Helen L. Henry

University of California, Riverside

Helen L. Henry received her Ph.D. in 1970 from Washington University, St. Louis, and did postdoctoral work in animal reproduction at Ohio State University. Following further postdoctoral work at the University of California, Riverside, she joined the faculty and is currently a professor of biochemistry. From 1990 to 1996, she served as Associate Dean of Biological Sciences in the College of Natural and Agricultural Sciences.

Dr. Henry's laboratory has made major contributions to the understanding of vitamin D metabolism, particularly regulation of the production of the active vitamin D hormone by the kidney. She pioneered the use of cell culture systems to study renal vitamin D metabolism. A related area of research focus is the regulation of gene expression in the kidney by 1,25-dihydroxyvitamin D_3. In addition to peer-reviewed research articles, Dr. Henry has authored chapters for the books *Vitamin D* and *Handbook of Physiology*, as well as the article "Vitamin D Metabolism" for this encyclopedia.

Dr. Henry was awarded a National Institutes of Health (NIH) Research Career Development Award in 1977. She received the Fuller Albright Award from the American Society for Bone and Mineral Research in 1984 and has served this society as a member of the council and on several scientific program committees. Dr. Henry has been a member of the NIH General Medicine B Study Section (1989–1993) and the National Science Foundation Panel on Integrative Biology (1994–1996). She has served on the editorial boards of several scientific journals, including *Endocrinology*, *American Journal of Physiology*, and *Journal of Bone and Mineral Research*. She is currently a member of the Endocrine Society, the American Society of Biochemistry and Molecular Biology, the American Society for Bone and Mineral Research, and the American Institute of Nutritional Sciences.

Anthony W. Norman

University of California, Riverside

Anthony W. Norman received an A.B. from Oberlin College in 1959, and an M.S. and Ph.D. in biochemistry in 1961 and 1963, respectively, from the University of Wisconsin, Madison. Following postdoctoral work in Paul D. Boyer's group at UCLA, in 1964 he joined the Department of Biochemistry at the University of California, Riverside, as an assistant professor. From 1976 to 1981, he served as chair of the department and currently holds a Presidential Chair and is a Distinguished Professor of Biochemistry and Biomedical Sciences. Dr. Norman has also been active for some 25 years in medical education on the UC Riverside campus and at UCLA through participation in the UC Riverside/UCLA Program in Biomedical Sciences, of which he was Dean and Director from 1986 to 1991.

Dr. Norman's biomedical research career has focused on the mechanism of action of the vitamin D family of steroids. His chief contributions to these areas of cellular and molecular endocrinology have played a pivotal role in defining the boundaries of this research domain via discoveries that have opened new areas of investigation. The first of these was the discovery in 1968, and chemical characterization in 1971, of the hormonally active form of vitamin D, $1\alpha,25(OH)_2$-vitamin D_3. Subsequent achievements include the discovery and characterization of the nuclear receptor for $1\alpha,25(OH)_2D_3$, the clinical evaluation of $1\alpha,25(OH)_2D_3$ in renal osteodystrophy, articulation of the concept of the vitamin D endocrine system, the importance of $1\alpha,25(OH)_2D_3$ to insulin secretion, and the discovery of a new rapid, nongenomic, signal transduction process for $1\alpha,25(OH)_2D_3$.

Dr. Norman has been the recipient of awards that include a Fulbright Fellowship, 1970; Public Health Service Career Development Award, 1970; Mead Johnson Award, American Institute of Nutrition, 1977; Ernst Oppenheimer Award, Endocrine Society, 1977; Visiting Lecturer, Australian Society of Endocrinology, 1978; Visiting Faculty Member, Mayo Clinic, 1981; Prix Andre Lichtwitz (INSERM, Paris, France), 1981; Faculty Research Lecturer, UC Riverside, 1982; MERIT Award from National Institutes of Health, 1986; David Curnow Plenary Lecturer, Australian Society for Clinical Biochemistry, 1989; Osborne and Mendel Award, American Institute of Nutrition, 1990; Visiting Professor, Catholic University of Leuven, Belgium, 1992; William F. Neuman Award, American Society for Bone and Mineral Research, 1995; Fellow of American Association for the Advancement of Science, 1995; and Visiting Professor, Department of Biochemistry, UC San Francisco/Presidential Chair in Biochemistry, UC Riverside, 1999.

Antony W. Burgess

Ludwig Institute for Cancer Research, Melbourne, Australia

Antony W. Burgess has had an interest in protein chemistry since his early studies on the conformational determinants of peptides and proteins. He received a Ph.D. at the University of Melbourne; after postdoctoral studies at Cornell University and the Weizmann Institute between 1972 and 1974, Dr. Burgess returned to Australia, to the Walter and Eliza Hall Institute, to study the growth factors that stimulate blood cell formation. He and his colleagues purified the first colony-stimulating factor (CSF) and discovered growth and differentiation factors controlling the development of blood cells. This work led to the molecular cloning of a CSF and the initial clinical studies with recombinant forms of these factors.

Dr. Burgess was involved in the detection and biology of the cell surface receptors for the CSFs before taking up studies on the epidermal growth factor (EGF)/receptor system. These studies have contributed to the understanding of the three-dimensional structure of EGF and its receptor, as well as the mechanisms associated with signal transduction from the different EGF receptor complexes. At present, Dr. Burgess is attempting to develop improved approaches to cancer therapy through the use of EGF receptor inhibitors. He has an active research program on the molecular basis of colon cancer, in particular the biology and molecular biology of the apc protein.

Presently on staff at the Ludwig Institute for Cancer Research in Melbourne, Dr. Burgess is a committee member of the ARC Selection Committee for Centres of Excellence, a past president of the Australian Society for Biochemistry and Molecular Biology, a former chairperson of the Board of the Biomolecular Research Institute, a former board member of the International Society of Differentiation, and a former World Committee member of the Society for Research into Comparative Leukemic and Associated Diseases. He has been awarded honors that include the Australian Academy of Science Gottschalk Medal, 1981; Australian Academy of Science Fellow, 1993; the Amgen Prize, 1996; Companion of the Order of Australia, 1998; and the MOG/AMRAD Cancer Achievement Award, 1999.

P. Michael Conn

Oregon National Primate Research Center, Beaverton, Oregon

P. Michael Conn is Associate Director and Senior Scientist of the Oregon National Primate Research Center and Special Assistant to the President and Professor of Physiology and Pharmacology at Oregon Health and Science University. After receiving a B.S. and teaching certification from the University of Michigan in 1971, an M.S. from North Carolina State University in 1973, and a Ph.D. from Baylor College of Medicine in 1976, Dr. Conn did a fellowship at the NIH/National Institute of Child Health and Human Development. He then joined the faculty in the Department of Pharmacology at Duke University Medical Center, where he was promoted to Associate Professor in 1982. In 1984, he became Professor and Head of Pharmacology at University of Iowa College of Medicine, a position he held for 11 years.

Dr. Conn is presently Editor-in-Chief of *Endocrine, Methods*, *Contemporary Endocrinology,* and *Contemporary Drug Therapy*; prior Editor-in-Chief of *Endocrinology*, *Molecular and Cellular Neurosciences*, *Methods in Neuroscience,* and *Recent Progress in Hormone Research*; and prior Editor of *Journal of Clinical Endocrinology and Metabolism*. He has edited texts in the fields of pharmacology (*Essentials of Pharmacology*), neuroscience (*Neuroscience in Medicine*), neuroendocrinology (*Neuroendocrinology in Physiology and Medicine*), endocrinology (*Endocrinology: Basic and Clinical Principles*), and molecular endocrinology (*Principles of Molecular Regulation),* as well as more than 100 volumes in endocrinology and neuroscience.

Best known for his research in the area of neuroendocrinology, Dr. Conn has focused on the cellular basis of action of gonadotropin-releasing hormone action in the pituitary and central nervous system. He has authored or coauthored nearly 300 publications in this area. The work of his laboratory has been recognized with the MERIT Award from the NIH, the J.J. Abel Award of the American Society for Pharmacology and Experimental Therapeutics, the Weitzman and Oppenheimer awards of the Endocrine Society, the National Science Medal of Mexico (the Miguel Aleman Prize), and the Stevenson Award of Canada. Dr. Conn has served on the National Board of Medical Examiners, including two years as

Chairman of the Reproduction and Endocrinology Committee, and is a previous member of council for the American Society for Cell Biology and a past president of the Endocrine Society. Conn is a member of the Mexican Institute of Medicine and an honorary investigator of the Mexican Institute of Social Security.

George H. Greeley, Jr.

University of Texas Medical Branch, Galveston, Texas

George H. Greeley, Jr. earned his Ph.D. in endocrinology at the Medical College of Georgia in 1974 and was recently recognized by the school as alumni of the year. Dr. Greeley did postdoctoral training in neuroendocrinology at the University of North Carolina in Chapel Hill. Presently, he directs an internationally recognized research program in physiology of gastrointestinal hormones in the Department of Surgery at the University of Texas Medical Branch in Galveston.

Dr. Greeley has authored or coauthored more than 190 peer-reviewed journal articles and serves on the editorial boards of *Endocrinology*, *American Journal of Physiology*, and *Regulatory Peptides*. His primary areas of research include feedback mechanisms underlying regulation of gut hormone secretion, a new stomach hormone called ghrelin, and luminal regulation of cholecystokinin (CCK) secretion. Honors awarded Dr. Greeley include the NATO Collaborative Research Grant, 1989 to present; Invited Participant, Second Galveston International Symposium, Galveston, Texas, 1989; Invited Participant, International Conference of Gut Hormones, Shizuoka, Japan, 1993; Mentor in the APS–NIDDK Travel Fellowship Program for minority students, Experimental Biology Meetings, 1995, 1996; and Mentor, American Gastroenterological Association, Endocrine Society, Summer Student Research Fellowship Recipients, 1995–1998.

Martin J. Kelly

Oregon Health and Science University, Portland, Oregon

Martin J. Kelly is a professor of physiology and pharmacology at Oregon Health and Sciences University (OHSU). He obtained his Ph.D. in 1976 from the University of Texas Southwestern Medical School in Dallas and did his postdoctoral training at the Max Planck Institute for Biophysical Chemistry (1976–1979). In 1980, Dr. Kelly joined the Department of Physiology at the University of Pittsburgh School of Medicine and moved to OHSU in 1982. His area of research is the cellular neurophysiology and neuropharmacology of hypothalamic neurons that control neuroendocrine functions, motivation, and reward in the female. Dr. Kelly has been the recipient of two research scientist development awards from the NIH, the Research Career Development Award from the National Institute of Child Health and Human Development (1987–1992), and the Research Scientist Development Award from the National Institute on Drug Abuse (1994–1999).

Dr. Kelly was the first to demonstrate rapid signaling of estrogen in the central nervous system and to show how it alters reproductive function in the female. In particular, he found that 17β-estradiol can directly alter the excitability of gonadotropin hormone-releasing hormone (GnRH) neurons, which are critical for the control of female reproduction. He also found that the rapid activation by estrogens of protein kinase activity in hypothalamic opioid and dopamine neurons alters the coupling of neurotransmitter receptors to their effector systems (e.g., channels) in the female. These results have significant ramifications in terms of stress responses, appetite control, fluid balance, and motivated behaviors, and may explain many of the gender differences in these functions.

Dr. Kelly and colleagues are also interested in characterizing the membrane properties of proopiomelanocortin (POMC), dopamine, and GnRH neurons in males and females, and the effects of neurotransmitters on these neurons. Using guinea pigs and transgenic mice as models, they are trying to identify the phosphorylated target proteins that are altered by neurotransmitters and steroids in hypothalamic neurons that are critical for the control of neuroendocrine functions, motivation, and reward in the female. Dr. Kelly's recent manuscripts include "Rapid Actions of Plasma Membrane Estrogen Receptors" with E. R. Levin in *Trends in Endocrinology and Metabolism* and "Rapid Membrane Effects of Estrogen in the CNS" with O. K. Rønnekleiv in the Academic Press book *Hormones, Brain and Behavior.*

Paul B. Larsen

University of California, Riverside

Paul B. Larsen received his Ph.D. from Purdue University in 1994, did postdoctoral work at Cornell University (1994–1997) and at the University of

Maryland (1997–2000), where he was also a U.S. Department of Agriculture Fellow. Dr. Larsen is presently an assistant professor of biochemistry in the College of Natural and Agricultural Sciences at the University of California, Riverside.

Dr. Larsen's laboratory focuses on two topics of plant biology. The first deals with the elucidation of the mechanism responsible for the signal transduction of ethylene, a plant hormone that regulates many physiological processes throughout plant growth and developement. Using *Arabidopsis thaliana* as a model genetic system, he has been responsible for identification of novel components of the ethylene signaling pathway, an approach that may ultimately give the means to better control such ethylene-regulated processes as fruit ripening, tissue senescence, and induction of pathogen defenses. Additionally, Dr. Larsen's group is exploring the mechanisms that plants utilize to cope with abiotic stress, particularly that of aluminum toxicity in acid soil. Aluminum toxicity in acid soils is a global problem limiting crop productivity for more than 30% of agriculturally available land. As for ethylene signaling, Dr. Larsen is also using *Arabidopsis* as a model system for identification of genes that are required for plant growth in aluminum toxic environments.

Dr. Larsen has presented papers in his areas of expertise at prestigious seminars at Cambridge University and at the American Society of Plant Physiologists and has authored or coauthored a number of articles published in scientific journals such as *Plant Physiology*, *Plant Molecular Biology*, and the *Proceedings of the National Academy of Science*. He also authored the article, "Ethylene" in this *Encyclopedia of Hormones*.

Warren J. Leonard

National Institutes of Health, Bethesda, Maryland

Warren J. Leonard is Chief, Laboratory of Molecular Immunology, at the National Heart, Lung, and Blood Institute of the National Institutes of Health. Dr. Leonard was a pioneer in the interleukin-2 field, having cloned the IL-2 receptor α chain in 1983. Dr. Leonard has published more than 200 articles and reviews, most of which are related to the IL-2 family of cytokines. His main research focus relates to IL-2 and other cytokines with receptors that contain the common cytokine receptor γ chain, γc, which Dr. Leonard's group demonstrated is the protein that is mutated in X-linked severe combined immunodeficiency. He demonstrated that this is a disease of defective cytokine signaling and that mutations in the Janus family tyrosine kinase, Jak3, which associates with γc, cause a similar clinical phenotype. Most of his research focuses on signal transduction and gene regulation related to γc-dependent cytokines.

Dr. Leonard is currently Vice President and President-elect of the International Cytokine Society, a member of the American Association of Immunologists, American Society for Clinical Investigation, and the American Association of Physicians, and a fellow of the American Association for the Advancement of Science. He is a current or past member of major editorial boards, including *Immunity*, *Journal of Immunology*, *Journal of Biological Chemistry*, and *Cytokine*. He has helped organize major international meetings in the cytokine field, including a Keystone Symposium and an annual meeting of the International Cytokine Society. Dr. Leonard has received a number of major awards, including the Outstanding Investigator Award of the American Federation for Clinical Research Foundation. (Note that Dr. Leonard's contributions to this book were performed in his private capacity, and the contents of this book do not necessarily reflect the views of NIH.)

Gerald Litwack

Thomas Jefferson University College of Medicine, Philadelphia, Pennsylvania

Gerald Litwack obtained his Ph.D. in biochemistry from the University of Wisconsin in 1953. After a postdoctoral year at the Biochemical Laboratories of the Sorbonne in Paris, he spent the early part of his academic career at Rutgers University and the University of Pennsylvania, where he was the recipient of a National Institutes of Health Career Development award. In 1964, Dr. Litwack became Professor of Biochemistry at the Fels Institute for Cancer Research and Molecular Biology at Temple University School of Medicine. In the 1980s, he became Deputy Director of the Institute and Laura H. Carnell Professor of Biochemistry and received the Faculty Research Award of Temple University.

In 1991, Dr. Litwack moved to the Jefferson Medical College as Chairman of the Department of Pharmacology and Deputy Director of the Jefferson Cancer Institute (now the Kimmel Cancer Institute), an appointment he continued when, in 1996, he became Chair of the newly fused Department of Biochemistry and Molecular Pharmacology and Associate Dean for Scientific Affairs. In 2000, he was appointed Vice Dean for Research.

Dr. Litwack's research has centered on regulation, particularly by hormones, and, during the past 15 years, the mechanism and regulation of apoptosis. The Litwack laboratory group characterized the mammalian glucocorticoid receptor and co-discovered "ligandin," subsequently found to be the glutathione *S*-transferase family of enzymes. Dr. Litwack has published more than 300 papers in these areas and is a co-discoverer on several patents covering many of the caspases in the apoptotic cascade. His service includes participation on scientific advisory boards (the Diabetes Center of the University of Pennsylvania) and on grant review panels of the National Science Foundation, National Institutes of Health, U.S. Army, Israel Cancer Research Fund, and American Cancer Society. His editorial board service includes *Endocrinology*, *Cancer Research*, *Anticancer Research*, *Oncology Research*, *Proceedings of Experimental Biology and Medicine*, *Journal of Nutrition, Growth and Cancer*, *ISI Atlas of Science*, *Cancer Communications*, *Chemtracts*, *Oncology Reports*, *Critical Reviews in Eukaryotic Gene Expression*, and *Apoptosis*.

The books and publications Dr. Litwack has authored, coauthored, or edited include *Experimental Biochemistry* (1960, John Wiley & Sons), *Biochemical Actions of Hormones* (1970–1987, Academic Press, a serial in 14 volumes), *Actions of Hormones on Molecular Processes* (1964, Academic Press), *Receptor Purification* (1989–1990, Humana Press), *Receptor* (renamed *Receptors & Signal Transduction*; 1990–1998, a journal founded by G. Litwack and Editor-in-Chief, Humana Press), *Hormones* (1987, 1997, Academic Press), and *Vitamins and Hormones* (Academic Press, the publisher's longest running serial).

Alexander S. Raikhel

University of California, Riverside

Alexander S. Raikhel is Professor at the University of California, Riverside. He received his Ph.D. in 1975 from the Zoological Institute of the Academy of Science in St. Petersburg, Russia. Dr. Raikhel is the leading authority in molecular endocrinology of insects. His research focuses on endocrine control of insect reproduction. In particular, he and his collaborators have elucidated a complex network of nuclear receptors that mediate the action of a steroid hormone ecdysone in gene activation and repression during egg maturation in mosquitoes.

Dr. Raikhel is the author of more than 100 research papers and reviews on molecular aspects of insect reproduction. He has served as a member of the World Health Organization Advisory Committee and has organized several symposia on the topic of insect reproduction and endocrinology, including several Keystone Symposia in Molecular Insect Science. He is the recipient of numerous awards for his research achievements. Dr. Raikhel is Editor-in-Chief of *Insect Biochemistry and Molecular Biology* and is a member of the editorial board of *Annual Reviews of Entomology*.

R. Paul Robertson

University of Washington, Seattle, Washington

R. Paul Robertson, M.D. is President, Scientific Director, and CEO of the Pacific Northwest Research Institute. He became Professor of Medicine and Pharmacology at the University of Washington in 1980, where he received most of his postgraduate training. He has been elected into membership of the American Society for Clinical Investigation and the Association of American Physicians.

Dr. Robertson has been Editor-in-Chief of *Diabetes*, the research journal of the American Diabetes Association, and is currently on the editorial board of the *Journal of Biological Chemistry*. Honors received by Dr. Robertson include the endowed Pennock Chair for Diabetes Research at the University of Minnesota, Banting and Best Lecturer at the Joslin Clinic, the Moses Barron Award of the Minnesota Affiliate of the American Diabetes Association, and the Albert Renold Award of the American Diabetes Association. He has published more than 260 manuscripts with primary emphasis on beta cell function in humans, animals, and clonal cell lines. His most recent research activities are centered on studies of glucose toxicity of the beta cell as seen in type 2 diabetic patients. He is also very active in studies of the metabolic consequences of successful pancreas and islet transplantation in patients with type 1 diabetes mellitus.

Charles Eugene Roselli

Oregon Health and Science University, Portland, Oregon

Charles Eugene Roselli is a professor in the Department of Physiology and Pharmacology at the Oregon Health and Science University, where he has

been on the faculty since 1985. He received his Ph.D. in 1981 from Hahnemann University in Philadelphia, Pennsylvania, and did his postdoctoral training at the Oregon Regional Primate Research Center (1981–1984). Dr. Roselli's research focuses on the neurobiological activity of androgens. His work has contributed to an integrated understanding of the subcellular signaling pathways, the steroid-sensitive brain circuitry, and the neurochemical mechanisms that are responsible for the behavioral and neuroendocrine actions of androgens.

A major emphasis of Dr. Roselli's research has been directed at the characterization of the aromatase (CYP19, or estrogen synthetase) signaling pathway in neural tissue, characterizing the distribution and regulation of CYP19, and defining its role in neural development, adult reproductive behavior, and gonadotropin secretion. Dr. Roselli and his colleague Dr. Resko were the first to demonstrate that androgens regulate their own efficacy in the mammalian brain through androgen receptor-dependent positive feedback of the aromatization pathway. His research also demonstrated for the first time that gender differences in neural responsiveness to androgens are expressed at the subcellular level through the differential expression of androgen receptors and aromatase. Dr. Roselli and collaborators recently identified a sexually dimorphic preoptic nucleus in the ovine brain and found that the volume of this nucleus correlates with sexual partner preference in rams. They are currently studying the neuroendocrine and neuroanatomical basis of naturally occurring variations in sexual partner preference.

Evan R. Simpson

Prince Henry's Institute of Medical Research,
Clayton, Australia

Evan R. Simpson began his career in 1964 and is presently Director of Prince Henry's Institute of Medical Research of Monash University, Australia. Historically, Dr. Simpson's research has been in three major fields: the regulation of steroid hormone biosynthesis in the adrenal cortex and in the ovary, the role of lipoprotein cholesterol as precursor for steroid hormone biosynthesis, and the study of estrogen biosynthesis, in particular the regulation of biosynthesis of the enzyme aromatase, responsible for the biosynthesis of estrogens. Most recently, Dr. Simpson's research group developed the aromatase knockout mouse as a model of estrogen insufficiency. This has provided insights into the role of estrogens in the physiology and pathophysiology of both males and females, revealing many unexpected and non-sexually dimorphic roles for estrogens unrelated to sexual differentiation or reproduction.

Dr. Simpson has authored more than 300 peer-reviewed articles and some 70 book chapters and nonreviewed publications. He has been a featured speaker at events ranging from closed workshops such as the Wyeth Ayerst sponsored symposium on Frontiers in Estrogen Action to international and national society meetings. Currently, he is Chairman of the International Organizing Committee of the International Congress of Hormonal Steroids and Hormones and Cancer, and until last year was Chairman of the International Aromatase Conference. In 1998, he was Chairman of the Program Organizing Committee of the U.S. Endocrine Society Annual Meeting. He is a member of the council of the Endocrine Society of Australia, Editor-in-Chief of the *Journal of Molecular Endocrinology*, and Associate Editor of *Endocrine Reviews*.

Dr. Simpson's honors and awards include the Transatlantic Medal Lecturer for the U.K. Society for Endocrinology in 1990, and in 2003 he is the society's Asia and Oceania Medal Lecturer; he received the President's Scientific Achievement Award from the Society for Gynecological Investigation (United States). He has been a guest lecturer at several institutions, including the University of Western Ontario, the University of Kansas, and Johns Hopkins University, and at Princess Takematsu's Annual Symposium on Breast Cancer in Tokyo.

Guido Verhoeven

Catholic University of Leuven, Leuven, Belgium

Guido Verhoeven was born in Antwerpen, Belgium, on March 26, 1945. In 1970, he completed medical studies at the Catholic University of Leuven, Belgium, and in 1974 obtained a Ph.D. from the same institution. He is a Registered Specialist in Clinical Chemistry with authorization for nuclear medicine *in vitro*. In 1974, he received a Biomedical Fellowship of the Population Council in New York and worked for one year in the laboratory of Professor Jean D. Wilson at the University of Texas Southwestern Medical School in Dallas on the problem of androgen insensitivity syndromes. Professor Verhoeven received several postdoctoral fellowships from the National Fund for Scientific Research from Belgium

and became Full Professor at the Catholic University of Leuven in 1986, where he teaches pathophysiology and general medicine both at the Medical School and at the School for Pharmacy.

Professor Verhoeven has been Chairman of the Department of Developmental Biology for 14 years. He is Full Member of the Belgian Royal Academy of Medicine and has served in a variety of capacities within the scientific community. These include Secretary of the Belgian Contact Group on Steroid Hormones and Secretary and Vice President of the Belgian Society for Endocrinology. He is a member of the Endocrine Society, an academician of the European Academy of Andrology, and a member of the Permanent Scientific Committee of the European Testis Workshops. In 1984, he organized the 8th European Workshop on the molecular and cellular endocrinology of the testis in De Panne, Belgium. Professor Verhoeven's main research interests are cell–cell interactions and androgen action in the testis, and androgens and the control of proliferation and differentiation in the normal prostate and in prostate tumor cells. In recent years, his research has increasingly focused on prostate cancer. Professor Verhoeven has published nearly 200 papers in international peer-reviewed journals.

Nancy L. Weigel

Baylor College of Medicine, Houston, Texas

Nancy L. Weigel earned undergraduate degrees at Cornell University and a Ph.D. from Johns Hopkins University. Dr. Weigel was named a National Institutes of Health Postdoctoral Fellow (1979–1981) and a Searle Scholar (1983–1986). Following postdoctoral work in steroid receptors, she joined the faculty of Baylor College of Medicine, where she is presently a professor in the Department of Molecular and Cellular Biology.

Dr. Weigel is engaged in a variety of research projects, including the regulation of human steroid receptors by phosphorylation, the role of androgen receptors in prostate cancer, and the effects of vitamin D on both bone loss and prostate cancer. She has authored or coauthored more than 100 scientific journal publications. Her manuscripts are also included in a number of books: *Gene Regulation by Steroid Hormones* (1982, Springer-Verlag), *Mechanisms of Steroid Action* (1981, Macmillan Press Ltd.), *Methods in Enzymology* (1982, Academic Press), *Steroid Hormone Receptors, Structure and Function* (1983, Elsevier), *Laboratory Methods Manual for Hormone Action and Molecular Endocrinology*, (1989, Houston Biological Associates), *Receptor Purification* (1990, Humana Press), *Endocrinology*, 4th Edition (2000, Saunders Company), and *Encyclopedia of Molecular Medicine* (2002, Wiley and Sons).

Dr. Weigel has served on a number of review panels and editorial boards and has participated in many invited lectures around the United States and Europe, most recently for the fifth consecutive year at Frontiers in Reproduction in Woods Hole, Massachusetts. She has chaired the American Cancer Society Tumor Biochemistry and Endocrinology Study Section, is an editorial board member for *Steroids*, *Endocrinology*, and *Journal of Biological Chemistry*, and is a member of the Endocrine Society, the American Association for Cancer Research, Women in Cancer Research, the American Society for Bone and Mineral Research, the American Society for Biochemistry and Molecular Biology, the American Association for the Advancement of Science, and Women in Endocrinology, serving as Secretary–Treasurer from 1998 until 2001.

Roy E. Weiss

University of Chicago, Chicago, Illinois

Roy E. Weiss is Professor of Medicine at the University of Chicago and is Associate Director of the Clinical Research Center. Since the mid-1980s, Dr. Weiss has been involved in efforts to understand the molecular basis of thyroid hormone action. As an active clinician, educator, and molecular biologist, he has studied the clinical and physiological abnormalities in patients with the syndrome of resistance to thyroid hormone, to understand mutant thyroid hormone receptor isoform and cofactor interaction. Dr. Weiss was the first to demonstrate that this syndrome could be diagnosed at birth and the effect of treatment on outcome. Dr. Weiss has also demonstrated the importance of nuclear coactivators in thyroid hormone action *in vivo*. Currently, he is working on understanding the basis for resistance to thyroid hormone in patients with normal thyroid hormone receptors.

FOREWORD

The discipline of endocrinology was born with the discovery of hormones, but the concept of endocrinology has been substantially expanded by the more recent discovery of paracrine and autocrine regulators. The field of hormone action was formed to understand the molecular mechanisms by which hormones act in cells, and continues to expand explosively. In the late 1960s, the prevailing view of hormone action ranged from effects on membrane transport of nutrients and precursors for RNA and protein synthesis to effects on the translation of mRNA at the level of ribosomes. Nevertheless, a cadre of voices predicted a possible nuclear action on mRNA synthesis. These voices were correct in that steroid hormones, acting via their receptors, indeed were proved to regulate gene transcription. To the best of my knowledge, the first paper to be presented at the national endocrine meetings in a new field of hormone action was in 1967, and it dealt with hormonal stimulation of oviductal protein synthesis. It was about this time that a small group of scientists interested in hormone effects in cells attended a Gordon Conference in New Hampshire; this was one of the first conferences to focus an entire program on hormone action and mechanisms. The attendees were primarily involved in aspects of steroid hormone and thyroid hormone actions; peptide hormone action was yet to experience its own birth and a similar expansive growth. Only a short time previously, Elwood Jensen had discovered the estrogen-binding protein that eventually became the "estrogen receptor," thus it was logical that the conference dealt mainly with steroid receptors; there were also a few papers presenting data that steroid hormones could induce specific enzyme/protein synthesis in target cells. The mechanisms of these effects were the subject of great debate at this first conference on steroid hormone action, a meeting that persists to this day in New England each summer.

Following the monumental discovery of peptide immunoassays, workers in the peptide field were immersed in the work of measuring hormones, ranging from insulin, to luteinizing hormone, to follicle-stimulating hormone, to thrytropin-releasing hormone, to growth hormone, to name a few. For over a decade, little attention was given to the more difficult task of understanding the functions of their receptors and intracellular signaling pathways. Nevertheless, the advent of this assay methodology, including the ability to synthesize radiolabeled peptide hormones, eventually allowed the identification and quantification of cell surface receptors for peptide and amine-containing hormones. The time of this application was about 1970. Researchers demonstrated that cAMP levels were induced in concert with ligand occupation of certain membrane receptors, and the second messenger cAMP was postulated to initiate intracellular phosphorylation of unknown targets. At this point, the field of peptide hormone action also was born.

The two distinct but related fields, steroid hormone action and peptide hormone action, developed together for much of the next decade. Hormone action conferences invariably contained talks on both types of receptors and progress was rapid and in concert with the development of molecular biology. In the steroid field, progress was more rapid initially, but by the mid 1980s, the peptide field attained equal mechanistic status.

Investigators of steroid hormone action concentrated on first understanding the "pathway of action" for their hormones. Scientists looked for model systems showing large responses to steroids. One approach was to assess changes in enzyme levels in cultured cells. The intact chicken oviduct was another of the more notable systems, in that regard because of the ability of sex steroids (estrogen, progesterone) to induce large increases both in certain egg-white proteins and in their respective mRNAs. Viral proteins also were shown to be induced by glucocorticoids. The finding that purified steroid receptors could bind to DNA directly led to a new understanding of the pathway of steroid, to intracellular receptor, to DNA, to mRNA, to protein, and to function. Still, many complexities remained to be sorted out when the receptor cDNAs were cloned in the 1980s.

Our concept of hormones expanded considerably with the advent of growth factors and cytokines. Arguably, the myriads of growth factors only represent an additional list of peptidelike hormones that often act within the tissue of their origin; they have a strong predilection for growth and cell cycle control. Cytokines have both local and distal actions and are particularly oriented to processes such as smooth muscle function and inflammation and apoptosis.

For a decade, it seems as if the peptide action researchers were unduly fixated on cAMP induction and protein kinase A activation. The complexity of signaling pathways emanating from membrane receptors increased logarithmically with the discovery of the numerous protein kinases that phosphorylated serine and tyrosine, the kinase-kinases, the phosphatases, the calcium and diacylgycerol regulators, and the regulators of all of the phosphorylation intermediates. The types of receptors that proliferated ranged from seven membrane (protein kinase A), growth factors (tyrosine kinase, protein kinase C), cytokine, and eventually even chemokine in nature. The appreciation of G-proteins as upstream targets of the cAMP pathway was key to eventual solutions of the signaling cascade. The discoveries of the ras/raf pathway for mediating the effects of mitogens, and the JAK/Stat pathway as mediator for cytokines and certain peptide hormone effects, were also important milestones in unraveling signal transduction in eukaryotic cells. The realization that CREB and Stat proteins were regulatable transcription factors that eventually acted on DNA united the steroid–peptide fields, in part, at the level of the nucleus. That order was made out of apparent chaos is a striking tribute to the intellectual prowess and perseverance of the workers in this field. Most importantly, the signaling pathways emanating from the membrane have brought new insights to pathologies such as cancer, and have led to an explosive development of new pharmaceutical stimulators and inhibitors, with good promise for therapies of neuropsychiatric disorders, cancer, and other human disorders.

After a consolidation period in the 1970s, the steroid action field heated up again with the cloning of the steroid, thyroid, vitamin D, and retinoic receptors. Certain unpredictable events occurred. Investigators began to clone (by cross-screening) numerous molecules that were similar to steroid receptors, but that were not known to be activated by an existing ligand. The term "orphan receptors" was born and the deduction was made that the steroid receptors were part of a giant superfamily of nuclear receptor transcription factors, numbering 48 in humans. The availability of cloned cDNAs and other reagents allowed mutational analyses of receptors, followed by their reintroduction into cells to monitor effects on synthetic reporter genes; structure–function relationships proved the existence of receptor domains for transcriptional activation, nuclear translocation, and DNA binding. Now at a frenetic pace, information on dimeric DNA binding and heterodimeric partners (retinoic acid X receptor), receptor crosstalk with peptide pathways, ligand-independent receptor activation, and receptor phosphorylation was accumulated. More definitive appreciation of the biology of classical and orphan receptors was accomplished by the emerging transgenic technologies and gene knockout strategies. The ability to screen for new ligands for orphan receptors extended the range of hormones to lipids (peroxisome proliferator-activated receptors) and other previously unsuspected metabolic regulators. The yearly stream of publications on the physiology of orphan receptors and their novel ligands continued to bring excitement and more expansion to the field. Pharmaceutical companies salivated at the possibilities of new drugs acting at the nuclear level. The tamoxifen paradox (it acts in one tissue as an agonist and in another as an antagonist) provided encouragement for the generation of a successful search for selective receptor modulators that contain tissue- and function-specific profiles.

Still, the field clamored for a greater molecular understanding of how the nuclear receptors worked at the level of DNA. The discovery of receptor-associated regulatory proteins provided this missing link and changed the field of hormone action further. We moved from a situation wherein many believed that intracellular receptors carried out the transcriptional regulation inherent to the actions of steroid/thyroid hormones and vitamins, to an understanding that the receptor-associated "coregulators" are the primary mediators of this genetic response. We now know that the receptor co-activators act as powerful transducers of hormone action, either through inherent enzyme activities or by serving as a scaffold for recruitment of additional co-activator proteins. The coregulators can be divided loosely into two camps: co-activators and co-repressors. Taken together, these molecules mediate the two main tasks of receptors: stimulation and repression of gene expression.

It is perhaps fitting that a burst of recent attention has focused again on the membrane, where both steroids and their receptors have been postulated to have biologically important effects. Actions of nuclear

receptors, and also of free hormones binding to traditional membrane receptors or ion channels, are likely to be of increasing future interest to workers investigating hormonal function. In this respect, we have traveled full circle. I have no doubt that the future will see many additional examples of membrane reinforcement of nuclear gene regulation, of important ligand-independent activities of receptors initiated at the membrane, and of pathway crosstalk among the varieties of hormones and their intracellular pathways.

These volumes of the *Encyclopedia of Hormones* represent one of the most ambitious projects completed to date in the field of hormones and their actions. The Editors have assembled articles that address a full spectrum of the biology and cellular physiology of numerous hormones and their actions in many species. This effort allows the reader the opportunity to survey the state of both membrane receptor-initiated signaling and nuclear receptor-initiated signaling from the viewpoints of a wide variety of leading investigators. The history and breadth of this field are evident within the articles of these volumes. The ambitious project will stand as a major reference source for the field, and I predict that readers will have no problem savoring the current rapid progress and heightened excitement that exists in this vast field of molecular endocrinology.

Baylor College of Medicine Houston, Texas

PREFACE

The publication of the *Encyclopedia of Hormones* is intended to provide a comprehensive reference work on all known hormones in vertebrate animals, insects, and plants. The list of classical hormones that had been discovered and characterized over the interval from 1914 to 1985 numbered approximately 55; however, as a consequence of the application of modern chemical characterization techniques and molecular biology methodology, this list now exceeds 150 and is still expanding. In fact, during the production interval for the *Encyclopedia,* several new hormones were discovered and new activities for existing hormones were clearly defined. In addition, enormous strides have been made in our understanding of the detailed actions of hormones at the molecular and cellular levels. There have been dramatic applications of this new knowledge in the medical arena with respect to both diagnosis and treatment of diseases; for the plant and insect hormones, new applications have arisen in the realms of agricultural biotechnology and biological control.

Some comment is appropriate concerning the definition of a hormone that has been utilized in compiling entries in the *Encyclopedia*. Of course, the classical definition of a hormone is that it is a chemical messenger in the body: it is secreted by an endocrine gland and is delivered through the circulatory system to target cells that possess receptors specific for the hormone. Occupancy of the receptor by its cognate hormone leads to the initiation of signal transduction processes that result in generation of specific biological responses. But in this post-human-genome era, and with the rich array of technologies used to study and define at the cellular and molecular levels the enormous array of signal transduction pathways employed by cells, the Editors have adopted a broader definition of hormone. Hormones can now be considered to include not only chemical messengers in the classical sense, but also local paracrine and autocrine signals. Thus, the *Encyclopedia* includes articles on many growth factors, interleukins, and intracellular mediators of signal transduction.

The *Encyclopedia of Hormones* is intended to serve as a useful and comprehensive source of information spanning all aspects of the general subject of hormones. It consists of nearly 300 articles that collectively describe hormones from several key perspectives: (1) the cellular and subcellular sites of functioning of the hormone, (2) the major physiological system(s) in which it is operative (e.g., reproductive, immune, neuroendocrine, digestive, and developmental), (3) the nature of the receptor and signal transduction pathway(s) used by the hormone (e.g., nuclear or membrane signal transduction), and (4) for the vertebrate hormones, the important diseases of deficiency or excess or other instances for which there is unusual molecular insight available. We expect that the *Encyclopedia of Hormones* will be as useful to the scientific expert concerned with cutting-edge questions as it will be to students and interested nonscientists.

Given the broad scope of such a major reference work, it was essential to assemble a team of Associate Editors. Each of these 14 individuals has dedicated his or her professional career to researching scholarly endeavors in a specific domain of hormones and, as a consequence of the breadth and depth of achievement in this area, is an acknowledged leader in their field. These interests include the hormone domains of adrenal cortex, calcium-regulating hormones, cytokines, female reproduction, male reproduction, gastrointestinal hormones, growth factors, thyroid, membrane signal transduction, neuroendocrinology, nuclear signal transduction, pancreas, plant hormones, and insect hormones.

The *Encyclopedia* was launched at a two-day meeting of the Editors, Associate Editors, and Elsevier–Academic Press representatives in La Jolla, California, in April, 2001. Here the preliminary list of article titles prepared by the Editors was refined and a list of potential authors created. Each Associate Editor was then responsible for the crucial process of recruiting authors for the individual entries. As the manuscripts were received by Academic Press,

they were critically reviewed by the Associate Editors and Editors, as well as by the editorial staff at Academic Press. The final total of 296 articles entered production in only 16 months.

All of the articles are formatted according to the same blueprint and each is intended to be a self-contained presentation. Each article begins with a brief topical content outline that provides the reader with a listing of the major topics presented in the article. The article body begins with an introductory paragraph that defines the topic under discussion and summarizes the content of the article. Following the article are reference citations to provide the reader with access to further in-depth consideration of the topic at hand and a cross-reference to related entries in the *Encyclopedia*. A glossary list defines key terms that may be unfamiliar to the reader and are important to an understanding of the article. A compilation of all glossary terms appearing in the complete multivolume *Encyclopedia* is presented in the final volume as a dictionary of subject matter relevant to hormones.

If the *Encyclopedia* has merit, it is due largely to the contributions of the authors of all the articles, and as well to the dedication of the Associate Editors. Shortcomings are, of course, the responsibility of the Editors and we would appreciate having them brought to our attention. The completion of this large project in the relatively short time, from launch meeting to the actual printing of the *Encyclopedia* (only 23 months), is the result of much hard work and dedication. Certainly the primary credit must go to the some 500 authors who prepared their contributions in a timely fashion. The board of Associate Editors also provided exceptional leadership and service. The Editors thank them all.

Finally, thanks are due to the staff of Elsevier–Academic Press, including Tari Paschall, Judy Meyer, Chris Morris, and Carolan Gladden, who each provided skillful and friendly ongoing management of the project.

Abscisic Acid

SÉBASTIEN MONGRAND, PETER D. HARE, AND NAM-HAI CHUA
Rockefeller University

The development of strategies that enable growth without excessive consumption of water was vital to the evolution of terrestrial plants. It is now well established that phytohormones, in particular, abscisic acid, regulate plant water status.

I. INTRODUCTION

During the 1960s, two independent groups identified a compound active in the initiation of bud dormancy in sycamore and cotton boll abscission, naming it dormin and abscisin II, respectively. Following its purification from cotton fruits, the chemical structure of this compound was determined in 1965 and it was renamed abscisic acid (ABA). Shortly after this, it was discovered that ABA levels increase considerably when plants wilt and that ABA causes stomatal closure. These two discoveries highlighted the importance of ABA in mediating responses of vegetative tissues to environmental stresses such as drought, high salinity, and low temperature. ABA is also required for the accumulation of seed nutrient reserves, the acquisition of desiccation tolerance, and the arrest of embryonic development during seed maturation. Despite its name, ABA is not a major regulator of absicission, which is primarily controlled by ethylene.

II. STRUCTURE AND OCCURRENCE

Like all hormones, ABA responses depend not only on the sensitivity of the tissue to ABA, but also on local ABA concentration. This is regulated by the biosynthesis, degradation, inactivation, transport, and subcellular compartmentation of the hormone.

A. Structure

The 15 carbon atoms of the sesquiterpene ABA configure an aliphatic ring with one double bond, three methyl groups, and an unsaturated chain containing the carboxyl group (Fig. 1). The *cis* and *trans* isomers differ in the orientation of the carboxyl group, and the asymmetric carbon at the 1′ position of the ring distinguishes between the *S*(+) and *R*(−) enantiomers. The different forms of ABA occur in different proportions in plants and can have different activities. The *S-cis* form is the most abundant naturally occurring form and is the active form in fast responses such as stomatal closure. Both enantiomers are active in long-term responses such as changes in gene expression and protein synthesis. In contrast to the *cis-trans* isomers, the *S* and *R* forms cannot be interconverted *in planta*. The exact ABA chemical structure is essential for its physiological activity, and the loss of a carboxyl group, a tertiary hydroxyl group, a 2-*cis* 4-*trans*-pentadienoic side chain, a 4′-ketone, or a double bond in the cyclohexane ring greatly reduces activity.

B. Occurrence

ABA is widespread in vascular plants, occurring in mosses, ferns, liverworts (where a similar compound, lunaric acid, plays a similar role), and all algal classes, including photosynthetic prokaryotes such as cyanobacteria. Some pathogenic fungi make ABA, but the biosynthetic pathway appears to be quite different from that of higher plants. ABA is also reported to occur in the mammalian brain, although its role there is not known.

III. SYNTHESIS

The endogenous ABA concentration can rise and fall dramatically in response to environmental or developmental cues. It appears that ABA is synthesized in almost all cells containing chloroplasts or amyloplasts (i.e., plastids), but the regulatory controls appear to differ between tissues. Not only do absolute ABA concentrations increase dramatically during embryogenesis, but the ABA content of leaves and roots increases 10- to 50-fold when water potentials fall below −1.0 MPa (approximately −10.0 bar).

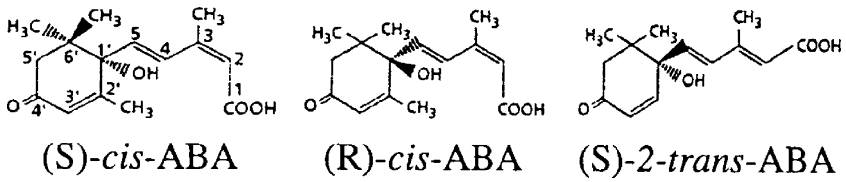

FIGURE 1 Chemical structures of the *S* and *R* forms of *cis*-ABA and the (*S*)-2-*trans* form of ABA.

The concentration of ABA in the xylem sap of well-watered plants is 1.0–15.0 nM and can increase to 3.0 μM after water stress. The main rise in ABA caused by water loss occurs some 2–3 h after the onset of wilting. The ability of cycloheximide to block this process indicates a requirement for *de novo* protein synthesis and thus implicates an up-regulation of ABA biosynthesis in stressed tissues.

The plant ABA biosynthetic pathway represents a minor branch of the carotenoid pathway and begins in plastids. In contrast with isoprene biosynthesis in animal cells, the main precursor of ABA, isopentenyl diphosphate (IPP), is generated by the methyl erythritol phosphate pathway and not from mevalonic acid. Eight IPP residues are combined to form geranylgeranyl diphosphate, the precursor for the biosynthesis of the C40 compound β-carotene. Both rings of β-carotene are hydroxylated to form the xanthophyll zeaxanthin, which can be regarded as the first intermediate in ABA synthesis (Fig. 2). The role of xanthophylls as intermediates in ABA biosynthesis is supported by the reduced ABA content of maize *vp* (*vivi*parous) mutants that are blocked in early steps of carotenoid synthesis. Zeaxanthin is then oxidized to antheraxanthine and to all-*trans*-violaxanthin by zeaxanthin epoxidase (ZEP), which is absent in the *Nicotiana plumbaginifolia aba2* mutant. ZEP contains a putative N-terminal transit sequence for targeting to chloroplasts. *ABA2/ZEP* expression is detected in stems, leaves, roots, and seeds and it is strongly induced by drought stress in roots but not leaves.

The oxidative cleavage of the 9-*cis*-epoxycarotenoid precursor generates the 15C skeleton of ABA. The maize *vp14* mutant is deficient in the chloroplastic 9-*cis*-epoxycarotenoid dioxygenase (NCED) responsible for the cleavage of the 9-*cis*-isomers, but not the all-*trans*-isomers, to xanthoxin. Therefore, the precise order of isomerization-type reactions remains uncertain. The gene is expressed constitutively in embryos and roots and in contrast with *ABA2/ZEP* transcripts, *NCED* transcripts accumulate to high levels in water-stressed leaves. Thus, ABA accumulation in wilted leaves is primarily regulated at the level of plastidic xanthoxin production, which appears to be rate-limiting in ABA biosynthesis. Transgenic experiments indicated that ZEP is primarily involved in the regulation of ABA synthesis during seed development.

The final steps are not yet completely defined. Xanthoxin is converted to ABA in the cytosol via either AB-aldehyde or xanthoxic acid. Genetic evidence suggests that xanthoxin is first oxidized to AB-aldehyde, although the involvement of xanthoxic acid as a precursor has not been completely eliminated. *Arabidopsis thaliana aba3* and tomato *flacca* and *sitiens* mutants are defective in the last oxidation step and are thus unable to oxidize AB-aldehyde to

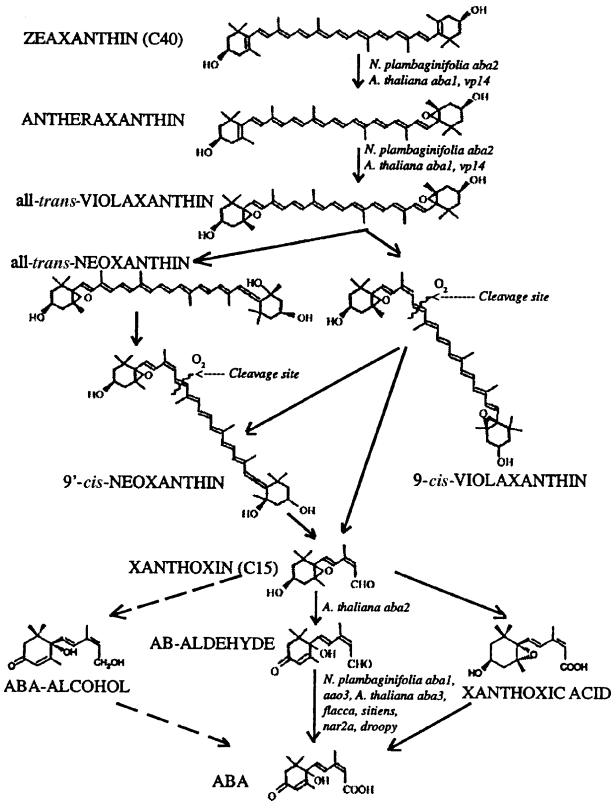

FIGURE 2 The ABA biosynthetic pathway. The metabolic blocks in various ABA-deficient mutants are indicated in italics. Adapted from Taylor *et al.* (2000).

ABA. This last step involves an enzyme that requires a molybdenum cofactor. *Arabidopsis aba3* and *N. plumbaginifolia aba1* mutants cannot produce the functional molybdate cofactor required by AB-aldehyde oxidase (AO). This last enzyme of ABA synthesis is not highly substrate-specific and interestingly, AO can also catalyze synthesis of another plant growth regulator, the auxin indole-3-acetic acid. In *Arabidopsis*, a multigene family comprising at least four members encodes AO, only one of which appears to act specifically in ABA synthesis.

A. Alternative Pathways

Although *ABA2* is a single-copy gene, the ABA content of the *N. plumbaginifolia aba2* null mutant is 23–48% that of the wildtype (WT). Moreover, ABA is present in tomato *flacca* and *sitiens* mutants that lack an effective AO. These results suggest either that there is more than one biosynthetic pathway or that there is some redundancy in part of the primary biosynthetic pathway. The 2-*trans*-ABA-alcohol accumulated during water stress in *flacca* and *sitiens* mutants could be formed via a P450 mono-oxygenase able to add a second oxygen atom to the C1 position and can be further slowly converted to ABA. This reaction may also occur to a small extent in WT plants. Unlike plants, fungi are able to synthesize ABA directly from the 15C compound farnesyl pyrophosphate.

IV. DEGRADATION

After wilted leaves regain turgor, ABA can be inactivated by oxidation to phaseic acid and dihydrophaseic acid or by conjugation to glucose to form a glucose ester. In the first case, catabolic inactivation proceeds via hydroxylation at the 8′ position to form an unstable intermediate that subsequently forms phaseic acid. The ABA-8′-hydroxylase considered as the pivotal enzyme in ABA degradation is a membrane-associated cytochrome P450 mono-oxygenase. It is expressed at high levels in plant tissues recovering from hyperosmotic stresses. Although phaseic acid is still able to trigger stomatal closure in some species, its activity is much weaker than that of ABA. In contrast, dihydrophaseic acid, which is the reduced form of phaseic acid, has no detectable activity. Conjugation of ABA to glucose not only renders ABA inactive but also changes its distribution in the cell. Whereas free ABA is mainly cytosolic, ABA-β-D-glycosyl ester accumulates in vacuoles and could be a storage form of the hormone. Until now, neither the enzymes involved in ABA catabolism nor the genes that encode them have been isolated.

V. TRANSPORT

ABA is secreted by cells into the apoplast (i.e., intercellular space) and is easily transported in both xylem and phloem sap to most plant parts, especially stems, leaves, roots, and ripening fruits. Since roots are the primary sites of perception of water deficit, ABA synthesized in roots can be transported to shoot tissues via the transpiration stream, where it triggers stomatal closure to reduce water loss from leaves.

Within leaves, ABA is redistributed as a function of pH. In a well-watered plant, the xylem sap is more acidic (approximately pH 6.3) and ABA occurs in its protonated form (ABAH). During drought stress, the sap becomes slightly alkaline (approximately pH 7.2), favoring the deprotonation of ABAH to ABA. As a result, less ABA is taken up by mesophyll cells and more is diverted to guard cells. Therefore, even though absolute ABA levels may not change, the pH-dependent redistribution of root-derived ABA to guard cells can induce stomatal closure.

A similar redistribution may exist within cells. When photosynthesis is active, the pH of the chloroplast stroma increases as protons are pumped into the thylakoid lumen. A prevalence of deprotonated ABA limits its ability to cross the chloroplast membrane, causing the accumulation of ABA in the stroma. During drought stress, photosynthetic rates decrease. The resulting drop in stromal pH increases levels of ABAH, which can traverse membranes and be released for transport to guard cells.

VI. ROLES OF ABA

ABA is unquestionably involved in a plant's response to stress and in the initiation and maintenance of seed dormancy. However, it also influences many other aspects of plant physiology, often by interacting synergistically/antagonistically with hormones such as ethylene, gibberellins, cytokinins, auxin, jasmonic acid, and brassinosteroids or by modulating metabolic sensing pathways such as those monitoring cellular sugar status.

A. ABA Triggers Stomatal Closure During Water Stress

Stomata are pores, found on the aerial surfaces of plants, that allow CO_2 uptake for photosynthesis and

at the same time the loss of water, which drives the transpiration stream. Stomatal pore diameter is regulated by turgor changes of the two surrounding guard cells. Unlike most other cells in higher-plant tissues, the absence of plasmodesmata in mature guard cells renders them independent of surrounding cells and enables them to respond autonomously to stimuli such as CO_2, water status, temperature, red/blue light, and plant pathogens. Applied ABA inhibits the opening and promotes the closure of stomata. The increased transpiration rates observed in ABA-biosynthetic mutants and the accumulation of ABA in stressed leaves with reduced transpiration are consistent with the view that endogenous ABA normally plays an important role in the reduction of water loss by transpiration. Expression of an anti-ABA antibody in transgenic tobacco plants retained ABA in the endoplasmic reticulum and caused leaves to wilt by impairing stomatal closure.

The molecular mechanism by which ABA induces stomatal closure has been studied using genetic, biochemical, single-cell, and electrophysiological approaches. Opening and closing of stomata is thought to provoke turgor and volume changes in guard cells. During water stress, the increase in cellular ABA or in apoplastic ABA at guard cell surfaces mediates guard cell closure by triggering a net efflux of K^+ and Cl^- from the vacuole to the cytoplasm and from the cytoplasm to the apoplast. Additionally, sucrose and malate are metabolized to osmotically inactive starch, all of which function to reduce the osmolarity in the guard cells. During stomatal opening, guard cells swell following the accumulation of K^+, anions, and sucrose. The resulting out-bowing of the guard cell pair increases pore aperture and allows reestablishment of transpiration.

B. ABA Promotes Seed Maturation and Dormancy

One of the clearest effects of ABA is to prepare the seed for desiccation and to impose embryo dormancy to prevent premature germination. Seeds of ABA-deficient mutants or transgenic plants depleted of endogenous ABA by expression of an ABA-specific antibody fail to mature fully and acquire dormancy.

Seed development can be divided into two phases of equal duration. The first includes growth and development of the embryo and the endosperm. The second phase begins with the arrest of cell division and the accumulation of storage reserves and is followed by preparation for desiccation, which occurs in the last stages of seed maturation. Seeds prepare for desiccation by accumulating nutritive reserves and proteins that allow the cell to survive the ensuing loss of up to 90% of its water content. As a consequence of dehydration, seeds become dormant. The ABA content of seeds increases during the first half of seed development and decreases during the second phase involving seed maturation.

ABA strongly induces genes that encode abundantly expressed seed storage proteins (e.g., zein, conglycinin, and lectin proteins) as well as proteins involved in desiccation tolerance. The highly conserved water-soluble and basic late-embryogenesis abundant (LEA) proteins are rich in glycine/lysine and low in hydrophobic residues and are thought to stabilize other proteins when the cell is dehydrated. They are related to members of the DHN (dehydrin) and RAB (Responsive to ABA) protein families.

C. ABA Inhibits Germination and Seedling Growth

Seed germination can be defined as the resumption of growth of the embryo following dormancy. As possibly the most critical developmental transition in the plant life cycle, germination is contingent on suitable environmental conditions. However, dormant seeds will not germinate even under normally permissive conditions of temperature or water, light, and oxygen availability. Seed dormancy introduces a delay in germination that provides additional time for geographical dispersal and also maximizes seedling survival by preventing germination under adverse conditions.

ABA appears to be the most important mediator of seed dormancy. The ability of exogenous ABA to prevent seed germination in many species has been used to isolate several *abi* (ABA-*i*nsensitive) *Arabidopsis* mutants (Table 1). Exogenous ABA can also inhibit the precocious germination of immature embryos in culture. ABA-deficient *Arabidopsis* (*aba*) mutants are nondormant at maturity, and embryos of maize *vp* mutants germinate directly on the cob while still attached to the mother plant. This precocious germination, named vivipary, suggests that ABA normally constrains developing embryos in an early developmental stage. In contrast with maize, ABA deficiency in *Arabidopsis* does not cause vivipary because the rigid seed coat prevents embryo growth while the seed is in the seed pod. Nevertheless, vivipary occurs when *Arabidopsis abi3* mutant embryos are dissected out of the seed coat before complete desiccation.

TABLE 1 Mutations Affecting ABA Biosynthesis and Signal Transduction Pathway in Plants

Plant species	Mutations[a]	Gene product/function
ABA-deficient mutants		
Zea mays	*vp2,5,7–9*	*Carotenoid biosynthesis*
Z. mays	*vp14*	9-*cis*-Epoxycarotenoid dioxygenase
Chlamydomnas reinhardtii	*M526*	ABA xanthophyll biosynthesis
Arabidopsis thaliana	*aba1*	Zeaxanthin epoxidase
A. thaliana	*aba2*	Xanthoxin oxidase
A. thaliana	*aba3*	Molybdenum cofactor biosynthesis
A. thaliana	*aao3*	Aldehyde oxidase
Nicotiana plumbaginifolia	*aba2*	Zeaxanthin epoxidase
N. plumbaginifolia	*aba1/ckr1*	Molybdenum cofactor biosynthesis
N. plumbaginifolia	*aba2*	ABA xanthophyll biosynthesis
N. plumbaginifolia	*cnxA*	Molybdenum cofactor biosynthesis
Lycopersicum esculentum	*notabilis*	9-*cis*-Epoxycarotenoid dioxygenase
L. esculentum	*flacca*	Molybdenum cofactor biosynthesis
L. esculentum	*sitiens*	Aldehyde oxidase
Solanum phureja	*droopy*	Aldehyde oxidase
Hordeum vulgare	*nar2a*	Molybdenum cofactor biosynthesis
Pisum sativum	*wilty*	ND
ABA-insensitive mutants		
A. thaliana	*abi1* (SD)	Type 2C protein phosphatase
A. thaliana	*abi2* (SD)	Type 2C protein phosphatase
A. thaliana	*abi3*	Seed-specific putative transcription factor
A. thaliana	*abi4*	Transcription factor
A. thaliana	*abi5*	bZIP transcription factor
A. thaliana	*axr2 (D)*	Auxin response factor (allelic to the auxin mutant *iaa7*)
A. thaliana	*gca1–8*	ND
A. thaliana	*gpa1*	Heterotrimeric G-protein α-subunit
Z. mays	*vp1*	Seed-specific bZIP transcription factor
Z. mays	*rea*	ND
Hordeum vulgare	*cool* (ND)	ND
Craterostigma plantagineum	*cdt-1* (D)	Regulatory RNA or short peptide
ABA-hypersensitive mutants		
A. thaliana	*abh1*	Subunit of a nuclear RNA cap-binding complex
A. thaliana	*bri1*	Steroid receptor kinase
A. thaliana	*era1*	Farnesyltransferase β-subunit
A. thaliana	*era2*	ND
A. thaliana	*era3*	Novel transmembrane protein (allelic to the ethylene mutant *ein2*)
A. thaliana	*fiery1*	Inositol polyphosphate 1-phosphate
A. thaliana	*jar1*	ND
A. thaliana	*jin4*	ND
A. thaliana	*hyl1*	Double-stranded RNA-binding protein
A. thaliana	*sax*	ND

[a]Unless indicated, all mutations are recessive (SD, semidominant; D, dominant; ND, not determined).

Germination is regulated by an antagonism between ABA, which promotes dormancy, and gibberellic acid (GA), which counteracts the effects of ABA by promoting growth and the mobilization of storage reserves. An elegant demonstration of this antagonism is the recovery of mutants defective in ABA synthesis in a screen for revertants of GA-deficient mutants.

D. ABA Controls Root and Shoot Growth

ABA shows different effects on root and shoot growth depending on plant water status. Under water stress, ABA depresses both shoot and root growth, but the overall effect is a dramatic increase in the root:shoot ratio, which facilitates water conservation.

E. ABA Mediates Wound Responses

After mechanical wounding, a specific set of defense-related proteins, such as protease inhibitors I and II, cathepsin D inhibitor, and threonine deaminase, accumulate both at the site of injury and systemically throughout the plant. ABA, together with jasmonic acid, appears to play a role in the induction of these genes.

VII. THE ABA SIGNAL TRANSDUCTION PATHWAY

Clues as to how the ABA signal is transduced to mediate its physiological and developmental processes are now beginning to emerge. It should be emphasized that although many individual components have been identified mainly by molecular genetic approaches, the complete network has not yet been elucidated.

A. Receptor(s)

ABA is thought to initiate its effects by binding to a receptor(s) that triggers the signal transduction cascade. Currently, the identity of the receptor(s) is unknown. Cells may possess at least two sites of ABA perception, one of which is located at the plasma membrane and is triggered by extracellular ABA. Biophysical studies indicate that ABA effects in stomatal guard cells also involve intracellular receptors accessible to the protonated form, ABAH, which readily permeates membranes.

B. Downstream Signaling Events

Recently, considerable insights have been gained into the identities of molecular components of the complex signaling network that mediates the actions of ABA. In particular, ion channels and fairly ubiquitous small second messengers have been implicated in ABA action.

1. Ion Channels Regulated by ABA Control Stomatal Aperture

Electrophysiological studies, either by whole cell impalement or by patch clamping of the plasma membrane of guard cell protoplasts or isolated vacuoles, have identified a number of membrane ion channels. The sequence of events in ABA-induced stomatal closure is thought to be the following: (1) ABA induces release of Ca^{2+} into the cytosol from an internal store, e.g., the vacuole. (2) The resultant increase in cytosolic Ca^{2+} inhibits plasma membrane H^+ pumps and inward K^+ (K^+_{in}) channels, but activates two types of plasma membrane anion-efflux channels. One of these shows voltage-dependent slow activation (S-type), whereas the other shows rapid transient activation (R-type). The two types may reflect different states of a single channel. (3) The conjugate actions of these channels lead to a transient or sustained depolarization and the alkalinization of the guard cell cytoplasm, which (4) deactivates (K^+_{in}) channels and also contributes to the opening of voltage-gated K^+_{out} channels. The ensuing long-term efflux of both anions and K^+ from guard cells contributes to loss of turgor and to stomatal closure.

2. Ca^{2+} Channels

Considerable evidence indicates that ABA produces repetitive, transient increases or oscillations in intracellular Ca^{2+} levels. These encode information required for stomatal closure. Ca^{2+}-induced $[Ca^{2+}]_{cyt}$ oscillations include a repetitive Ca^{2+} influx across the plasma membrane coupled to Ca^{2+} release from an intracellular compartment. Stomatal closure is abolished in guard cells when a nonoscillating Ca^{2+} plateau is imposed experimentally. Many other stimuli responsible for stomatal closure (cold shock, oxidative stress, and increases in CO_2) also cause $[Ca^{2+}]_{cyt}$ elevations. Anion channel regulation and stomatal movement phenotypes of *Arabidopsis abi1-1* or *abi2-1* mutants are suppressed by experimentally elevating $[Ca^{2+}]_{cyt}$.

The mechanisms by which ABA activates guard cell plasma membrane Ca^{2+} channels remain unknown. In *Arabidopsis* guard cells, ABA causes a rapid increase of reactive oxygen species (ROS) that activate hyperpolarization-activated Ca^{2+}-permeable channels. ROS-induced stomatal closure and Ca^{2+} activation are abolished in the ABA-insensitive mutant *gca2*. The origin of the Ca^{2+} required to elevate $[Ca^{2+}]_{cyt}$ in response to ABA is unclear, but is probably mediated by inositol 1,4,5-trisphosphate ($InsP_3$) and/or cyclic ADP-ribose (cADPR). *RAB18* expression in *Arabidopsis* suspension culture cells requires rapid ABA-induced Ca^{2+} influx and S-type anion channel activation. ABA-induced membrane depolarization in radish seedlings and tobacco epidermal and mesophyll cells indicates that these mechanisms are of general importance for ABA signaling in different cell types. A Ca^{2+}-independent pathway also appears to exist.

3. H^+ Channels

Inhibition of the plasma membrane H^+-ATPase mediated by both cytosolic alkalinization and the increase in cytosolic Ca^{2+} may also contribute to

membrane depolarization. The origin of ABA-induced cytosolic alkalinization is unknown.

4. Cyclic Nucleotides (cAMP, CGMP, CADPR)

Cyclic ADP-ribose (cADPR) plays a central role in ABA responses. Microinjection of hypocotyl cells of the tomato *aurea* mutant with both potential intermediates in the ABA signaling cascade and fusions of the *Arabidopsis RD29A* and *KIN2* promoters to a reporter gene suggested that ABA triggers a transient accumulation of cADPR, which induces a release of Ca^{2+} from internal stores such as vacuoles and the endoplasmic reticulum. Microinjection of mutant *abi1-1* protein inhibited ABA-, cADPR-, and Ca^{2+}-induced gene expression, and these effects were reversed by an excess of WT ABI1 protein.

Other cyclic nucleotides may also act in a Ca^{2+}-dependent stomatal opening pathway. For example, cAMP or the membrane-permeable cyclic GMP analog 8-Br-cGMP stimulates stomatal opening. cGMP-induced stomatal opening is inhibited by chelation of external Ca^{2+} or by inhibitors of intracellular Ca^{2+} release.

5. Lipid-Derived Second Messengers

Various lines of evidence suggest that ABA stimulates phosphoinositide metabolism. ABA-treated guard cell protoplasts showed a slight increase in $InsP_3$. The release of caged $InsP_3$ into the cytosol of guard cells caused $[Ca^{2+}]_{cyt}$ increases, inhibition of K^+_{in} channels, and stomatal closure. The *Arabidopsis fry1* (*fiery*1) mutant, which is defective in an inositol polyphosphate 1-phosphatase, accumulates more $InsP_3$ than WT plants after ABA treatment and is hypersensitive to ABA in germination and gene expression assays. Similarly, overexpression of a different $InsP_3$ phosphatase blocked the inhibition of germination and seedling growth in *Arabidopsis*. Overexpression of a stress- and ABA-inducible phosphatidylinositol-specific phospholipase C (PI-PLC) in *Arabidopsis* suggests that although increased $InsP_3$ levels are necessary for maximal ABA-induced gene expression in vegetative tissues, the AtPLC1 isoform is normally latent and probably participates in secondary ABA responses. A reduction in $InsP_3$ levels in transgenic lines expressing antisense *AtPLC1* correlated with their insensitivity to ABA in germination and seedling growth assays.

ABA also stimulates production of myo-inositol-hexakisphosphate ($InsP_6$) in guard cells to a greater extent than $InsP_3$. $InsP_6$ inhibits K^+_{in} channels in a Ca^{2+}-dependent manner with greater efficiency than $InsP_3$. Whether $InsP_6$ causes $[Ca^{2+}]_{cyt}$ elevations and whether both messengers function in the same or separate signaling branches is unknown.

Phosphatidic acid (PtdOH) generated from phospholipase D (PLD) increases transiently following ABA treatment of *Vicia faba* guard cells. PtdOH promotes stomatal closure and inactivates K^+_{in} channel currents but does not elicit a $[Ca^{2+}]_{cyt}$ increase, suggesting that PLD acts either in a parallel Ca^{2+}-independent pathway or downstream of Ca^{2+} release. Both U-73122 (a PI-PLC inhibitor) and 1-butanol (a PLD inhibitor) only partially inhibit ABA-dependent stomatal closure, and simultaneous application of both inhibitors does not have additive effects. Thus, PLC and PLD appear to act in the same pathway that requires the cooperation of an additional pathway(s) to attain the complete effects of ABA. This may be mediated by cADPR, since simultaneous application of 1-butanol with the cADPR antagonist nicotinamide increases the extent to which ABA-induced stomatal closure is reduced.

