM-C7 leukemic cells to chemical mutagens and cancer chemotherapeutic drugs. In contrast, spontaneously arising resistant cells are predominantly receptor positive but activation labile, suggesting that spontaneous and induced mutations may occur at different loci in human leukemic cells.

An association between a *Bcl*I restriction fragment length polymorphism in the human GR gene and hyperinsulinemia in obese women suggests that mutations in the GR gene may cause alterations in the regulation of the hypothalamic–pituitary axis and in target tissue sensitivity to glucocorticoid hormones. It has been reported that obese individuals have decreased glucocorticoid sensitivity in their adipose tissue and a decreased central sensitivity to glucocorticoids with a blunted negative feedback mechanism. In CEM-C7 glucocorticoid-sensitive leukemic cells, this polymorphic *Bcl*I fragment has actually been shown to contain a sequence from exon 2, which is deleted from glucocorticoid-resistant CEM clones.

VI. GLUCOCORTICOID RESISTANCE IN HUMAN IMMUNODEFICIENCY VIRUS INFECTION

A major question concerning the clinical manifestations of human immunodeficiency virus (HIV) infection is that some of the symptoms and signs seen in the earlier stages of this disease cannot be easily explained by the relatively small proportion of infected $CD4^+$ T-lymphoid cells. One possible explanation for this observation is that there may be altered responses to hormones and hormone-like substances in HIV-infected cells. Several neuroendocrine orders have been described in HIV-infected individuals, and these include alterations in the hypothalamic–pituitary–adrenal axis. Several studies of adrenal function in HIV-infected patients have revealed high circulating levels of cortisol, as well as ACTH, and it has been speculated that this hypercortisolism may be associated with the immunodysfunction, neurological deterioration, and weight loss often seen in patients with acquired immunodeficiency syndrome (AIDS). It is well known that the physiological effects of glucocorticoid hormones include catabolic responses like those just mentioned. However, when a group of AIDS patients with high serum and urinary cortisol levels were studied, they exhibited a number of symptoms and signs associated with adrenal insufficiency, rather than hypercortisolism. Thus, the clinical picture associated with AIDS appears to be consistent with peripheral resistance to cortisol. The possibility that a GR abnormality is responsible for this glucocorticoid resistance was therefore investigated. Since the ability of glucocorticoid hormones to induce apoptosis of T-lymphocytes is well documented, and since HIV infection has also been reported to induce this programmed cell death, it was speculated that the hormone and virus might synergize to cause even greater cell death. However, when this hypothesis was directly tested in human CEM cells, an HIV-sensitive $CD4^+$ cell line, antagonism between HIV infection and glucocorticoids was actually detected. *In vitro* chronically infected CEM cells thus appear to be resistant to glucocorticoid-induced cell lysis. These infected CEM cells exhibit reduced numbers of GR-binding sites with little or no change in the affinity between the glucocorticoid hormone and its receptor. Of course, the obvious question to ask was whether

this same GR abnormality is detected in the $CD4^+$ lymphocytes from HIV-infected patients. A published study of GR in HIV-infected homosexual men reported changes in the dissociation constant of the GR in these individuals. In more than half of the patients studied, the GR–ligand affinity was reduced. In another clinical study, GRs were analyzed in intravenous drug users with AIDS. These patients exhibited hypercortisolism and the clinical features associated with peripheral resistance to glucocorticoids. Again, the GRs expressed in the lymphocytes from these patients were not reduced in number (they actually increased in number based on binding of [^{3}H]dexamethasone), but did show a significantly reduced affinity for ligand. This reduction in GR-binding affinity was reflected by the fact that these lymphocytes were less sensitive to dexamethasone-induced inhibition of thymidine incorporation than lymphocytes from control subjects. Thus, the mechanisms underlying *in vitro* versus *in vivo* glucocorticoid resistance in HIV-infected cells may differ somewhat. Clearly, the elevated cortisol levels detected in HIV-infected individuals may have serious consequences. For example, if the HIV-infected $CD4^+$ T-cells in these patients are less sensitive to the lytic effects of cortisol than the uninfected T-cells, then the infected T-cells may survive longer in the presence of elevated cortisol. This theoretically would allow the HIV^+ cells to preferentially expand and hasten the onset of acquired immunodeficiency syndrome.

VII. HUMAN MULTIPLE HORMONE RESISTANCE SYNDROME

Several years ago, the first report of human multiple steroid-resistance syndrome was published. A 14-year-old Native American girl presented with the syndrome of apparent mineralocorticoid excess. However, further evaluation revealed that she was resistant to glucocorticoids, mineralocorticoids, and androgens, but not to Vitamin D or thyroid hormones. Despite the fact that her circulating cortisol level was high, she did not exhibit any Cushingoid features such as obesity (primarily in the trunk), buffalo hump, moon face, or bruising. Her menstruation was regular, and there was no clinical evidence of masculinization (acne, hirsutism, enlargement of clitoris), despite the fact that her serum androgen levels were very high. This patient's younger sister showed similar clinical features. Both girls were partially resistant to exogenous glucocorticoids and mineralocorticoids.

Obviously, the mechanism(s) underlying this resistance to multiple steroid hormones could have been caused by defects at various points in the cascade of hormone–receptor DNA interactions. Mutations resulting in reduced expression of receptor proteins, reduced ligand-binding affinity of receptors, decreased nuclear translocation of activated steroid–receptor complexes, or reduced transactivating capability of nuclear receptor complexes could potentially explain this resistance. However, since each individual steroid hormone receptor is encoded by a different gene on a separate chromosome, it seemed very unlikely that simultaneous genetic mutations of each of these steroid receptors was the cause of this multiple hormone resistance in these two sisters. In fact, the involvement of several receptor pathways suggested a shared defect involving multiple steroid receptors. Therefore, a co-activator defect was deemed to be the most likely mechanism underlying this partial multiple hormone resistance. Although deletion analysis of several co-activators was performed, no deletions or major rearrangements were detected. However, since deletion analysis detects only large gene arrangements, other defects in these steroid receptor co-activators could not be totally ruled out. It was thus concluded that these two patients might represent the first cases of partial resistance to multiple steroids due to a co-activator defect. The phenotypic features of knockout mice lacking SRC-1 are apparently very similar to those reported in these two patients. The partial multiple hormone resistance reported in these sisters resembles the multiple hormone resistance syndrome that has been well described in New World primates.

VIII. GLUCOCORTICOID RESISTANCE IN OTHER SPECIES

Although resistance to cortisol as a clinical syndrome in humans is fairly uncommon, this resistance is characteristic of several species, including New World monkeys, guinea pigs, and the prairie vole. By thoroughly analyzing the GRs in these species in which physiological anomalies exist in glucocorticoid-regulated responses, it has been possible to increase our understanding of how the different GR domains function to mediate a hormonal response. In both the New World primates and the guinea pig, which is a New World hystricomorph rodent, the circulating levels of endogenous glucocorticoids (cortisol) are high. Both species express GRs with a significantly lower affinity for ligand than the human GR.

Although the nucleotide sequences of the GR genes in these species are similar to those of the human gene, several amino acid substitutions in the GR proteins from these species have been reported. These amino acid substitutions, located primarily in the ligand-binding domains of these GR proteins, are the basis for the cortisol resistance observed *in vivo* in these species.

Analysis of the guinea pig GR ligand-binding domain has revealed that in the region reported to mediate association with a dimer of hsp90, there are 11 changes at residues that are completely conserved in the human, rat, and mouse GRs. The most important of these substitutions is a tryptophan at position 632 within this domain. The equivalent position in the human, rat, and mouse GRs has a conserved cysteine. This specific cysteine residue has been shown to be one of three sites of covalent attachment of the synthetic ligand, dexamethasone 21-mesylate, and therefore is most likely very important for steroid binding. In fact, mutation of this tryptophan to a cysteine in the ligand-binding domain of the guinea pig GR increases the sensitivity to dexamethasone by an order of magnitude. Another critical region involved in ligand binding and the interaction of hsp90 lies between residues 550 and 626 of the ligand-binding domain. The guinea pig sequence differs from the human GR by seven amino acids within this region. These substitutions may provide additional evidence for the molecular basis of glucocorticoid resistance in this species. In summary, in comparing the ligand-binding domain of the guinea pig GR with that of the human GR sequence, 10 of the 24 nucleotide differences result in amino acid substitutions. Finally, two additional amino acid substitutions, Pro112 and Asn140, for serine residues in the N-terminal domain of the guinea pig GR may also underlie this glucocorticoid resistance. These serine residues have been shown to be important phosphorylation sites, and their elimination may affect (decrease) transactivation by agonist-GR complexes. The marmoset (*Saguinus oedipus*), a tropical New World monkey, also exhibits high circulating levels of endogenous glucocorticoids and an altered GR ligand-binding domain when compared with the human GR. The marmoset GR is also one amino acid longer than the human GR, and this results from the insertion of a codon for arginine (Arg452) in the interfinger region of the DNA-binding domain. This amino acid insertion influences the affinity of the receptor for GREs and could potentially contribute to the end-organ resistance phenotype. The majority of amino acid substitutions in the marmoset GR are located within the amino-terminus of the receptor.

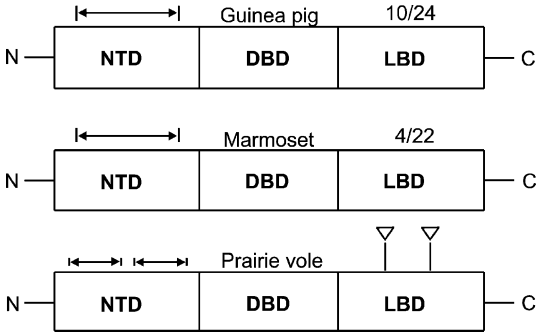

FIGURE 3 Glucocorticoid receptor mutations in New World species clustering within specific regions of the receptor gene. Arrows and ▽ indicate positions of amino acid variations compared with the human receptor. The numbers of nucleotide substitutions in the ligand-binding domain resulting in codon differences that change the primary amino sequence are indicated. NTD, amino-terminal domain, DBD, DNA-binding domain, LBD, ligand-binding domain. Reprinted from *Steroids*, **61**, S. Werner and M. Bronnegard, Molecular basis of glucocorticoid-resistant syndromes, pp. 216–221. Copyright 1996, with permission from Elsevier Science.

More precisely, they are located within subdomains critical for binding to glucocorticoid-response elements and transactivation. These substitutions may well affect the capacity of the GR to regulate gene transcription. Of the 22 nucleotide substitutions in the marmoset GR ligand-binding domain, only 4 result in amino acid substitutions. Two of these amino acid substitutions are located within the site (amino acids 532–697) that has been shown to be crucial for association of the human GR with hsp90.

The prairie vole (*Microtus ochrogaster*), a New World rodent, is also very resistant to glucocorticoids. Although plasma corticosterone levels are very high in this species, these animals do not exhibit the signs of hypercortisolism and thus are a novel rodent model for tissue resistance to glucocorticoids. As seen in Fig. 3, the vole GR contains several nonconservative amino acid substitutions in the N-terminal domain and two in the ligand-binding domain. These substitutions clearly have the potential to alter ligand-binding affinity as well as transactivation of gene expression. Binding assays have in fact revealed a significantly lowered dexamethasone affinity for brain and liver GRs in the prairie vole compared with rat GRs in the same tissues.

IX. SUMMARY

Resistance to glucocorticoid hormones, such as cortisol, occurs when these adrenal steroids are

unable to mediate their full physiological effects on specific target tissues and cells. Expression of this phenotype has numerous consequences, since endogenous glucocorticoids regulate important metabolic pathways and exogenous glucocorticoids are used therapeutically to treat a wide range of nonmalignant as well as malignant diseases. This resistant phenotype may be inherited, as is the case with generalized glucocorticoid resistance. This type of resistance is characterized clinically by elevated ACTH and cortisol levels, both of which occur because glucocorticoids are unable to exert their normal negative feedback at the level of the hypothalamus and anterior pituitary gland. Because of the generalized nature of this form of glucocorticoid resistance, the clinical signs and symptoms normally associated with Cushing's syndrome are not detected. Alternatively, glucocorticoid resistance may be acquired or, in some situations, pharmacologically induced. In some situations, such as steroid-resistant asthma and rheumatoid arthritis, the clinical symptoms are transient and tissue-specific. Most of these forms of resistance are the result of specific defects in the intracellular GR that mediate glucocorticoid responses within a target cell. However, it has been speculated that the glucocorticoid resistance that occurs as part of the human multiple hormone resistance syndrome may result from a defective co-activator molecule (transcriptional-activating protein) that is shared by multiple steroid receptor pathways. Finally, although resistance to glucocorticoids is fairly rare in humans, partial resistance to these hormones is characteristic of several species, including New World monkeys and rodents. Analysis of the specific GR defects in these species has shed light on how the different domains of this protein function to mediate a glucocorticoid response.

Glossary

generalized inherited (familial) glucocorticoid resistance A rare inherited syndrome characterized by elevated plasma cortisol levels but lacking the symptoms characteristic of Cushing's syndrome because of general target tissue resistance to glucocorticoids.

glucocorticoid receptor The intracellular receptor protein that binds glucocorticoid hormones, such as cortisol, with high affinity and specificity and subsequently functions as a ligand-activated transcription factor in glucocorticoid target cells.

glucocorticoid-response elements Specific DNA sequences (15 nucleotides) that are located in proximity to hormone-responsive gene promoters and reversibly bind activated glucocorticoid receptor complexes.

multiple hormone resistance syndrome This rare syndrome characterized by partial resistance to several steroid hormones including glucocorticoids, mineralocorticoids, and androgens may be caused by a defect in a co-activator molecule that is shared by multiple steroid receptor pathways.

receptor domains The three major functional regions of the glucocorticoid receptor include the N-terminal, or variable, domain that contains the epitopes recognized by several monoclonal antibodies; the central DNA-binding domain containing two zinc-fingers required for binding to DNA; and the carboxy-terminal ligand-binding domain that is involved in steroid binding.

Glucocorticoids and Asthma

PETER J. BARNES
Imperial College, London

Glucocorticoids (GCs), or corticosteroids, are by far the most effective therapy currently available for the management of asthma, and clinical improvement with GC is one of the hallmarks of asthma. Inhaled GCs have revolutionized asthma treatment and have become the mainstay of therapy for patients with persistent disease. We now have a much better understanding of the molecular mechanisms whereby GCs suppress inflammation in asthma and why they may be ineffective in rare patients who are steroid resistant. There is now a much better understanding of how to use inhaled GCs in asthma treatment and of the safety of these drugs in the long-term management of adults and children with asthma. Systemic GCs are used to treat exacerbations of asthma, but their use in chronic management has been superceded by that of inhaled GCs in all but the most severe cases of asthma.

I. MOLECULAR MECHANISMS

Glucocorticoids (GCs) constitute a highly effective anti-inflammatory therapy in asthma and the molecular mechanisms involved in the suppression of airway inflammation in asthma are now better understood. GCs are extremely effective in asthma because they block many of the inflammatory pathways that are abnormally activated in asthma and they have a wide spectrum of anti-inflammatory actions.

A. Glucocorticoid Receptors

GCs bind to members of a single class of glucocorticoid receptor (GR) that are localized in the cytoplasm of target cells. GCs bind at the C-terminal end of the receptor, whereas the N-terminal end of the receptor is involved in gene transcription. Between these domains is the DNA-binding domain, which has two finger-like projections formed by a zinc molecule bound to four cysteine residues that bind to the DNA double helix. The inactive GR is bound to a protein complex that includes two molecules of the 90 kDa heat shock protein (hsp90) and various other proteins that act as "molecular chaperones," preventing the unoccupied GR from moving into the nuclear compartment. Once a GC binds to a GR, conformational changes in the receptor structure result in the dissociation of these chaperone molecules, thereby exposing nuclear localization signals on the GR, resulting in rapid nuclear localization of the activated GR–GC complex and its binding to DNA (Fig. 1). Two GR molecules bind to DNA as a dimer, resulting in changed transcription. A splice variant of the GR, termed GR-β, that does not bind to GCs but does bind to DNA and that may theoretically interfere with the action of GCs has been identified.

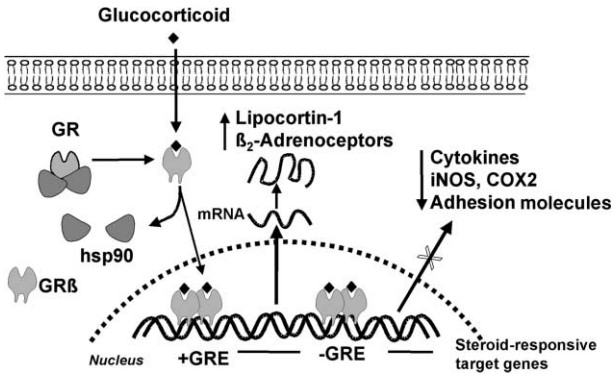

FIGURE 1 Classical model of corticosteroid action. GCs enter the cell and bind to cytoplasmic GRs that are complexed with two molecules of hsp90. GR translocates to the nucleus, where, as a dimer, it binds to a GRE on the 5′-upstream promoter sequence of steroid-responsive genes. GREs increase transcription, whereas negative GREs may decrease transcription, resulting in increased or decreased mRNA and protein synthesis. An isoform of GR, GR-β, binds to DNA but is not activated by GCs.