Sphingosine-1-phosphate (S1P) is another lipid-derived Ca^{2+}-mobilizing agent capable of inducing stomatal closure. An increase in S1P levels occurs in leaves following drought stress, but disruption of S1P production causes only partial inhibition of ABA-induced stomatal closure.

6. Protein Kinases and Protein Phosphatases

Phosphorylation/dephosphorylation events are central mediators in ABA signaling. In guard cells, the Ca^{2+} signal is possibly relayed by specific protein kinases and phosphatases. Protein kinase inhibitors abolish the activation of S-type anion channels and thus block ABA-induced stomatal closure. Reciprocally, the protein phosphatase inhibitor okadaic acid (OKA) maintains guard cell S-type channels in the active state. In-gel phosphorylation assays demonstrated that ABA rapidly activates a Ca^{2+}-independent 48 kDa Ser/Thr protein kinase in *V. faba* guard cells. ABA fails to activate anion channels or induce stomatal closure in guard cells that express a dominant loss-of-function allele of this kinase.

Several stress- and ABA-inducible protein kinases have been identified. In epidermal peels of *Pisum sativum*, the ABA-induced accumulation of a *DHN* transcript was reduced by K-252a (an inhibitor of Ser/Thr protein kinases) and also by OKA or cyclosporin A (an inhibitor of Ser/Thr protein phosphatases type 2B). In barley aleurone protoplasts, the stimulation of a MAP kinase activity appeared to be correlated with the induction of *RAB16* transcript. OKA inhibited the induction

of *HVA1* and *RAB16* transcripts by ABA, and phenylarsine oxide (an inhibitor of Tyr protein phosphatases) blocked *RAB16* induction.

The analysis of *abi1* and *abi2* has shed new light on the involvement of phosphorylation events in ABA signaling. These two dominant ABA-insensitive mutants, originally isolated in a screen for mutants able to germinate and grow in nonpermissive ABA concentrations, have phenotypes reminiscent of ABA deficiency viz. reduced seed dormancy, improper regulation of stomatal aperture, and decreased expression of various ABA-inducible genes. *ABI1* and *ABI2* encode Ser/Thr protein phosphatases type 2C (PP2C). The dominant mutant alleles *abi1-1* and *abi2-1* have point mutations that substitute a conserved Gly with Asp, probably disrupting the conformation of a site required for Mg^{2+}-binding or phosphatase activity. Several downstream responses to ABA are impaired in *abi1-1* and *abi2-1*, including K^+_{out} and K^+_{in} channel regulation, anion channel activation, and increases in $[Ca^{2+}]_{cyt}$. Because the mutations are dominant, it remains unclear whether the ABI1 and ABI2 are positive or negative regulators of ABA signaling or, indeed, whether they affect ABA signaling at all in WT plants. However, because intragenic revertants of *abi1-1* and *abi2-1* have reduced or no phosphatase activity *in vitro* and a double mutant of both revertants is hypersensitive to ABA, ABI1 and ABI2 are probably negative regulators of ABA signaling. Accordingly, overexpression of WT ABI1 in maize mesophyll protoplasts blocks ABA regulation of gene expression. The precise roles of kinases and phosphatases in ABA signaling and the identities of their protein substrates have not been clearly established.

7. Farnesylation

Although researchers have focused mainly on positively acting components of the ABA signaling pathway, inactivation of negative regulators of ABA signaling should result in an enhanced response to ABA. An *Arabidopsis* mutant *era1* (*e*nhanced *r*esponse to *A* BA) was isolated based on its inability to germinate in the presence of low concentrations of ABA (0.3 μM) that do not inhibit germination of WT seeds. The *era1* mutation markedly increases seed dormancy and ABA hypersensitive activation of S-type anion currents in this mutant increases stomatal closure, reducing water loss during drought. The *ERA1* gene encodes the β-subunit of a heterodimeric farnesyltransferase. Farnesyltransferases catalyze the attachment of a 15-carbon farnesyl lipid to C-terminal target sequences, which localizes specific soluble signaling proteins to membranes. In addition to enhancing ABA signaling, loss of *ERA1* function affects several other signaling pathways and developmental programs, including meristem development. Thus, although *ERA1* targets are not restricted to ABA action, a factor that normally suppresses ABA responses requires farnesylation. The exact relationship between *ERA1* and the *ABI* loci remains unknown.

8. RNA Binding and ABA

Arabidopsis abh1 mutants are hypersensitive to ABA-mediated inhibition of germination as well as induction of stomatal closure and increases in $[Ca^{2+}]_{cyt}$. *ABH1* is expressed in stomata and encodes a nuclear transcript cap-binding protein that apparently functions in a heterodimeric complex. *ABH1*, by analogy to yeast and mammalian RNA cap-binding proteins, is proposed to regulate the strength of ABA signaling by transcript modification of early signaling components.

9. Heterotrimeric G-Protein Action

Heterotrimeric G-proteins are central to many signaling processes. *Arabidopsis* contains only a single gene (*GPA1*) encoding a prototypic Gα subunit. ABA-mediated inhibition of stomatal opening, but not ABA-controlled promotion of stomatal closure, is impaired in *gpa1* null mutants. *GPA1* is required for negative regulation of K^+_{in} channels and the pH-independent activation of anion channels.

10. Role of the Actin Cytoskeleton in Stomatal Movements

A reorganization of the actin cytoskeleton of guard cells has been observed after ABA treatment. Cytochalasin D (an actin filament-depolymerizing agent) activates K^+_{in} channels, while phalloidin (an actin filament stabilizer) inhibits K^+ channel currents. ABA treatments reorganize actin cytoskeleton architecture from a radial arrangement to a randomly oriented and fragmented pattern. A small *Arabidopsis* GTP-binding protein, AtRac1, is a negative regulator in ABA-induced actin reorganization. The inactivation of AtRac1 by ABA is impaired in *abi1-1*.

C. Regulation of Gene Expression by ABA

ABA regulates the expression of numerous genes during embryogenesis and seed maturation as well as under stress conditions such as heat shock, low temperature, drought, and high salinity.

1. ABA-Inducible Genes

The use of ABA-deficient and ABA-insensitive mutants has demonstrated that ABA contributes to the regulation of numerous genes involved in seed maturation and/or the response of vegetative tissues to hyperosmotic stress. Characterization of the promoters of ABA-responsive genes has enabled identification of the *cis*- and *trans*-acting elements that act at the termini of branches in the ABA signaling cascade. Considerable evidence indicates the existence of ABA-independent dehydration and cold-induced signaling pathways.

2. Cis-Acting Elements

Gene activation is mediated by the binding of transcription factors to ABA-responsive elements (ABREs) located in the promoters of ABA-induced genes. To date, more than 20 functional ABREs have been found in ABA-inducible genes that are abundantly expressed in desiccating seeds and/or are responsive to drought stress and ABA in vegetative tissues.

The first type of ABRE defined was a sequence of 8–10 bp that shares a conserved ACGT core motif, named the G-box. The sequence flanking the ACGT core is important for *in vivo* and *in vitro* function. Some ACGT elements confer developmental and tissue-specific expression on a minimal promoter. In a natural promoter context, an ABRE functions with a coupling element (CE). ABA-responsive complexes comprising an ABRE and a CE can confer ABA-inducible transcription upon a minimal promoter. The sph element, first identified in the promoter of the *C1* gene involved in anthocyanin synthesis in maize endosperm, is a second category of *cis*-acting element distinct from the G-box.

3. Trans-Acting Factors

Yeast one-hybrid assays to identify ABRE-binding proteins (AREBs) have enabled cloning of several homologous transcription factors of the basic leucine zipper (bZIP) family. ABA-regulated transcription factors of the homeodomain leucine zipper, basic helix-loop-helix leucine zipper, and MYB classes have also been identified. AREBS are capable of activating reporter genes fused to ABREs and their induction by ABA at the transcript level frequently precedes the induction of other ABA-responsive genes. *Arabidopsis* ABI5, the only bZIP AREB recovered in a genetic screen, is also subject to posttranscriptional modification by ABA. Maize VP1 and *Arabidopsis* ABI3 appear to be orthologous seed-specific transcriptional activators, the loss of which affects several aspects of seed maturation, including the expression of storage proteins and *LEA* genes. VP1/ABI3-like proteins appear to activate transcription by distinct mechanisms depending on the target *cis* elements. VP1 interacts directly with the sph element of the C1 promoter and acts on ABREs via association with a distinct *trans*-acting factor(s).

D. Novel Genetic Screens

Quantitative and mechanistic characterization of new signaling mutants is necessary for a complete molecular understanding of the ABA signaling cascade. Several mutants have been isolated in screens for deregulated ABA control of ABREs fused to reporter genes. Eight *gca* (growth control by ABA) mutants are characterized by reduced sensitivity to the inhibition of seedling growth by exogenous ABA and aberrant stomatal regulation. An elegant screen that uses small differences in leaf temperature to distinguish transpiration rates in mutants and WT plants is likely to identify new elements which mediate ABA action in guard cells. Screens for enhancer or suppressor mutations offer one approach to identify genes which interact genetically with known participants in ABA signaling.

VIII. BIOTECHNOLOGICAL FEATURES

Fresh water scarcity is currently one of the principal threats to global food security. Plants account for approximately 65% of global fresh water use. Losses in agricultural yields resulting from the desiccation of crops and horticultural plants during periods of drought have severe social and economic repercussions. Unfortunately, because of the high cost of synthesis and its instability in UV light, there are no practical uses of ABA. However, synthetic ABA analogs such as the acetyleneacetal-type compounds LAB 173 711 and LAB 144143 reduce crop water use and increase cold-hardiness. Engineering the ABA signal transduction network in guard cells to control CO_2 intake and water loss could contribute substantially to more sustainable water use under adverse environmental conditions. The manipulation of seed maturation and dormancy in certain species by modification of ABA-regulated developmental programs may also be of considerable agricultural significance.

IX. CONCLUSIONS

Recent advances have filled in many gaps concerning the biochemistry and subcellular localization of ABA synthesis as well as demonstrating the unquestionable involvement of ion channels, cytosolic pH, protein (de)phosphorylation, and cADPR- and phosphoinositide-mediated increases in $[Ca^{2+}]_{cyt}$ in transducing the ABA signal. Substantial progress has been made in characterization of the terminal signaling elements involved in ABA-mediated transcriptional regulation. Nonetheless, the mechanism(s) of ABA perception and early signaling events that result in cADPR synthesis or $InsP_3$ release remain to be resolved. Considering the multitude of physiological responses modulated by ABA, it will be interesting to assess the extent of overlap in the signaling events involved in well-characterized ABA effects such as the regulation of stomatal closure, the inhibition of seed germination, and the induction of stress-responsive gene expression. The striking degree of phenotypic pleiotropy observed in many mutants recovered in screens for altered sensitivity to ABA indicates extensive overlap between ABA action and other signaling pathways. Better insight into the regulation of ABA concentrations and the cellular capacity for response to ABA will provide a more complete picture of its importance to growth and development throughout the plant life cycle.

Glossary

abscission The rejection of plant organs at an abscission zone where hydrolytic enzymes reduce cell adhesion.

dormancy A resting condition with reduced metabolic rate found in ungerminated seeds and nongrowing buds.

stomata Small openings located in the epidermal layers of plants allowing uptake of CO_2 and loss of water. Stomata are surrounded by two guard cells that control the pore size.

stress The consequence of suboptimal environmental conditions that significantly decrease plant growth and/or reproductive capacity below potential.

vivipary The ability of a plant embryo to bypass dormancy and proceed directly from embryogenesis to germination if rescued from the normal dehydration that occurs during seed maturation.

Activating and Inactivating Receptor Mutations

ILPO T. HUHTANIEMI

University of Turku, Finland and Imperial College London

Human hereditary diseases can be divided according to the Mendelian inheritance pattern into three categories: autosomal dominant, autosomal recessive, and X-linked recessive. The same division applies to the mutations that are known today in hormone receptor genes. The autosomal dominant mutations of receptor genes cause *activating* or *gain-of-function*

mutations. In these cases, the structure of the receptor protein is usually altered in such a fashion that its signal transduction is constitutively activated in the absence of ligand hormone, and one altered allele is sufficient to cause the phenotype. The autosomal recessive mutations are usually of the *inactivating* or *loss-of-function* type; i.e., the mutant allele encodes a functionally inactive receptor protein. In most cases, the normal allele is sufficient to maintain normal hormonal function, but in some situations the heterozygous carrier has a phenotype, usually in the form of mild hormone resistance. X-linked recessive mutations cause a phenotype in all males and in homozygous females, and in some cases heterozygous females have a milder phenotype. A special case of inactivating receptor mutations is the *dominant negative* mutations, where the mutated receptor inhibits the function of that encoded by the wild-type allele. This is the only situation where an inactivating mutation causes the phenotype in dominant fashion. Besides the above hereditary (germ line) mutations, somatic mutations are also known in hormone receptors. They are invariably found in tumors, are of the activating type, and play a role in tumor formation or growth. In addition, numerous polymorphisms are known in receptor genes; they either cause no phenotype or may alter susceptibility to certain diseases.

I. INTRODUCTION

A large number of hormone receptor mutations are known today, and this article presents appropriate examples of the different mechanisms by which the mutated receptor brings about either receptor inactivation or constitutive activation. Hormone receptors can be subdivided into two functional categories on the basis of their cellular location, i.e., those present on the plasma membrane and those present inside the cell, in the nucleus and/or cytoplasm. Because of differences in the function of these two receptor types, they are presented separately, under the headings of activating and inactivating mutations. Table 1 summarizes the phenotypes, types of functional alteration, and modes of inheritance of most of the currently known hormone receptor mutations.

II. ACTIVATING MUTATIONS

Activating or gain-of-function mutations can be classified, according to the functional alteration, into four categories: (1) constitutive receptor activation in the absence of ligand hormone, (2) increased sensitivity of the receptor to its normal ligand, (3) relaxed specificity of the receptor to ligands, and (4) acquired novel functions of the mutated receptor. Category 1 is most common among the activating receptor mutations. Some of these mutations are inherited via the germ line, but some, in particular those encountered in tumors, are somatic (Table 1).

A. Nuclear Receptors

Only a few cases of gain-of-function mutations of nuclear receptors are currently known, although it is possible to produce constitutively activated nuclear receptors through site-directed mutagenesis *in vitro*. The reason for their paucity may be the fundamental role that many of the nuclear receptors play in cellular functions and because their inappropriate activation may be embryo-lethal. In fact, almost the only germline mutations known in nuclear receptors are those of the androgen receptor (AR), not necessary for life. The extensions of the polyglutamine (CAG) repeat in the N-terminal part of AR (see below) in Kennedy's disease apparently bring about novel neurotoxic functions for the mutated receptor protein. Conversely, if this repeat is shortened, as is found in somatic mutations in advanced forms of prostatic cancer, the mutated AR either is constitutively activated or has relaxed ligand specificity. Activating mutations of retinoic acid receptors may play a role in the pathogenesis of certain leukemias and hepatomas, due to chromosomal rearrangements within the retinoic acid receptor genes, resulting in fusion proteins with novel functions. The only other piece of information on constitutively activated nuclear receptors concerns estrogen receptors that may contribute to the formation of estrogen-independent cell clones in breast cancer.

B. Cell Membrane Receptors

The receptors for the glycoprotein hormones, i.e., luteinizing hormone (LH), follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH), constitute a good example of gain-of-function mutations of cell membrane receptors. They all belong to the family of G-protein-associated seven-transmembrane domain receptors. Normal receptor activation entails binding of the ligand to the extracellular receptor domain, whereby a conformational change occurs in the transmembrane domain, allowing activation of the intracellular second-messenger generation and ultimately the functional response of the target cell to hormonal stimulation. Accordingly, most of the activating mutations in these

TABLE 1 Currently Known Mutations in Hormone Receptor Genes

Receptor	Type of mutation	Type of inheritance	Phenotype
Nuclear receptors			
Thyroid hormone	Dominant negative	D	Thyroid hormone resistance
	Inactivating	R	Thyroid hormone resistance
Estrogen-α	Inactivating	R	Male: unfused epiphyses, poor sperm, osteoporosis, insulin resistance
	Activating	S	Receptor positive, hormone-resistant breast cancer
Androgen	Inactivating	XR	Lack of male sexual differentiation (testicular feminization)
	Activating	XR	Kennedy's disease
		S	Advanced prostate cancer
Glucocorticoid	Inactivating	R	Variable symptoms of glucocorticoid resistance
		S	Nelson's syndrome (pituitary adenoma)
Mineralocorticoid	Inactivating	D	Autosomal dominant pseudohypoaldosteronism I
Vitamin D	Inactivating	R	Hypocalcemic vitamin D-resistant rickets
Retinoic acid	Activating	S	Various malignant tumors
	Dominant negative	D	
Plasma membrane receptors			
TSH	Activating	S	Toxic thyroid adenomas
		D	Toxic thyroid hyperplasia (hereditary)
	Inactivating	R	Euthyroid, elevated TSH (mild)
		R	Hypothyroidism (severe)
LH	Activating	D	Males: gonadotropin-independent precocious puberty Females: no phenotype
		S	Leydig cell tumors
	Inactivating	R	Males: lack of male sexual differentiation Females: anovulatory infertility
FSH	Activating	D	Normal spermatogenesis in the absence of gonadotropins
	Inactivating	R	Females: infertility with arrest of follicular maturation Males: suppressed spermatogenesis
ACTH	Inactivating	R	Familial glucocorticoid deficiency
	Activating	D	Normal cortisol, low ACTH
MSH	Inactivating	R	Red hair and light skin
Vasopressin	Inactivating	XR	Nephrogenic diabetes insipidus
GnRH	Inactivating	R	Hypogonadotropic hypogonadism
Ca^{2+}-sensing	Inactivating	R	Familial hypocalciuric hypercalcemia, neonatal severe hyperparathyroidism
	Activating	D	Hypoparathyroidism, hypocalcemia
PTH/PTHrP	Activating	D	Jansen's metaphyseal chondrodysplasia
GH	Inactivating	R	Dwarfism
	Dominant negative	D	Dwarfism
GHRH	Inactivating	R	Dwarfism
Insulin	Inactivating	R	Leprechaunism, Rabson–Mendenhall syndrome
	Dominant negative	D	Type A insulin resistance
Erythropoietin	Activating	D	Primary polycythemia
Leptin	Inactivating	R	Obesity, pituitary dysfunction

D, dominant; R, recessive; S, somatic; X, X-linked; TSH, thyroid-stimulating hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone; ACTH, adrenocorticotropic hormone; MSH, melanocyte-stimulating hormone; GnRH, gonadotropin-releasing hormone; PTH, parathyroid hormone; PTHrP, parathyroid hormone-related peptide; GH, growth hormone; GHRH, growth hormone-releasing hormone.

receptors have been discovered in the third intracellular loop or the sixth transmembrane region of the receptor, assumed to be the hot spot for activating mutations. The mutation apparently brings about a conformational change in the transmembrane receptor domain, allowing activation of signal transduction without preceding ligand binding. The functional alteration can be demonstrated by transfecting cDNA that encodes the mutated receptor into a cell line, which then displays the cellular response,

for instance, cAMP production, in the absence of ligand hormone (Fig. 1).

Both activating germ-line and somatic mutations have been observed in the TSH receptor (R), and the latter mutations explain the molecular pathogenesis of a large proportion of toxic thyroid adenomas; they have also been implicated in some follicular thyroid carcinomas. Tens of this type of mutations are currently known in the TSHR, but why this receptor in particular is prone to somatic mutations remains unclear. Activating germ-line mutations of the TSHR are found in hereditary and sporadic toxic thyroid hyperplasia. The hereditary form is characterized by autosomal dominant transmission, hyperthyroidism with variable age of onset, hyperplastic steadily growing goiter, and absence of stigmata of autoimmunity. The sporadic cases present with congenital hyperthyroidism, due to neomutations in the TSHR gene. The mutations found in toxic adenomas and neomutations overlap, but another set of mutations are found in hereditary hyperthyroidism. The latter present with milder phenotypes and, hence, the autonomous receptor activation is milder than in the other two cases with more severe phenotypes. Natural selection may explain this difference. The sporadic cases display such strong TSHR activation that carriers of the same mutations in the germ line would apparently not have survived until fertile age in the past.

The other examples of activating mutations in cell membrane receptors are those of the LHR. Approximately 15 activating mutations of the LHR are currently known, but interestingly, not a single unequivocally documented case of activating FSHR mutation is known. The latter may be due to the fact that activating FSHR mutations do not cause a clear phenotype or to the fact that the phenotype is unexpected and the right types of patients have not been investigated. Gain-of-function mutations of the LHR cause in males gonadotropin-independent early onset precocious puberty (testotoxicosis), but in women, for reasons not clearly understood, there is no phenotype. Most of the activating LHR mutations bring about a clear, approximately 10-fold increase in basal cAMP production in cell lines expressing the mutated receptor. This explains why testosterone production in affected boys is activated well before the normal age of puberty. An interesting special case is an activating somatic LHR mutation that was recently discovered in Leydig cell tumors. This mutation activated, in addition to cAMP, the inositol phosphate signaling pathway, providing an example of an activating mutation with acquired novel function.

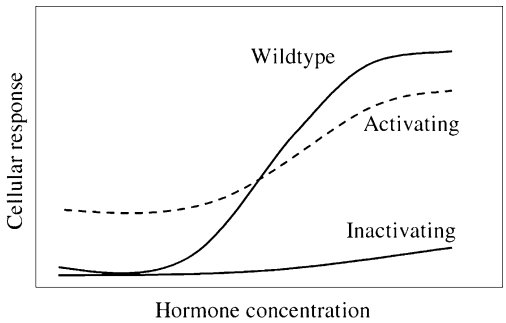

FIGURE 1 Schematic presentation of hormone-stimulated response, for instance. cAMP production, in cells transfected with cDNA encoding the wild-type receptor and one carrying an activating or inactivating mutation. The elevated response in the absence of hormonal stimulation is typical for activating mutation. In inactivating mutation the response is totally or nearly completely missing.

III. INACTIVATING MUTATIONS

An inactivating mutation can cause the following functional aberrations in the receptor protein: (1) decreased synthesis, (2) aberrant intracellular processing, (3) impaired or missing ligand-binding activity, (4) impairment or lack of signal transduction, (5) inability to anchor to the plasma membrane, (6) inability to dimerize, if needed for signal transduction, or (7) increased degradation.

A. Nuclear Receptors

A good example of a nuclear receptor with inactivating mutations is the AR, a member of the steroid hormone/thyroid hormone/retinoic acid receptor family. It is extremely polymorphic and more than 250 AR mutations are known today. Because the AR gene is located on the X chromosome, mutational AR defects exist only in men (X-linked dominant inheritance). A homozygous female is impossible due to obligatory infertility of men carrying a mutated AR gene. The AR protein is a single polypeptide chain, containing, like all nuclear receptors, three functional domains, i.e., the transactivation domain, DNA-binding domain, and ligand-binding domain. The phenotypes with androgen insensitivity vary from mild defects of virilization (Reifenstein's syndrome) to complete female phenotype (testicular feminization), and the extent and location of the AR mutation often predict the phenotype. Splicing defects, frameshifts, immature termination codons,

and partial or complete gene deletions invariably result in total androgen insensitivity. Single amino acid substitutions, in contrast, result in a wide variety of phenotypes, with severity depending on location of the mutation. Substitutions in the DNA-binding domain are a relatively homogenous group in which ligand binding is not altered, but the capability of the AR to modulate androgen-responsive genes is impaired. Mutations in the hormone-binding domain have more varying effects. The mutated receptor is seldom totally unable to bind hormone, whereas the ligand binding may be qualitatively altered or has low affinity. The phenotype of these mutations is often difficult to predict. Mutations in the transactivation domain are relatively rare. This part of the AR is the least conserved and it possibly allows greater variability in structure without hampering receptor function. In addition, no abnormalities in ligand binding can be detected in a large proportion of the patients despite their clear phenotype of androgen insensitivity. Some other genes involved in androgen action, e.g., those of AR co-activators, may be mutated in these cases.

AR has been found to have an intriguing type of structural polymorphism, a polyglutamine repeat (CAG at the DNA level), in exon 1 of its N-terminus. Short repeats (20 residues) are detected in advanced forms of prostatic cancer, apparently as somatic mutations, in which case the ligand specificity of the AR is relaxed and various steroidal and nonsteroidal ligands can activate it. The normal length of the repeat is 23–27 residues. Slight androgen insensitivity is apparent when the repeat length is 28, as can occur in men with oligo-azoospermia. Finally, clearly extended polyglutamine repeats (40 repeats) exist in spinal and bulbar muscular atrophy due to degeneration of motor neurons (Kennedy's disease) where the receptor function is more drastically altered, and it may have acquired novel toxic effects on motor neurons.

Inactivating mutations are also known in other steroid receptors. Only one case of estrogen receptor-α mutations has been described. This was detected in an adult male with tall stature, incomplete closure of epiphyses, osteoporosis, and insulin resistance. The receptor inactivation was due to a point mutation that induced a premature stop codon and hence formation of nonfunctional receptor protein. No progesterone receptor mutations have been described, possibly since they would be effectively eliminated from the genetic pool due to their adverse effect on reproduction. Glucocorticoid receptor (GR) mutations present a variable range of phenotypes from asymptomatic to isolated chronic fatigue and hypertension with or without hypokalemic alkalosis and/or hyperandrogenism. All GR mutations detected cause partial hormone resistance, since complete inactivation of glucocorticoid function would probably be lethal. Differences in impact of the various mutations on glucocorticoid sensitivity of the different target organs probably explain the variability of phenotypes encountered in this syndrome. A mild form of autosomal dominant hypoaldosteronism (type I) has been found to be due to inactivating mutations in the mineralocorticoid receptor. Inactivating mutations of thyroid hormone receptors cause, as expected, thyroid hormone resistance. The vitamin D receptor mutations cause hypocalcemic vitamin D-resistant rickets. In this case, the mechanism of receptor inactivation falls into three categories: (1) suppressed DNA binding/nuclear localization, (2) suppressed hormone binding, and (3) inhibition of heterodimerization with retinoic acid X receptor (RXR). The latter effect is incompatible with the mechanism of vitamin D action, where the vitamin D-receptor complex must heterodimerize with RXR to evoke a biological response.

B. Cell Membrane Receptors

An inactivating mutation of a cell membrane-associated receptor causes hormone resistance usually in the recessive mode of inheritance. Large deletions of the gene often predict the inactivation mechanism of the receptor, but especially if a point mutation is discovered, it is difficult to decipher from the small structural alteration the type of functional impact of the mutation. Functional analysis of synthesis, intracellular processing, and function of the mutated receptor protein in cell culture transfections is therefore needed to prove its functional significance and to solve the molecular basis of the inactivation mechanism. A typical finding with an inactivating receptor in functional analysis is schematically presented in Fig. 1. Similar functional tests are available for nuclear receptors.

Mutations of the growth hormone receptor (GHR) provide good examples of the various mechanisms of receptor inactivation. More than 30 GHR mutations are currently known, mostly in the area encoding the extracellular receptor domain, including exonic deletions and nonsense, frameshift, splice-site, and missense mutations. As is well known, the phenotype of this condition is GH resistance (Laron dwarfism), which is usually inherited in an autosomal recessive manner. The various categories of GHR inactivation

in this syndrome can be grouped according to their effects on circulating GH-binding protein (GHBP), which is a proteolytic cleavage product of the plasma membrane GHR. In some of the cases, the GHBP level is suppressed, as a sign of failure of the mutated GHR protein to bind GH or to be expressed at the cell membrane. In other types of this syndrome, the GHBP levels are either normal or elevated. One of them, with normal GHBP levels and a point mutation in the extracellular domain, was found to be caused by inactivated GHR due to impairment of expression and signaling. The third type of GHR mutation has increased GHBP levels, and in this case a point mutation resulted in alternative splicing and a premature stop codon, with the resulting receptor protein lacking the transmembrane domain and most of the intracellular domain. The truncated receptor was unable to anchor to the cell membrane, but was instead secreted in large amounts into the circulation, thus causing the elevated GHBP levels and lack of GH response. In addition, there are cases of GH insensitivity with normal GHR function, explained by abnormalities in postreceptor signaling mechanisms. A fourth mechanism of GHR inactivation, through a dominant negative mutation, will be discussed below.

Another example of inactivating receptor mutations is that of the TSHR. A number of mutations are known, and depending on the extent of receptor inactivation, their phenotypes vary greatly. The mildest cases represent euthyroidism with elevated TSH levels; the mutation lowers only the affinity of the TSHR-ligand complex, and higher TSH levels can maintain euthyroidism, since otherwise the receptor function is normal. In more severe cases, the affected individual is hypothyroid, and the mutation causes sequestration of the mutated receptor inside the cells and near total abolition of its function.

A third example of inactivating receptor mutations concerns those of the gonadotropins LH and FSH. The inactivating LHR mutation in the male causes, depending on the extent of receptor inactivation, an array of phenotypes ranging from micropenis and hypospadias to total lack of male sexual differentiation (XY, pseudohermaphroditism). The female phenotype is much milder, entailing only anovulatory infertility. In functional analyses of the LHR mutations there is a good correlation between the severity of phenotype and the completeness of receptor inactivation, as demonstrated by the variably suppressed functional responses to gonadotropin stimulation in cells expressing the various forms of mutated receptors. In most cases, the real mechanism of receptor inactivation, whether a defect in synthesis, intracellular processing, transport to the plasma membrane, ligand binding, or signal transduction, has not been studied.

As with the LHR, inactivating mutations of the FSHR show correlation between the severity of phenotype and the completeness of receptor activation. Complete receptor inactivation in women causes primary hypergonadotropic amenorrhea with impaired pubertal development, lack of follicular maturation, and infertility, whereas the phenotype of incomplete receptor activation is secondary amenorrhea with arrest of follicular maturation. In men, a surprisingly mild phenotype with variable derangement of spermatogenesis, but no obligatory infertility, is observed with complete FSHR inactivation. The impairment of function of the mutated FSHR is primarily due to sequestration of the synthesized receptor protein inside the cell. The few mutated receptors expressed at the plasma membrane of transfected cells seem to display a normal cAMP response to hormonal stimulation.

IV. DOMINANT NEGATIVE MUTATIONS

The concept of dominant negative mutation means that a heterozygously inherited mutated receptor has the capability of blocking the action of functional receptors encoded by the wild-type allele. Abolition of hormone action occurs thus even though only one allele is mutated, and therefore, the mode of inheritance is dominant despite a loss-of-function mutation. This type of inactivation mechanism is encountered with receptors that need to be homo- or heterodimerized in order to achieve their biological effects. The different modes in which a dominant negative mutation brings about inactivation of the wild-type receptor are presented in Fig. 2.

In thyroid hormone resistance, typical loss-of-function mutations with recessive inheritance are rare. Usually, the mutation causes receptor inactivation in a dominant negative fashion. In most cases, the patients have an inactivating mutation in one of their thyroid hormone receptor (TR) β alleles. The mutated receptor interferes negatively with functional receptor proteins encoded by the two normal TRα alleles and one TRβ allele. Unliganded TR is bound as a homodimer, or as a heterodimer with RXR, to the thyroid hormone response element of a target gene and is associated with a complex of corepressor proteins, being transcriptionally inactive. Mutations usually abolish ligand-binding activity

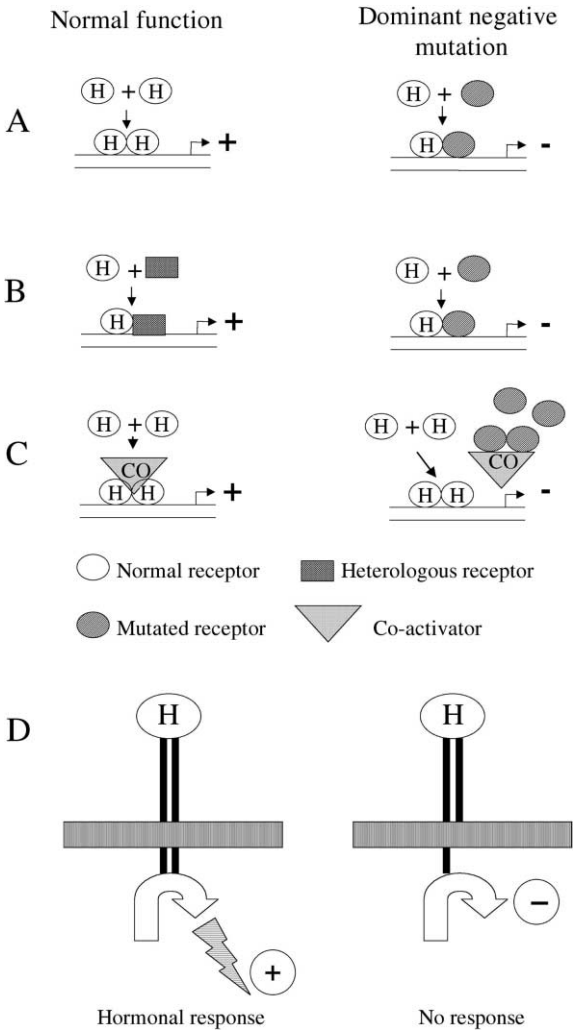

FIGURE 2 Models for mechanisms of receptor inactivation by dominant negative mutations of nuclear (A–C) and cell membrane (D) receptors. In each case, this type of receptor inactivation requires that the wild-type receptor forms homo- or heterodimers in order to exert its biological action.

of the TR. Normally, ligand binding promotes replacement of co-repressor with co-activators, which results in receptor activation. Since the mutated receptor dimerizes with wild-type TR, it keeps the complexes transcriptionally inactive, explaining the dominant negative effect. Mutated TR may also make stable dimers with RXR at the TR recognition site, thus blocking the binding of wild-type TR, needed for activation of the heterodimer.

In retinoic acid receptors, chromosomal rearrangements and other types of mutations have been described in connection with various malignancies; some of the mutated genes function in dominant negative fashion and some in gain-of-function fashion.

Dominant negative mutations can explain hormone resistance in the molecular pathogenesis of a rare syndrome with insulin resistance, acanthosis nigricans and polycystic ovary syndrome (type A insulin resistance). Another example of a dominant negative mutation in cell membrane receptors concerns GHR. In this case, a particular single base substitution can cause skipping of exon 9 of the GHR upon transcription with consequent formation of a receptor without the intracellular domain, which is an essential part for signal transduction. The mutated receptor was unable to transmit signal, but it effectively heterodimerized with a wild-type receptor to form dimers devoid of signal transduction capability (Fig. 2D).

V. SUMMARY

The hormone receptor mutations can be divided in two categories: (1) the constitutively activating mutations that cause inappropriate activation of a hormonal effect in the absence of ligand hormone and (2) the inactivating mutations that are the most common cause of hormone resistance syndromes. Mutations have already been detected in a number of hormone receptor genes, and new mutations are expected to be found. However, it should be kept in mind that the receptor mutations may represent only the tip of the iceberg. All genes encoding the various components of a hormonal regulatory cascade, from synthesis of ligand to specific cellular responses downstream of receptor activation, are prone to mutations. Conditions with a clear phenotype of activating or inactivating receptor mutation, but intact receptor function, are candidates for mutations of the other genes involved in hormone action. Due to the large number of such candidate genes it will be a long time before all aspects of the molecular pathogenesis of inappropriate hormone action and hormone resistance are fully understood.

Glossary

activating (gain-of-function) mutation Structural alteration of the receptor makes it constitutively activated, i.e., in the absence of ligand hormone. Activating mutation can also increase the receptor's affinity for the ligand hormone, alter its binding specificity, or permit new functions.

cell membrane receptor A hormone-binding transmembrane protein. Binding of the ligand hormone triggers a cascade of responses: conformational change of the receptor → activation of the intracellular second-messenger response(s) → secondary intracellular

response(s) → functional target cell response(s) to hormone stimulation.

dominant negative mutation A mutation in a receptor that must be dimerized to evoke the functional response. When the mutated receptor dimerizes with wild-type receptor, the heterodimer remains functionally inactive.

hormone resistance Disease condition in which a specific hormone is unable to exert its biological actions; it is usually caused by an inactivating receptor mutation.

inactivating (loss-of-function) mutation A mutation that inactivates the function of a receptor by one of the following mechanisms: decreased synthesis, aberrant intracellular processing, impaired or missing ligand binding, impaired or missing signal transduction, inability to anchor to plasma membrane (cell membrane receptors), inability to dimerize (if needed for action), or increased degradation.

nuclear receptor A hormone receptor present inside the cell, in either the cytoplasm or the nucleus, binding hormones that are able to pass through the cell membrane (e.g., steroid and thyroid hormones). The hormone-receptor complex binds in dimerized form to specific promoter sequences of hormone-responsive genes, thus functioning as a transcription factor.

Activin Receptor Signaling

PETER C. K. LEUNG* AND CHUN PENG†

University of British Columbia, Vancouver • †York University, Toronto

Activins are dimeric proteins consisting of two inhibin β-subunits. Homo- and heterodimerization of two isoforms of β subunits, βA and βB, result in three forms of activins, activin-A, -B, and -AB. It is now recognized that activins function mainly as autocrine/paracrine factors to regulate the proliferation, differentiation, and apoptosis of many types of cells and are involved in a variety of physiological processes. Activins also play important roles during embryonic development. Activins elicit their biological effects through interaction with a receptor complex that contains two types of structurally related transmembrane serine/threonine kinases referred to as type I and type II receptors, respectively. The signal is then propagated from the receptors at the cell surface to target genes in the nucleus by intracellular mediators, the Smad family of proteins. This signaling cascade can be modulated at the cell surface by interfering with the interaction between activins and their receptors and in the cytoplasm by facilitating or blocking the activation

response(s) → functional target cell response(s) to hormone stimulation.

dominant negative mutation A mutation in a receptor that must be dimerized to evoke the functional response. When the mutated receptor dimerizes with wild-type receptor, the heterodimer remains functionally inactive.

hormone resistance Disease condition in which a specific hormone is unable to exert its biological actions; it is usually caused by an inactivating receptor mutation.

inactivating (loss-of-function) mutation A mutation that inactivates the function of a receptor by one of the following mechanisms: decreased synthesis, aberrant intracellular processing, impaired or missing ligand binding, impaired or missing signal transduction, inability to anchor to plasma membrane (cell membrane receptors), inability to dimerize (if needed for action), or increased degradation.

nuclear receptor A hormone receptor present inside the cell, in either the cytoplasm or the nucleus, binding hormones that are able to pass through the cell membrane (e.g., steroid and thyroid hormones). The hormone-receptor complex binds in dimerized form to specific promoter sequences of hormone-responsive genes, thus functioning as a transcription factor.

Activin Receptor Signaling

PETER C. K. LEUNG* AND CHUN PENG†

University of British Columbia, Vancouver • †York University, Toronto

Activins are dimeric proteins consisting of two inhibin β-subunits. Homo- and heterodimerization of two isoforms of β subunits, βA and βB, result in three forms of activins, activin-A, -B, and -AB. It is now recognized that activins function mainly as autocrine/paracrine factors to regulate the proliferation, differentiation, and apoptosis of many types of cells and are involved in a variety of physiological processes. Activins also play important roles during embryonic development. Activins elicit their biological effects through interaction with a receptor complex that contains two types of structurally related transmembrane serine/threonine kinases referred to as type I and type II receptors, respectively. The signal is then propagated from the receptors at the cell surface to target genes in the nucleus by intracellular mediators, the Smad family of proteins. This signaling cascade can be modulated at the cell surface by interfering with the interaction between activins and their receptors and in the cytoplasm by facilitating or blocking the activation

of Smads. Finally, activin signaling can be terminated through ubiquitin-mediated degradation of Smads.

Activins share structural similarities with transforming growth factor-β (TGF-β) and are recognized as members of the TGF-β superfamily. In addition to activins and TGF-βs, bone morphogenetic proteins (BMPs), growth and differentiation factors, inhibins, Müllerian inhibiting hormone, glial cell line-derived neurotrophic factors, and Nodal are also members of this superfamily.

Originally, activin-A was isolated from porcine follicular fluids and identified as a stimulator of pituitary follicle-stimulating hormone (FSH). This molecule was found to be identical to a protein that exhibited potent differentiating effects on erythroleukemia cells and was designated erythroid differentiation factor.

I. ACTIVIN RECEPTORS

Initial affinity labeling and cross-linking studies using activin-A as a ligand revealed the presence of two activin receptor complexes with molecular weights of approximately 65 and 85 kDa, designated type I and type II activin receptor complexes, respectively. Subsequently, cDNAs and genes for type I and type II activin receptors were cloned. Receptors that can bind to activin in transfection assays include activin type I (ActR-I, also known as ActR-IA or activin receptor-like kinase 2, ALK-2), ActR-IB (or ALK-4), ActR-II (also named ActR-IIA), and ActR-IIB. However, as discussed below, these receptors can also bind to and mediate the actions of other ligands of the TGF-β superfamily.

A. Type II Receptors

Using an expression cloning strategy, in 1991 Mathwes and Vale cloned the first activin receptor from AtT20 mouse corticotropic cells. The cDNA encodes a protein of 513 amino acids. The mature peptide has 494 amino acids and contains an extracellular ligand-binding domain, a single transmembrane domain, and an intracellular region containing a juxtamembrane region, a kinase domain predicted to be a serine/threonine kinase, and a C-terminal tail (Fig. 1). Based on its ability to bind activin and its size, the receptor was identified as the type II activin receptor and is now referred to as ActR-IIA. Another activin receptor that showed a structure similar to that of ActR-IIA was subsequently

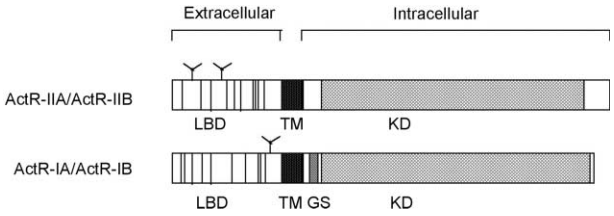

FIGURE 1 Schematic representation of activin receptors. Both type I and type II receptors have an extracellular region where the ligand-binding domain (LBD) is located, a transmembrane (TM) region, and an intracellular region containing a juxtamembrane region, a serine/threonine kinase domain (KD), and a C-terminal tail. The LBD has 10 cysteine residues (indicated by vertical lines) and one or two glycosylation sites (ϒ). Type I receptors have a GS domain in the juxtamembrane region and a shorter C-terminal tail.

cloned and designated ActR-IIB. The human ActRII-A gene is mapped to 2q22.2–q23.3 while the ActR-IIB gene is located in 3p22. When type II receptors are expressed alone in mammalian cells, they are able to bind to activins with high affinity. The K_d value of activin type II receptors ranged from 0.1 to 0.7 nM.

The extracellular domain of activin type II receptors has two N-glycosylation sites and 10 cysteine residues (Fig. 1). The spacing between each cysteine is identical between ActR-IIA and ActR-IIB and is conserved in different groups of vertebrates. Studies on the ActR-IIA have shown that deglycosylation of the receptor resulted in only a moderate decrease in receptor affinity, suggesting that it is not critical for receptor binding. On the other hand, disulfide bonds formed by cysteine residues are important in maintaining the proper confirmation required for activin binding. In ActR-IIA, five disulfide bonds are formed from the cysteines in the following arrangement: C1–C3, C2–C4, C5–C8, C6–C7, and C9–C10. The crystal structure of the extracellular ligand-binding domain has been solved. This region exhibits a three-finger toxin-like fold formed by seven disulfide-cross-linked β sheets. Further analyses have revealed that three conserved hydrophobic residues (Phe42, Trp60, and Phe83) interact with one another to form a binding site on ActR-IIA for activin-A.

The kinase domain of ActR-IIA and ActR-IIB contains sequence similar to that of serine/threonine protein kinases. Studies have shown that they indeed have kinase activities. Substrates of type II receptor kinases include the receptors themselves and type I activin receptors. Type II receptors are constitutively phosphorylated, even in the absence of ligands. The phosphorylation of type II receptors is, at least

in part, the result of autophosphorylation. The phosphorylation occurs predominantly on serine residues and to some extent on threonine.

Gene knock-out studies in mice have shown that deletion of the ActR-IIA gene resulted in severe suppression of FSH secretion and impaired reproductive functions. Female mice showed defects in folliculogenesis and were infertile. Male mice showed decreased sperm production and delayed fertility. These findings demonstrate that ActR-IIA is a functional receptor that mediates the action of activin on FSH secretion. On the other hand, the ActR-IIA-deficient mice had several developmental defects that are quite distinct from those found in activin-deficient mice, suggesting that other ligands, rather than activins, signal through ActR-IIA to regulate embryonic development. Targeted disruption of the mouse ActR-IIB gene caused abnormal left–right axis formation and lateral asymmetry. Mice deficient in the ActR-IIB gene died shortly after birth due to complicated cardiac defects. The developmental abnormality of axial formation observed in ActR-IIB knockout mice is a characteristic nodal activity, suggesting that ActR-IIB mediates Nodal signaling during embryonic development.

Type II activin receptors have a broad specificity. In addition to binding to activins, they have been shown to bind to BMPs, such as BMP2 and BMP7, and Nodal when co-expressed with appropriate type I receptors. Studies using truncated ActR-IIA and IIB have shown that these receptors mediate both activin and BMP signaling. As discussed above, gene knock-out experiments also support the notion that other ligands signal through type II activin receptors to regulate vertebrate embryonic development.

B. Type I Receptors

Following the cloning of type II receptors, the sequences of type I activin receptors were also obtained. Similar to type II receptors, the type I receptors also have an extracellular ligand-binding domain, a transmembrane domain, and an intracellular kinase domain. The extracellular domains of type I receptors also have 10 cysteine residues; however, the spacing among these residues is different between ActR-IA and ActR-IB and also differs from that in the type II activin receptors. A unique feature of the type I receptors is that they contain a segment of about 30 residues that is rich in serine, threonine, and glycine, located between the transmembrane and kinase domains. This segment has a characteristic sequence of SGSGSG and therefore was named the GS domain. The GS domain is present in all type I receptors of the TGF-β superfamily. The C-terminal tail in the type I receptors is shorter than that in the type II receptors. The human ActR-IA is mapped to 2q23–q24 and the ActR-IB gene is located at 12q13.

Unlike type II receptors, type I receptors do not bind to activins on their own. They can bind to ligands only in the presence of activin type II receptors. On the other hand, type I receptors are essential for receptor signaling to downstream mediators. It is well established now that activins first bind to type II receptors, which then recruit type I receptors to form a complex that contains two or more of each of the type I and type II receptors. Type II receptors subsequently phosphorylate type I receptors, primarily, but not exclusively, at the GS domain, which then in turn propagate the signals to downstream targets, namely, Smads.

Although initial studies demonstrated that ActR-IA, when co-expressed with type II activin receptors, can bind to activins, increasing evidence has indicated that the physiological ligand for this receptor is not an activin. In *Xenopus laevis* embryos, ActR-IA mimics the role of BMP-4, but not activins. Many other reports have documented that ActR-IA binds to and/or mediates the signaling of other members of the TGF-β superfamily, including Müllerian inhibiting substance, BMP-2, BMP-4, and BMP-7. Also, ActR-IA activates Smad1, which is known to mediate BMP, but not activin, signaling. On the other hand, the role of ActR-IB in activin signaling has been confirmed. ActR-IB mediates the growth-inhibitory effects of activin in several cell lines. Also, the regulatory effects of activins on target gene expression, such as plasminogen activator inhibitor-1, are conferred by ActR-IB.

II. SMADS AS INTRACELLULAR MEDIATORS

Once type I receptors are phosphorylated by type II receptors, they become active kinases and can phosphorylate downstream signaling molecules. Smad proteins are intracellular mediators of the TGF-β superfamily. They function as effector molecules to transduce the signals of the TGF-β superfamily from the cell surface to the nucleus. The first member of the Smad family was discovered in *Drosophila melanogaster* through genetic screenings and was named Mad (mother against *dpp*). A related protein was also identified in *Caenorhabditis elegans* and is referred to as Sma. Subsequently, homologues of Mad and Sma were found in various vertebrates and are now called Smads.

A. Structural Features of Smads

To date, eight Smads have been identified in vertebrates and they are classified into three subfamilies based on their structural and functional characteristics: receptor-regulated Smads (R-Smads), common Smads (Co-Smads), and inhibitory Smads (I-Smads). The R-Smads, Smad1, 2, 3, 5, and 8, are activated by specific type I receptors of the TGF-β superfamily through phosphorylation. Smad4, also referred to as "deleted in pancreatic carcinoma" (DPC4), is the only Co-Smad in vertebrates and can form a complex with phosphorylated R-Smads. The I-Smads (Smad6 and 7) function as inhibitors of the receptor-regulated Smads. Figure 2 shows the major structural features of Smads. In R-Smads and Co-Smads, there are two highly conserved regions, MH1 and MH2. These two domains, located at the N-and C-terminals, respectively, are linked by a less conserved linker region. The MH1 domain is much shorter in the inhibitory Smads than in the R-Smads and Smad4. R-Smads also have a characteristic phosphorylation site, SSXS, at their C-termini. All Smads lack intrinsic enzyme activity. They function primarily through regulation of protein–protein and protein–DNA interactions.

Smads that have been identified as being involved in activin receptor signaling include Smad2, 3, 4, and 7. This set of Smads also mediates TGF-β signal transduction. In human, genes for Smad2, Smad4, and Smad7 are all mapped to the region 18q21.1, and the Smad3 gene is found at 15q21–q22. The MH1 domain of Smad3 can bind to DNA directly, but the MH1 domain of Smad2 lacks DNA-binding activity. This is apparently due to an insertion of 30 residues in the MH1 domain of the Smad2. This insertion is thought to alter the conformation of the MH1 domain, thereby preventing the direct interaction of Smad2 with DNA. The MH1 domain of Smad4 also has DNA-binding activity. The MH2 domain of Smad2, Smad3, Smad4, and Smad7 is mainly responsible for protein–protein interactions. Proteins that are found to associate with this region include Smad themselves to form oligomers and many transcription factors. In the case of Smad2 and Smad3, this domain also contains phosphorylation sites for ActR-IB and a binding site for a Smad anchor for receptor activation (SARA), which recruits Smad2 and 3 to activin and TGF-β receptors. The linker region, although poorly conserved, also has important functions. This region is known to contain the phosphorylation sites for mitogen-activated protein kinases. The linker region of Smad4 has a Smad activation domain that is important for transcriptional activation.

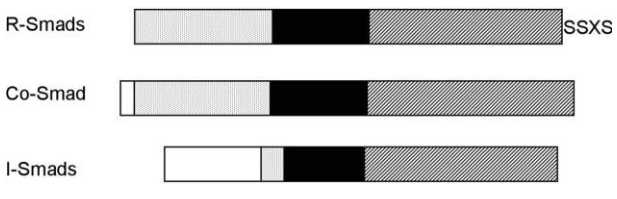

FIGURE 2 Structural features of Smads. R-Smads and Co-Smad (Smad4) have two conserved domains, MH1 (gray) and MH2 (vertical rules), connected by a linker region (black). I-Smads have a much shorter MH1 domain.

B. Signal Transduction via Smads

Upon activin binding, Smad2 and (or) Smad3 are transiently associated with activin receptor complexes. Both Smad2 and Smad3 can be phosphorylated by ActR-IB. Subsequently, the activated Smad2 and (or) Smad3 form a complex with Smad4 and are translocated into the nucleus. This Smad complex then interacts with DNA to regulate target gene expression. Although the Smad complex can bind to DNA directly, the affinity and specificity of such binding are low and therefore DNA-binding partners are required for regulation of specific target gene expression. The best-characterized transcription factor that interacts with Smads to regulate activin-induced transcription is the forkhead activin signal transducer (FAST), a winged helix forkhead transcription factor. Activin induces the transcription of homeobox genes *Mix*. 2 in *Xenopus* and *goodecoid* in mouse during embryonic development. Activation of these genes by activin involves the formation of a transcription complex comprising Smad2, Smad4, and FAST. The protein complex binds to specific elements in the promoter regions of these genes through both FAST- and Smad-binding sites. Following the binding of Smad and DNA-binding partners to the DNA, Smads can further recruit transcription co-activators or co-repressors to positively or negatively regulate gene expression.

III. MODULATION OF ACTIVIN SIGNALING

A. Inhibition of Signaling at the Cell Surface

Activin signaling can be blocked at the receptor level by two types of molecules, follistatins and inhibins. Follistatins are binding proteins of activins that neutralize activin actions in many biological systems

by controlling the accessibility of activins to their receptors. There are two major forms of follistatins, FS-288 and FS-315, generated from alternative splicing of the same gene. Each β-subunit can bind to one follistatin and therefore, the activin–follistatin complex consists of one activin molecule and two follistatin molecules. The affinity of follistatin binding to activins is similar to that between activins and their receptors. Follistatins neutralize activin bioactivity by inhibiting the binding of activins to their type II receptors. In addition, FS-288 inhibits activin action by increasing the endocytotic degradation of activin through the association with cell surface heparan sulfate.

Inhibins are structurally related to activins by sharing the same β-subunit. It is well documented that inhibins block many actions of activins and function as activin antagonists. Several studies have shown that inhibins can bind to ActR-IIA and, therefore, antagonize activin actions. The binding affinity of inhibins to ActR-IIA is 10-fold lower than that between activins and ActR-IIA; however, it has been recently shown that betaglycan, a proposed TGF-β type III receptor, can bind to inhibins with high affinity and that the binding of inhibins to betaglycan results in an increased affinity of inhibin binding to ActR-IIA. It was therefore suggested that inhibins bind to betaglycan and ActR-IIA and block activin signaling by competing with activins for their type II receptors.

B. Modulation in Cytoplasm

The interaction between activin receptors and Smads in the cytoplasm is facilitated by some proteins with a FYVE (Fab1p, YOTB, VAC1p, EEAI) domain, such as SARA and Hgs. It has been shown that SARA and Hgs (Hrs) cooperate to recruit Samd2 and Smad3 to

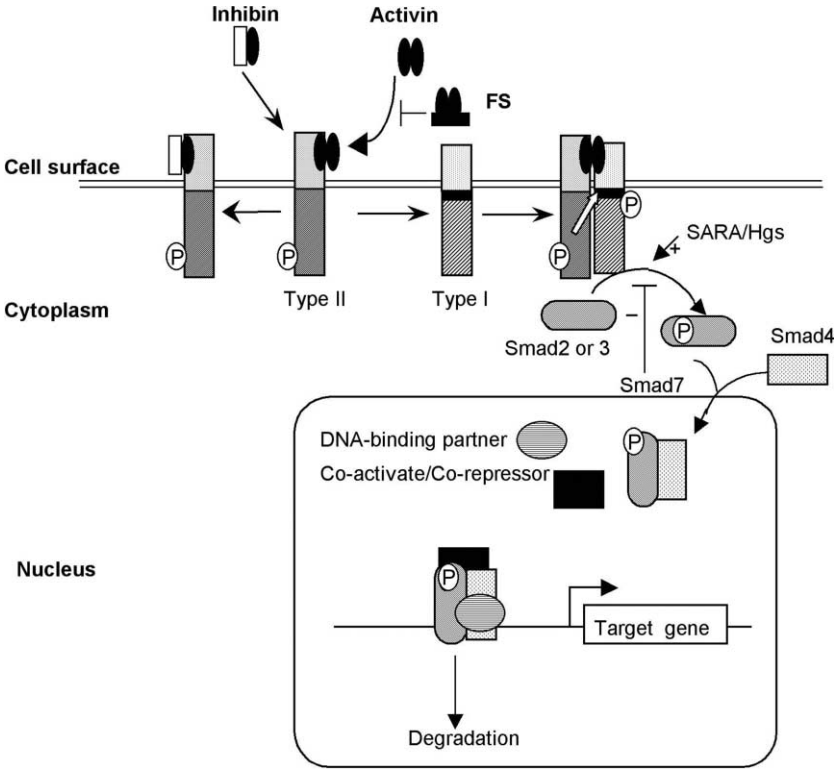

FIGURE 3 Activin signaling via the Smad pathway. Activin first binds to the type II receptors, which in turn recruit and phosphorylate type I receptors. The type I receptors then phosphorylate Smad2 and/or Smad3. The phosphorylated R-Smad forms a complex with Smad4 and is then translocated to the nucleus. The R-Smad–Smad4 complex interacts with other DNA-binding co-factors to regulate gene expression. Follistatin inhibits activin signaling by binding to activin and making it unavailable to its receptor. Inhibin blocks activin signaling by competing with activin for type II receptors. SARA and Hgs enhance activin signaling by recruiting R-Smads to the activin receptors while Smad7 inhibits activin signaling by preventing phosphorylation of R-Smads by the activin receptor. Finally, Smad signaling may be turned off via ubiquitin-mediated degradation.

the activin receptor complex. Overexpression of SARA and Hgs enhances activin signaling by increasing the phosphorylation and activation of Smad2 and Smad3 by ActR-IB. On the other hand, overexpression of a nonfunctional mutant of SARA or Hag decreases activin signaling.

Smad7 inhibits activin signaling by binding stably to the activated receptor complex and thereby blocking the association of Smad2 and/or Smad3 with the receptors and preventing the phosphorylation and activation of R-Smads. Smad7 may also facilitate the degradation of the active receptor complex. Interestingly, the Smad7 gene is induced by activin. Therefore, Smad7 likely plays a role in the negative feedback control of activin signaling. Smad7 has been shown to attenuate the actions of activin on cell growth, apoptosis, and *Xenopus* embryonic development.

C. Termination of Signaling in the Nucleus

The activated Smad2 has been shown to be degraded through the ubiquitin-dependent 26S proteasome pathway. Although the precise involvement of this pathway in activin signaling requires further studies, degradation of activated Smads in the nucleus could provide a mechanism to switch off activin signaling.

IV. SUMMARY

Although activin receptors were discovered almost a decade ago, the signaling mechanisms underlying activin actions have been uncovered only in recent years. As shown in Fig. 3, activins bind to cell surface serine/threonine kinase receptors via two activation steps. First, activins bind to constitutively active type II receptors and this complex then recruits type I receptors. Second, type II receptors phosphorylate type I receptors at the GS domain. Following receptor activation, the activin signal is transmitted into the nucleus via intracellular mediators, Smads. The type I receptor, ActR-IB, phosphorylates Smad 2 and/or Smad 3. The phosphorylated Smad2 and (or) Smad3 then form(s) a complex with Smad4, and the complex enters the nucleus. The Smad complex then interacts with other transcription factors, such as FAST-1, and recruits transcription co-activators or co-repressors to regulate the expression of target genes. Activin signaling can be blocked at the receptor level by their binding proteins, follistatins, and by their antagonists, inhibins. In the cytoplasm, SARA and Hgs facilitate activin signaling by recruiting R-Smads to activin receptors while Smad7 inhibits activin signaling by blocking the interaction between R-Smads and receptors. Finally, Smad signaling can be terminated through the proteolytic degradation of Smads via the ubiquitin-dependent pathway.

Glossary

activins Protein hormones belonging to the transforming growth factor-β superfamily that regulate many developmental and physiological processes, particularly reproduction. They are either homo- or heterodimers of two related inhibin β-subunits, βA and βB.

receptor serine/threonine kinase A membrane receptor that phosphorylates serines and/or threonines on target proteins. The receptor has an extracellular domain, a transmembrane region, and an intracellular kinase domain.

Smad proteins A group of intracellular proteins that mediate signaling by members of the TGF-β superfamily. They are vertebrate homologues of *Drosophila* Mad (mother against *dpp*) and *Caenorhabditis elegans* Sma. They include receptor-mediated Smads that are phosphorylated and activated by type I receptors, common Smads that form complexes with receptor-mediated Smads, and inhibitory Smads that antagonize signaling by members of the TGF-β superfamily.

type I activin receptor A component of the activin receptor complex. It is a serine/threonine kinase that phosphorylates intracellular mediators after being phosphorylated by a type II activin receptor.

type II activin receptor A component of the activin receptor complex. It binds to activins and in turn phosphorylates type I receptors via its intracellular serine/threonine kinase domain.

Activins

GAIL P. RISBRIDGER
Monash University, Melbourne

Activins, acting in opposition to inhibins, are involved in diverse physiological activities, including stimulating pituitary, hypothalamic, and gonadal hormones, insulin secretion, germ cell development and differentiation, erythroid differentiation, nerve cell survival, and embryonic development. Activin β-subunit types A–E form homodimers and heterodimers that play different roles in health and disease in different tissues throughout the body. Assays that allow comparisons of specific subunit activities are necessary to understand the complex roles of each of the activin subunits.

I. INTRODUCTION

Activin subunits are present in numerous human tissues of both endocrine and nonendocrine organs. Homo- or heterodimers of activin β_A or β_B subunits are members of the transforming growth factor-β (TGF-β) superfamily of growth and differentiation factors. Since these proteins were first described as regulators of the release of follicle-stimulating hormone (FSH) from the pituitary, multiple actions have been assigned to them in a variety of tissues. An additional three activin β-subunit proteins have been described, i.e., β_C, β_D, and β_E, and there is a growing family of recognized activin- and inhibin-binding proteins, receptors, and signaling molecules (Table 1).

II. EXPRESSION AND BIOSYNTHESIS OF ACTIVINS

The TGF-β superfamily of growth factors includes bone morphogenetic proteins (BMPs) and Müllerian inhibitory substance (MIS), and currently over 45 members of this family have been identified. Structural similarities between activins and other members of the TGF-β superfamily are based on the conservation of the number and spacing of the cysteines within each subunit and the disulfide linkages between the two subunits that form the characteristic cysteine knots. Other similarities relate to dimer formation, the location of the bioactive peptide in the carboxy-terminal region of the precursor molecule, and the similarities in intracellular signaling mechanisms.

The biosynthesis of activins requires the formation of homo- or heterodimers of disulfide-linked β_A- or β_B-subunit proteins that share 63% amino acid identity. The assembly of different combinations of activin subunits β_A and β_B is reflected in their nomenclature; thus, activin A is a dimer composed of $\beta_A\beta_A$, activin B is composed of $\beta_B\beta_B$, and activin AB is composed of $\beta_A\beta_B$. There is an independent pattern of synthesis of the two subunit genes, which are located on different chromosomes; the activin β_A-subunit gene is located on 7p15–7p14 and the activin β_B-subunit gene on 2qcen–2q13.

Another subset of activin β-subunits (β_C, β_D, and β_E) was identified more recently, based on their homology to subunits β_A and β_B; this subset of subunits shares 62% amino acid identity with each other. The activin β_C-subunit shows close similarity to the activin β_E-subunit in terms of genomic organization and chromosomal localization on 12q13.1, and subunits β_C, β_D, and β_E are considered to be a separate subset of activins. The β_C-subunit dimerizes with itself *in vitro* and with subunits β_A and β_B to form the putative activins, activin C, AC, and BC. Activin subunits β_D and β_E have been isolated from *Xenopus* and mouse cDNA libraries, respectively, but their capacity to form activin heterodimers

Activins

GAIL P. RISBRIDGER
Monash University, Melbourne

Activins, acting in opposition to inhibins, are involved in diverse physiological activities, including stimulating pituitary, hypothalamic, and gonadal hormones, insulin secretion, germ cell development and differentiation, erythroid differentiation, nerve cell survival, and embryonic development. Activin β-subunit types A–E form homodimers and heterodimers that play different roles in health and disease in different tissues throughout the body. Assays that allow comparisons of specific subunit activities are necessary to understand the complex roles of each of the activin subunits.

I. INTRODUCTION

Activin subunits are present in numerous human tissues of both endocrine and nonendocrine organs. Homo- or heterodimers of activin β_A or β_B subunits are members of the transforming growth factor-β (TGF-β) superfamily of growth and differentiation factors. Since these proteins were first described as regulators of the release of follicle-stimulating hormone (FSH) from the pituitary, multiple actions have been assigned to them in a variety of tissues. An additional three activin β-subunit proteins have been described, i.e., β_C, β_D, and β_E, and there is a growing family of recognized activin- and inhibin-binding proteins, receptors, and signaling molecules (Table 1).

II. EXPRESSION AND BIOSYNTHESIS OF ACTIVINS

The TGF-β superfamily of growth factors includes bone morphogenetic proteins (BMPs) and Müllerian inhibitory substance (MIS), and currently over 45 members of this family have been identified. Structural similarities between activins and other members of the TGF-β superfamily are based on the conservation of the number and spacing of the cysteines within each subunit and the disulfide linkages between the two subunits that form the characteristic cysteine knots. Other similarities relate to dimer formation, the location of the bioactive peptide in the carboxy-terminal region of the precursor molecule, and the similarities in intracellular signaling mechanisms.

The biosynthesis of activins requires the formation of homo- or heterodimers of disulfide-linked β_A- or β_B-subunit proteins that share 63% amino acid identity. The assembly of different combinations of activin subunits β_A and β_B is reflected in their nomenclature; thus, activin A is a dimer composed of $\beta_A\beta_A$, activin B is composed of $\beta_B\beta_B$, and activin AB is composed of $\beta_A\beta_B$. There is an independent pattern of synthesis of the two subunit genes, which are located on different chromosomes; the activin β_A-subunit gene is located on 7p15–7p14 and the activin β_B-subunit gene on 2qcen–2q13.

Another subset of activin β-subunits (β_C, β_D, and β_E) was identified more recently, based on their homology to subunits β_A and β_B; this subset of subunits shares 62% amino acid identity with each other. The activin β_C-subunit shows close similarity to the activin β_E-subunit in terms of genomic organization and chromosomal localization on 12q13.1, and subunits β_C, β_D, and β_E are considered to be a separate subset of activins. The β_C-subunit dimerizes with itself *in vitro* and with subunits β_A and β_B to form the putative activins, activin C, AC, and BC. Activin subunits β_D and β_E have been isolated from *Xenopus* and mouse cDNA libraries, respectively, but their capacity to form activin heterodimers

TABLE I Activin Ligands: Purified Homo- or Heterodimers of Activin β-Subunit Proteins

Subgroups of activin β-subunits	Purified proteins	Evidence of putative dimeric proteins
β_A	Activin A[a]	—
β_B	Activin B[a], activin AB[a]	—
β_C	Activin C[b]	Activin AC[c], activin BC[c]
β_D	?	—
β_E	Monomeric activin β_E	—

[a]Bioactive and detected in biological fluids.
[b]No known bioactivity.
[c]Heterodimeric proteins formed *in vitro*; currently there is no evidence for their existence *in vivo*.

with subunits β_A and β_B or between themselves is unknown.

Homo- and heterodimers of activin subunits β_A and β_B were originally isolated from follicular fluid as inactive full-length precursor proteins. Similar to other growth and differentiation factors, the precursor activins require intracellular processing for full bioactivity. Precursor activins are 110-kDa dimers and consist of a signal peptide, a glycosylated prodomain (Pro-β), and a mature C-terminal domain (β) that is bioactive. Proteolytic cleavage releases the pro and signal peptides, resulting in mature, unglycosylated activin subunits.

Dimers of the activin β-subunits form activin ligands, but heterodimers of activin β-subunits with the inhibin α-subunit result in the formation of inhibin proteins (inhibin A or B). The inhibin α-subunit gene is located on 2q33–q36 and the pattern of expression of the inhibin α-subunit is independent of the activin β-subunits. As is the case for activins, the inhibins are synthesized as precursor proteins and proteolytic cleavage occurs intracellularly as well as in serum.

III. SIGNALING OF ACTIVIN LIGANDS

The high degree of homology between the ligands extends to the elements in their signaling pathways. At the cell surface, activin ligands interact with a dual receptor system involving a family of transmembrane serine/threonine kinase receptors classified as type I or type II receptors. Activin binding to the type II receptor (ActRII) leads to the recruitment of the type I receptor (ActRI) and formation of a heteromeric complex. Formation of this complex induces phosphorylation of the type I receptor, leading to activation of the receptor-regulated Smad (R-Smad). R-Smads are ligand specific, with Smad2 and Smad3 mediating activin and TGF-β signaling and Smad1, Smad5, and Smad8 mediating BMP signaling. The interaction between the R-Smads and the receptor complex involves a membrane-bound protein named Smad anchor for receptor activation (SARA). After phosphorylation, the R-Smads are released and form heteromeric complexes with Smad4, a common mediator (Co-Smad). The R-Smad and Co-Smad complexes then translocate to the nucleus to regulate gene expression. A third class of Smads, the inhibitory Smads (I-Smads; Smad6 and Smad7), antagonize the signaling events just described and prevent access and phosphorylation of the R-Smads or interfere with the formation of the R-Smad/ Co-Smad complexes.