B. Increased Gene Transcription

GCs produce their effect on responsive cells by activating GRs to directly or indirectly regulate the transcription of certain target genes. The number of genes per cell directly regulated by GCs is estimated to be between 10 and 100, but many genes are indirectly regulated through an interaction with other transcription factors. GR dimers bind to DNA at consensus sites termed glucocorticoid-response elements (GREs) in the 5′-upstream promoter region of steroid-responsive genes. This interaction changes the rate of transcription, resulting in either induction or repression of the gene. Interaction of the activated GR homodimer with the GRE usually increases transcription, resulting in increased protein synthesis. GR may increase transcription by interacting with a large co-activator molecule, CREB (cyclic AMP response element binding protein) binding protein (CBP), which is bound at the start site of transcription and switches on RNA polymerase, resulting in the formation of messenger RNA (mRNA) and the subsequent synthesis of protein. Binding of activated GR to CBP results in increased acetylation of core histones around which DNA is wound within the chromosomal structure. This results in the binding and activation of RNA polymerase, which then results in mRNA formation.

C. Decreased Gene Transcription

In controlling inflammation, the major effect of GCs is to inhibit the synthesis of inflammatory proteins, such as cytokines. This was originally believed to occur through the interaction of GRs with negative GREs, resulting in repression of transcription. However, negative GREs have rarely been demonstrated. GRs may also affect the synthesis of some proteins by reducing the stability of mRNA, through effects on ribonucleases that break down mRNA.

D. Interaction with Transcription Factors

Activated GRs may bind directly with several other activated transcription factors as a protein–protein interaction. Most of the inflammatory genes that are activated in asthma do not appear to have GREs in their promoter regions yet are repressed by GCs. GCs inhibit the effects of transcription factors that regulate the expression of genes that code for inflammatory proteins, such as cytokines, inflammatory enzymes, adhesion molecules, and inflammatory receptors. These "inflammatory" transcription factors include activator protein-1 (AP-1) and nuclear factor-κB (NF-κB), which may regulate many of the inflammatory genes that are switched on in asthmatic airways.

E. Effects on Chromatin Structure

There is increasing evidence that GCs may have effects on the structure of chromatin. DNA in chromosomes is wound around histone molecules in the form of nucleosomes. Several transcription factors interact with large co-activator molecules, such as CBP, that bind to the basal transcription factor apparatus. Several transcription factors bind directly to CBP, including AP-1, NF-κB, and GR. At the microscopic level, chromatin may become dense or opaque due to the winding or unwinding of DNA around the histone core. CBP has histone acetylation activity, which is activated by the binding of transcription factors, such as AP-1 and NF-κB. Acetylation of histone residues results in the unwinding of DNA coiled around the histone core, thus opening up the chromatin structure, which allows transcription factors to bind more readily, thereby increasing transcription. Repression of genes follows the reversal of this process by histone deacetylation. Deacetylation of histone increases the winding of DNA around histone residues, resulting in a dense chromatin structure and reduced access of transcription factors to their binding sites, thereby leading to repressed transcription of inflammatory genes. Activated GRs may bind to several transcription co-repressor molecules that associate with histone deacetylases (HDACs), leading to repression of inflammatory genes. In addition, activated GRs recruit HDACs to the transcription start site, resulting in deacetylation of histones and a further decrease in inflammatory gene transcription.

F. Target Genes in Inflammation Control

GCs may control inflammation by inhibiting many aspects of the inflammatory process in asthma; this is achieved by increasing the transcription of anti-inflammatory genes and decreasing the transcription of inflammatory genes (Table 1).

Anti-inflammatory proteins that are increased by corticosteroids include lipocortin-1, interleukin-1 (IL-1) receptor antagonist, IL-10, and secretory leukoprotease inhibitor. In addition, corticosteroids increase the expression of β_2-adrenoceptors and this may prevent the down-regulation of these receptors that may occur with regular dosing with β_2-agonist bronchodilators.

TABLE 1 Effect of GCs on Gene Transcription

Increased transcription
Lipocortin-1 (phospholipase A_2 inhibitor)
β_2-Adrenoceptor
Secretory leukoprotease inhibitor
Clara cell protein (CC10, phospholipase A_2 inhibitor)
IL-1 receptor antagonist
IL-1R2 (decoy receptor)
IκB-α (inhibitor of NF-κB)
Decreased transcription
Cytokines
(IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-9, IL-11, IL-12, IL-13, IL-16, IL-17, IL-18, TNF-α, GM-CSF, SCF)
Chemokines
(IL-8, RANTES, MIP-1α, MCP-1, MCP-3, MCP-4, eotaxins)
Inducible nitric oxide synthase
Inducible cyclo-oxygenase (COX-2)
Cytoplasmic phospholipase A_2
Endothelin-1
NK_1 receptors, NK_2 receptors
Bradykinin B_1 and B_2 receptors
Adhesion molecules (ICAM-1, E-selectin)

Corticosteroids inhibit all of the inflammatory genes that are abnormally expressed in asthmatic airways, including cytokines, chemokines, adhesion molecules, inflammatory enzymes, and receptors for inflammatory mediators.

G. Effects on Cell Function

GCs may have direct inhibitory actions on several inflammatory cells and structural cells that are implicated in asthma, including macrophages, eosinophils, T-lymphocytes, and dendritic cells (Fig. 2). Corticosteroids reduce the number of mast cells in the airway mucosa and this may account for the marked inhibitory effects of corticosteroids on allergen- and exercise-induced asthma. A striking effect of corticosteroid therapy is a reduction in the number of eosinophils in the airways, due to (1) an inhibitory effect on the release of eosinophil chemotactic chemokines, such as eotaxin, (2) inhibition of eosinophil differentiation resulting from a reduction in IL-5, and (3) a direct increase in apoptosis.

It is now apparent that corticosteroids also have an important inhibitory effect on the expression of inflammatory genes by structural cells of the airway, such as epithelial, endothelial, and airway smooth muscle cells, which may be the major source of inflammatory mediators in chronic asthma. Of particular importance for inhaled corticosteroids are airway epithelial cells, which are exposed to the highest concentration of steroids. Corticosteroids also suppress mucus hypersecretion, which is another characteristic of asthmatic inflammation.

II. EFFECTS ON AIRWAY INFLAMMATION

GCs are remarkably effective at suppressing inflammation in asthmatic airways. Biopsy studies in patients with asthma show that inhaled GCs reduce the number and activation of inflammatory cells in the airway mucosa and in bronchoalveolar lavage. The disrupted epithelium is restored and the ciliated cell to goblet cell ratio is normalized after 3 months of therapy with inhaled GCs.

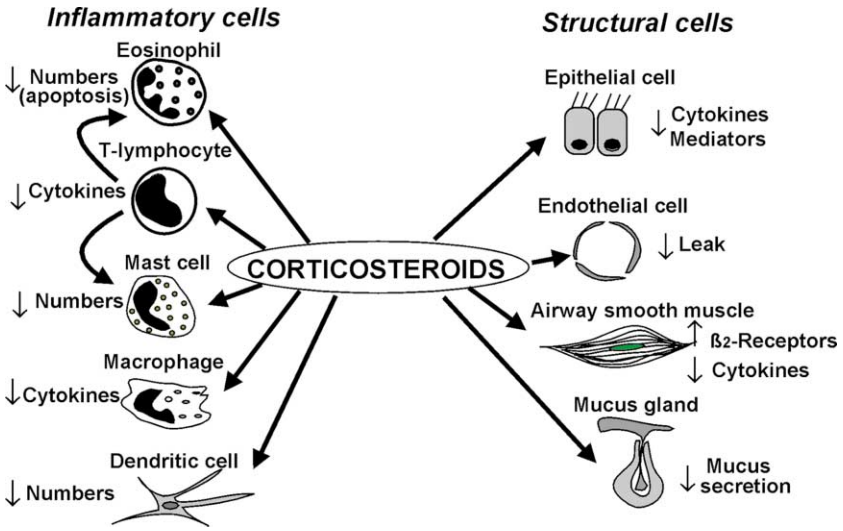

FIGURE 2 Cellular effect of GCs.

By reducing airway inflammation, inhaled GCs consistently reduce airway hyperresponsiveness (AHR) in asthmatic adults and children. Chronic treatment with inhaled GCs reduces responsiveness to histamine, cholinergic agonists, allergen (early and late responses), exercise, fog, cold air, bradykinin, adenosine, and irritants (such as sulfur dioxide). The reduction in AHR takes place over several weeks and may not be maximal until several months of therapy have been completed. In many patients, AHR does not return to normal and this may reflect suppression of the inflammation but persistence of structural changes that cannot be reversed by GCs.

III. CLINICAL EFFICACY IN ASTHMA

Inhaled GCs are very effective at controlling asthma symptoms in asthmatic patients of all ages and at all levels of disease severity. Inhaled GCs improve the quality of life of patients with asthma and allow many patients to lead normal lives; they improve lung function, reduce the frequency of exacerbations, and may prevent irreversible airway changes. They were first introduced to reduce the requirement for oral GCs in patients with severe asthma, and many studies have confirmed that the majority of patients can be weaned off oral GCs. But as experience was gained with inhaled GCs, they were introduced in patients with milder asthma, with the recognition that inflammation is present even in patients with mild asthma. Inhaled anti-inflammatory drugs have now become the first-line therapy in any patient who needs to use a β_2-agonist inhaler more than once a day and this is reflected in national and international guidelines for the management of chronic asthma. Inhaled GCs reduce asthma symptoms and the need for rescue β_2-agonists and they also significantly reduce exacerbations and the need for hospitalization.

Inhaled GCs are used to treat mild, moderate, and severe persistent asthma, with dosage increasing as asthma severity increases. A fourfold increase in dosage controls exacerbations of asthma. However, when inhaled GCs are discontinued, there is usually a gradual increase in symptoms and airway responsiveness back to pretreatment values.

Inhaled GCs are equally effective in children at all grades of asthma severity and are effective in young children. Nebulized GCs reduce the need for oral GCs and also improve lung function in children under the age of 3 years.

A. Dose–Response Studies

Surprisingly, the dose–response curve for the clinical efficacy of inhaled GCs is relatively flat and, although all studies have demonstrated a clinical benefit of inhaled GCs, it has been difficult to demonstrate differences between doses, with the most benefit obtained at the lowest doses used. This is in contrast to the steeper dose response for systemic effects, indicating that although there is little clinical benefit from increasing doses of inhaled GCs, the risk of adverse effects is increased. However, the dose–response effect of inhaled GCs may depend on the parameters measured and, although it is difficult to discern a dose response when traditional lung function parameters are measured, there may be a dose–response effect in prevention of asthma exacerbations.

B. Prevention of Irreversible Airway Changes

Some patients with asthma develop irreversible airflow obstruction, presumably due to structural changes in the airways resulting from uncontrolled chronic inflammation. There is some evidence that the annual decline in lung function may be slowed by the introduction of inhaled GCs. Increasing evidence also suggests that a delay in starting inhaled GCs may result in less overall improvement in lung function in both adults and children. These studies suggest that introduction of inhaled GCs at the time of diagnosis is likely to have the greatest impact, and extensive studies are now under way to assess the benefit of very early introduction of inhaled GCs in children and adults. Thus far, there is no evidence that early use of inhaled GCs is curative, and even when inhaled GCs are introduced at the time of diagnosis, symptoms and lung function revert to pretreatment levels when GCs are withdrawn.

C. Reduction in Mortality

Inhaled GCs may reduce the mortality from asthma but it is not possible to conduct prospective studies. In a retrospective review of the risk of mortality and prescribed anti-asthma medication, there was a significant protection provided by regular inhaled corticosteroid therapy.

D. Cost Effectiveness

Although inhaled GCs may be more expensive than short-acting inhaled β_2-agonists, they are the most cost-effective way of controlling asthma, since

reducing the frequency of asthma attacks will save on total costs. Inhaled GCs also improve the quality of life of patients with asthma and allow many patients to lead a normal lifestyle, thus saving costs indirectly.

IV. ADD-ON THERAPIES

It was previously recommended that if asthma was not controlled, there should be a stepwise increase in the dose of inhaled GCs until symptom control was achieved. However, many studies have now demonstrated that adding another class of anti-asthma therapy gives better control than increasing the dose of inhaled GCs. This partly reflects the flatness of the dose response to inhaled GCs but may also reflect the complementary actions of the add-on therapy.

Inhaled long-acting β_2-agonists (LABAs), such as salmeterol and formoterol, appear to be the most effective add-on therapies and provide improved symptom control and reduced exacerbations. This has led to the introduction of fixed combination inhalers that contain a LABA and a GC (salmeterol/fluticasone, formoterol/budesonide). These inhalers provide the most effective and convenient means to control asthma.

Low-dose theophylline is an alternative add-on therapy, which is more effective than doubling the dose of inhaled corticosteroids but less effective than adding a LABA. Anti-leukotrienes, another oral add-on therapy, are also less effective than LABA.

A. Steroid-Sparing Therapy

In patients who have serious side effects with maintenance GC therapy, there are several treatments that have been shown to reduce the requirement for oral GCs. These treatments are commonly termed corticosteroid sparing, although this is a misleading description that could be applied to any additional asthma therapy (including bronchodilators). The amount of GC sparing with these therapies is not impressive. Several immunosuppressive agents have been shown to have GC-sparing effects in asthma, including methotrexate, oral gold, and cyclosporin A. These therapies all have side effects that may be more troublesome than those of oral GCs and are therefore indicated only as an additional therapy to reduce the requirement of oral GCs. None of these treatments is very effective, but there are occasional patients who appear to show a good response. Because of side effects, these treatments cannot be considered as a way to reduce the requirement for inhaled GCs. Several other therapies, including azathioprine, dapsone, and hydroxychloroquine, have not been found to be beneficial. The macrolide antibiotic troleandomycin is also reported to have corticosteroid-sparing effects, but this is seen only with methylprednisolone and is due to reduced metabolism of this corticosteroid, so that there is little therapeutic gain.

V. PHARMACOKINETICS

The pharmacokinetics of inhaled GCs is important in determining the concentration of drug reaching the target cells in the airways and in the fraction of drug reaching the systemic circulation and therefore causing side effects. Beneficial properties in an inhaled corticosteroid are a high topical potency, a low systemic bioavailability of the swallowed portion of the dose, and rapid metabolic clearance of any corticosteroid reaching the systemic circulation. After inhalation, a large proportion of the inhaled dose (80–90%) is deposited on the oropharynx and is then swallowed and therefore available for absorption via the liver into the systemic circulation (Fig. 3). This fraction is markedly reduced by using a large-volume spacer device with a metered dose inhaler (MDI) or by using mouthwash and discarding the mouthwash with dry powder inhalers. Between 10 and 20% of inhaled drug enters the respiratory tract, where it is deposited in the airways, and this fraction is available for absorption into the systemic circulation. Most of the early studies on the distribution of inhaled GCs were conducted in healthy volunteers, and it is not certain what effect inflammatory disease, airway obstruction, age of the patient, or concomitant medication may have on the disposition of the inhaled dose. There may be important differences in the metabolism of different inhaled GCs. Beclomethasone dipropionate is metabolized to its more active metabolite, beclomethasone monopropionate, in many tissues including lung, but there is no information about the absorption or metabolism of this metabolite in humans. Flunisolide and budesonide are subject to extensive first-pass metabolism in the liver so that less reaches the systemic circulation. Little is known about the distribution of triamcinolone. Fluticasone propionate is almost completely metabolized by first-pass metabolism, which reduces systemic effects.

When inhaled GCs were first introduced, it was recommended that they be administered four times daily, but several studies have now demonstrated that twice daily administration gives comparable control, although four times daily administration may preferable in patients with more severe asthma.

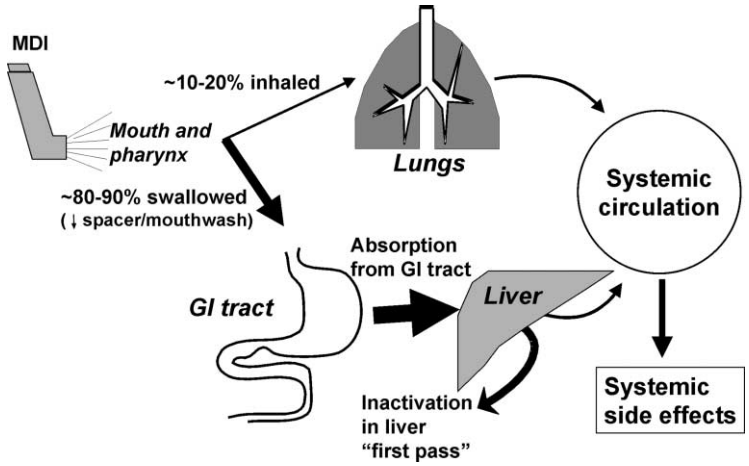

FIGURE 3 Pharmacokinetics of inhaled GCs.

However, patients may find it difficult to comply with such frequent administration unless they have troublesome symptoms. For patients with mild asthma who require ≤ 400 μg/day, once daily therapy may be sufficient.

VI. SIDE EFFECTS OF INHALED GCs

The efficacy of inhaled GCs is now established in short- and long-term studies in adults and children, but there are still concerns about their side effects, particularly in children and when high doses are needed. Several side effects have been recognized (Table 2).