In the nucleus, Smads target specific gene promoters with low binding affinity for DNA, and Smad binding alone is insufficient for gene activation. Smads use members of the forkhead activin signal transducer (FAST; also called FoxH1) family as DNA-binding partners to regulate gene transcription. Other transcription factors likely to be involved in the Smad pathway include *fos*, *jun*, and the vitamin D receptor. However, in contrast to FAST/FoxH1, many of the other DNA binding partners can function independently of Smads, whereas FAST/FoxH1 target genes require Smad function for transcriptional activation. Thus, the binding of activin ligands to the membrane-bound receptor initiates a cascade of protein–protein interactions that controls gene expression and specific biological responses.

IV. ACTIVINS IN PHYSIOLOGY

A. Biological Actions of Activins

Activins were originally isolated based on the stimulation of FSH production and secretion by rat pituitary cells *in vitro*. It is now recognized that activins have a range of biological activities that include, but are not limited to, mesoderm induction in *Xenopus laevis* embryos, reproduction through

the regulation of pituitary FSH production, bone growth, nerve cell survival, wound healing, and tissue differentiation in pancreas, kidney, and heart.

In some instances, the actions of activins are antagonized by inhibins. The most well-known opposing actions of activin and inhibin relate to effects on the reproductive system, including the regulation of pituitary FSH and gonadal steroidogenesis. Both ligands also oppose each other during chondrogenesis in chick limb bud mesoderm and in T-cell proliferation. However, there are other instances when the effects of activins are not opposed by inhibin, such as during mesoderm induction, in neuronal cell survival, and in some developmental processes. In these circumstances, other factors, such as activin-binding proteins (e.g., follistatins) are powerful antagonists of activins. In general, inhibins are regarded as endocrine factors that function primarily in the regulation of FSH, whereas activins are local paracrine and/or autocrine growth factors.

As predicted by their wide pattern of expression throughout the body and during all stages of life, the bioactivities of activins have been recorded in many cells and tissues (Table 2). *In vitro* model systems of cell growth (using cell lines and organ cultures) are common means to demonstrate significant effects that involve proliferative or antiproliferative actions, as well as those that alter cell differentiation. Most studies have been performed with activin A, less with activin B, and even fewer have reported the actions of activin AB; there are no reports of bioactivity of other putative activin dimers or heterodimers. Many of the effects of activins *in vivo* are inferred by expression of subunit mRNA or protein; due to the limited supply of purified ligands, very few studies have directly demonstrated *in vivo* actions of dimeric ligands. However, significant progress in understanding the roles for activins has been made using other approaches. Knockout and knock-in mouse models have been critical in the evaluation of the functional effects of activins, and many of these were developed in the Matzuk laboratory. As well, the development of specific immunoassays for the different forms of activins, follistatins, and inhibins has been essential in evaluating the expression and roles for specific ligands or binding proteins in physiology and in disease.

B. Knockout and Knock-in Mouse Models

A number of activin β-subunit knockout mice that exhibit unique phenotypes have been generated (Table 3). These studies confirm an essential role for activins in normal development of reproductive organs as well as other tissues. Activins are mesoderm-inducing factors, but mice deficient in subunits β_A or β_B develop to term. Activin β_A-subunit-deficient mice lack whiskers and lower incisors, have defects in their secondary palates, and die within 24 h of birth. Mice deficient in activin β_B are viable and fertile but have defects in eyelid development. The defects are additive in mice deficient in both subunits β_A and β_B and suggest that the subunits do not have overlapping functions up to this age of development. To determine if the unique phenotypes of these mice are related to differences in the temporal and spatial expression of the two subunits or to specific ligand–receptor signaling interactions, mice were generated in which activin β_B was expressed in the spatial and temporal pattern of activin β_A (i.e., activin β_B knock-in to the activin β_A locus). The craniofacial malformations

TABLE 2 Examples of Biological Fluids and Tissues in Which Activins A or AB or Follistatins Have Been Detected or Measured

Protein	Fluid or tissue
Activin A	Sera, e.g., from pubertal boys and girls, women with pre-eclampsia, or patients with chronic hepatitis
	Extracts, e.g., from gonadal, placental, choriodecidual, and allantoic tissues or fluids
	Media from cell lines, e.g., human prostate tumor cells, gonadotropin-releasing hormone-secreting neurons, and pituitary-derived folliculo-stellate cells
	Fluids, e.g., follicular fluid, seminal plasma, and amniotic fluid in normal and Down syndrome pregnancies
Activin AB	Follicular fluid from human, bovine, ovine, and porcine tissues
	Media from granulosa cells
Follistatin	Sera from pubertal girls, pre-eclamptic pregnancies, hypertensive pregnant women, postmenopausal women with epithelial ovarian cancer, and patients with chronic hepatitis
	Extracts from amnion, choriodecidual, and placental tissues
	Supernatants from prostate tumor cell line cells
	Amniotic fluid in normal and Down syndrome pregnancies

TABLE 3 Summary of Some of the Transgenic Mouse Model Phenotypes Bearing Modifications to Activin Subunits or Intermediates in Activin Signaling

Genetic modification	Phenotype
β_A knockout	Craniofacial defects, e.g., lack whiskers and lower incisors; cleft palate; die < 24 h after birth
Overexpression of β_A	Sterility in male and females; testicular degeneration, but no testicular tumors
β_B knockout	Viable and fertile but defects in eyelid development
β_A and β_B combined knockout	Additive defects; mice develop to term with defects in whiskers, incisors, and secondary palate formation
β_B knock-in to β_A locus	Rescues craniofacial malformations and neonatal lethality of β_A deficiency, but defects in hair, gonads, and external genitalia
Activin type II receptor knockout	Gonadal defects and altered fertility; some mice die due to mandible defects
Follistatin knockout	Craniofacial defects, growth retardation, and skin defects; neonatal lethal
Follistatin overexpression	Defects in testes, ovary, and hair
Inhibin α knockout	Gonadal and adrenal tumors develop, followed by cachexia-like wasting syndrome
Inhibin α + activin type II receptor knockout	Tumors develop, but without cachexia
Inhibin α + overexpression of follistatin	Reduced rate of tumor development and reduced symptoms of cachexia

and neonatal lethality were rescued and the results implied that activin subunits signaled through the same receptors in these tissues; further analyses revealed a greater level of complexity. In older mice, during testicular growth, $_B$-subunit does not replace the $_A$-subunit function and the knock-in mice show delayed testicular maturation and onset of fertility. Similarly, there are other defects in hair, ovarian growth, development of external genitalia, and somatic growth. Thus, although some actions of the $_A$ subunit are replaced by $_B$, others are not and the importance of the spatial and temporal patterns of expression of the subunits has been confirmed. The success of the approach of generating null mice for functional analyses of the activin subunits is less informative for the other activin subunits, $_C$ and $_E$. Mice lacking these subunits alone or in combination are viable and have no obvious abnormalities. Unequivocal evidence for a functional role for activin homo- or heterodimers of $_C$ or $_E$ or combinations with the $_A$ or $_B$ subunits has yet to be revealed.

C. Assays for Activins

The development of specific assays to measure the activin ligands in biological fluids and tissues, including serum, has significantly increased our understanding of the role of these ligands. Many, but not all, of the assays were developed in the Groome laboratory. The activin A assay measures total activin A, i.e., bound and unbound forms of the ligand, and is used to measure activin A in sera and other biological fluids (e.g., follicular fluid) in a number of species, including humans. A specific assay for activin B is unavailable, but an enzyme-linked immunosorbent assay (ELISA) for activin AB detects the homodimer in some biological fluids. A specific antibody for subunit β_C has been developed by Mellor *et al.*, who have also shown that β_C dimerizes with subunit β_A or β_B. The field awaits the development of new activin assays to expand our understanding of the role and expression of the different activin ligands in diverse tissues and systems. By analogy, the use of specific assays for inhibin A and B has been fundamental to understanding the roles of the inhibins in men and women, particularly in the field of reproductive physiology.

D. Overlapping Functions of Activins and Other Ligands in the TGF-β Superfamily

The relative redundancy between the ligands relates to the demonstration that β_B can replace β_A in some circumstances. The degree of overlap in functions of subunits that are less similar to subunits β_A and β_B is unknown, although activin subunit β_C can dimerize with β_A and β_B *in vitro*. The degree of overlap in the functions of activins and other members of the

TGF-β family is also unclear. TGF-β and activins signal through type I and type II receptors and utilize Smad2 and Smad3, but it is uncertain if the biological responses to the ligands are the same or different. Apparently, not all of the actions of activins are mimicked exactly by TGF-β or vice versa. For example, separate studies have shown that TGF-β inhibits cell proliferation in human prostate tumor cell lines PC3 and DU145, whereas the same cell lines fail to respond to activin A. Conversely, the LNCaP androgen-dependent human prostate tumor cells are growth inhibited by activin A, but are unresponsive to TGF-β. Relatively few studies have directly compared the ligands in the same biological systems, and the question of the redundancy between activins and TGF-β remains unexplored.

E. Follistatin-Binding Proteins

Prior to any signaling event, activins can be bound to binding proteins such as follistatins (FSs). In many tissues, the interplay between activins and FSs provides a potent mechanism to regulate the access of the ligands to their receptors. Follistatins are encoded from a single gene located on chromosome 5q11.2 and alternative splicing of the mRNA generates different molecular weight isoforms. The FS proteins include an "FS domain" of 10-cysteine structures and an extracellular calcium-binding domain that makes them structurally homologous with epidermal growth factor (EGF), a group of enzyme inhibitors of the Kazal family, and other proteins such as SPARC, agrin, testican, and follistatin-related protein (FSRP). The function of the FS domains is not known but binding to activins differentiates follistatins from other members.

The biological activity of FS is mediated via its high-affinity binding to activins. The binding is nearly irreversible and prevents ligand access to receptors on the cell surface, making FS binding a critical regulator of activin bioactivity in cells in which FS is expressed. FS also contains a heparin-binding domain that permits high-affinity association with cell surface heparin-sulfated proteoglycans (HSPGs). When activins are bound to FS–HSPG complexes at the cell surface or in the extracellular matrix, access to the receptors is restricted and hence the paracrine actions of locally or systemically derived ligands are inhibited. As well as activins, FS binds and neutralizes the mesoderm-inducing actions of other members of the TGF-β superfamily, such as BMP-2, -4, and -7, although the affinity of FS for the BMPs is significantly lower than that for the activins.

V. ACTIVINS IN PATHOLOGY AND DISEASE

The role and regulation of activin ligands in disease have received little attention in comparison to almost a decade of research into the use of inhibins for the detection of ovarian cancer or Down syndrome. Almost exclusively, the investigations center on activin A.

A. Pregnancy

In pregnancy, activin A (as well as inhibin A) is a product of the healthy placenta, but changes that have been reported to occur in pathological conditions might lead to diagnostic applications. Follistatins are also consistently higher at all stages of pregnancy, suggesting that activin A is present in bound form during a healthy pregnancy. Higher levels of activin A have been reported in women with pre-eclampsia, gestational hypertension, and chronic hypertension. In established cases of pre-eclampsia, several groups have shown that activin A (and inhibin A) levels are ~10 times higher, but it is not clear that changes in activin A are useful to predict the onset of pre-eclampsia in asymptomatic women. Research continues to assess if activin A, in combination with other markers, may be useful. The normal elevation in activin A in late pregnancy is related to the onset of parturition, but might also be used for the detection of preterm labor. There is no evidence of the usefulness of any activins as markers for Down syndrome, similar to that reported for inhibin A.

B. Inflammation

Activin A and FS have been implicated in inflammatory processes. In synovial fluid from patients with the inflammatory condition of rheumatoid arthritis, levels of activin A are elevated compared to those patients with degenerative osteoarthritis. An increased expression of activins related to change in β_A-subunit expression is implied in patients with inflammatory bowel diseases such as Crohn's disease and in ulcerative colitis. Indirect evidence for a role of activins has emerged from the detection of elevated levels of FS in patients with sepsis and meningitis, although activin levels in these conditions are unknown.

C. Kidney/Renal Ischemia

Evidence for a role of activin A in renal regeneration after ischemic injury has emerged from animal studies. Activin A, produced in the tubules, delays tubular

regeneration by inducing apoptosis, and FS antagonizes this effect. However, the interplay between activins and FS in the pathophysiology of renal diseases such as chronic glomerulonephritis remains unknown.

D. Bone

The osteogenic actions of activin A in bone have been demonstrated *in vivo* and *in vitro*. In animal models, activin A promotes fracture healing, and the detection of significant levels of activin A in bone matrix indicates an involvement in bone resorption and formation. Thus, activins (as well as FS) have potential roles to play in osteoporosis.

E. Tissue and Wound Repair

Mechanisms involved in tissue repair often closely resemble those involved in embryonic development. A number of studies have implicated activins in repair or regeneration of kidney, skin, and hair. During cutaneous wound repair in mice, activin A regulates formation of granulation tissue and extracellular matrix deposition. In animal models of acute brain injury, basic fibroblast growth factor (bFGF) is neuroprotective and neurotropic and induction of activin A appears to be a part of the signaling cascade for bFGF in this process. A potential role for activins in the prevention of neuronal loss during ischemic and traumatic brain injury in humans remains unknown.

F. Cancer

Activin, like TGF-β, can inhibit or stimulate tumor cell growth. For example, activins have growth inhibitory effects on breast, liver, and prostate cancer cells and pituitary adenomas, whereas growth stimulatory actions are described in ovary and testis. The role of activins in cancers is unclear and may be different in different organs and tissues or may vary even within the same tissue type. In tissues in which the effects are growth inhibitory, it is relevant to ask if the tumors become resistant to activins due to mutations in the signaling pathway, but very little is known about mutations in activin receptors or signaling factors specific for activin in cancer, compared to TGF-β. In tissues in which growth-promoting effects of activins have been documented, the sustained synthesis of the ligands in malignancy may contribute to tumorigenesis due to other effects of activins, e.g., on immune suppression, tissue remodeling, and angiogenesis. Apart from local effects on tumor tissues, activins are implicated in the promotion of cachexia. Mutant mice bearing deletions of both the inhibin α-subunit and the ActRII receptor develop gonadal tumors, but cachexia is reduced relative to animals with a single gene deletion.

VI. CLINICAL APPLICATIONS

In contrast to the assays for inhibins or the α-subunit, assays for activins remain to be validated for use as new diagnostic tools in clinical medicine.

VII. SUMMARY

There is substantial evidence for a role for activins in normal physiological systems and in disease. However, much of the information about these ligands relates to activin A (not activin B or activin AB), and even less is known about the biological roles of the other subset of activins (C and E) or the putative ligands formed between the groups of subunits. The overlap or redundancy between activins and other members of the superfamily is largely unexplored and few studies have made direct comparisons of the different members of the superfamily. For example, the bioactivities of TGF-β and activin A or B are seldom compared in the same models, and the regulatory actions of binding proteins such as follistatins, which bind both activins and BMPs, are unknown. Development of new assays and purified ligands to study these ligands and direct comparisons of activin and other TGF-β family members using new mouse models and new systems will facilitate and promote our understanding of the wide and diverse roles for activins in biology and disease.

Adipokinetic Hormones and Carbohydrate Metabolism

WIL J. A. VAN MARREWIJK
Utrecht University, The Netherlands

Insect adipokinetic hormones (AKHs) belong to a large AKH/red pigment-concentrating hormone family, whose members are involved in the mobilization of energy substrates for flight activity. This article provides a survey of the way in which adipokinetic and other related hormones play a key role in the mobilization of carbohydrate reserves as flight fuels. Special emphasis is put on the hormonal control of the enzymes involved and on the mechanism of intracellular transduction of the hormonal signals.

I. CARBOHYDRATE MOBILIZATION

Carbohydrate is the major fuel in insects that fly only short distances, such as flies and bees, and it also provides most of the energy for the initial period of flight in long-term flying insects, such as locusts. Reserves of carbohydrate are stored in the fat body in the form of glycogen, which upon flight is degraded by the action of the enzyme glycogen phosphorylase. Unlike glucose in vertebrates and most invertebrates, the carbohydrate transport form in insects is trehalose, a nonreducing disaccharide that contains two D-glucose residues. The mobilization of fat body glycogen and the subsequent release of trehalose into the hemolymph is controlled by adipokinetic hormone/red pigment-concentrating hormone (AKH/RPCH) peptides, which are released by the corpus cardiacum upon the onset of flight. The involvement of these hormones in carbohydrate metabolism was demonstrated *in vivo* by the activation of fat body glycogen phosphorylase or by increases of trehalose in hemolymph after hormone injection and in fat body *in vitro* by activation of the enzyme or by increased trehalose release into the medium when isolated fat body tissue was incubated in the presence of hormone. The hormonal stimulation of carbohydrate mobilization in an insect does not necessarily lead to increased trehalose concentrations in the hemolymph under the appropriate physiological conditions. In the locust, for instance, in which the trehalose utilization rate is increased during prolonged flight, the enhanced rate of trehalose release does not lead to hypertrehalosemia.

II. HORMONAL ACTIVATION OF GLYCOGEN PHOSPHORYLASE

The rate of glycogenolysis in the fat body depends on the activity of glycogen phosphorylase. Hormonal stimulation of glycogenolysis leading to an increased

Adipokinetic Hormones and Carbohydrate Metabolism

WIL J. A. VAN MARREWIJK
Utrecht University, The Netherlands

Insect adipokinetic hormones (AKHs) belong to a large AKH/red pigment-concentrating hormone family, whose members are involved in the mobilization of energy substrates for flight activity. This article provides a survey of the way in which adipokinetic and other related hormones play a key role in the mobilization of carbohydrate reserves as flight fuels. Special emphasis is put on the hormonal control of the enzymes involved and on the mechanism of intracellular transduction of the hormonal signals.

I. CARBOHYDRATE MOBILIZATION

Carbohydrate is the major fuel in insects that fly only short distances, such as flies and bees, and it also provides most of the energy for the initial period of flight in long-term flying insects, such as locusts. Reserves of carbohydrate are stored in the fat body in the form of glycogen, which upon flight is degraded by the action of the enzyme glycogen phosphorylase. Unlike glucose in vertebrates and most invertebrates, the carbohydrate transport form in insects is trehalose, a nonreducing disaccharide that contains two D-glucose residues. The mobilization of fat body glycogen and the subsequent release of trehalose into the hemolymph is controlled by adipokinetic hormone/red pigment-concentrating hormone (AKH/RPCH) peptides, which are released by the corpus cardiacum upon the onset of flight. The involvement of these hormones in carbohydrate metabolism was demonstrated *in vivo* by the activation of fat body glycogen phosphorylase or by increases of trehalose in hemolymph after hormone injection and in fat body *in vitro* by activation of the enzyme or by increased trehalose release into the medium when isolated fat body tissue was incubated in the presence of hormone. The hormonal stimulation of carbohydrate mobilization in an insect does not necessarily lead to increased trehalose concentrations in the hemolymph under the appropriate physiological conditions. In the locust, for instance, in which the trehalose utilization rate is increased during prolonged flight, the enhanced rate of trehalose release does not lead to hypertrehalosemia.

II. HORMONAL ACTIVATION OF GLYCOGEN PHOSPHORYLASE

The rate of glycogenolysis in the fat body depends on the activity of glycogen phosphorylase. Hormonal stimulation of glycogenolysis leading to an increased

biosynthesis and release of trehalose has been investigated extensively in cockroaches, which rely mainly on carbohydrate as a fuel for flight activity. Hypertrehalosemic hormones (HTHs), representatives of the AKH/RPCH family, were shown to activate fat body glycogen phosphorylase and to stimulate trehalose synthesis in *Periplaneta americana* and *Blaberus discoidalis*. Activation of fat body phosphorylase by AKH peptides has been demonstrated in locusts, the moth *Manduca sexta*, and the beetle *Pachnoda sinuata*. In the locust *Locusta migratoria*, all three known AKHs (AKH-I, -II, and -III) are able to activate glycogen phosphorylase in a bioassay, although with different potencies. In vertebrates, phosphorylase is regulated by reversible phosphorylation/dephosphorylation between nonphosphorylated inactive

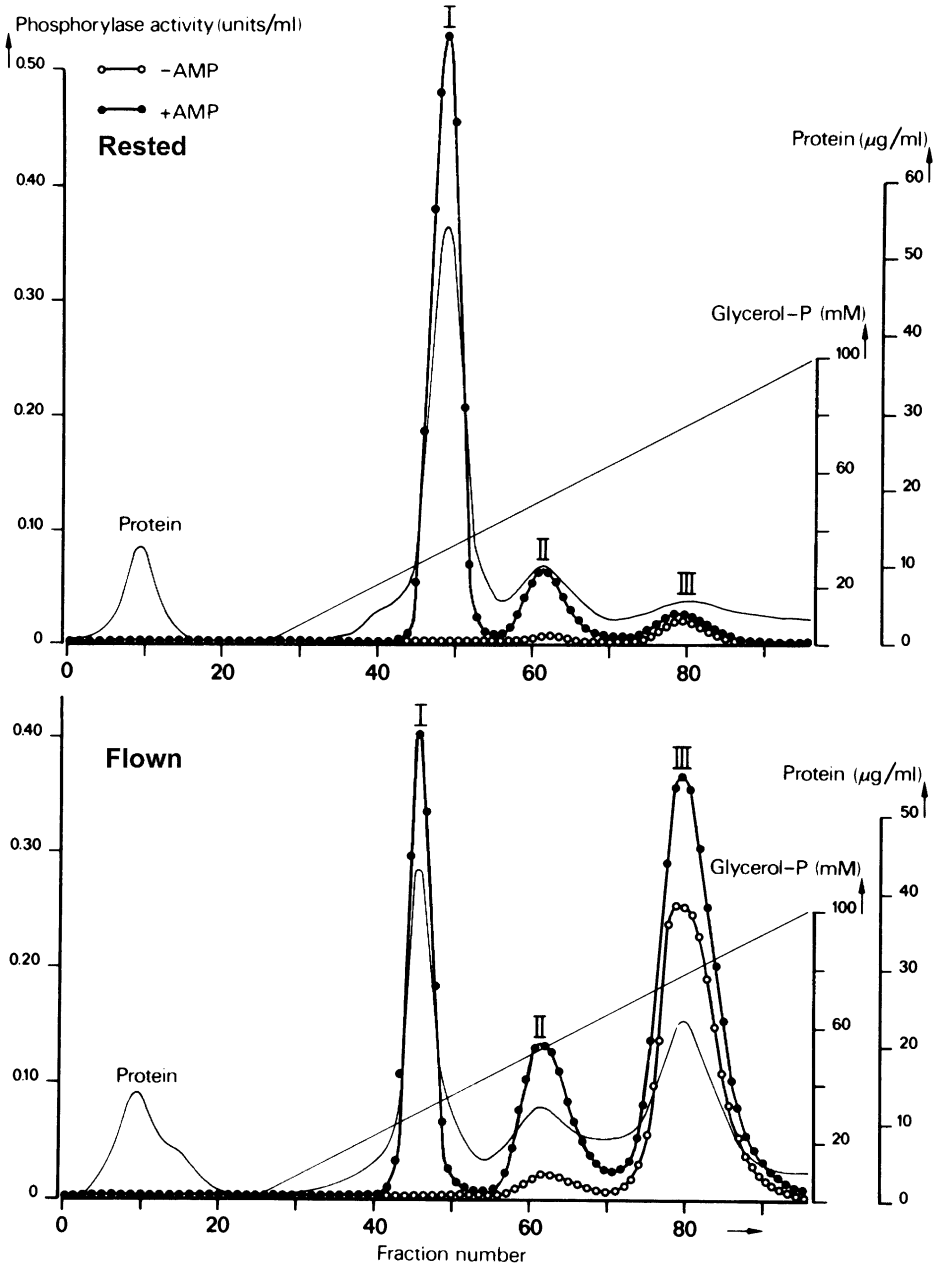

FIGURE 1 Fractionation of locust fat body phosphorylase by DEAE–Sephacel chromatography. Elution profiles were obtained with partially purified enzyme from the pooled fat bodies of 80 locusts at rest (Rested) and of 120 flown locusts (Flown).

phosphorylase *b* and phosphorylated active phosphorylase *a*. Also in locusts, flight activity as well as AKH injection induces the conversion of fat body phosphorylase *b* into the *a* form. This activating conversion indicates phosphorylation of each of the two subunits of the enzyme, which takes place in two steps, thereby giving rise to an intermediate hybrid *ab* form (Fig. 1). Activation of fat body phosphorylase by flight activity or hormone injection, combined with the occurrence of three forms of the enzyme including the partially phosphorylated phosphorylase *ab*, has also been demonstrated in *M. sexta* and *P. americana*. It has been suggested that the presence of this hybrid phosphorylase would provide for a sophisticated way of regulating carbohydrate metabolism in insects.

III. HORMONAL SIGNAL TRANSDUCTION

Binding of the AKH/RPCH peptides to their plasma membrane receptor(s) in the insect fat body results in the induction of a variety of signal transduction events that ultimately lead to the activation of target enzymes. As discussed above, the target enzyme in the mobilization of carbohydrate reserves is glycogen phosphorylase, which initiates the conversion of glycogen into trehalose. Signal transduction mechanisms have been investigated mainly in locusts and cockroaches, with focus on GTP-binding (G) proteins, cyclic AMP (cAMP), Ca^{2+}, inositol phosphates, signaling cross-talk, and hormone receptors. Some major results are discussed in this article.

A. Cyclic AMP and G-Proteins

In the fat body of *L. migratoria*, an accumulation of the second messenger cAMP, brought about by AKH-I has been demonstrated both *in vivo* and *in vitro*. Moreover, this accumulation of cAMP leads to the activation of glycogen phosphorylase, which is evidence in favor of a role of cAMP in AKH signal transduction. Each of the AKHs stimulates cAMP production in a dose-dependent manner in the fat body within 1 min. At a physiological dose of 4 nM, AKH-III is the most potent and AKH-I the least potent peptide hormone in stimulating cAMP production, and the same order of potency holds for the activation of glycogen phosphorylase by this hormonal dose. The observation that AKH-II is somewhat stronger than AKH-I in activating glycogen phosphorylase is in line with suggestions that the second AKH would be the major trigger for carbohydrate mobilization from the fat body and that the action of cAMP is directed more toward carbohydrate mobilization than lipid mobilization. The involvement of cAMP in the stimulation of glycogen mobilization is not a general feature of insects, since the HTHs of several cockroach species studied do not utilize this second messenger to activate trehalose synthesis in the fat body.

Experiments on locust fat body using cholera toxin (CTX) and pertussis toxin (PTX) suggest that the AKH receptor(s) is coupled to the G_s-protein (and not to G_i). The demonstration that AKH-I-, AKH-II-, and AKH-III-stimulated phosphorylase activation is ablated by the universal G-protein inhibitor guanosine-5′-*O*-(2-thiodiphosphate) strongly substantiates this suggestion.

B. Calcium

The relative importance of Ca^{2+} in signal transduction in the fat body is not equal in several closely related insect species. For example, the influx of extracellular Ca^{2+} into the fat body of *L. migratoria* has a much stronger stimulating effect on glycogen phosphorylase activity than the release of calcium ions from intracellular stores, but in *B. discoidalis* the opposite result holds. The presence of extracellular Ca^{2+} ions has been shown to be indispensable for the induction of fat body phosphorylase by AKH in *L. migratoria* and by HTH in *P. americana*. In the absence of Ca^{2+} in the medium, none of the three locust AKHs is capable of enhancing cAMP production and inducing glycogen phosphorylase activation in the fat body, but 1.5 mM Ca^{2+} (which is the Ca^{2+} concentration in hemolymph) is sufficient for complete activation (Fig. 2). Since the induction of

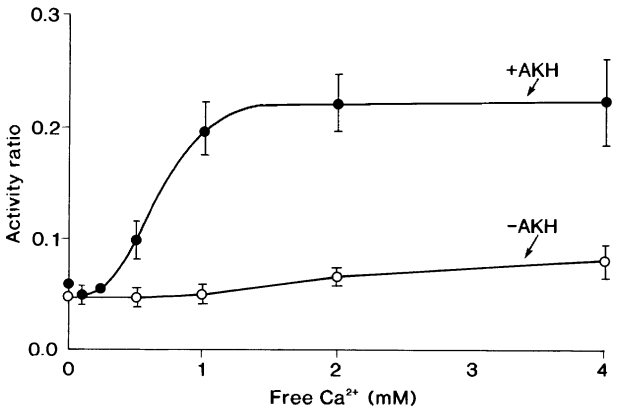

FIGURE 2 Dependence of AKH-induced activation of locust fat body phosphorylase on extracellular Ca^{2+}. Fat body was incubated for 15 min in the presence or absence of 40 nM AKH-I. Similar results were obtained with AKH-II and -III.

phosphorylase by cAMP in fat body was shown to be independent of extracellular Ca^{2+}, data suggest that at least part of the action of extracellular Ca^{2+} is at a site proximal to cAMP, e.g., the binding of the hormones to their receptor(s) or a Ca^{2+}-sensitive adenylyl cyclase.

All three locust AKHs are capable of stimulating the Ca^{2+} inflow into the fat body cells within 30 s with equal potency. This hormone-induced Ca^{2+} influx appeared to be mediated through depletion of intracellular Ca^{2+} stores, suggesting the functioning of a store-operated or capacitative Ca^{2+} entry mechanism. Simultaneously, the AKHs also enhance the efflux of Ca^{2+} from the fat body. At a physiological dose, AKH-III caused the strongest efflux and AKH-I the weakest; at a massive dose, their efficacy was equal. As the influx of Ca^{2+} exceeded the efflux, it is feasible that the intracellular Ca^{2+} concentration rises as a result of incubation of fat body with AKH.

C. Inositol Phosphates

For a maximal effect of AKH on glycogen phosphorylase activity in locust fat body, the release of Ca^{2+} from intracellular stores is required in addition to the availability of extracellular calcium. The same holds for the activation of glycogen phosphorylase and the stimulation of trehalose synthesis by HTH in *B. discoidalis* fat body. In the regulation of Ca^{2+} mobilization from intracellular stores, inositol phosphates ($InsP_n$) play a pivotal role, and the formation of these putative second messengers is induced by the locust AKHs. Each of the *Locusta* AKHs stimulates the synthesis of total $InsP_n$ within 1 min with different potencies: AKH-II barely induces any $InsP_n$ and AKH-III is more potent than AKH-I. The observation that the activation of glycogen phosphorylase by each of the AKHs is dampened by the phospholipase C (PLC) inhibitor U73122 suggests the involvement of $InsP_n$ (and/or diacylglycerol) in AKH signaling in the locust fat body.

All individual forms of $InsP_n$ are elevated by the AKHs, with $InsP_3$ and $InsP_4$ being the most interesting because of their presumed Ca^{2+} mobilizing actions (Fig. 3). With respect to $InsP_3$, AKH-III is again more potent than AKH-I, and the AKH-II-enhanced $InsP_3$ formation is quite small. The most prolonged effect on $InsP_3$ is caused by AKH-III. The high potency and prolonged effects of AKH-III with respect to the induction of various second-messenger systems apparently compensate (in part) for its low abundance relative to that of the other AKHs, and therefore, the effects of this hormone may be stronger than estimated from its relative amount in the circulation.

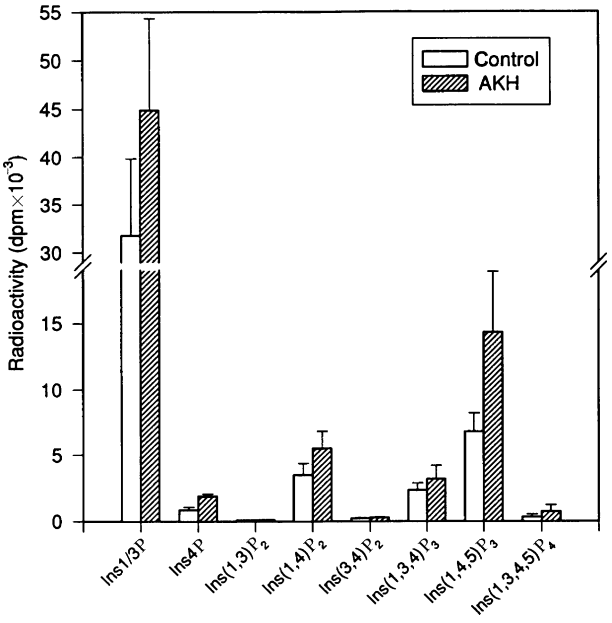

FIGURE 3 Effect of AKH on the formation of inositol phosphate isomers from locust fat body. Fat body tissue prelabeled with *myo*-[2-^{3}H]inositol was incubated for 1 min in the presence or absence (controls) of 40 nM AKH-I; then $InsP_n$ were isolated and separated by high-performance liquid chromatography and their radioactivity was measured. Results are expressed as disintegrations per minute per milligram of protein.

$Ins(1,4,5)P_3$ levels are greatly increased by HTH in the fat body of *B. discoidalis* in a time- and dose-dependent manner, which, along with the strong evidence for Ca^{2+} as component in the HTH second-messenger cascade, argues strongly for $InsP_3$ as a primary second messenger in response to HTH followed by the mobilization of intracellular Ca^{2+}.

D. Signaling Crosstalk

Crosstalk between signal transduction cascades provides the cell with a complex intracellular system for fine-tuning of hormone-induced signals. In locust fat body an elevation of cAMP levels does not influence the intracellular $InsP_n$ content, indicating that the basal PLC activity is not regulated by this cyclic nucleotide. Moreover, none of the signal transducing elements between the AKH receptor and PLC is affected by cAMP, since preincubation of fat body tissue with forskolin or dibutyryl-cAMP does not have an impact on AKH-induced $InsP_n$ production. Proof of a direct linkage between the AKH

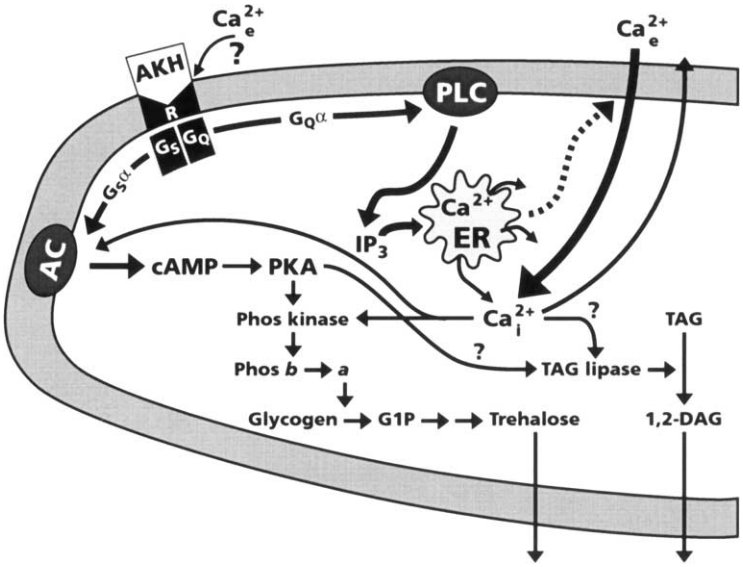

FIGURE 4 Tentative model for the coupling of AKH signaling pathways mediating the mobilization of energy substrates in the locust fat body cell. R, receptor; ER, endoplasmic reticulum; AC, adenylyl cyclase; PLC, phospholipase C; Phos, phosphorylase; G1P, glucose 1-phosphate; TAG, triacylglycerol; DAG, diacylglycerol.

receptor(s) and PLC (instead of a route via cAMP) came from the substantiation that the G-protein activator aluminum fluoride increases $InsP_n$ levels. Experiments using CTX, PTX, and GP antagonist-2A, a specific inhibitor of G_q, preclude the involvement of G_i and a G_s-sensitive isoform of PLC and evidence the involvement of G_q in the transduction of AKH signals toward fat body PLC (Fig. 4).

Glossary

adipokinetic hormone Peptide hormone in insects involved in the mobilization of substrates (predominantly lipids and carbohydrates) for energy generation needed by contracting flight muscles.

corpus cardiacum Neuroendocrine organ situated caudal to the brain to which it is connected by paired nerves. The organ combines the functions of neurohemal storage and adipokinetic/hypertrehalosemic hormone production.

fat body Organ whose functional role in insects is analogous to the combined functions of liver and adipose tissue in mammals. Fat body is the chief site of intermediary metabolism, detoxification, storage of nutrient reserves, and, in some species, deposition of nitrogenous waste products.

glycogenolysis Breakdown of glycogen; in insect fat body, the resulting glucose monomers are used for the biosynthesis of the disaccharide trehalose, the carbohydrate transport form in insects.

glycogen phosphorylase Enzyme that catalyzes the sequential removal of glycosyl residues from the nonreducing end (i.e., with a free 4′-OH group) of the glycogen molecule, using orthophosphate as a co-substrate and releasing glucose-1-phosphate.

hemolymph Blood of insects, which circulates in the body cavity between the various organs, bathing them directly. It consists of a fluid plasma in which the blood cells or hemocytes are suspended.

hypertrehalosemia Condition characterized by an increase in the level of trehalose in the hemolymph (insect blood) to values that significantly exceed the normal resting level.

hypertrehalosemic hormone Peptide hormone from the corpus cardiacum involved in the mobilization of fat body glycogen to fuel flight activity. For transport to the flight muscles, glycogen is converted into the disaccharide trehalose, the carbohydrate transport form in insects, whose level in hemolymph is raised during flight.

red pigment concentrating hormone Peptide hormone from the eyestalk of crustaceans; member of the adipokinetic hormone/red pigment-concentrating hormone family that comprises structurally related but functionally diverse peptides.

signaling cross-talk Occurrence of communication/interaction between different signaling pathways, resulting in an integrated response to a hormone-induced signal.

trehalase Enzyme that catalyzes the hydrolytic reaction by which trehalose is brought into the glycolytic mainstream: Trehalose + $H_2O \rightarrow$ 2D-glucose.

Adipokinetic Hormones and Lipid Mobilization

DICK J. VAN DER HORST AND ROB C. H. M. OUDEJANS
Utrecht University, The Netherlands

In the migratory locust, *Locusta migratoria*, the flight activity-induced release of adipokinetic hormones (AKHs; AKH-I, -II, and -III) from the neurosecretory cells of the corpus cardiacum, a neuroendocrine gland located caudal to the insect brain, has been studied extensively. The direct actions of these hormones on their fat body target cells trigger signal transduction processes that lead to the mobilization of lipid (diacylglycerol). This substrate fulfills a major role in energy metabolism of the contracting flight muscles during sustained flight activity. The molecular mechanism of diacylglycerol transport in insect blood involves a reversible conversion of the insect lipoprotein lipophorin, which has revealed a novel concept for lipid transport in the circulatory system.

I. INTRODUCTION

The flight activity of insects provides an exceptionally suitable yet relatively simple model system for studying the regulatory phenomena involved in energy expenditure during extreme physical activity. Similar to the processes used by vertebrates to generate energy for sustained locomotion, long-distance flying insects mobilize endogenous lipid (triacylglycerol) reserves to fuel oxidative metabolism during migratory flight. The fat body, which combines many of the properties and functions of vertebrate liver and adipose tissue, plays a fundamental role in lipid storage, as well as in the process of lipolysis controlled by adipokinetic hormones (AKHs). This article discusses the action of AKHs on lipid mobilization in fat body cells and the eventual AKH-induced transformation of the transport system of lipids in the insect blood, which will be exemplified using mainly the migratory locust (*Locusta migratoria*) as an insect model.

II. ADIPOKINETIC HORMONE SIGNAL TRANSDUCTION IN INSECT FAT BODY

Binding of the peptide adipokinetic hormones to their plasma membrane receptor(s) at the fat body cells results in the induction of a variety of signal transduction events that ultimately lead to the activation of target key enzymes. The first insect AKH receptors have recently been identified at the molecular level. The signal transduction mechanism of the three locust AKHs has been studied extensively and involves stimulation of cAMP production, which is dependent on the presence of extracellular Ca^{2+}. Additionally,

Adipokinetic Hormones and Lipid Mobilization

DICK J. VAN DER HORST AND ROB C. H. M. OUDEJANS
Utrecht University, The Netherlands

In the migratory locust, *Locusta migratoria*, the flight activity-induced release of adipokinetic hormones (AKHs; AKH-I, -II, and -III) from the neurosecretory cells of the corpus cardiacum, a neuroendocrine gland located caudal to the insect brain, has been studied extensively. The direct actions of these hormones on their fat body target cells trigger signal transduction processes that lead to the mobilization of lipid (diacylglycerol). This substrate fulfills a major role in energy metabolism of the contracting flight muscles during sustained flight activity. The molecular mechanism of diacylglycerol transport in insect blood involves a reversible conversion of the insect lipoprotein lipophorin, which has revealed a novel concept for lipid transport in the circulatory system.

I. INTRODUCTION

The flight activity of insects provides an exceptionally suitable yet relatively simple model system for studying the regulatory phenomena involved in energy expenditure during extreme physical activity. Similar to the processes used by vertebrates to generate energy for sustained locomotion, long-distance flying insects mobilize endogenous lipid (triacylglycerol) reserves to fuel oxidative metabolism during migratory flight. The fat body, which combines many of the properties and functions of vertebrate liver and adipose tissue, plays a fundamental role in lipid storage, as well as in the process of lipolysis controlled by adipokinetic hormones (AKHs). This article discusses the action of AKHs on lipid mobilization in fat body cells and the eventual AKH-induced transformation of the transport system of lipids in the insect blood, which will be exemplified using mainly the migratory locust (*Locusta migratoria*) as an insect model.

II. ADIPOKINETIC HORMONE SIGNAL TRANSDUCTION IN INSECT FAT BODY

Binding of the peptide adipokinetic hormones to their plasma membrane receptor(s) at the fat body cells results in the induction of a variety of signal transduction events that ultimately lead to the activation of target key enzymes. The first insect AKH receptors have recently been identified at the molecular level. The signal transduction mechanism of the three locust AKHs has been studied extensively and involves stimulation of cAMP production, which is dependent on the presence of extracellular Ca^{2+}. Additionally,

the AKHs enhance the production of inositol phosphates including inositol 1,4,5-trisphosphate, which may mediate the mobilization of Ca^{2+} from intracellular stores. This depletion of Ca^{2+} from intracellular stores stimulates the influx of extracellular Ca^{2+}, indicative of the operation of a capacitative (store-operated) calcium entry mechanism. The interactions between the AKH signaling pathways ultimately result in the mobilization of stored reserves as fuels for flight. Although the carbohydrate (mainly trehalose) in the insect blood (hemolymph) provides the energy for the initial period of flight, additional trehalose is mobilized from fat body glycogen reserves by the AKH-induced activation of glycogen phosphorylase. At the same time, the concentration of lipid (diacylglycerol, DAG) in the hemolymph is increased progressively at the expense of stored triacylglycerol (TAG) reserves in the fat body and gradually constitutes the major substrate during prolonged flight.

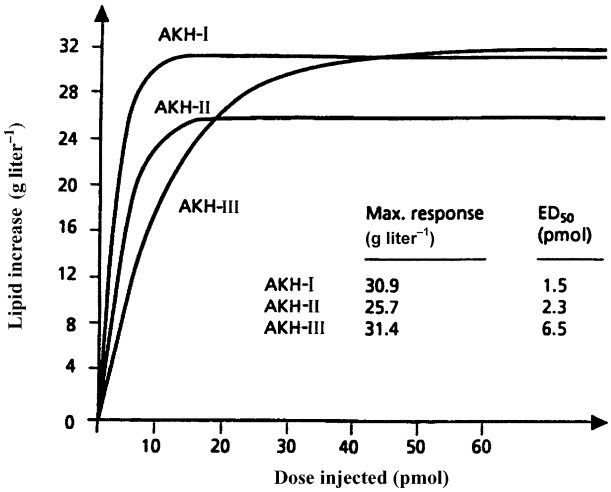

FIGURE 1 Dose–response curves for the lipid-mobilizing effects of AKH-I, -II, and -III in *L. migratoria*. Adult male locusts were injected with different doses of AKH or, in the controls, with saline, and after 120 min, the lipid content in hemolymph was determined. Responses represent increases in hemolymph lipid in AKH-injected locusts, expressed as grams per liter. For clarity, data points and standard error bars were omitted. ED_{50}, effective dose eliciting 50% of the maximum response.

III. EFFECT OF ADIPOKINETIC HORMONE ON LIPID MOBILIZATION

The namesake action of the AKHs on insect fat body cells results in the mobilization of lipid (TAG) stores. The increased production of DAG reflected by the increased concentration of DAG in the hemolymph indicates hormonal activation of the key enzyme, fat body TAG lipase. In a bioassay, all three *L. migratoria* AKHs (-I, -II, and -III) are able to stimulate lipid mobilization, although their relative potencies are different, as inferred from the dose–response curves shown in Fig. 1. This recalls the concept of a hormonally redundant system involving multiple regulatory molecules with overlapping actions. Results obtained with combinations of two or three AKHs, which are likely to occur together in locust hemolymph under physiological conditions *in vivo*, revealed that the maximal responses for the lipid-mobilizing effects were much lower than the theoretically calculated responses based on the dose–response curves for the individual hormones. In the lower (probably physiological) range, however, combinations of the AKHs were more effective than the theoretical values calculated from the responses elicited by the individual hormones.

The mechanism by which TAG lipase catalyzes AKH-controlled production of the DAG on which long-distance flight depends is only poorly understood, mainly due to technical problems in isolating or activating the lipase. In vertebrates, hormone-sensitive lipase (HSL) controls mobilization of TAG stores in adipose tissue, and although, in contrast to the situation in insects, free fatty acids (FFA) are released into the blood for uptake and oxidation in muscle, there is a clear functional similarity between vertebrate adipose tissue HSL and insect fat body TAG lipase. In vertebrate HSL, specific regulatory sites are phosphorylated *in vitro* by cAMP-dependent protein kinase (PKA), resulting in activation of HSL. The mechanism behind this activation of HSL upon phosphorylation by PKA is not well understood, but seems to involve translocation of HSL from the cytosol to the lipid droplet as well as conformational changes in the HSL molecule. Different phosphorylation sites in HSL may play different roles in the process of translocation and the increase in specific activity of the enzyme. Additionally, perilipins, a family of unique proteins intimately associated with the limiting surface of neutral lipid storage droplets, are acutely polyphosphorylated by PKA on stimulation of lipolysis, hinting at a role in this lipolytic process. Conformational changes of phosphorylated perilipins may expose the neutral lipid cores of the lipid droplets, facilitating the ensuing hydrolysis.

Even though a translocation of the insect fat body TAG lipase has not been established, the involvement

of AKHs in the process of lipolysis is beyond dispute. The effect of AKHs was demonstrated not only *in vivo* from enhanced levels of DAG in hemolymph of insects injected with the hormones as shown above, but also *in vitro* by the accumulation of DAG in isolated *L. migratoria* fat body tissue that was incubated in the presence of AKH. In later *in vitro* experiments, both cAMP and Ca^{2+} were shown to play an important role in the effect of AKH on lipolysis. The involvement of cAMP suggests a role for PKA in the phosphorylation and activation of fat body TAG lipase. In addition, an increase of fat body TAG lipase activity was measured in gregarious locusts *in vivo* when injected with AKH-I, whereas in solitary locusts, which do not store sufficient amounts of TAG in the fat body, AKH-I administration had no significant effect on lipase activity. The reason that the measured factorial increases of lipase activity after stimulation with lipolytic agents are relatively modest in these and other similar studies may reside in the applied experimental procedure, in which the enzyme is assayed in extracts of fat body or adipose tissue in the presence of optimally accessible TAG substrate. In this way, only the effects of (de)phosphorylation or other conformational changes of the enzyme on its lipolytic activity will be measured, and other potential effects such as enzyme translocation and the involvement of lipid droplet-associated proteins, factors that may be highly important for lipase activity as discussed above for vertebrate HSL, remain confounded. This may also explain why phosphorylation by PKA did not change the activity of TAG lipase that had been purified from fat body of the adult hawkmoth, *Manduca sexta*.

In two insect species that rely on lipid mobilization during sustained flight activity, *L. migratoria* and *M. sexta*, it has been shown that DAG, which is released from the fat body by the action of AKH, is stereospecific and has the *sn*-1,2-configuration. Although conclusive evidence on the pathway for the stereospecific synthesis of this *sn*-1,2-DAG is still lacking, the most probable route involves stereospecific hydrolysis of TAG into *sn*-1,2-DAG by a stereospecific lipase acting at the *sn*-3 position of the TAG.

IV. ADIPOKINETIC HORMONE-INDUCED LIPOPHORIN CONVERSIONS

For insect species that recruit fat body TAG depots to power their flight muscles during the vast distances covered nonstop by migratory flight, an efficient mechanism for lipid transfer is a premier issue. The action of AKH on lipid release has revealed a novel concept for lipid transport in the circulation of animal organisms. Insect hemolymph generally contains abundant amounts of a single multifunctional lipoprotein particle, high-density lipophorin (HDLp), that performs the tasks of transporting dietary and endogenously produced lipids to peripheral tissues during all developmental stages. A characteristic feature of HDLp is its ability to function as a reusable vehicle for a variety of lipids by the selective loading and unloading of lipid components at target tissues. In the flying insect, however, the increased transport of the released DAG in the hemolymph appears to require an AKH-stimulated transformation of the lipophorin particle, which is capable of alternating between the relatively lipid-poor HDLp form and a lipid-enriched (low-density lipophorin, LDLp) form. In this reversible conversion the exchangeable apolipoprotein apoLp-III, which exists in a lipid-free form and a lipid-bound form, plays an essential role. A schematic overview of the process is depicted in Fig. 2. Recent advances on the structural properties of HDLp and apoLp-III demonstrate a remarkable similarity to their counterparts in the mammalian system (the two nonexchangeable apolipoproteins of HDLp are similar to apoB; apoLp-III is similar to apoE). However, the functioning of the insect lipoprotein as a shuttle mechanism operating in energy transport during flight activity is intriguingly different, since in mammals lipoproteins do not play a role as carriers of mobilized lipids during exercise.

Both HDLp and apoLp-III are abundantly present in the hemolymph of resting insects. The loading of DAG onto HDLp particles at the fat body cell plasma membrane induces the association of multiple copies of apoLp-III with the expanding lipoprotein surface. The resulting LDLp, which is both larger and lipid-enriched, travels in the circulation to the flight muscles, where a lipophorin lipase specifically hydrolyzes the LDLp-carried DAG. The liberated FFA are imported into the muscle cells and oxidized to yield energy. Once the lipid content of the LDLp has diminished, apoLp-III dissociates from the particle, and finally, its HDLp constituent is recovered. Both HDLp and apoLp-III are recycled to the fat body and reutilized for DAG uptake (see Fig. 2). This concept of a reusable lipoprotein shuttle for lipid transport during flight activity was initially reported for the locust, but thereafter found to be present in many other long-distance flying insects.

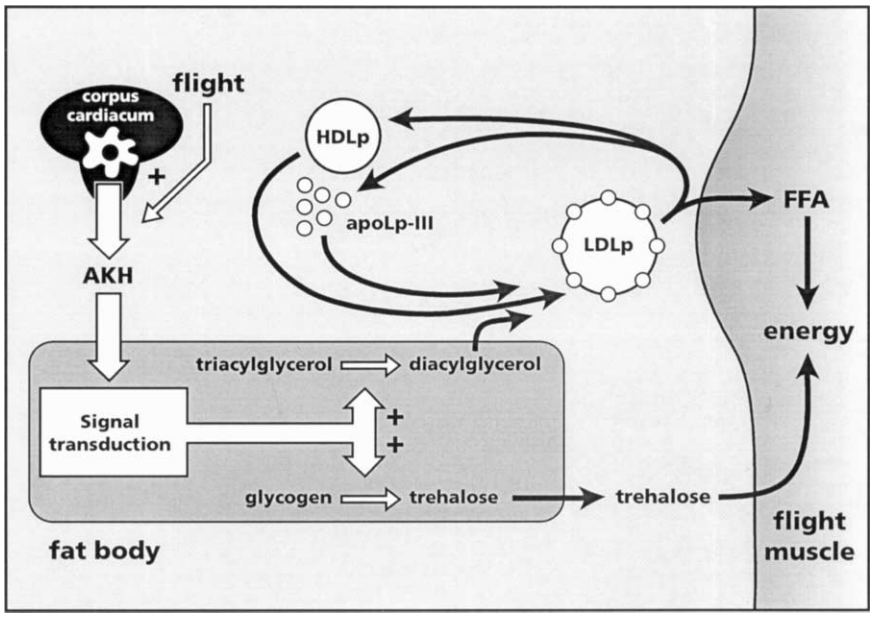

FIGURE 2 Schematic overview of AKH-controlled substrate mobilization from insect fat body during flight activity. AKH, adipokinetic hormones; HDLp, high-density lipophorin; LDLp, low-density lipophorin; apoLp-III, apolipophorin III; FFA, free fatty acids.

This shuttle mechanism is specific to the adult stage of the insect. During all stages of locust development, high circulating levels of HDLp are present to transport lipid components between tissues. However, the apoLp-III gene is expressed only after the first week of adult life and is apparently related to the adult-specific capacity of the insect to fly. The molecular basis of the interaction of apoLp-III with the lipoprotein surface is of great interest and value since the locust apoLp-III represents the only full-length apolipoprotein for which a three-dimensional structure has been disclosed. In the absence of lipid, apoLp-III reveals a globular bundle of five amphipathic α-helices. These helices are oriented such that the hydrophobic amino acid side chains are buried in the bundle interior and the hydrophilic residues face outward. A plausible model postulates that lipid binding induces a significant reorganization of the helical segments, allowing interaction of the hydrophobic face of the helices with the lipoprotein lipid surface. A critical event in lipid surface recognition seems to be the disturbance of the phospholipid monolayer by the appearance of patches of DAG molecules in the lipoprotein surface. Mechanistic details underlying the opening of the amphipathic helix bundle and the lipid-binding activity of apoLp-III, however, remain to be defined.

Glossary

adipokinetic hormone Peptide hormone in insects involved in the mobilization of substrates (predominantly lipids and carbohydrates) for energy generation needed by contracting flight muscles.

apolipophorin III (apoLp-III) Exchangeable apolipoprotein (mol wt 17–20 kDa) in the hemolymph of insects engaging in long-distance flights for which lipids are used as an energy source. In the resting blood, apolipophorin III forms a stable particle consisting of a bundle of five amphipathic α-helices; during lipid loading of lipophorin the conformation of apoLp-III changes and allows the peptide to unfold and reversibly bind to the expanding particle.

fat body Organ whose functional role in insects is analogous to the combined functions of liver and adipose tissue in mammals. Fat body is the chief site of intermediary metabolism, detoxification, storage of nutrient reserves, and, in some species, deposition of nitrogenous waste products.

HDLp High-density lipophorin (density approximately 1.12 g/ml), the abundant and generally single lipoprotein particle in insect hemolymph, transporting several classes of lipids between organs and tissues in the resting situation.

LDLp Low-density lipophorin (density approximately 1.04 g/ml), the adipokinetic hormone-induced form of lipoprotein in the hemolymph of insects engaging in long-distance flights for which lipids are used as an

energy source. The particle consists of lipid (diacylglycerol)-loaded and apoLp-III-associated HDLp.

lipophorin The abundant and generally single lipoprotein particle in insect hemolymph. The density of lipophorin (lipid-bearing protein) is similar to that of human high-density lipoprotein (HDL); for the insect lipophorin, HDLp is used to distinguish it from HDL.

Adipokinetic Hormones: Structure and Biosynthesis

ROB C. H. M. OUDEJANS AND
DICK J. VAN DER HORST
Utrecht University, The Netherlands

The structure and biosynthesis of the adipokinetic hormones (AKHs) are reviewed and their storage, release, and inactivation in insect blood (hemolymph) are discussed. Since most of our knowledge on the biosynthesis of the AKHs has been obtained from locust species, these insects will serve as a general model system.

I. INTRODUCTION

Insect long-distance flight activity involves extremely high metabolic rates, and insect flight muscles are among the most energy-demanding tissues known. The energy substrates needed to fuel the flight muscles are stored in the fat body and their mobilization is under the control of adipokinetic hormones (AKHs). Additional functions of the AKHs are revealed during a variety of other metabolic "stress" situations (energy-consuming processes), such as starvation, diapause, and molting. The AKHs are peptide hormones that (with a few exceptions) are synthesized and stored in the so-called adipokinetic cells of the glandular lobes of the corpus cardiacum, a neuroendocrine organ situated in the insect head and connected to the central nervous system.

II. PRIMARY STRUCTURE OF ADIPOKINETIC HORMONES

Since the elucidation of the structure of the first AKH in 1976 from 3000 locust corpora cardiaca, analytical techniques have been revolutionized and today it is possible to determine the structure of a new AKH from just a few picomoles of the hormone. To date, the structures of some 37 different AKHs are known from representatives of most insect orders (Table I).

energy source. The particle consists of lipid (diacylglycerol)-loaded and apoLp-III-associated HDLp.

lipophorin The abundant and generally single lipoprotein particle in insect hemolymph. The density of lipophorin (lipid-bearing protein) is similar to that of human high-density lipoprotein (HDL); for the insect lipophorin, HDLp is used to distinguish it from HDL.

They are short peptides consisting of 8–11 amino acid residues and constitute the so-called AKH/RPCH (red pigment-concentrating hormone) family. The nomenclature of the members of this family (by acronym) is based on the use of the first two characters of the genus name and the first character of the species name of the animal from which the hormone was first isolated, supplemented by an abbreviation of its function.

The name is followed by a roman numeral in case there is more than one hormone per function. So Lom-AKH-I, -II, and -III are the three AKHs isolated from *Locusta migratoria*, and Lom-AKH-I and Scg-AKH-II are the two AKHs from *Schistocerca gregaria*.

In addition to the AKHs, the family contains hypertrehalosemic (HrTH) and hypotrehalosemic hormones (HoTH), corpus cardiacum factors (CC), etc. All members are found in insects, except for RPCH, which is restricted to the X-organ-sinus gland of crustaceans. Curiously, the variation in the structure of AKHs of insects is extremely large, whereas in all crustaceans investigated to date, just one RPCH structure has been found. All members (except Vac-AKH) are fully blocked peptides: They are N-terminally blocked by a pyroglutamate (pGlu) residue and C-terminally blocked by an amide group. Although the variation in structure has increased by an increasing number of new hormones, characteristic features are still present. At the bottom of Table I the variation per amino acid residue position is indicated. At position 1 a pGlu is always found, at position 8 a Trp is always found, and at position 4 an aromatic amino acid residue is always found. At position 2 most members contain a branched-chain amino acid residue, and at position 5 either a Ser or a Thr is present. Except for Lom-HrTH, all longer members possess a Gly at position 9. Most variation occurs at positions 6, 7, and 10. In only one member (Cam-HrTH-I), a sugar moiety with an as yet unknown structure has been found as a posttranslational modification. Except for a few members (Lom-HrTH, Mem-CC, Ona-CC-II, and Pht-HrTH), all peptides are uncharged.

Adipokinetic activity of a substance can be shown in the locust (*L. migratoria*) by using a simple bioassay of injecting the substance into resting animals and measuring the increase in lipid content in the hemolymph. Potential hypertrehalosemic activity can be measured using a bioassay in the cockroach (*Periplaneta americana*). Interestingly, all members of the AKH/RPCH family (including RPCH itself) exert an adipokinetic effect in the locust assay, suggesting that the AKH receptor(s) of *L. migratoria* is (are) less specialized or that all AKHs share structural similarities. In contrast to locusts and cockroaches, some insect species have a low response to their own AKH and a higher response to the hormone from other species. There are even members of the family with an as yet unknown function (for instance, Lom-HrTH, which stimulates in a heterologous assay the mobilization of carbohydrates only in the cockroach). In many insect species a particular physiological function seems to be supported by two, or in some locust and grasshopper species even three, hormones, suggesting sophisticated hormonal control. Whether there are quantitative or qualitative differences that result in the fine-tuning of apparently identical or just pleiotropic functions is still under investigation.

III. BIOSYNTHESIS OF ADIPOKINETIC HORMONES

All AKHs studied thus far are translated from separate mRNAs. They code for preprohormones with a simple structure: a signal sequence, a monocopy AKH sequence (starting with a Gln to form pGlu), a Gly residue (to form the terminal AKH amide group), a dibasic processing site, and an AKH-associated peptide sequence. In particular, in *L. migratoria* the signal sequences of the three preprohormones are cotranslationally cleaved, and the resulting prohormones of AKH-I and -II dimerize at random by oxidation of their Cys residues and give rise to two homodimeric precursor molecules (AKH-I/I and AKH-II/II) and one heterodimeric precursor molecule (AKH-I/II). This dimerization is a rather unique phenomenon, first established for another locust species (*S. gregaria*). Further proteolytic processing of the dimeric products in the secretory granules of the AKH cells of the corpus cardiacum results in the bioactive hormones and one heterodimeric and two homodimeric AKH-precursor-related peptides (APRPs) with as yet unknown functions (see Fig. 1). The biosynthesis of AKH-III is not yet fully understood. Recently, dimerization of the AKH-III prohormone with itself (it contains two Cys residues itself) has been established. Dimerization with the prohormones of AKH-I and -II has not been observed, and whether a cyclic prohormone of AKH-III can arise by formation of an internal disulfide bond is unknown.

In vitro studies on the biosynthesis of AKHs in locusts have revealed that the total time required for their biosynthesis from the starting point when radiolabeled amino acids are made available to the moment that radiolabeled bioactive hormones appear is 30–60 min. In *L. migratoria* the time for biosynthesis of AKH-III is shorter than that for AKH-I and -II, suggesting that there are two different pathways or different processing procedures for AKH-I/II, on the one hand, and for AKH-III, on the other.

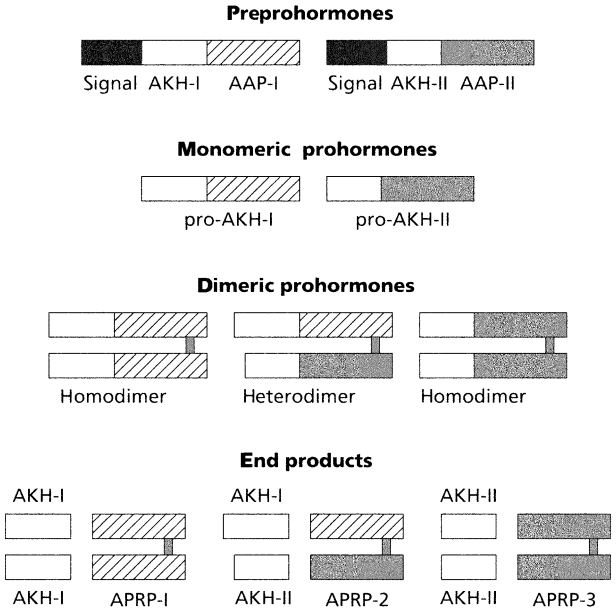

FIGURE 1 The biosynthesis of the locust adipokinetic hormones AKH-I and -II and the adipokinetic precursor-related peptides APRP-1, -2, and -3. After cleavage of the signal peptide from the preprohormones, the resulting monomeric prohormones, which consist of the AKH sequence and the AKH-associated peptide (AAP), form three dimeric prohormones, which are then processed to the AKHs and the APRPs.

IV. STORAGE, RELEASE, AND INACTIVATION OF ADIPOKINETIC HORMONES

AKHs are stored in the secretory granules of the adipokinetic cells of the corpus cardiacum. In *L. migratoria* the total content of the AKHs increases continuously during the larval stages and throughout adult life. In aging locusts an increasing number of intracisternal granules that contain stores of AKH prohormones/precursors are also found. The three AKHs, colocalized and stored in the same secretory granules, are released during flight. Since the membrane of the pertinent secretory granule fuses with the plasma membrane, the total contents of the granule are released into the hemolymph: the bioactive AKHs, the APRPs, and possibly other end products.

The release of the AKHs in *L. migratoria* is subjected to many regulatory substances, which are of either a stimulatory or an inhibitory nature and can be of both neural and humoral origin. A detailed description falls beyond the scope of this article. The only natural stimulus of release of the AKHs is flight and the relative contributions of all known substances effective in the release process remain to be established *in vivo*.

The situation in *L. migratoria* is even more complex, since secretory granules of only a particular age can be released. Newly formed granules containing the AKHs must mature before they can release their contents (or before they can fuse with the plasma membrane). Granules more than 8 h old are believed to enter a nonreleasable pool. Determination of the total hormone content of a neuroendocrine structure has therefore a limited physiological value, because only the releasable amount of hormone is relevant.

Finally, the balance between released hormones (a mixture of many compounds present in the secretory granule) and the rate of their inactivation prior to reaching the target tissue will be of eminent importance for their ultimate effect. The three AKHs of *L. migratoria* appear to be inactivated differentially after their release, with half-lives during flight of 35, 37, and 3 min obtained for AKH-I, -II, and -III, respectively.

Glossary

adipokinetic hormone Peptide hormone in insects involved in the mobilization of substrates (predominantly lipids and carbohydrates) for energy generation needed by contracting flight muscles.

corpus cardiacum Neuroendocrine organ situated caudal to the brain to which it is connected by paired nerves. The organ combines the functions of neurohemal storage and adipokinetic/hypertrehalosemic hormone production.

fat body Organ whose functional role in insects is analogous to the combined functions of liver and adipose tissue in mammals. Fat body is the chief site of intermediary metabolism, detoxification, storage of nutrient reserves, and, in some species, deposition of nitrogenous waste products.

hemolymph Blood of insects, which circulates in the body cavity between the various organs, bathing them directly. It consists of a fluid plasma in which the blood cells or hemocytes are suspended.

hypertrehalosemic hormone Peptide hormone from the corpus cardiacum involved in the mobilization of fat body glycogen to fuel flight activity. For transport to the flight muscles, glycogen is converted into the disaccharide trehalose, the carbohydrate transport form in insects, whose level in hemolymph is raised during flight.

red pigment concentrating hormone Peptide hormone from the eyestalk of crustaceans, a member of the adipokinetic hormone/red pigment-concentrating hormone family that comprises structurally related but functionally diverse peptides.

Adrenal Cortex Role in Medullary Synthesis of PNMT

I. C. McMillen and M. B. Adams
University of Adelaide, Australia

During development, two anatomically and functionally distinct structures merge to form the adrenal gland. These structures comprise the central adrenal medulla, which synthesizes and secretes the catecholamines noradrenaline and adrenaline, and the peripheral adrenal cortex, which synthesizes and secretes steroid hormones, most notably the mineralocorticoids (e.g., aldosterone) and the glucocorticoids (e.g., corticosterone or cortisol).

I. INTRODUCTION

Although the adrenal medulla and cortex have different embryological origins and are regulated predominantly by separate reflex neurogenic and endocrine mechanisms, respectively, there is substantial functional cross talk between these two separate components of the adrenal gland, which is important in the maintenance of an adequate physiological stress response to a range of metabolic and other physiological stressors. One important aspect of the functional interaction between the adrenal cortex and the medulla is the role of the adrenal cortex in the control of the synthesis of the adrenaline-synthesizing hormone, phenylethanolamine *N*-methyltransferase (PNMT). This article reviews the separate developmental origins of the adrenal medulla and adrenal cortex, the anatomical relationship between these two structures, and the role of the glucocorticoid hormones in the induction and maintenance of PNMT synthesis during different physiological conditions.

Adrenal Cortex Role in Medullary Synthesis of PNMT

I. C. McMillen and M. B. Adams
University of Adelaide, Australia

During development, two anatomically and functionally distinct structures merge to form the adrenal gland. These structures comprise the central adrenal medulla, which synthesizes and secretes the catecholamines noradrenaline and adrenaline, and the peripheral adrenal cortex, which synthesizes and secretes steroid hormones, most notably the mineralocorticoids (e.g., aldosterone) and the glucocorticoids (e.g., corticosterone or cortisol).

I. INTRODUCTION

Although the adrenal medulla and cortex have different embryological origins and are regulated predominantly by separate reflex neurogenic and endocrine mechanisms, respectively, there is substantial functional cross talk between these two separate components of the adrenal gland, which is important in the maintenance of an adequate physiological stress response to a range of metabolic and other physiological stressors. One important aspect of the functional interaction between the adrenal cortex and the medulla is the role of the adrenal cortex in the control of the synthesis of the adrenaline-synthesizing hormone, phenylethanolamine *N*-methyltransferase (PNMT). This article reviews the separate developmental origins of the adrenal medulla and adrenal cortex, the anatomical relationship between these two structures, and the role of the glucocorticoid hormones in the induction and maintenance of PNMT synthesis during different physiological conditions.