A. Local Side Effects

Side effects due to the local deposition of the inhaled corticosteroid in the oropharynx may occur with inhaled GCs, but the frequency of complaints depends on the dose and frequency of administration and on the delivery system used. The most common complaint is hoarseness of the voice (dysphonia) and this may occur in over 50% of patients using MDI. Dysphonia is not appreciably reduced by using spacers, but may be reduced with dry powder devices. Dysphonia may be due to myopathy of laryngeal muscles and is reversible when treatment is withdrawn. Oropharyngeal candidiasis (thrush) may be a problem in some patients, particularly in the elderly, with concomitant oral GCs and more than twice daily administration. Large-volume spacer devices protect against this local side effect by reducing the dose of inhaled corticosteroid that is deposited in the oropharynx.

TABLE 2 Side Effects of Inhaled GCs

Local side effects
Dysphonia
Oropharyngeal candidiasis
Cough
Systemic side effects
Adrenal suppression
Growth suppression
Bruising
Osteoporosis
Cataracts
Glaucoma
Metabolic abnormalities (glucose, insulin, triglycerides)
Psychiatric disturbances

B. Systemic Side Effects

The efficacy of inhaled GCs in the control of asthma is undisputed, but there are concerns about the systemic effects of inhaled GCs, particularly because they are likely to be used over long periods and in children of all ages. The safety of inhaled GCs has been extensively investigated since their introduction 30 years ago. One of the major problems is deciding whether a measurable systemic effect has any significant clinical consequence, and this necessitates careful long-term follow-up studies. As biochemical markers of systemic corticosteroid effects become more sensitive, systemic effects may be seen more often, but this does not mean that these effects are clinically relevant. The systemic effect of an inhaled corticosteroid will depend on several factors, including the dose delivered to the patient, the site of delivery (gastrointestinal tract and lung), the delivery system used, and individual differences in the patient's response to the corticosteroid. Recent studies suggest that systemic effects of inhaled

corticosteroids are reduced in patients with more severe asthma, presumably as less drug reaches the lung periphery.

The systemic side effects of inhaled GCs that have been studied most extensively are their effects on growth in children and the development of osteoporosis in adults. Recent careful studies in children with long-term follow-up have shown that inhaled GCs do not affect final adult height, although there may be some initial slowing of growth. Studies of bone density are complicated by the fact that patients with more severe asthma who are on higher doses of inhaled GCs are also treated with courses of oral GCs that are known to have a prolonged effect on bone metabolism. Thus far, no studies have shown a convincing effect on bone density and there is no evidence that inhaled GCs increase the risk of fracture. Other systemic effects attributed to inhaled GCs include cataracts and glaucoma, but this has not been convincingly demonstrated in controlled studies.

Based on extensive clinical experience, inhaled GCs appear to be safe in pregnancy, although no controlled studies have been performed. There is no evidence for any adverse effects of inhaled GCs on the pregnancy, the delivery, or the fetus. It is important to recognize that poorly controlled asthma may increase the incidence of perinatal mortality and retard intrauterine growth, so that more effective control of asthma with inhaled GCs may reduce these problems.

VII. SYSTEMIC GCs

Oral or intravenous GCs may be indicated in several situations. Prednisolone, rather than prednisone, is the preferred oral corticosteroid, as prednisone must be converted in the liver to the active prednisolone. Enteric-coated preparations of prednisolone are used to reduce side effects (particularly gastric side effects) and give delayed and reduced peak plasma concentrations, although the bioavailability and therapeutic efficacy of these preparations are similar to those of uncoated tablets. Prednisolone and prednisone are preferable to dexamethasone, betamethasone, or triamcinolone, which have longer plasma half-lives and therefore an increased frequency of adverse effects.

Short courses of oral GCs (30–40 mg prednisolone daily for 1–2 weeks or until the peak flow values return to best attainable) are indicated for exacerbations of asthma, and the dose may be tailed off over 1 week once the exacerbation is resolved. The tailing-off period is not strictly necessary, but some patients find it reassuring. Maintenance oral GCs are needed in only a small proportion (approximately 1%) of asthmatic patients with the most severe asthma that cannot be controlled with maximal doses of inhaled GCs (2 mg daily) and additional bronchodilators. The minimal dose of oral corticosteroid needed for control should be used, and reductions in the dose should be made slowly in patients who have been on oral GCs for long periods (e.g., reduce by 2.5 mg prednisolone per month for doses down to 10 mg daily and thereafter by reduce by 1 mg per month). Oral GCs are usually given as a single morning dose, as this reduces the risk of adverse effects since it coincides with the peak diurnal concentrations of GCs. Alternate-day administration may also reduce adverse effects, but control of asthma may not be as good on the day when the oral dose is omitted in some patients.

Systemic GCs are given for acute severe asthma, and they speed the resolution of exacerbations and reduce the rate of readmission. Oral prednisolone is as effective as intravenous hydrocortisone or methylprednisolone and there is no evidence that high intravenous doses have any advantage. There is some evidence that high doses of nebulized GCs may also be effective in acute exacerbations of asthma, with a more rapid onset of action.

VIII. STEROID-RESISTANT ASTHMA

Although GCs are highly effective in the control of asthma and other chronic inflammatory or immune diseases, a small proportion of patients with asthma fail to respond even to high doses of oral GCs. Resistance to the therapeutic effects of GCs is also recognized in other inflammatory and immune diseases, including rheumatoid arthritis and inflammatory bowel disease. Steroid-resistant patients, although uncommon, present considerable management problems. Corticosteroid-resistant asthma is defined as a failure to improve FEV_1 (forced expiratory volume in 1s) by $>15\%$ after treatment with oral prednisolone at a dose of 30–40 mg daily for 2 weeks, provided that the oral steroid is taken (verified by plasma prednisolone level or a reduction in early morning cortisol levels). These patients are not Addisonian and they do not suffer from the abnormalities in sex hormones described in the very rare familial glucocorticoid resistance. Plasma cortisol and adrenal suppression in response to exogenous cortisol are normal in these patients, so they suffer from side effects of GCs. Complete corticosteroid resistance in asthma is very rare, with a prevalence of

$<$1:1000 asthmatic patients. Much more common is a reduced responsiveness to GCs, so that large inhaled or oral doses are needed to control asthma adequately (steroid-dependent asthma). It is likely that there is a range of responsiveness to GCs and that steroid resistance is at one extreme of this range.

It is important to establish that the patient has asthma, rather than chronic obstructive pulmonary disease (COPD), "pseudo-asthma" (a hysterical conversion syndrome involving vocal cord dysfunction), left ventricular failure, or cystic fibrosis, which do not respond to GCs. Asthmatic patients are characterized by a variability in peak expiratory flow (PEF) and, in particular, a diurnal variability of $>$15% and episodic symptoms. Biopsy studies have demonstrated the typical eosinophilic inflammation of asthma in these patients.

The molecular mechanisms of steroid resistance are still not understood, but there are likely to be several mechanisms. GRs appear to function normally, but there are defects in the interactions of GRs with other transcription factors. Certain cytokines are able to reduce steroid responsiveness by enhancing the activity of transcription factors, such as AP-1, which then combine with and divert GRs. Other patients appear to have a defect in nuclear localization of the GR.

Glossary

asthma Chronic inflammatory disease of the airways, resulting in variable airflow obstruction manifested as intermittent wheezing and shortness of breath.

glucocorticoid receptor Specific receptor for glucocorticoids that acts as a transcription factor on ligand activation.

glucocorticoid-response element Specific consensus DNA-binding site of the glucocorticoid receptor in the promoter region of steroid-sensitive genes.

histone deacetylases (HDACs) Proteins that deacetylase core histones around which DNA is wound, resulting in inflammatory gene suppression. Glucocorticoids recruit HDACs to activated inflammatory genes and thereby switch off inflammation.

nuclear factor-κB Pro-inflammatory transcription factor that regulates many of the inflammatory genes overexpressed in asthmatic airways and whose effects are inhibited by glucocorticoids.

Glucocorticoids and Autoimmune Diseases

J. Bruce Smith, Mark K. Haynes, John L. Abruzzo, and Ralphael J. DeHoratius
Thomas Jefferson University, Pennsylvania

Cortisol and its several synthetic derivatives are widely employed in the treatment of systemic autoimmune conditions. They have a well-established place in the therapy of inflammatory and autoimmune conditions because of their profound anti-inflammatory and immune suppressive effects. However, their use is not without danger or controversy. While glucocorticoid treatment may allow patients to lead normal or near normal lifestyles, there are often concomitant undesirable and sometimes serious side effects and physicians must be vigilant regarding these.

I. INTRODUCTION

The anti-inflammatory effects of glucocorticoids were first investigated at the Mayo Clinic in 1948 by Hench and colleagues in patients with rheumatoid arthritis (RA). The history dates to 1929 when Hench noted that a patient who developed the sudden onset of jaundice experienced remission of RA symptoms. This was felt to be due to increased plasma cortisol because of the inability of the failing liver to metabolize it. These observations were later extended to pregnancy, also associated with increased cortisol levels. In 1938, Hench and co-workers reported pregnancy-related remission of arthritis in two patients with RA and one with psoriatic arthritis. These observations led to widespread use of cortisol and the development of more potent synthetic analogues (Table 1) Although the clinical results were dramatic, it was soon realized that significant toxicity was associated with glucocorticoid use. This article will address the mechanisms of action of glucocorticoids in systemic inflammatory processes, the clinical preparations available, their use in systemic autoimmune diseases, and their side effects.

II. ANTI-INFLAMMATORY MECHANISMS

The inflammatory process is complex and includes activation of T and B lymphocytes, activation of cells of the monocyte/macrophage series, production of numerous cytokines and chemical mediators, alterations in leukocyte trafficking, and production of substances that result in vascular permeability. The anti-inflammatory effects of glucocorticoids are a result of their down-regulation of most of these processes.

Approximately 90% of glucocorticoid hormones are transported in the plasma bound to transcortin, an α-2 globulin that is produced by hepatocytes. The remaining 10% of glucocorticoid hormones are loosely bound to albumin and are able to enter the cytoplasm of cells. Once in the cytoplasm, they attach to high-affinity glucocorticoid receptor elements (primarily heat-shock protein 90), and these complexes are then transported to the cell nucleus where they bind to DNA (mostly in interphase cells) and modulate the transcription of DNA by competing with transcription factors such as activator protein-1 and nuclear factor κB. Thus, the subsequent production of messenger RNA and new protein synthesis are reduced. These transcription factors are particularly active in the production of tumor necrosis factor α (TNFα) and interferon-γ (IFN-γ), both important cytokines in the inflammatory process. Glucocorticoid receptors in the cytoplasm of cells exist in α and β

TABLE 1 Glucocorticoid Preparations and Their Potency

Drug	Anti-inflammatory properties	Salt-retaining properties	Equivalent oral dose (mg)
Short-to-medium acting			
Hydrocortisone	1	1	20
Cortisone	0.8	0.8	25
Prednisone	4	0.3	5
Prednisolone	5	0.3	5
Methylprednisolone	5	0	4
Medium-to-long acting			
Triamcinolone	5	0	5
Fluprednisolone	15	0	4
Long acting			
Dexamethasone	30	0	0.75

Note. All preparations are compared to 20 mg hydrocortisone with its anti-inflammatory and salt-retaining properties set to 1 by convention.

isoforms. Only the α isoform binds glucocorticoids. The β isoform acts as a glucocorticoid inhibitor and is found to be increased in blood lymphocytes of patients with RA who may exhibit resistance to the anti-inflammatory effects of glucocorticoid treatment. The α isoform of glucocorticoid receptor is highly expressed in monocytes, neutrophils, eosinophils, and most subpopulations of lymphocytes.

Transcortin becomes saturated when plasma cortisol levels are over 20–30 μg/dl. Thus, immune suppression and other clinical effects of steroid hormones occur in situations in which plasma glucocorticoid levels are elevated, as a result of either a disease state or exogenous administration. Via that mechanism, glucocorticoids profoundly inhibit the production of mediators involved in immune responses and inflammation (Fig. 1). These include the suppression of synthesis of nearly all cytokines, inhibition of phospholipase A_2, thus decreasing production of prostaglandin and leukotriene, and inhibition of histamine and bradykinin production. Glucocorticoids also reduce the expression of cyclooxygenase 2 (COX-2). Additional effects include direct cytotoxic activity for lymphocytes and it also seems likely that other direct effects of high-dose glucocorticoids occur. The fundamental mechanism of action is probably related to glucocorticoid suppression of transcription factors involved in the production of the various mediators mentioned above. The main effects of glucocorticoids on inflammatory processes are listed in Table 2.

The effects of glucocorticoid treatment on most immune functions is profound. Many functions of T lymphocytes are affected, especially delayed-type hypersensitivity and cytokine production. Within a few weeks of beginning glucocorticoid treatment, serum levels of immunoglobulins (Ig), particularly IgG, decrease. This is most likely related to the decreased synthesis of Ig by B cells. However, glucocorticoid treatment does not suppress all immune functions. For example, glucocorticoid treatment does not alter the function of natural killer (NK) cells or cells mediating antibody-dependent cellular cytotoxicity although these cells express the cytoplasmic receptors to approximately the same degree as monocytes and neutrophils and probably mediate their cytotoxic effects ultimately via production of TNFα.

Probably the most immunologically powerful effect of high-dose glucocorticoid treatment is inhibition of production of interleukin-1 (IL-1) by monocytes. IL-1 is a pivotal player in the cytokine cascade. It induces the production of IL-2 and IFN-γ, both highly pro-inflammatory. Increased IL-2 levels stimulate the activation of both T and B lymphocytes and the subsequent production of numerous other cytokines including TNFα, transforming growth factor-β, IL-6, IL-8, and others. Some of the biological effects of these cytokines are listed in Table 3.

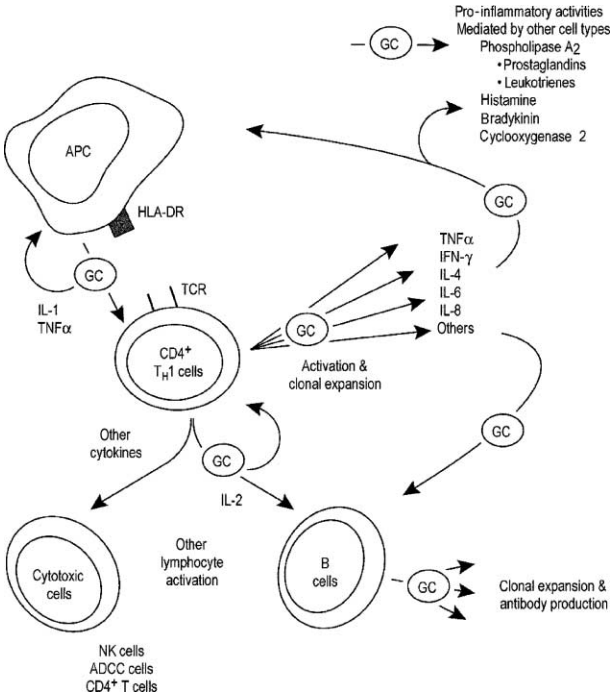

FIGURE 1 Schematic of immune responses and cytokine production indicating where glucocorticoids intervene or suppress. The immune response results from interaction of $CD4^+$ T cells with environmental or autoantigens processed and presented to them by antigen-presenting cells (APC) in conjunction with histocompatibility class II molecules represented by human leukocyte antigen (HLA) class II in the diagram. The antigen is associated with HLA class II on the APC surface and interacts with the T-cell receptor (TCR) expressed on $CD4^+$ T cells. These T cells become activated and expand as clones of cells that specifically recognize the relevant antigen. Cytokines as indicated in the diagram mediate a variety of immune responses as noted in Table 3. These include further clonal expansion of T cells, enhancement of other immune cell activities, and activation and clonal expansion of B cells that produce specific antibodies. Glucocorticoids (GC) inhibit most of these responses via suppression of transcription factors as noted in the text. The cytotoxic functions of natural killer (NK) cells and cells mediating antibody-dependent cell-mediated cytotoxicity (ADCC cells) are not affected by GC. T_H1, T helper cell type 1; T_H2, T helper cell type 2; TNFα, tumor necrosis factor α; IFN-γ, interferon-γ; IL-4, IL-6, and IL-8, interleukin-4, -6, and -8.

TABLE 2 Cellular Targets of Glucocorticoids

Cell target	Effect
Lymphocytes	Short-term lymphopenia
	Depletion of recirculating lymphocytes
	Decreased production of IL-2 resulting in decreased clonal expansion of T and B lymphocytes
	Decreased production of chemoattractants
	Decreased proliferative response to antigens
	Decreased immunoglobulin synthesis in general
Monocytes/ macrophages	Transient monocytopenia
	Decreased delayed-type hypersensitivity
	Inhibition of Fc receptor binding
	Decreased chemotaxis
	Decreased bacteriocidal activity
Neutrophils	Increased in peripheral blood
	Slight decrease in chemotaxis but not much effect on function
	Decreased egress from vascular space
Eosinophils	Decreased in peripheral blood
	Decreased movement to immediate hypersensitivity test sites

III. CLINICAL USE IN AUTOIMMUNE DISEASES

A detailed review of the clinical characteristics of the autoimmune diseases in which glucocorticoids are prescribed is beyond the scope of this article, and readers are referred to current specialty textbooks for information. Diseases in which glucocorticoids are commonly employed include systemic lupus erythematosus (SLE), RA, multiple sclerosis (MS), inflammatory bowel diseases (IBDs) such as ulcerative colitis and Crohn's disease, various syndromes associated with vasculitis such as giant cell arteritis (GCA and polyarteritis nodosa), and other systemic diseases thought to have an immune component.