II. THE ADRENAL MEDULLA AND ADRENAL CORTEX—ANATOMY AND DEVELOPMENT

In early development, ectodermal neural crest cells migrate ventrally from the apex of the neural tube to the dorsal aorta, where they aggregate and differentiate to form sympathetic neurons, or to the adrenal gland primordia, where they differentiate to form chromaffin cells. The migratory primitive chromaffin cells invade the medial side of the developing adrenal cortical anlage and pass between the cortical cells and as the medulla occupy the center of the gland. In the developing mammalian adrenal medulla, three types of cells can be observed depending on the stage of development. The first type includes the primitive sympathetic migratory neurons, which are known as sympathogonia and are totipotent, being capable of differentiating into either sympathetic neurons or chromaffin cells depending on migratory route and the levels of environmental factors, such as the presence of glucocorticoids, nerve growth factor (NGF), and fibroblast growth factors. These cells are characterized by a small rounded nucleus with only a very thin peripheral rim of cytoplasm. The second type of cell is the phaeochromoblast, which has large elongated nuclei and a cytoplasm that is devoid of catecholamine secretory granules. The third and final cell type is the mature "chromaffin" cell or phaeochromocyte, which possesses a smaller ovoid nucleus and contains catecholamine-storing granules, with the cytoplasm giving a positive staining reaction to chromic acid due to the oxidation of the catecholamines to melanin. The mammalian adrenal cortex has its embryological origins in the mesoderm arising from mesenchymal tissue adjacent to the coelomic epithelium lying close to the urogenital ridge. Mesothelial cells between the root of the mesentery and the developing gonad undergo proliferation and subsequently penetrate the underlying mesenchyme. These cells then differentiate to form the adrenocortical masses, which are invaded during development by migrating sympathochromaffin cells. An important feature of the anatomical juxtaposition of the adrenal medulla and cortex is the fact that the continuous networks of blood vessels that supply the adrenal cortex converge and empty into the larger sinusoids present within the corticomedullary and medullary regions, so that the medulla is directly exposed to blood that has passed through the adrenal cortex. The medullary sinusoids then drain into medullary veins.

Aside from the cortical effluent, which drains into the medullary sinusoids, the medulla also receives blood directly from arteries known as arteriae medullae. The presence of arteriae medullae within the adrenal gland is species specific, with relatively few being observed in the rat adrenal gland, whereas substantially greater numbers are found in cat and bovine adrenals. The arteriae medullae derive from branches of the large capsular arteries that pass directly through the adrenal cortex before entering the medulla and branching into arterioles and capillaries. These vessels then empty into the medullary veins, which in turn empty into the central adrenal vein.

From a range of studies in different species, it appears that the adrenal medullary cells are exposed to high concentrations of glucocorticoids delivered either through the vasculature or through paracrine interactions within the gland. In the human adrenal, it has been shown, for instance, that there are variously protrusions, clusters, islets, and single cortical cells that occur diffusely within the adrenal medulla, providing the opportunity for paracrine interactions. Similarly, specific immunostaining for the neuroendocrine protein chromogranin-A has identified the occurrence of chromaffin cells within all three zones of the human adrenal cortex, again supporting a close functional relationship between these cell types. In species such as the sheep or cow, adrenomedullary cells directly adjacent to the zona reticularis and zona fasiculata of the adrenal cortex characteristically synthesize large amounts of adrenaline and the area of the adrenaline-synthesizing zone varies directly with the activity of the adrenal steroidogenic cells. Before discussing the range of mechanisms by which adrenal glucocorticoids may regulate the synthesis of adrenaline, it is necessary to review the synthetic pathway for both of the major adrenal catecholamines, noradrenaline and adrenaline.

Cholinesterase staining and nerve degeneration studies confirm that the majority of the nerve fibers that project to the chromaffin cells of the mammalian adrenal medulla are preganglionic cholinergic sympathetic fibers arising from the splanchnic nerve. Retrograde tracer studies reveal that the preganglionic sympathetic fibers that innervate the adrenal gland arise ipsilaterally from the intermediolateral horn of the spinal cord between thoracic level 3 (T3) and lumbar level 2, with the majority arising from T8–T11. There is a body of evidence to suggest that splanchnic nerve stimulation can enhance ACTH-induced glucocorticoid output from the adrenal cortex. Postganglionic sympathetic fibers containing catecholamines have been found using fluorescence

histochemistry to run in close association with vascular supply of the gland. The adrenal gland also appears to have an intrinsic innervation with ganglion cells having been identified within the gland with their numbers being species specific. In the rat, two populations of ganglion cells have been identified. One population of cells, termed the type I ganglion cells, are relatively large and exhibit properties consistent with a postganglionic, noradrenergic phenotype. These cells are probably derived from neural crest cells that invaded the cortical anlage but unlike the chromaffin cells were exposed to a different set of environmental factors that led to their differentiation into neurons. Type II ganglion cells are smaller, have a nonclassical peptidergic transmitter phenotype, and express nitric oxide synthase. Intra-adrenal ganglion cells have fibers that project to cortical, medullary, and capsular regions of the gland, with a number appearing in close proximity to blood vessels and chromaffin cells. Little is known about the physiological function of these intrinsic ganglion cells but they may act to regulate adrenal blood flow and also secretory output from the adrenal medullar and adrenal cortex.

III. SYNTHESIS OF ADRENOMEDULLARY CATECHOLAMINES

Catecholamines are synthesized in the chromaffin cells of the adrenal gland from the dietary amino acid tyrosine, as illustrated in Fig. 1. The initial step in the synthesis of adrenomedullary catecholamines is the oxidation of tyrosine to dihydroxyphenylalanine (DOPA) by the enzyme tyrosine hydroxylase [TH; tyrosine 3-monooxygenase; tyrosine, tetrahydropteridine:oxygen oxidoreductase (3-hydroxylating), EC 1.14.16.2]. TH is a mixed-function oxidase, which requires molecular oxygen and utilizes a tetrahydrobiopterine as a co-substrate. The tetrahydropteridine co-substrate is oxidized to dihydrobiopteridine in the conversion of tyrosine to DOPA; dihydropteredine reductase (EC 1.6.99.7) and nicotinamide adenine dinucleotide phosphate are required to regenerate the pool of the reduced form of the biopterine. Tyrosine hydroxylase is the rate-limiting enzyme in the catecholamine synthetic pathway, as TH has a substantially lower specific activity than any of the other catecholamine synthetic enzymes and the pool of tyrosine is greater than that of any of the other catecholamine synthetic enzyme substrates. Tyrosine hydroxylase is located in the soluble fractions of adrenal medullary homogenates, indicating its presence in the cytoplasm of the chromaffin cells. DOPA is subsequently decarboxylated by DOPA decarboxylase, also known as aromatic L-amino acid decarboxylase (AADC; EC 4.1.1.28), to form dopamine. AADC is not specific for catecholamine synthesis as it is involved in the decarboxylation of a number of aromatic L-amino acids and appears to have a wide distribution in a number of tissues. Like TH, AADC activity in the chromaffin cell is found in the water-soluble fraction of adrenal homogenates, indicating that it is located in the cytosol of chromaffin cells. Dopamine is actively transported into the chromaffin granules and converted to noradrenaline by dopamine β-hydroxylase [DBH; 3,4-dihydroxyphenylethylamine, ascorbate:oxygen oxidoreductase (β-hydroxylating), EC 1.14.17.1]. DBH is the only enzyme in the catecholamine biosynthetic pathway located within the chromaffin granules; all of the other enzymes are situated in the cytoplasm of the chromaffin cells. DBH is present in the chromaffin granules in one of two similar forms, either bound to

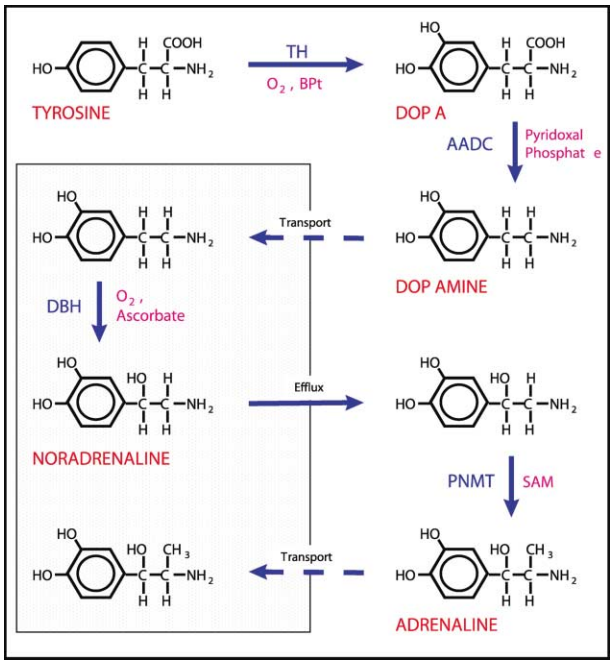

FIGURE 1 Biosynthetic pathway of adrenomedullary catecholamines. Schematic diagram of the synthesis of catecholamines within the chromaffin cells of the adrenal medulla, with substrates and products, enzymes, and co-factors indicated. Shaded area represents chromaffin granule; the unshaded area depicts the cytosol of the chromaffin cell. DOPA, dihydroxyphenylalanine; TH, tyrosine hydroxylase; AADC, aromatic amino acid decarboxylase; DBH, dopamine β-hydroxylase; PNMT, phenylethanolamine *N*-methyltransferase; BPt, tetrahydrobiopterine; SAM, *S*-adenosylmethionine.

the internal membrane or free in the internal matrix of the chromaffin granule. The relative proportions of the enzyme that are free versus membrane-bound vary between species, with the free form probably being derived from a membrane-bound precursor that undergoes proteolysis. Like TH, DBH is a mixed-function oxidase and it catalyzes the oxidation of dopamine to noradrenaline, requires molecular oxygen, and utilizes ascorbate as a co-factor. The final step in the catecholamine biosynthetic pathway is the N-methylation of noradrenaline, which passively permeates into the cytosol from chromaffin granules, to adrenaline. This is achieved by transfer of the *S*-methyl group from *S*-adenosylmethionine to the primary nitrogen group of noradrenaline by the enzyme PNMT.

IV. GLUCOCORTICOIDS AND PNMT SYNTHESIS

Early endocrine ablation and replacement experiments clearly demonstrated that glucocorticoids play a role in the maintenance of the activity of TH and PNMT. Hypophysectomy of the adult rat, which abolishes pituitary ACTH secretion and reduces adrenal corticosterone output, dramatically decreases both adrenaline content and PNMT activity within the adrenal gland. Administration of corticosterone or the potent synthetic glucocorticoid dexamethasone reverses the fall in PNMT activity after hypophysectomy. Glucocorticoids are also found to inhibit the enhanced degradation of the PNMT enzyme that occurs as a consequence of hypophysectomy, by stabilization of the enzyme co-substrate, *S*-adenosylmethionine. A number of studies have found that glucocorticoid administration to hypophysectomized rats also increases PNMT mRNA expression due to increased transcription of the PNMT gene. Analysis of the PNMT gene has revealed the presence of consensus sequences for the glucocorticoid-response element in the 5′ upstream regulatory/promoter sequence. In primary cultures of isolated bovine chromaffin cells that have been removed from any cortical influence, dexamethasone is a powerful inducer of PNMT activity with an EC_{50} for PNMT mRNA and activity induction of 1–10 nM. Bovine chromaffin cells have been found to possess glucocorticoid-binding receptors with a K_d of approximately 1 nM, and binding of glucocorticoids to the type II glucocorticoid receptors (GRs) present in chromaffin cells results in dimerization and transport into the nucleus, where the complex interacts with glucocorticoid-response elements on the PNMT gene to stimulate transcription. Furthermore, substantially higher levels of GR immunoreactivity have been identified in the adrenaline-containing cells than in the noradrenaline-containing cells of the adrenal medulla of the rat. There is evidence from a range of studies that glucocorticoids appear to play a crucial role in the induction of adrenal PNMT activity and mRNA expression that occurs in response to a range of stressors, thus demonstrating the importance of the anatomical juxtaposition of the adrenal cortex and adrenal medulla in the generation of the adaptive stress response.

V. GLUCOCORTICOIDS AND PNMT SYNTHESIS DURING DEVELOPMENT

Previous studies have shown that when dissociated chromaffin cells from immature adrenals are cultured in the absence of glucocorticoids they exhibit poor long-term survival in culture. The addition of NGF to these cultures is able to rescue many of the chromaffin cells; however, they subsequently undergo a phenotypical change exhibiting extensive neurite outgrowth. Glucocorticoid administration is able to block or delay NGF-induced neurite outgrowth. Long-term culture of rat adrenal chromaffin cells in the presence of NGF and the absence of glucocorticoids results in a complete transition to a sympathetic neuron phenotype as assessed by a number of morphological and biochemical criteria. Hence, glucocorticoids appear to act as a survival factor for chromaffin cells and repress the neuronal transdifferentiation of these cells. The levels of corticosterone present in the fetal rat adrenal gland at the time of invasion by the SA progenitor cells would be more than sufficient to suppress neural transdifferentiation by these cells. It has therefore been considered that the sympathetic progenitor cells that migrate from the sympathetic ganglion primordium through the developing adrenal anlage develop into chromaffin cells in the adrenal medulla under the influence of the glucocorticoid-rich environment. Recent studies, however, have challenged this view as an analysis of mice carrying targeted mutations of the GR gene found that the mice lacking a GR gene product had normal numbers of adrenal chromaffin cells. The GR mutant mice did, however, lack adrenomedullary PNMT. It therefore appears that the role of glucocorticoids in development is to modulate directly or indirectly the expression of PNMT, but that

the expression of PNMT itself does not determine the chromaffin phenotype.

There are also important interactions between the adrenal cortex and the adrenal medulla in those species, such as sheep and human, that have a prolonged gestation period and in which there are intact neuroendocrine responses to intrauterine stressors present before birth. Classical studies in the sheep fetus have shown that adrenaline content in the adrenal gland increased markedly during the 10–15 days preceding parturition coincident with the prepartum surge in adrenal cortisol output. Intrafetal administration of adrenaline to the sheep halts lung liquid secretion and stimulates lung liquid absorption by a β-adrenergic-dependent mechanism. Stimulation of β_2-adrenoreceptors in the fetal sheep and fetal rabbit lung with adrenaline and specific β_2-adrenoreceptor agonists also elicits an increase in pulmonary phospholipid synthesis and also the levels of phospholipids in lung lavage fluid. Catecholamines, in particular adrenaline, via β_2-adrenoreceptor stimulation are able to stimulate an increase in pulmonary surfactant secretion and synthesis. The well-established actions of glucocorticoids on surfactant synthesis in the lungs are therefore enhanced by the concomitant actions of the catecholamines. Newborns that are delivered by caesarean section do not experience the substantial catecholamine surge that occurs in babies that are vaginally delivered and have a lower lung compliance after delivery.

VI. SUMMARY

The functional interactions between the neighboring cells of the adrenal medulla and adrenal cortex are initiated early in development and are maintained by the paracrine and endocrine actions of the adrenocortical glucocorticoids on PNMT and hence adrenaline synthesis in the adrenomedullary chromaffin cells. The array of strategies that exist across a range of species to ensure that adrenomedullary cells that synthesize adrenaline are in close contact with the adrenocortical cells highlight the importance of a coordinated adrenocortical–medullary response to a range of acute and chronic stressors from before birth and into adult life. The chromaffin cells are therefore well placed to integrate both neurogenic and hormonal stimuli to ensure that adrenaline and the glucocorticoids act in a tightly regulated partnership to enhance the metabolic, cardiovascular, and respiratory responses to physiological challenges that threaten homeostasis.

Glossary

chromaffin cell The functional cell of the adrenal medulla; it contains catecholamine-storing granules, with the cytoplasm giving a positive staining reaction with chromic acid due to the oxidation of the catecholamines.

dopamine β-hydroxylase The only enzyme in the catecholamine biosynthetic pathway located within the catecholamine-containing granules of the chromaffin cell, where it catalyzes the conversion of dopamine to noradrenaline.

glucocorticoid receptors Proteins that are present in chromaffin cells and which, after binding with the glucocorticoids, dimerize and are transported to the nucleus of the cell, where the complex interacts with the glucocorticoid-response elements on the phenylethanolamine *N*-methyltransferase gene to stimulate transcription.

phenylethanolamine N-methyltransferase An enzyme that catalyzes the final step in the catecholamine biosynthetic pathway, i.e., the N-methylation of noradrenaline to result in the synthesis of adrenaline.

tyrosine hydroxylase The enzyme that catalyzes the oxidation of tyrosine to dihydroxyphenylalanine; it is the rate-limiting enzyme in the catecholamine synthetic pathway in the adrenal medulla.

Adrenocorticosteroids and Cancer

THOMAS J. DILLING AND W. GILLIES MCKENNA
University of Pennsylvania

Adrenocorticosteroids play several distinct roles for the clinical oncologist. Rarely, patients may have a primary tumor of the adrenal gland itself, leading to a clinical excess (or dearth) of adrenocortical hormones. Sometimes, too, tumors outside the adrenal axis can produce these hormones, causing well-described clinical syndromes. Expansile tumors in the brain or spinal column are an oncologic emergency, managed in part with adrenocorticosteroids. Sometimes steroids are also used as a primary chemotherapeutic agent in the treatment of the cancer itself. Finally, despite the oncologist's best efforts, patients sometimes experience side effects from chemotherapy and/or radiation, particularly in the lung; these side effects can effectively be managed by adrenocorticosteroids in many cases.

I. ADRENOCORTICAL TUMORS

Adrenal cortical carcinoma is a very rare tumor, comprising 0.05 to 0.20% of all cancers. It may be either functional or nonfunctional in terms of hormone production. When functional, the carcinomas may secrete excessive amounts of either adrenocorticotropic hormone (ACTH, or corticotropin) or sex hormones. Children less than 6 years of age can present with evidence of virilization, precocious puberty, or Cushing's syndrome. Adults (typically between the ages of 40 and 50) can also present with these tumors, as evidenced by hormonal syndromes (feminization, virilization, hypercortisolism, or hyperaldosteronism). Surgery is curative if total resection is possible, though 70% of patients present with positive lymph nodes or distant metastasis and therefore require chemotherapy.

II. PARANEOPLASTIC SYNDROMES

It should be noted that tumors outside the adrenal axis sometimes secrete adrenal corticosteroids. The classic tumors with ectopic endocrine production are some small-cell cancers of the lung and pituitary adenomas, though other less frequent tumors appear on this list as well. Pituitary ACTH overproduction (also known as Cushing's disease) is the most common syndrome, occurring in 55 to 82% of patients, and adrenal dysfunction occurs in 5 to 32% of patients, ectopic ACTH production in 11 to 25% of patients, and CRH overproduction in approximately 1% of patients. The resultant paraneoplastic syndromes are numerous. Cushing's initial description of the peripheral effects of hyperfunctioning pituitary adenoma included truncal obesity, purple striae, hypertension, fatigue, moon facies, buffalo hump, weakness, depression, amenorrhea, hirsutism, and edema. Complete treatment of this vast topic is beyond the scope of this article, though the reader is encouraged to consult the citations under Further Reading for additional information.

III. MANAGEMENT OF TUMOR SEQUELAE

Two dreaded complications of malignancy include spinal cord compression and life-threatening brain edema. In the former condition, a metastatic clone of malignant cells grows and expands within the spinal column, eventually compressing the spinal cord to the point that permanent paralysis can quickly ensue if not treated urgently. Likewise, primary brain tumors (or lesions metastatic to the brain) can expand within the fixed volume of the skull and cause life-threatening edema, leading to gross alteration of personality, seizures, or death.

Adrenocorticosteroids have a potent anti-inflammatory activity that plays an important role in the management of these conditions. Dexamethasone is commonly prescribed in doses ranging from 16 to

III. MANAGEMENT OF TUMOR SEQUELAE

Two dreaded complications of malignancy include spinal cord compression and life-threatening brain edema. In the former condition, a metastatic clone of malignant cells grows and expands within the spinal column, eventually compressing the spinal cord to the point that permanent paralysis can quickly ensue if not treated urgently. Likewise, primary brain tumors (or lesions metastatic to the brain) can expand within the fixed volume of the skull and cause life-threatening edema, leading to gross alteration of personality, seizures, or death.

Adrenocorticosteroids have a potent anti-inflammatory activity that plays an important role in the management of these conditions. Dexamethasone is commonly prescribed in doses ranging from 16 to

100 mg/day, tapering over time. Studies on spinal cord compression have failed to demonstrate a distinct advantage for the higher doses, though patients do appear to experience diminished pain after 24 h on the higher doses. Lower doses are usually used to treat brain edema. In any case, radiation therapy or surgical decompression is then performed urgently to debulk the tumor.

IV. TREATMENT OF CANCER

In 1943, a corticosteroid (the so-called Compound E) was reported to cause atrophy of lymphatic tissue in mice. Cortisone acetate and adrenocorticotropic hormone became clinically available in 1948. In November 1949, a group of researchers published a report in which they noted cancer regression in a pair of patients with different types of lymphoma. They stated that enlargement of lymph nodes occurred approximately 6 weeks after ACTH was discontinued in the patient with Hodgkin's disease, but found that there was no recurrence in the patient with lymphosarcoma 10 weeks after discontinuation of therapy. A number of studies followed in the 1950s and 1960s, confirming the earlier results regarding the importance of prednisone in treating lymphoma.

Although individual compounds were shown to be helpful, they did not always completely cure patients of these lymphomas or produce lasting remission. In 1968, Vincent DeVita and co-workers reported their landmark study, first published in 1970, in which they combined four different chemotherapeutics that had previously demonstrated individual activity against Hodgkin's disease. They combined cyclophosphamide, vincristine, procarbazine, and prednisone to create the MOPP chemotherapy regime. When tested on 43 patients, it induced complete remission in 35, 17 of whom had lasting remission—a vast improvement over any previously published results. In the years since, prednisone has also been shown to have activity against chronic leukemia and non-Hodgkin's lymphoma. In addition, different combinations (most notably CHOP, which also contains prednisone) have been tested and have become standards in the treatment of some lymphatic/leukemic cancers.

V. MANAGEMENT OF SEQUELAE FROM CANCER TREATMENT

In the years since chemotherapy and radiation therapy were introduced, physicians and scientists have improved the efficacy of these treatments while simultaneously diminishing their side effects on the patient. Occasionally, however, despite physicians' great determination, patients do experience problems related to the cancer therapy itself. While the specifics of all these potential problems are far beyond the scope of this article, one requires mention here. The lung is a relatively sensitive organ, and the tumors that occupy it can be quite resistant to treatment, requiring high doses of radiation or chemotherapy in an attempt to achieve patient cure. Clinicians, therefore, must balance these opposing problems by examining the therapeutic ratio—the ability to sterilize the tumor while sparing normal tissues.

Chemotherapy and radiation sometimes cause a hypersensitivity-type reaction called radiation pneumonitis. Chemotherapy has been shown to be a radiation sensitizer in the lung, which is important to remember in this era of combination chemotherapy and radiation. Approximately 43% of patients demonstrate radiologic changes within the lung from chemoradiotherapy treatment. Interestingly, symptomatic radiation pneumonitis occurs in only approximately 7% of patients. Patient variability seems to play a role. The volume of lung actually being irradiated, which can vary greatly depending upon the exact disease process, also determines whether a patient will experience this problem. It has also been shown that prior irradiation or chemotherapy can predispose a patient to radiation pneumonitis. Preexisting lung disease has also been implicated. Likewise, it has been shown that subclinical radiation pneumonitis can become symptomatic after steroid withdrawal.

Clinically, the syndrome generally manifests itself within about 2 to 3 months after the completion of therapy. Occasionally it presents as quickly as 1 month or as late as 6 months after the completion of treatment. Patients present with shortness of breath, which can vary from mild to severe. Cough is also typically prominent in about half of these patients. Fever is also sometimes seen. The symptoms can be relatively minor if the area of lung treated is small. On the other hand, the clinical course can be fulminant, leading to respiratory insufficiency and cyanosis, progressing to cor pulmonale (right heart failure) in a matter of days.

The histopathology and cellular biology of this disease process are fairly well elucidated. At 0 to 2 months after radiation, injury to small vessels and capillaries can be seen. This leads to vascular congestion and increased capillary permeability. As a result, proteinaceous material is deposited within

the alveoli of the lungs. In the range of 2 to 9 months postradiation, one can note microscopic evidence of obstruction of pulmonary capillaries. In addition, one sees hyperplasia of the vascular endothelium, and the walls of the alveoli become infiltrated with fibroblasts. If the radiation injury is mild, these changes may subside. However, if the injury is severe enough, it can progress to a chronic stage.

Corticosteroid administration dramatically improves the physiologic changes in mice and decreases their mortality. When given prophylactically, the steroids failed to prevent radiation pneumonitis, but when given at the first sign of clinical symptoms, they produced a clinical response. Other reports, however, failed to show amelioration of severe radiation pneumonitis with steroid administration. No controlled clinical trials have been conducted, however, to prove their efficacy in humans. Despite this fact, they are commonly given when the diagnosis is reasonably ascertained, at a dose of 1 mg/kg. This dose is maintained for several weeks and then slowly weaned.

Glossary

paraneoplastic syndromes Clinical syndromes experienced by some cancer patients due to the production of hormones or other substances by a tumor. The symptoms of the syndrome depend upon the exact substance(s) produced.

radiation pneumonitis Pathologically demonstrable series of changes seen in the lung tissue of some patients after irradiation. The syndrome can range from subclinical to highly toxic in severity and may be either self-limited or chronic.

spinal cord compression Oncologic emergency in which a clone of tumor cells expands within the spinal column, leading to permanent paralysis if not treated urgently.

Adrenocorticotropic Hormone (ACTH) and Other Proopiomelanocortin (POMC) Peptides

RICHARD G. ALLEN

Oregon Health & Science University, Portland

Adrenocorticotropin (ACTH) is a 39-amino-acid peptide derived from the prohormone proopiomelanocortin (POMC). ACTH stimulates adrenocortical steroid synthesis in response to stress and circadian fluctuations. ACTH is synthesized in corticotropes in the anterior lobe of the pituitary gland and, to a much lesser extent, in melantropes of the intermediate pituitary of many species with the exception of humans. It was first thought that ACTH was exclusively an endocrine hormone; however,

ACTH and its POMC relatives are expressed abundantly in the nervous system. POMC is a complex prohormone cleaved by specific prohormone convertases. In addition to ACTH, POMC contains the amino acid sequences of β-lipotropic hormone (β-LPH), β-endorphin, the melanocortins, corticotropin intermediate lobe peptide, and joining peptide. POMC is also highly expressed in neurons of the arcuate nucleus of the hypothalamus and the nuclear trachis solitacius. Even though the structure of POMC is the same wherever it is expressed, posttranslational cleavage of POMC can produce a different variety of biologically active peptides in each cell.

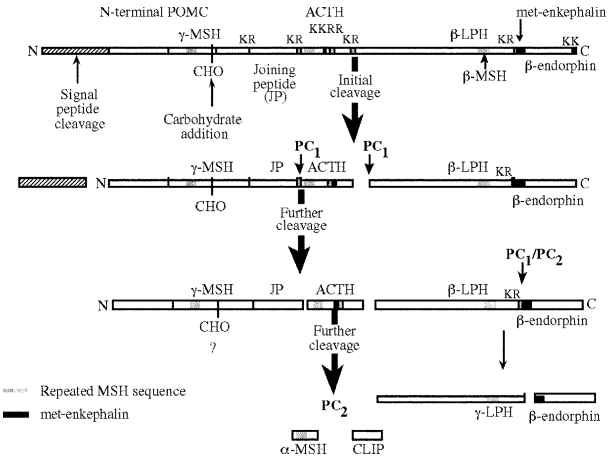

FIGURE 1 Processing of human proopiomelanocortin (POMC). The processing proceeds in stages, yielding a variety of forms of secreted peptides; N-terminal peptide, adrenocorticotropic hormone (ACTH), and β-lipotropin are the principal circulating forms produced by the anterior pituitary corticotroph. In the rodent, approximately 40% of ACTH has a posttranslational addition of a phosphate moiety. γ-MSH, γ-melanocyte-stimulating hormone; α-MSH, α-melanocyte-stimulating hormone; β-LPH, β-lipotropin, CHO, carbohydrate. In the CNS, ACTH is converted to α-MSH and CLIP.

I. ACTH AND POMC PEPTIDES

The biologically active peptides derived from POMC are the result of proteolytic processing by the prohormone convertases PC1/3 and PC2. Several such enzymes have been characterized and include the PCs, as well as furan and PACE 4. These enzymes are members of the family of kexin/subtilisin-like serine proteases. PCs cleave at single or multiple basic amino acid residues; however, as is the case with PC2, an accessory protein may be required for activity. The basic amino acid sequence lysine, arginine (KR) is the most often observed cleavage motif, but KK, RR, and RK will subserve this function as well. The PCs have different affinities for these basic cleavage motifs and thus generate different bioactivities from a common prohormone in a given cell type.

Peptide processing studies established that the principal peptide derivatives of POMC in the anterior lobe cells of humans are the N-terminal peptide, ACTH, and β-lipotropin (Fig. 1). The intermediate lobe POMC cells, called melanotropes, are present in other mammals and in the human fetus, but largely are vestigial in the human adult. The melanotropes produce additional products such as α-melanocyte-stimulating hormone (α-MSH) and corticotropin-like intermediate lobe peptide (CLIP) from ACTH, and β-endorphin from γ-lipotropin. The smaller POMC peptides are also produced in the human nervous system, with ACTH serving as a biosynthetic intermediate for the production of α-MSH. In rodents, the biological activity of α-MSH is enhanced by α-N-acetylation; however, the acetylation state of human α-MSHs is unclear at present. Human β-MSH probably is not secreted as a distinct hormone but is a by-product of postsecretory proteolysis. It is also interesting to note that the nonhuman primate exhibits the same lobe-specific POMC processing found in rodents and not humans.

In humans, each of the three principal products of POMC contains a common tetrapeptide core (His-Phe-Arg-Trp), which in turn is contained in the three melanocortin peptides, α-MSH, β-MSH, and γ-MSH. In addition, ACTH itself contains the tetrapeptide core and has melanotropic (pigment-producing) activity. This tetrapeptide core is the recognition site for the ACTH and melanocortin receptors. Previously, it was suggested that the hyperpigmentation found in disorders of excess ACTH may be related to ACTH itself or to the other melanotropic derivatives of the POMC molecule. The melanotropic activities of these peptides, particularly γ-MSH, have not been fully elucidated, and the circulating concentrations of these melanotropin peptides have not yet been determined simultaneously. Nonetheless, the absence of significant amounts of γ-MSH, and of β-MSH in humans, support ACTH as the likely candidate.

The cloning of five different melanocortin receptors (MC1–5) began a new era in studying POMC peptides. All of the receptors for POMC peptides that have been cloned belong to the seven-transmembrane G-protein-coupled receptor superfamily. ACTH binds to the adrenal ACTH receptor (MC2) with

nanomolar affinity. It then activates adenylyl cyclase via Gαs, increasing intracellular cAMP, activating protein kinase A, and thus resulting in the phosphorylation of proteins. Activation of this pathway induces cortisol synthesis and secretion.

The melanocortins (the MSHs) bind to MC1 and MC3–5 with nanomolar affinity to mediate a variety of physiological actions described below. All of the MC receptors stimulate cAMP production when activated by their respective ligands. In contrast, β-endorphin binds the μ class of opioid receptors and inhibits cAMP production through the Gαi/o class of G-protein-coupled receptors. The receptor for β-LPH has not been cloned.

II. PHYSIOLOGY OF ACTH AND POMC-DERIVED PEPTIDES

ACTH, released from the anterior pituitary corticotroph, is the major physiologic regulator of the synthesis and secretion of glucocorticoids by the adrenal glands. Glucocorticoids act on many processes mainly by altering gene transcription and protein synthesis in the target cells. In, addition, glucocorticoids permit metabolic adaptation during fasting to prevent low blood sugar. They also play an important role in the body response to physical and emotional stress. Other actions include their inhibitory effect on inflammation and regulation of vascular responsiveness to norepinephrine.

ACTH rapidly stimulates steroidogenesis, which can result in a great rise in blood glucocorticoids within seconds or minutes. To support this function, ACTH stimulates adrenal blood flow and the rate-limiting step of glucocorticoid synthesis: the conversion of cholesterol to pregnenolone. It also exerts several long-term tropic effects on adrenal cells that maintain the cellular machinery necessary to carry out steroidogenesis.

In addition to ACTH, β-lipotropin is cleaved from POMC in anterior pituitary corticotrophs. β-Lipotropin has effects on lipid metabolism, but its physiologic function in humans has not yet been established. When stimulated, corticotrophs secrete ACTH and β-lipotropin in a 1:1 ratio into the bloodstream.

The circulating levels of ACTH and glucocorticoids are greatly influenced by stress. When an individual is exposed to a stressful situation, levels of ACTH and glucocorticoids rise rapidly in the blood. Stress stimulates the hypothalamic–pituitary–adrenal axis regardless of the existing concentrations of circulation glucocorticoids. This occurs because stress increases neural activity in the CNS, stimulating the hypothalamic parvicellular neurons in the paraventricular nucleus to secrete corticotropin-releasing hormone (CRH) at a greater rate. If stress persists, the hypothalamic–pituitary–adrenal axis will function at a higher setpoint, maintaining higher concentrations of ACTH and glucocorticoids, which may eventually have detrimental effects on the individual. The role of the intermediate lobe melanotrope in stress response is not clear. For instance, in all nonhuman species studied, the majority of the endorphins produced by the intermediate lobe are α-N-acetylated and thus do not bind the opioid receptors. In lower organisms, circulating melanocortins may be involved in pigmentation responses to stress.

Whereas the first two decades of POMC research were heavily focused on endorphins, their expression in the pituitary, and the expression of these peptides in the CNS, recently there has been intense interest in POMC peptides and feeding behavior. The cloning of the melanocortin and ACTH receptors contributed greatly to this interest as α-MSH had been implicated in food intake regulation for many years. The melanocortins also have wide variety of physiological effects including alterations in motor activity and sexual behavior, analgesia, memory, nerve regeneration, antipyretic actions, pigmentation, and grooming behavior.

Though many studies have been performed in rodent models examining POMC peptides and obesity, only in the past 5 years has firm evidence for POMC's involvement in obesity emerged. Much of this information comes from genetic studies. A current hypothesis is that mutations in regulatory elements of the POMC gene decrease the levels of POMC expression in the brain, thus causing alterations in energy metabolism.

There have been a small number of children with null mutations in the POMC gene resulting in undetectable levels of ACTH. The common phenotype presented was red hair, adrenal insufficiency, and severe, early onset obesity. Furthermore, recessive and dominant mutations in the MC4 receptor (MC4-R) gene have been seen in humans and these mutations are proposed to cause 5% of childhood obesity. These and other data suggest that obesity may be a genetic disease of the hypothalamus and that POMC may be a major player.

The POMC and neuropeptide Y systems are the most extensively studied regarding energy intake. The POMC system receives input detailing

the nutritional status and energy storage via insulin and leptin signaling mediated by receptors on POMC neurons in the arcuate nucleus of the hypothalamus. There is a complex interaction of food intake inhibition by α-MSH and agouti-related protein at the level MC4-R. CRH is the mediator of food intake and environmental conditions. It inhibits food intake and weight gain, activates the hypothalamic–pituitary axis, and modulates energy storage in adipose tissue. The link between the CRH system and POMC neurons in the hypothalamus and other brain areas remains to be completely defined.

III. REGULATION OF ACTH AND POMC-DERIVED PEPTIDES

Pituitary ACTH secretion is under two primary regulatory influences. There is a positive peptidergic influence from the hypothalamus, mediated by CRH, which varies diurnally and is subject to extreme perturbation by stress. There also is a negative feedback influence of glucocorticoids, acting both at the pituitary level to inhibit the corticotrope and at the hypothalamic level to inhibit CRH neurons. Cortisol is the major physiologic glucocorticoid inhibitor of ACTH secretion; there is no other important endogenous ACTH inhibitor in humans. Figure 2 shows a scheme that depicts a variety of neurotransmitter inputs to the hypothalamus that have been postulated to regulate CRH release and ultimately, the secretion of ACTH. Further, vasopressin (AVP) and melatonin have been implicated in the regulation of ACTH secretion. In particular, AVP and melatonin released from the suprachiasmatic nucleus appear to be intimately involved in the circadian rhythm of glucocorticoids. In addition, AVP released from the neural lobe of the pituitary has long been thought to act synergistically with CRH to enhance ACTH secretion from the anterior lobe.

In humans, ACTH has a diurnal rhythm, exhibiting the highest plasma levels at approximately 6–8 AM and a nadir at approximately midnight. In rats, this pattern is reversed, and both lighting and activity may alter this cycle. In humans, there is also a free-running cycle of plasma cortisol that varies between 25 and 33 h. All of the other peptides derived from pituitary POMC demonstrate these cycles; however, due to differences in the half-lives of the peptides, the plasma concentrations are not superimposable.

The negative feedback effect of glucocorticoids on ACTH secretion results from actions on both the hypothalamus and the corticotroph. Glucocorticoids act directly on the corticotrophs to decrease POMC

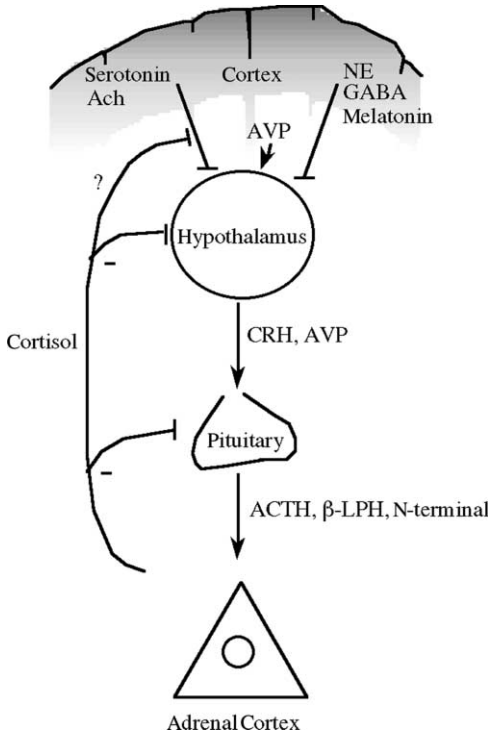

FIGURE 2 Scheme for control of ACTH secretion. Ach, acetylcholine; NE, norepinephrine; GABA, γ-aminobutyric acid; CRH, corticotropin-releasing hormone; AVP, arginine vasopressin.

synthesis and secretion. Glucocorticoids inhibit the release of CRH from the hypothalamus, which also decreases ACTH release. In addition, glucocorticoids inhibit ACTH secretion by acting directly on the corticotroph to inhibit the action of CRH. As a result, CRH becomes less effective at stimulating ACTH release. In species other than humans, the synthesis and secretion of POMC peptides are tonically inhibited by hypothalamic neurons releasing dopamine. Intermediate lobe melanotropes do not express the glucocorticoid receptor and therefore are not regulated by glucocorticoids.

Cortisol and its synthetic analogues (e.g., prednisone and dexamethasone) suppress ACTH secretion. After the administration of a dose of a glucocorticoid, ACTH secretion diminishes within minutes ("fast feedback") and, in a second phase ("delayed feedback"), is suppressed for hours or days, depending on the glucocorticoid used. It is unclear whether the fast and delayed feedback actions are associated with different anatomic sites. It is likely, however, that delayed feedback is an intracellular event operating through changes in nuclear mechanisms, whereas fast feedback may be dependent on

effects on the cell membrane mediated through other classes of receptors.

Although pituitary POMC regulation by circulating glucocorticoids is fairly well understood, much less is known about POMC peptide regulation in the brain. In the rodent, a large cell group of POMC neurons is bilaterally distributed in the arcuate nucleus of the hypothalamus and projects extensively to other regions of the brain. These projections pass through limbic structures, the diencephalon, and amygdala, as well as the thalamus and periaqueductal gray, areas associated with nociception and sensory integration. In addition, there are projections to the brainstem, which are thought to be involved in the regulation of cardiovascular and respiratory systems. In the nucleus tractus solitarius, POMC neurons send projections to the spinal cord and probably interact with local POMC circuits in the spinal cord itself. It appears that human central nervous system POMC expression resembles that found in the rodent, thus serving as a good model for future POMC peptide research.

IV. SUMMARY

POMC is a prohormone that gives rise to several biologically active peptides that are expressed primarily in the pituitary and brain. ACTH, the melanotropins, and endorphins are liberated by specific proteolytic enzymes called PCs. By expressing the PCs in a cell-type-specific fashion, a variety of POMC-derived products can be differentially expressed. When combined with the tissue-specific expression of POMC peptides and their cognate receptors, an incredibly diverse array of physiological responses can be produced. Since all of the peptides derived from POMC are co-released from large secretory granules, a myriad of biological activities are modulated simultaneously. In the case of POMC, these are glucocorticoid production, food intake, stress responses, and modulation of pain perception. There is much to learn about how the modulation of these specific POMC-derived bioactivities evolved to be regulated in a coordinated manner.

Glossary

adrenocorticotropic hormone A peptide that elicits glucocorticoid secretion from the adrenal cortex.

β-endorphin A peptide possessing analgesic properties mediated through the opioid receptors.

β-LPH A peptide derived from proopioimelanocortin containing γ-MSH and β-endorphin.

α-MSH, β-MSH, γ-MSH α-, β-, and γ-Melanocyte-stimulating hormones, collectively called the melanocortins. These peptides are thought to stimulate pigmentation and may be involved in appetite and feeding behavior.

prohormone convertase A class of proteolytic enzymes responsible for cleaving proopioimelanocortin into biologically active peptides.

prohormone A protein that is converted to biologically active molecules via posttranslational processing by specific proteolytic enzymes or other modifications.

proopioimelanocortin A prohormone expressed in the neuroendocrine system.

Amino Acid and Nitric Oxide Control of the Anterior Pituitary

MICHAEL SELMANOFF
University of Maryland School of Medicine

Hypothalamic neurosecretory neurons regulate the secretion of the six anterior pituitary tropic hormones. In turn, these first-order, final common pathway neurons of the neuroendocrine system are immediately controlled by second-order afferent neurons. Most of these hypothalamic afferent neurons utilize either the inhibitory neurotransmitter γ-aminobutyric acid (GABA) or the excitatory neurotransmitter glutamate (Glu). Second-order neurons also regulate the neurosecretory neurons by elaborating the neuroactive gas nitric oxide (NO). Second-order GABA neurons uniformly decrease the secretion of the anterior pituitary tropic hormones, whereas Glu neurons increase their secretion. Second-order NO neurons mostly increase, but in one case decrease, anterior pituitary tropic hormone secretion.

I. HYPOTHALAMIC CONTROL OF PITUITARY GLAND FUNCTION

A. Hypothalamic Releasing and Inhibiting Hormones

Neurons situated in the hypothalamus control the synthesis and secretion of the hormones of the anterior and posterior pituitary gland (Fig. 1). The posterior pituitary hormones, oxytocin and vasopressin, are synthesized in the cell bodies of neurons located in the hypothalamic supraoptic and paraventricular nuclei. Axons of these neurons project to terminals in the posterior lobe (PL), from which oxytocin and vasopressin are released on depolarization. In contrast, the anterior pituitary hormones are controlled by hypothalamic neurons, whose cell bodies are located in arcuate nuclei (AN) and other

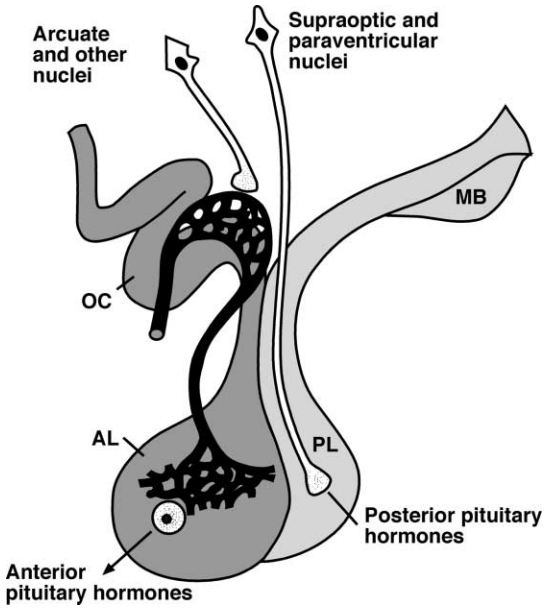

FIGURE 1 Secretion of hypothalamic hormones. The hormones of the posterior lobe (PL) are released into the general circulation from the endings of supraoptic and paraventricular neurons, while hypophysiotropic hormones are secreted into the hypophysial portal circulation from the endings of arcuate and other hypothalamic neurons. The hormones circulate in the portal vessels to the anterior lobe (AL), where they control the synthesis and secretion of the anterior pituitary tropic hormones. Amino Acid and Nitric Oxide Control of the Anterior Pituitary

MICHAEL SELMANOFF
University of Maryland School of Medicine

Hypothalamic neurosecretory neurons regulate the secretion of the six anterior pituitary tropic hormones. In turn, these first-order, final common pathway neurons of the neuroendocrine system are immediately controlled by second-order afferent neurons. Most of these hypothalamic afferent neurons utilize either the inhibitory neurotransmitter γ-aminobutyric acid (GABA) or the excitatory neurotransmitter glutamate (Glu). Second-order neurons also regulate the neurosecretory neurons by elaborating the neuroactive gas nitric oxide (NO). Second-order GABA neurons uniformly decrease the secretion of the anterior pituitary tropic hormones, whereas Glu neurons increase their secretion. Second-order NO neurons mostly increase, but in one case decrease, anterior pituitary tropic hormone secretion.

I. HYPOTHALAMIC CONTROL OF PITUITARY GLAND FUNCTION

A. Hypothalamic Releasing and Inhibiting Hormones

Neurons situated in the hypothalamus control the synthesis and secretion of the hormones of the anterior and posterior pituitary gland (Fig. 1). The posterior pituitary hormones, oxytocin and vasopressin, are synthesized in the cell bodies of neurons located in the hypothalamic supraoptic and paraventricular nuclei. Axons of these neurons project to terminals in the posterior lobe (PL), from which oxytocin and vasopressin are released on depolarization. In contrast, the anterior pituitary hormones are controlled by hypothalamic neurons, whose cell bodies are located in arcuate nuclei (AN) and other

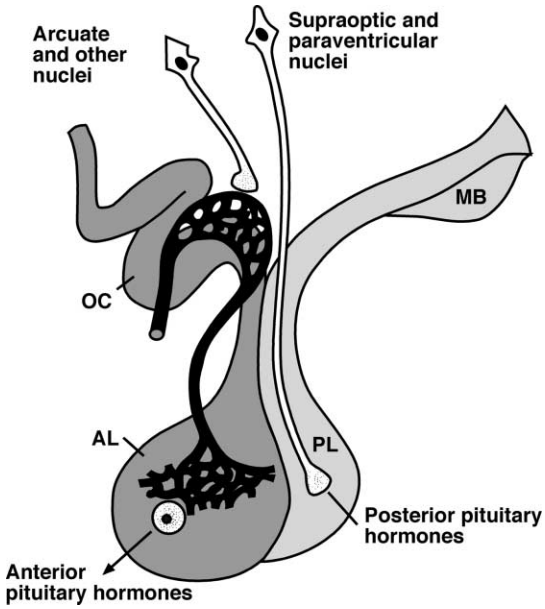

FIGURE 1 Secretion of hypothalamic hormones. The hormones of the posterior lobe (PL) are released into the general circulation from the endings of supraoptic and paraventricular neurons, while hypophysiotropic hormones are secreted into the hypophysial portal circulation from the endings of arcuate and other hypothalamic neurons. The hormones circulate in the portal vessels to the anterior lobe (AL), where they control the synthesis and secretion of the anterior pituitary tropic hormones. MB, Mamillary bodies; OC, optic chiasm. Modified from Ganong (2001), with permission.

hypothalamic nuclei, and whose axons project to terminals situated in the median eminence (ME). On depolarization, these neurons release their hypothalamic releasing and inhibiting hormones into the hypophysial portal circulation, which carries them to the anterior lobe (AL). There the hormones bind to specific high-affinity, low-capacity receptors on the AL cells, which synthesize and secrete the anterior pituitary tropic hormones. Although there is some evidence that GABA, Glu, and NO affect anterior pituitary tropic hormone secretion by direct actions at the level of the pituitary, at the present time most of this evidence is not compelling; hence, further discussion here is restricted to the hypothalamic actions of these neurotransmitters.

B. Tropic Hormones of the Anterior Pituitary Gland

Six anterior pituitary tropic hormones (Fig. 2) control the functioning of the adrenal glands [adrenocorticotropic hormone (ACTH)], the thyroid gland [thyroid-stimulating hormone (TSH)], the mammary glands [prolactin (PRL)], and the gonads [luteinizing hormone and follicle-stimulating hormone (LH and FSH)] and exert widespread effects on body growth [growth hormone (GH)]. These AL tropic hormones are regulated by the hypothalamic releasing and inhibiting hormones corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), prolactin-inhibiting hormone (PIH or dopamine), prolactin-releasing factor (PRF), gonadotropin-releasing hormone (GnRH), growth hormone-releasing hormone (GHRH), and somatostatin (SS or growth hormone-inhibiting hormone). The cell bodies of these neurons reside in several hypothalamic structures (Fig. 3). The regulation of these hypophysiotropic hormone-secreting neurons by second-order, afferent neurons, which synapse on them and increase or decrease their firing rate in response to physiological stimuli, is an intensely active area of neuroendocrine research. It is now clear that some of these afferents are neurons utilizing inhibitory (GABA, glycine, taurine, β-alanine) and excitatory (Glu, aspartate, cysteic acid, homocysteic acid) amino acid neurotransmitters, and neurons that elaborate neuroactive gases (NO, carbon monoxide). Most workers in this area to date have studied the principal inhibitory and excitatory amino acid and neuroactive gas neurotransmitters: GABA, Glu, and NO. Electrophysiological and whole-cell patch-clamp work by van den Pol and co-workers indicates that almost all fast synaptic activity in the hypothalamus is generated by the release of the inhibitory transmitter GABA or the excitatory transmitter Glu. Hence, this article focuses on three systems of neuronal afferents, GABA, Glu, and NO neurons, which likely affect the activity of all of the hypophysiotropic hormone-secreting neurons. To date, the majority of the research in this area has focused on the regulation of the GnRH neurons by afferent GABA, Glu, and NO neurons. Evidence for the regulation of GnRH is presented here in some detail; the effect of these afferent neurons on the neuroendocrine control of the other anterior pituitary hormones is limited to a summary table.

C. The Hypothalamic GnRH Pulse Generator

GnRH is released in episodic bursts that produce the pulses of LH observed in male and female mammals, and in other vertebrate species as well. In humans, the LH pulses in men occur at a frequency of one every 90 min; the LH pulse frequency in women ranges

from one every 90 min during the follicular phase of the menstrual cycle to one every 3 h during the luteal phase. The frequency and amplitude of the GnRH secretory episodes are essential for maintaining the sensitivity of anterior pituitary gonadotropes to GnRH stimulation and for generating the other hormonal events responsible for reproductive cycles in females and normal testicular function in males. The hypothalamic GnRH pulse generator may be composed solely of the GnRH neurons, or may also consist of additional GnRH afferent circuitry, which, in conjunction with the GnRH neurons, generate the oscillatory bursting patterns of the GnRH neurons. Hence, the GABA, Glu, and NO neurons may indeed be components of the GnRH pulse generator, or may instead be significant modulators of GnRH pulse generator activity by virtue of their being GnRH neuronal afferents. Even relatively small changes in GnRH pulse generator function are associated with menstrual disorders in females and with infertility in both sexes. Dramatic changes in GnRH pulse generator function also are responsible for controlling the onset of puberty, the waning of reproductive function associated with menopause in women, and, to a lesser extent, andropause in men.

The activity of the GnRH pulse generator is modulated by numerous physiological stimuli, including circulating hormones. For example, the sex steroid hormones—estradiol and progesterone in females and testosterone in males—exert negative and positive feedback effects on GnRH pulse generator function as part of homeostatic, physiological regulatory mechanisms coordinating the integrated functions of the hypothalamic–pituitary–gonadal (i.e., the reproductive) axis. Another example is the adipose cell hormone leptin, which exerts a positive effect on the GnRH pulse generator in its role in communicating the nutritional status of the individual to the neurons controlling reproductive function. Hence, the presence of sex steroid or leptin receptors on hypothalamic GABA, Glu, or NO neurons thought to be GnRH afferents, or documented effects of these hormones on these GnRH afferents, may both be considered lines of evidence indicating that specific populations of GABA, Glu, and NO neurons are physiologically significant GnRH afferents.

II. HYPOTHALAMIC GABA NEURONS AND THE NEUROENDOCRINE REGULATION OF LH SECRETION

A. Hypothalamic GABA Neurons

GABA, a four-carbon amino acid, was discovered in brain tissue in 1950 by Eugene Roberts and coworkers. GABA, produced by the enzymatic decarboxylation of glutamic acid by the rate-limiting enzyme, glutamic acid decarboxylase (GAD), is

catabolized primarily to succinic semialdehyde by GABA-transaminase (GABA-T) (Fig. 4). Whereas monoaminergic (dopamine, norepinephrine, epinephrine, and serotonin) and cholinergic neurons constitute relatively small populations of neurons, GABA is thought to be the most ubiquitous transmitter in brain. GABA neurons comprise 30–50% of all nerve cell bodies, and perhaps 20% of the estimated 10^{15} central nervous system (CNS) synapses utilize GABA as their transmitter. In the hypothalamus, morphometric analysis at the electron microscopic (EM) level indicates that about 50% of all synapses are GABAergic. Most nuclei of the hypothalamus have high concentrations of GAD and GABA and this brain region has heavy concentrations of GABA cell bodies. Medial (compared with lateral) hypothalamic structures in particular are among the most densely GABA innervated regions in brain. It is in these medial structures that most hypothalamic releasing and inhibiting hormone cell bodies and their dendrites are located (Fig. 3). GABA cells make up 50–90% of all cells in the rostral hypothalamus [the medial preoptic area (MPOA)], where the GnRH cell bodies are located, and 15–50% of all cells in the arcuate nucleus. A tuberoinfundibular system of GABA (TIGA) neurons exists with cell bodies in the AN and axons that project to GABA terminals in the external layer of the ME. In the ME the terminals of the TIGA neurons are observed closely apposed to the GnRH terminals. Double-label immunohistochemistry at the EM level indicates that rostral MPOA GABA neurons form axodendritic and axosomatic synapses with the GnRH neurons. Hence, GABA neurons may provide inhibitory input to the GnRH neurons in either the MPOA or the ME, or both. Indeed, recent quantitative EM work in the primate AN indicates that inhibitory (not excitatory) synapses comprise the dominant input to the GnRH neurons. van den Pol and co-workers have provided compelling electrophysiological evidence that almost all fast inhibition in the hypothalamus is caused by GABA release. Despite GABA being a dominant neurotransmitter in the hypothalamus, this very large population of hypothalamic neurons has been understudied by neuroendocrine investigators.

GABA was first convincingly shown to be an inhibitory transmitter in 1967, and subsequent iontophoretic studies indicate that GABA inhibits virtually every neuron in the adult CNS. GABA is thought to be released by a depolarization-induced, Ca^{2+}-dependent exocytotic process, although physiologically significant GABA release also may occur by reversal of the Na^{+}-dependent presynaptic GABA transporter (GAT) (Fig. 4). At the level of the membrane, activation of the postsynaptic $GABA_A$ receptor and its integrated Cl^{-} channel produces

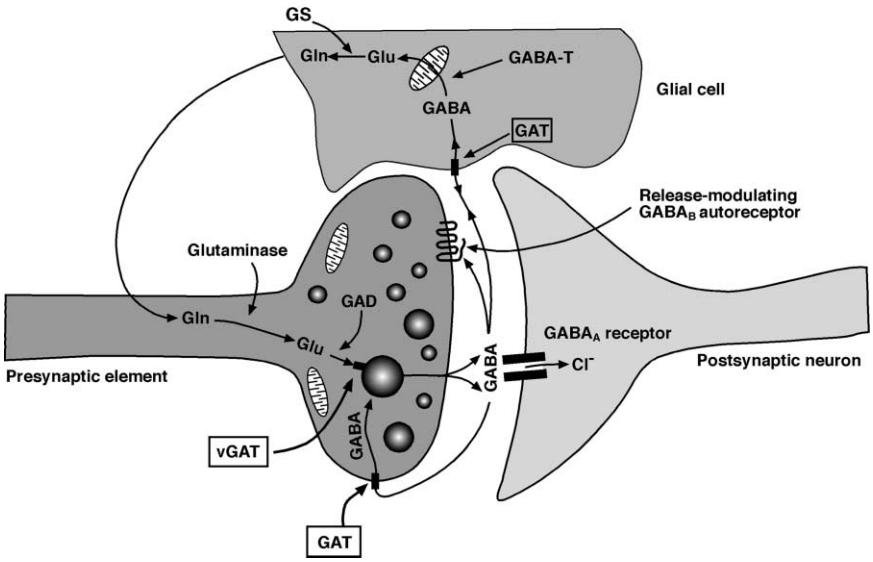

FIGURE 4 Schematic representation of a GABA synapse. The α-ketoglutarate formed in the Krebs cycle is transaminated to glutamate (Glu) by mitochondrial GABA-transaminase (GABA-T). The transmitter GABA is formed from Glu by glutamic acid decarboxylase (GAD). Released GABA may bind to postsynaptic $GABA_A$ receptors or to presynaptic $GABA_B$ autoreceptors, or may be taken up by high-affinity GABA transporters (GAT) present on neurons and glia. GS, Glutamine synthetase; vGAT, vesicular GABA transporter. Modified from Zigmond *et al.* (1999), with permission.

membrane hyperpolarization, whereas presynaptic $GABA_B$ receptors control synaptic transmission by inhibiting Ca^{2+} influx and/or by affecting K^+ channels, thus inhibiting transmitter release at the nerve terminal (Fig. 4). Less is known about the recently cloned G-protein-coupled $GABA_B$ receptor, which is structurally similar to the Glu metabotropic receptors, and the putative $GABA_C$ receptor. The $GABA_A$ receptor, a heteropentameric protein, is more correctly referred to as a receptor complex because it has separate binding sites for GABA agonists and antagonists, benzodiazepines, barbiturates, alcohol, steroids, and certain convulsants. This variety of binding sites on the $GABA_A$ receptor makes it highly susceptible to modulation by physiological and pharmacological parameters. It is composed of combinations of at least 20 different subunits and their functional splice variants: α_{1-6}, β_{1-3}, γ_1 and $_3$, γ_{2L} and $_{2S}$, δ, ε, θ, π, and ρ_{1-3}.

B. GABA Regulation of GnRH Pulse Generator Function

Several lines of evidence are consistent with the hypothesis that hypothalamic GABA neurons inhibit the GnRH pulse generator, and may indeed comprise pulse generator circuitry. First, GnRH neurons *in situ* express the $GABA_A$ α_1, α_5, β_1, β_3, and γ_2 receptor subunit mRNAs, demonstrating that GnRH neurons are targets for the neurotransmitter GABA. Second, evidence indicates that MPOA and AN GABA neurons express estrogen receptor (ER) and progesterone receptor (PR) mRNA and protein. In the MPOA, about 40% of all estrogen-receptive cells immunostain for GAD, indicating they are GABA neurons. Third, in several tissues, including brain, one of the physiological actions of estrogen is to induce the progesterone receptor. The TIGA neurons are reported to express such estrogen-inducible PR, as well as the leptin receptor. Indeed, it is reported that all ER immunoreactive cells in the hypothalamus, including the MPOA and AN, also express leptin receptor protein. GnRH neurons studied in hypothalamic slices *in vitro* are directly inhibited by applied GABA, and this effect is $GABA_A$ receptor mediated. This additional evidence demonstrates that the $GABA_A$ receptors expressed in the GnRH neurons are, indeed, physiologically functional. Similarly, GnRH neurons studied in hypothalamic slices are generally silent, suggesting that they are tonically inhibited, but also exhibit episodes of burst firing, which may underlie pulsatile GnRH release. Recent electrophysiological evidence from hypothalamic slices indicates that MPOA GABA neurons may mediate estrogen negative feedback by reducing the autoinhibition of GABA neurons brought about by presynaptic, $GABA_B$ autoreceptor stimulation (Fig. 4). A better understood oscillator in the thalamus and the hypothalamic rhythm generator in the suprachiasmatic nucleus both rely on GABA neurons for their function. A network oscillator model for hypothalamic pulse generators consisting of Glu and GABA neurons would function more reliably than would a single-cell oscillator (i.e., composed solely of the GnRH neurons). Finally, reflecting on the overall function and importance of GABA neurons in brain, Eugene Roberts concludes that "disinhibition, coupled to variability generation… is the major organizing principle in nervous system function."

More physiologically oriented work in intact animals indicates that GABA has an inhibitory action on LH secretion. Administration of GABA or the $GABA_A$ receptor agonist muscimol (MUS) into the MPOA or intracerebroventricularly (icv) inhibits pulsatile LH release, and the $GABA_A$ receptor antagonist bicuculline (BIC) blocks this effect. $GABA_A$ agonists and antagonists inhibit and stimulate, respectively, GnRH pulse generator function as assessed by multiunit activity recordings from the AN–ME region. Systemic administration of the GABA-T (Fig. 4) inhibitor aminooxyacetic acid (AOAA) blocks GABA degradation, resulting in increased brain GABA levels. This GABA increase is associated with inhibition of pulsatile LH secretion. MUS and AOAA administration also block LH surge release and BIC prevents the $GABA_A$ agonist effect. Sex steroid removal down-regulates, and sex steroid administration up-regulates, several components of GABA transmission in MPOA and TIGA neurons: GAD mRNA levels and enzymatic activity, GAT-1 mRNA levels and transport activity, $GABA_A$ receptor binding and the levels of receptor subunit mRNAs, and the rate of GABA turnover. In females, MPOA GAD mRNA levels, the rate of GABA turnover, and the extracellular GABA concentrations in microdialysates all decrease before and during the LH surge. Most recently, a group reported that grafting genetically engineered astrocytes that release GABA in the ME near GnRH terminals disrupts estrous cyclicity in rats; this finding demonstrates that GABA released in the vicinity of the ME can inhibit the GnRH pulse generator, raising the possibility that similar local alterations in GABA neurotransmission may contribute to the pathology of hypothalamic amenorrhea/oligomenorrhea in humans.

III. HYPOTHALAMIC GLUTAMATE NEURONS AND THE NEUROENDOCRINE REGULATION OF LH SECRETION

A. Hypothalamic Glu Neurons

Iontophoresis of Glu onto many different mammalian neurons rapidly depolarizes them. Perhaps 75% of excitatory transmission in the brain is attributable to Glu synapses, and van den Pol and co-workers have published evidence confirming that Glu is the principal excitatory neurotransmitter in the hypothalamus. Utilizing Glu-specific antibodies, immunohistochemical work reveals relatively dense Glu nerve terminal immunostaining throughout most of the hypothalamus. In neurons, Glu is thought to be synthesized principally from glutamine by the mitochondrial enzyme phosphate-activated glutaminase and also from aspartate by the cytoplasmic enzyme aspartate aminotransferase (Fig. 5). Presynaptic Glu is sequestered in secretory vesicles at concentrations exceeding 20 m*M*. When Glu nerve terminals are depolarized, Glu is released in a Ca^{2+}-dependent manner.

Two kinds of Glu receptors are recognized: ionotropic and metabotropic. The ionotropic receptors are ligand-gated cation channels and are of three types: kainate (KA), α-amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA), and *N*-methyl-D-aspartate (NMDA). KA and AMPA receptors permit Na^+ influx and K^+ efflux; NMDA receptors pass relatively large amounts of Ca^{2+}. The ionotropic receptors are either pentamers or tetramers, and to date six NMDA (NR_1, NR_{2A-D}, and NR_{3A}), five KA ($GluR_{5-7}$ and $KA_{1\ and\ 2}$), and four AMPA ($GluR_{1-4}$) subunits have been identified and their genes have been cloned. The Glu concentration required for half-maximal (EC_{50}) stimulation of AMPA receptors is 200 μ*M*, whereas the EC_{50} for NMDA receptors is only 10–15 μ*M*. Hence, Glu is a much more potent activator of NMDA receptors, compared to AMPA receptors.

Eight metabotropic receptor subunits have been described ($mGluR_{1-8}$). These receptors are G-protein-coupled serpentine receptors that increase intracellular inositol trisphosphate and diacylglycerol levels or decrease intracellular cAMP levels. In addition to binding to these pre- and postsynaptic receptors, released Glu may be taken up by neurons or surrounding glia via the Glu transporters: excitatory amino acid carrier-1 (EAAC1), glutamate transporter-1 (GLT-1), or glutamate–aspartate transporter (GLAST) (Fig. 5).

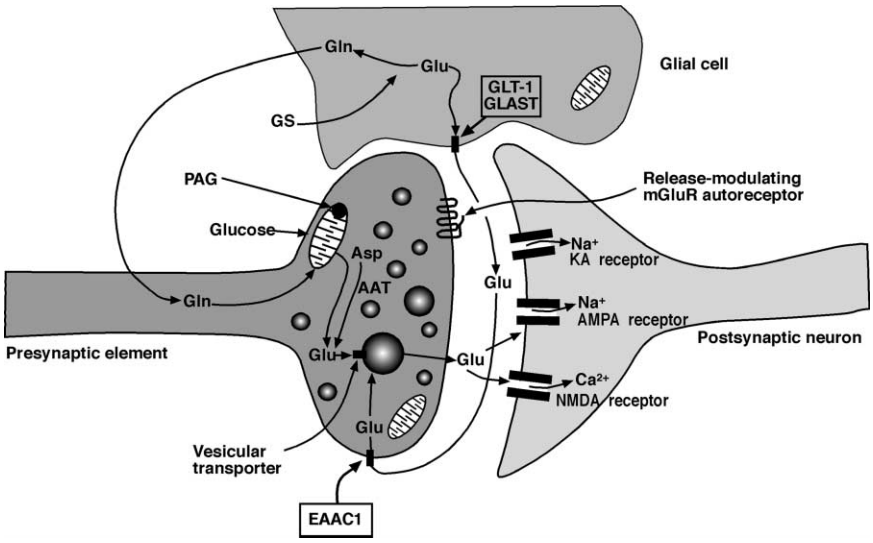

FIGURE 5 Schematic representation of a glutamate synapse. Glutamate (Glu) is synthesized from glutamine (Gln) by the action of phosphate-activated glutaminase (PAG), and from aspartate (Asp) by the action of aspartate aminotransferase (AAT). Glu is concentrated in secretory granules by a vesicular transporter. Released Glu can bind to postsynaptic *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA), or kainate (KA) receptors or to presynaptic metabotropic autoreceptors (mGluR), or can be taken up by the high-affinity Glu transporters, excitatory amino acid carrier-1 (EAAC1), glutamate transporter-1 (GLT-1), or glutamate-aspartate transporter (GLAST), which are present on neurons and glia as indicated. Modified from Zigmond *et al.* (1999), with permission.

Double-label immunohistochemistry at the EM level indicates that Glu-immunoreactive neurons synapse with GnRH dendrites and that ME Glu terminals are closely apposed to GnRH terminals, suggesting that asynaptic neurotransmission may occur in this structure. Autoradiographic mapping demonstrates a relatively dense distribution of Glu receptors in the hypothalamus, particularly in the AN. More specifically, NMDA ($NMDAR_1$ and $NMDAR_{2A-D}$ subunits), AMPA ($GluR_{1-4}$ subunits), KA ($GluR_{5\ and\ 6}$ and KA_2 subunits), and mGlu ($mGluR_{1,2,3\ and\ 5}$ subunits) receptor mRNAs and/or proteins are found widely expressed in hypothalamic neurons. In most hypothalamic regions the NMDA receptor predominates. Finally, mRNA and protein for the Glu transporters EAAC1, GLT-1, and GLAST are detected in the hypothalamus.