The rationale for treatment with glucocorticoids includes quick onset of action, their potency as anti-inflammatory agents and analgesics, and their ability to modify the clinical course of certain diseases. There are several studies that show a favorable disease-modifying effect of long-term low-dose prednisone in patients with RA. Also, early intervention with high oral doses (60–80 mg) of prednisone clearly prevents ocular complications including blindness in patients with GCA (also known as temporal arteritis). Although the side effects discussed below are often severe, treatment with glucocorticoids may permit patients to lead a normal daily existence and on some occasions can be life-saving. In addition, inhibition of inflammation may in some cases modify the disease process.

Glucocorticoids can be given orally, by intramuscular or intra-articular injection, or by intravenous infusion. The object of therapy is to prevent serious autoimmune damage to organs while adjusting the dose downward in an attempt to prevent serious adverse reactions (Table 4).

There are various glucocorticoid preparations in use. These preparations and their relative strengths compared to cortisone are presented in Table 1. In this article, oral glucocorticoid use generally refers to the use of prednisone and intravenous (iv) glucocorticoid usually refers to methylprednisolone (Solumedrol) since these are the preparations most commonly used in the treatment of patients.

A. Low Dose Glucocorticoids

While it is true that most serious adverse reactions seen with glucocorticoid use occur with daily doses of 15–20 mg prednisone or greater, low oral doses generally mean less than 10 mg daily of prednisone or equivalent. Even so, most clinicians attempt to use 5 mg daily or less, often prescribing pills of 1 mg strength in order to be able to titrate to the lowest possible dose that alleviates symptoms. Dosing schedules include once a day, divided daily doses, and every other day. It is convenient and easy to prescribe prednisone in a once daily dose. It allows for more convenient manipulation of dosage in 1 mg increments and a single daily dose, as with other medications, provides better patient compliance. Dosing on a twice daily schedule is sometimes prescribed but it is key to remember that the clinical effect of this schedule is different from that of a single daily dose. For example, because of more sustained blood levels, 5 mg of prednisone twice a day provides a steroid effect that is more equivalent to 12 or 13 mg as a single daily dose than to 10 mg once a day. An every other day schedule is often prescribed because of the decrease in unwanted side effects. However, again there are clinical differences. For example, a single dose of 20 mg every other day provides a clinical effect that is somewhat less than that seen with 10 mg daily. In addition, patients with rheumatologic diseases often experience "breakthrough" symptoms on the days they do not take the medication. Often dosing schedules must be tailored to the individual patient. For example, some patients with polymyalgia rheumatica may require small maintenance doses of prednisone given twice daily

TABLE 3 Biological Effects of Selected Cytokines

Cytokine	Activity
Primarily pro-inflammatory cytokines	
Interleukin-1	Stimulates proliferation of T and B lymphocytes; activates T cells; activates metalloproteinases; increases production of ACTH and other pituitary hormones; has endogenous pyrogen activity; increases production of colony-stimulating factors (G-CSF, M-CSF, GM-CSF); increases expression of adhesion molecules; promotes thrombosis; chemoattractant for leukocytes; stimulates production of TNFα and additional IL-1
Interleukin-2	Stimulates proliferation of T and B lymphocytes; activates T lymphocytes; induces progression of cell cycle phases in resting cells; stimulates production of numerous other cytokines, especially IFN-γ and TNFα; induces proliferation of lymphokine-activated killer (LAK) cells
Interferon-γ	Enhances IL-1 production; enhances expression of cell surface HLA class II molecules on antigen-presenting cells and other cell types; stimulates expression of intercellular adhesion molecules; stimulates release of reactive oxygen species; stimulates production of TNFα and other T_H1-related lymphocyte functions
Tumor necrosis factor-α	Enhances IL-1 production; enhances expression of cell surface HLA class II molecules on antigen-presenting and other cells; enhances expression of intracellular adhesion molecules; stimulates additional production of TNFα
Interleukin-5	Hematopoetic growth factor; promotes proliferation and activation of eosinophils; promotes generation of cytotoxic T cells
Interleukin-6	Stimulates B-cell differentiation to plasma cells; increases antibody production; stimulates production of acute-phase reactants by hepatocytes; increases platelet counts; is prothrombotic; induces resting T cells to become cytotoxic
Interleukin-8	Chemotactic factor for neutrophils and other migratory cell types; activates neutrophils; increases expression of adhesion molecules; increases angiogenesis
Interleukin-12	NK-cell growth factor; promotes proliferation of LAK cells; enhances activation and proliferation of T_H1 lymphocytes
Primarily anti-inflammatory cytokines	
Interleukin-4	Down-regulates T_H1-mediated immune functions; down-regulates IL-6 synthesis; decreases production of IL-1; stimulates B-cell differentiation and antibody production
Transforming growth factor-β	Inhibits many IL-1, IL-2, IFN-γ and TNFα activities; blocks activity of cytotoxic cells (LAK and T cells); pro-fibrotic; enhances matrix protein secretion; enhances production of tissue inhibitor of metalloproteinases inhibitor; chemoattractant for neutrophils
Interleukin-10	Inhibits proliferation of cytokines produced by T_H1 and T_H2 cells; inhibits IL-1 production; promotes differentiation of cytotoxic T lymphocytes

because they experience breakthrough symptoms as soon as 12 h after a dose.

Low-dose oral glucocorticoid treatment is indicated in systemic autoimmune disease patients who have mild to moderate symptoms despite prescription of nonsteroidal anti-inflammatory drugs (NSAIDs) or other indicated immune-suppressive treatments such as hydroxychloroquine or methotrexate. It should also be noted that patients with systemic autoimmune diseases who are being treated with glucocorticoids may benefit from adding an immune-suppressant drug as this may allow a reduction in the dose of glucocorticoid—the so-called "steroid-sparing effect."

Higher doses of orally administered glucocorticoids are indicated for acute flares of autoimmune diseases. For relatively mild flares, a "minipulse" with prednisone may be sufficient. It could be prescribed

TABLE 4 Adverse Reactions Associated with Glucocorticoid Treatment

Common	Uncommon	Rare
Hypertension	Metabolic acidosis	Congestive heart failure
Osteoporosis	Diabetic ketoacidosis	Arrhythmias
Azotemia	Peptic ulcer disease	Hirsutism
Secondary Cushing's disease	Glaucoma	Fatty liver
Impaired wound healing	Pseudotumor cerebri	Pancreatitis
Increased susceptibility to infections	Spontaneous fractures	Convulsions
Elevated blood glucose	Psychosis	
Atherosclerosis/hyperlipidemia		
Myopathy		
Osteonecrosis		
Mood alterations		
Posterior subcapsular cataracts		

for 6 days as 30, 25, 20, 15, 10, and 5 mg and then discontinued or continued when the patient has reached his or her usual dose. For more severe flares, doses in the 60 mg range may be required and it may be necessary to continue at the high dose until symptoms abate before tapering to the usual dose.

B. Intravenous Glucocorticoids

Intravenous glucocorticoids, usually Solumedrol, are administered for serious or life-threatening clinical situations. Common scenarios include flares in lupus involving vital organs (brain, kidney), vasculitis, and severe flares of rheumatoid arthritis, multiple sclerosis, inflammatory bowel disease, and others. They are also used in conjunction with starting other immune-suppressive treatment. For example, a patient with dermatomyositis or vasculitis who is being started on methotrexate or cyclophosphamide will benefit from the anti-inflammatory and immune suppressive effects of iv methylprednisolone with rapid symptomatic improvement (over a period of days) while the more profound immune suppressive effects of methotrexate or cyclophosphamide will take weeks to develop.

A typical regimen for iv glucocorticoid administration in a patient with one of the rheumatic diseases is 1 g of methylprednisolone in 250 or 500 ml iv saline given over a period of 2–3 h on 3 consecutive days. Neurologists treating MS may use 1 g daily for a week or more. These regimens can be repeated on a periodic basis dictated by the clinical condition of the patient. When treating with monthly iv methylprednisolone, low doses of oral preparations are generally prescribed. Gastroenterologists, when they employ iv steroids for treating IBD, usually use hydrocortisone at 100 mg or methylprednisolone at 60 mg three times daily. In steroid-naive patients, some gastroenterologists use adrenocorticotropic hormone to stimulate endogenous glucocorticoid production.

IV. ADVERSE REACTIONS TO STEROID TREATMENT

The immune and anti-inflammatory effects of glucocorticoids are highly potent and desirable in the treatment of autoimmune diseases. However the metabolic effects are also profound and account for the wide variety of side effects. The best way to prevent side effects is to keep the dose of glucocorticoid as low as possible while still maintaining the desired clinical effect. As noted above, strategies such as every-other-day dosing may be effective in preventing or minimizing side effects but may not provide the desired clinical effect. There are also medical interventions that serve to minimize potential side effects. Concomitant treatment with an immunosuppressive drug, most commonly Methotrexate, will often allow a reduction in the glucocorticoid dose without compromising the beneficial clinical response. Other measures are discussed in the individual sections that follow.

Many side effects are not particularly serious but are disconcerting to the patient. These include physical changes similar to Cushing's disease, such as centripetal obesity, "moon" facies, hirsutism, and striae. Other usually nonserious side effects include thinning of the skin, acne, alopecia, and purpura. More serious side effects and their possible prevention are discussed below with respect to the various target organ systems.

A. Musculoskeletal System

Osteoporosis is one of the most serious side effects of glucocorticoid treatment. The mechanism appears to be a combination of inhibition of osteoblast function, increased bone resorption, increased urinary calcium loss, decreased calcium absorption, and decreased sex hormone production. Osteoporosis may develop after short term-low dose glucocorticoid treatment and it may occur in as many as 50% of patients receiving long-term glucocorticoid treatment. Osteoporosis occurs primarily in trabecular bone but cortical bone may also be a target. Preventive measures may be taken in patients who are being treated with glucocorticoids. This includes prescribing adequate doses of calcium and vitamin D along with an exercise program. Treatment with a bisphosphonate may also be considered unless there are contraindications. One is cautioned against using bisphosphonates in women of child-bearing potential as the effects on developing bone could be profound.

Osteonecrosis (avascular necrosis) occurs in patients receiving long-term glucocorticoid treatment and it is particularly common in patients with SLE. In SLE, osteonecrosis may occur with or without glucocorticoid treatment but it is certainly most commonly found in patients receiving greater than 20 mg daily of prednisone or equivalent. Osteonecrosis should be considered in at-risk patients who complain of sudden onset of joint pain when they are otherwise doing well. Diagnosis by typical X-ray findings can be accomplished in the later stages of osteonecrosis but magnetic resonance imaging may be required to see early changes in at-risk patients. Osteonecrosis is most commonly seen in the weight bearing joints, notably the hip, knee, and ankle. However, it can occur in non-weight-bearing joints such as the shoulder and it has been seen in the wrists and elbows of at-risk patients who stress these joints using canes or walkers. Growth retardation may be seen in children receiving systemic glucocorticoids.

Myopathy clinically presenting as muscle weakness is a common complication of glucocorticoid use. It may prove to be a diagnostic dilemma when treating patients with immune inflammatory diseases of muscle such as polymyositis or dermatomyositis. Onset of proximal muscle weakness is insidious and may occur at any time after starting glucocorticoid treatment. Myopathy appears to be dose-related and is generally not seen in patients receiving less than 20 mg prednisone or equivalent daily. Diagnosis is by combined electromyogram (EMG) and muscle biopsy. The EMG may or may not show myopathic changes and the biopsy usually shows dropout of type II muscle fibers.

Paradoxically, especially when higher doses are employed in the treatment of patients with rheumatoid arthritis, too rapid tapering of the glucocorticoid dose may result in diffuse polyarticular pain.

B. Ocular

Posterior subcapsular cataracts are commonly seen in patients receiving long-term glucocorticoid treatment. These cataracts develop slowly and often occur bilaterally. Children may be more susceptible than adults to cataract formation. Increased intraocular pressure is also a common side effect. This side effect is most common after steroid eyedrop use but it can occur with systemic administration. Glaucoma usually occurs in patients who are otherwise predisposed by family history and in those receiving more than 10 mg daily over long time periods. Periodic ophthalmology examinations—at least once a year—are recommended.

C. Gastrointestinal System

While glucocorticoids alone are not usually associated with peptic ulcer disease, concomitant use of glucocorticoids and traditional NSAIDs appears to be synergistic with respect to the development of gastritis, peptic ulcer disease, and gastrointestinal (GI) bleeding. It is not currently known whether glucocorticoids and COX-2 inhibitors will demonstrate the same synergy with respect to GI adverse events. Glucocorticoid use is also associated with pancreatitis and fatty infiltration of the liver but these are less common.

Patients being treated with glucocorticoids often exhibit increased blood sugar but usually do not become ketotic. Hepatic gluconeogenesis, decreased peripheral sugar utilization, and suppression of insulin secretion by pancreatic islet cells all contribute to the elevated blood sugar. Development of overt diabetes mellitus in a patient with a negative family history and a normal glucose tolerance test is unusual but the relative risk rises with the glucocorticoid dose.

D. Cardiovascular and Renal

Hypertension is one of the most common cardiovascular effects and azotemia is the most common renal side effect. Hypertension is related in part to salt and fluid retention but other factors are also important.

These include higher baseline blood pressure, age, and enhanced activity of the renin–angiotensin system. Azotemia can occur due to the catabolic effect of glucocorticoids on muscle. Glucocorticoid treatment elevates levels of lipoproteins and that probably represents a mechanism for an increased incidence of atherosclerosis along with increased peripheral vascular calcifications found in patients being treated with these drugs. This side effect is not likely to be found in patients receiving less than 20 mg daily unless treatment has been long-term (years versus weeks or months). Acute cardiac death has been reported in patients receiving high-dose pulse iv methylprednisolone. Arrhythmias and electrolyte balance disturbances in patients with concomitant cardiac disease were probably factors regarding these adverse events.

E. Central Nervous System

Euphoria is a common side effect of high-dose glucocorticoid treatment. Memory loss has been reported and insomnia may occur, particularly when patients take their glucocorticoid medications in the evening or at bedtime. Psychiatric states such as depression and mania are also observed. Overt psychosis may be seen in patients receiving more than 20 mg prednisone for extended periods. This may be diagnostically confusing in patients who also have central nervous system involvement from SLE or in MS patients.

F. Immune System

In addition to the desired effects regarding immune suppression, there is a concomitant undesirable dose-related effect regarding infections. These include reactivation of latent tuberculosis (TB) and increased susceptibility to bacterial, viral, and fungal infections. Herpes zoster is common and should be treated with an anti-herpes agent as soon as it is clinically suspected. Infections with opportunistic organisms are vastly increased in patients receiving glucocorticoids compared to patients not receiving these medications. Close monitoring for symptoms of infectious processes and other precautions are warranted. Skin testing for TB and a screening chest X ray should be performed in patients who are going to be treated with high-dose or long-term glucocorticoids. Individuals with a positive result in either test should receive TB prophylaxis prior to starting glucocorticoid therapy. Vaccination against *Pneumococcus* and influenza should also be recommended to patients who are going to be treated with glucocorticoids or who are already on long-term treatment.

V. SUMMARY

Glucocorticoids are commonly employed in the treatment of systemic autoimmune diseases. Clinical use may be required to manage unacceptable day-to-day symptoms (general quality of life issues), for maintenance of the patient at an acceptable disease activity level, for treating acute flares of diseases, for treatment of vital organ involvement, or occasionally as a life-saving measure such as in multiple organ failure. The effects of glucocorticoids on the immune response and on the production of a variety of mediators of inflammation are profound and the desired immune suppression may be attended by a number of unwanted side effects such as susceptibility to opportunistic infections. In addition, no organ system is exempt from the metabolic side effects of these drugs. Since unwanted side effects are generally dose-related, one should attempt to use the lowest dose required to obtain the desired clinical effect. Measures to prevent side effects in both acute and chronic use situations are discussed.

Glossary

antigen-presenting cells Cells such as macrophages and dendritic cells that can bind and engulf foreign substances or "antigens," break them down into smaller units, and insert them into their cell surface membranes where they are "presented" for interaction with T lymphocytes.

arteritis A condition in which the walls of arteries are infiltrated with inflammatory cells, causing damage to the arterial walls and often leading to compromised blood flow and local clotting.

cytokine Intercellular hormone-like messenger proteins that are usually active within a small radius of the cells producing them. They are products of many different cell types but particularly of activated cells of the immune system.

immune response Series of events that occurs after T and B cells are exposed to antigens for which they have a specific receptor. T cells that are thus activated produce cytokines that foster the proliferation of activated cells (clonal expansion) plus the recruitment and activation of other cells of the immune system. B cells also proliferate as a result of the actions of cytokines and secrete the antibody specific for the antigen.

myositis Inflammation of muscle.

osteonecrosis A condition in which there is decreased blood supply to bones—usually weight-bearing bones near joints. It is also known as avascular necrosis.

osteoporosis A condition in which there is decreased bone density as a result of loss of calcium. It commonly occurs after menopause, after long periods of inactivity, and as a result of drug treatment, particularly with glucocorticoids.

T cells and B cells Lymphocytes in general are divided into T and B cells. Subgroups of T cells exhibit diverse activities including production of cytokines, mediation of delayed-type hypersensitivity, regulation of on-going immune responses, cytotoxic functions, and "help" for the activation of B cells. T cells interact with APCs via an antigen-binding molecule, the T-cell receptor (TCR). The general T-cell population has TCRs for all the antigens that they would encounter in an individual's lifetime. B cells produce antibodies. The B-cell surface receptor molecule is an antibody and when it binds to its specific antigen, activated B cells secrete antibodies of the same specificity.

Normal levels of glucocorticoids are essential for the maintenance of physiologic homeostasis and for an adequate response to stress. Both the lack of glucocorticoids (adrenal insufficiency) and excess glucocorticoids (as seen in Cushing syndrome) lead to life-threatening conditions.

I. INTRODUCTION

The adult human adrenal gland is composed of two parts: the cortex (outer part), which originates from mesenchymal cells, and the catecholamine-producing medulla (inner part), which is derived from neuroectodermal cells. The cortex, which represents 90% of the weight of the gland, is made of three zones: the zona glomerulosa (outermost, just under the adrenal capsule), the zona fasciculata (middle), and the zona reticularis (innermost, next to the medulla). Each cortical zone has the capacity to secrete its own specific steroids. The fasciculata and reticularis zonae synthesize glucocorticoids (in humans, cortisol in the fasciculata and androgenic steroids in the reticularis); the zona glomerulosa synthesizes aldosterone.

II. STEROID BIOSYNTHESIS

All adrenal steroid hormones have a 21-carbon structure containing a four-ring nucleus derived from cholesterol (Fig. 1). Cholesterol is converted to steroid hormones after specific cytochrome P450

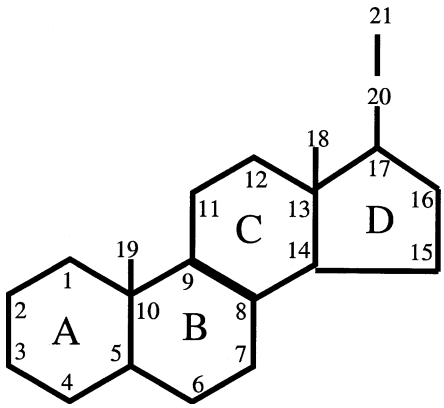

FIGURE 1 All adrenal steroid hormones have 21 carbons distributed mainly in a four-ring nucleus (rings A, B, C, and D) derived from the cholesterol molecule.

(CYP) enzymes act on its different ring carbons. The CYPs are oxidative enzymes localized in the mitochondria or in the endoplasmic reticulum. They act on steroids by oxygen insertion (hydroxylation) reactions or by oxidative carbon–carbon bond cleavage reactions. There are five CYP enzymes involved in adrenal steroid biosynthesis; CYP11A1 (cholesterol side chain cleavage enzyme), CYP17 (17α-hydroxylase enzyme), CYP21A2 (21-hydroxylase enzyme), CYP11B1 (11β-hydroxylase enzyme), and CYP11B2 (aldosterone synthetase enzyme). Although the cortex has the ability to synthesize cholesterol *de novo*, most of the cholesterol utilized in adrenal steroid biosynthesis is taken up from the blood. In humans, the major source of adrenal cholesterol is carried in blood by circulating plasma low-density lipoproteins (LDLs). The adrenal cortex, which contains cell surface receptors for LDLs, may then take up the cholesterol. Cholesterol is transported into the mitochondria from the outer membrane to the inner membrane. This transport is facilitated by steroidogenic acute regulatory protein (StAR), which plays a rate-limiting role in steroid synthesis. Cholesterol is converted to pregnenolone by the cholesterol side chain cleavage enzyme (CYP11A1) at the mitochondrial level. In the zona fasciculata, pregnenolone is transferred from the mitochondria to the smooth endoplasmic reticulum, where most is hydroxylated by the 17α-hydroxylase enzyme to 17α-hydroxypregnenolone, which, in turn, is converted to 17α-hydroxyprogesterone. The latter reaction is catalyzed by 3β-hydroxysteroid dehydrogenase (3β-HSD) (type 2), one of the few non-P450 enzymes involved in steroidogenesis. 17α-Hydroxyprogesterone then undergoes two successive hydroxylations: first, it is hydroxylated at position 21 by the 21-hydroxylase enzyme, resulting in 11-deoxycortisol (also called compound S); second, compound S is hydroxylated at position 11 by the 11β-hydroxylase enzyme to cortisol (also called compound F).

In the zona fasciculata, a percentage of pregnenolone is directly converted by 3β-HSD to progesterone; the latter is then hydroxylated at the 17 position to 17α-hydroxyprogesterone. In the zona reticularis, 17,20-lyase removes the two-carbon side chain at C-17, the first step in the pathway leading to the synthesis of two adrenal androgens, dehydroepiandrosterone (DHEA) from 17-hydroxypregnenolone and Δ^4-androstenedione from 17α-hydroxyprogesterone. DHEA may be converted to Δ^4-androstenedione by 3β-HSD; testosterone is then produced from Δ^4-androstenedione by the action of 17-ketosteroid reductase, another non-P450 enzyme. Aromatization to estrogens by P450 aromatase both in the adrenal as well as in other steroidogenic and peripheral tissues may follow for both testosterone and/or Δ^4-androstenedione (which is aromatized directly to estrone).

In contrast to the other two zones, the zona glomerulosa has no 17α-hydroxylase enzyme and thus all pregnenolone present in glomerulosa cells is transformed to progesterone. Progesterone is hydroxylated at C-21 by 21-hydroxylase to 11-deoxycorticosterone (DOC), which, in turn, follows the pathway for the synthesis of aldosterone. Aldosterone synthase, which is expressed only in glomerulosa cells, catalyzes the last three steps of aldosterone synthesis: the 11β-hydroxylation of deoxycorticosterone to corticosterone, the 18-hydroxylation of corticosterone, and the 18-methyl oxidation of 18α-hydroxycorticosterone to aldosterone. These biosynthetic pathways are outlined in Fig. 2.

III. REGULATION OF STEROID SECRETION

The regulation of cortisol synthesis and secretion is mediated by the hypothalamus, the pituitary, and the adrenal glands. Adrenocorticotropic hormone (ACTH; corticotropin) is synthesized and secreted by the corticotrophs of the adenohypophysis, which are regulated mainly by two hypothalamic hormones: the corticotropin-releasing hormone (CRH) and arginine vasopressin. Pituitary ACTH is secreted in the peripheral circulation and reaches ACTH receptors [the product of the melanocortin-2 receptor (MC2R) gene] located on the surface of the adrenocortical cells. ACTH binds to these cell surface receptors and initiates a cyclic adenosine monophos-

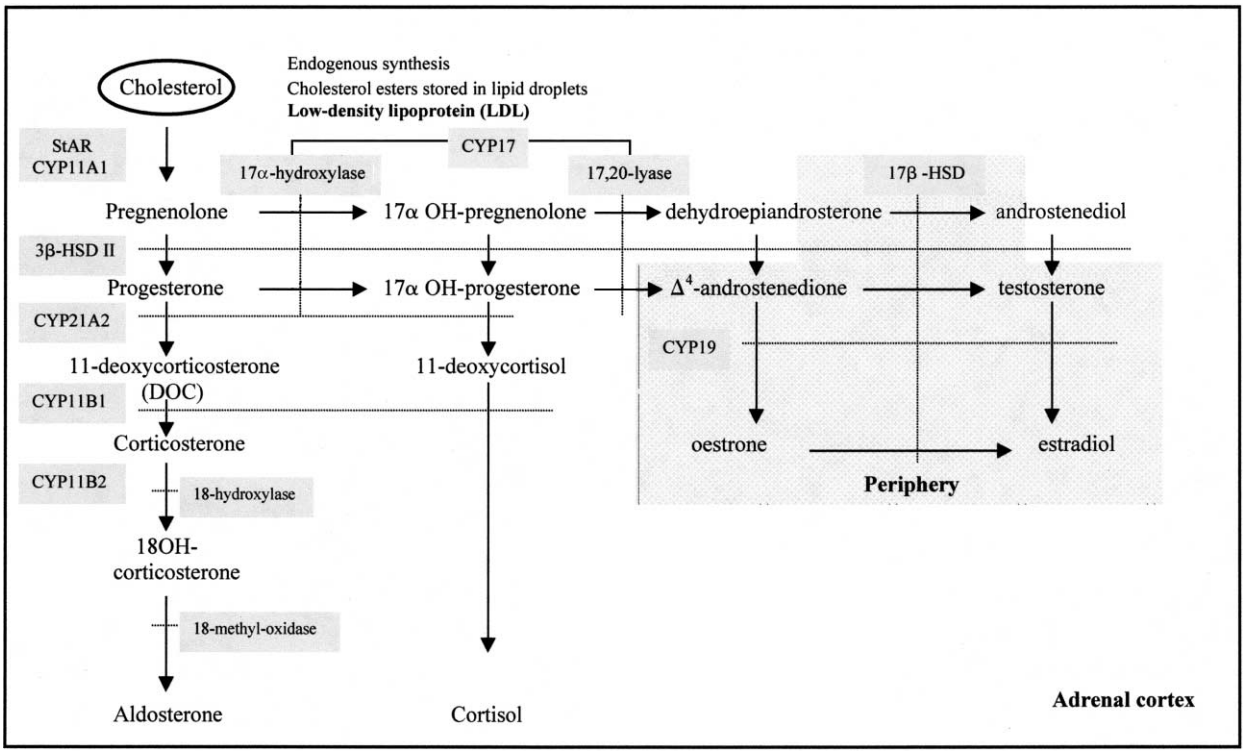

FIGURE 2 Biosynthesis of steroids in the adrenal cortex and conversion in the periphery from substrates originating from the adrenal glands. Abbreviations: StAR, steroidogenic acute regulatory protein; 3β-HSD II, 3β-hydroxysteroid dehydrogenase enzyme II; CYP11A1, cholesterol side chain cleavage enzyme; CYP17, 17α-hydroxylase; CYP21A2, 21-hydroxylase; CYP11B1, 11β-hydroxylase; CYP11B2, aldosterone synthetase; 17β-HSD, 17β-hydroxysteroid dehydrogenase; CYP19, aromatase.

phate (cAMP)-dependent protein kinase pathway, increasing the conversion of cholesterol to pregnenolone, the initial step in the cortisol biosynthesis, which results in the acute increase of cortisol production. In addition, the chronic effects of ACTH, which occur in hours or days, include increased synthesis of most of the enzymes of the steroidogenic pathway and its role as a growth factor on the cortical zone. Thus, a decrease of plasma ACTH may lead to gradual atrophy of the adrenal cortex. Most ACTH is released in a series of secretory episodes followed by an equal number of bursts in plasma cortisol concentration. These secretory episodes of ACTH and cortisol are characterized by a sharp rise of cortisol levels followed by a slower decline, due to its relatively long plasma half-life of about 80 min. In a 24-h period, ACTH peaks occur in highest amplitude in the second half of the night; consequently, plasma cortisol levels are maximal in the early morning hours around the time of awakening. Plasma cortisol levels decline throughout the morning and reach nadir values late in the evening. This diurnal variation of ACTH and cortisol values constitutes the normal circadian rhythm of endogenous glucocorticoid synthesis that is mimicked pharmacologically when exogenous glucocorticoids are given as replacement therapy.

The key mineralocorticoid aldosterone that serves as a primary regulator of extracellular fluid volume and as a major determinant of potassium metabolism is mainly regulated by the renin–angiotensin system and by potassium ion. Renin, a serine protease enzyme that is produced by the kidney, cleaves the angiotensinogen and α_2-globulin (synthesized by the liver) to angiotensin I. Angiotensin I is then converted to angiotensin II by the angiotensin-converting enzyme, which originates in part from the lungs. Angiotensin II stimulates aldosterone secretion.

IV. MECHANISMS OF ACTION OF GLUCOCORTICOID RECEPTORS

All natural and synthetic glucocorticoids act by binding to a specific cytoplasmic glucocorticoid receptor. There are two isoforms of the glucocorticoid

receptor; the α-isoform is a 777-amino-acid protein and the β-isoform has 742 amino acids. The α-isoform is the most abundant and represents the functional receptor that can be divided into three domains. The glucocorticoid-binding domain is located near the carboxy-terminal region of the molecule and is where the ligand binds. The DNA-binding domain is located in the middle of the proteins and is a cysteine-rich region that binds the molecule to DNA sequences in the promoter regions of target genes; these sequences (which have a specific motif) are called glucocorticoid response elements. This region folds into a two-finger structure stabilized by zinc ions, connected to cysteines to form two tetrahedrons. The zinc fingers represent the basic structure by which the DNA-binding domain recognizes specific nucleic acid sequences. The third domain, the amino-terminus domain of the receptor, is highly antigenic and contains a ligand-independent transcriptional activation function (AF-1).

The inactive forms of the glucocorticoid receptors are located in the cytoplasm as polymers bound with other proteins, one of which is the heat-shock protein Hsp 90. This heteromeric protein complex has no metabolic effect. Binding of a glucocorticoid to its receptor activates the receptor by changing the spatial conformation of the inactive protein. Activation includes dissociation of the receptor from the heat-shock proteins and a change in conformation of the hormone-binding domain. The activated glucocorticoid ligand–receptor complex then enters the nucleus (translocation), where its hormone-binding domain binds to DNA glucocorticoid-responsive elements and alters the transcription of specific genes.

V. SYNTHETIC STEROIDS

Synthetic glucocorticoids have related structural properties to endogenous glucocorticoids. However, cortisol and prednisolone possess a hydroxyl group at C-11, which provides their glucocorticoid activity. Thus, exogenous cortisone and prednisone, which have a keto group at C-11, must undergo *in vivo* (mainly hepatic) hydroxylation to cortisol and prednisolone, respectively, to become active (Fig. 3).

Each glucocorticoid has a specific chemical structure that imparts a particular glucocorticoid and mineralocorticoid potency. For example, prednisolone has the same structure as hydrocortisone (cortisol), but also has a double bond between the C-1 and C-2, and thus has about four times more glucocorticoid activity compared to cortisol. Also, the addition of a fluoro atom in the 9α position of hydrocortisone produces fludrocortisone. This molecular change provides fludrocortisone with 10 times more potent glucocorticoid activity and 125 times

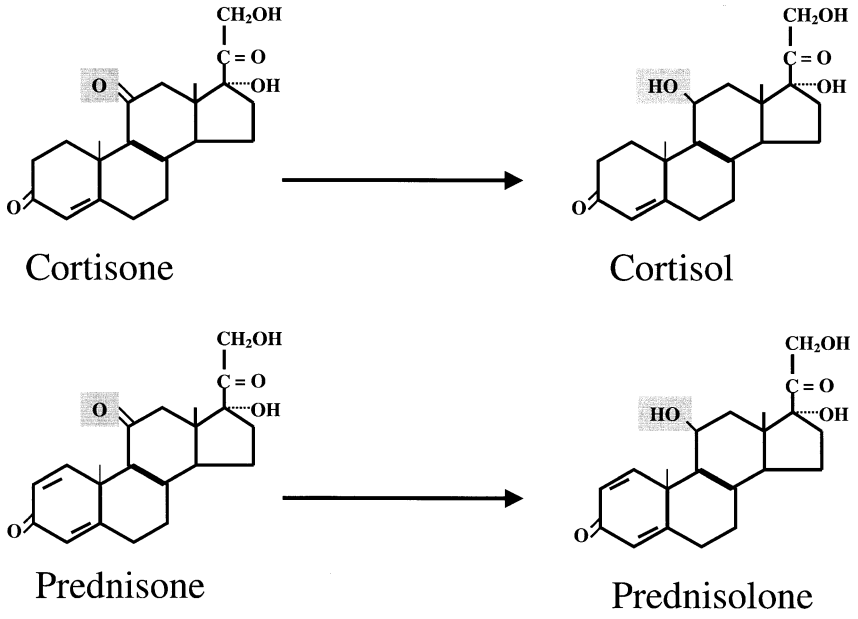

FIGURE 3 Cortisone and prednisone, which have a keto group at C-11, must undergo *in vivo* hydroxylation to cortisol and prednisolone, respectively, to become active.

TABLE 1 Comparison of the Most Commonly Used Synthetic Corticosteroids[a]

Steroids	Half-life (minutes)	Duration of action (hours)	Glucocorticoid potency	Mineralocorticoid potency	Replacement dose (mg)
Glucocorticoids					
Hydrocortisone (cortisol)	80	8–12	1.0	1.0	20
Cortisone	30	8–12	0.8	0.8	25
Prednisone	60	12–36	4.0	0.3	5
Prednisolone	200	12–36	4.0	0.3	5
Methylprednisolone	200	12–36	5.0	0.0	4
Triamcinolone	200	12–36	5.0	0.0	4
Betamethasone	300	36–72	25.0	0.0	0.6
Dexamethasone	300	36–72	30.0	0.0	0.75
Mineralocorticoids					
Fludrocortisone	240	12–24	10.0	125.0	2

[a]Cortisol is arbitrarily assigned a value of 1.0.

more mineralocorticoid activity compared to hydrocortisone. Thus, fludrocortisone is used mainly for mineralocorticoid replacement therapy. The clinically used glucocorticoids and mineralocorticoids and their pharmacology are listed in Table 1.