B. Glu Regulation of GnRH Pulse Generator Function

Several lines of evidence are consistent with the hypothesis that hypothalamic Glu neurons stimulate the GnRH pulse generator and may indeed comprise pulse generator circuitry. First, *in situ*, about 50% of GnRH neurons express the kainic acid 2 (KA_2) receptor subunit mRNA, whereas about 80% express the $NMDAR_1$ receptor subunit mRNA, demonstrating that GnRH neurons are targets for the neurotransmitter Glu. Second, double-label immunofluorescence work in several hypothalamic structures indicates that an average of 80% of Glu neurons express ER and as many as of 93% of Glu neurons express PR. Third, Glu evokes currents in GnRH neurons studied in hypothalamic slices; subsequent patch-clamp work indicates these currents are mediated by NMDA and AMPA channels, indicating that the Glu receptors expressed by GnRH neurons are physiologically functional. In addition, antisense oligodeoxynucleotides against the $NMDAR_{2A}$ receptor subunit mRNA decrease the protein levels of this receptor subunit and suppress pulsatile GnRH secretion from MPOA–ME hypothalamic fragments studied *in vitro*. Another finding is that NMDA, AMPA, and KA agonists all stimulate GnRH release from hypothalamic fragments incubated *in vitro*. Finally, mathematical modeling of hypothalamic pulse generators indicates that neuronal oscillators consisting of Glu and GABA neurons exhibit greater stability than would a single-cell oscillator composed solely of GnRH neurons.

In vivo work in intact animals indicates that Glu stimulates GnRH and LH secretion. Systemic or icv administration of Glu and the Glu receptor agonists NMDA, KA, and AMPA induce a rapid release in LH secretion, and Grattan and co-workers demonstrated that intravenous NMDA directly stimulates GnRH release into anterior pituitary perfusates collected by push–pull cannulae. NMDA microinfusion specifically into the MPOA stimulates LH release. Pulsatile LH release is suppressed by NMDA and AMPA/KA receptor blockers. Microdialysis studies suggest that Glu release increases at the time of the LH surge in the MPOA but not in the AN–ME region. Administration of NMDA or AMPA receptor blockers inhibits LH surge release. Also, sex steroid administration to gonadectomized animals up-regulates components of hypothalamic Glu transmission, including Glu release, the activity of Glu transporters, and the expression of Glu receptors. Specifically, Glu transport into hypothalamic Glu nerve terminals varies across the rat estrous cycle, and hypothalamic $GluR_1$, $GluR_{2/3}$, and AMPA receptor subunit proteins increase with sex steroid administration.

IV. HYPOTHALAMIC NITRIC OXIDE NEURONS AND THE NEUROENDOCRINE REGULATION OF LH SECRETION

A. Hypothalamic NO Neurons

In the 1980s it was determined that the potent vasodilatory factor released by endothelial cells was the gas nitric oxide; it was proposed that in brain, Glu acting at the NMDA receptor caused rapid NO synthesis and subsequent NO-induced cGMP level increases in nearby cells, and that an isoform of the enzyme producing NO, neuronal nitric oxide synthase (nNOS), was present in neurons (Fig. 6). These data suggested that NO might be a neurotransmitter in brain. If this were so, however, it was soon appreciated that its neurotransmitter characteristics would be quite unconventional, because NO is not stored in synaptic vesicles, nor indeed in any other cellular compartment, is not released by Ca^{2+}-dependent exocytosis, does not bind to membrane receptors on target cells, sometimes functions as a retrograde signaling molecule, and is not inactivated by reuptake into neurons or glia or by enzymatic degradation. Instead, NO is synthesized in a one-step reaction in which nNOS converts L-arginine to NO and citrulline (Fig. 6). nNOS is present in NO neurons but requires calmodulin-bound Ca^{2+} for activation. Once nNOS is activated, NO is immediately synthesized; NO increases cGMP levels by binding to and stimulating the enzyme guanylyl

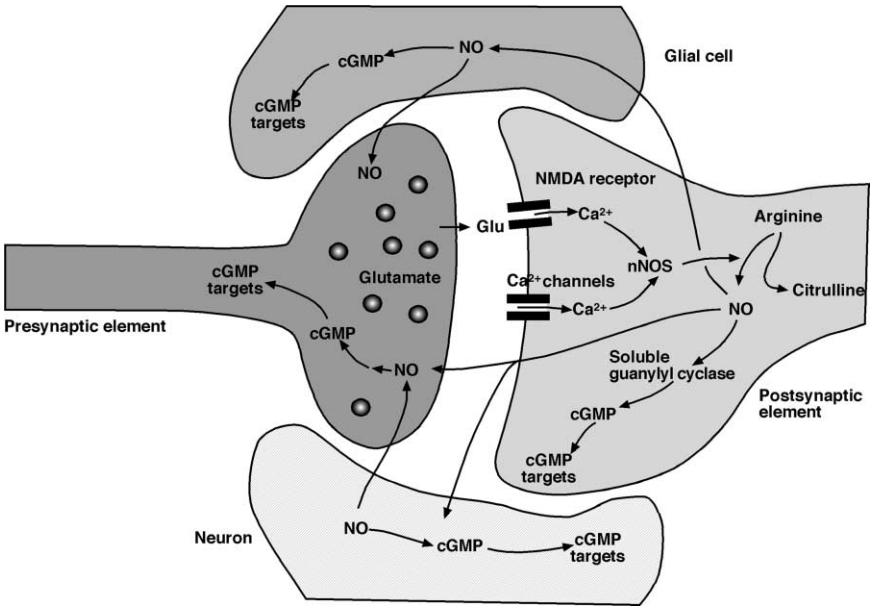

FIGURE 6 Schematic representation of a nitric oxide (NO)-releasing neuron. NO is formed from arginine by the action of neuronal nitric oxide synthase (nNOS). NO freely diffuses across cell membranes and can thereby influence both presynaptic neurons, such as the glutamatergic presynaptic neuron in the figure, and other cells that are not directly apposed to the nNOS-containing neuron, such as the other neuron and glial cell depicted. In each case NO stimulates guanylyl cyclase, increasing cGMP and activating cGMP-sensitive intracellular targets. As indicated in the figure, Glu can trigger NO formation by activating the NMDA receptor, which results in Ca^{2+} influx and Ca^{2+} activation of nNOS. The half-life of NO is less than 30 s; it decays spontaneously to nitrite. Modified from Zigmond *et al.* (1999), with permission.

cyclase. In this way cGMP levels increase and cGMP-sensitive targets are activated in the NO neuron or in the surrounding cells, including NO afferent neurons. Message termination rapidly occurs by spontaneous degradation to nitrite.

Although nNOS is present in only about 1% of brain neurons, the processes of these cells ramify so extensively that it is estimated that every neuron in brain is likely exposed to NO. Because vesicular release of NO is not regulated in neurons, as is the case for other transmitters, it seems reasonable that the biosynthetic enzyme be highly regulated. Indeed, no other enzyme is known to be regulated by so many factors. nNOS regulators include five oxidative–reductive cofactors, four phosphorylating enzymes, and three binding proteins, and its mRNA is regulated by hormones and other factors. Although stored NO is not released in an impulse-dependent manner, neuronal stimulation indeed causes NO release, by the Glu and NMDA receptor mechanism (Fig. 6) and/or by other as yet unknown mechanisms.

In the hypothalamus, many nNOS immunoreactive neuronal cell bodies, processes, and terminals are observed. Although some macrophage-inducible NOS (miNOS) is observed in microglia, and some endothelial NOS (eNOS) is expressed by CNS vascular endothelial cells, nNOS is found to be the major NOS isoform present in the hypothalamus.

B. NO Regulation of GnRH Pulse Generator Function

Several lines of evidence are consistent with the hypothesis that hypothalamic NO neurons stimulate the GnRH pulse generator, may comprise pulse generator circuitry, and may mediate NMDA-induced GnRH secretion. nNOS immunoreactive neurons are visualized in several hypothalamic structures, including the MPOA, and some immunostaining is also present in terminals in the ME. Hence, NO neurons may affect the GnRH neurons in either the MPOA cell body and dendrite region or the ME preterminal axon and terminal location. A few GnRH neurons appear nNOS-positive and many nNOS immunoreactive neurons surround GnRH cell bodies in the MPOA. Some hypothalamic NO neurons express ER and PR, and estradiol increases hypothalamic nNOS mRNA and protein levels. Similarly, MPOA nNOS mRNA, protein, and enzyme

activity vary across the rat estrous cycle. NO stimulates MPOA and AN–ME cGMP in a dose-related manner and this stimulation is blocked by hemoglobin, an NO scavenger.

In vivo work in intact animals indicates that NO stimulates GnRH and LH secretion in rats. First, icv administration of an nNOS inhibitor suppresses pulsatile LH secretion. Second, nNOS inhibitors block LH surge release and icv administration of the NO precursor L-arginine potentiates the LH surge. Third, antisense oligodeoxynucleotides against nNOS mRNA, delivered icv, decrease hypothalamic nNOS protein and diminish LH surge release. Fourth, microinfusion of the NO precursor L-arginine into the AN–ME region increases the amount of cGMP and GnRH recovered in AN–ME push–pull perfusates. Fifth, NO and GnRH are secreted in a copulsatile fashion from ME fragments incubated *in vitro*, and the amplitude of these secretions varies across the estrous cycle.

The precise neuronal mechanism whereby NO stimulates GnRH release is uncertain. NO may directly stimulate guanylyl cyclase in GnRH neurons, resulting somehow in GnRH release. However, there is more evidence for other indirect actions. Evidence exists suggesting that NO induction is required for Glu-induced GnRH secretion, that NO releases prostaglandin E_2 (which activates adenylate cyclase and protein kinase A, and then GnRH secretion), and that NO-stimulated GnRH secretion is mediated by neuropeptide Y neurons. Clearly, a great deal of additional work is required before it will be possible to distinguish between these and other neuroendocrine regulatory mechanisms.

V. THE ROLE OF GABA, GLUTAMATE, AND NITRIC OXIDE NEURONS IN THE NEUROENDOCRINE REGULATION OF OTHER ANTERIOR PITUITARY TROPIC HORMONES

The evidence indicating significant physiological roles for GABA, Glu, and NO neurons in the regulation of GnRH and LH secretion is well documented. Related evidence suggests that these neurons are significant afferents to the other hypothalamic neurons that secrete releasing and inhibiting hormones [CRH, TRH, GHRH, SS (somatostatin), PIH, and PRF], which in turn regulate the secretion of the anterior pituitary hormones (ACTH, TSH, GH, and PRL). However, the data supporting the latter role are fewer and in some cases substantially less well developed, compared to the evidence for GnRH regulation. Some of this evidence is presented in reviews cited in the bibliography of this article. Evidence substantial enough to form a reasoned judgment is included in Table 1, which summarizes the neuroendocrine effect of GABA, Glu, and NO on the secretion of ACTH, TSH, GH, and PRL. So that the table is complete, the effects on LH and FSH secretion are included. Although a great deal is known about hypothalamic GABA, Glu, and NO neurons and how they function as physiologically significant afferents to the hypophysiotropic hormone-secreting neurons, considerably more than that remains to be learned about these neuroendocrine regulatory mechanisms.

TABLE 1 Net *In vivo* Effect of GABA, Glu, and NO on the Secretion of the Anterior Pituitary Tropic Hormones[a]

Effector	LH/FSH	ACTH	TSH	GH	PRL
GABA	↓	↓	↓	↓	↓
Glu	↑	↑	↑	↑	↑
NO	↑	↓	ND	↑	↑

[a]LH, Luteinizing hormone; FSH, follicle-stimulating hormone; ACTH, adrenocorticotropic hormone; TSH, thyroid-stimulating hormone; GH, growth hormone; PRL, prolactin; ↑, increases; ↓, decreases; ND, not determined.

Glossary

afferent neuron Neuron that conveys incoming nerve impulses to another neuron or nerve center with which it synapses.

γ-aminobutyric acid Principal inhibitory neurotransmitter in the mammalian central nervous system (CNS), inhibiting virtually every neuron in the adult CNS at physiological concentrations.

glutamate Principal excitatory neurotransmitter in the mammalian central nervous system, stimulating virtually every neuron in the adult CNS at physiological concentrations.

gonadotropin-releasing hormone Hypothalamic releasing hormone that stimulates luteinizing hormone and follicle-stimulating hormone secretion from the anterior pituitary gland.

hypophysiotropic hormone-secreting neurons Hypothalamic neurons that secrete into the hypophysial portal circulation various releasing or inhibiting hormones, which in turn control secretion of the six anterior pituitary tropic hormones.

luteinizing hormone and follicle-stimulating hormone Anterior pituitary tropic hormones controlling the reproductive functions of the testes and ovaries.

median eminence That portion of the medial basal hypothalamus from which the hypophysial portal vessels arise.

nitric oxide Neuroactive gas, released from neurons, which functions as a neurotransmitter, probably affecting every neuron in brain.

Amphiregulin

EUNKYUNG CHUNG*, PAUL W. COOK†, AND ROBERT J. COFFEY*

**Vanderbilt University and VA Medical Center • †Cascade Biologics, Inc., Oregon*

The epidermal growth factor (EGF) family of polypeptide growth factors includes EGF, transforming growth factor-α, amphiregulin, heparin-binding EGF-like growth factor, betacellulin, epiregulin, epigen, heregulin, neuregulin, and cripto.

I. INTRODUCTION

The epidermal growth factor (EGF) receptor ligands can interact with four known EGF receptor (EGFR) subtypes, and, in some cases, distinct intracellular signaling pathways can be activated in a ligand/receptor-dependent fashion. Like the other EGFR ligands, amphiregulin (AR) is synthesized in a proform and is inserted into the plasma membrane, where it is cleaved in its ectodomain to release soluble growth factor. AR was originally identified as an EGFR ligand from a phorbol ester-treated human breast adenocarcinoma cell line, MCF-7. Although the growth inhibitory properties of AR have not been subsequently validated, Shoyab and co-workers named it "amphi" because of its growth inhibitory effects on A431 and several other cancer cell lines and growth stimulation of many other cell lines, normal and transformed. This article will attempt to provide a biological perspective on AR by discussing its

nitric oxide Neuroactive gas, released from neurons, which functions as a neurotransmitter, probably affecting every neuron in brain.

The epidermal growth factor (EGF) family of polypeptide growth factors includes EGF, transforming growth factor-α, amphiregulin, heparin-binding EGF-like growth factor, betacellulin, epiregulin, epigen, heregulin, neuregulin, and cripto.

I. INTRODUCTION

The epidermal growth factor (EGF) receptor ligands can interact with four known EGF receptor (EGFR) subtypes, and, in some cases, distinct intracellular signaling pathways can be activated in a ligand/receptor-dependent fashion. Like the other EGFR ligands, amphiregulin (AR) is synthesized in a proform and is inserted into the plasma membrane, where it is cleaved in its ectodomain to release soluble growth factor. AR was originally identified as an EGFR ligand from a phorbol ester-treated human breast adenocarcinoma cell line, MCF-7. Although the growth inhibitory properties of AR have not been subsequently validated, Shoyab and co-workers named it "amphi" because of its growth inhibitory effects on A431 and several other cancer cell lines and growth stimulation of many other cell lines, normal and transformed. This article will attempt to provide a biological perspective on AR by discussing its

structure and processing, mechanisms of action, factors that regulate its expression, and conditions associated with its overexpression.

II. STRUCTURE AND PROCESSING OF AR

At the genomic level, human AR maps to chromosome 4q13–q21 and is partitioned into six exons that span 10.2 kb of genomic DNA. As deduced from the cDNA, the transcript is 1.4 kb and the translation product is 252 amino acids with a predicted mass of 25.9 kDa without glycosylation. Fig. 1 depicts the chromosomal location of AR in human and mouse. AR is contiguous with epiregulin in human and with betacellulin in mouse, respectively. The tight linkage between these EGFR ligands in both human and mouse suggests that they may have arisen through a tandem gene duplication event. In addition, AR is in close proximity to the chemotactic cytokines for neutrophils, B cells, and melanocytes, such as Gro1, Gro2, Gro3, and interleukin-8 (IL-8) in human and Gro1 in mouse. Of interest, AR has been shown to be pro-inflammatory in the skin of keratin 14 promoter (K14)-AR transgenic mice, in which there is targeted overexpression of human AR in the basal layer of the epidermis.

As illustrated in Fig. 2, mature AR is initially synthesized as a 252-amino-acid transmembrane precursor that is proteolytically cleaved to its mature 78- to 84-amino-acid form. Following the signal peptide, the pro-region consists of potential N- or O-linked glycosylation sites and three potential tyrosine sulfation sites. Subsequent work from the authors' laboratory has revealed that N-linked glycosylation of the pro-region predominates over O-linked glycosylation and that tyrosine sulfation occurs in this region. Mature AR consists of a heparin-binding domain (HBD) made up of positively charged amino acids and followed by the EGF domain, which is composed of the conserved spacing of six cysteine residues ($CX_7CX_4CX_1CX_8C$) shared among EGFR ligands. Plowman and co-workers have shown that the HBD of AR prevents the secretion of mature AR when the pro-region is deleted. In this

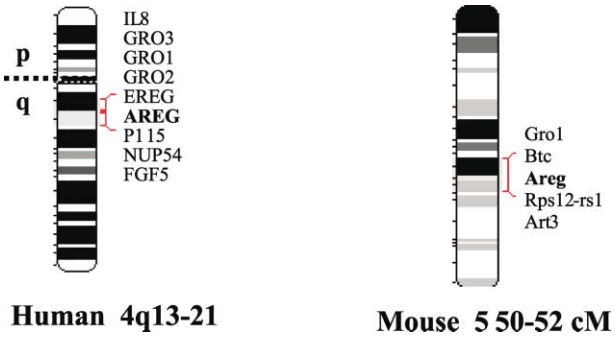

FIGURE 1 Chromosomal location of AR and adjacent genes in human and mouse genomes. Human AR is in close proximity to epiregulin on chromosome 4q13–q21, and mouse AR is adjacent to betacellulin on chromosome 5 at 50–52 cM. (In human) IL-8, interleukin-8; GRO1, 2, 3 oncogene, melanoma growth stimulating activity α; EREG, epiregulin; AREG, amphiregulin; p115, vesicle-docking protein p115; NUP54, nucleoporin p54; FGF5, fibroblast growth factor 5. (In mouse) Gro1, the mouse homologue of human GRO1; Btc, betacellulin; Areg, amphiregulin; Rps12-rs1, ribosomal protein S12; Art3, ADP-ribosyl transferase 3.

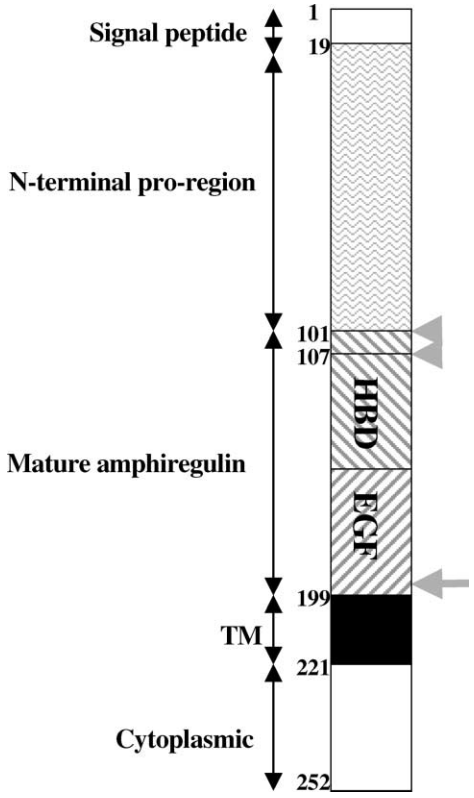

FIGURE 2 Structure of AR precursor. AR is synthesized as a 252-amino-acid, single-pass transmembrane glycoprotein. After the signal peptide (1–19), there is an N-terminal pro-region (amino acids 20–100) containing N- and O-linked glycosylation sites and potential tyrosine sulfation sites, followed by mature AR. Mature AR consists of two distinct parts, a heparin-binding domain (HBD) and an EGF repeat. TM represents the transmembrane domain (amino acids 199–221) that is followed by the cytoplasmic domain (amino acids 222–252). Arrow at a distal site indicates a TACE-mediated cleavage site, and two arrowheads show alternative proteolytic processing sites that give rise to different isoforms of mature AR.

study, deletion of the pro-region resulted in the prevention of secretion of AR into the medium. Moreover, fusion of the HBD of AR to the EGF repeats of transforming growth factor-α (TGF-α) and EGF, along with TGF-β's signal peptide, prevented secretion of these constructs. From these studies, an electrostatic model has been proposed in which the negatively charged pro-region of AR interacts with its positively charged HBD to facilitate proper folding and secretion. However, replacement of AR's pro-region with the pro-region of heparin-binding EGF-like growth factor (HB-EGF) (which is positively charged) allowed secretion of mature AR, whereas TGF-α's pro-region (which is negatively charged) did not. Therefore, it may be that only specific negatively charged amino acid sequences can confer proper folding and secretion of AR.

In the C-terminus of AR's EGF repeat, a leucine that is conserved in all other EGFR ligands is converted to methionine at residue 186, a change that reduces binding to EGFR. The transmembrane domain and cytoplasmic domain of AR are not required for secretion of mature AR, although proteolytic removal of the N-terminal pro-region is less efficient in the absence of the membrane anchor. However, the loss of basolateral sorting was observed by deletion of these regions in polarized Madin-Darby canine kidney (MDCK) II epithelial cells (see below). Fig. 3 depicts various isoforms of AR in the cell lysates and medium following its posttranslational modification. Although some of these isoforms have been shown to possess biological activity, it is not known whether all of these soluble AR forms are biologically active and, if so, whether they may differ in their biological activities.

III. SELECTED ASPECTS OF AR SIGNALING

The sorting and processing of AR in the context of polarized epithelial cells have been examined. This approach assumes biological relevance when it is recalled that the EGFR is localized preferentially to the basolateral surface of all polarized epithelial cells. Studies have examined the trafficking of wild-type and mutant forms of AR in polarized MDCK II cells that had been stably transfected with these cDNAs, as well as trafficking of endogenous AR in polarized HCA-7 cells, a human colon cancer cell line that was generated from an individual with a well-differentiated rectal cancer. These HCA-7 cells, like MDCK II cells, form a uniform polarizing monolayer when cultured on polycarbonate-coated Transwell filters. Both of these cells contain 20,000–40,000 basolateral EGFRs. In both lines, AR is delivered preferentially to the basolateral surface, where it is cleaved by tumor necrosis factor α-converting

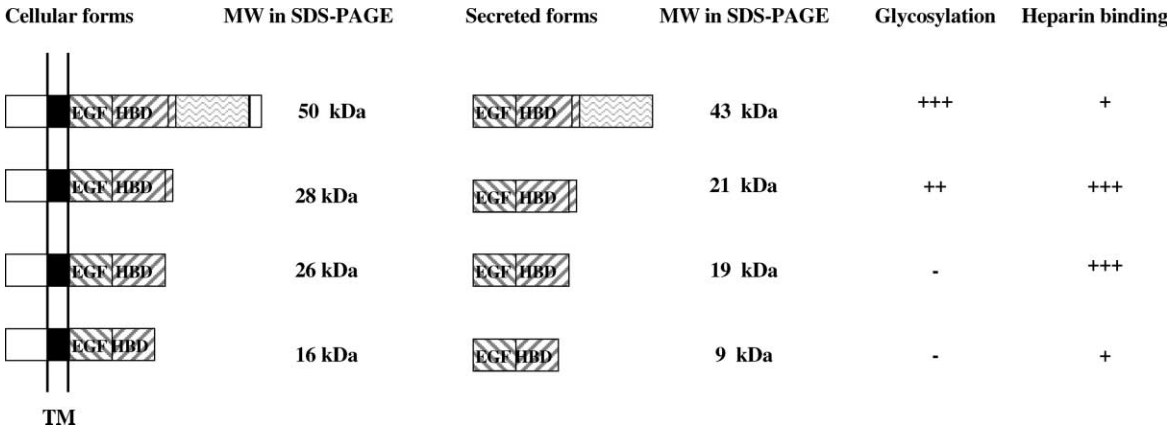

FIGURE 3 Various forms of cellular and secreted AR. Different forms of cell-associated and secreted AR are depicted and the extent of glycosylation and the ability to bind heparin are described quantitatively. Cell surface, membrane-anchored forms of AR are proteolytically processed to multiple soluble isoforms. TACE-mediated cleavage of the ectodomain of 50 kDa pro-AR at a distal site releases 43 kDa soluble AR into conditioned medium. Alternatively, in the absence of primary proteolytic cleavage at the distal site, secondary cleavage at proximal sites removes the N-terminal domain, resulting in 28 and 26 kDa cell surface pro-AR forms, which appear as a doublet. These forms are then released by TACE-mediated cleavage at the distal site. This soluble doublet probably represents the originally described mature form of AR. In the absence of cleavage at the distal site, further proteolytic processing at a proximal site results in a 16 kDa cell surface form of AR, which has a reduced HBD and is not glycosylated. The 16 kDa cell surface form can be cleaved by TACE at a distal site to release a 9 kDa soluble AR.

enzyme/a disintegrin and metalloprotease 17 (TACE/ADAM17) (see Fig. 4). The basolateral sorting information resides in the cytoplasmic tail as AR cDNA constructs that lack the tail are missorted in polarized MDCK II cells. However, cell surface processing of AR appears to be unaffected, suggesting that information in the tail is not required for cell surface proteolytic cleavage. AR exhibits punctate immunoreactivity at both the basal and the lateral surfaces of these polarized epithelial cells, likely due to its ability to bind to heparan sulfate proteoglycans (HSPGs) at the cell surface and in the extracellular matrix. Levels of AR in the basolateral medium are not significantly altered after administration of an antibody to the EGFR that blocks ligand binding (MAb 528 or 225). This contrasts with TGF-α levels that increase promptly in the basolateral medium after EGFR MAb blockade, a finding that has been interpreted as evidence that TGF-α is a locally acting growth factor. These differences in post-cleavage disposition of TGF-α and AR underscore the possibility of distinct biological activities.

A speculative view of possible participants in endogenous AR signaling is presented in Fig. 5. Signaling pathways initiated by endogenous AR are thought to be complex due to a number of factors. These include glycosylation, multiply processed forms, ability to bind HSPGs, and variable-affinity binding to EGFR. Although all seven EGFR ligands bind to the EGFR and thereby activate conserved downstream effectors, such as Ras-mitogen-activated protein kinase and phosphatidylinositol 3-kinase–Akt/protein kinase B, the complexity of the production and processing of endogenous AR allows for activation of alternative signaling pathways. It should be emphasized, however, that activation of such alternative pathways has not been proven. In the following discussion, possible effects due to the ability of AR to bind heparin are considered in light of what has been established for the other heparin-binding EGFR ligand, HB-EGF.

Immunohistochemical studies have identified several binding proteins that may be involved in AR signaling. AR has been shown to co-localize with CD44, a hyaluronan receptor, which is modified by HSPGs in its v3 region. This interaction with CD44 may facilitate the juxtacrine activity of AR as has been shown for HB-EGF. It should be noted, however, that CD44 also has been reported to co-localize with EGFR, erbB-4, and matrilysin/matrix metalloprotease-7. CD9, a tetra-spanning transmembrane protein, has also been found to co-localize with AR by immunofluorescence studies. It has been reported that CD9 co-localizes with α3β1 integrins, which, in turn, increases the juxtacrine activity of HB-EGF and possibly TGF-α, respectively; however, to date, this interaction has not been shown to increase the juxtacrine activity of pro-AR. In addition, cell surface HSPGs, members of the syndecan and glypican family, have been postulated as possible binding partners of AR. In polarized epithelial cells, glycosylphosphatidylinositol (GPI)-linked glypican, which is generally targeted to the apical domain, would be less likely to participate in AR-induced signaling than syndecan-1, which is sorted to the basolateral compartment of polarized epithelial cells like AR and EGFR. It is possible that HSPGs on the cell surface and extracellular matrix (perlecan, agrin) act

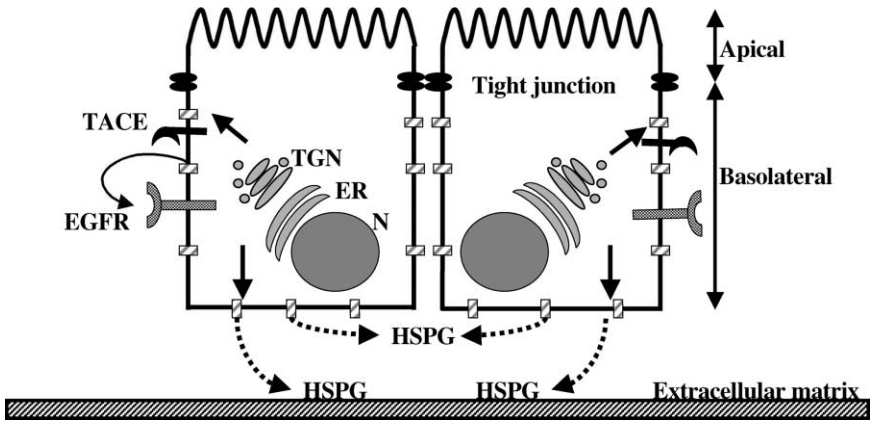

FIGURE 4 Sorting and processing of AR in polarized epithelial cells. This simplified schematic depicts cell surface cleavage of one AR molecule and its binding to EGFR. It should be noted that TACE, AR, and EGFR are all found within the basolateral compartment. N, ER, and TGN represent the nucleus, endoplasmic reticulum, and *trans*-Golgi network, respectively.

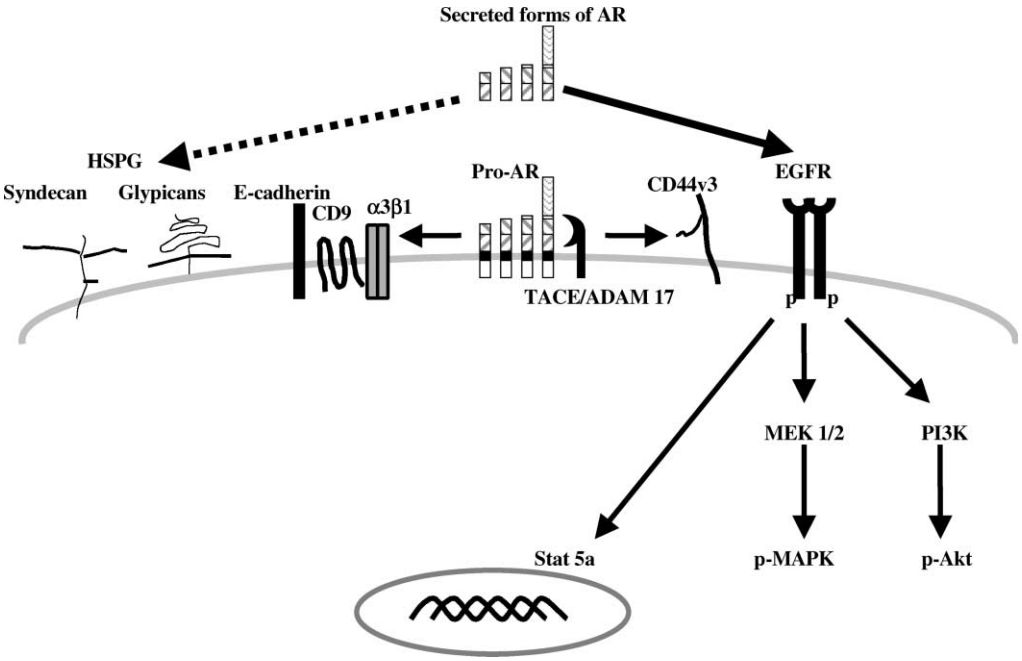

FIGURE 5 Participants in AR signaling. A model of protein interactions that appear to regulate AR signaling is presented (see text for details). Both CD44v3 and CD9 directly interact with AR. Whether TACE interacts directly with AR is not known.

as depots for AR in its pro-AR form or after it is cleaved and released from the cell surface. These depot forms of AR may increase local concentrations of AR or regulate its access to the EGFR. In summary, these accessory molecules presumably influence the nature of the interaction between AR and EGFR, as there is no evidence at the present time for EGFR-independent signaling by AR.

What is the evidence that endogenous AR has effects distinct from those of the other EGFR ligands? *In vitro*, AR differed from EGF in its recruitment of downstream molecules when these ligands were administered to cells expressing an EGFR with a C-terminal truncation (C′1000). It is also possible that distinct actions of AR may ensue from differences that arise after ligand binding to the EGFR. For example, Derynck's group previously reported that TGF-α dissociated from the EGFR earlier in the endocytic pathway than EGF based on differences in their isoelectric points (the p*I* for TGF-α is 5.9 and that for EGF is 4.6). Thus, TGF-α is less likely to be degraded and more likely to be recycled. AR has a p*I* of 9.84 and therefore would be predicted to dissociate from EGFR even earlier than TGF-α during endocytosis. AR also possesses biological properties that in some cases are distinct from those of TGF-α or EGF. These properties include affinity for heparin and heparin-like molecules, heparin-dependent inhibition of mitogenic activity, and cell density-dependent responsiveness in Balb MK-2 cells.

More convincing evidence for distinct biological actions of AR comes from mouse studies in which there was a targeted overexpression or disruption of AR. In the study of triple knockouts of EGFR ligands (EGF, TGF-α, and AR), a specific role for AR was identified in mammary gland development with signal transducers and activators of transcription (Stat) 5a involved in this AR-specific effect. Two separate groups used the K14 promoter to overexpress AR and TGF-α to the basal layer of the epidermis. Both transgenic lines exhibited hyperplasia of the epidermis; however, only AR mice exhibited marked inflammation of the skin and synovium with features strikingly similar to psoriasis and psoriatic arthritis. These features included epidermal T-lymphocytic and neutrophilic infiltration and tortuous dilated blood vessels within the dermis, indicating that AR may exert unexpected and unique pro-inflammatory and angiogenic activities. This study also demonstrated that epidermally targeted AR expression in transgenic mice stimulated psoriatic pathological processes in the skin that were different from those of other transgenically targeted cytokines and growth factors such as vascular endothelial growth factor, keratinocyte growth factor, IL-1α, tumor necrosis factor α, interferon-γ (IFN-γ), and IL-6. Additionally, because

AR is significantly induced by barrier disruption as well as placing human skin into explant culture, it has been proposed that cutaneous injury (wounding) induces AR expression and initiates the isomorphic, Koebner response (wound-dependent lesion formation) in psoriatic individuals. Collectively, these K14–AR transgenic studies suggest that AR may act as a cutaneous injury signaling factor that initiates epidermal proliferation, angiogenesis, and innate immune responses in the skin.

IV. REGULATION OF AR EXPRESSION

Table 1 lists factors that affect AR expression. Multiple lines of evidence support increased EGF-related peptide signaling and activation of the EGFR as important components of oncogenic Ras transformation of rat intestinal epithelial cells (RIE-1 cells). For example, oncogenic Ras-transformed RIE-1 cells exhibit increased production of EGFR ligands AR, TGF-α, and HB-EGF. EGFR blockade partially reverts the transformed morphology of oncogenic Ras RIE-1 cells and prevents the morphological transformation of parental RIE-1 cells caused by constitutively activated Ras-conditioned medium. Moreover, the growth inhibitory effects of the farnesyltransferase inhibitor L744, 832 for oncogenic Ras-transformed RIE-1 cells is preceded by decreased expression of AR, HB-EGF, and TGF-α. Also, in mouse models of skin carcinogenesis and melanoma, EGFR signaling (with AR likely being an active participant) plays a pivotal role in mediating the Ras-transformed phenotype. Thus, the oncogenic Ras-transformed phenotype is mediated, at least in part, through increased production of EGFR ligands (including AR) that presumably bind to and activate EGFR. It is thought that EGFR signaling will further augment Ras signaling as well as activate Ras-independent signals that contribute to the Ras-transformed phenotype.

TABLE 1 ***In Vitro*** **and** ***In Vivo*** **Conditions with Altered AR Expression**

Condition	Target cells	mRNA	Protein
In vitro **conditions with altered AR expression**			
Up-regulation			
Mutated Ras	RIE-1, IEC-6	+	+
EGFR ligands	RIE-1, HK, LIM1215	+	+
Insulin/IGF-I	HK	+	+
IL-1α and TNFα	Cervical epithelial cells	+	+
IFN-γ	NHBECs	+	+
Gastric injury	Rat gastric epithelial cells	+	+
Helicobacter pylori	MKN 28	+	+
$1,25(OH)_2D_3$	SCC25, MCF-7, MDA-231	+	ND
Androgen	LNCaP	+	+
E2	MCF-7	+	+
Phorbol esters	MCF-7, T-47D, MDA-231	+	+
Gastrin	Rat stomach cells	+	ND
TARP	PC3	+	ND
WT1	U20S	+	ND
Down-regulation			
TGF-β	A549	−	−
PPAR-γ agonists	Ha-Ras-transformed IEC	−	−
In vivo **conditions with increased AR expression**			
Psoriasis	Skin	+	+
Neoplasia	Pancreatic cancer,	+	+
	GI cancer (gastric, CRC),	+	+
	mammary gland cancer	+	+

Note: +, induction; −, down-regulation; ND, not determined. RIE-1, IEC-6, rat intestinal epithelial cells; HK, human keratinocytes; NHBECs, normal human bronchial epithelial cells; LIM1215, colon adenocarcinoma cell line; MKN 28, gastric adenocarcinoma cell line; $1,25(OH)_2D_3$, 1,25-dihydroxy vitamin D_3; SCC25, head and neck squamous cell carcinoma cell line; MCF-7, estrogen receptor (ER)-positive breast carcinoma cell line; T-47D, ER-positive breast carcinoma cell line; MDA-231 (MDA-MB-231), ER-negative breast carcinoma cell line; LNCaP, androgen-sensitive prostate cancer cell line; E2, 17β-estradiol; phorbol esters, TPA (12-*O*-tetradecanoylphorbol-13-acetate); TARP, T-cell receptor γ-chain alternate reading frame protein; PC3, androgen-independent prostate cancer cell line; U20S, osteosarcoma cell line; A549, lung adenocarcinoma cell line; PPAR-γ agonists, peroxisome proliferator-activated receptor-γ agonists (troglitazone, resiglitazone); GI, gastrointestinal tract; CRC, colorectal cancer.

In addition, there is extensive autoinduction and cross-induction of EGFR ligands in RIE-1 cells and other EGF growth-responsive epithelial cells. Under EGFR ligand stimulation, there is often a prompt and robust induction of AR. Various pro-inflammatory cytokines, such as IFN-γ and IL-1α, and growth hormones, such as androgen, estrogen, and gastrin, have been reported to induce AR expression in various cell types. TGF-β and peroxisome proliferator-activated receptor-γ agonists have been found to down-regulate AR expression. Table 1 also lists *in vivo* conditions in which AR expression has been reported to be increased.

V. BIOLOGICAL ROLES FOR AR

A. AR as an Autocrine Growth Factor

AR has been shown to act as an autocrine growth factor for normal human keratinocytes, mammary epithelial cells, and bronchial epithelial cells. Moreover, evidence has been presented for AR acting as an autocrine growth factor in certain human cancer cell lines. These include ovarian (OVCAR3, OVCAR8), prostatic (DU145 and PC3), colonic (HCA-7 and Caco-2), bladder, cervical, and gastric cell lines.

B. AR as a Morphogen

Previous studies have shown that AR influences organ development in the lung, mammary gland, and kidney. In lung development, AR contributes to the growth of the mesenchyme and epithelium, thus participating in the process of branching morphogenesis. These effects are mediated through interactions with HSPGs, as glycosaminoglycan-degrading enzymes abolished AR-induced mitogenesis and branching morphogenesis. The role of AR in mammary gland development has been demonstrated by studies of mice with targeted disruption of AR, TGF-α, and EGF. Mice lacking AR singly and in combination with TGF-α showed defects in ductal outgrowth in glands. In triple-null glands, alveoli were poorly organized and poorly differentiated, and milk protein gene expression was decreased. A role for AR in kidney differentiation was found initially in studies using an embryonic epithelial cell line derived from c-met mice. In addition, AR was identified in a search for genes with altered expression following induction of the Wilms tumor suppressor (WT1), a zinc-finger transcription factor implicated in kidney differentiation and tumorigenesis. It appears that WT1 acts as a transcriptional regulator during kidney differentiation through direct binding to the AR promoter. Furthermore, recombinant AR stimulates epithelial branching in organ cultures of embryonic mouse kidney. Taken together, these studies support a role for AR as an important modulator of branching morphogenesis in developing lung, mammary gland, and kidney. AR appears to act on both epithelium and mesenchyme with the participation of HSPGs.

VI. SUMMARY

Human AR is a heparin-binding, heparin-inhibited, polypeptide growth factor of the EGF family, which was initially isolated from the conditioned medium of human MCF-7 breast tumor cells that had been treated with phorbol ester. The human AR gene is located on chromosome 4q13–q21 and is expressed as a 252-amino-acid precursor that is processed into several different cell surface and soluble isoforms. In polarized epithelial cells, AR is preferentially delivered to and processed at the basolateral surface. AR is thought to associate with extracellular and cell-associated HSPGs (e.g., syndecans, CD44) as well as other accessory molecules (e.g., CD9). Interaction with these molecules may facilitate a depot form of AR and promote productive interactions between AR and cell surface EGFRs.

AR displays some biological properties that are distinct from those of either TGF-α or EGF. These properties include affinity for heparin, heparin-mediated inhibition of mitogenic activity, and cell density-dependent responsiveness. Distinct biological actions of AR were identified from a comparison of mice with targeted overexpression of AR and TGF-α in the skin, where AR mice exhibit an inflammatory psoriasis-like phenotype. Furthermore, experiments with AR null mice have revealed a role for AR in mammary gland development through activation of Stat5a. AR also participates in branching morphogenesis in the lung and kidney. Additional studies will be needed to elucidate mechanisms underlying these biological properties of AR. It is anticipated that AR will be an important target of the protease-mediated cleavage of EGFR ligands that underlie G-protein-coupled receptor transactivation of the EGFR.

AR has been shown to be regulated by a variety of agents and conditions that include up-regulation by EGFR ligands and mutant Ras. AR has also been shown to be up-regulated in pathological states such as psoriasis and a number of neoplasms, where it may act in an autocrine manner to stimulate growth and/or prevent apoptosis.

Glossary

epidermal growth factor receptor (EGFR) Type I transmembrane protein that has tyrosine kinase activity in its cytoplasmic domain. There are four mammalian members of this receptor family. Signaling from the EGFR is initiated by binding of its ligands, which then induces receptor dimerization and autophosphorylation to propagate downstream signaling cascades.

epidermal growth factor receptor (EGFR) ligands There are currently seven members of the mammalian epidermal growth factor family that exhibit conserved spacing of six cysteine residues in the mature domain of the growth factor. The ligands are synthesized in a proform, delivered to the cell surface as a transmembrane protein, and then cleaved to release mature soluble growth factor.

psoriasis Hyperproliferative skin disorder with infiltrating lymphocytes and neutrophils in the epidermis and dermis.

tumor necrosis factor α-converting enzyme/a disintegrin and metalloprotease 17 (TACE/ADAM17) Enzyme that is involved in the cleavage of pro-transforming growth factor-α and pro-amphiregulin at the cell surface.

Androgen Effects in Mammals

SHALENDER BHASIN

Charles R. Drew University of Medicine and Science, Los Angeles

Testosterone, a 19-carbon steroid secreted by the testis, is the predominant androgen in most mammalian species. Androgens directly or indirectly affect almost all body systems during fetal and pubertal development and in adult life. The sexual differentiation of the mammalian fetus is a complex, multifactorial process that requires not only the genetic information carried on the sex chromosomes, but also the hormonal secretions of the fetal testis, namely, testosterone and Müllerian-inhibiting hormone. Testosterone masculinizes the Wolffian structures and causes the external genitalia to form a scrotum and penis. In addition, increasing testosterone levels during puberty promote somatic growth and virilization of boys. Testosterone plays a critical role in mammalian reproduction; it is essential for maintaining sexual function, germ cell development, and accessory sex organs. In the adult animal, testosterone has additional effects on the muscle, bone, hematopoeisis, coagulation, plasma lipids, protein and carbohydrate metabolism, and psychosexual and cognitive function.

I. TESTOSTERONE SECRETION, TRANSPORT, AND METABOLISM

A. Testosterone Secretion

In males of most mammalian species, 95% of circulating testosterone is derived from testicular secretion. Only a small amount of dihydrotestosterone (DHT; approximately 70 μg daily) is secreted directly by the human testis; most circulating DHT is derived from the peripheral conversion of testosterone. Testosterone is produced in the testis by a heterogeneous group of cells that includes the adult Leydig cells, Leydig cell precursors, and immature Leydig cells. Studies in hypogonadotropic (*hpg*) mice suggest that fetal development of both Sertoli and Leydig cells is independent of gonadotropins; however, normal differentiation and proliferation of the adult Leydig cell population require the presence of gonadotropins. The number of Sertoli cells after birth is regulated by gonadotropins. A number of 46,XY male humans with inactivating mutations of the luteinizing hormone (LH) receptor have been studied; these patients have varying degrees of genital ambiguity and Leydig cell agenesis, pointing to the important role of LH in the regulation of Leydig cell development in humans.

In man, 3–10 mg of testosterone is secreted daily by the testis; direct secretion of testosterone by the adrenal and the peripheral conversion of androstenedione, which is secreted by the adrenal and converted to testosterone, collectively account for another 500 μg of testosterone daily. Leydig cells arise from poorly characterized mesenchymal precursor cells under the influence of luteinizing hormone, insulin-like growth factor-I, transforming growth factor-β, transforming growth factor-α, interleukin 1, and basic fibroblast growth factor. Leydig cells exist in two distinct generations in higher mammals, fetal and adult, that are separated in higher mammals by a prepubertal period during which the testis is devoid of Leydig cells.

Testosterone secretion by Leydig cells is under the control of LH, a pituitary glycoprotein hormone. LH binds to specific G-protein-coupled receptors on the Leydig cells and activates the cyclic AMP pathway. Although LH also activates the phopholipase C pathway, it is unclear whether this pathway is essential for LH-mediated stimulation of testosterone production. The rate-limiting step in testosterone biosynthesis is the delivery of cholesterol to the inner mitochondrial membrane, which is the site of the cholesterol side chain cleavage complex that converts cholesterol to pregnenolone. A steroidogenesis acute regulatory protein makes cholesterol available to the cholesterol side chain complex and regulates the rate of testosterone biosynthesis. Peripheral benzodiazepine receptor, a mitochondrial cholesterol-binding protein known to be involved in mediating cholesterol transport, is present in high concentrations in the outer mitochondrial membrane and has also been proposed as an acute regulator of Leydig cell steroidogenesis. In addition, another group of poorly characterized mitochondrial proteins has been implicated in the control of steroidogenesis in Leydig cells.

Leydig cell production of testosterone is modulated by a number of paracrine factors within the seminiferous tubule and the interstitium of the testis, including insulin-like growth factor-I, insulin-like growth factor-binding proteins, inhibins, activins, transforming growth factor-β, epidermal growth factor, interleukin-1, basic fibroblast growth factor, gonadotropin-releasing hormone, and vasopressin.

B. Androgen Transport in the Body

Ninety-eight percent of circulating testosterone is bound to plasma proteins: the sex hormone-binding globulin (SHBG) and albumin. The sex hormone-binding globulin binds testosterone with much greater affinity than albumin. Only 1 to 3% of testosterone is unbound; although the dogma has been that only the unbound fraction is biologically active, it has been argued that albumin-bound hormone may dissociate readily in the capillaries and thus become bioavailable. In fact, Pardrige *et al*. have demonstrated that albumin- and SHBG-bound androgens represent the major circulating pool of bioavailable hormone for testis or prostate. Furthermore, these investigators have argued that the SHBG–sex steroid complex may be nearly completely available for influx through the blood–testis barrier or prostate plasma membrane; this view is not universally shared.

SHBG is a glycoprotein, synthesized in the liver, that displays high-affinity binding for testosterone and estradiol. Hepatic production of SHBG is regulated by insulin, thyroid hormones, dietary factors, and the balance between androgens and estrogens. SHBG is involved in the transport of sex steroids in plasma and its concentration is a major factor regulating their distribution between the protein-bound and free states, although its functional role in testosterone delivery to target organs is not clear. Plasma SHBG concentrations are decreased by androgen administration, obesity, insulin, and nephrotic syndrome. Conversely, estrogen administration, hyperthyroidism, many types of chronic inflammatory illnesses, and aging are associated with high SHBG concentrations. A locus that is associated with SHBG concentrations in African Americans and Caucasians has been mapped to 1q44. In addition, several other loci in African Americans exhibit linkage with SHBG concentrations, suggesting that many genes likely regulate SHBG levels. The binding of testosterone to SHBG or albumin is not essential for androgen action or steroid homeostasis; rats that are deficient in both sex hormone-binding globulin and albumin are fertile and have normal mating behavior.

C. Testosterone Metabolism

Testosterone is metabolized predominantly in the liver (50–70%) although some degradation also occurs in peripheral tissues, particularly the prostate and the skin. Liver takes up testosterone from the blood and through a series of chemical reactions that involve 5α- and 5β-reductases, 3α- and 3β-hydroxysteroid dehydrogenases, and 17β-hydroxysteroid dehydrogenase converts it into androsterone and etiocholanolone, which are both inactive metabolites, dihydrotestosterone, and 3-α-androstanediol. These compounds undergo glucoronidation or sulfation before their excretion by the kidneys. Free and conjugated androsterone and etiocholanaolone are the predominant urinary metabolites of testosterone.

II. TESTOSTERONE AS A PROHORMONE

Testosterone can be converted in many peripheral tissues into its active metabolites, 17β-estradiol and 5α-DHT (Fig. 1). Aromatization of the A ring converts it into 17β-estradiol. In addition, reduction of the δ4 double bond can convert testosterone into 5α-DHT. Testosterone's actions in many tissues are mediated through these metabolites. For instance, testosterone's effects on trabecular bone resorption and the sexual differentiation of the brain require its aromatization to estradiol. Testosterone's effects on plasma lipids, atherosclerosis progression, and some types of behaviors are also mediated through its conversion to estrogen. Considerable gains in insight into the role of estrogen in mammalian physiology have been made through the study of three mouse knockout models: the estrogen receptor-α, estrogen receptor-β, and aromatase knockouts. These models of estrogen deficiency exhibit significant disruption of spermatogenesis and fertility, elevated testosterone and LH levels, decreased bone mass, and increased adiposity, indicating the important role of estrogens in the regulation of bone mass, gonadotropin regulation, body composition, and spermatogenesis. A very small number of humans with inactivating mutations of the CYP19 aromatase gene have been

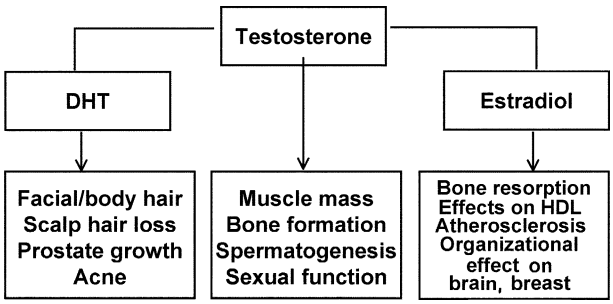

FIGURE 1 Effects of testosterone and its metabolites in men. DHT, dihydrotestosterone; HDL, high-density lipoprotein. Modified from Bhasin and Fisher (2002), with permission.

reported. Females with CYP19 gene mutations are masculinized, fail to undergo female pubertal development, have elevated levels of androgens, LH, and follicle-stimulating hormone, have polycystic ovaries, and are tall in stature. Males with CYP19 aromatase mutations have been characterized by osteoporosis, increased bone turnover, delayed epiphyseal fusion, tall stature, and increased testosterone but markedly decreased estradiol levels.

At least two isoenzymes of steroid 5α-reductase have been cloned and characterized. Type 1 steroid 5α-reductase isoenzyme is expressed in many nongenital tissues, has been mapped to chromosome region 5p15, and has a pH optimum of 8. Type 2 steroid 5α-reductase isoenzyme is expressed in the prostate and other genital tissues, has been mapped to 2p23, and has a pH optimum of 5.0. The biological role of 5α-reductase type 1 has not yet been ascertained. Gene-targeting experiments suggest that type 1 enzyme plays a role in progesterone metabolism at the end of pregnancy. The mice lacking 5α-reductase enzyme type 1 have failure of cervical ripening and fail to deliver.

Testosterone's effects on the prostate and sebaceous glands of the skin require its 5α-reduction to DHT. DHT has been implicated in the pathophysiology of benign prostatic hyperplasia and androgenic alopecia. Type 2 isoenzyme is the predominant form in the prostate and has been implicated in the pathophysiology of benign prostatic hypertrophy, hirsutism, and possibly male-pattern baldness. During embryonic life, testosterone controls the differentiation of the Wolffian ducts into epididymis, vasa deferentia, and seminal vesicles. The development of structures from the urogenital sinus and the genital tubercle such as the scrotum, penis, and penile urethra require the action of DHT. The role of 5α-reduction of testosterone in mediating its effects on muscle and sexual function remains unclear. Although testosterone and DHT can both exercise anabolic effects on the muscle, steroid 5α-reductase activity is very low or absent in the skeletal muscle, and it is not known whether 5α-reduction of testosterone to DHT is obligatory for mediating androgen's effects on the muscle. Similarly, previously published data are unclear on whether androgen's effects on sexual function in adult men are mediated through testosterone or its 5α-reduced metabolite, DHT. Although the enzyme 5α-reductase is expressed in the muscle at low levels, it is generally believed that conversion of testosterone to DHT is not obligatory for mediating its anabolic effects on the muscle.

A large body of information about the role of DHT has emerged from the study of patients with the autosomal recessive genetic disorder of steroid 5α-reductase deficiency. 46,XY males with this syndrome contain normal male internal structures including testes but exhibit ambiguous or female external genitalia at birth. At puberty, these individuals undergo partial virilization, which includes development of a male gender identity in many but not all 46,XY individuals, even if they have been brought up as females. Their development suggests that testosterone itself is able to stimulate psychosexual behavior, libido, development of the embryonic Wolffian duct, muscle development, voice deepening, spermatogenesis, and axillary and pubic hair growth. In contrast, DHT is required for prostate development and growth, the development of the external genitalia, and male patterns of facial and body hair growth or male-pattern baldness. All the 5α-reductase-deficient kindreds that have been studied to date have been shown to have mutations in steroid 5α-reductase type 2, the predominant form in the prostate. Many patients with congenital deficiency of the type 2 isoform of 5α-reductase have low or low normal DHT levels at puberty, either due to the activity of type 1 isoenzyme or due to the residual low activity of type 2 isoenzyme. Therefore, it is not clear whether the normal muscle development and male psychosexual behavior observed in many of these patients after puberty are due to the low normal DHT levels or testosterone itself.

III. MECHANISM OF ANDROGEN'S ACTION

Most of androgen's actions are mediated through its binding to an intracellular androgen receptor that acts as a ligand-dependent transcription factor. The androgen receptor has homology to other nuclear receptor proteins including the receptors for glucocorticoids, progesterone, and mineralocorticoids. The predominant 919-amino-acid, 110–114 kDa, androgen receptor protein has three conserved functional domains: the steroid-binding domain, the DNA-binding domain, and the transcriptional activation domain; of these, the central, cysteine-rich, DNA-binding domain is the most conserved. The single-copy androgen receptor gene spans a 90 kb region on chromosomal region Xq11–q12. In the absence of its ligand, the androgen receptor protein is distributed both in the nucleus and in the cytoplasm. However, androgen binding to the receptor causes it to translocate within the nucleus; the sequence between amino acids 617 and 633 of the androgen receptor is

important for its nuclear migration and transactivation function. There is emerging evidence that some of the effects of androgens may be mediated through nongenomic receptors on the cell membrane.

Binding of androgens by the androgen receptor results in conformational changes in this protein; there is evidence that binding of anti-androgens to the androgen receptor might induce a different set of conformational changes. The androgen receptor can use two transactivation domains, AF1 and AF2. The transactivation domain AF1 (including the so-called 1 and 5 regions) is located in the amino-terminal portion of the receptor, whereas AF2 is located in the carboxy-terminal, ligand-dependent domain. In the intact receptor, both AF1 and AF2 are ligand-dependent and influenced by nuclear receptor co-activators. In contrast, in a truncated androgen receptor that is missing the ligand-binding domain, AF1 becomes constitutively active. Hormone binding to the androgen receptor results in the assembly of tissue-specific co-activators and co-repressors that determine the specificity of hormone action.

In a majority of androgen target tissues, either testosterone or its 5α-reduced metabolite, DHT, binds to the androgen receptor and regulates gene expression. Testosterone binds to the androgen receptor with half the affinity of DHT, although the maximal binding capacity is similar for both androgens. The DHT–androgen receptor complex has greater thermostability and a slower dissociation rate than the testosterone–receptor complex. This may confer greater potency to DHT in mediating androgen's effects in some androgen-sensitive tissues, such as the prostate. However, the reason that 5α-reduction is necessary for mediating androgen's effects in some tissues and not others is unclear. Why this metabolic conversion step evolved for testosterone and not for other steroid hormones is also unknown.

The mutations of the androgen receptor gene have been associated with a wide spectrum of phenotypic abnormalities. Some patients with complete androgen insensitivity present with male pseudohermaphroditism characterized by female external genitalia, a blind vaginal pouch, and well-developed breasts. Other patients with androgen receptor mutations may have a male phenotype and milder abnormalities such as hypospadias, gynecomastia, and infertility.

A number of polymorphisms in the androgen receptor gene have been described; the lengths of the CAG and GCG repeats in exon 1 of the androgen receptor gene have been linked to transcriptional activity of androgen receptor protein. An abnormal length of the polyglutamine tract in exon 1 of the androgen receptor has been associated with spinal and bulbar muscular atrophy, also known as Kennedy's disease. Although some studies have reported an association of androgen receptor polymorphisms in the lengths of polyglutamine and polyglycine tracts with male infertility and risk of prostate cancer, other studies have not confirmed these findings.

IV. TESTOSTERONE'S EFFECTS ON REPRODUCTIVE ORGANS

A. Testosterone and the Prostate

Androgens are required for normal prostate development; however, it is not known whether androgens play a role in the initiation of prostate neoplasms. Conversion of testosterone to DHT is obligatory for mediating its effects on the prostate. The prostate increases in size during the peripubertal period in parallel with the rise in serum testosterone levels. Androgen imprinting prior to puberty is an important determinant of the number of stem cells within the prostate and hence adult prostate size in rats and dogs. Castration before puberty, 5α-reductase deficiency, and inactivating mutations of the androgen receptor prevent subsequent development of benign prostatic hypertrophy. Many of the effects of androgen on the prostatic epithelium are mediated through the stromal cells; thus, the interaction between the stromal cells and the epithelial cells is important for normal prostatic development. Androgen's effects on prostatic growth are mediated in part through the regulation of apoptotic genes. Androgen deficiency in adult males is associated with increased expression of many apoptotic genes, resulting in involution of the prostate.

Only the human and the dog develop benign prostatic hypertrophy. Androgens are essential, but not sufficient, for the development of benign prostatic hypertrophy. Abnormal stromal activation and dysregulation of several growth factors play a role in the pathogenesis of this complex disorder. Although androstanediol and DHT can induce prostatic enlargement in the dog, physiologic testosterone administration to hypogonadal men has not been associated with pathologic prostatic enlargement beyond the levels observed in healthy, age-matched controls. Estradiol accentuates prostatic hypertrophy induced by androgen administration in the dog. The critical role of androgens in prostatic growth is supported by clinical findings that lowering serum testosterone

levels by surgical orchidectomy or by pharmacologic inhibitors of testosterone production decreases prostate volume in men with benign prostatic hyperplasia. Similarly, clinical trials have established that finasteride, an inhibitor of 5α-reductase enzyme, produces a clinically significant reduction in prostate size in men with benign prostatic hypertrophy.

B. Testosterone and Spermatogenesis

High intratesticular testosterone concentrations are required for the initiation and maintenance of spermatogenesis. Gonadotropin deficiency resulting from hypophysectomy or administration of a gonadotropin-releasing hormone (GnRH) antagonist is associated with a marked depletion of intratesticular testosterone concentrations and azoospermia in the rat, monkey, and human male. High doses of testosterone can reinitiate and maintain spermatogenesis in rats made gonadotropin-deficient by hypophysectomy or GnRH antagonist treatment. In men with acquired gonadotropin deficiency, luteinizing hormone can reinitiate and maintain spermatogenesis by stimulating testosterone production within the testis. The mechanism by which testosterone maintains germ cell development is not well understood. Testosterone receptors are present on the Sertoli and peritubular cells, some Leydig cells, and endothelial cells of the small arterioles. However, it has not been established whether androgen receptors are also present on germ cells. It is generally believed that androgen's effects on spermatogenesis are mediated indirectly through Sertoli cells, although it is possible that testosterone might also directly affect germ cell development. Testosterone affects protein secretion by both round spermatids and Sertoli cells. The expression of androgen receptors is maximal at stages VI–VII of the seminiferous epithelium; the effects of testosterone might be exerted on the germ cells as they pass through these stages. More recent evidence suggests that testosterone regulates germ cell apoptosis in a stage-specific manner.

C. Testosterone's Effects on the Epididymis

Androgens are important regulators of epididymal structure and function. A variety of epididymal biochemical processes, such as the transport of small molecules across the epididymal epithelium, DNA and RNA synthesis, protein synthesis, activity of a number of epididymal enzymes, and maturation and storage of spermatozoa, are under androgen control. The regulation of epididymal function by androgens is highly region-specific. Some genes, such as proenkephalin, are down-regulated after castration but are not restored by androgen replacement, whereas expression of other genes, such as E-cadherin, is decreased by castration in a region-specific manner and is restored to varying degrees by androgen administration.

V. ANDROGEN'S EFFECTS ON NONREPRODUCTIVE BODY SYSTEMS

A. Androgen's Effects on Bone

Androgens are important regulators of bone maturation and maintenance of bone mass. Androgens promote linear bone growth and endochondral ossification in rats. In humans, the peri-pubertal bone accretion is androgen dependent; consequently, men with androgen deficiency during the peri-pubertal period have diminished peak bone mass. Adult men with testosterone deficiency have lower bone density than age-matched, healthy controls; testosterone replacement therapy of hypogonadal men increases but does not normalize bone density. Suppression of serum testosterone levels by administration of GnRH agonist analogues or surgical orchidectomy leads to a progressive decrease in bone density. Testosterone's effects on bone are mediated in part through its conversion to estradiol. The critical role of aromatization in mediating androgen's effects on bone is supported by observations that 46,XY men with mutations of the genes that code for the estrogen receptor or the aromatase enzyme have delayed epiphyseal fusion and decreased bone density. Also, in epidemiological studies, bioavailable estradiol levels correlate better with bone mineral density than total testosterone levels. Testosterone has additional direct effects in stimulating cortical bone formation. Androgen receptors have been demonstrated on the osteoblasts. Testosterone might also indirectly affect bone mineral density through stimulation of insulin-like growth factor-I and by increasing muscle mass and muscle strength.

B. Androgen and Body Composition—Effects on Muscle and Fat Metabolism

Testosterone is a major determinant of body composition in male mammals. The sexual dimorphism of several androgen-responsive muscles such as the masseter and levator ani in several mammalian species has been attributed to differences in androgen levels in males and females. Testosterone administration increases nitrogen retention in castrated males

of several mammalian species and in hypogonadal men, women, and boys before puberty. Recent studies have established that testosterone replacement in hypogonadal men increases fat-free mass, muscle size, and maximal voluntary strength. Supraphysiologic doses of androgens further increase muscle mass and strength in eugonadal men, especially when given in association with resistance exercise. Controlled clinical trials have demonstrated that testosterone supplementation in older men with low testosterone concentrations and in men with human immunodeficiency virus (HIV) infection or chronic obstructive lung disease and low testosterone concentrations is associated with significant gains in fat-free mass and maximal voluntary muscle strength.

Widespread abuse of androgenic steroids by athletes and recreational body builders is based on the premise that androgens promote muscle hypertrophy. Testosterone's effects on muscle mass, strength, and leg power are dependent on the administered dose of testosterone and the circulating testosterone concentrations. The effects of androgen administration on muscle performance and physical function have not been well studied, although the available evidence indicates that testosterone does not improve aerobic performance. There is some evidence that testosterone might reduce reaction time by its effects on neuromuscular transmission.

A testosterone-induced increase in muscle mass is associated with hypertrophy of both type I and type II muscle fibers but no change in muscle fiber number. Testosterone administration in healthy young men is also associated with an increase in the number of myonuclei and satellite cells. Emerging evidence suggests that testosterone stimulates the differentiation of muscle pluripotent cells into the myogenic lineage and inhibits their differentiation into the adipogenic lineage.

Androgen-deficient men have a greater amount of fat than eugonadal men. In middle-aged men, serum testosterone levels correlate inversely with visceral fat and cardiovascular risk. In healthy, young men, administration of graded doses of testosterone leads to a dose-dependent decrease in whole body fat; the decrease in fat mass occurs in both the trunk and the appendices and is evenly distributed in both the superficial subcutaneous and the deep intermuscular and visceral fat compartments. Physiologic testosterone replacement in middle-aged men with midsegment obesity decreases visceral fat, glucose, and insulin levels. Androgen's effects on body composition in men are modulated by pretreatment body composition, genetic and nutritional factors, the growth hormone secretory status, the existence of co-morbid conditions, cytokines, and exercise status.

C. Testosterone's Effects on Intermediary Metabolism and Cardiovascular Risk

Testosterone is an anabolic hormone that increases muscle mass by stimulating fractional muscle protein synthesis. The mechanism by which testosterone increases protein synthesis is not known. It has been proposed that testosterone increases muscle protein synthesis by increasing the expression of the insulin-like growth factor-I gene within the muscle. It is not known whether testosterone affects muscle protein degradation. Androgen receptors are present on adipocytes and testosterone stimulates lipolysis in some experimental models. The effects of testosterone on lipid uptake and metabolism are region-specific. Cross-sectional studies of middle-aged men demonstrate a direct correlation of serum testosterone levels with insulin sensitivity and an inverse correlation with visceral fat. However, physiologic replacement or slightly supraphysiologic doses of testosterone have not been shown to affect glucose tolerance or insulin sensitivity in lean, young men.

D. Androgen's Effects on the Skin

The hair follicles, sebaceous glands, and apocrine sweat glands in the skin are androgen-sensitive structures. Increased testosterone levels during pubertal development stimulate the growth of terminal hair in the axillary and pubic areas in both men and women and on the face in men. Excessive androgen production or action has been implicated in the pathophysiology of clinical disorders such as acne, hirsutism, androgenic alopecia, and suppurative hidradenitis. Many investigators believe that local abnormalities in androgen metabolism within the skin in hirsute women make their skin more sensitive to the effects of circulating androgens. Testosterone's effects on the skin are mediated through its conversion to DHT. Type 1 isoenzyme is the major form of steroid 5α-reductase in the skin. The highest level of activity of the steroid 5α-reductase enzyme has been located in the apocrine glands and the sebaceous glands. Inhibitors of type 1 steroid 5α-reductase enzyme in the skin, such as aliphatic unsaturated fatty acids, are being explored as therapeutic agents for the treatment of androgen-responsive skin disorders such as hirsutism and acne. Finasteride, a weak inhibitor of type 2 isoenzyme, has been approved by the Food and Drug Administration for the treatment of androgenic alopecia.

E. Androgen's Effects on Hematopoiesis, the Coagulation System, and the Vascular System

Testosterone increases red cell mass; this effect is mediated primarily by increasing the production of erythroid precursors from the pluripotent stem cells in the bone marrow. Testosterone has also been reported to increase erythropoietin production in the kidney, although other data show that testosterone can increase red cell production independent of its effects on erythropoietin. There are numerous anecdotal reports of sudden death, vascular thrombosis, myocardial infarctions, and cardiomyopathy in relatively young athletes abusing large quantities of anabolic steroids, leading to speculation that testosterone increases the thromobogenicity of plasma. However, the effects of testosterone on the coagulation system remain controversial. Fibrinogen and plasminogen activator inhibitor concentrations in plasma correlate directly with endogenous testosterone; these changes may be viewed as favoring plasma thrombogenicity. However, androgens also increase tissue plasminogen activator, protein C, and antithrombin III levels; these factors protect the body from vascular thrombosis. Testosterone and DHT increase platelet aggregation at the site of endothelial trauma. Danazol, a weak synthetic androgen, has been reported to increase platelet count. Androgens may increase vascular reactivity to trauma and decrease aortic smooth muscle prostaglandin I_2. Therefore, some effects of androgens appear to favor hypercoagulability and others appear to oppose it. The net effect in a person may vary with the type and dose of androgen used, genetic predisposition, simultaneous use of other medications, and the presence of co-morbid conditions.

F. Androgens and Plasma Lipids and Cardiovascular Risk

The effects of androgens on plasma lipids depend on the dose (physiologic or supraphysiologic), the route of administration (oral or systemic), and the type of androgen used (aromatizable or not aromatizable). Supraphysiologic doses of testosterone and other androgenic steroids decrease plasma high-density lipoprotein (HDL) cholesterol levels in men. Androgenic steroids that can be aromatized produce a smaller decrease in high-density lipoprotein levels than those that cannot be aromatized. Lowering serum testosterone levels experimentally by GnRH antagonist administration increases plasma HDL cholesterol levels; conversely, testosterone replacement of hypogonadal men modestly lowers plasma HDL cholesterol levels. Other studies using physiologic replacement doses in older men or HIV-infected men have reported either no change or only minor changes in plasma lipid profiles. Cross-sectional epidemiological studies demonstrate a direct relationship between serum testosterone levels and HDL cholesterol levels and an inverse relationship between testosterone levels and visceral fat. Therefore, these data suggest that testosterone levels in the mid- to high normal range may be optimum for cardiovascular health in men. Indeed, physiologic testosterone replacement decreases visceral fat, glucose, and insulin levels in middle-aged men with visceral obesity. It is not known what testosterone levels are consistent with optimum cardiovascular risk in men.

The prevalent dogma that physiologic testosterone replacement increases cardiovascular risk and accelerates atherosclerosis progression is not supported by data. Of the 30 cross-sectional studies reviewed by Alexanderson *et al*., 18 reported lower testosterone concentrations in men with coronary artery disease than in age-matched controls, 11 reported similar levels, and only 1 study reported higher concentrations of dehydroepiandrosterone sulfate in men with coronary artery disease than age-matched controls. In mice with low-density lipoprotein receptor mutations, surgical orchidectomy is associated with accelerated atherogenesis, and testosterone replacement retards atherosclerosis progression. Testosterone infusion has been reported to improve coronary blood flow in humans and dogs. Testosterone's effects on blood vessel walls require its conversion to estradiol because concomitant administration of an aromatase inhibitor can attenuate the beneficial effects of testosterone in retarding atherogenic lesions. The effects of testosterone replacement on atherosclerosis progression in older men with low testosterone levels have not been studied.

VI. TESTOSTERONE'S EFFECTS ON BEHAVIOR

A. Androgen's Effects on Sexual Function

Sexual function in men is a complex multicomponent process that includes central mechanisms for the regulation of sexual desire and arousability and local mechanisms for penile tumescence, orgasm, and ejaculation. The primary effects of testosterone are on sexual interest and motivation. Observations that eunuchs and hypogonadal men can have erections are consistent with the proposal that testosterone regulates libido rather than erectile function. Davidson

et al. demonstrated that although overall sexual activity is reduced in hypogonadal men, these patients have a normal erectile response to visual erotic stimuli. Testosterone replacement of young, androgen-deficient men improves a wide range of sexual behaviors including frequency of sexual activity, sexual daydreams, sexual thoughts, feelings of sexual desire, spontaneous erections, episodes of nocturnal penile tumescence, and the duration of penile erections in response to visual erotic stimuli. Testosterone regulates nitric oxide synthase activity in the cavernosal smooth muscle, and it is possible that achievement of optimal penile rigidity might require physiologic testosterone concentrations. Orgasm and ejaculation are androgen-independent. In male mammals, relatively low normal levels of serum testosterone can maintain sexual function.

There is considerable confusion among clinicians with respect to the relationship between androgen deficiency and erectile dysfunction. In middle-aged and older men, erectile dysfunction and androgen deficiency are two common but independently distributed clinical disorders that sometimes co-exist in the same patient. Eight to 10% of men presenting with erectile dysfunction have low testosterone levels. The prevalence of low testosterone levels is not significantly different between middle-aged and older men with impotence and those without impotence. Testosterone administration does not improve sexual function in impotent men with normal testosterone levels. On the other hand, many, but not all, older men with low testosterone levels experience improvements in their libido and overall sexual activity with androgen replacement therapy. The response to testosterone supplementation in this group of men is variable because of the co-existence of other disorders such as diabetes mellitus, hypertension, cardiovascular disease, and psychogenic factors. A meta-analysis of the usefulness of androgen replacement therapy concluded that testosterone administration is associated with greater improvements in sexual function than placebo treatment in men with sexual dysfunction and low testosterone levels. However, previous studies of testosterone replacement in older men have been flawed because of failure to include a placebo-control group, small sample sizes, selection of men with erectile dysfunction associated with multiple systemic illnesses, which may attenuate the response to testosterone therapy, and inclusion of men with normal testosterone levels. Testosterone might also favorably affect marital interactions and intimacy due to an overall increase in sexual desire and sense of well-being, independent of the change in erectile function; this hypothesis has not been examined.

In rats, mating behavior can be maintained at serum testosterone levels that are at the lower end of the normal male range. Similarly, in men in whom endogenous testosterone secretion has been suppressed by a GnRH agonist, low doses of testosterone that bring serum testosterone levels to the lower end of the normal range can maintain sexual desire and activity and nocturnal erections. However, supraphysiologic doses of testosterone might further increase some aspects of sexual arousability.

The role of 5α-reductase in mediating androgen's effects on sexual function remains unclear. Although DHT can restore sexual behavior in castrated monkeys, patients with 5α-reductase deficiency have normal libido and erectile function. Furthermore, the relatively low frequency of sexual dysfunction in men treated with finasteride, an inhibitor of 5α-reductase enzyme, suggests that testosterone conversion to DHT is not required for androgen's effects on sexual function. Important insights into the role of 5α-reduction in regulating male sexual behavior have emerged from the studies of a synthetic steroid, 7α-methyl-19-nortestosterone (MENT). This androgen binds the androgen receptor and exerts biologic effects at some peripheral tissues with a greater potency than testosterone. *In vivo*, MENT does not undergo 5α-reduction. MENT, when administered to castrated rats, maintains full copulatory behavior similar to that observed in testosterone-treated rats. These studies of MENT suggest that 5α-reduction of testosterone is not necessary for maintaining normal mating behaviors in the male rat. However, penile nitric oxide synthase activity in the rat is stimulated by testosterone, and it is possible that conversion of testosterone to DHT may be required for achieving penile rigidity.

B. Testosterone's Effects on Nonreproductive Behaviors

Testosterone is aromatized to estradiol in the brain and some effects of testosterone may be mediated through its conversion to estradiol. However, androgen receptors are expressed in specific regions of the brain and likely mediate some of testosterone's organizational effects during brain development and some activational effects postnatally. There are gender differences in the distribution of androgen receptor in the human hypothalamus.

During fetal life, testosterone is essential for sexual differentiation of the brain along male lines.

There are structural sex differences in the volume and the synaptic organization of many brain nuclei or regions. Testosterone promotes aggression among males, particularly at the time of mate selection. The scent marking behavior, a marker for territoriality, is testosterone-dependent in many mammalian males. The effects of testosterone on human aggression remain controversial. There is a significant, though not strong, correlation between serum testosterone levels and some aspects of aggressive behavior in men. A significant proportion of anabolic steroid users report mood disorders, manic and hypomanic syndromes characterized by aggressiveness, and other psychiatric disorders. Administration of high doses of testosterone to men is associated with increased aggressive responses compared to placebo. However, other well-controlled studies have failed to find clear increases in aggressive behaviors in androgen-treated men. Testosterone affects the development of sex-typed nonreproductive behaviors such as maze learning and juvenile play. Androgens are considered to be responsible for the greater visuospatial ability and lower verbal ability in men than in women. Exposure to testosterone through its conversion to estradiol during the neonatal period is responsible for the development of brain structures that subserve spatial functions. Alterations of androgen levels in adult animals do not affect spatial processing but may influence memory storage and affective properties.

The data on the relationship of circulating androgen concentrations with cognitive function are conflicting. Androgen's effects on cognitive function are domain-specific. Observations that men outperform women in a variety of visuospatial skills suggest that androgens enhance visuospatial skills. Clinical trials in older men suggest that testosterone administration might enhance visuospatial skills and verbal memory. Hypogonadal men perform worse on tests of verbal fluency than eugonadal men and show improvement after testosterone replacement. In transsexual males, administration of anti-androgen and estrogen decreases anger and aggression, sexual arousability, and spatial skills and increases verbal fluency. Conversely, testosterone administration to female transsexuals decreases verbal fluency and increases spatial skills.

The reported literature on testosterone and cognition is equivocal but these inconsistencies should not be interpreted to mean that there is no effect. Furthermore, previous studies of androgen supplementation have focused on a very limited number of domains. Prospective, randomized, placebo-controlled trials are needed to comprehensively determine the effects of testosterone supplementation over a wider range of doses on a number of domains of cognitive function.

VII. TESTOSTERONE REPLACEMENT IN ANDROGEN-DEFICIENT MEN

Testosterone, when administered by mouth, is absorbed readily from the gastrointestinal tract; however, most of it is destroyed during its first pass through the liver. Therefore, an appropriate delivery system is needed to achieve sustained levels of testosterone in the blood. Because of the potential contraceptive and anabolic applications of androgens, there has been considerable interest in developing more physiologic and long-acting testosterone delivery systems (Table 1).

A. Testosterone Esters

Esterification of the 17β-hydroxyl group makes the compound more hydrophobic. Therefore, when these esters are injected in an oil suspension in the muscle, they are absorbed very slowly from the muscle depot into the bloodstream. It is the slow release rather the slow deesterification that accounts for the extended duration of testosterone esters. The longer the side chain, the more hydrophobic the compound and the longer the duration of action. Testosterone enanthate and cypionate, the two commonly used testosterone esters, have identical kinetics. After injection of 200 mg testosterone enanthate or cypionate, the usual replacement dose in hypogonadal men, serum testosterone levels rise into the supraphysiologic range within 24 to 48 h and then gradually decline into the hypogonadal range 10–17 days later. These fluctuations in serum testosterone levels are associated with changes in the patient's mood and energy level and are a major drawback of this formulation. Variations in serum testosterone levels during treatment with testosterone esters can be minimized by giving 100 mg of testosterone enanthate or cypionate every week. With administration of physiologic replacement doses, serum levels of estradiol and DHT are normal. Given an adequate dose, testosterone esters can produce virilization, restore sexual function, and increase muscle mass, bone mass, and hematocrit in hypogonadal men.

B. Testosterone Transdermal Systems

Three transdermal testosterone systems are commercially available to treat hypogonadal men: a scrotal

TABLE 1 Clinical Pharmacology of the Testosterone Formulations

Formulation	Regimen	Pharmacokinetic profile	DHT and estradiol	Advantages	Disadvantages
Testosterone enanthate or cypionate (127–129)	100 mg im weekly or 200 mg im every 2 weeks	After a single im injection, serum T levels rise into the supraphysiological range and then decline gradually into the hypogonadal range by the end of the dosing interval (127–129)	DHT and E2 levels rise in proportion to the increase in T levels; T:DHT and T:E2 ratios do not change	Corrects symptoms of androgen deficiency; relatively inexpensive, if self-administered; flexibility of dosing	Requires im injection; peaks and valleys in serum T levels
Scrotal testosterone patch (130–131)	One scrotal patch designed to nominally deliver 6 mg over 24 h, applied daily	Normalizes serum T levels in many but not all androgen-deficient men	Serum E2 levels are in the physiological male range, but DHT levels rise into the surpraphysiological range; T:DHT ratio is significantly lower than in healthy men (130–132)	Corrects symptoms of androgen deficiency	To promote optimum adherence of the patch, scrotal skin needs to be shaved; high DHT levels
Nongenital transdermal system (133–134)	One or two patches, designed to nominally deliver 5–10 mg T over 24 h, applied daily on nonpressure areas	Restores serum T, DHT, and estradiol levels into the physiological male range	T:DHT and T:E2 levels are in the physiological male range	Ease of application; corrects symptoms of androgen deficiency; mimics the normal diurnal rhythm of testosterone secretion; lesser increase in hemoglobin than injectable esters	Serum testosterone levels in some androgen-deficient men may be in the low normal range; these men may need application of two patches daily; skin irritation at the application site may be a problem for some patients
Testosterone gel	Testosterone gel containing 50–100 mg testosterone, should be applied daily	Restores serum T and estradiol levels into the physiological male range	Serum DHT levels and T:DHT ratios are lower in hypogonadal men treated with the testosterone gel than in healthy eugonadal men	Corrects symptoms of androgen deficiency; provides flexibility of dosing; ease of application; good skin tolerability	Potential of transfer to a female partner or child by direct skin-to-skin contact; moderately high DHT levels
17α-Methyl testosterone (135)	Orally active, 17α-alkylated compound that should not be used because of potential for liver toxicity	Orally active			Clinical responses variable; potential for liver toxicity; should not be used for treatment of androgen deficiency
Testerone pellets	Three or four 200 mg pellets inserted under the skin	Maintains serum T and free T in normal range for 3–4 months	Normal DHT and E2 concentrations	Long duration	Requires insertion through a trocar
Testosterone undecanoate	80–160 mg daily	Serum T increases transiently into normal range, but needs 3–4 times a day administration	High DHT but normal E2 concentrations	Oral route	Requires insertion through a trocar; spontaneous extrusion; suboptimal clinical responses; variability in serum T levels

Note. DHT, dihydrotestosterone; E2, 17β-estradiol; im, intramuscular; T, testosterone.

testosterone patch (Testoderm, ALZA Corp., Palo Alto, CA) and two nongenital patches (Androderm, Watson Pharmaceuticals, Pomona, CA; Testoderm TTS, ALZA Pharmaceuticals, Mountainview, CA).

Scrotal patches deliver either 4 or 6 mg/day of testosterone depending on their size. Serum testosterone levels in hypogonadal men peak in the midnormal range 4 to 8 h after application of the patch and then decline through the day in a pattern similar to the circadian pattern in normal young men. Hypogonadal men treated with the scrotal patch have normal serum estradiol levels but much higher DHT levels than untreated eugonadal men. This is likely the result of the high activity level of 5α-reductase in the scrotal skin. It is not known whether long-term exposure to high serum DHT levels will have deleterious effects on the prostate or whether intraprostatic DHT levels are also elevated.

Two nongenital transdermal systems, Androderm and Testoderm, can maintain physiologic testosterone levels in hypogonadal men. Four to 12 h after application of the patch, serum testosterone and estradiol levels are in the midnormal range. The nongenital patches also produce physiologic levels of serum DHT and estradiol and normal DHT:testosterone and estradiol:testosterone ratios. Some patients treated with the patches may experience skin irritation at the site of patch application.

C. Oral Testosterone Formulations

17α-Alkylation of testosterone makes it less susceptible to hepatic degradation. However, these 17α-alkylated androgens should not be used because of the potential for hepatotoxicity. Testosterone undecanoate, an oral form of testosterone, when administered in oleic acid, is absorbed preferentially through the intestinal lymphatics into the lymphatic duct and general circulation and is therefore spared the first-pass degradation in the liver. Its short half-life necessitates dosing two to three times per day for clinical effects. Circulating levels of testosterone vary among subjects receiving the same dose of this formulation; overnight levels are low and clinical response is not as good as with other forms of testosterone. A sublingual preparation of cyclodextrin-complexed testosterone is rapidly absorbed from the sublingual mucosa into the bloodstream, leading to rapid peaks in serum testosterone levels followed by a decline within 2 h. Frequent dosing several times a day is necessary to maintain normal serum levels.

D. Novel Androgen Formulations under Development

Interest in developing more physiologic, sustained-release testosterone formulations has increased due to the potential application of testosterone as an anabolic agent and as a male contraceptive. With long-acting injectable testosterone preparations (testosterone buciclate, 600 mg intramuscularly every 3 to 4 months), serum levels peak at 6 weeks and can remain in the normal range for 12 weeks. Testosterone pellets (three 200 mg pellets or six 100 mg pellets) are implanted under the skin and can provide normal testosterone levels as well as physiologic levels of estradiol and DHT for up to 6 months. A single intramuscular injection of a biodegradable testosterone microsphere formulation produces normal levels of testosterone in hypogonadal men for up to 11 weeks; serum estradiol and DHT levels are maintained in the normal range. A number of transdermal, buccal, sublingual, parenteral, and oral testosterone formulations are currently under development.

VIII. ANABOLIC EFFECTS OF ANDROGENS IN PATIENTS WITH CHRONIC ILLNESSES AND AGE-RELATED FRAILTY

Many chronic illnesses such as cancer, HIV infection, chronic obstructive lung disease, and end-stage renal disease are associated with substantial loss of muscle mass and function. Although these diseases are not yet curable, disease stability can often be achieved. Muscle wasting in these illnesses produces debility and is associated with poor quality of life, adverse disease outcomes, and increased utilization of health care resources. There is a high prevalence of low testosterone levels in these sarcopenic disorders. Furthermore, low testosterone levels correlate with loss of muscle mass and exercise capacity. Because testosterone replacement in hypogonadal men increases lean body mass and muscle strength, it has been speculated that testosterone supplementation in men with chronic illnesses such as HIV infection will have similar anabolic effects. Clinical trials have shown that androgen administration in HIV-infected men is associated with modest increases in fat-free mass, hematocrit, and some aspects of health-related quality of life. However, further studies are needed to determine whether testosterone replacement can produce clinically meaningful changes in muscle function or disease outcomes in patients with chronic illnesses.

There is agreement that total and free testosterone levels and testosterone production rates are lower in older men than in young healthy men. Some studies that exclusively recruited healthy, middle-income older men failed to detect significant differences in serum testosterone levels between old and young men. Recent studies with more representative population samples have reconfirmed the age-related decrease in serum testosterone levels. Interpretation of serum testosterone levels in the older men in these studies has been complicated by several confounding factors: the cross-sectional nature of these studies, the loss of diurnal variation in serum testosterone levels in the elderly so that studies that obtain samples in the afternoon underestimate the age-related changes in testosterone levels, and higher sex hormone-binding globulin levels in older men so that total testosterone levels underestimate the greater decline in free testosterone levels (both dialyzable and bioavailable). A meta-analysis of 44 studies of testosterone levels in older men demonstrated an unequivocal decrease in morning testosterone levels. Recent longitudinal studies of normal men have verified the age-related decline in serum testosterone levels. Lower testosterone levels are the result of changes at multiple levels of the hypothalamic–pituitary–gonadal axis. Testicular response to gonadotropins is diminished in older men, gonadotrope responsiveness to androgen suppression is attenuated, and the pulsatility of the hypothalamic GnRH pulse generator is altered. In addition, there are abnormalities of feed-forward and feedback systems. Co-existing diseases, malnutrition, and concomitant medications also affect serum testosterone levels. A number of clinical problems prevalent in older men may be related to androgen deficiency, including sexual dysfunction, muscle weakness and wasting, changes in body composition, osteopenia, increased prevalence of hip and vertebral fractures, decreased body hair, decreased hematopoiesis, and memory loss. It has been speculated but not proven that androgen replacement may help prevent or reverse these disorders. Four long-term studies of 1 to 3 years in duration have demonstrated that testosterone supplementation in older men with low testosterone levels is associated with modest increases in fat-free mass, grip strength, and hematocrit and a decrease in fat mass. The frequency of adverse events associated with testosterone administration has been low in these studies, although these studies were not powered to detect significant increases in prostate or cardiovascular event rates. Furthermore, the effects of physiologic testosterone replacement on health-related outcomes such as fracture rates, falls, disability, cognitive function, progression to dementia, and psychosexual function have not been rigorously evaluated in adequately powered studies. Thus, the long-term risks and benefits of testosterone supplementation in older men remain largely unknown.

Glossary

anabolic steroid Any substance related to the male sex hormone testosterone that promotes the growth of skeletal muscle (anabolic effects) and the development of male sexual characteristics (androgenic effects).

andropause A controversial term used to describe the clinical syndrome associated with the age-related decline in serum testosterone concentrations in older men. There is considerable debate over whether the age-related decline in serum testosterone concentrations is clinically important and whether this should be corrected by testosterone replacement.

aromatase CYP19 An enzyme associated with cytochrome P450 that catalyzes the final step in the biosynthesis of C-18 estrogens from C-19 steroids and converts the A ring into an aromatic ring.

dietary steroidal supplements Compounds such as dehydroepiandrosterone (DHEA) and androstenedione that can be purchased in the United States without a prescription through many health food stores. They are often taken because the user believes they have anabolic effects. Steroidal supplements such as DHEA and androstenedione can be converted into testosterone and other sex steroids in the body.

steroid 5α-reductase An enzyme complex that converts testosterone to 5α-dihydrotestosterone. It has two isoforms that have different biochemical properties and tissue distribution.

testosterone esters The compounds that result from esterification of testosterone at the 17β-hydroxy position. Two common, clinically used testosterone esters include testosterone enanthate and testosterone cypionate.

Androgen Receptor Crosstalk with Cell Signaling Pathways

ZORAN CULIG, HELMUT KLOCKER, GEORG BARTSCH, AND ALFRED HOBISCH

University of Innsbruck, Austria

The androgen receptor (AR) is a nuclear transcription factor that regulates the expression of specific genes in male reproductive and visceral organs. The function of the human AR has been investigated in models of prostate carcinoma and in heterologous cells that transiently express wild-type or mutated steroid receptors. The AR can be activated in a ligand-independent manner by a number of cellular regulators. AR activation by peptide growth factors, agents that stimulate protein kinase A activity, interleukin-6, and the differentiation agent phenylbutyrate has been investigated in detail. Ligand-independent activation of the AR has implications regarding the regulation of both proliferation and differentiation. Cellular regulators potentiate AR activity induced by low concentrations of androgenic hormones. This mechanism is, at least in part, relevant to the failure of endocrine therapy in prostate cancer but it might also occur in other tissues. Although in some cases AR antagonists inhibit AR activation by intracellular kinase pathways, there are also examples of their diminished efficiency in the presence of nonsteroidal regulators of AR function. It is hypothesized that nonsteroidal AR activators modulate receptor phosphorylation, most probably in the N-terminus.

I. STEROID RECEPTORS AND NONSTEROIDAL ACTIVATION

In the 1990s, it became clear that steroid receptors are activated not only in the classical way by their respective ligands but also by a variety of nonsteroidal compounds, which in turn stimulate intermediary signal transducers activating protein kinases. Early studies on steroid receptor activation by cellular regulators were focused mainly on the human estrogen receptor-α, which is a classic example of activation by growth factors and analogues of cAMP in the absence of ligand. In contrast, human progesterone and glucocorticoid receptor display ligand-dependent activation in the presence of growth

Androgen Receptor Crosstalk with Cell Signaling Pathways

ZORAN CULIG, HELMUT KLOCKER, GEORG BARTSCH, AND ALFRED HOBISCH

University of Innsbruck, Austria

The androgen receptor (AR) is a nuclear transcription factor that regulates the expression of specific genes in male reproductive and visceral organs. The function of the human AR has been investigated in models of prostate carcinoma and in heterologous cells that transiently express wild-type or mutated steroid receptors. The AR can be activated in a ligand-independent manner by a number of cellular regulators. AR activation by peptide growth factors, agents that stimulate protein kinase A activity, interleukin-6, and the differentiation agent phenylbutyrate has been investigated in detail. Ligand-independent activation of the AR has implications regarding the regulation of both proliferation and differentiation. Cellular regulators potentiate AR activity induced by low concentrations of androgenic hormones. This mechanism is, at least in part, relevant to the failure of endocrine therapy in prostate cancer but it might also occur in other tissues. Although in some cases AR antagonists inhibit AR activation by intracellular kinase pathways, there are also examples of their diminished efficiency in the presence of nonsteroidal regulators of AR function. It is hypothesized that nonsteroidal AR activators modulate receptor phosphorylation, most probably in the N-terminus.

I. STEROID RECEPTORS AND NONSTEROIDAL ACTIVATION

In the 1990s, it became clear that steroid receptors are activated not only in the classical way by their respective ligands but also by a variety of nonsteroidal compounds, which in turn stimulate intermediary signal transducers activating protein kinases. Early studies on steroid receptor activation by cellular regulators were focused mainly on the human estrogen receptor-α, which is a classic example of activation by growth factors and analogues of cAMP in the absence of ligand. In contrast, human progesterone and glucocorticoid receptor display ligand-dependent activation in the presence of growth

factors or peptide hormones. The function of the human androgen receptor (AR) has been studied in prostate cancer models and in heterologous cells that are transiently transfected with AR cDNA. The AR is a nuclear transcription factor that is expressed in benign prostate tissue and nearly all prostate cancers and is involved in the regulation of proliferation and differentiation. This article will summarize findings on the crosstalk between signaling pathways of peptide hormones and cytokines and that of the AR. It is particularly interesting that nonsteroidal activation of the AR has been observed both with compounds that stimulate and with those that retard tumor cell proliferation. Data regarding the action of AR antagonists in the presence of nonsteroidal receptor activators and the involvement of protein kinases will also be presented.

II. PEPTIDE GROWTH FACTORS AND ANDROGEN RECEPTOR FUNCTION

The growth of the prostate gland is regulated by, in addition to steroid hormones, several growth factors in a paracrine or an autocrine manner. In the late stages of prostate cancer, expression of growth factors or their receptors is frequently disregulated and therefore their potential interactions with other signaling pathways are of special interest. Interactions between these polypeptides and the AR were initially studied in DU-145 prostate cancer cells, which lack endogenous steroid receptors. In transient transfection experiments, AR ligand-independent activation was caused by insulin-like growth factor-I (IGF-I), keratinocyte growth factor (KGF), and epidermal growth factor (EGF). In that experimental system, IGF-I was a more potent AR activator than KGF or EGF and it was effective with three different androgen-responsive reporters. Thus, although there are structural and functional similarities between the AR and human progesterone and glucocorticoid receptors, only the AR could be activated in the absence of ligand. Proliferation of prostate cells is stimulated by IGF-I, and IGF receptors are detectable in the majority of prostate cancers. IGF-II, which binds to IGF receptor type I with lower affinity than IGF-I, was not effective in co-transfection–transactivation experiments. The importance of IGF-I activation of the AR could reflect the fact that elevated serum IGF-I is associated with prostate cancer risk.

The effect of KGF on the AR was seen with a reporter gene that was driven by a promoter consisting of two androgen-responsive elements in front of the TATA box. KGF is a stromal growth factor that is, in co-culture models, induced by androgenic hormones and whose receptor is expressed on the surface of epithelial cells. Experiments performed on explant cultures of developing rat seminal vesicle and prostate tissues provided evidence that the crosstalk between KGF and the AR is important *in vivo*. KGF-stimulated development was blocked by anti-androgens, in concordance with findings previously reported for transfected prostate cancer cells. The growth of prostate primary epithelial cultures was stimulated by KGF and the effect was abolished by the anti-androgen hydroxyflutamide. Taken together, these findings demonstrate up-regulation of AR function by KGF.

In addition to ligand-independent activation of the AR, growth factors potentiate receptor activation via low concentrations of androgen. Synergistic ligand-dependent activation of the AR was also observed with other cellular regulators and is pathophysiologically significant. Low concentrations of androgenic hormones persist in patients who receive endocrine therapy for advanced carcinoma of the prostate. AR activation in conditions in which androgen levels are substantially reduced might be, at least in part, responsible for failure of androgen ablation. In PC-3 prostate cancer cells stably transfected with the AR, dihydrotestosterone and EGF regulated the proliferative response in a synergistic manner. This might be due to both AR activation by EGF and EGF receptor up-regulation by androgen.

HER-2/neu tyrosine kinase is an EGF receptor-related molecule that is expressed at high levels in androgen-independent sublines of the LAPC-4 prostate cancer xenograft. Similar to previously reported effects of EGF, ligand-independent and synergistic activation of the AR by HER-2/neu was documented (Fig. 1). This activation resulted in induction of expression of the endogenous androgen-regulated prostate-specific antigen (PSA) gene. The AR is involved in the regulation of molecules that govern cell cycle progression, such as cyclin-dependent kinases. Enhanced AR activity induced by growth factors and HER-2/neu might therefore facilitate tumor progression. Interestingly, the nonsteroidal anti-androgens hydroxyflutamide and bicalutamide were less efficient at blocking AR activation by HER-2/neu than at blocking AR activation induced by androgenic hormones. A substantial reduction of the ligand-independent effect was achieved with an inhibitor of the mitogen-activated protein kinase (MAPK) signaling pathway and MAPK phosphatase. The effect of HER-2/neu on

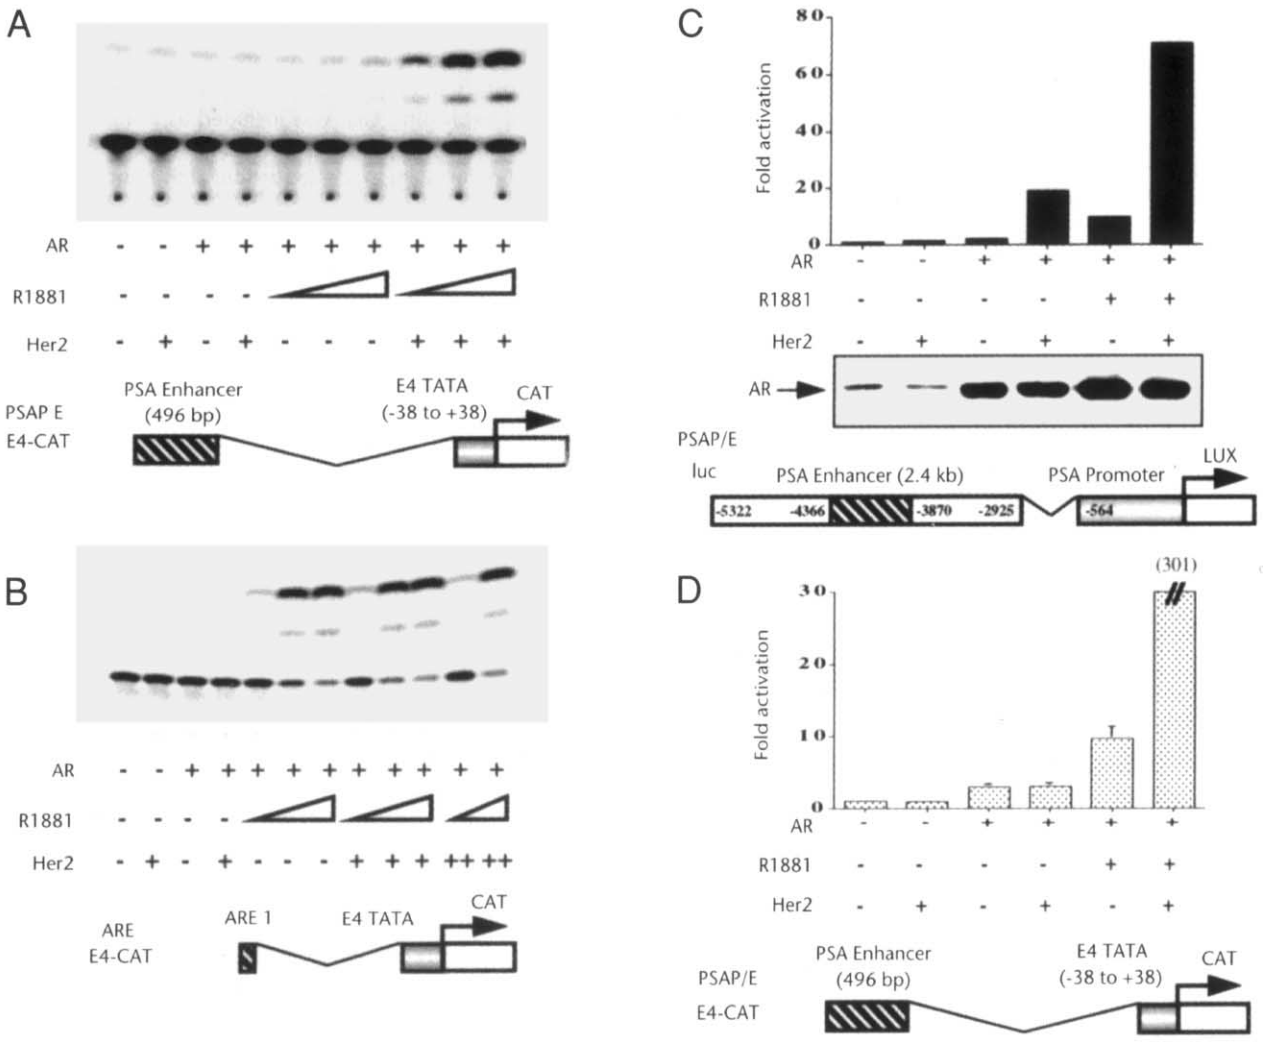

FIGURE 1 Effects of HER-2/neu on androgen receptor function. (A) TS-13 hamster kidney epithelial cells were transfected with PSA P/E luc in conjunction with plasmids expressing androgen receptor (AR) and/or HER-2 in various combinations and in the presence or absence of 1.0 nM R1881 (+ or −). Expression of AR was measured by immunoblot analysis of whole-cell lysates. Luciferase results are expressed as the fold activation relative to TS13 cells transfected with PSA P/E luc in the absence of AR, HER-2/neu, and R1881, which was designated as onefold. (B) Similarly, TS-13 cells were transfected with the PSA E E4-CAT reporter construct in the presence or absence of AR, HER-2/neu, and/or 1.0 nM R1881. CAT results were analyzed by thin-layer chromatography and quantitated using a phosphorimager. Data are expressed as the fold activation relative to TS13 cells transfected with PSA E E4-CAT in the absence of AR, HER-2/neu, and R1881, which was designated as onefold, and represent the mean of three independent experiments. (C) Dose response of the PSA E E4-CAT reporter to R1881, generated by transfection of TS13 cells with AR [HER-2/neu with R1881 at concentrations of 0.1, 0.3, and 1.0 nM (wedges)]. CAT activity was measured by thin-layer chromatography. At higher doses of R1881, the PSA E E4-CAT construct was maximally activated and no additional effect of HER-2/neu was observed (data not shown). (D) Dose response of a reporter containing a single androgen-response element (ARE E4-CAT) to R1881 with AR [HER-2/neu with R1881 at concentrations of 0.01, 0.1, and 1.0 nM (wedges)]. CAT activity was measured by thin-layer chromatography. The two rightmost lanes contain higher doses of HER-2/neu plasmid (++). Reprinted from Craft *et al.*, 1999, *Nat. Med.* **5**, 280–285, with permission.

AR function was also seen in LNCaP cells in which AR protein levels did not change following transfection. The HER-2/neu effect on the AR requires functionality of the phosphatidylinositol (PI) 3-kinase pathway. The AR is phosphorylated at serine residues 213 and 791 by Akt, which is downstream of PI 3-kinase. Consistent with these observations, constitutively active Akt stimulated an androgen-inducible

reporter, and a dominant-negative mutant abolished the effect of HER-2/neu. Another example of the inability of AR antagonists to reduce nonsteroidal regulation of AR-mediated gene expression is activation by the protein kinase C pathway inducer, phorbol ester. The outcome of experiments to investigate nonsteroidal activation is cell type-dependent. In CV-1 and HeLa cells, mainly androgen-dependent effects of growth factors on AR transcriptional activity were noted.

III. ANDROGEN RECEPTOR ACTIVATION AND PROTEIN KINASE A SIGNALING PATHWAY

In addition to being influenced by growth factors, prostate cell growth is affected by peptide hormones and neurotransmitters that increase intracellular levels of cAMP and activate protein kinase A (PKA). AR activation by forskolin (which activates adenylylcyclase to synthesize cAMP and stimulates PKA activity) in monkey kidney and prostate cancer cell lines that transiently expressed the AR was investigated. It was confirmed that the AR could be activated in a ligand-independent manner and that AR antagonists block the activity in these circumstances. Forskolin was maximally efficient at a concentration of 1 μM. In the same series of experiments, forskolin showed a synergistic rather than a ligand-independent effect with the human progesterone receptor, thus pointing to specificity of action. In transfected cells, there were no changes in AR expression following forskolin treatment. AR mutants that lack the DNA-binding domain could not be activated by forskolin, and there is also evidence that residues of the N-terminal region of the AR are needed for AR activation through the PKA pathway. The extent of ligand-independent activation of the AR depends on cell type, promoter, presence of an endogenous or a transfected AR, and the use of a particular inducer of PKA activity. Forskolin was more efficient with reporter constructs that consisted of natural probasin and PSA promoters coupled to the luciferase gene than with the reporter that was driven by a promoter consisting of three androgen-response elements (Fig. 2). It is clear that the PKA pathway has an important role in the regulation of function of the AR since forskolin also up-regulated PSA secretion in prostate explants. From experiments with the PKA inhibitor PKI, it became obvious that the PKA signal transduction cascade is also implicated in receptor activation by ligand. Administration of the inhibitor partially reduced androgen-induced AR activity and similar findings were reported for other steroid receptors.

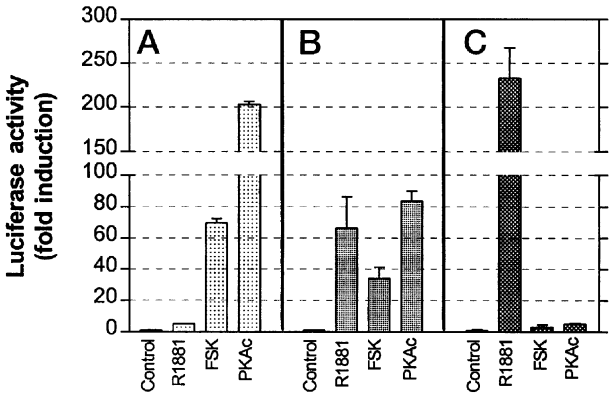

FIGURE 2 Induction of the activities of androgen-responsive promoters by forskolin and PKA. LNCaP cells were transfected with 1.0 μg of PSA (−630 to +12) (A), PB (B), or ARR_3-tk-luciferase reporter constructs (C) and either with or without the expression vector for the catalytic subunit of PKA (PKAc, 0.5 μg). Cells were incubated with forskolin (FSK, 50 μM), R1881 (10 nM), or vehicle (Me_2SO, 0.5%) for 48 h under serum-free conditions and harvested, and luciferase activities were measured. The normalized luciferase activities were divided by the normalized activity of cells transfected with reporter plasmid and with empty PKAc plasmid to give the fold induction. IV. REGULATION OF ANDROGEN RECEPTOR ACTIVITY BY PLEIOTROPIC COMPOUNDS

Luteinizing hormone-releasing hormone (LHRH) analogues are used for prostate cancer therapy because their systemic application leads to long-term suppression of serum androgen levels. Prostate cancer cells express LHRH receptors and their growth is differentially affected by LHRH. Modest AR activation by LHRH analogues was observed in transfected cells, and these compounds reduced the concentration of androgen needed for maximal activation of the AR.

There is an increasing interest in AR activation by interleukin-6 (IL-6). IL-6 is a multifunctional cytokine that is involved in the regulation of immune and inflammatory responses and causes direct effects in target tissues. In prostate cells, IL-6 either induces G1 growth arrest or acts as an anti-apoptotic factor. IL-6 is of special interest in human prostate cancer because its serum levels increase in patients with metastatic disease. IL-6 ligand-independent and synergistic activation of the AR was demonstrated both in cells

that transiently express the AR and in LNCaP cells in which expression of the PSA gene was up-regulated in response to IL-6. LNCaP cells were growth-inhibited by IL-6 and it was concluded that IL-6-induced activation of the AR is important for the maintenance of prostatic differentiation function. There is no evidence of changes in AR expression by a nonsteroidal compound in any cell line transiently transfected with AR cDNA. In contrast, IL-6 increases the activity of the endogenous AR gene promoter, AR mRNA, and protein in LNCaP cells. Thus, in that cell line, IL-6-induced AR activity is associated with increased protein expression. In concordance with these observations, nuclear localization of the AR was enhanced by IL-6. The AR nonsteroidal antagonists hydroxyflutamide and bicalutamide nearly completely blocked AR activation. The two major signaling pathways of IL-6 in target cells are those of Janus kinases, which in turn lead to nuclear translocation and activation of signal transducers and activators of transcription (STAT) and MAPK. Inhibitors of these pathways as well as those of PKA and PKC down-regulate the effect of IL-6 on the AR. In contrast, the inhibitor of the PI 3-kinase pathway, wortmannin, was ineffective (Fig. 3).

The presence of IL-6 and its receptor was investigated in prostate cells by immunohistochemistry. It was revealed that, in benign prostate tissue, IL-6 expression is confined to basal cells, whereas tumor cells themselves acquire the ability to produce IL-6. Prostate stromal cells secrete large amounts of IL-6 into their supernatants. The IL-6 receptor, which consists of the ligand-binding subunit gp 80 and the signal-transducing subunit gp 130, is present in benign and malignant prostate tissues. IL-6 binding to the receptor activates intracellular signaling by protein kinase pathways that leads to the activation of the AR. Because of the presence of IL-6 and the AR in prostate tissues, one can conclude that the cross talk between IL-6 and the AR is significant for numerous cellular events. The crosstalk between androgen and the IL-6 signaling cascade is bidirectional; androgenic hormones enhance activation of STAT3 and expression of classic IL-6-target genes. Endogenous protein inhibitors of activated STAT3 down-regulate AR activity induced by IL-6.

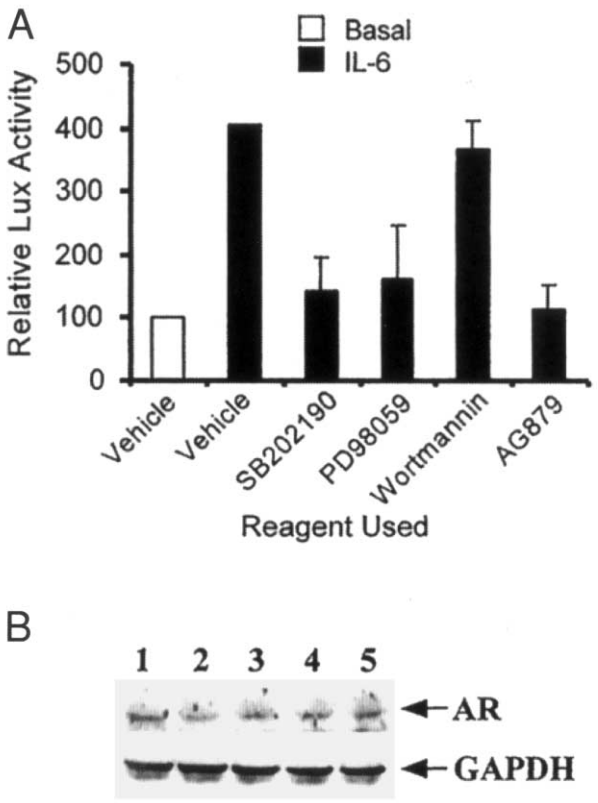

FIGURE 3 PSA promoter induction by IL-6 was blocked by specific inhibitors to signal transducers. (A) LNCaP cells were co-transfected with pRL-CMV (for normalization using the dual lux assay) and p1.5kPSA-Lux. The cells were then incubated with vehicle, SB202190 (5 μM), PD 98059 (15 μM), wortmannin (100 nM), or tyrphostin AG879 (10 μM) for 30 min prior to IL-6 administration (10 ng/ml) for 24 h. After incubation, lux levels were measured using a luminometer. Data are reported as the mean (± SE) lux activity relative to the basal activity, which was set as 100%, of three independent experiments. (B) The immunoblot of AR and GAPDH from 40 μg of cell lysate. LNCaP cells were cultured in medium containing IL-6 (lane 1) or IL-6 plus pretreatment of the inhibitor reagents described above (lanes 2–5, respectively). Reprinted from Lin *et al.*, 2001, *Clin. Cancer Res.* 7, 1773–1781, with permission.

V. WIDE SPECTRUM OF ANDROGEN RECEPTOR ACTIVATORS

One of the experimental therapies for prostate cancer is application of the differentiation agent phenylbutyrate. The butyrate derivative increases PSA gene expression by activation of the AR and induces androgen-inducible promoters to various extents. The binding of the AR to DNA-response elements is enhanced by differentiation-promoting compounds. Butyrate does not change total AR levels but does increase nuclear AR.

The level of AR ligand-dependent activation is also enhanced by caveolin, which is implicated in the development of therapy-resistant prostate disease. AR co-immunoprecipitates with caveolin through

interactions between the ligand-binding domain of the AR and the NH_2-terminal domain of caveolin. Examples of nonsteroidal activation of the AR also include cadmium; the thyroid gland hormone T3, which shows a co-stimulatory effect on PSA with androgen; MAPK kinase kinase I, whose overexpression induces apoptosis; and β-catenin.

In conclusion, ligand-independent and/or synergistic activation of the AR by cellular regulators is important in advanced prostate cancer and it offers an explanation of why androgen-responsive genes are up-regulated in late stages of the disease and in respective xenograft models. A better understanding of the mechanisms underlying activation of the AR in the absence of ligand or synergistic regulation of AR activity is crucial for the development of novel endocrine therapies.

Glossary

androgen receptor Nuclear transcription factor that regulates expression of androgen-inducible genes.
caveolin The principal protein component of caveolar membranes.
growth factors Polypeptide hormones that regulate growth in an autocrine and paracrine manner.
IGF-I, IGF-II Growth factors with structures similar to that of insulin.
interleukin-6 Proinflammatory cytokine that either inhibits proliferation or suppresses apoptosis in target tissues.
phenylbutyrate Butyrate derivative used in differentiation therapy.
protein kinase Enzymes that catalyze protein phosphorylation.
xenograft Tumor maintained in host animals.

Androgen Receptor Structure and Function

ELIZABETH M. WILSON
University of North Carolina, Chapel Hill

The androgen receptor (AR) is a ligand-activated transcription factor that binds with high affinity to the biologically active androgens, testosterone and dihydrotestosterone. Androgen binding targets the AR to the nucleus, where it binds to specific androgen-response element DNA sequences associated with promoter or intron sequences of androgen-regulated genes. AR-mediated gene activation is required for male sexual development during embryogenesis and sexual maturation at puberty. The domain structure of the AR parallels that of other steroid receptors. An important aspect of AR structure and function is an androgen-specific interaction between the NH_2-terminal and carboxyl-terminal regions that contributes to stabilization of the AR. Genetic defects in the AR gene in humans prevent normal male sexual development or cause adult onset muscular atrophy. Androgens are required in prostate development and growth and may contribute to prostate cancer proliferation.

I. BIOLOGICALLY ACTIVE ANDROGENS

In the male, testosterone is produced in Leydig cells of the testis in response to placental chorionic gonadotropin during male sexual development of the fetus. The testosterone concentration in circulating blood increases again at the time of puberty under stimulation by pituitary gonadotropin (luteinizing hormone or interstitial cell-stimulating hormone) and remains at relatively high levels until a decline later in life. Testosterone is synthesized by a series of cytochrome P450 enzymes, some of which are also used in the biosynthetic pathways for steroid hormones. Testosterone is the major circulating androgen, the majority of which is bound to serum-binding proteins. Only approximately 1% of the total testosterone is free and thus available to enter cells by diffusion. Most cells are exposed to similar levels of circulating androgen, an exception being the testis, where levels are high due to testosterone production by the Leydig cells. Whether a particular cell responds to testosterone or dihydrotestosterone (DHT) depends on the androgen concentration in the cell and on the presence of the androgen receptor (AR).

In some tissues that are highly responsive to androgen stimulation, such as the prostate and epididymis, testosterone is bioactivated to 5α-DHT by the cytochrome P450 enzyme 5α-reductase type 2. DHT is a more active androgen than testosterone in part because it dissociates more slowly from the AR. That testosterone cannot replace all of the functions of DHT is dramatically revealed in the 5α-reductase syndrome. In this genetic disorder, a mutation in the 5α-reductase gene results in a deficiency in the conversion of testosterone to DHT during embryogenesis. 46,XY genetic males with the 5α-reductase syndrome are born with incomplete development of the male genitalia due to reduced circulating levels of DHT. Remarkably, at puberty, increases in testosterone synthesis by the testes and an increase in the activity of the 5α-reductase type 1 overcome, to a certain extent, the DHT deficiency, resulting in virilization of the male.

A secondary source of androgen in the male is the adrenal gland, but this is not considered a highly significant contribution to overall androgen levels under normal physiological conditions. In the female, by contrast, adrenal androgens contribute a significant portion of circulating androgen levels, which are low compared to those of the male under normal conditions, minimizing the induction of androgen-responsive genes in the female. Adrenal androgens, such as androstenedione, are produced by the same steroidogenic enzyme pathways that function in the testis. Adrenal androgens serve as precursors for testosterone production.

Certain endocrine conditions associated with excess adrenal androgen production are problematic in the female. Congenital adrenal hyperplasia results from a genetic defect in an enzyme in the pathway to hydrocortisone (cortisol) biosynthesis. The most frequently mutated gene that causes congenital adrenal hyperplasia is the 21-hydroxylase gene. This enzyme defect reduces the synthesis of cortisol, which

results in the loss of negative feedback to the hypothalamus and anterior pituitary. The consequence is an increase in the secretion of adrenocorticotropic hormone by the anterior pituitary and the subsequent overstimulation of the adrenal glands. This leads to accumulation of 17-hydroxyprogesterone, which results in increased conversion to androstenedione and testosterone in the adrenal gland with increased circulating testosterone. During embryonic development, congenital adrenal hyperplasia causes differing degrees of virilization (development of male external genitalia) in the female fetus and increased virilization in affected males.

II. MECHANISMS OF ANDROGEN REGULATION OF GENE EXPRESSION

Under normal physiological conditions, the AR is bound to a biologically active androgen, testosterone or DHT, which induces the AR to translocate to the nucleus. In the nucleus, the AR binds as a homodimer to specific DNA sequences known as androgen-response elements. Thus, the AR is a ligand-inducible transcription factor. The androgen-bound AR complex recruits associated co-regulatory proteins that act during the process of chromatin modification necessary for gene activation. Many associated proteins have been reported to have a role in AR-mediated gene activation. These proteins include the family of p160 co-activators, named for their approximate size of 160 kDa and for their capacity to increase the transcriptional response to ligand-activated steroid receptors as measured in transcription assays. The p160 group of transcriptional co-activators include steroid receptor co-activator 1 (SRC1), transcriptional intermediary factor 2 (TIF2, SRC2, GRIP1), and the SRC3/TRAM1/AIB1/pCIP/ACTR/RAC3 group of co-activators. Many of these are associated with histone acetyl transferase activity and can recruit CBP, pCAF, and other co-regulatory proteins required for chromatin modification and gene activation.

The use of two-hybrid screening methods in yeast expression systems has revealed many proteins in addition to the p160 co-activators that associate with the AR and are reported to increase AR-mediated transcriptional activation. The extent of increased gene activation is typically measured using transient transfection DNA transfer methods in cultured cell lines. Plasmid DNA transfected into cells includes expression vectors containing the DNA coding sequence for the AR or other steroid receptors and a reporter plasmid. Reporter plasmids contain a responsive DNA element (DNA sequence that binds the nuclear receptor) linked to a gene such as luciferase or chloramphenicol acetyltransferase, whose activity can be quantitated in *in vitro* assays. Co-transfection of expression plasmids for the interacting proteins is used to determine their effects on ligand-induced receptor regulation of gene transcription.

All but a few tissues in the body express the AR. However, the levels of AR expression differ among tissues. The highest levels are observed in androgen-responsive tissues, such as prostate, seminal vesicle, epididymis, testis, and the genitalia. High AR levels are also reported in the ovary; however, the role of androgen in female reproduction remains to be clearly defined. Genes that are activated by the AR contain an androgen-response element sequence in the promoter or intron region that allows for selective binding of AR to the DNA. In addition, there have been reports of nongenomic effects of the AR; however, it remains to be determined by what mechanisms these effects are mediated.

III. DOMAIN STRUCTURE AND INTERACTIONS OF THE ANDROGEN RECEPTOR

The AR is encoded on the X chromosome. Thus, 46,XY genetic males have only one allele for the AR gene. 46,XX genetic females have two X chromosomes but also express only one allele due to the random inactivation of the X chromosome. There appears to be a single AR gene and only one form of the AR. This contrasts with other steroid receptors for which there are multiple genes and forms. For example, estrogen receptor α and β are encoded by different but related genes. The A and B forms of the progesterone receptor are synthesized from alternative transcripts and have different cellular effects. Recent evidence supports the existence of only one human AR gene and only the full-length form of the human AR in cells. In some fish, however, there is evidence for more than one form of the AR.

The AR shares with other steroid and nuclear receptors a common overall structural arrangement of its functional domains (Fig. 1). A striking aspect of these domains is a relatively high degree of functional independence. Each of the domains can be expressed and shows its respective activity to a significant degree. However, as described below, important interactions that have an impact on AR function occur among the domains.

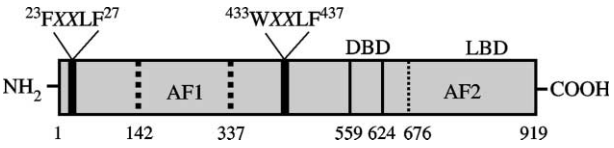

FIGURE 1 Diagram of the structural domains of the human androgen receptor. Shown are activation functions 1 (AF1) and 2 (AF2), the DNA-binding domain (DBD), and the ligand-binding domain (LBD). Also shown are the N/C interaction motifs F*XX*LF and W*XX*LF. Reprinted from He et al. (2001), with permission.

A. NH_2-Terminal Region

The NH_2-terminal region is the largest domain in the AR, making up about 60% of the receptor protein. This contrasts with other nuclear and steroid receptors in which the NH_2-terminal region may be short. But like the AR, the glucocorticoid, progesterone, and mineralocorticoid receptors have a similarly large NH_2-terminal region. The AR NH_2-terminal region is unusual because it contains several repeated sequences, the most striking being the glutamine and glycine repeats. The glutamine repeat is encoded by a CAG trinucleotide repeat whose length is polymorphic in the normal population, ranging from 13 to 35 glutamine residues. An increase beyond 36 glutamine residues is associated with adult onset muscular atrophy or Kennedy's disease (see Section IV.B). The glycine repeat is usually 23 residues in length and is less polymorphic than the glutamine repeat. Significant expansion or contraction of the glycine repeat has not been associated with a disease. A short 8-residue proline repeat, the function of which is not known, also occurs in the NH_2-terminal region of the AR.

The NH_2-terminal region is the least conserved domain of the ARs of different species and is the least conserved domain among different steroid receptors. Homology comparisons of the amino acid sequence of the NH_2-terminal region in primates indicates 92% similarity between human and the prosimian lemur AR amino acid sequence. Lemurs arose during primate evolution from the lower mammals. The glutamine repeat at this position in the NH_2-terminal domain expanded throughout primate evolution, increasing from 4 CAG repeats in lemur AR to its present average length of 22 CAG repeats coding for the glutamine repeat region in human AR. In lower mammals, such as rat and dog, a variable-length glutamine repeat also occurs, but remarkably, this glutamine repeat, also encoded by a CAG repeat, is in a different position within the NH_2-terminal region. One aspect of the NH_2-terminal region that may allow these amino acid repeat expansions to occur without severe disruption of AR function could be a lack of strict structural constraints in the region. Binding of transcription factors to the NH_2-terminal region may impose a more structured arrangement. The allowable flexibility in length and position of the glutamine repeat relative to AR function suggests that the NH_2-terminal region of AR is tolerant of a significant amount of alteration in protein structure. This contrasts with the very strict structural requirements for the DNA- and ligand-binding domains.

The NH_2-terminal region is nevertheless critical for AR function because it contains the major transactivation region referred to as the activation function 1 (AF1) region. Deletion of the NH_2-terminal region results in the loss of its major transcriptional activation domain. The NH_2-terminal region likely acts to recruit specific transcription factors, some of which have been reported. The AF1 region is located between amino acid residues 142 and 337 in the 1- to 558-residue NH_2-terminal region (Fig. 1). Although it is not well defined, the NH_2-terminal AF1 region requires androgen binding for transcriptional activity and appears to be critical for AR-mediated gene activation.

B. DNA-Binding Domain and Hinge Region

The NH_2-terminal region is contiguous with the centrally positioned DNA-binding domain that allows for specific binding to androgen-response DNA elements present in androgen-regulated genes (Fig. 1). The AR DNA-binding domain is composed of a two zinc-finger structure where two zinc atoms are held in position by tetrahedral coordination with highly conserved cysteine residues. The zinc-finger structure of the DNA-binding domain is characteristic of all steroid and nuclear receptors. The DNA-binding domain and flanking sequence can be expressed as an isolated domain that binds DNA. A region of genomic DNA associated with androgen-regulated genes that interacts with the AR DNA-binding domain is referred to as an androgen-response element, or hormone-response element. Androgen-response elements vary in sequence, but for many genes, they adhere to the DNA consensus sequence 5′-GGTACAnnnTGTTCT-3′, where n represents an unspecified spacer nucleotide.

A short hinge region at amino acid residues 624–676 (Fig. 1) is positioned between the AR DNA-binding domain and the carboxyl-terminal region. Within the hinge region is the AR nuclear-targeting

signal that triggers the subcellular transport of AR from the cytoplasm to the nucleus. Androgen binding to the AR activates this bipartite targeting sequence, which is composed of two closely spaced clusters of the basic amino acids lysine and arginine. Mutation of these basic residues inhibits androgen-induced nuclear translocation of the AR.

C. Ligand-Binding Domain

The carboxyl-terminal ligand-binding domain at amino acid residues 676–919 (Fig. 1) is approximately one-fourth the size of the AR protein and constitutes the high-affinity hormone-binding site. The ligand-binding region of AR and that of several other nuclear receptors have been crystallized in the presence of bound hormone. The carboxyl-terminal ligand-binding domain forms a series of alpha-helical folds that create a hydrophobic cavity for hormone binding. The size of the binding cavity varies among the steroid receptors, with the smaller binding cavities showing a higher degree of hormone specificity. The ligand-binding domain of the AR can function as an isolated domain with apparent high-affinity androgen binding when the recombinant protein is expressed in the absence of the NH_2-terminal region. However, as described below, the NH_2-terminal region influences the kinetics of androgen binding.

Steroid hormone binding in the hydrophobic pocket of the ligand-binding domain is relatively specific for the ligand. For example, the AR shows highest binding affinity and specificity for the biologically active androgens testosterone and DHT. However, AR and other steroid receptors also bind additional ligands, but with lower affinity. For example, the mineralocorticoid and glucocorticoid receptors bind each other's preferred hormone, aldosterone and hydrocortisone, with similar affinity. A variety of mechanisms including receptor concentration and selective steroid metabolism contribute to facilitating a specific hormone response. In the case of the mineralocorticoid receptor, there are enzymes in certain tissues, such as the placenta and kidney, that facilitate the rapid metabolism of cortisol to its inactive form, cortisone, thereby allowing the mineralocorticoid receptor to bind aldosterone, the active mineralocorticoid. The AR can bind other hormones and ligands depending on their concentration.

Within the carboxyl-terminal region is an activation region referred to as activation function 2 (AF2; Fig. 1). AF2 forms a hydrophobic binding site for the L*XX*LL motifs of the p160 transcriptional co-activators, where L refers to leucine and *X* is any amino acid. The AF2 region of the AR appears to have a lower binding affinity for the L*XX*LL motifs of the p160 co-activators than do the other nuclear receptors when expressed as a DNA- and ligand-binding domain fragment. It is therefore not clear to what extent the AF2 region in the AR ligand-binding domain contributes to AR transcriptional activity *in vivo*. A mutation at lysine residue 720 in the AR AF2 region of the ligand-binding domain decreased the interaction with p160 co-activators but did not significantly alter AR transactivation when determined in a transient transfection assay, where recombinant AR was expressed in cultured cells in the presence of a reporter vector.

D. Interaction Between NH_2- and Carboxyl-Terminal Regions

As indicated above, two regions of the AR appear to be involved in androgen-induced transactivation of genes, AF1 in the NH_2-terminal region and AF2 in the ligand-binding domain. In comparison to other steroid receptors, AF2 in AR is weak, apparently reflecting a reduced ability to recruit p160 co-activators through their L*XX*LL motifs. In addition, inhibition of p160 co-activator binding results from a strong androgen-induced NH_2- and carboxyl-terminal (N/C) interaction between an F*XX*LF motif in the NH_2-terminus at amino acid residues 23–27 (Fig. 1) and the carboxyl-terminal AF2 hydrophobic binding surface. A second AR NH_2-terminal N/C interaction site, W*XX*LF at amino acid residues 433–437, also interacts with AF2 in the ligand-binding domain (Fig. 1).

Androgen dissociation studies provided the first evidence that the NH_2-terminal region of the AR interacts with the ligand-binding domain. Deletion of the NH_2-terminal domain increases the rate at which bound androgen dissociates, whereas the apparent equilibrium binding affinity is not altered, indicating that the association rate is increased. These studies were followed with a two-hybrid interaction assay that supported a direct interaction between these regions. More recently, F*XX*LF and W*XX*LF motifs in the NH_2-terminal region that interact in the presence of testosterone or DHT with the AF2 region in the ligand-binding domain were identified. Recent studies suggest that the N/C interaction stabilizes the AR protein against degradation and interferes with the binding of p160 co-activators to the AF2 region. The F*XX*LF motif appears to have a higher affinity for the AF2 region than do the L*XX*LL motif sequences of the p160 co-activators. A major effect

of the androgen-dependent F*XX*LF/W*XX*LF interaction with the ligand-binding domain is to slow the dissociation rate of bound androgen and to stabilize the AR against degradation.

IV. ANDROGEN RECEPTOR MUTATIONS ASSOCIATED WITH DISEASE

A. Androgen Insensitivity Syndrome

Steroid receptor-regulated gene transcription is required for cell proliferation, differentiation, and development and involves the formation of active transcription initiation complexes composed of a specific steroid receptor and a host of co-activators. The essential role of the AR in male sex differentiation is well established. Naturally occurring AR gene mutations in 46,XY genetic males result in a phenotypic spectrum known as the androgen insensitivity syndrome, characterized by incomplete male sexual development *in utero*. Because the AR gene is located on the X chromosome (Xq11–q12), there is only one allele in the male. Thus, mutations that abolish AR function can have a dramatic effect on the response to androgen. Androgen insensitivity is an end-organ defect because the individual cannot respond to the high circulating androgen levels due to a genetic defect in the AR protein.

The severity of the defect in male sexual development reflects the importance of specific amino acid residues in AR function. Partial or total loss of AR function can affect any one of a number of functional properties of the AR including high-affinity androgen binding, DNA binding, and AR stability. Depending on the position and type of the substituted amino acid, the degree of phenotypic expression varies. Mutations causing partial androgen insensitivity can alter steroid-binding affinity and specificity. Mutations that severely disrupt androgen- or DNA-binding affinity result in the complete form of the syndrome. This is characterized by a female genital phenotype in a 46,XY genetic male. These individuals lack a uterus and have abdominal testes that produce normal to elevated male levels of testosterone. The majority of AR gene mutations are single-base missense mutations in the DNA-binding or carboxyl-terminal regions (exons 2–8) with more than 200 unique mutations reported. In some cases, there is partial or complete deletion of the AR gene.

Most of the naturally occurring AR gene mutations are in the DNA- or ligand-binding domain, with a surprising absence of missense mutations in the NH_2-terminal region. The genetic errors include missense mutations where a new amino acid residue is substituted or nonsense mutations where a premature termination codon is introduced. Many of the premature mutant stop codons occur within the NH_2-terminal region. A compilation of the more than 200 different AR mutations that cause partial or complete androgen insensitivity is available on the Internet at http://www.mcgill.ca/androgendb/. The frequency of AR gene mutations in the human population is about 1 in 20,000 individuals. Females can be carriers of an AR gene mutation without significant effects to themselves probably because of the presence of one normal allele for the AR gene and random inactivation of the X chromosome.

Partial forms of the androgen insensitivity syndrome occur in a spectrum of forms, ranging from the mildest form, which causes male infertility in the adult, to a more severe form that leads to ambiguous genitalia in the newborn. The presence of the 46,XY male sexual karyotype with partial disruption or complete loss of the male genital phenotype is the hallmark of the androgen insensitivity syndrome. In some cases, phenotypic expression of the same AR gene mutation varies between individuals from different families and among family members, illustrating that other factors contribute to phenotypic expression of a given AR gene mutation. Mutations that significantly decrease androgen- or DNA-binding affinity result in the complete form of the syndrome.

B. Kennedy's Disease

Neurodegenerative diseases are sometimes caused by trinucleotide repeat expansions. The first trinucleotide repeat expansion discovered was Kennedy's disease or adult onset spinal/bulbar muscular atrophy. Others include Huntington's disease and spinocerebellar ataxia type 1. The diseases are caused by a CAG repeat expansion that codes for glutamine. Differences occur in repeat length, stability, and location of the expansion. Within the NH_2-terminal domain of the AR is a CAG repeat that codes for a glutamine repeat that is polymorphic in the normal population, ranging from 13 to 35 glutamine residues in length. Expansion of the AR CAG repeat in the first exon of the coding region of the NH_2-terminal domain to greater than 40 Gln residues results in X-linked adult onset spinal/bulbar muscular atrophy or Kennedy's disease. Clinical features of Kennedy's disease are progressive muscle weakness after the age of 25–30 years, muscle atrophy associated with loss of lower motor and primary sensory neurons, and partial androgen insensitivity, evidenced by elevated

serum gonadotropin levels, gynecomastia (breast enlargement in the male), testicular atrophy, impotence, and oligo- or azoospermia (low or absent sperm production). Early onset, severity of muscle weakness, and degree of androgen resistance correlate with longer repeats. Instability of triplet repeats associated with human hereditary disease may result from errors in DNA mismatch repair through the formation of single-stranded hairpin structures and DNA polymerase slippage during replication. Polymorphisms of the AR CAG repeat are stable in the normal population and can be useful as genetic markers in clonality analysis and forensic science. How repeat expansions cause adult-onset muscle wasting is being actively investigated; current evidence suggests that the expanded glutamine repeat contributes to protein aggregation in the nucleus.

C. Prostate Cancer

There are conflicting reports in the literature concerning the incidence of AR gene mutations associated with prostate cancer. Earlier reports suggested frequencies of AR mutations of up to 50% or more in prostate cancer specimens. However, many of these early reports were confounded by the presence of artifactual polymerase chain reaction DNA incorporation errors. The actual frequency of AR mutations in prostate cancer specimens is probably not more than 5% of cases. Additional studies will help to resolve the conflicting reports but the preponderance of recent information supports the view that AR gene mutations are uncommon, particularly in early stage disease, but may become more prevalent in later forms of the disease when overall genetic instability is increased.

Despite their apparent low incidence, it is nevertheless of interest that the AR gene mutations that have been reported in prostate cancer specimens are sometimes associated with a broadened ligand specificity. In this case, the AR responds by increasing gene transcription in response to not only the biologically active androgens, testosterone and DHT, but also to other circulating steroids. For example, an AR T877A mutation in the ligand-binding domain is present in the LNCaP human prostate cancer cell line. An AR H874Y gene mutation is present in a human prostate cancer xenograft. The xenograft is a transplant of a human prostate cancer into an immune-deficient mouse, where it can be propagated for further study. These mutant ARs show a normal transcriptional response to testosterone and DHT but, in addition, have a greater response than wild-type AR to other ligands, such as estradiol, and to AR antagonists, such as hydroxyflutamide. It is not clear to what extent this broadened ligand specificity contributes to the proliferation of prostate cancer in these cases. Activation of the AR by other circulating hormones increases the possibility for stimulation of tumor growth in the absence of the usual stimulating androgens, testosterone and DHT. This may be particularly critical in late stage prostate cancer where patients have undergone androgen deprivation therapy by castration or chemical treatment. Under these conditions of low androgen levels, other circulating ligands, such as the adrenal androgen dehydroepiandrosterone, might gain the ability to act as a more active androgen and promote the growth of late stage cancer in the androgen-deprived patient.

More recently, it was discovered that certain of the p160 co-activators are highly expressed in the majority of prostate cancer samples analyzed. These highly expressed p160 co-activators include SRC1 and TIF2, whereas AIB1 (amplified in breast cancer 1) was not detected. p160 co-activator expression was low to undetectable in benign prostatic hyperplasia, which is a common form of enlarged prostate in the aging male. It is conceivable that high-level expression of co-activators offers a mechanism for AR activation through other ligands including the adrenal androgens or by ligand-independent mechanisms.