Various factors affecting the therapeutic activity of the various synthetic glucocorticoids should be taken into account. Different formulations of glucocorticoids are available for systemic therapy (intravenous or oral) or nonsystemic therapy. Nonsystemic therapy includes local applications as topicals, aerosols (lungs, sinus), enemas, and intra-articulars, which may decrease the occurrence of systemic side effects (see later). However, high doses and long-term administration of local therapy may also lead to significant absorption and thus systemic effects. The glucocorticoid dose may have to be increased in patients receiving other medications, including phenytoin, barbiturates, and rifampin, which induce hepatic microsomal enzyme activity and lead to increased metabolism of glucocorticoids.

VI. STEROID-BINDING PLASMA PROTEIN AND METABOLISM

In normal conditions, more than 90% of the circulating cortisol is bound to plasma protein; most is bound to cortisol-binding globulin (CBG) and the remaining, to albumin. Thus, approximately less than 10% of cortisol is in the free, unbound form, which is biologically active. Conditions such as pregnancy or estrogen therapy, which may lead to increased synthesis of CBG by the liver, are associated with elevated total plasma cortisol concentrations. In contrast, only 20% of plasma aldosterone is bound to CBG, 40% is bound to albumin, and about 40% is free. Among the synthetic steroids, only prednisone and its metabolite prednisolone may bind to proteins. This means that close to 100% of a given concentration of other synthetic steroids (including dexamethasone and fludrocortisone, which are commonly used) will circulate in the free (and metabolically active) form.

The liver and kidneys are the two major sites of glucocorticoid inactivation by metabolism. In the liver, the pathways leading to inactivation of cortisol include reduction of the double bond between positions 4 and 5 in the A ring, reduction of the keto group of the C-3, hydroxylation at the C-6 position, and subsequent conversion to tetrahydrocortisol and tetrahydrocortisone by 3-hydroxysteroid dehydrogenase. These metabolites of cortisol are then conjugated with glucuronic acid or sulfate and excreted in the urine. This biotransformation is applied to both endogenous and synthetic glucocorticoids.

Perhaps the most (metabolically) important cortisol inactivation step takes place in the kidneys and involves cortisol oxidation to cortisone by the 11β-hydroxysteroid dehydrogenase (11β-HSD) enzyme. The inactive metabolite cortisone does not bind to the kidney mineralocorticoid receptor, which normally can be activated by both cortisol and aldosterone. Thus, 11β-HSD plays a major role in balancing glucocorticoid versus mineralocorticoid activity; indeed, 11β-HSD genetic defects (syndrome of apparent mineralocorticoid excess) or acquired, functional defects (from substances such as licorice) result in cortisol-mediated mineralocorticoid effects and clinical hypertension.

VII. THERAPEUTIC USES OF GLUCOCORTICOIDS AND MINERALOCORTICOIDS

The primary therapeutic application of glucocorticoids is replacement therapy for adrenal insufficiency with hydrocortisone at a dose of 12–15 mg/m^2/day. For this purpose, physiological doses of glucocorticoids are administered in order to mimic adrenal axis secretion under normal and stressful conditions. Synthetic glucocorticoids may also be required at supraphysiological doses (pharmacologic doses) to provide anti-inflammatory and immunosuppressive effects. These therapeutic uses of glucocorticoids apply to a large spectrum of conditions, including pulmonary diseases (asthma), allergic reactions, rheumatoid arthritis, gastrointestinal inflammatory diseases, autoimmune disorders, and vasculitis syndromes; in the field of transplantations, glucocorticoids are administered to avoid graft rejection.

In all applications, the goal is to optimize the therapeutic effect of glucocorticoids using the smallest dose, in order to minimize adverse side effects. In addition, in certain conditions, corticosteroids are used transiently until an alternative therapy can control the disease. Synthetic glucocorticoids, usually dexamethasone, are also useful for the evaluation of the hypothalamic–pituitary–adrenal axis. Mineralocorticoids may be needed to replace aldosterone deficiency in primary adrenal insufficiency or after surgical adrenalectomy at the usual starting dose of fludrocortisone 0.1 mg/day.

VIII. GLUCOCORTICOID EFFECTS

Glucocorticoids regulate a large number of physiological processes and affect almost every tissue. The side effects of exogenous synthetic glucocorticoids are similar to those found in endogenous oversecretion of glucocorticoids (Cushing syndrome).

A. Hypothalamic–Pituitary–Adrenal Axis Suppression

The hypothalamic–pituitary–adrenal axis is very sensitive to negative feedback by circulating cortisol or synthetic glucocorticoids. Supraphysiological plasma concentrations of glucocorticoids suppress hypothalamic–pituitary–adrenal activity by decreasing normal endogenous production of cortisol. Thus, an abrupt cessation of a chronically administered glucocorticoid can result in the simultaneous lack of both endogenous and exogenous glucocorticoids. This situation is potentially life threatening because the hypothalamic–pituitary–adrenal axis may need up to a year to adjust and secrete cortisol at a normal rate after the cessation of exogenous glucocorticoids. The suppressive effect of glucocorticoids on the hypothalamic–pituitary–adrenal axis appears within days after starting glucocorticoid treatment. Usually, any patient who has received glucocorticoids equivalent to 10 mg or more of prednisone daily for longer than 2–3 weeks should be considered to have a suppressed hypothalamic–pituitary–adrenal axis. The time needed for the axis to recover depends on the type of glucocorticoid given, the dose and frequency of administration (i.e., daily versus alternate days), the individual metabolism, and the length of treatment. In cases of prolonged glucocorticoid administration, recovery may take 12–24 months. CRH secretion recovers first, then the normal pulsatile ACTH secretion is restored, which then leads to adrenal cortex stimulation and growth and normalization of endogenous cortisol secretion.

B. Gonadal Axis

Pharmacological doses of glucocorticoids also act on the hypothalamic–pituitary–gonadal axis by inhibiting the secretion of gonadotropins, suppressing the effect of gonadotropins on the gonads, and affecting the action of sex steroids on their target tissues. Chronic treatment with pharmacological doses of glucocorticoids produces hypogonadism associated with erectile dysfunction and infertility in men and menstrual irregularities or even secondary amenorrhea in women.

C. Glucocorticoid Effects on Catecholamines

Glucocorticoids influence the conversion of norepinephrine to epinephrine, which is carried out in the adrenal medulla. The adrenal cortex surrounds the chromaffin-containing cells in the adrenal medulla. The latter receives the adrenocortical venous effluent and thus is normally exposed to high concentrations of endogenous cortisol. The cortisol in the adrenocortical venous effluent regulates the enzyme phenylethanolamine *N*-methyltransferase, which catalyzes the conversion of norepinephrine to epinephrine and is located exclusively in the adrenal medulla and the organ of Zuckerkandl.

D. Mineralocorticoid Effects

The various glucocorticoids exhibit different affinities toward the mineralocorticoid receptor.

Glucocorticoid-induced activation of the mineralocorticoid receptor causes elevation of blood pressure, sodium retention, and potassium and hydrogen ion excretion from the kidneys. In severe cases, patients develop hypertension and hypokalemic alkalosis. Among the glucocorticoids, cortisol and, indirectly, cortisone have the highest mineralocorticoid activity. Dexamethasone and betamethasone have minimal mineralocorticoid activity, whereas prednisone and prednisolone have some, but very limited, activity.

E. Glucocorticoid Effects on the Hematopoietic and Immune Systems

Glucocorticoids, as well as other steroids, have beneficial effects on erythropoiesis and they are being used therapeutically in the treatment of various aplastic anemias. But the main use of glucocorticoids has to do with their effect on the immune system. Glucocorticoids affect the immune system at multiple levels: (1) neutrophil traffic, (2) antigen processing, (3) growth, proliferation, and function of eosinophils and mastocytes, and (4) general inhibitory effects on growth and function of lymphocytes. Within hours after administration of glucocorticoids the, number of circulating neutrophils increases as a result of alterations on their trafficking dynamics. Neutrophilia may be due to glucocorticoid-induced decrease of neutrophil adherence to the vascular endothelium and the inability of neutrophils to egress toward bone marrow or inflammatory sites.

Glucocorticoids inhibit antigen processing by macrophages, suppress T-cell helper function, inhibit synthesis of cellular mediators of the inflammatory response (i.e., interleukins and other cytokines and porstanoids), and inhibit phagocytosis. In addition, glucocorticoids stabilize lysosomal membranes and induce eosinopenia and lymphopenia. These latter effects may be due to modification of production, distribution, and/or cell lysis and are more profound on T lymphocytes as compared to B lymphocytes. Glucocorticoids also inhibit accumulation of neutrophils and monocytes at inflammatory sites. These effects explain the increased susceptibility to opportunistic infections (such as *Pneumocystis carinii* and others) seen in patients exposed to supraphysiological levels of glucocorticoids.

F. Glucocorticoid Effects on Bone Metabolism

One of the major side effects of glucocorticoids is their detrimental action on bone metabolism, growth, and function. In patients exposed to high levels of glucocorticoids, this is usually seen as low bone mineral density. Glucocorticoids cause osteoporosis by reducing bone formation and increasing bone resorption. Bone formation is decreased at several levels by direct inhibitory effects on osteoblasts, inhibition of production of insulin-like growth factor-I (IGF-I), and an increase in osteoblast and osteocyte apoptosis.

Glucocorticoids may increase bone resorption by acting directly on bone and, indirectly, by reducing androgen and estrogen secretion as a result of inhibition of the hypothalamic–pituitary–gonadal axis, and by causing dysregulation of calcium homeostasis. Glucocorticoids appear to decrease calcium intestinal absorption and increase renal calcium excretion. The combined effect of these actions leads to hypocalcemia. The parathyroid glands respond to hypocalcemia by increasing the secretion of parathyroid hormone, which, in turn, stimulates bone to release calcium into the circulation.

The inhibition of osteoblastic activity may be documented by the low concentrations of osteocalcin, a protein produced by osteoblasts. Bone resorption, on the other hand, is documented by the increased number of osteoclasts (i.e., increasing the transformation of precursor cells to osteoclasts) and increased concentrations of urine hydroxyproline, an index of bone collagen catabolism. Bone density usually increases after discontinuation of exogenous glucocorticoids or treatment of Cushing syndrome. In general, therapy for prevention of bone loss is given to patients who undergo long-term glucocorticoid therapy.

G. Glucocorticoid Side Effects on the Central Nervous System

Acute exposure to high-dose glucocorticoids may induce psychosis. Chronic exposure is often associated with neuropsychological and emotional alterations. Psychiatric disease is present in up to 70% of patients suffering from Cushing syndrome and is expressed primarily by major, atypical depression in about half of the patients. In addition, apparent cerebral atrophy has been described in patients with endogenous hypercortisolism and who are using pharmacological doses of exogenous glucocorticoids. Recent data suggest that this brain volume loss may be partially reversible following correction of hypercortisolism.

H. Glucocorticoid Effects on the Gastrointestinal Tract

Chronic administration of high doses of glucocorticoids increases the incidence of peptic ulcers. The exact mechanism is unknown, but glucocorticoids inhibit the synthesis of mucopolysaccharides, which protect the gastric mucosa from acid; glucocorticoids also increase gastric acid output in response to histamine.

I. Glucocorticoid Effects on Glucose Metabolism

Glucocorticoids were given their name because of the profound role they play in glucose metabolism. Glucocorticoids increase plasma glucose by (1) activating hepatic enzymes involved in gluconeogenesis in liver, (2) decreasing glucose uptake and utilization by peripheral tissues, (3) having a permissive role in the gluconeogenic action of counterregulatory hormones such as glucagon and catecholamines, and (4) increasing the availability of substrates for gluconeogenesis (for example, by increasing muscle proteolysis). Glucocorticoids also maintain hepatic glycogen stores by activating glycogen synthesis and inactivating glycogenolysis.

J. Glucocorticoid Effects on Lipid Metabolism

Glucocorticoids activate lipolysis in adipose tissue. On a chronic basis, supraphysiological cortisol secretion or glucocorticoid administration may lead to weight gain. The obesity is central and is characterized by moon facies, enlarged supraclavicular fat pads, and a dorsal fat pad.

IX. SUMMARY

Glucocorticoids are the "hormones of life"—they are important for the maintenance of metabolic homeostasis. It is not surprising that their pharmacological use is riddled with a number of effects, both desired and detrimental. Successful pharmacologic use requires knowledge of glucocorticoid synthesis, action, and metabolism, and complicated physiology.

Glossary

Addison's disease Autoimmune process leading to adrenal hypofunction; may be isolated or associated with polyglandular autoimmune syndrome, including diabetes, hypoparathyroidism, hypothyroidism, and mucocutaneous candidiasis.

adrenocorticotropic hormone Peptide synthesized in the pituitary and composed of 39 amino acids; stimulates the adrenal cortex to secrete cortisol and adrenal androgens.

Cushing syndrome First described by Harvey Cushing in 1912; clinical symptoms and signs secondary to chronic oversecretion of adrenal glucocorticoids (mainly cortisol); may result from increased secretion of adrenocorticotropic hormone due to pituitary or nonpituitary tumors or to a benign or malignant adrenal tumor.

cytochrome P450 A family of oxidative enzymes with a characteristic 450-nm absorbance maximum when reduced with carbon monoxide; transfer electrons from NADPH to molecular oxygen. One subgroup of these enzymes is involved in adrenal steroid biosynthesis.

glucocorticoid response elements Specific DNA sequences that are activated by the glucocorticoid receptor complex; following activation, transcription of the glucocorticoid target gene is induced.

Glucose-Dependent Insulinotropic Polypeptide (GIP)

TIMOTHY J. KIEFFER

University of British Columbia, Canada

Gastric inhibitory polypeptide (GIP) was isolated from intestinal extracts in the early 1970s as an enterogastrone—a hormone secreted in response to fat or its digestive products in the intestinal lumen and that acts to inhibit gastric acid secretion. However, a more definitive physiological role for GIP came in 1973 with the discovery that GIP is a so-called "incretin" hormone—a factor released from the gut during ingestion of glucose in order to potentiate insulin release. Notably, the insulinotropic action of GIP is dependent upon the ambient glucose concentration. Therefore, GIP was given the alternate designation glucose-dependent insulinotropic polypeptide, retaining the same acronym. In addition to the role of GIP in glucose homeostasis, GIP has a recognized role in lipid metabolism. Glucose is a potent stimulator of GIP release, as would be expected for an incretin hormone, and so too is fat. Indeed the release of GIP in response to fat is sustained beyond that which occurs with glucose. Furthermore, GIP release by fat that is not accompanied by glucose will not stimulate the release of insulin, supporting a role for GIP in fat metabolism. In such a circumstance, it is certainly desirable to have a hormone with insulin-like capabilities at the level of adipocytes in order to promote lipid absorption, without any glucose-lowering actions. GIP appears to provide this role, being quite effective at promoting postprandial triglyceride clearance without generating hypoglycemia. This article explores the metabolic roles of GIP in carbohydrate and triglyceride disposal as well as the corresponding possibility that GIP might play a role in the pathophysiology of diabetes mellitus and obesity.

I. THE ROLE OF GIP IN FAT METABOLISM

A. Discovery of GIP as an Enterogastrone

In the early 1900s, Pavlov demonstrated that fat added to a meal fed to dogs inhibited the secretion of gastric acid and pepsin. It was later discovered that this response could be mimicked by injection of extracts of the duodenal mucosa and thus suggested that a hormonal mechanism must be involved. The term "enterogastrone" was proposed to describe a putative hormone that was secreted in response to fat or its digestive products in the intestinal lumen and that inhibited gastric acid secretion. In 1970, GIP was isolated from impure intestinal extracts of cholecystokinin, a potent stimulator of gall bladder contraction. Purified porcine GIP was shown to be a potent inhibitor of gastric acid and pepsin secretion in the dog. Subsequently, it was demonstrated in rodents that this action of GIP appears to be indirectly mediated by GIP-induced release of the potent inhibitory peptide, somatostatin, from the stomach. The relative contribution of GIP as an enterogastrone in humans remains controversial, yet the highly conserved nature of the 42-amino-acid peptide suggests an important physiological function.

B. GIP Release by Fats

Consistent with the role of GIP as an enterogastrone, immunoreactive GIP (IRGIP) cells are concentrated in the upper small intestine where most fat digestion and absorption occur. Although they are most highly concentrated in the duodenum and jejunum, GIP-producing cells, termed K cells, are scattered as

far as the terminal ileum, and GIP expression has been detected in the stomach and submandibular salivary gland. The K cells are typically flask-shaped and pass through adjacent epithelial cells reaching to the lumen of the gut. The basolateral side of the cell contains secretory granules that release GIP into the blood following stimulation of the cell. The cells are believed to last for a few days before they are sloughed off; new K cells are derived from stem cells residing in the crypts of Lieberkühn.

In humans, the constituents of a mixed meal that largely determine the magnitude of GIP secretion are fats and carbohydrates (Fig. 1). While fat ingestion is a potent stimulator for GIP release in humans who typically attain ~40% calories as fat on a Western diet, fat alone is a poor stimulus of GIP secretion in species such as rats and pigs where typical diets usually provide <10% calories as fat. In the upper intestine, triglycerides are converted to free fatty acids and monoglycerides, form micelles, and then diffuse among the microvilli that form the enterocyte brush border. The high lipid solubility of the fatty acids and monoglycerides promotes their diffusion into the enterocytes. Which step in this process evokes GIP release is currently unknown, but the release of GIP in response to fat appears to require hydrolysis. Notably, long-chain fatty acids are much more potent GIP secretagogues than medium- or short-chain fatty acids, with saturated fats preferred over polyunsaturated fats. Generally, the duration of GIP release by fat is greater than that of glucose, likely attributable to the reduced rate of gastric emptying that accompanies fat ingestion and therefore the prolonged exposure of K cells to the stimulus.

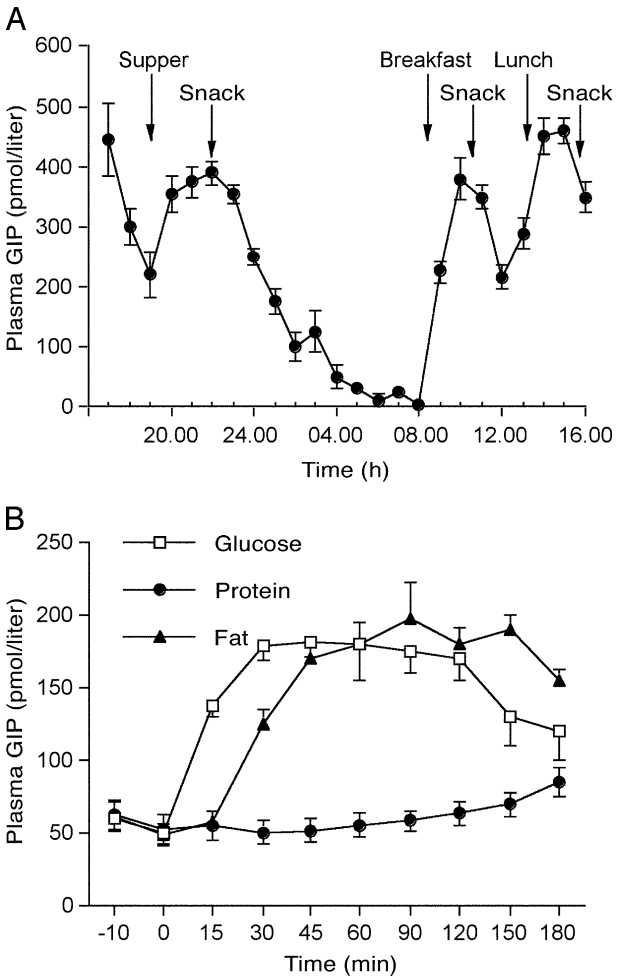

FIGURE 1 Mean plasma GIP in healthy subjects (A) consuming a normal diet over a 24 h period ($n = 6$) and (B) following ingestion of 375 kcal meals of glucose, protein, or fat ($n = 8$). Elliott *et al.*, Glucagon-like peptide-1(7-36)amide and glucose-dependent insulinotropic polypeptide secretion in response to nutrient ingestion in man: Acute post-prandial and 24-h secretion patterns. *J. Endocrinol.* **138**, 159–166, 1993, with permission of the Society for Endocrinology.

C. Lipid-Lowering Actions of GIP

While fats such as corn oil are potent stimulators of GIP release in humans, fitting with the role of GIP as an enterogastrone, the physiological function of fat-induced GIP release extends beyond that of a simple enterogastrone. There are data suggesting that GIP is an important hormonal regulator of postprandial triglyceride levels. Plasma GIP levels parallel that of triglycerides, and antibody-mediated neutralization of GIP in rats increases the triglyceride increment late in the time course of a fat load. Furthermore, exogenous GIP promotes the clearance of chylomicron triglycerides from the circulation in dogs (Fig. 2) and reduces plasma triglyceride increments following intraduodenal infusion of a lipid test meal in rats. Both inhibition of fat absorption and stimulation of triglyceride uptake by peripheral tissues may be involved in GIP action. The GIP receptor was cloned in 1993 and characterized as a member of the secretin-vasoactive intestinal polypeptide family of seven-transmembrane-spanning G-protein-coupled receptors. In support of a direct action of GIP on adipose tissue, both GIP-binding sites and receptor mRNA have been detected in adipocytes.

One way in which GIP appears to reduce plasma triglycerides is through the activation of lipoprotein lipase (LPL). Adipose tissue LPL plays a key regulatory role in the hydrolysis of circulating triglyceride, liberating nonesterified fatty acids for

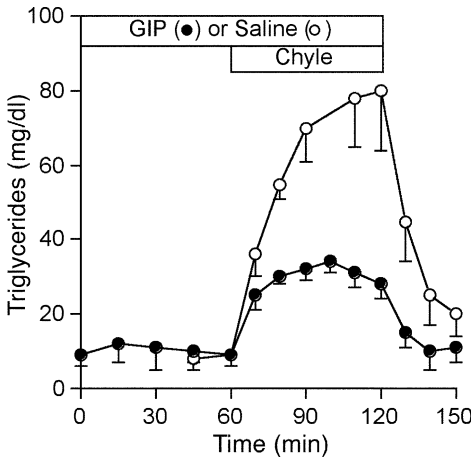

FIGURE 2 Effect of intravenously infused porcine GIP (1 μg/kg/h; filled circles) or saline (open circles) on plasma levels of triglyceride before and during infusion of chyle in normal dogs ($n = 6$ in each group). Chyle was obtained from donor dogs via a thoracic duct fistula and was infused at a rate of 2 ml/min intravenously during the period indicated by the bar. Adapted from T. Wasada *et al.*, Effect of gastric inhibitory polypeptide on plasma levels of chylomicron triglycerides in dogs. *J. Clin. Invest.* **68**, 1106–1107, 1981, with permission.

uptake and storage within the adipocyte. There are progressive parallel increases in postheparin plasma LPL and plasma GIP *in vivo* following meals of increasing fat content, without changes in insulin levels. Therefore, the postprandial lipid responses to meals of increasing fat content could be moderated by stepwise increases in LPL activity, which in turn is mediated by fat-stimulated GIP secretion. In support of this concept, GIP, in common with insulin, stimulates LPL activity in explants of rat epididymal adipose tissue and stimulates both the synthesis and the release of LPL activity in cultured mouse 3T3-L1 preadipocytes. Therefore, GIP may be the major hormonal signal linking meal size to the postprandial LPL activity in the physiological control of blood lipids.

The action of GIP on adipocytes is not limited to LPL activity. GIP has been found to enhance the insulin sensitivity of adipocytes. Interestingly, the anti-lipolytic potency of insulin is increased after oral but not intravenous administration of glucose, an effect perhaps attributable to GIP. In support of this hypothesis, adipocytes incubated with GIP develop increased insulin receptor affinity and sensitivity to insulin-stimulated glucose transport. GIP itself also stimulates glucose uptake in isolated adipocytes as well as the conversion of glucose to extractable lipids. In common with insulin, physiological concentrations of GIP were shown to stimulate fatty acid synthesis in a dose-dependent manner in explants of rat adipose tissue, as determined by measuring the incorporation of [^{14}C]acetate into saponifiable fat. Therefore, *in vivo* GIP might contribute to more effective postprandial uptake of glucose and may enhance the effect of insulin on fatty acid synthesis from glucose as a precursor.

Consistent with an overall anabolic role, GIP has been observed to inhibit glucagon-stimulated lipolysis in rat adipocytes. This is somewhat counterintuitive given that GIP itself, like glucagon, increases cAMP levels in adipocytes. One might therefore anticipate that GIP would exhibit lipolytic rather than lipogenic effects. Indeed, GIP is lipolytic in differentiated 3T3-L1 adipocytes. However, studies on the effect of insulin on GIP-stimulated glycerol release revealed that insulin is capable of antagonizing this GIP-induced lipolysis in a phosphatidylinositol 3′-kinase-dependent manner. The physiological significance of this observation remains to be established, but it is possible that the lipolytic action of GIP may normally occur only during periods of fasting when insulin levels are at their lowest. GIP levels are also at a minimum during fasting so this hypothesis requires that basal GIP be sufficient to induce lipolysis. Nevertheless, in light of observations that fatty acids are important in the maintenance of optimal β-cell function, basal GIP-induced elevations in circulating fatty acids during fasting could be important in ensuring efficient insulin secretion upon ingestion of a meal.

II. THE ROLE OF GIP IN GLUCOSE HOMEOSTASIS

A. Discovery of GIP as an Incretin

Following the 1960s development of a radioimmunoassay for insulin, the observation was made that absorption of nutrients from the gut seemed to be accompanied by the release of factors that potentiated glucose-stimulated insulin release. Indeed, the insulin response in humans to intravenous glucose was much smaller than to either oral glucose or intrajejunal infusion, even though there was a greater increase in blood glucose levels with intravenous administration. Early estimates suggested that as much as half of the insulin secreted following an oral glucose load was the result of gastrointestinal factors. This connection between the gut and the pancreatic islets was termed the "enteroinsular axis," and the putative gastrointestinal factors that augmented insulin secretion were

termed "incretins." Given that GIP was found in the upper intestine, the possibility that GIP may be an incretin hormone was raised. In 1973, it was demonstrated that a purified preparation of GIP infused intravenously in humans in concert with glucose resulted in the stimulation of insulin release and an improvement in glucose tolerance (Fig. 3). The insulin response was sustained for the duration of the GIP infusion and was not observed in the euglycemic state. With the 1978 development of a radioimmunoassay to quantify plasma GIP levels, the role of GIP as an incretin was fully established because oral glucose was found to be a potent stimulus for GIP release.

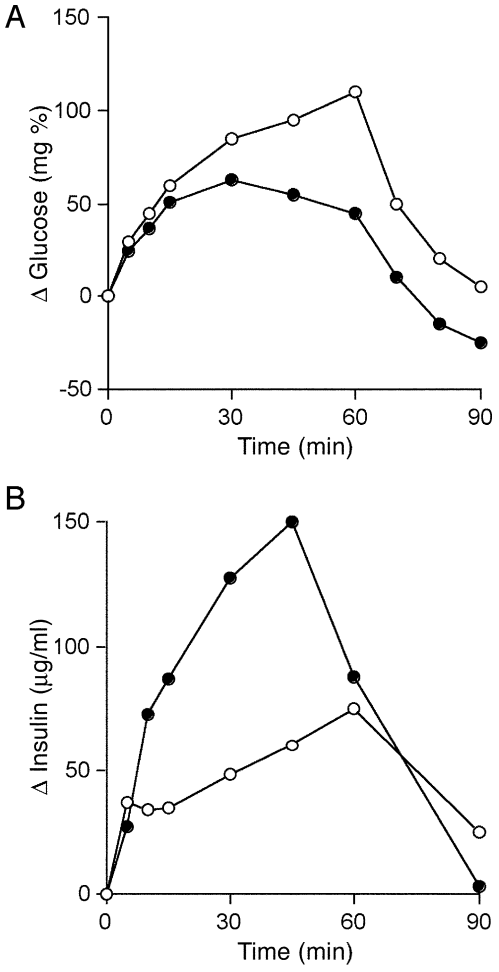

FIGURE 3 Mean changes in (A) plasma glucose and (B) serum insulin in six subjects receiving intravenous glucose alone (0.5 g/min for 60 min; open circles) or intravenous glucose with porcine GIP (1 μg/min during the first 30 min; filled circles). Adapted from J. Dupre *et al.*, Stimulation of insulin secretion by gastric inhibitory polypeptide in man. *J. Clin. Endocrinol. Metab.* **37**, 826–828, 1973, © The Endocrine Society, with permission.

Evidence from patients who had undergone intestinal resection and studies in which the activity of GIP was curtailed with antisera suggested that other incretins exist. Over a decade after the isolation of GIP, analysis of the proglucagon gene revealed that whereas glucagon is the main proglucagon-derived product in pancreatic α-cells, glucagon-like peptides 1 and 2 are liberated by tissue-specific processing of the same precursor protein in endocrine cells located in the distal small intestine. Shortly thereafter, GLP-1, but not GLP-2, was determined to be a potent insulin secretagogue, whose action, like that of GIP, is glucose dependent. Plasma GLP-1 levels increase briskly following oral glucose administration, albeit not nearly as much as the GIP levels increase. The site of release of GLP-1, predominantly the ileum, does not entirely fit with the concept of an incretin hormone, given that the bulk of nutrients are already absorbed in more proximal regions of the gut. Interestingly, however, a proximal-distal loop has been identified in which GIP release from the proximal gut stimulates GLP-1 release from the distal gut, at least in rats. Evidence for a similar pathway in humans is lacking. Nevertheless, GIP and GLP-1 collectively appear to fully account for the intestinally derived hormonal augmentation of insulin secretion following oral nutrients.

B. GIP Release by Carbohydrates

The concentration of K cells in the duodenum and jejunum fits with the role of GIP as an incretin hormone, as this is where most carbohydrate digestion and absorption occur. Interestingly, IRGIP has been localized to a distinct cell type in the islet organ of elasmobranchs, and evolutionarily it appears that GIP cells are not found in the gut mucosa until a distinct islet organ evolves upon which the peptide may act, i.e., the hagfish. K cells respond relatively poorly to complex carbohydrates but release GIP in response to the digestion products galactose and glucose, with the latter being the most potent. Fructose is a poor GIP secretagogue. There is a direct relationship between the glucose load ingested and the magnitude of GIP release. In general, plasma GIP levels increase several fold following oral glucose administration, slightly preceding insulin release with a peak in peripheral venous blood at 15–30 min and a return to basal levels by 2 h. Notably, the magnitude of the increase is much greater in pigs, monkeys, and humans than it is in rodents. It appears as though the cells respond directly to lumenal glucose and not changes in plasma glucose levels. The mechanism by

which K cells "sense" glucose is not entirely clear, but appears to require active transport as opposed to the mere presence of glucose in the lumen. It is possible that they receive a signal from neighboring enterocytes during the transport of glucose from the lumen into the blood. However, K cells express the so-called glucose sensor, glucokinase, and K-cell cultures respond to changes in glucose concentrations, suggesting that the K cells themselves may be directly glucose-sensitive.

C. Insulinotropic Action of GIP

Once released, GIP stimulates insulin secretion in a dose-dependent manner, provided that there is sufficient plasma glucose. At a fasting concentration of glucose, GIP is not insulinotropic. In the perfused rat pancreas, an ambient glucose concentration of ~5.5 mM is required to see significant potentiation of insulin release by physiological concentrations of GIP. In addition, the insulinotropic action of GIP increases with increasing glucose concentrations, with maximal potentiation at ~16 mM glucose in the perfused rat pancreas. The glucose dependency of GIP-stimulated insulin secretion provides an important safeguard against hypoglycemia by preventing the inappropriate stimulation of insulin release during a high-fat, low-carbohydrate meal. In addition to stimulating insulin release, GIP has been found to stimulate insulin gene expression, perhaps an important mechanism in balancing insulin stores to nutritional status.

The direct action of GIP on pancreatic β-cells is supported by the finding of GIP receptors in pancreatic islets and in membranes from insulin-secreting tumor-derived β-cell lines. In pancreatic β-cells, GIP binding is associated with activation of adenylate cyclase and increases in cAMP content with a resultant increase in intracellular Ca^{2+} concentration that parallels insulin release. In Chinese hamster ovary cells transfected with the GIP receptor, GIP has also been reported to activate mitogen-activated protein kinase through a wortmannin-sensitive pathway and to generate the signaling molecule arachidonic acid through phospholipase A_2-mediated hydrolysis of membrane phospholipids. The mechanism of the glucose-dependent nature of GIP-induced insulin secretion is not fully understood.

Although C-terminal truncation of GIP to GIP 1-30 does not impair the ability of GIP to stimulate insulin secretion, an intact N-terminal portion is required for full activity. Following its release, the metabolic action of GIP is curtailed through rapid clearance and degradation. The circulating half-life of GIP in plasma as determined by immunoreactivity is approximately 20 min, with the kidney being the major site of clearance. However, the biological half-life is much shorter, in the range of 1 to 2 min. GIP 1-42 is rapidly cleaved by the ubiquitous protease dipeptidyl peptidase IV (DPPIV), rendering GIP 3-42, which has been found to possess little if any insulinotropic activity. Thus, the biological activity of exogenous or endogenous GIP can be significantly extended with the use of DPPIV inhibitors.

The physiological significance of the insulinotropic action of GIP has been investigated by the use of antagonists and immunoneutralizing antisera. Collectively, these studies confirm that GIP plays an important anticipatory role in promoting brisk insulin secretion following the ingestion of glucose. Thus, when GIP action is impaired, insulin secretion is delayed, resulting in impaired glucose tolerance. Blocking GIP action does not alter basal glucose levels or the glucose excursion following administration of intraperitoneal glucose, suggesting that the role of GIP in glucose control is restricted to functioning as an incretin in the postabsorptive state. These findings have been confirmed by the recent generation of mice harboring a disrupted GIP receptor. These mice have normal fasting blood glucose, but higher glucose levels with an impaired initial insulin response after oral glucose administration (Fig. 4). In contrast, studies with GLP-1 antagonists and GLP-1 receptor knockout mice indicate that GLP-1 signaling appears to be essential for glycemic control both during fasting and after a glucose challenge, independent of the mode of glucose entry. Although most reports indicate that GLP-1 has more potent insulinotropic activity than GIP, it is generally agreed that GIP levels increase more dramatically following a meal. When GIP and GLP-1 are administered at doses chosen to produce plasma levels roughly comparable to values measured after oral glucose in humans (~450 and ~50 pM, respectively), the β-cell response to intravenous glucose is augmented to values not significantly different from those after oral glucose, and GIP appears to make the larger contribution.