V. ANDROGEN RECEPTOR ANTAGONISTS AND AGONISTS IN THE ENVIRONMENT

Over the past several years, certain environmental chemicals used as pesticides or herbicides in crop protection have been identified as precursors to chemicals with endocrine disruptor activity involving the AR. A number of environmental chemicals were previously established to have estrogenic activity, but until recently, these activities related only to the estrogen receptor. At least five or more chemicals previously or currently in use in the United States were found to be AR antagonists. An antagonist is a chemical or pharmaceutical ligand that competes for hormone binding and fails to induce receptor-mediated activation of gene transcription. Antagonist activities are detected using *in vitro* assays to demonstrate inhibition of androgen-induced AR transcription activity and inhibition of DNA binding. Thus far, it has been the *in vivo* metabolites of the parent chemicals that interfere with androgen binding

to the AR, resulting in antagonist activity. The apparent equilibrium binding affinity of a pesticide or herbicide metabolite is in the micromolar range as opposed to nanomolar binding affinity of androgens for the AR. Like androgens and other antagonists, these chemicals bind to the ligand-binding domain in the carboxyl-terminal region of the AR and block binding of androgen. Binding of these chemicals does not elicit conformational changes in the AR, such as those required for the N/C interaction, and thus these chemicals are ineffective in promoting agonist-related effects on activation of gene transcription.

It is not known whether there is sufficient exposure from pesticide or fungicide residues on fruits and vegetables or in farming practices to elicit AR antagonist activity. The micromolar binding affinity indicates that relatively high levels of pesticide exposure would be required to disrupt androgen-induced effects. Of particular potential concern, however, is the developing male fetus, which depends on the action of androgens produced from the fetal testes during embryonic development for sexual differentiation and development of the external genitalia. Exposure of the pregnant mother to sufficient levels of chemicals with AR antagonist activity during the critical period of male sexual development could possibly inhibit development, resulting in incomplete formation of the external genitalia. In some countries, an increasing incidence of incomplete masculinization has been observed, characterized by the hypospadias deformity, in which the urethra opens on the shaft or base rather than at the tip of the penis. It is not known to what extent this relatively common form of incomplete masculinization is attributable to endocrine disruptor activity. This type of defect can be repaired by surgery, resulting in full male sexual function. However, it is not known whether other anti-androgen effects could occur in the brain to interfere with androgen imprinting or in other organs of the developing male.

Recent evidence suggests, in addition, the presence of environmental androgens. Female Eastern mosquitofish, *Gambusia holbrooki*, present in a Florida river downstream of a paper mill effluent discharge were uniformly masculinized as evidenced by the presence of male-like elongated anal fins. Androstenedione, a known precursor of testosterone, was confirmed by liquid chromatography mass spectrometry to be a component of the river water. Androstenedione was present in the river at a concentration of 0.14 nM. Phytosterols derived from paper pulp, such as β-sitosterol, campesterol, and stigmastanol, can be modified to androgen precursors by the bacteria *Mycobacterium smegmatis* or *Escherichia coli*, which have been shown to produce androstenedione from steroid precursors. Conversion of plant sterols by bacterial metabolism provides a likely source for androstenedione in the contaminated Florida river.

VI. SUMMARY

The androgen receptor is a ligand-activated transcription factor that binds testosterone or dihydrotestosterone. The androgen-activated AR binds to DNA sequences known as androgen-response elements to regulate gene transcription. The AR has a domain structure characteristic of the nuclear receptor family of transcription factors, with an NH_2-terminal transactivation domain, a DNA-binding domain, and a carboxyl-terminal ligand-binding domain. An unusual property of the AR is an androgen-induced interdomain NH_2- and carboxyl-terminal interaction that stabilizes the AR against degradation and inhibits p160 co-activator activation of AF2 in the ligand-binding domain. The AR gene is on the X chromosome. In 46,XY genetic males, a single-nucleotide base change causing a missense amino acid mutation can inhibit normal male sexual development, resulting in the androgen insensitivity syndrome. Other diseases related to the AR are Kennedy's disease and prostate cancer. Finally, metabolites of certain chemicals used as pesticides and herbicides have anti-androgen activity that could inhibit sexual development of the male fetus. On the other hand, androgens in the environment have been reported to masculinize entire populations of fish. Thus, the AR is a critical gene regulatory protein. Loss or gain of AR function through genetic mutation or environmental inhibition or activation can have a wide range of adverse effects on sexual development.

Glossary

activation function regions Segments in a steroid receptor that mediate transcriptional activation through their interaction with co-activators or proteins of the basic transcriptional machinery of the cell.

androgen insensitivity syndrome 46,XY genetic males with an androgen receptor gene mutation that results in infertility or partial or complete lack of masculinization of the genitalia. The androgen insensitivity syndrome has also been referred to as testicular feminization.

androgen receptor A transcription factor that is activated by binding a biologically active androgen, testosterone or dihydrotestosterone; it is required for induction of gene transcription in response to androgen.

hormone-response element Segment of DNA sequence that binds to the DNA-binding domain of a steroid receptor and thereby facilitates the activation of a gene. Androgen-response elements are nucleotide sequences that bind the androgen receptor.

N/C interaction Interaction between the NH_2-terminal and carboxyl-terminal (N/C) regions of the androgen receptor that is selectively induced by the binding of a biologically active androgen, testosterone or dihydrotestosterone. This interaction is mediated by F*XX*LF- and W*XX*LF-binding motifs in the NH_2-terminal region and activation function 2 in the ligand-binding domain.

p160 co-activators A group of co-regulatory proteins of approximately 160 kDa in size that interact with nuclear receptors to increase the transcriptional response.

Androgens: Pharmacological Use and Abuse

MARIA M. BYRNE AND EBERHARD NIESCHLAG
University of Münster

Androgen preparations are widely prescribed for a variety of medical conditions in both men and women. Misuse of androgens, however, has become an extensive problem of increasing proportion. Therefore, it is important for students, scientists, and clinicians to be familiar with the risks and benefits of androgen use.

I. INTRODUCTION

The principal medical use of androgens is for the treatment of male hypogonadism and delayed puberty. However, many new indications for androgen treatment are emerging. This article focuses on

Androgen Receptor-Related Pathology

MICHAEL J. MCPHAUL
University of Texas Southwestern Medical School

In mammals, testosterone and 5α-dihydrotestosterone are the principal circulating male hormones (androgens). These hormones serve to modulate a number of important processes, from the development of the male phenotype during embryogenesis to the regulation of spermatogenesis and the secretion of gonadotropins in the adult. Mutations of the human androgen receptor gene have been implicated in pathogenesis of several different diseases.

I. INTRODUCTION

Biochemical and genetic data have demonstrated that the male hormones, testosterone and 5α-dihydrotestosterone (DHT), are not equivalent and that they regulate some processes selectively. Although the mechanism of such selective regulation is an area of active investigation, it is clear that the events controlled by each hormone are exerted via the single, X-linked androgen receptor (AR). In mammals, the hormones produced by the gonads during specific periods of embryogenesis govern sexual development. The peptide and steroid hormones that are produced are, in turn, dictated by whether the bipotential gonad differentiates into a testis or ovary, a process that is governed by the fetal sex chromosome composition and distinct genes encoded on autosomes. At approximately 9 weeks of development, the testes begin to secrete testosterone. In combination with its 5α reduced metabolite, 5α-dihydrotestosterone, testosterone acts to induce the virilization of the internal and external genitalia. The Wolffian ducts grow, forming the pelvic portion of the urogenital sinus and giving rise to the seminal vesicles and the epididymis, while the external genitalia respond with the formation and enlargement of the phallus and the fusion of the genital ridges to form the scrotum. In this process, the formation of DHT is particularly important to the virilization of the external genitalia. In addition to events that are mediated by the action of the androgens, a polypeptide hormone produced by the Sertoli cells of the testes, Müllerian inhibiting substance (MIS), induces the regression of structures derived from the Müllerian ducts, particularly the uterus and fallopian tubes.

II. PHENOTYPIC SPECTRUM OF ANDROGEN INSENSITIVITY

Mutations of the AR associated with androgen resistance have been described in a large number of patients with a wide range of phenotypic abnormalities of male development. At least three different influences are responsible for the relatively large number of clinically apparent defects of AR. The first is the chromosomal location of the AR gene. The AR gene is located on the human X chromosome and is present in only a single copy in 46,XY genotypic males. As such, no second AR allele is present that might serve to mask or compensate the effect of any mutation that impairs the function of the AR gene. In addition, it is apparent that the actions of androgens, although important for normal male sexual development, are not required for life. Even patients with complete defects of AR function mature to adulthood. Finally, many defects of AR function result in abnormalities of sexual development that are evident at birth; such defects have prompted endocrine and genetic studies designed to identify the etiology.

The phenotypic spectrum of androgen insensitivity syndrome (AIS) is most easily conceived as reflecting the degree to which the androgen-regulated events of male sexual development have been disturbed. In individuals with the clinical phenotype of complete androgen insensitivity (complete testicular feminization), the function of the AR is completely defective and there is no development of internal or external male structures that are regulated by androgen. Such individuals show no signs of virilization. The inability to respond to androgens is not sufficient to explain the entire phenotype of complete androgen insensitivity, however. Although circulating androgens cannot act via the AR, testosterone is aromatized to estrogen, which mediates feminization because of the presence of the normal estrogen receptors. As such, affected individuals appear to be normally developed women with normal breast development. Careful evaluation of such subjects

will identify testes within the labia majora or the abdominal cavity. In addition, because the testes in such individuals produce Müllerian inhibiting substance, the Müllerian-derived structures (the uterus and fallopian tubes) are absent and the vagina is blind ending.

Other intermediate phenotypes have been described and reflect differing levels of impairment of AR function. These have been referred to using a variety of terms, including incomplete testicular feminization, Reifenstein syndrome, and partial androgen insensitivity. The phenotypes of such individuals are characterized by varying degrees of virilization. Subjects may display a phenotype that is predominantly male in character but with defects of urogenital development, such as perineal hypospadias (the Reifenstein phenotype). Others exhibit phenotypes that are predominantly female with varying degrees of clitoromegaly or labial fusion (incomplete testicular feminization). In recent years, Quigley and colleagues have published a more detailed system with which to categorize patients with partial forms of androgen insensitivity.

Finally, in a small number of patients, specific processes that are regulated by androgen are disturbed, even though male sexual development is normal or near normal. In some, subtle signs of undervirilization, such as gynecomastia, may be present. In other individuals, infertility or oligospermia appear to be the only manifestations of defective AR function.

A. Characterization of AR Defects: Biochemical Studies

The phenotypic abnormalities that accompany the androgen-resistant states can be viewed as a continuum that relates directly to the extent to which the androgen-mediated processes of male sexual development have been disturbed. In parallel with the description of the clinical syndromes, characterization of the type of AR defect became possible using binding assays to measure the level and character of AR present in patient samples. The application of such techniques has permitted recognition of a number of quantitative and qualitative abnormalities of androgen binding in patients with different forms of androgen insensitivity.

The use of these methods has permitted diagnosis and classification of many types of patients with androgen insensitivity. Despite the utility of these techniques, the information derived from such methods is limited. First, no binding abnormality is evident in a substantial proportion of patients analyzed, even after the application of qualitative and quantitative assessments of AR binding. Second, it is clear that no direct relationship exists between the clinical phenotype and the type of ligand binding abnormality. More detailed studies of the nature of the defects causing androgen insensitivity awaited characterization of the AR at the molecular level.

B. Structure of the AR

The AR is a member of a large gene family, the nuclear receptor family. In addition to the classic steroid receptors, such as the AR, this family also contains a number of related proteins, including the receptors for thyroid hormone, vitamin D, and retinoic acid. Most members of this family display a similar organization. Each contains a central DNA-binding domain (DBD) and a carboxyl-terminal ligand-binding domain (LBD) domain that mediates the high-affinity binding of ligand. In addition, each protein possesses an amino-terminal segment that is of variable length and is required for full transcriptional activity. In the case of the human AR, the amino terminus is large and comprises nearly half of the molecule (Fig. 1).

III. AR MUTATION TYPES

Initial efforts categorized the syndromes of androgen insensitivity syndrome on the basis of the associated abnormalities of ligand binding. At present, the number of mutations of the AR that have been identified in patients with different forms of AIS permits additional information to be used in the classification of such patients.

A. Interruption of the AR Open Reading Frame

A number of distinct mechanisms have been identified that cause an interruption of the primary amino acid sequence of the human AR. Large-scale deletions, small-scale deletions, insertions, and alterations in AR structure caused by changes in mRNA splicing have been reported. Although mechanistically distinct, in each instance the final protein product differs in primary amino acid sequence from that of the normal human AR protein. This difference may be caused by a premature truncation or by the addition or removal of one or more amino acids from the receptor sequence. Because the LBDs and DBDs of the AR are located toward the C-terminus of the receptor, mutations that result in a shift of the open reading frame and premature termination of

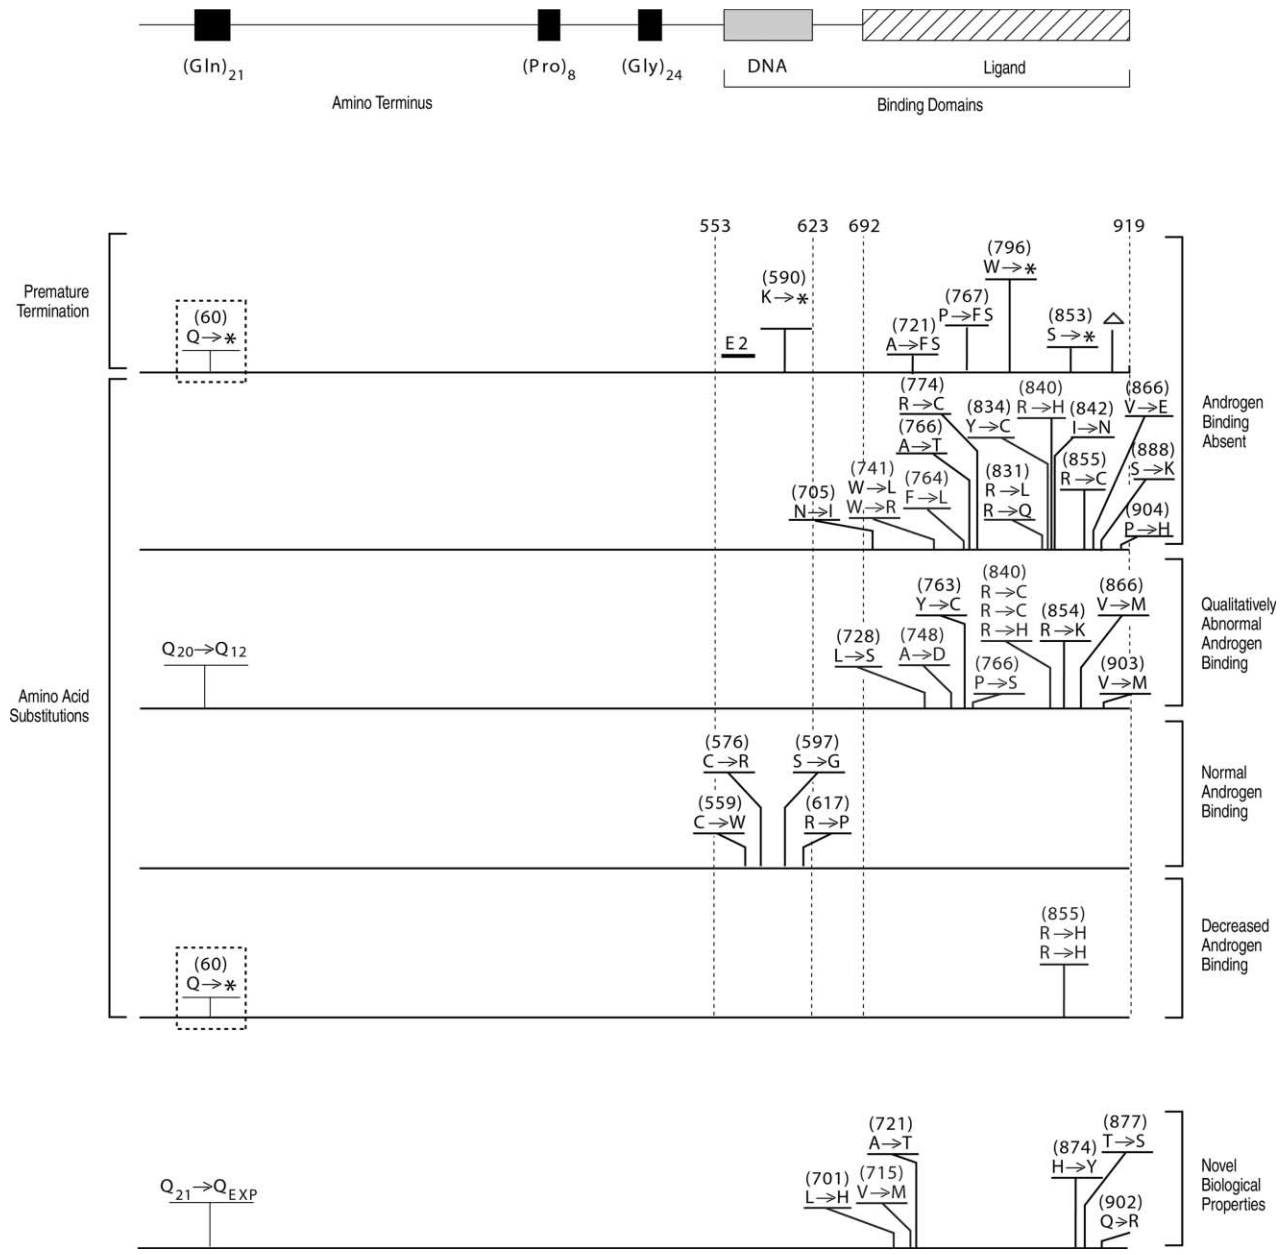

FIGURE 1 Alterations of androgen receptor structure associated with human disease. Top: Schematic of the human AR showing the relative positions of the segments critical to the binding of DNA and ligand by the receptor protein. The predicted amino acid sequence of the AR also encodes a large amino-terminal segment that comprises approximately half of the molecule. This region contains motifs composed of repeated glutamine, glycine, and proline residues. Alterations of the length of the glutamine repeat have been associated with the pathogenesis of spinal and bulbar muscular atrophy, a propensity to develop aggressive forms of prostate cancer, and infertility. Middle: Representative mutations of the AR associated with androgen insensitivity syndrome. Categorization by type of genetic mutation is shown on the left; the observed effects on androgen binding in patients with different forms of androgen insensitivity syndrome are shown on the right. Bottom: A schematic of AR mutations that result in acquisition of novel biological properties. In addition to expansion of the glutamine repeat within the amino terminus of the AR that is associated with spinal and bulbar muscular atrophy ($Q_{21} \rightarrow Q_{EXP}$), also shown are examples of mutations that have been identified in prostate cancer cell lines and tumors that result in novel responsiveness of the AR. (Modified with permission from McPhaul, M. J., Marcelli, M., Zoppi, S., Griffin, J. E., Wilson, J. D. (1993). The spectrum of mutations in the androgen receptor gene that causes androgen resistance. *J. Clin. Endocrinol. Metab.* **76**, 17–23. Copyright The Endocrine Society.)

the receptor have a dramatic effect on receptor function when introduced at virtually any position within the primary amino acid sequence. By contrast, mutations that result in the insertion or removal of single or multiple amino acids from the normal AR sequence behave more like amino acid substitution mutations (see later) and cause syndromes of androgen resistance only when occurring within the DNA- or ligand-binding domains.

B. Mutations in the DBD of the AR

In the characterization of some patients, endocrine studies or family histories have been suggestive of androgen insensitivity, but abnormalities of ligand binding could not be identified (~20% in one series). This group includes individuals with diverse phenotypes, ranging from the most severely affected individuals to those with much lesser affected phenotypes. At the time, these patients were postulated to harbor either subtle defects of the AR or defects in other genes that are required for the normal AR function.

In pedigrees in which the family history suggests the inheritance of an X-linked trait, mutations within the conserved DBD of the receptor are frequently detected. In one study of four unrelated subjects with complete or near complete forms of androgen resistance, amino acid substitutions were localized to the DNA-binding region of the receptor protein in each instance. When these mutant ARs were analyzed in detail, they were found to bind androgen with normal or near normal kinetics, as predicted on the basis of binding studies performed in fibroblasts established from the individual patients. When assayed in transfection assays using a model androgen-responsive reporter gene, these mutant ARs were found to be markedly impaired. Studies of fusion proteins containing the DBDs of the normal and mutant ARs demonstrated that in each instance the mutant ARs displayed an impaired capacity to bind to target DNA sequences.

AR mutations other than the replacement of individual amino acids can have similar effects on receptor function when they disrupt the structure of the DNA-binding domain while maintaining the AR open reading frame. Such inferences are based on the identification of patients in whom in-frame deletions or insertions have removed or inserted one or more amino acid residues. The characterization of mutant ARs of this type has revealed that regardless of the nature of the causative mutation, changes that alter the structure of only the DNA-binding domain of the receptor cause androgen insensitivity by interfering with a capacity of the receptor to recognize specific target DNA sequences. The published data suggest that the extent to which DNA binding by the mutant receptors is impaired correlates with the degree of receptor function and the phenotype that is observed. The data of Nguyen et al. are interesting in this regard. These scientists identified a mutation in the P-box of the AR DBD in a patient with partial androgen insensitivity. This study demonstrated that the mutant AR (G577R; in the one-letter amino acid code, G is glycine and R is arginine) resulted in the synthesis of a receptor protein that displayed selective impairment of binding of the AR to specific types of androgen response elements. It was further suggested that such differential impairment of DNA binding might contribute to the diversity of androgen-resistant phenotypes.

C. Mutations in the AR LBD

Mutations that change single amino acid residues in the LBD are the most frequent type of AR mutation. This category accounts for approximately 60% of all AR gene mutations causing clinical androgen resistance. Mutations in this segment of the receptor have been identified in patients with all of the phenotypes associated with androgen insensitivity. These mutations fall into two categories: amino acid substitutions causing absent ligand binding and qualitative abnormalities of ligand binding.

1. Amino Acid Substitutions Causing Absent Ligand Binding

Two broad groups of amino acid substitutions in the AR LBD have been identified in patient fibroblasts that exhibit undetectable levels of ligand binding. Only a few examples of the first type have been characterized and represent the replacement of residues critical to the formation of a LBD that is capable of binding ligand with high affinity. When expressed and studied using eukaryotic or prokaryotic expression systems, such mutant ARs are incapable of binding ligand. The mutant AR containing a single amino acid substitution at residue 739 (W739R; W, tryptophan) is one such mutation. Inspection of the crystal structures of the AR LBD reveals that this mutation results in the substitution of a hydrophobic residue (tryptophan) at the amino terminus of helix 4 with a charged amino acid (arginine). These structures demonstrate that this residue is localized in an area that makes important contacts with the C ring of testosterone and is located

deep within the hydrophobic core of the LBD. In addition to disrupting important receptor–ligand contacts directly, the insertion of a charged residue into this region of the receptor is likely to have dramatic effects on the overall tertiary structure of the LBD.

More commonly, when analyses are performed to analyze such mutant ARs by expression in bacteria or in eukaryotes, they frequently reveal that the AR is capable of interacting with ligand with measurable affinity, even when parallel studies performed in patient fibroblasts indicate that the mutant AR lacks the capacity to bind ligand. The mutant receptor containing an amino acid replacement at residue 774 (R774C; C, cysteine) is an illustrative example. When analyzed in cultured fibroblasts, the levels of ligand binding that are measured are below the detection limits of ligand-binding assays. When this mutant receptor (R774C) is expressed in heterologous cells, however, the mutant receptor can be shown to bind ligand. The marked instability of the ligand binding that is detected in these assays is likely the reason that ligand binding is undetectable in the patient samples. Many additional mutant ARs that exhibit the same type of behavior as that of the R774C mutant have been reported, in which normal or near normal-levels of immunoreactive receptor are expressed. This discordance appears simply to reflect differences in the sensitivity of the assays employed and the higher levels of receptor that can be expressed using eukaryotic and prokaryotic expression systems.

2. Qualitative Abnormalities of Ligand Binding

In some samples obtained from patients with androgen insensitivity, the number of ARs measured in ligand-binding assays is normal. In many instances, when such samples are carefully assessed, the AR that is present can be shown to exhibit qualitative abnormalities of ligand binding (e.g., affinity, reduced increased thermal instability, and accelerated ligand dissociation).

The first study to identify the genetic basis of androgen insensitivity associated with a qualitative abnormality of the AR (increased K_d) was reported by Lubahn and colleagues. These workers identified a single nucleotide substitution mutation that resulted in a single amino acid substitution (V866M; V, valine; M, methionine) in the LBD of the mutant AR that was associated with a phenotype of complete androgen insensitivity. Functional studies of this mutant AR demonstrated a reduced capacity to stimulate model androgen-responsive genes in transfection experiments. Of interest, in these analyses the ability of the mutant AR to induce the activity of androgen-responsive genes increased as ligand concentrations were increased.

A large number of the reported different amino acid substitutions are associated with qualitative abnormalities of ligand binding. In virtually all instances, the causative mutations are localized to the LBD of the receptor. An inspection of the locations of mutations in the AR that cause qualitative abnormalities of ligand binding and absent ligand binding shows a similar distribution. This suggests that the degree to which the structure of the LBD is disrupted dictates the type of binding abnormality that is identified. Alterations that cause more dramatic changes of structure are associated with absent ligand binding and those causing less extensive alterations are associated with qualitative defects of the AR. Studies of mutant ARs in which a single residue has been mutated to different amino acid residues in different pedigrees have supported this concept. For example, Prior *et al.* identified a mutation that resulted in the replacement of an arginine residue by a cysteine residue (R774C) in a patient with complete androgen insensitivity. In fibroblasts, this alteration is associated with an absence of ligand binding. By contrast, in a different pedigree, a mutation that causes a replacement of this same arginine by a histidine residue has been shown to be associated with normal levels of AR that exhibit pronounced thermal instability. Similar studies of additional subjects with androgen insensitivity have characterized other mutant ARs in which different amino acid substitutions at the same residue lead to different effects on ligand binding and receptor function.

The study of mutant ARs that exhibit different types of qualitative abnormalities and contain amino acid substitutions in the LBD has provided additional insights. In most target cells, enzymes (such as members of the 17-hydroxysteroid dehydrogenase family) actively convert testosterone and 5α-dihydrotestosterone to inactive metabolites. Several studies have noted that when mutant ARs containing amino acid substitutions in the LBD are stimulated with such androgens, the dosing, concentration, and type of androgen employed have a dramatic effect on the levels of AR function that are measured in functional assays. In the studies of Marcelli and co-workers, testosterone was the least potent, and dihydrotestosterone and mibolerone exhibited greater activity. In several instances, these investigators were able to show that repeated dosing of physiologic concentrations of androgen could restore the function of

the mutant AR. These experiments have demonstrated the importance of the stability of the hormone–AR complex. Conditions that enhance the formation and stability of these complexes exert major effects on the function of the mutant receptors in functional assays. In addition, these results suggest that mutant receptors capable of binding hormone can be manipulated pharmacologically to normalize AR function, inferences that have been supported clinically in a limited number of instances. Finally, such experiments demonstrate that care must be taken when considering the relationship between measurements of AR function and patient phenotype. In this regard, it is quite likely that minor changes in the methods used (e.g., the use of different ligands) could result in considerable differences in the levels of receptor function that are measured.

D. Mutations That Result in the Synthesis of Decreased Levels of AR

Two different mechanisms have been identified in relationship to mutations that result in reduced quantities of AR, underscoring the diversity that is likely to be encountered in this category of genetic alteration. The first mutation associated with this type of abnormality was reported by Zoppi et al. Using monolayer binding assays, affected individuals were found to express reduced amounts of AR. These results contrasted dramatically with the results established by immunoblot assays measuring AR in extracts of fibroblasts in affected family members. In these assays, no immunoreactive AR protein was detected using antibodies directed at the amino terminus of the AR (residues 1–20). This basis for this paradox was identified as an AR open reading frame mutation that introduced a premature termination codon in place of amino acid residue 60. The low level of AR detected in the initial fibroblast monolayer binding assays was shown to be the result of downstream initiation at Met-189. Functional characterization using transfection into heterologous cells suggested that the phenotype associated with this mutation in the pedigree (complete androgen insensitivity) was caused by a combination of reduced receptor expression and a reduced function of the receptor protein that is synthesized. Additional studies demonstrate that this receptor protein, which is analogous to the A-form of the progesterone receptor, is present in normal cells, although more recent reports have raised the possibility that the shortened AR (AR-A) is the result of protein degradation.

The mechanism implicated in the analysis of the patient characterized by Choong and co-workers differs considerably. In this pedigree, the propositus was an individual with partial AIS in which reduced levels of apparently normal AR were synthesized. Analysis of samples from affected subjects revealed a single nucleotide mutation that causes an amino acid replacement at amino acid residue 2 (a lysine residue in place of the normal aspartate residue at this position). On the basis of cell transfection and in vitro translation studies, the authors postulated a reduced efficiency of translation initiation that led to diminished levels of AR.

E. Additional Perspectives on the Function of Mutant ARs (Interaction of Termini)

Work in a number of laboratories has identified ligand-dependent interactions occurring between the amino and carboxyl termini of the AR. Initially inferred from the influence of changes in the length of the amino-terminal glutamine repeat on the activity of a mutant AR containing an amino acid substitution in the LBD of the receptor, several groups have defined the basis for this interaction and have implicated it as an important component of normal AR function. Despite considerable attention to this interaction, experiments conducted by Chang and McDonnell have failed to demonstrate that alterations of gene activation can be observed to accompany the disruption of the amino- and carboxyl-terminal interaction using small peptides.

In one instance, these results have been extended to examine the interactions between the amino and carboxyl termini in mutant ARs containing LBD mutations. There is evidence that the disrupted amino- and carboxyl-terminal interactions may represent a marker of the potential molecular defect in patients with AIS, in whom normal or near-normal androgen binding is present. Given the limited number of AR mutations that have been analyzed in this fashion, it is not clear whether such studies provide information, or if they simply represent additional properties that reflect the formation of an inherently unstable hormone–receptor complex.

IV. AR MUTATIONS, FUNCTION, AND CLINICAL PHENOTYPE

It has become evident that the nature of the AR defect does not have a simple relationship to the phenotype exhibited by affected individuals. Despite this, the large number of AR mutations that have been

reported in patients with various forms of androgen resistance permits a number of generalizations to be made. First, truncation or interruption of the AR protein is associated with a phenotype of complete androgen resistance. This association is caused by the location of the critical DNA- and ligand-binding domains in the carboxyl-terminal segments of the AR open reading frame. For this reason, interruptions of the coding sequence remove one or both of these important functional domains and result in the synthesis of ARs that are inactive in assays of receptor function. By contrast, amino acid substitutions in the AR can cause variable effects on AR function and have been associated with the complete range of androgen-resistant phenotypes.

The second generalization pertains to the relationship between the AR gene defect and the observed clinical phenotype. In some instances, no AR is expressed or the genetic mutation completely abolishes AR function. In these instances, the clinical phenotype—complete androgen insensitivity—agrees with assessments of receptor function and is consistent between pedigrees. Such considerations do not apply when the AR that is expressed is not completely defective. In these instances, the quantitation of the degree of deficiency is considerably more difficult, because the results of functional assays may show marked differences, depending on the conditions under which such assays are performed. Although a number of examples of this phenomenon can be found in the literature, the experiments of Marcelli are representative, i.e., changes in the incubation conditions or the type of the ligand used can lead to dramatic differences in the level of receptor function measured.

Although in many instances similar phenotypes are observed in different pedigrees in which the same mutation is identified, a significant proportion of patients with identical mutations will exhibit various phenotypes. In the analysis of Gottlieb *et al.*, as many as 10–15% of cases contained in the AR Mutation Database have been reported to have distinctive phenotypes but have identical mutations. The issues raised by these inferences have been more carefully directly assessed in the Netherlands in a nationwide survey of patients with AIS. In this study, fully one-third of families with partial AIS showed considerable variation in phenotype. At least two distinct mechanisms have been identified that may contribute to such differences.

Boehmer *et al.* reported the characterization of two siblings with partial forms of AIS: one with a predominantly female phenotype (classified as grade 5 AIS) and the second with a predominantly male phenotype (perineal hypospadias, micropenis, and bifid scrotum; classified as grade 3 AIS). Investigations of the structures of the AR genes in these individuals identified identical AR mutations (R855H; H, histidine) within the receptor LBD. Analyses of fibroblasts established from both subjects revealed similar levels of androgen binding in both strains that were within the normal range. In these analyses, the mutant AR exhibited only a minor reduction in binding affinity, compared to normal controls. In contrast to these findings, measurements of 5α-reductase levels revealed substantial differences between the strains. In the subject with the greater degree of virilization, levels of 5α-reductase were similar to the levels present in normal male and female fibroblasts. By contrast, the level of 5α-reductase detected in the subject with the predominantly female phenotype was in a range consistent with that observed in patients with 5α-reductase deficiency. This finding could not be explained on the basis of mutations of 5α-reductase 2 gene and was felt possibly to reflect "secondary" 5α-reductase deficiency, as had been observed in other AIS pedigrees. In any event, the differences in local formation of DHT were proposed to underlie the differences in the degree of virilization observed in these two subjects. The postulated effect in these patients would be expected to mirror the effects of DHT versus testosterone in cell transfection experiments using different ligands to stimulate mutant receptors containing amino acid substitution in the LBD.

In some instances, the mutation identified appears inconsistent with the observed phenotype. (e.g., a mutation causing premature termination of the AR in a subject with substantial levels of virilization) This is the circumstance in the pedigree examined by Holterhus and co-workers, who identified a premature termination codon occurring at amino acid 172 in the open reading frame of the AR. Surprisingly, this mutation was identified in a patient exhibiting subtle signs of virilization (clitoromegaly). Investigation of the level and nature of AR expressed in this patient indicated that the reduced level of ligand binding that was detected reflected the presence of reduced amounts of full-length normal AR. The derivation of this normal AR was shown to be the result of a somatic mosaicism in which a proportion of the cells in this patient expressed normal AR. This reduced level of normal AR was proposed to account for the degree of virilization that was observed in this patient. The investigators have identified additional pedigrees in which both normal and mutant ARs are

present. The proportion of mutant AR that is present is believed to influence the clinical phenotype.

V. SPINAL AND BULBAR MUSCULAR ATROPHY

In 1968, Kennedy, Alter, and Sung reported the description of two families with an adult-onset form of spinal and bulbar muscular atrophy. Although similar to other "muscular atrophies" that had been described previously, affected individuals in these pedigrees were noted to exhibit several unusual features. First, the disease became clinically evident in the fourth and fifth decades of life and was slowly progressive. Affected individuals described low backache and muscle cramps. These initial symptoms were followed by the appearance of overt muscle weakness and fasciculations. The muscle weakness was most notable in the proximal musculature; distal muscular involvement occurred later and was less pronounced. Bulbar involvement was present in affected individuals and resulted in both dysarthria and dysphagia. Nerve conduction velocities were normal and electromyelogram (EMG) analyses identified patterns consistent with degeneration of motor neurons within the anterior horns and cranial motor nuclei. Although sensation and cerebellar function were judged to be normal in clinical assessments, subsequent studies identified abnormal sensory action potentials, leading some to term this disorder "bulbospinal neuronopathy." Pathologic findings have supported that changes in ganglia are likely the basis for these changes. Although such sensory abnormalities are consistently demonstrable in a proportion of affected subjects, symptoms and signs referable to the degeneration of affected spinal and bulbar motor nuclei predominate. Importantly, only males are affected in these families, suggesting inheritance as a sex-linked recessive trait. In addition to these neurological features, 3 of the 11 affected individuals were noted to have findings consistent with a defect of androgen action (gynecomastia).

Given the involvement of the AR in mediating the effects of androgen in virilization and fertility, the AR, known to be localized to the human X chromosome, represents a potential candidate gene for this disorder. Seminal work by La Spada and colleagues has demonstrated that an expansion of a CAG triplet repeat in the amino terminus of the AR is the genetic change responsible for the development of Kennedy's syndrome. The increased size of this repeat segment results in the expansion of a segment of repeated glutamine residues (homopolymeric segment) within the open reading frame of the AR, from its normal size (11–33) to a larger size not observed in normal individuals (>38). This expansion is believed to influence at least two distinct properties of the AR that contribute to the overall phenotype that is observed in individuals affected by spinal and bulbar muscular atrophy (SBMA). First is the contribution of this genetic change to the mild androgen resistance that is observed in a proportion of affected individuals. Males carrying this genetic change develop normally and exhibit normal sexual function early in life. Despite this, a proportion of affected subjects begin to exhibit phenotypic changes characteristic of mild androgen resistance as they enter adulthood. In several series, 25–50% of subjects had gynecomastia and several had been investigated for infertility. The expansion of the size of the glutamine repeat has been suggested to contribute to these endocrine effects in two different ways. First, it appears that the glutamine repeat expansion impairs the activity of the receptor protein in transfection assays of receptor function. When examined carefully, these changes appear to reflect true decreases in the specific activity of the receptor protein in modulating the activity of model reporter genes. In addition to these changes, however, it appears that the expansion of the glutamine repeats may in fact impair the efficiency of translation of the AR mRNA, resulting in lower levels of AR expression. Both of these changes may well contribute to the evolution of the mild androgen resistance that is a component of the SBMA phenotype. Perhaps with the decline of testicular function that occurs with age even in normal subjects, the impairment of function of ARs containing the glutamine repeat expansion becomes evident clinically.

La Spada and colleagues were the first to link the expansion of a glutamine repeat within the open reading frame of a protein to the pathogenesis of a disease. In the case of SBMA, they correlated this disorder to the expansion of a homopolymeric domain within the amino terminus of the AR gene (from ~20 in normal controls to >38 in affected individuals). Subsequent investigations have implicated similar genetic changes in the pathogenesis of several progressive neurological diseases, including Huntington's disease, spinocerebellar ataxia-type 1, Machado–Joseph disease, and dentatorubral pallidoluysian atrophy.

The mechanisms by which such glutamine repeat expansions cause neurological symptoms remain the subject of active investigation. Several lines of

evidence have suggested that the proteins containing expanded polyglutamine tracts, such as the AR, acquire a toxic property that is not possessed by the normal protein. Several groups have proposed that the central mechanism may involve accumulation of peptides that are produced as a result of the presence of the glutamine repeat expansion. Supporting such a mechanism are studies that have identified intracellular inclusions containing fragments of ARs that contain the glutamine repeat expansion. In such models, the toxicity of these fragments is believed to result in the degeneration of neurons within selected spinal and bulbar nuclei. The mechanism of this toxicity may derive from the sequestration of critical proteins, such as transcription factors by the glutamine repeat-containing peptides. The toxicity may also involve distinct mechanisms that contribute to the neural pathology. It is likely that several different properties of proteins containing glutamine repeat expansions may contribute to the toxicity that these proteins exhibit. Further investigations will be needed to clarify which of these properties represent critical pathologic properties and which are essentially ancillary findings.

Despite the insights that such experiments have provided, a number of important questions still remain pertaining to the mechanisms by which this toxicity emerges. A particularly intriguing and unexplained aspect of this disease is the timing of its onset. The onset of the disease occurs later in life (i.e., middle age), in a time frame that is difficult to explain based on what is known regarding the expression of the gene product (the AR) that has been implicated. Finally, it is remarkable that the toxicity observed in SBMA is restricted to cells of neural lineage, suggesting that some aspect of the neuronal cell type might make it particularly susceptible to the effects of proteins containing the expanded glutamine repeats.

VI. SUMMARY

Mutations of the human androgen receptor gene have been implicated in pathogenesis of several different diseases. In androgen insensitivity, AR function is defective to varying extents, causing a range of abnormalities of male sexual development. At one end of this spectrum, individuals with complete androgen insensitivity (complete testicular feminization) exhibit a normal female phenotype, with normal breast development and female external genitalia. On the other end of the spectrum, individuals with AR defects have male external genitalia, but exhibit either subtle undervirilization or infertility. Between these extremes are individuals with substantial defects of AR function that are associated with phenotypes between that of a normal male and a normal female. Although diverse at the molecular level, the genetic alterations causing androgen insensitivity can be explained as reflecting loss-of-function mutations.

The same is not true for spinal and bulbar muscular atrophy (Kennedy's disease). This disease is characterized by the appearance in adulthood of signs and symptoms of mild androgen insensitivity and the progressive deterioration of function of muscles innervated by spinal and bulbar motor nuclei. The pathogenesis of this disorder has been linked to the expansion of a triplet repeat encoding a series of repeated glutamine residues. As with other diseases caused by the expansion of glutamine repeats, the basis of this toxic gain-of-function mutation has been the subject of intense mechanistic studies.

Glossary

17-hydroxysteroid dehydrogenases Group of enzymes responsible for the reversible conversion of testosterone and 5α-dihydrotestosterone to inactive metabolites (androstenedione and 5α-androstenedione, respectively). In specific tissues, selected members of this enzyme group are responsible for synthesis of active androgens (e.g., 17β-hydroxysteroid dehydrogenase type 3 in the testis).

P-box Segment of the DNA-binding domain of nuclear receptors that is responsible for the specificity of DNA binding by the receptor protein.

5α-reductase Enzyme responsible for the conversion of testosterone to 5α-dihydrotestosterone.

target cell Type of cell in which a specific hormone exerts its actions (e.g., the prostate is a classic androgen target tissue).

Androgen Receptors and Prostate Cancer

DOLORES J. LAMB

Baylor College of Medicine

Diseases of the prostate account for an enormous portion of the morbidity, mortality, and economics in health care of males in the United States. Prostate cancer represents a major health problem for adult men and is the second leading cause of cancer deaths in the United States. If men are castrated before puberty, prostate cancer does not develop. Accordingly, androgens are thought to be required for the initiation and initial progression of prostate cancer.

I. INTRODUCTION

Androgens are required for the normal development and differentiated function of the prostate. It is not surprising that tumors that form in the prostate respond to androgens during the early stages of disease. For tumors that have not spread outside of the prostate, radical prostatectomy is a favored form

of treatment. If the tumor has spread and metastasized, androgen ablation therapy, first proposed by Charles Huggins (who received the Nobel Prize in 1966 for this hypothesis), is a treatment for this disease. Like metastatic breast cancers, initially the tumors respond to steroid deprivation, with regression resulting from apoptosis of androgen-dependent prostate cancer cells. Although nearly all tumors continue to express the androgen receptor, some tumors may contain a heterogeneous mixture of androgen-dependent and androgen-independent cells. The androgen-independent cells will escape apoptosis induced by androgen ablation. Other androgen-dependent cells may adapt to a state of androgen depletion and then gain an androgen-independent phenotype. Ultimately, prostate cancer progresses to a state of androgen independence with uncontrolled growth. For the patient, this represents the failure of their therapy and a probable poor outcome. The molecular basis for this progression to androgen independence is largely unknown at this time. One possibility is that mutations in the androgen receptor contribute to this progression of the prostate cancer to an androgen-independent state.

The androgen receptor is a member of the steroid receptor superfamily. The gene is located on the X chromosome and there are eight exons that encode a protein of 919 amino acids. Because the gene is located on the X chromosome, mutation of only one allele is required for a phenotypic change. Importantly, androgen action is dependent on not only a functioning receptor with high affinity and steroid-binding specificity, but also on the interactions of growth factor signaling pathways and the complex interaction of co-activators, co-repressors, and other factors to regulate specific gene expression. Changes in any of these factors could influence androgen action.

Mutant receptors with an altered function were first described in breast cancer, leading investigators to propose that point mutations in the androgen receptor may account for progression from androgen-dependent to androgen-independent growth in prostate cancer. Molecular changes in receptor structure or concentration may result in part in hormone-independent tumor growth. The types of androgen receptor mutations/alterations and their functional consequences are described here. In addition to mutations, there are a number of other potential changes in the androgen receptor signaling pathway that can stimulate androgen receptor activity at suboptimal levels of hormone. The potential role of these alterations in the androgen receptor in prostate cancer progression is also discussed.

II. CHANGES IN THE ANDROGEN RECEPTOR GENE

A. Amplification of the Androgen Receptor Gene

An increased copy number or amplification of the androgen receptor gene has been observed in some prostate cancers. Investigators have proposed that this amplification may lead to overexpression of the androgen receptor and, ultimately, to tumor growth stimulation at low levels of circulating androgens. Some investigators have questioned whether the amplification has physiologic relevance and it is somewhat controversial in the literature. An increase in androgen receptor copy number does not correlate with the response to initial androgen ablation therapy, although it does appear to correspond to a positive outcome of secondary treatment with complete androgen blockade. The increase in androgen receptor copy number was correlated with an increased secretion of prostate-specific antigen that did not correlate with tumor burden, again suggesting a functional consequence of this amplification. Although androgen receptor gene amplification and an increased level of the androgen receptor gene expression occur in a significant percentage of samples obtained from hormone-independent tumors, the frequency of androgen receptor gene amplification is too low to account for all prostate cancer progression to androgen independence.

B. Point Mutations Producing Superactive Androgen Receptors

Theoretically, an androgen receptor mutation could enhance the transcriptional activation of the receptor, especially at low ligand concentrations. In a transgenic adenocarcinoma of the prostate mouse, mutation was detected at residues (668)QPIF(671) at the boundary of the hinge and ligand-binding domain, resulting in a receptor that exhibits two- to fourfold increased activity compared with wild-type AR. This enhanced activity was noted in response to administration of dihydrotestosterone, estradiol, progesterone, and adrenal androgens, as well as the androgen receptor antagonist hydroxy flutamide without an apparent effect on receptor levels, ligand-binding kinetics, or DNA binding. The receptor could be activated by low circulating levels of androgen. Thus, if such a mutation were present in

a human prostate cancer, the growth of the tumor might be stimulated by the low levels of androgen remaining following androgen ablation. Preliminary studies suggest that these types of mutations may occur in some advanced human prostate cancers, but further investigations are required to confirm that this occurs and, if so, to define the frequency. This would be considered to be a "gain of function" mutation.

C. Point Mutations Generating a Promiscuous Receptor Protein That Is Activated by Ligands Other Than Androgen

Mutations that change steroid-binding specificity are thought to be important in the progression of some prostate cancers. In fact, the first mutation found in the androgen receptor in a prostate cancer was identified in the LNCaP cell line. This cell line is an androgen-responsive cell line derived from a human prostate cancer that was metastatic to bone. The functional consequence of this mutation in exon 8 of the androgen receptor is to change the steroid-binding specificity of the androgen receptor, resulting in estradiol and the anti-androgens hydroxy-flutamide, nilutamide, and cyproterone acetate becoming agonists. Since the identification of this first prostate cancer androgen receptor mutant, mutations have been identified in the androgen receptor in other specimens of prostate cancer and cell lines, and these mutations broaden or change the binding specificity of the androgen receptor for glucocorticoids, some adrenal and weaker androgens, anti-androgens, estrogens, and progesterone. In human prostate cancer, the consequence of this type of mutation is obvious. Treatment of the patient with an anti-androgen or an estrogen would have a detrimental effect. Rather than inhibiting tumor growth, the antagonist has become an agonist for the mutated receptor and might enhance the growth of the tumor. These mutations would all be considered to be in the category of gain of function.

D. Inactivating Mutations of the Androgen Receptor

A mutation in the androgen receptor may result in either the total loss of receptor protein (such as in a total deletion) or, more commonly, a truncation of the receptor or a "loss of function" in one of the functional domains of the protein. An example of this type of mutation is C619Y, found in a metastatic lymph node of a patient with prostate cancer. This androgen receptor mutation resulted in a receptor that could bind steroid and translocate to the nucleus but was localized in abnormal discrete foci, resulting in cytoplasmic and nuclear aggregates, perhaps due to protein misfolding. The mutated androgen receptor could not activate androgen-regulated transcription. Since androgens are normally thought to enhance prostate growth, the presence of an "inactivating" mutation in advanced prostate cancer may be surprising. Recently, Tindall and colleagues showed that disruption of the androgen receptor protein in prostate cancer cell lines inhibited their proliferation, suggesting that these loss of function mutations may not provide a growth advantage to the tumor. Accordingly, the mechanism of androgen regulation of prostatic growth is unclear, and loss of androgen receptor function in the tumor may result in a progressive loss of differentiated function and loss of growth control or it may inhibit tumor growth.

E. Androgen Receptor Polymorphisms That Modulate Transcriptional Activation

The length of a polymorphic polyglutamine tract in exon 1 of the androgen receptor influences the relative transcriptional activity of the androgen receptor *in vitro*. The length of the tract is inversely correlated with the transcriptional activation of the receptor by androgen. The shorter the tract, the more active the receptor; receptor transcriptional activation is diminished as the tract lengthens. There are racial differences in the average length of the tract, with African American males having approximately 18 repeats, Caucasian males having an average of 21 repeats, and Asian males having the highest repeat number within the normal polymorphic range. Expansion of these repeats to 40 or more results in Kennedy disease (spinobulbar muscular atrophy), a progressive degenerative neuromuscular illness. Some, but not all, investigators have reported that the CAG repeat length (within the normal range) might be related to the age of the patient at diagnosis of prostate cancer and their response to endocrine therapy. It has been reported that a shorter polyglutamine tract is associated with the presence of metastatic disease at the time of diagnosis, a younger age of onset, increased incidence, higher mortality, and a more aggressive nature of prostate cancer in the African American population; however, not all authors agree. In general, it is accepted that the shorter polyglutamine repeat correlates with an earlier age of onset and a diminished response of the prostate cancer to endocrine therapy.

III. CHANGES IN THE RECEPTOR PROTEIN

A. Intracellular Changes That Influence Androgen Receptor Sensitivity or Protein Stability

Receptor function may be modulated indirectly by changes in the expression of specific proteins, such as caveolin, that enhance androgen receptor action by influencing androgen receptor sensitivity. Similarly, enhanced expression of the receptor, stabilization of the protein, and nuclear localization of the receptor at very low ligand concentrations enhanced androgen-mediated growth in human prostate cell lines tested *in vitro*. These types of changes in receptor characteristics, whether through a direct action on the receptor or an indirect action, serve to enhance androgen receptor action at low concentrations of androgen, and presumably this contributes to enhanced growth of prostate cancer after endocrine ablation treatment.

IV. CHANGES IN INTERACTING FACTORS THAT MODULATE RECEPTOR FUNCTION

A. Co-activator or Co-repressor Modulation of Androgen Action in Advanced Prostate Cancer

Steroid receptors require co-activators to mediate their transcriptional activation functions with proteins in the general transcription complex to stimulate the steroid-regulated transcription of target genes. These factors interact with either the amino- or the carboxy-terminal regions of the receptor to enhance transcription. Some co-activators modulate a broad range of transcription factors, others stimulate the activities of nuclear receptors in general, and others show specificity for one or a few nuclear receptors. Many proteins have been identified that enhance androgen receptor transcriptional activity *in vitro*. Loss of co-activator interaction may diminish androgen receptor transcriptional activation or may broaden the ligand specificity of the receptor. Conversely, overexpression of specific co-activators, such as steroid receptor co-activator 1 and transcriptional intermediary factor 2, enhance androgen receptor transactivation at physiological concentrations of adrenal androgen, providing an alternative mechanism for enhanced prostate cancer growth despite androgen ablation therapy. It is clear that these co-activators play a critical role in androgen action and this is an area of ongoing investigation in several laboratories.

B. Ligand-Independent Activation of Androgen Receptor

The direct or indirect transcriptional activation of the androgen receptor by growth factors, neurotransmitters, or other agents that increase intracellular kinase activity or decrease phosphatase activity has been shown for chicken progesterone receptor and the human estrogen receptor. Similarly, the androgen receptor can be activated in the absence of androgen by several growth factors thought to be acting through the mitogen-activated protein kinase pathway, through the protein kinase A signaling pathway, or through Her-2-neu overexpression signaling androgen receptor phosphorylation by Akt. Support for a role of kinases in androgen receptor action comes from the observation that the tumor suppressor gene PTEN appears to inhibit androgen receptor action. As a result of this complex cross-talk between different signal transduction pathways, the androgen receptor has the potential for activation.

V. CHANGES IN STEROID BIOAVAILABILITY

A. Altered Steroid Bioavailability or Circulating Levels

Only a small portion of circulating androgen is unbound in the circulation and it is the "free" testosterone that is available to diffuse into the cells, bind to the receptor, and initiate androgen action. Changes in the relative concentrations of free to bound androgen may influence prostate cancer growth. There may be local increased or decreased intraprostatic bioavailability of dihydrotestosterone to activate the androgen receptor. Similarly, racial differences in the average levels of circulating androgens may lead to conditions more permissive of prostate cancer development and/or progression. Thus, conditions that modulate the relative concentration of androgen available to the cell may influence prostate cancer.

VI. ALTERNATIVE ROUTES TO GROWTH STIMULATION

A. Activation of Growth-Stimulating Signaling Pathways with the Ability to Bypass Androgen Receptor-Regulated Growth and Differentiation

Growth factors may act directly to enhance prostate cancer growth. Conceptually, androgens are normally considered to be the major stimulator of prostate

cancer growth; however, it is known that there are many alternative pathways (growth factors, cAMP, kinases, apoptosis, etc.) involved in growth regulation. Accordingly, all of these pathways may contribute to the loss of growth regulation by androgens that occurs in advanced prostate cancer. Since there is a limit to enhancement of the rate of cell proliferation by these growth stimulatory agents, maximal stimulation of growth by an alternative pathway may not be impacted by the loss of androgens upon ablation therapy. Furthermore, the cells may adapt to a state of androgen deprivation and seek to maximize their growth rate through these alternative pathways.

VII. SUMMARY

These studies demonstrate the important, but relatively poorly understood, function of the androgen receptor in the development and maintenance of differentiated function of the normal prostate, as well as the development of prostate cancer and the progression of this disease. It is clear that there are multiple routes to androgen-independent disease. Alterations of the androgen receptor structure and modulation of its function provide an important route for the development of new therapies to treat advanced prostate cancer.

Glossary

androgen A steroid hormone, such as testosterone or dihydrotestosterone, that promotes the development and maintenance of male secondary sex characteristics and structures.

androgen receptor A member of the steroid receptor superfamily of genes that mediates the action of androgens on the target cell; a ligand-activated transcription factor.

apoptosis Programmed cell death that requires gene transcription and specific protein synthesis (physiologically regulated event). The cells shrink and convolute, the nucleus condenses, the DNA fragments, and the cell membrane swells and blebs. Ultimately, proteases are activated.

casodex, cyproterone acetate, hydroxyflutamide, and nilutamide Androgen receptor antagonists that block androgen receptor function.

co-activators and co-repressors Factors that positively or negatively influence androgen receptor transcriptional activity.

Kennedy disease (spinal bulbar muscular atrophy) A progressive degenerative neuromuscular disease of genetic origin resulting from expansion of a polyglutamine repeat in the androgen receptor gene.

prostate-specific antigen A protein that serves as a tumor marker for prostate cancer; elevated concentrations in the bloodstream may indicate the presence of prostate cancer.

transgenic adenocarcinoma of the prostate (TRAMP) mouse A transgenic mouse model of prostate cancer.

hormone-response element Segment of DNA sequence that binds to the DNA-binding domain of a steroid receptor and thereby facilitates the activation of a gene. Androgen-response elements are nucleotide sequences that bind the androgen receptor.

N/C interaction Interaction between the NH_2-terminal and carboxyl-terminal (N/C) regions of the androgen receptor that is selectively induced by the binding of a biologically active androgen, testosterone or dihydrotestosterone. This interaction is mediated by F*XX*LF- and W*XX*LF-binding motifs in the NH_2-terminal region and activation function 2 in the ligand-binding domain.

p160 co-activators A group of co-regulatory proteins of approximately 160 kDa in size that interact with nuclear receptors to increase the transcriptional response.

Androgens: Pharmacological Use and Abuse

MARIA M. BYRNE AND EBERHARD NIESCHLAG
University of Münster

Androgen preparations are widely prescribed for a variety of medical conditions in both men and women. Misuse of androgens, however, has become an extensive problem of increasing proportion. Therefore, it is important for students, scientists, and clinicians to be familiar with the risks and benefits of androgen use.

I. INTRODUCTION

The principal medical use of androgens is for the treatment of male hypogonadism and delayed puberty. However, many new indications for androgen treatment are emerging. This article focuses on

the pharmacology of the various androgen preparations currently available and includes a discussion of the variety of clinical indications (accepted and experimental) for androgen use. In addition, the escalating problem of androgen abuse is addressed.

II. PHARMACOLOGY

In human males, gonadotropin-releasing hormone (GnRH) released from the hypothalamus stimulates the pituitary to secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH stimulates the Leydig cells of the testes to secrete approximately 7 mg of testosterone per day. This amount is necessary to induce and maintain secondary sexual characteristics, sexual behavior, muscle development, bone density, and male phenotype. The biological action of testosterone is due to its direct binding to the androgen receptor (AR), to its conversion to dihydrotestosterone (DHT) by the 5α-reductase enzyme, or to its aromatization to estrogen. DHT has a higher affinity, compared to testosterone, for the AR and is therefore a more potent androgen. The principal biological effects of testosterone include (1) stimulation of prenatal differentiation and pubertal development of the testes, penis, epididymis, seminal vesicles, and prostate, (2) increased retention of nitrogen and increase in lean body mass and body weight, (3) larynx growth, sebum production, beard growth, and pubic hair growth via DHT, (4) increased bone mineral density (BMD) via estrogen, and (5) reduction in high-density lipoprotein (HDL) and increase in low-density lipoprotein (LDL) cholesterol levels, with increases in triglycerides. The 5α-reductase enzymes are most abundant in the prostate, skin, and reproductive tissues. DHT is required for fetal development of external genitalia, prostate, and seminal vesicles, and adult secondary hair growth. Aromatization of testosterone to estradiol is necessary for sexual differentiation of the brain, for bone mass accretion, and for fusion of the epiphyses at the end of puberty. Testosterone circulates bound to sex hormone-binding globulin (SHBG), with only 1–2% remaining unbound and hence biologically active. Whereas androgen status is typically defined solely on the basis of serum testosterone levels, the AR is clearly another important determinant of androgen action. The majority of studies demonstrate no correlation between endogenous testosterone levels and the subsequent development of prostate cancer. However, an inverse correlation exists between the length of the AR polyglutamate tract and both an increased risk and an earlier onset of prostate cancer. CAG repeats are considered to play a modifying role in prostate cancer risk. Therefore, polymorphisms in the AR may be as important as absolute testosterone levels in mediating androgen effects.

Because of the short duration of action of testosterone, pharmacological strategies have been developed to produce more sustained blood levels of testosterone, resulting in prolongation of its androgenic action. These strategies include (1) new modes of testosterone administration and (2) chemical modification of the testosterone molecule, including esterification of the 17β-hydroxyl group or alkylation of the 17α position of the D ring of the molecule, with or without other modifications of the ring structure (Fig. 1).

A. Oral Testosterone

Orally administered unmodified testosterone is rapidly absorbed from the gastrointestinal tract into the portal blood and then degraded by the liver (first-pass effect), resulting in a minimal amount of testosterone reaching the systemic circulation. Large doses (200–400 mg/day), taken several times a day, are necessary to achieve physiological levels. Oral testosterone induces production of the liver enzymes that are responsible for testosterone metabolism. Although long-term hepatotoxicity of large doses is unknown, unmodified oral testosterone is not recommended to achieve physiological testosterone levels in blood.

1. Testosterone Undecanoate

Testosterone is esterified in the 17β position with a long aliphatic side chain to produce an oral hydrophobic 17β-hydroxyl testosterone ester. It is administered in doses of 80–240 mg/day for androgen replacement therapy, and 40 mg/day for the treatment of constitutionally delayed puberty. Due to the nonpolar nature of the ester, it is preferentially absorbed through the lymphatic system, thereby avoiding first-pass metabolism in the liver. Although testosterone has been widely used for the treatment of male hypogonadism in Australia, Canada, and Europe since the 1970s, its clinical use is limited by a short half-life, necessitating multiple daily dosing. Maximum serum levels were obtained 4 to 5 h after ingestion, with huge interindividual variability. The DHT/testosterone ratio is increased secondary to intestinal 5α-reductase activity, and uncommon gastrointestinal side effects include flatus, oily stool, and diarrhea.

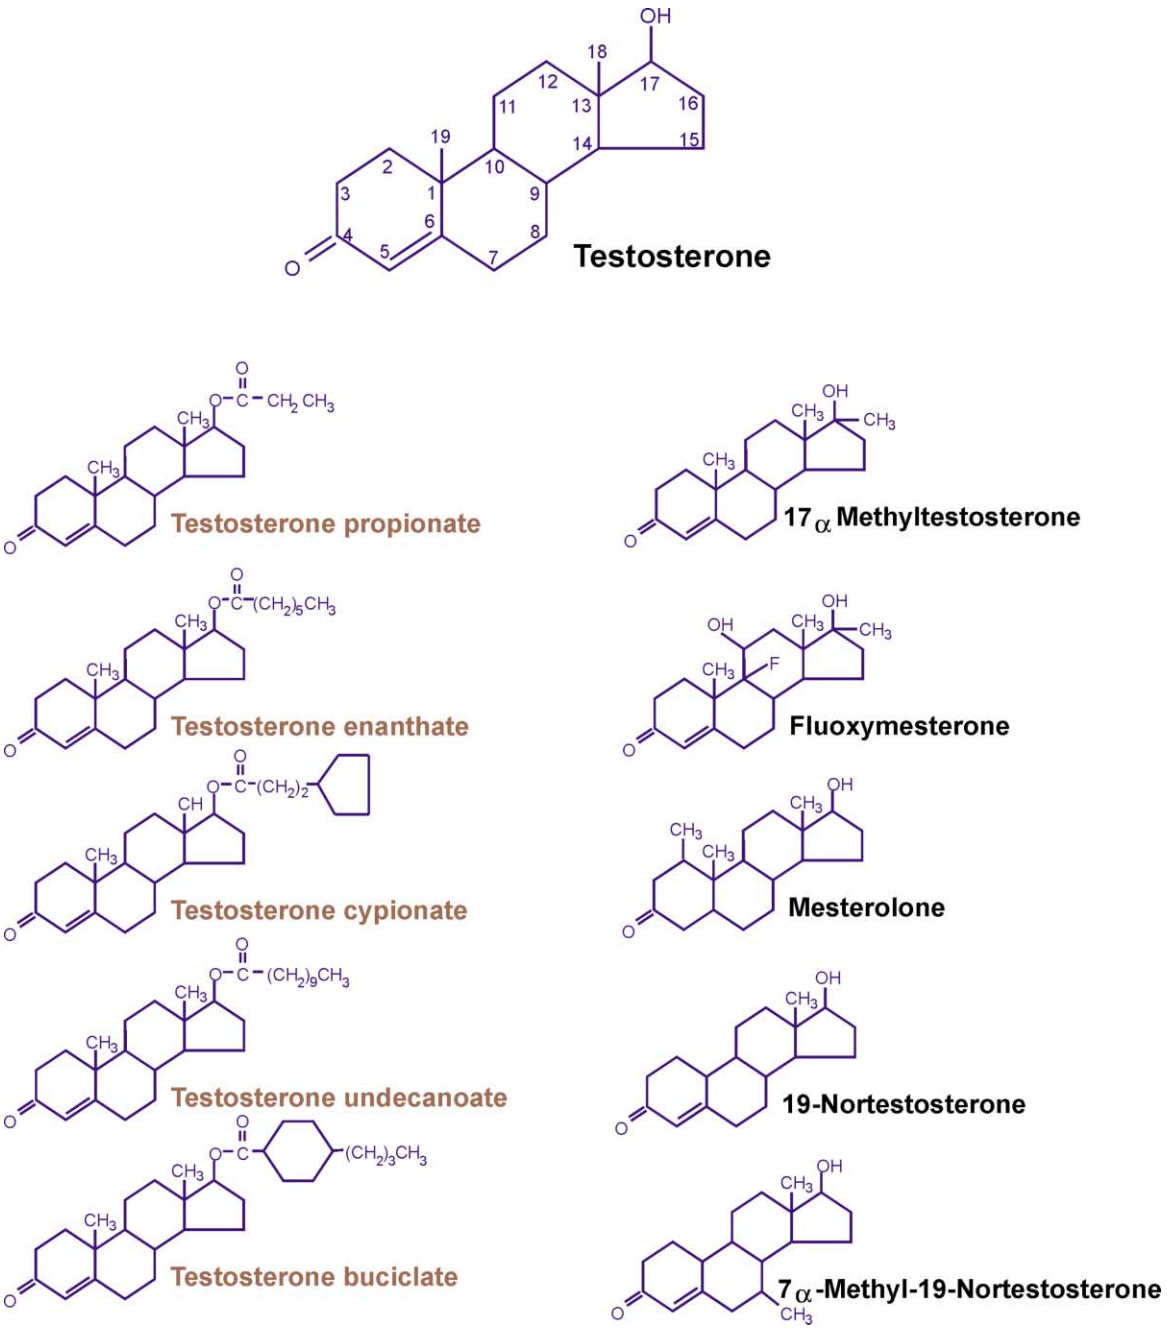

FIGURE 1 Molecular structures of testosterone and some of its modifications.

2. 17α-Methyltestosterone

Alkylation at the 17α position reduces hepatic metabolism, resulting in improved systemic concentrations of testosterone. 17α-Methyltestosterone is rapidly absorbed, with maximal testosterone levels achieved 90–120 min after ingestion; plasma half-life is 150 min. 17α-Alkylated derivatives of testosterone and fluoxymestrone (addition of a fluorine and a hydroxyl group into the steroid skeleton of testosterone) are rarely used due to lack of potency and potential serious hepatotoxicity (hepatitis, cholestasis, peliosis, and benign and malignant hepatic tumors). Use of these derivatives has been discontinued in Europe. Other 17α-alkylated derivatives

include oxandrolone, oxymetholone, stanozolol, and danazol, which are less androgenic and more anabolic.

Mesterolone, a 1α-methyl derivative of 5α-DHT, contains only modifications in the A ring of testosterone, without modification of position 17. Mesterolone and DHT cannot be metabolized to estrogen and therefore will exert questionable clinical effects on bone and brain. Mesterolone is considered to be a relatively weak androgen and therefore not suitable for the treatment of male hypogonadism.

B. Transdermal Testosterone

The development of transdermal testosterone preparations in the late 1980s was an important advance in androgen replacement therapy. Transdermal substitution of estradiol is a well-established method of treating ovarian insufficiency. However, only micrograms of estradiol are required for replacement therapy. In contrast, up to 7 mg/day of testosterone is required for treating male hypogonadism. Due to the superficial vascularity of the scrotal skin, there is a 5- to 40-fold increase in steroid absorption when compared to other skin sites. The scrotal transdermal testosterone system (TTS) is a 40 or 60 cm^2 large polymeric membrane loaded with 10 or 15 mg of testosterone. The patches are applied daily in the morning to the shaved scrotum and result in physiological levels of testosterone (mimicking the normal circadian rhythm), rising to a maximum 2–4 h after application and remaining within the normal range until the patch is removed. DHT levels rise above normal within a few hours of application and remain constantly elevated during the treatment period. This is the result of the high levels of 5α-reductase activity in the scrotal skin. The clinical significance of supraphysiological levels of DHT remains currently unknown, but use over several years has not resulted in untoward side effects. Careful monitoring is still recommended.

In recent years the availability of nongenital patches has led to a decline in the use of scrotal preparations. Permeation-enhanced transdermal delivery systems with a reservoir containing testosterone (12.2 mg) in an alcohol base (Androderm) have been shown to maintain serum testosterone levels more consistently within the normal range, compared to an equivalent intramuscular (im) dose. The recommended dosage for adult hypogonadism is two 2.5-mg patches or one 5-mg patch applied at night to nonscrotal skin (e.g., abdomen, thighs, upper arm, or back). This regimen delivers 5 mg/day of testosterone, with 60% being absorbed within the first 12 h, maintaining serum testosterone levels in the physiological range and mimicking the normal circadian rhythm. In contrast to scrotal TTS, DHT levels also remain within the physiological range. The main drawback of this patch is local skin irritation, which occurs in ~30% of patients compared to ~5% of patients using scrotal TTS. The patch can also cause an allergic contact dermatitis (~12% of patients). Simultaneous treatment with 0.1% triamcinolone acetonide under the patch will improve local tolerability without altering the pharmacokinetics. Skin irritation limits the acceptability of this treatment, resulting in 10–15% of patients having to discontinue treatment.