III. GIP IN THE PATHOPHYSIOLOGY OF OBESITY AND DIABETES

A. Role of GIP in Obesity

Given the clear physiological metabolic roles of GIP in glucose and lipid disposal, there is a possibility that

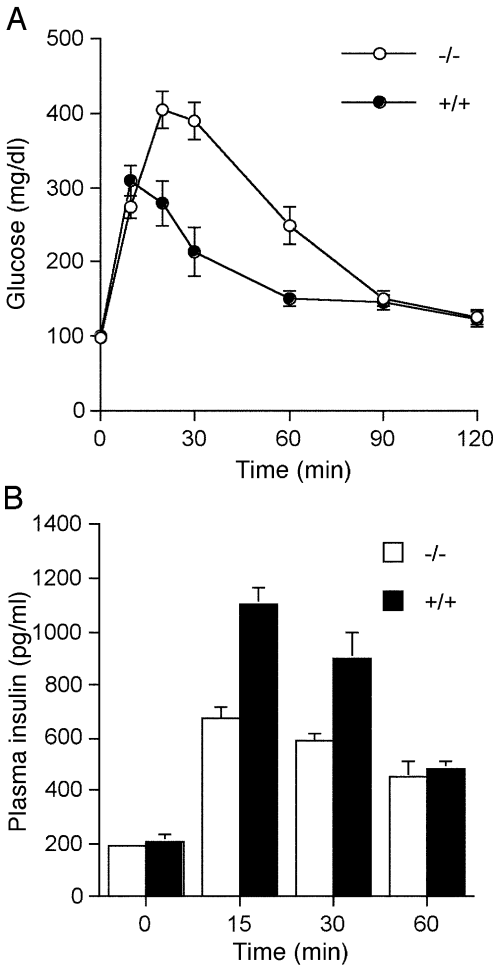

FIGURE 4 Oral glucose tolerance test in age-matched wild-type mice (+/+, filled symbols, $n = 4$) and GIP receptor knockout mice (−/−, open symbols, $n = 6$). After a 16 h fast, mice were administered glucose (2 g/kg body weight) and blood samples were collected from the tail vein at the indicated times for (A) glucose and (B) insulin determinations. From K. Miyawaki *et al.*, Glucose intolerance caused by a defect in the entero-insular axis: A study in gastric inhibitory polypeptide receptor knockout mice. *Proc. Natl Acad. Sci. USA* **96**, 14843–14847, 1999, with permission. Copyright (1999) National Academy of Sciences, U.S.A.

GIP may be involved in the pathophysiology of obesity and/or diabetes. Some studies have detected elevated fasting and fed plasma GIP levels in obese subjects, which, given the adipogenic nature of GIP combined with the typically elevated insulin levels, could contribute to excess fat mass. Elevated GIP levels might be explained by the observation that the expression of GIP appears to be coordinated with nutritional status. In response to fasting, rodent intestinal GIP mRNA levels decrease. One day after refeeding with either fat or glucose, GIP mRNA levels increase several fold. In response to oral glucose, increases in duodenal GIP mRNA can be detected within a few hours, as can mucosal GIP concentrations. Increased GIP expression in response to glucose seems to involve both pre- and posttranslational mechanisms. In humans, glucose-stimulated GIP secretion is increased following a high-fat diet, and caloric restriction can abolish the exaggerated GIP response to a mixed meal in obese subjects, suggesting that a previously high calorie intake might have been responsible for the excessive GIP production. Even an increased number of K cells themselves could be a contributing factor, as in mice fed high-fat or high-carbohydrate cafeteria diets there is an ~50% increase in the density of K cells in the upper duodenum. Elevated levels of an anabolic hormone such as GIP, especially at a time when food is plentiful, might be a predicted physiological response to efficiently store calories as fat in order to survive a prolonged fast. In this sense, GIP can be considered the product of a so-called "thrifty gene." However, given readily available high-calorie foods and the Western diets rich in fats and ingested in large quantities, combined with the virtually limitless fuel storage capacity of adipocytes, this function may have become maladaptive. Therefore, elevated GIP levels may play a role in the development of obesity, and it is possible that strategies that attenuate GIP action might reduce body weight. However, given the important role of GIP in promoting insulin secretion, therapies involving the use of a GIP antagonist, for example, could have accompanying undesirable effects on glucose homeostasis. In this regard, it is notable that in GIP receptor knockout mice, there is a failure to enhance insulin secretion following a high-fat diet. Thus, while control mice maintain normoglycemia on the diet with elevated insulin levels, the GIP receptor knockout mice gain less weight at the expense of becoming glucose intolerant. These findings underscore the important role that GIP plays in the compensatory enhancement of insulin secretion produced by a high insulin demand and raises the possibility that a defect in this action of GIP may contribute to the pathogenesis of diabetes.

B. Role of GIP in Diabetes

It has been recognized for some time that subjects with type 2 diabetes mellitus have a severely attenuated incretin response; insulin release is no longer stimulated more by oral glucose than by "isoglycemic" intravenous glucose. Given that diabetes develops only when insulin secretion becomes

inadequate, it is of considerable importance to understand the mechanism behind this impaired insulin secretion. In subjects with diabetes, circulating GIP and GLP-1 levels have been reported to be increased, normal, or decreased following administration of nutrients, relative to controls. Thus, there is no clear evidence that the secretion of either GIP or GLP-1 is consistently impaired in subjects with diabetes. However, when one compares the insulinotropic activity of the two hormones in patients with type 2 diabetes, an interesting difference emerges. GLP-1 is typically very potent in these patients. Indeed, the peptide is so effective that numerous studies have now shown that its administration may completely normalize blood glucose levels. In contrast, GIP has little or no effect on insulin secretion in subjects with type 2 diabetes. In parallel studies of GLP-1 and GIP, the full efficacy of GLP-1 and the lack of effect of GIP have been documented in the same patients. Therefore, the possibility has been raised that a defect in the insulinotropic action of GIP could contribute to the impaired secretion of insulin associated with diabetes. However, to date, the reason for the inability of GIP to potentiate insulin secretion in subjects with diabetes has not been identified. GIP receptor mutations do not appear to be responsible. Furthermore, given that both GLP-1 and GIP signal via the same pathways, there does not appear to be a postreceptor defect. Interestingly, in obese *fa/fa* rats that are unresponsive to GIP but display normal sensitivity to GLP-1, there is a dramatic reduction in the expression of islet GIP receptors compared to expression in lean controls. Whether the same phenomenon occurs in humans and contributes to the impaired incretin effect associated with diabetes remains to be determined.

IV. CONCLUSION

Originally identified as an enterogastrone, GIP has emerged as a critical metabolic hormone for the maintenance of normal energy homeostasis. The secretion of GIP from gastrointestinal K cells is acutely regulated by the absorption of glucose and fat and is produced in direct proportion to the quantities of these nutrients ingested. By its glucose-dependent insulinotropic actions on pancreatic β-cells and synergistic effects with insulin on adipocytes, GIP ensures the efficient disposal of the absorbed nutrients. K-cell number and GIP production are also adjusted over the long term in order to accommodate changes in nutritional intake. Although a hyperphagia-induced increase in GIP levels is undoubtedly important in producing compensatory increases in plasma insulin levels, the adipogenic nature of GIP, combined with hyperinsulinemia, could contribute to the development of obesity. It is possible that prolonged hypergipemia followed by eventual GIP desensitization could explain the impaired incretin effect that is associated with type 2 diabetes, itself so often accompanied by obesity. Thus, whereas incretin research has largely focused on GLP-1 as a result of its retained therapeutic potential, a full understanding of the factors contributing to the pathogenesis of diabetes associated with obesity may require a closer look at GIP.

Glossary

crypts of Lieberkühn The base of tubular invaginations in the intestinal mucosa containing rapidly dividing undifferentiated stem cells that continuously produce new epithelial cells.

enterogastrone An intestinal hormone that is secreted in response to fat or its digestion products and inhibits gastric acid secretion.

enteroinsular axis Nutrient, neural, and hormonal signals arising from the gut that regulate hormone secretion from the endocrine pancreas.

incretin A hormone that is released from the intestine in response to the ingestion of glucose and stimulates insulin secretion from pancreatic β-cells.

Gonadotropin-Releasing Hormone (GnRH)

JON E. LEVINE
Northwestern University

The central nervous system regulates reproductive hormone secretions primarily through the neurosecretion of gonadotropin-releasing hormone. The decapeptide is synthesized in neurons of the basal forebrain, transported intraneuronally to neurovascular junctions in the median eminence of the hypothalamus, and released into the hypothalamic–hypophyseal portal vasculature.

I. INTRODUCTION

Following portal transport to the anterior pituitary, gonadotropin-releasing hormone (GnRH) can bind receptors located in the plasma membranes of gonadotropes and activate their associated signal transduction pathways. The major actions of GnRH include stimulation of the synthesis and secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). In the absence of GnRH release, secretion and synthesis of LH are virtually halted, FSH production is diminished, and gonadal activities are either impaired or completely arrested. Infertility is an invariant consequence of total GnRH deficiency.

Neurosecretion of GnRH is almost invariably intermittent, consisting of pulses of secretion that occur regularly at intervals of 20 min or more, depending on the species and physiological circumstances. The pulsatile GnRH release pattern, moreover, is obligatory for maintaining normal gonadotropin secretion and synthesis. Although

control, substantial evidence now exists implicating astrocytes and several of the growth factors they produce as essential components of the facilitatory mechanisms by which the hypothalamus controls GnRH secretion during sexual development. This article develops the concept that the pubertal activation of GnRH secretion is not determined by a single mode of transsynaptic communication but is instead set in motion by at least three interrelated events, two involving transsynaptic pathways (a decrease in GABAergic inhibition and an increase in glutamatergic stimulation) and a third involving the activation of reciprocal glial–neuronal communication mechanisms.

II. THE TRANSSYNAPTIC CONTROL OF GnRH NEURONS

Studies in rhesus monkeys have demonstrated that the most important inhibitory transsynaptic input controlling GnRH secretion during prepubertal development is provided by GABAergic neurons, which appear to use mainly a type of intrinsic membrane protein known as the $GABA_A$ receptor to exert this effect. The physiological importance of this regulatory mechanism is highlighted by the dramatic advancement of puberty induced in female monkeys by the pharmacological blockade of hypothalamic $GABA_A$ receptors. Whether this inhibition is directly exerted on GnRH neurons, which contain functional $GABA_A$ receptors, or through neurons synaptically connected to the GnRH neuronal network is currently the subject of intense investigation. It has been recently shown by DeFazio and colleagues that GnRH neurons respond with excitation to direct GABA inputs mediated by $GABA_A$ receptors. There is, however, electrophysiological evidence indicating that another type of membrane-embedded GABA recognition molecule, the $GABA_B$ receptor, present on GnRH neurons, mediates a direct and powerful GABAergic inhibitory signal of GnRH neuronal activity. It would appear intuitively reasonable to infer that if GABA utilizes $GABA_B$ receptors to directly inhibit GnRH neurons, then a second inhibitory influence provided by the same neurotransmitter would be exerted on excitatory neuronal subsets connected to GnRH neurons, instead of GnRH neurons themselves. Experimental verification of this idea has not yet been provided.

In opposition to the GABAergic system, enhancement of glutamatergic neurotransmission—the primary mode of transsynaptic excitatory communication used by hypothalamic neurons—accelerates the initiation of puberty. For instance, the premature activation of a class of glutamate recognition molecules present in the cell membrane, and known as *N*-methyl-D-aspartate (NMDA) receptors, has been shown to increase GnRH secretion and advance sexual maturation in both rats and monkeys. During normal sexual development, there is an activation of NMDA receptors at the onset of puberty that occurs even in the absence of the gonads. The physiological importance of this activation was demonstrated by the ability of the pharmacological blockade of NMDA receptors to delay sexual development in female rats. Despite its effectiveness in affecting the timing of puberty, NMDA receptors are not the only class of glutamate recognition molecule involved in stimulating GnRH secretion in developing animals. In fact, only a small subset of GnRH neurons express NMDA receptors during prepubertal development. In contrast, many of them express another class of cell membrane-associated proteins, known as kainate receptors, that also recognize glutamate with high affinity. Stimulation of the hypothalamus with kainate increases both LH and GnRH release, indicating that glutamatergic neurons utilize at least two classes of glutamate receptors to facilitate GnRH secretion: NMDA receptors, located mostly on neurons synaptically connected to GnRH neurons, and kainate receptors, present on GnRH neurons themselves. Using a more sensitive method, Ottern and colleagues showed that up to 80% of GnRH neurons express NMDA receptors. An appropriate strength of the glutamatergic inputs converging onto the GnRH neuronal network appears to be critical for the maintenance of pulsatile GnRH release, as these pulses are obliterated when glutamate synthesis is blocked in the developing hypothalamus.

The above considerations make clear that opposite changes in glutamatergic and GABAergic neurotransmission are critical components of the cell–cell communication process underlying the activation of GnRH release at puberty. They do not, however, tell us which of the two events occurs first. An increase in glutamatergic transmission may precede the pubertal loss in GABAergic inhibitory inputs, as activation of certain glutamate receptors in other brain regions inhibits GABA release. The facts that the primate hypothalamus contains twice as many glutamatergic synapses as GABAergic synapses and that in this species GABAergic neurons receive a strong glutamatergic input suggest that a glutamate-to-GABA hierarchy may, indeed, represent a critical transsynaptic relationship underlying the initiation of puberty. Evidence favoring the alternative possibility,

i.e., that a decrease in GABAergic inhibitory transmission precedes the increase in glutamatergic input at the onset of puberty, also exists. For instance, glutamate release into the median eminence of peripubertal monkeys has been shown to increase following an experimental reduction of GABA synthesis, and GABA neurons have been observed to innervate a subset of glutamatergic neurons in the primate hypothalamus.

Other neurotransmitters/neuropeptides, such as norepinephrine and Neuropeptide Y (NPY), contribute to facilitating the advent of puberty, but in a secondary fashion. The role of NPY is, however, controversial, as NPY has been shown to either facilitate or inhibit GnRH secretion during peripubertal development.

III. THE GLIAL CONTROL OF GnRH neurons

Astroglial cells regulate GnRH secretion via both plastic rearrangements and direct cell–cell communication. Several growth factors, produced by glial cells, have been implicated in the mechanism by which astrocytes facilitate GnRH secretion. The most well studied are transforming growth factor-β (TGF-β), insulin-like growth factor1 (IGF-I) basic fibroblast growth factor, and the family of epidermal growth factor (EGF)-related polypeptides. Nonpeptidergic molecules produced in astrocytes (such as calcium, prostaglandin E2 (PGE2), and glutamate) have also been shown to stimulate GnRH release.

An involvement of TGF-βs in the facilitatory control of GnRH secretion was suggested by studies using a GnRH neuronal cell line and hypothalamic astrocytes in culture. In these experiments, TGF-β1, secreted from astrocytes, was found to stimulate GnRH release directly via receptors located on "immortalized" GnRH neurons (i.e., neurons able to perpetuate themselves in culture). Moreover, TGF-β1 release from hypothalamic astrocytes was enhanced by estradiol, suggesting that astrocytic TGF-β1 may contribute to the mechanism by which the hypothalamus generates the surge of GnRH that, by stimulating the secretion of pituitary gonadotropins, triggers ovulation. Adult GnRH neurons do contain TGF-β receptors, indicating that they—like immortalized GnRH neurons—are also a target for TGF-β1 action. Whether TGF-β1 is physiologically involved in the control of the onset of puberty remains to be determined. Likewise, it is unclear whether the main effect of TGF-β1 on GnRH neurons *in situ* is to facilitate GnRH secretion, because—in contrast to their stimulatory effect on immortalized cells—neither TGF-β1 nor TGF-β2 is able to stimulate GnRH release from the median eminence of the hypothalamus. Perhaps the main role of TGF-β1 is to promote some other aspect of GnRH neuronal function, such as changes in neuronal shape and/or changes in the contact that exists between GnRH nerve terminals and glial cells in the median eminence of the hypothalamus.

In contrast to TGF-β1, a stimulatory effect of IGF-I on GnRH release from the prepubertal hypothalamus is well established. It is also clear that IGF-I is a facilitatory signal for puberty to occur. The central administration of IGF-I advances puberty in both rodents and primates, and the loss of IGF-I in mutant mice lacking growth hormone receptors (which upon growth hormone binding stimulate the production of IGF-I) results in delayed sexual development. Although IGF-I is produced in astrocytes, it appears that the bulk of IGF-I-stimulating GnRH secretion either at puberty or during the estrous cycle derives from a peripheral source(s) (likely the liver) instead of hypothalamic astrocytes. Thus, IGF-I represents one of the metabolic signals long suspected to play a role in facilitating the onset of mammalian puberty.