The recently approved nonscrotal patch Testoderm TTS, which has a larger surface area but does not contain a reservoir, causes less skin irritation (itching and erythema, in ~12% and ~3% of patients, respectively). However, adherence of the patch to the skin poses a problem in some patients, especially those engaged in strenuous exercise. When applied nightly it provides a steady-state delivery of testosterone to the circulation that mimics the normal diurnal rhythm. The long-term use of these transdermal patches has been efficacious in maintaining sexual function, secondary sexual characteristics, and bone and muscle mass in hypogonadal young and elderly men.

The latest development in androgen replacement therapy is an open testosterone delivery system using a hydroalcoholic gel (Androgel 1%), which is now licensed in the United States and several other countries for the treatment of hypogonadal men. When applied to the skin, the gel dries rapidly and the steroid is absorbed into the stratum corneum, which serves as a reservoir. Pharmacokinetic studies of this gel (50 or 100 mg) applied to hypogonadal men indicate that testosterone levels increase into the normal range within 30 min, with steady-state levels achieved by 24 h. Hypogonadal men treated for 6 months with this gel had improved sexual function, increased lean body mass and muscle strength, and decreased fat mass. There was a significant dose-related increase in hematocrit levels reported. Serum DHT levels were also increased. Transdermal gel is user friendly, providing flexibility in dosing with little skin irritation and thereby good compliance. One concern may be the contact transfer of androgens and the induction of androgenic side effects in females or children.

DHT is available as a 2% hydroalcoholic gel that is applied to a large area of skin and washed off

10 min after application. This results in stable DHT plasma levels for 24 h, an elevated DHT/testosterone ratio, lack of aromatization to estrogen, and suppression of endogenous estrogen and testosterone. There is also a risk of contact transfer to female partners. DHT has been shown to maintain sexual function in hypogonadal men but is less efficient than testosterone in preventing bone loss. Prostate volume and prostate-specific antigen (PSA) remain unchanged with long-term DHT gel treatment in older men. A 0.7% hydroalcoholic dermal gel is being developed for the treatment of aging men. Daily application for 3 months to elderly partially androgen-deficient men results in stable pharmacokinetic features with consistent negative feedback on the pituitary–testicular axis and reduced body fat, but minimal effects on muscle mass, strength, or function. Prostate volume and PSA levels remain unchanged.

C. Intramuscular Testosterone

The most widely used testosterone replacement therapy is in the form of im injection of testosterone esters. Esterification at the 17β-hydroxyl group increases the solubility of testosterone in oil and thereby slows its release into the circulation, prolonging its duration of action. However, only the unesterified testosterone is biologically active. Testosterone propionate must be injected every 2–3 days, but testosterone enanthate (doses of 200–250 mg) and testosterone cypionate have longer durations of action and can be injected every 2–3 weeks, for replacement therapy of hypogonadism.

The disadvantage of all these esters is that they produce initially supraphysiological testosterone levels, which then decline slowly to the hypogonadal range prior to the next injection. Some patients correlate these fluctuations in testosterone levels with changes in well being, mood, and sexual activity. For these reasons, preparations containing a combination of a short- and a long-acting 17β-hydroxyl testosterone ester have been developed and are available in Europe (e.g., Testoviron Depot 50 and 100, containing a combination of testosterone propionate and enanthate, and Sustanon 100 and 250, containing combinations of testosterone propionate, phenylpropionate, isocaproate, and decanoate). These preparations result in even higher initial testosterone peaks with no prolongation in the duration of action and are therefore not recommended ahead of testosterone enanthate or cypionate for the treatment of male hypogonadism.

Longer acting preparations, including testosterone buciclate and testosterone undecanoate, are being developed. Single injections of testosterone buciclate (600 mg) have been shown to maintain serum testosterone levels in the low normal range for 12 weeks in hypogonadal men. This is the longest duration of action of any injectable ester tested so far and this ester appears to have great potential for clinical use. In China, injection of testosterone undecanoate dissolved in teaseed oil (125 mg/ml of teaseed oil) in doses of 500–1000 mg results in serum testosterone levels within the normal range for 6–8 weeks. However, this is limited by an injection volume of 8 ml, which renders its use impractical. Treatment of hypogonadal men with 1000 mg of testosterone undecanoate dissolved in 4 ml of castor oil (250 mg/ml), every 6 weeks for 6 months, produced serum testosterone levels above the lower limit of normal, with good tolerability. The slowly increasing testosterone levels at the end of the injection interval suggested that the interval could be extended. A recent study has shown that injections every 12 weeks for 2 years resulted in stable testosterone levels within the normal range. Maximal serum testosterone levels were lower than with the Chinese preparation and did not exceed 25 nmol/liter. Slight increases in body weight, hemoglobin, hematocrit, prostate volume, and PSA were observed.

D. Testosterone Subcutaneous Implants

A single implantation procedure delivering three to six 200-mg pellets of unmodified testosterone provides stable, effective, and well-tolerated testosterone replacement for 4 to 6 months. Disadvantages include the need for a minor surgical procedure and the cumbersome delivery system, requiring the use of a large trocar, leading to a small risk of bleeding and infection. The major side effect is the extrusion of pellets, which occurs after ~8.5% of implant procedures. 7α-Methyl-19-nortestosterone (MENT), a long-acting sc implant, is currently under investigation. This is a modified androgen that can be aromatized to estrogen but not 5α-reduced. The relative sparing effects of MENT on the prostate, compared with testosterone, suggest that it may be useful for androgen therapy and for male contraception.

E. Sublingual Testosterone

Testosterone cyclodextrin (2.5–5.0 mg given three times daily) is also being developed. Testosterone has been complexed with hydroxypropyl-β-cyclodextrin

to enhance its solubility and sublingual absorption. Testosterone rises into the supraphysiological range in ~20 min and falls to baseline within 4–6 h. This may be useful for the treatment of delayed puberty, of postmenopausal women with reduced libido, and of elderly men with hypogonadism.

III. ANDROGEN USE

The principal uses of androgens are for the treatment of adult male hypogonadism and for the treatment of delayed puberty.

A. Treatment of Adult Male Hypogonadism

Before treating hypogonadal men, it is important to distinguish between primary hypogonadism (low testosterone with elevated LH and FSH concentrations) and secondary hypogonadism (low testosterone with serum LH and FSH concentrations that are low, or low normal), as shown in Table 1. In males with primary hypogonadism, androgen-dependent processes can be stimulated and maintained by exogenous hormone replacement; however, fertility cannot be induced by hormonal therapy. For secondary hypogonadism in males who are potentially fertile, there are two treatment options, exogenous androgens or exogenous gonadotropins; these hormones can stimulate spermatogenesis and endogenous androgen secretion until paternity is achieved.

The principle of testosterone replacement in the treatment of male hypogonadism is to induce and maintain secondary sexual characteristics, sexual behavior, muscle development, bone density, and male habitus. Testosterone will inhibit endogenous gonadotropin secretion and thereby suppress spermatogenesis, resulting in infertility. The preparations commonly used in the treatment of hypogonadism in adult males are shown in Table 2.

Traditionally, long-acting esters such as testosterone enanthate and testosterone cypionate have been classically used im every 2–3 weeks (in doses of 200–250 mg) for the treatment of adult hypogonadism. Their use has been safe and free of significant side effects, and they are currently the cheapest form of testosterone replacement. Patients can usually be taught to self-administer im injections, or a family member or friend may be trained to give them. The disadvantage of these esters is that they produce supraphysiological testosterone levels for 2–3 days after injection. The levels then decline slowly into the hypogonadal range prior to the next injection. In some men, these large fluctuations in testosterone levels result in undesired changes in mood, libido, and energy levels. This form of replacement therapy is not optimal because it does not mimic stable physiological levels and is associated with only minor diurnal variations. If patients have symptoms of androgen deficiency with documented low serum testosterone levels a few days before the next injection, the dosage interval can be reduced. In elderly hypogonadal men with symptoms of bladder outlet obstruction or enlarged prostate glands, prostate carcinoma must be excluded, and then it is recommended to commence therapy with 50–100 mg im every 2–4

TABLE 1 Causes of Hypogonadism

Primary (hypergonadotropic)	Secondary (hypogonadotropic)	Combined (primary and secondary)
Klinefelter's syndrome	Panhypopituitarism	Aging
XX males	Hyperprolactinemia	Hepatic cirrhosis
XY/XO mixed gonadal dysgenesis	Isolated gonadotropin deficiency	Sickle cell disease
XYY syndrome	Kallman's syndrome and variants	
Ullrich–Noonan syndrome	Idiopathic hypothalamic hypogonadism	
Myotonic dystrophy	Isolated LH or FSH deficiency	
Sertoli-cell-only syndrome	Genetic disorders	
Enzymatic defects in testosterone biosynthesis	Prader–Willi syndrome	
Male pseudohermaphroditism (with AR defects or LH receptor defects)	Laurence–Moon–Biedl syndrome	
	Severe systemic illness	
Testicular feminization	Massive obesity	
Viral orchitis (mumps most common)	Nutritional deficiency or starvation	
Cryptorchidism	Constitutional delay of puberty	
Polyglandular autoimmune disease		
Testicular trauma		
After chemotherapy or testicular irradiation		
Congenital or acquired anorchia		

TABLE 2 Preparations Commonly Used in the Treatment of Adult Male Hypogonadism

Preparation	Route	Dosage
Currently approved		
Testosterone undecanoate		
(Restandol, Andriol)	Oral	80–240 mg/day
Testosterone enanthate	Intramuscular	200–250 mg every 2–3 weeks
Testosterone cypionate	Intramuscular	200 mg every 2 weeks
Transdermal testosterone patch		
(Testoderm)	Scrotal skin	1 patch/day
(Androderm, Testoderm TTS)	Nonscrotal	1–2 patches/day
Testosterone gel		
(Androgel 1%)	Skin	50–100 mg/day
Dihydrotestosterone (Andractim)	Skin	125–150 mg/day
Testosterone pellets	Subcutaneous implants	3–6 doses of 200 mg every 6 months
Investigational		
Testosterone undecanoate	Intramuscular	1000 mg every 8–12 weeks
Testosterone buciclate	Intramuscular	600 mg every 12 weeks
Testosterone cyclodextrin	Sublingual	2.5–5.0 mg twice daily
Dihydrotestosterone 0.7% gel	Skin	16–64 mg/day
Obsolete		
17 α-Methyltestosterone	Oral	10–40 mg/day
Fluoxymesterone	Oral	10–20 mg/day

weeks. Prostate examination and a PSA level assay are recommended after 3, 6, and 12 months and then at yearly intervals for men <45 years old and at 6-month intervals for men >45 years old during testosterone replacement therapy. All patients should be informed about the expected somatic and behavioral changes that occur during treatment.

Transdermal testosterone applied to scrotal (Testoderm) and nonscrotal skin (Testoderm, Androderm) is now widely used for the treatment of male hypogonadism. However, some men find the scrotal application cumbersome, and in men with hypogonadism of prepubertal onset, the surface area of the scrotum may not be large enough to accommodate the patch. Androderm is applied once nightly to nonscrotal skin (e.g., abdomen, thighs, upper arm, or back) and the recommended dosage for adult hypogonadism is two 2.5-mg patches or one 5-mg patch. This regimen delivers 5 mg/day of testosterone, with 60% being absorbed within the first 12 h, maintaining serum testosterone levels in the physiological range and mimicking the normal circadian rhythm. The main side effect of Androderm is local skin irritation in $\sim$30% of patients; however, pretreatment of the skin with triamcinolone cream reduces adverse skin reactions and only 10% of subjects have to discontinue therapy. Nonscrotal Testoderm TTS is associated with less skin irritation but does not always adhere well to the skin. Testosterone patches have the disadvantage of relatively limited flexibility in dosing and are 10 times more expensive than testosterone esters. In comparison with testosterone esters, the patches provide similar symptomatic relief of androgen deficiency; increase energy, libido, and sexual function; and improve BMD.

Daily administration of 50, 75, or 100 mg of 1% Androgel to hypogonadal men for 180 days results in constant testosterone levels in the middle to upper physiological range throughout the entire day. Androgel provides flexibility in dosing and little skin irritation. Within days or weeks of starting therapy, men will notice an increase in libido, improved energy levels, and sense of well being. Changes in physical appearance, including breaking of the voice, will evolve over 6 months. Almost all studies of androgen replacement therapy in hypogonadal men have shown a significant increase in hematocrit, due to stimulation of erythropoiesis, which can potentially cause symptoms of hyperviscosity, and a modest increase in prostate volume comparable to that seen in age-matched eugonadal men. Despite an increase in PSA levels within the normal range, there are no data to suggest a link between testosterone administration and the induction of prostate cancer, although longer term follow-up is necessary. However, once a carcinoma has developed, testosterone will promote its growth. The impact of androgens on lipids varies depending on the dose, route of administration, and whether

aromatizable or nonaromatizable androgens are used. Most studies describe a decrease in total cholesterol with a decrease in high-density lipoprotein cholesterol. Hepatotoxicity is generally limited to oral androgens. Therefore, patients should be carefully monitored by physicians with expertise in this area for changes in hematocrit, liver function, lipid parameters, and PSA. The prostate should be evaluated by digital examination and by ultrasound to detect changes in volume or development of nodules or carcinoma. Absolute contraindications to testosterone use include prostate carcinoma and elevations in PSA.

B. Treatment of Aging Males

Although elderly men with hypogonadism are treated like younger men according to the principles just described, it is currently disputed whether aging males in general should receive hormone substitution. Male aging is associated with a gradual, progressive decline in circulating testosterone concentrations. After decades of controversy, epidemiological studies clearly show that, in the general male population, total testosterone concentrations decrease by up to 1% per year. This decline in testosterone is due to a combination of a primary steroidogenic defect in the aging Leydig cells and a decreased pituitary secretory capacity and responsiveness to GnRH. Normal aging is associated with decreased lean body mass, muscle mass, and strength; diminished libido and erectile function; decreased bone mass; increased fracture risk; and diminished sleep quality. Controlled clinical trials of testosterone replacement in healthy older males with testosterone deficiency have demonstrated some equivocal moderate improvement in muscle mass and strength. However, the clinical and functional relevance of these changes and the risks of testosterone replacement therapy in elderly men in general remain to be determined.

C. Treatment of Delayed Puberty in Boys

Androgen replacement therapy in male adolescents with constitutional delay of growth and adolescence has been shown to be beneficial psychologically as well as physiologically, and should be initiated promptly on diagnosis. Boys with delayed puberty are at risk for not obtaining adequate peak bone mass and for having deficiencies in developing social skills, an impaired body image, and low self-esteem. Younger boys with short stature, delayed bone age (at least 10.5 years), and delayed pubertal development in the absence of other endocrinological abnormalities can be treated with 50–100 mg of testosterone enanthate or cypionate (im, every 4 weeks for 3 months), whereas boys >13 years old may be treated with 250 mg (im, every 4 weeks for 3 months). After a 3-month "wait and see" period, another course of treatment may be offered if pubertal development does not continue. An increase in testes size is the most important indicator of spontaneous pubertal development, (testes volume >3 ml). Overtreatment with testosterone may result in premature closure of the epiphyses of long bones, resulting in reduced adult height. Therefore, treatment of patients who have not yet reached full adult height has to be undertaken carefully. At the beginning of therapy it is often difficult to distinguish between boys with delay of growth and puberty, who require only temporary androgen replacement, and boys with idiopathic hypogonadotropic hypogonadism, who require lifelong androgen therapy to stimulate puberty and to maintain adult sexual function. However, boys with permanent hypogonadotropic hypogonadism will not have testicular growth with androgen therapy. Because pubertal growth is a product of the interaction of growth hormone (GH) and insulin-like growth factor I(IGF-I) and the hypothalamic–pituitary–gonadal axis, boys with concomitant GH deficiency will require the simultaneous administration of GH and androgens for the treatment of delayed puberty.

D. Treatment of Osteoporosis

Testosterone and its conversion to estradiol are important for the attainment of peak bone mass and for the maintenance of bone density. Delayed puberty is associated with a reduction in peak cortical and trabecular bone mass, and testosterone therapy is associated with an increase in BMD. Bone mass in men >20 years old declines linearly with age, and the decrease in trabecular mass is greater than that in cortical mass. Androgen deficiency is associated with osteopenia and osteoporosis and increased risk of vertebral and hip fractures. Administration of testosterone to hypogonadal men improves levels of bone turnover markers (causing a dampening of bone resorption) and causes increases in particular trabecular bone and also cortical BMD. However, it still remains unknown whether testosterone replacement reduces the fracture risk in osteoporotic hypogonadal men. Administration of androgens to eugonadal men with idiopathic osteoporosis increases lumbar spine BMD, with no change in the femoral neck, trochanter, or total hip. Further long-term studies are

necessary to establish if testosterone therapy can be recommended for eugonadal men with idiopathic osteoporosis or glucocorticoid-induced bone loss.

E. Treatment of Hereditary Angioneurotic Edema

Hereditary angioneurotic edema is characterized by markedly reduced levels of the serum C1 esterase inhibitor and by a syndrome of episodic angioedema of the skin and mucous membranes, commonly affecting the extremities, face, pharynx, and gastrointestinal tract. 17α-Alkylated androgens stimulate the production of C1 esterase inhibitor and can therefore be used prophylactically in the treatment of this condition. To minimize virilizing effects, danazol, a weak androgen, is used in women.

F. Treatment of Hematological Disorders

Androgens enhance erythropoiesis via indirect stimulation of erythropoietin secretion from renal and extrarenal sources. Androgens also act directly on the bone marrow to increase red blood cell production in response to erythropoietin. They are therefore beneficial for the treatment of anemia due to chronic renal failure, raising hemoglobin levels by approximately 1–2 g/dl in the presence of adequate iron and folate stores. With the availability of recombinant erythropoietin, androgens are now used infrequently for the treatment of anemia associated with chronic renal failure, especially in women, due to virilizing side effects. However, erythropoietin is very expensive and androgens can be used in combination with lower doses of erythropoietin. Androgens can also be beneficial to treat patients with aplastic anemia, Fanconi's anemia, hemolytic anemia, and sickle cell anemia, and some anemia secondary to hematological malignancies. Danazol (600–800 mg/day) has been used to treat patients with autoimmune hemolytic anemia and idiopathic thrombocytopenia purpura by directly lowering autoantibody titers.

G. Micropenis and Microphallus

Enlargement of a micropenis or microphallus can be achieved by treatment with 25–50 mg of testosterone enanthate or cypionate (im, every 3 to 4 weeks for 3 months) or with 1.25–5% testosterone cream, 5% DHT cream, or 10% testosterone propionate cream (twice daily for 3 months). High-dose androgen therapy may be necessary to achieve some adrogenization in male pseudohermaphroditism due to 5α-reductase deficiency and certain androgen receptor defects.

H. Experimental Use of Androgens

1. Male Contraception

Hormonal male contraceptives include exogenously administered testosterone alone or in combination with progestogens or GnRH analogues. Gonadotropin secretion is inhibited, resulting in inhibition of spermatogenesis. Androgens are essential to inhibit gonadotropin secretion and to replace endogenously suppressed testosterone. Clinical trials using intramuscular testosterone injections or subcutaneous testosterone implants in combination with oral, intramuscular, or subcutaneously implanted gestagens are under way and result in high rates of azoospermia, the prerequisite for effective contraceptive protection. Self-administered oral or transdermal regimes have been less successful in inducing azoospermia.

2. Treatment of Wasting Syndromes

Recent studies have shown that replacement doses of testosterone in hypogonadal men and supraphysiological doses in eugonadal men increase fat-free mass, muscle size, and strength. It has therefore been proposed that androgens may be useful in conditions associated with muscle wasting (sarcopenia) and protein catabolism. Interventions that prevent or reverse the sarcopenia associated with aging, human immune deficiency virus (HIV) infection, cancer, chronic illness, major surgery, or burns could result in an improved quality of life, improved disease outcomes, and reduced health care costs.

Hypogonadism occurs in approximately 30% of HIV-infected men. Therapy with supraphysiological doses of testosterone, nandrolone decanoate, or oxandrolone can benefit HIV-infected men and women with wasting and/or low levels of circulating androgen. However, it remains unclear whether physiological testosterone replacement can produce clinically meaningful changes in quality of life, independent living, body composition, and muscle function in HIV-infected patients.

3. Overtall Stature

In some European countries supraphysiological doses of testosterone (500 mg of testosterone enanthate, im, every 2 weeks for 1–4 years until epiphyseal closure) have been used to treat constitutional tall stature in boys (predicted adult height of 205 cm). Because tall stature is often desirable, this treatment is very rarely indicated. Follow-up studies have shown that this treatment has no long-term negative effect on testicular development.

4. Androgen Therapy in Women

Evidence is emerging that testosterone plays a physiological role in female brain development, sexual function, mood, cognitive function, and well being. Premenopausally, 50% of testosterone is secreted directly by the ovaries and an equal amount is produced by the peripheral conversion of androstenedione and dehydroepiandrosterone (DHEA, produced in the ovary and the adrenals). Testosterone levels decline with increasing age in women during the reproductive years such that levels in women aged 40 years are only 50% of those in women aged 21. This decline in androgen levels in females appears to be largely associated with increased age, rather than being linked to menopause. DHEA sulfate (DHEAS) levels fall linearly with age, and probably contribute to the decline of their main metabolite, testosterone. The clinical indications for testosterone replacement therapy in women include adrenal insufficiency and premature ovarian failure, including Turner's syndrome, premenopausal iatrogenic androgen deficiency (surgical menopause, chemotherapy, irradiation), and symptomatic deficiency following natural menopause. Estrogen replacement therapy further reduces free testosterone levels and thereby may enhance the symptoms of androgen deficiency (i.e., reduced libido and sexuality). These symptoms are improved with androgen replacement therapy. Testosterone is usually recommended in combination with estrogen. Examples of preparations used in studies include oral esterified estrogen–methyltestosterone, combined estradiol (E2) and subcutaneous testosterone implants, transdermal matrix delivery of testosterone, and intramuscular nandrolone decanoate, tibolone, and stanazol. For the treatment of adrenal insufficiency, 50 mg/day of DHEA for months increased both androstenedione and testosterone levels, improved the sense of well being, and increased the frequency of sexual thoughts, interest, and satisfaction. With regard to osteoporosis, the combined administration of testosterone and estrogen increases trabecular and cortical BMD in postmenopausal women to a greater extent compared to estrogen alone. However, because there are no prospective data confirming a reduction in fracture risk with this therapy, it cannot currently be recommended for protecting against bone fracture. Side effects include masculinization, hirsutism, acne, temporal balding, deepening of the voice, and hepatotoxicity (particularly if 17α-alkylated steroids are used). The effects on body composition, lipids, risk of coronary heart disease (CHD), and breast cancer remain unclear.

IV. ANDROGEN ABUSE

The observation that androgens promote nitrogen retention and muscle mass led to their use to improve physical performance as early as the 1940s. Androgenic anabolic steroids (AASs) have been classically used by weight lifters, bodybuilders, and hammer and discus throwers, but today their use is more prevalent, extending to football players, swimmers, and track-and-field participants (both male and female). AAS abuse is also prevalent in peripubertal boys to enhance athletic performance and to improve appearance. In one survey in the United States, 7% of male high school seniors reported having used AAS, and the majority had started at or before the age of 16 years. AASs are most frequently distributed illegally to athletes via a "black market." Androgen sales due to increasing misuse and abuse in the United States are reported to be increasing by 20–30% each year.

It still remains controversial as to whether androgens improve athletic performance. It is known that androgens have muscle-growth-promoting effects in boys, women, and hypogonadal men. The assumption that exogenous androgens have less effect on muscle growth in normogonadal men is based on the fact that the androgen receptor in striated muscle is down-regulated after puberty and is nearly completely saturated, within physiological concentrations of testosterone. Therefore, the biological response may well have reached a plateau within the physiological range. Nandrolone, the 19-nor analogue of testosterone, was the first compound to show enough myotrophic–androgenic dissociation in animal experiments to justify its introduction in clinical therapy as an anabolic steroid. Supraphysiological doses of testosterone enanthate (600 mg/week) for 10 weeks, with or without resistance exercise training, have been shown to increase fat-free mass, muscle size, and muscle strength in normal men. The effects of exercise were shown to be additive. However, the long-term effects on muscle strength and the side effects of such doses remain unknown. Some of the reported enhancement in performance may have been due to the effects of anabolic steroids in increasing aggression and competitiveness, to differences in intensity of training or dietary intake, and to important placebo effects. The problem with studying the effects of androgens in athletes is that the athletes often take multiple anabolic agents simultaneously ("stacking"). Frequently, the regimen starts with lower doses, with doses progressively increasing over a period of several weeks. The most frequently misused androgens in

controlled competition sports are testosterone, nandrolone, stanozolol, and metandienone. Doses used may be 100 times the doses used for hormone replacement therapy.

Although no systematic studies have been performed (the difficulty being that many preparations are abused simultaneously), the androgenic adverse effects of anabolic steroids are known to include virilization (e.g., acne, hirsutism, and alopecia, sometimes irreversible) in women and premature epiphyseal closure with stunted final height, gynecomastia, decreased testicular volume, impaired spermatogenesis resulting in infertility (reversible), increased sexual interest, and decreased HDL and cholesterol in men. The toxic effects of anabolic steroids established from single reports include (1) cardiovascular effects, including cardiomyopathy, acute myocardial infarct, cerebral vascular accident, and pulmonary embolism, (2) hepatic effects, including cholestatic jaundice, peliosis hepatitis, and tumors, and (3) psychological effects, including increased aggression, dysphoria, psychosis, addiction, withdrawal-like symptoms, and depression; a fourth negative impact relates to needle sharing, i.e. hepatitis and HIV infection.

Because the misuse of androgens is clearly an escalating problem, there has been a marked increase in urine testing prior to many athletic events. Many athletes previously stopped the administrations of AASs in the last few weeks before a competition and changed to androgens that are difficult to detect in the urine or those that are rapidly metabolized and excreted within a few days (e.g., stanozolol and testosterone). These deceptions were termed "precompetition bridging programs" in former Eastern Block countries. Today, the introduction of out-of-competition testing has improved the detection rate of androgen misuse. Analytically, testosterone administration is much more difficult to detect compared to doping with synthetic steroids. The ratio of testosterone to epitestosterone (an inactive metabolite of testosterone secreted largely from the gonads, with only small amounts produced from the peripheral metabolism of testosterone) is used to detect exogenous androgen misuse. The normal ratio is approximately 1:1 in men and women. A ratio of 6:1 is considered to be indicative of steroid abuse. However, competitors are known to titrate their dose to below the testosterone:epitestosterone ratio of 6, or to coadminister epitestosterone in an attempt to normalize their testosterone:epitestosterone ratio. Direct methods such as gas chromatography/combustion/carbon isotope ratio mass spectrometry are currently available to identify unambiguously doping with exogenous steroids. Administration of human chorionic gonadotropin (hCG) will stimulate testicular steroidogenesis without altering the testosterone:epitestosterone ratio. However, hCG can be detected by immunoassay in the serum and urine. Synthetic androgens are extensively metabolized and doping tests are focused on urinary metabolites. Derivatization methods for steroid analysis improve the detection limits for anabolic steroids. The potential risks of high-dose anabolic steroids clearly outweigh their potential benefits.

Glossary

anabolic androgenic steroids Synthetic derivatives of testosterone having pronounced anabolic properties and relatively weak androgenic properties.

dehydroepiandrosterone The most abundant human steroid hormone and its sulfated derivative are produced by the adrenal gland (approximately 30 mg/day), and are universal precursors for androgenic and estrogenic steroids. Conversion and metabolism occur in the peripheral tissues.

dihydrotestosterone Testosterone is metabolized via 5α-reductase to the potent androgen dihydrotestosterone, which binds directly to the androgen receptor and cannot be aromatized to estrogen.

testosterone The major androgenic steroid hormone produced by the Leydig cells of the testes (~7 mg/day in an adult man).

Angiogenesis

LENA CLAESSON-WELSH
Uppsala University, Sweden

Physiological processes such as embryonic development, wound healing, and menstruation are known to require the formation of new blood vessels to meet increased needs for oxygen and nutrients. Pathological processes involving growth of tissues, such as tumors and chronic inflammatory diseases, also depend on the blood vessel supply.

I. INTRODUCTION

A number of different growth factors are implicated in blood vessel formation and one of these, vascular endothelial growth factor (VEGF), is a focus of attention due to its critical and specific role both in vasculogenesis (establishment of the vascular tree during embryogenesis) and in angiogenesis (formation of new vessels from preexisting vessels). A number of approaches have been taken to inhibit the function of VEGF in order to inhibit angiogenesis and thereby halt the progress of diseases such as cancer.

II. FORMATION OF BLOOD VESSELS

During growth and development of the embryo, there is a continuously increasing need for oxygen and nutrients. This metabolic need, together with genetic programming, results in the maturation of endothelial cells from stem cells, the angioblasts. The maturation probably occurs in discrete steps, but much work remains to be done until this process is understood completely. Once formed, the endothelial cells assemble into crude vascular plexa with coarse tubes, which are remodeled into finer vessels. The "*de novo*" establishment of the vascular tree is denoted vasculogenesis. Interruption of vasculogenesis results in

Angiogenesis

LENA CLAESSON-WELSH
Uppsala University, Sweden

Physiological processes such as embryonic development, wound healing, and menstruation are known to require the formation of new blood vessels to meet increased needs for oxygen and nutrients. Pathological processes involving growth of tissues, such as tumors and chronic inflammatory diseases, also depend on the blood vessel supply.

I. INTRODUCTION

A number of different growth factors are implicated in blood vessel formation and one of these, vascular endothelial growth factor (VEGF), is a focus of attention due to its critical and specific role both in vasculogenesis (establishment of the vascular tree during embryogenesis) and in angiogenesis (formation of new vessels from preexisting vessels). A number of approaches have been taken to inhibit the function of VEGF in order to inhibit angiogenesis and thereby halt the progress of diseases such as cancer.

II. FORMATION OF BLOOD VESSELS

During growth and development of the embryo, there is a continuously increasing need for oxygen and nutrients. This metabolic need, together with genetic programming, results in the maturation of endothelial cells from stem cells, the angioblasts. The maturation probably occurs in discrete steps, but much work remains to be done until this process is understood completely. Once formed, the endothelial cells assemble into crude vascular plexa with coarse tubes, which are remodeled into finer vessels. The "*de novo*" establishment of the vascular tree is denoted vasculogenesis. Interruption of vasculogenesis results in

the death of the embryo. In the later stages of development and during adulthood, new blood vessels are formed from already existing blood vessels, by migration of endothelial cells away from the mother vessel, followed by cell division and organization into a new vessel. The formation of blood vessels from existing blood vessels is known as angiogenesis. Recent findings also indicate that the formation of new blood vessels depends on or at least involves circulating, bone marrow-derived precursor cells.

Angiogenesis is important in wound healing and for the normal growth of tissues, such as during the later stages of embryo development. Growth of the endometrium during the menstrual cycle and the process of ovulation are accompanied by angiogenesis. In recent years, there has been an increased awareness of the role of angiogenesis in a number of diseases. These include diseases that are characterized by the presence of too many blood vessels, such as cancer, chronic inflammatory diseases, retinopathy, and psoriasis. In these conditions, the tissues secrete an increased amount of angiogenic growth factors. There are also conditions characterized by a deficiency in the blood vessel supply. Such conditions include coronary and peripheral ischemia.

III. BLOOD VESSEL COMPOSITION

Blood vessels occur in three principal variants, arteries, veins, and capillaries. All vessels contain a single layer of endothelial cells, which face the lumen of the vessel. Arteries transport the oxygenated blood from the heart throughout the body. The main artery, the aorta, branches out into finer vessels (arteriolae). In arteries, several layers of contractile smooth muscle cells, which are important for maintaining the blood pressure, surround the endothelial cell layer. Arterioles branch into a plexa of thread-thin vessels, called capillaries. The exchange of oxygen and nutrients occurs through the capillary wall. In addition, new blood vessels are formed from capillaries and not from larger vessels. Capillaries are composed of a single layer of endothelial cells, surrounded by a specialized coat containing extracellular matrix proteins (laminin, fibronectin, collagen, perlecan, etc.), called the basement membrane. Pericytes, which are supporting cells, may be embedded in the basement membrane or rest on the membrane. The function of pericytes is not clear, but it has been suggested that both pericytes and the basement membrane are critical for the stability of the capillary.

Different types of capillaries can be distinguished (Fig. 1). Continuous capillaries, which occur in the skin, muscles, lungs, and central nervous system, have a low permeability, due to the presence of tight junctions between the cells. The tight junctions are specialized structures that bridge adjacent cells and keep them in close contact. A specialized variant of these junctions, the blood–brain barrier, occurs in the central nervous system. Fenestrated capillaries are found in endocrine glands, kidney, intestine, and other tissues where large amounts of fluid or metabolites enter or leave capillaries. Discontinuous capillaries or sinusoids are found in the liver, spleen, and bone marrow. These contain gaps between endothelial cells that are wide enough to allow large proteins to cross the capillary wall.

The capillaries fuse into venules and then into larger vessels, veins, which transport the blood back to the heart and lungs for renewed oxygenation. Similar to arteries, veins have a muscular coat, although it is somewhat thinner. The pressure is lower in veins than in arteries, and therefore, the lumen of veins is often collapsed on sectioning and histological analysis of the tissue. The veins of the limbs contain paired valves, which ensure that the blood does not move backward.

It is generally thought, but has not yet been formally proven, that endothelial cells from different

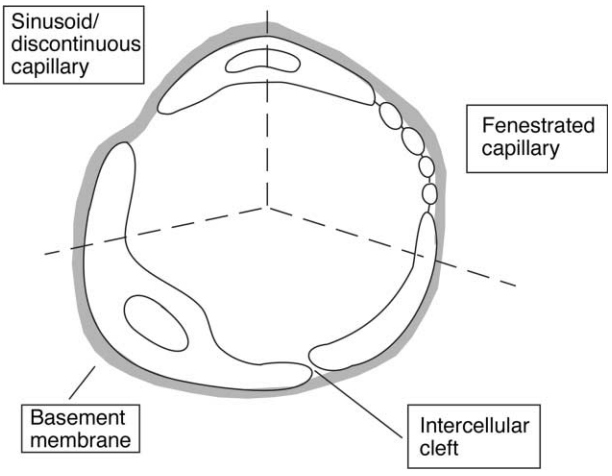

FIGURE 1 Schematic illustration of a capillary composed of endothelial cells surrounded by the basement membrane (shaded). Different types of capillaries are indicated, such as sinusoid and fenestrated capillaries, which have gaps of different sizes allowing the flow of proteins (sinusoid) and fluid and metabolites (fenestrated). In the continuous capillaries, individual cells meet in the intercellular clefts.

types of vessels, such as arteries, veins, and capillaries, have different properties. These distinct properties cannot be distinguished morphologically when endothelial cells are explanted and cultured *in vitro*. During development, arterial and venous specification can be traced before the onset of circulation by their specific expression of the growth factor ephrin-B2 and its receptor ephB-4 on primitive arteries and veins, respectively.

IV. ANGIOGENIC GROWTH FACTORS

Many growth factors have been implicated in the stimulation of angiogenesis. Some of these are considered to act directly and some indirectly, depending on whether or not receptors for these growth factors have been detected on endothelial cells. Growth factors bind to receptors that belong to a class of proteins called the tyrosine kinases. Thus, binding of the growth factor to the extracellular domain of the receptor leads to the activation of an enzymatic activity that is harbored in the intracellular domain of the receptor. This enzymatic activity, the tyrosine kinase activity, catalyzes the transfer of a phosphate group to particular tyrosine residues, either within the receptor molecule itself or on cytoplasmic proteins, the so-called signal transduction molecules. In many cases, these signal transduction molecules are enzymes themselves, and phosphorylation on tyrosine residues leads to their activation. In this manner, a signal is propagated in the cell, which eventually results in a cellular response of some kind, such as migration or division.

The directly acting endothelial growth factors include the vascular endothelial growth factor/vascular permeability factor (VEGF/VPF) family and the angiopoietins, for which there are receptors on endothelial cells. However, there may not be receptors for these factors on all kinds of endothelial cells in, e.g., arteries, veins, and capillaries, or on endothelial cells in vessels with specialized functions such as in capillaries forming the blood–brain barrier. Furthermore, receptors may not be expressed on endothelial cells at all different developmental stages.

The VEGF family currently encompasses six members, and for several of these members, there are a number of splice variants that may have distinct functions. The first identified VEGF family member was originally denoted VPF, but is now most commonly referred to as VEGF-A. However, the original nomenclature, VPF, indicates what is perhaps the most important function of this factor, namely, to induce vascular leakage. VEGF-A is produced by many cells in the body in a manner that is dependent on the oxygen tension in the tissue. Thus, the promoter element in the VEGF-A gene contains a binding site for the hypoxia-induced factor. Solid tumors often have a central hypoxic core, which leads to increased VEGF-A production by the tumor cells and therefore increased angiogenesis. Genetically unstable cells, such as tumor cells, may also start to produce VEGF-A or other angiogenic growth factors as a consequence of chromosomal rearrangements that may lead to altered regulation of growth factor production. As a rule, tumors can grow only up to a certain size, a few mm^3, unless they start producing angiogenic growth factors, i.e., VEGF-A. This restriction point, the angiogenic switch, must be overcome to allow further tumor growth. This is the rationale for the interest in developing therapies for treatment of cancer based on inhibition of VEGF function.

The additional members of the family are VEGF-B, -C, and -D and placenta growth factor. The sixth family member is VEGF-E, which thus far has been detected only as a virus-encoded protein and not in mammalian cells. None of the VEGF family members, except for VEGF-A, appear to be regulated by hypoxia. The VEGF family members bind in a particular pattern to three receptors, which belong to the receptor tyrosine kinase family. Two VEGF receptors, VEGF receptor-1 and -2, are expressed in vascular endothelial cells, whereas VEGF receptor-3 is expressed in endothelial cells in lymph vessels. The essential role of VEGF-A and the VEGF receptors in vascular development has been demonstrated genetically, in experiments in which the individual genes for VEGF-A or the three receptors have been destroyed. Mice lacking expression of VEGF-A and VEGFR-2 die at approximately embryonic day 8.5 due to the lack of blood vessels. Mice lacking VEGFR-1 die slightly later. In these animals, the endothelial cell pool is enlarged and the cells fill the lumen of the vessels, rendering them nonfunctional. Elimination of VEGFR-3 leads to embryonal death due to abnormal vessel formation.

Tyrosine phosphorylation sites in the VEGF receptors have been identified and to some extent signal transduction molecules interacting with these sites have also been identified. A theme appears to be that the signaling molecules bind with low affinity to the phosphorylated tyrosine residues. Phospholipase Cγ1 has been shown to be an important signaling molecule downstream of VEGFR-2. These types of studies are complicated by the fact that the properties of VEGFR-2-mediated signal transduction appear to be correctly revealed only when primary endothelial

cells are studied, rather than the more convenient standard tissue culture models based on transformed cells. In addition, VEGFR-2 signal transduction appears to be channeled through or modified by a number of co-receptors, such as the neuropilins, heparan sulfated proteoglycans, integrins, and cell–cell adhesion molecules.

The Tie family of receptor tyrosine kinases and their ligands, the angiopoietins, are indispensable for normal embryonic blood vessel development, by their critical function in the regulation of angiogenic remodeling and vessel stabilization. All known angiopoietins bind to one of the two known Tie receptors, Tie2. Interestingly, the Tie2 ligands have opposing actions on endothelial cells. Accordingly, angiopoietin-1 and -4 function as activating ligands for Tie2, whereas angiopoietin-2 and -3 behave as competitive antagonists. Activation of Tie2 facilitates the association between endothelial cells and adjacent supporting cells and leads to decreased permeability of the vessel, even in the presence of VEGF-A.

Other growth factors are assumed to act indirectly on endothelial cells, but in most cases, the mechanisms involved are unresolved. The exception may be platelet-derived growth factor-BB (PDGF-BB), which is known to act on supporting smooth muscle cells such as pericytes. The endothelial cells produce PDGF-BB, and the PDGF β-receptor is expressed on the pericytes. There are also growth stimulatory loops in the other direction, as the smooth muscle cells produce angiopoietins, for which there are receptors on the endothelial cells.

How fibroblast growth factor (FGF), hepatocyte growth factor, epidermal growth factor, and other growth factors act on endothelial cells is unclear. It is possible that an important mechanism for the angiogenic effect of these growth factors is the stimulation of VEGF-A production. It is also possible that endothelial cells in certain circumstances, for example, during development or in pathological conditions such as in tumors, express receptors for these growth factors.

V. MOLECULAR MECHANISMS IN BLOOD VESSEL FORMATION

A large array of molecules regulate vasculogenesis, as can be inferred from the results of gene inactivation of many different classes of proteins, which affect vascular development in different ways. Apart from growth factors and their receptors such as the VEGF/VEGFR family and the angiopoietin/Tie receptor family described above, other important proteins are required, for example, growth modulatory factors such as the transforming growth factor-β family of ligands and receptors, the cell–cell adhesion protein vascular endothelial cadherin, and different second-messenger proteins. Nuclear factors such as the Id1–Id3 complex, which exert their effects by regulating the binding of helix-loop-helix factors to DNA, are essential for proper vascular development.

Angiogenesis involves the stimulation of endothelial cells in capillaries by growth factors produced by the adjacent tissue or released by, e.g., platelets. Another possible growth factor source is a nearby, growing tumor. Morphologically, angiogenic capillaries are composed of a stalk, where the endothelial cells proliferate. The cells in the tip of the stalk do not proliferate, but send out cytoplasmic extensions (sprouts) toward the source of the stimulus. Proliferation of endothelial cells in response to growth factor stimulation is probably regulated in a manner similar to that shown for other cell types and involves progression through the cell cycle, which eventually leads to cell division. The first important step in this process is the binding of the growth factor to its receptor, leading to activation of the receptor tyrosine kinase and recruitment of signaling molecules. To start the cell cycle, specific sets of signaling molecules interact in a chain reaction, involving the small, guanine triphosphate-hydrolyzing (GTPase) molecule Ras, which eventually results in changes in the transcriptional machinery and induction of cell cycling. It has been questioned whether Ras is critical for the proliferation of VEGF-A-stimulated endothelial cells; it is possible that the signaling chain leading to proliferation in this case is dependent on phospholipase Cγ1 rather than Ras. Thus, it is possible that the design of signaling chains is specific to endothelial cells.

The cells in the tip of the angiogenic stalk are in the process of differentiation to form a new lumen-containing vessel, which is dependent on changes in how the cytoskeleton is arranged. There are abundant data indicating that cytoskeletal regulation in cell types other than endothelial cells involves Ras-related GTPases of the Rho family. It is likely that these proteins are also very important in endothelial cells. Much work remains to be done to dissect the roles of other signal transduction molecules activated by angiogenic growth factors that stimulate angiogenesis. A considerable problem in the field is the lack of appropriate models for endothelial cell differentiation. Studies based on microarray techniques in which gene expression in endothelial cells forming

vessel-like structures in a three-dimensional extracellular matrix was compared to that in proliferating endothelial cells indicate that thousands of genes are specifically induced during endothelial cell differentiation. These genes encode proteins with diverse functions and include proteases and novel gene products.

VI. CLINICAL THERAPIES TO SUPPRESS OR STIMULATE ANGIOGENESIS

The steadily increasing number of clinical trials to test the effects of drugs targeted to regulate the vascular bed demonstrates the enormous potential of basic research in this area. As discussed above, pathological conditions involving the vascular bed may be characterized by either too many or too few vessels. Clinical trials aimed at alleviating ischemic conditions, such as coronary ischemia that may precede heart infarction, are based on the delivery of VEGF-A and other growth factors to the ischemic site, to allow ingrowth of new blood vessels. The mode of delivery may be based on different types of vectors, such as novel forms of adenovirus vector, naked DNA, or purified protein.

Drugs aimed at suppressing angiogenesis are targeted to inhibit the function of growth factors or growth factor receptors (Fig. 2) or inhibit endothelial cell function in an unknown manner (see NIH Cancer Website at http://www.cancer.gov/clinical_trials/doc). The targeted growth factor is in most cases VEGF-A, although the importance of inhibiting the function of a broader spectrum of growth factor receptors, such as FGF, PDGF, as well as VEGF-A receptors, has also been stressed.

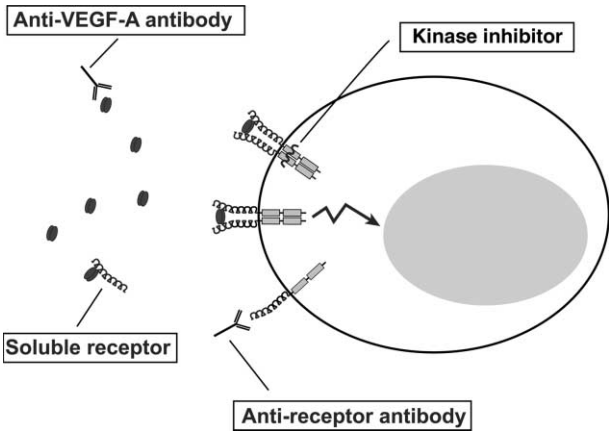

FIGURE 2 Schematic illustration showing different strategies for inhibiting the effect of VEGF-A on an endothelial cell, such as the administration of neutralizing anti-VEGF antibodies, kinase inhibitors that block the activation of VEGF receptors, soluble receptors that bind and neutralize VEGF, and anti-receptor antibodies that block VEGF binding to the receptor.

VII. PERSPECTIVES

The increasing awareness of the role of blood vessel formation in diseases, together with refined tools to study endothelial cells, has led to an explosion in the number of studies about angiogenic growth factor function in health and disease. The many ongoing clinical trials of drugs aimed at suppressing or enhancing blood vessel formation point to the difficulties in reestablishing vascular balance once it is lost. Many different proteins are involved in regulating this balance, and modulating just one protein, such as VEGF-A, is not sufficient. Another emerging complication is that the growth factors thought to be specific for endothelial cells are also found on other cell types. Thus, it is striking that many proteins are shared between endothelial cells and neuronal cells.

Glossary

angiogenesis Formation of new blood vessels from existing capillaries.
capillary The smallest-diameter vessel in the body; origin of new vessels.
endothelial cells Cells that line the inner face of a blood vessel.
vascular endothelial growth factor A protein acting on endothelial cells to induce vascular leakage; it is of critical importance for vasculogenesis and angiogenesis.
vascular permeability factor Another name for vascular endothelial growth factor.
vasculogenesis Establishment of the vascular system during embryonic development.

Angiotensins

NADHEIGE LOCHARD AND
TIMOTHY L. REUDELHUBER
Clinical Research Institute of Montreal

In 1898, Tigerstedt and Bergman first made a correlation between hypertension and a soluble component in kidney extracts. This pioneering work and that of many others eventually led to the biochemical description of the renin–angiotensin system, an enzymatic cascade that results in the synthesis of a family of vasoactive peptides called angiotensins. The activity of this system plays a key role in the regulation of blood pressure and fluid volume in mammals, and its inhibition has become a primary tool for the treatment of hypertension and, more recently, myocardial infarction in North America.

I. INTRODUCTION

All of the components necessary for the production of angiotensin peptides are found in the circulation (Fig. 1). Juxtaglomerular cells in the kidney release the aspartyl protease renin, as well as its enzymatically inactive precursor prorenin, into the circulation. Once there, renin acts on its only known substrate, the 60,000 Da liver-derived glycoprotein angiotensinogen, releasing the decapeptide angiotensin (1–10) (Ang I) from the amino terminus of angiotensinogen. Ang I is in turn converted to the octapeptide angiotensin (1–8) (Ang II) by the removal of two carboxy-terminal amino acids by angiotensin-converting enzyme (ACE). ACE is a metalloprotease bound to the plasma membrane of endothelial cells throughout the circulation. Ang II is the principal effector of the renin–angiotensin system (RAS) through its interaction with angiotensin (AT) receptors type 1 and type 2 (AT_1 and AT_2), members of the seven-transmembrane G-protein-coupled receptor

Angiotensin II Receptor Signaling

ALESSANDRO M. CAPPONI
University Hospital, Geneva

Angiotensin II, an octapeptide hormone, is the product of two successive enzymatic proteolytic cleavages. Angiotensin II is produced in blood and in some tissues by the action of renin and angiotensin-converting enzyme on angiotensinogen (an α_2-globulin) and angiotensin I (a decapeptide), respectively. Initially described as a hypertensive factor, angiotensin II has proved to be a remarkably pleiotropic peptide. It exerts pressor effects by acting peripherally (in vascular smooth muscle, adrenal cortex, and kidney tissues) as well as centrally, but is also involved in the regulation of metabolic pathways (in liver and adipose tissues), inflammatory responses (by macrophages), tissue growth, and developmental processes.

I. INTRODUCTION

In spite of the spectrum of different responses elicited by angiotensin II in a host of distinct tissues, only two major angiotensin (Ang II) receptor subtypes, AT_1 and AT_2, have been identified to date. The vast majority of the biological functions of the hormone are mediated through the AT_1 receptor subtype, whereas the AT_2 subtype is essentially involved in developmental and remodeling processes. Clearly, therefore, the specificity of the response within a given tissue or cell type cannot be conferred by the receptor but must rely on the intracellular signaling mechanisms activated beyond the receptor. In this respect, signal transduction events following binding of the hormone to the AT_1 receptor have been extensively studied and are fairly well understood; less is known of the downstream events triggered by activation of the AT_2 subtype.

II. ANGIOTENSIN II RECEPTOR SUBTYPES

Angiotensin II receptor subtypes were first characterized pharmacologically in the early 1990s, when nonpeptidic Ang II antagonists were developed that were able to bind to Ang II receptors and block differentially Ang II binding, depending on the tissue examined. A few years later, the AT_1 subtype was first identified, followed by the AT_2 subtype, both by expression cloning. Another receptor subtype, AT_4, mainly located in the brain and involved in memory retention processes, has been recently cloned and identified to be insulin-regulated aminopeptidase (IRAP). By binding to IRAP, the angiotensin (3–8)-hexapeptide and its analogues may inhibit IRAP and thus prolong the half-life of some neuropeptides. Although the existence of other atypical Ang II receptors has also been reported, their characterization is still incomplete.

Both the AT_1 (359 amino acids) and the AT_2 (363 amino acids) subtypes are classic seven-transmembrane-domain receptors. They share only 32–34% sequence homology. Although they display the same binding affinity for Ang II, they discriminate among nonpeptidic Ang II antagonists, losartan being the archetypal blocker for the AT_1 subtype and the PD123177 compound being, among others, specifically recognized by the AT_2 receptor subtype.

The two Ang II receptor subtypes also differ in their tissue distribution. AT_1 receptors are found throughout life in all tissues involved in the cardiovascular actions of Ang II, i.e., adrenal cortex, brain, liver, kidney, and vascular smooth muscle. In contrast, AT_2 receptors are highly expressed in various tissues in the fetus but their level of expression decreases considerably after birth; in adults they are found only in a few organs, e.g., brain, adrenal gland, or heart. Interestingly, AT_2 receptor expression increases in certain tissues (heart, vasculature, and kidney) after injury and wound healing.

III. COUPLING MECHANISMS

The AT_1 receptor subtype belongs to the ever-growing family of G-protein-coupled receptors (GPCRs). The message carried by the hormone that binds to the receptor is transduced to intracellular effectors via heterotrimeric guanosine triphosphate (GTP)-binding proteins (G-proteins) composed of three subunits, α, β, and γ. For each of these subunits, various isoforms have been described, and it is the cell-, receptor-, and effector-specific assembly of one particular α, β, and γ combination that is responsible for conveying the information to a given effector. Interestingly, the AT_1 receptor can couple to more than one G-protein, even within the same cell type. For example, in adrenal glomerulosa cells, which make aldosterone in response to Ang II, the AT_1 is coupled to phospholipase C-β (see later) via a G_{q11}-protein and to L-type calcium channels via a G_i-protein and/or a G_o-protein. Similarly, in vascular smooth muscle, activation of phospholipase C-β1 is mediated through a G-protein of the $G_{\alpha q11/\beta\gamma}$ and/or $G_{\alpha 12/\beta\gamma}$ isoform. Besides G-protein-mediated activation of intracellular effectors, direct physical interaction of the AT_1 receptor with either an effector—mainly various cytosolic tyrosine kinases—or an adapter protein can also occur, essentially via the C-terminal cytoplasmic tail of the receptor. This interaction then triggers kinase cascades within the cell.

The AT_2 receptor displays structural features that are related to those of GPCRs and, indeed, it appears to couple to G-proteins of the inhibitory type (G_i). In contrast to the AT_1 receptor, the major effectors of AT_2-mediated angiotensin II action are tyrosine or serine/threonine phosphatases.

IV. INTRACELLULAR EFFECTORS COUPLED TO AT_1 RECEPTORS

Occupancy of the AT_1 receptor subtype triggers most known signaling processes, leading to activation of various phospholipases and recruitment of the calcium messenger system and/or to stimulation of numerous kinase cascades (Fig. 1).

A. Phospholipases

Phospholipase C (PLC), which hydrolyzes phosphatidylinositol 4,5-bisphosphate to inositol 1,4,5-trisphosphate and *sn*-1,2-diacylglycerol, is the best known effector enzyme activated by angiotensin II (Ang II). Depending on the cell type (adrenal glomerulosa cell, vascular smooth muscle cell) and the enzyme subtype, this occurs through coupling to a $G_{q/11}$-protein (for PLC-β2) or through tyrosine phosphorylation mediated by the cytoplasmic tyrosine kinase $pp60^{c\text{-}src}$ (for PLC-γ1). The activation of PLC is generally rapid and transient. In contrast, in adrenal glomerulosa cells and in vascular smooth muscle cells, Ang II also activates a less rapid generation of diacylglycerol through hydrolysis of phosphatidylcholine by phospholipase D. This response is sustained and displays slower kinetics.

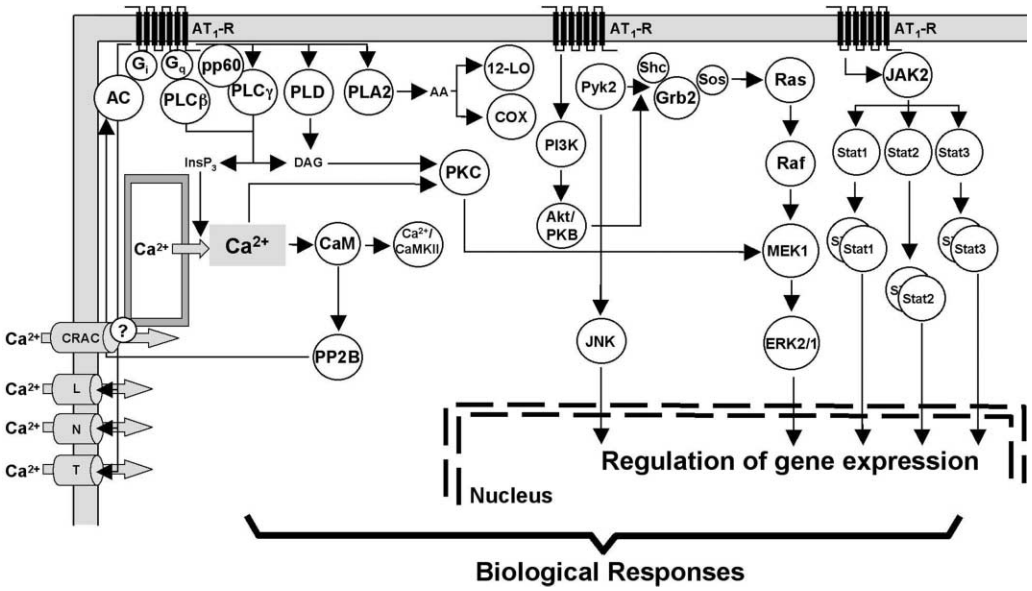

FIGURE 1 Intracellular signaling mechanisms coupled to the AT_1 receptor (AT_1-R) subtype. The main signaling pathways described in this article are illustrated, but most cells do not express all of these pathways. AA, arachidonic acid; AC, adenylyl cyclase; CaM, calmodulin; CaMKII, Ca^{2+}/calmodulin-dependent kinase II; COX, cyclooxygenase; CRAC, calcium release-activated calcium channel; DAG, *sn*-1,2-diacylglycerol; ERK2/1, extracellular signal-regulated kinases 2 and 1; G_q and G_i, GTP-binding protein of the q11 and i family; $InsP_3$, inositol 1,4,5-trisphosphate; JAK, Janus kinase; JNK, c-Jun N-terminal kinase; Shc, Src homology and collagen protein; Grb2, growth factor receptor-binding protein 2; L, N, and T, voltage-operated calcium channel of the L-, N-, and T-types; 12-LO; 12-lipoxygenase; MEK1, mitogen-activated protein kinase kinase 1; PI3K, phosphoinositide 3-kinase; PKB, protein kinase B; PKC, protein kinase C; PLA2, phospholipase A2; PLC, phosphoinositide-specific phospholipase C; PLD, phospholipase D; PP2B, phosphoprotein phosphatase 2B (calcineurin); Pyk2, proline-rich tyrosine kinase 2; Raf, Raf protein kinase; Ras, small G-protein belonging to the Ras family of G-proteins; Sos, son of sevenless; Stat, signal transducer and activator of transcription.

The result of the combined activation of phospholipases C and D is a rapid and transient increase in intracellular inositol 1,4,5-trisphosphate, superimposed over a biphasic, sustained production of diacylglycerol. These two metabolites will in turn activate the calcium messenger system and protein kinase C, respectively (see later). Phospholipase A2, which releases arachidonic acid from membrane phospholipids, is also a major effector of Ang II action in various cell types. Arachidonic acid then enters either the cyclooxygenase pathway to be converted into prostaglandins, as in vascular smooth muscle and mesangial cells, or the 12-lipoxygenase pathway, to give rise to metabolites such as 12-hydroxyeicosatetraenoic acid (12-HETE).

B. The Calcium Messenger System

Although the signaling mechanisms mediating Ang II action have long remained elusive, once tools became available to record changes in intracellular calcium homeostasis, the hormone soon became an archetype for calcium-mobilizing agents. What is now known of the initial steps of this process is indeed an exemplar of phenomena that occur practically in every cell type.

The inositol 1,4,5-trisphosphate ($InsP_3$) that is produced on activation of PLC binds to tetrameric receptors that are located on some compartments of the endoplasmic reticulum. These receptors function as calcium storage organelles and are actually channels that open on binding of $InsP_3$, allowing calcium efflux into the cytosol. $InsP_3$ binding to its receptor is inhibited by elevated concentrations of cytosolic calcium, $[Ca^{2+}]_c$, so that, once a substantial amount of calcium has been emptied from the stores, $InsP_3$ receptor channels will close again. Through mechanisms that are still poorly understood, the emptying of intracellular calcium stores activates a "capacitative" influx of calcium from the extracellular medium, through so-called calcium release-activated calcium (CRAC) channels, which will replenish the stores. In addition to activating CRAC channels, Ang II also modulates the activity of various

voltage-gated membrane calcium channels (of the L-, N-, and T-types), either directly, through cell membrane depolarization, or indirectly, via G-proteins or via protein kinases or phosphatases. This control can be either positive (channel activation) or negative (channel inhibition).

The net result of these numerous impacts of Ang II on regulators of calcium fluxes is a dramatic alteration of intracellular calcium homeostasis. In most cases, this can be observed with fluorescent probes in intact cells, as repetitive spikes of $[Ca^{2+}]_c$, often described as oscillations. At the subcellular level, videomicroscopy imaging reveals that these oscillations actually correspond to localized, confined rises of $[Ca^{2+}]_c$ and are sometimes seen propagating through the cell as "waves" or "tides."

Special mention should be made here of the adrenal glomerulosa cell. Because most enzymes that are required for the biosynthesis of aldosterone are located in the mitochondrial matrix, this organelle appears as a most likely target for the calcium messenger system. Indeed, the changes in $[Ca^{2+}]_c$ elicited by Ang II are relayed and even amplified within the mitochondrial matrix. Concomitantly, there is an increased supply of cholesterol precursor to the mitochondrial steroidogenic machinery, through an increased expression and mitochondrial importation of the steroidogenic acute regulatory (StAR) protein, a crucial factor for the rate-limiting step in the steroidogenic cascade.

C. Protein Kinase C

The biphasic, sustained elevation in the membrane of *sn*-1,2-diacylglycerol resulting from the activation of phospholipases C and D on Ang II challenge contributes to the recruitment and anchoring to the cell membrane of various isoforms of the calcium-sensitive, phospholipid-dependent protein kinase C (PKC). A rapid and marked redistribution of PKC enzyme and activity from the cytosol to the cell membrane is observed, for example, in adrenal glomerulosa cells and vascular smooth muscle cells after Ang II stimulation. The AT_1 receptor bears consensus PKC phosphorylation sites in its sequence and PKC-mediated phosphorylation of these sites results in receptor desensitization. However, the identity and nature of the substrates that contribute to the downstream induction of biological responses to Ang II (steroidogenesis, vasoconstriction, etc.) following PKC phosphorylation remain mostly unknown.

D. Kinase Cascades

As in most intracellular signaling systems, various kinases are mobilized as a consequence of the initial events following Ang II binding to the AT_1 receptor. These kinases can be activated either by intracellular messengers generated through the induction of a first series of effectors (phospholipases, membrane channels, etc.) or by protein-protein interactions.

1. Ca^{2+}/Calmodulin-Dependent Kinase II

The rises in $[Ca^{2+}]_c$ elicited by Ang II in practically all major target cells of the hormone are sensed by the ubiquitous calcium-binding protein, calmodulin. Once it has bound four atoms of calcium, calmodulin becomes able to interact with, among others, Ca^{2+}/-calmodulin-dependent kinase II (CaMKII), a major transducer of extracellular signals to functional cellular responses. In adrenal glomerulosa cells, in which the involvement of CaMKII has been most extensively studied, the enzyme is clearly involved in Ang II-induced modulation of voltage-gated calcium channel activity.

2. Extracellular Signal-Regulated Kinases

Activation of serine-threonine extracellular signal-regulated kinases [ERK2/1 or p44/p42 mitogen-activated protein (MAP) kinases] is one of the earliest events that occurs following Ang II challenge. This has been shown in numerous cell types, such as adrenal glomerulosa cells, cardiac myocytes and fibroblasts, vascular smooth muscle cells, and mesangial cells. The response is usually transient, peaking within 5 to 10 min and decreasing thereafter. The p38 MAP kinase, another member of the MAP kinase family, undergoes activation in response to Ang II, following the same pattern. Although pharmacological studies with selective inhibitors have clearly demonstrated that MAP kinase activation is a necessary prerequisite to the induction of a full biological response to Ang II, the protein mediators that are phosphorylated by MAP kinases remain to be identified in most target cells.

MAP kinases are activated by phosphorylation of adjacent threonine and tyrosine residues. In the case of Ang II action in adrenal glomerulosa cells, cardiac myocytes, and vascular smooth muscle cells, this activation has been shown to occur through a proximal signaling module linking the activated receptor to the small GTPase, Ras, via an Src family kinase, which phosphorylates the adapter molecule Shc. The latter then binds to the Grb-Sos complex and activates Ras. The more distal signaling cascade linking Ras to MAP kinase activation involves several

kinases that are sequentially activated: activated Ras interacts with and activates the serine-threonine kinase Raf, which in turn phosphorylates and activates the dual-specificity kinase MEK1. Once activated, MEK1 will phosphorylate the adjacent threonine and tyrosine residues in ERK2/1 or p42/p44. Moreover, in vascular smooth muscle cells, an alternative Raf-independent mechanism involving a specific isoform of PKC, PKCζ, can be recruited by Ras to stimulate MEK1 and ERK2/1.

3. Signal Transducers and Activators of Transcription (JAK–Stat Pathway)

In vascular smooth muscle cells and in cardiomyocytes—where, in addition to its specific effects, Ang II also plays the role of a growth factor—ligand binding to the AT_1 receptor activates members of a family of intracellular tyrosine kinases, the Janus kinases (JAKs). Specifically, the occupied receptor associates with JAK2, which then autophosphorylates, becomes activated, and phosphorylates proteins of a family of signal transducers and activators of transcription (Stat), in particular Stat1, Stat2, and Stat3. Once phosphorylated, Stat proteins form homo- or heterodimers and translocate to the nucleus, where they bind to specific DNA response elements and stimulate the transcription of the c-*fos* gene, for example, an important factor in cell proliferation.

4. Phosphoinositide 3-Kinase

In adrenal glomerulosa cells as well as in vascular smooth muscle cells, Ang II has been clearly shown to activate yet another kinase, phosphatidylinositol 3-kinase (PI3-K), and its effector, Akt/protein kinase B, which may represent, besides PKC, one of the upstream elements linking the binding of Ang II to its GPCR receptor to activation of the Ras–Raf–ERK2/1 cascade.

5. Pyk2 Tyrosine Kinase and C-Jun N-Terminal Kinase

Activation of tyrosine kinases also appears to play an important role in Ang II signaling. In particular, in vascular smooth muscle cells, the proline-rich tyrosine kinase 2 (Pyk2) has been shown to act as an upstream regulator of the activation by Ang II of both ERK2/1 and yet another kinase, the c-Jun N-terminal kinase (JNK). These kinases may be involved in the growth and vascular remodeling responses elicited by the hormone.

6. Tyrosine Phosphatases

Kinase activation is often coupled to the concomitant induction of phosphatases, as a counterregulatory mechanism. This is indeed the case for Ang II, which mobilizes the Ca^{2+}/calmodulin-dependent protein phosphatase, calcineurin, and possibly other serine-threonine phosphatases in adrenal glomerulosa cells, as well as phosphotyrosine phosphatase 1D.

E. Adenylyl Cyclase

Ang II is known to modulate cAMP production, either through a G_i-mediated inhibition of adenylyl cyclase or through potentiation of the activity of a Ca^{2+}-sensitive adenylyl cyclase involving Ang II-induced capacitative Ca^{2+} influx.

V. SIGNALING THROUGH THE AT_2 RECEPTOR SUBTYPE

The AT_2 receptor subtype plays its major roles in developmental processes and in vascular, cardiac, and renal remodeling. It is now fairly established that the AT_2 receptor subtype couples to G-proteins, a characteristic shared by most seven-transmembrane-domain receptors, although in an atypical way (Fig. 2).

A. Phosphoprotein Phosphatases

The binding of Ang II to its AT_2 subtype receptors leads to activation of tyrosine or serine-threonine phosphatases, three of which have been identified: SH2-domain-containing phosphatase 1 (SHIP-1), protein phosphatase 2A (PP2A), and mitogen-activated protein kinase phosphatase 1 (MKP-1). With distinct substrate specificities and kinetics, all these phosphatases mediate the inactivation of the ERK pathway that is observed with AT_2 stimulation in various cells types and that often leads to growth inhibition or to an apoptotic response.

B. Nitric Oxide Synthase

Some effects of Ang II mediated by the AT_2 receptor subtype involve the activation of nitric oxide (NO) synthase and generation of NO, which will in turn activate a cytosolic guanylyl cyclase and lead to cyclic guanosine monophosphate (cGMP) production. The latter messenger may participate with the signaling mechanisms responsible for the observed natriuretic effect observed with AT_2 receptor stimulation.

C. Phospholipase A2

In epithelial cells of the renal proximal tubule and in cardiac myocytes, AT_2 receptor activation triggers

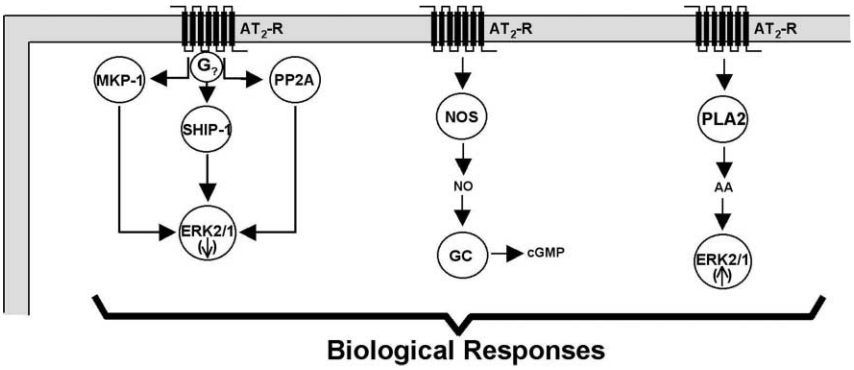

FIGURE 2 Intracellular signaling mechanisms coupled to the AT_2 receptor (AT_2-R) subtype. The main signaling pathways described in this article are illustrated, but most cells do not express all of these pathways. AA, arachidonic acid; cGMP, cyclic GMP; ERK2/1, extracellular signal-regulated kinases 2 and 1; GC, soluble guanylyl cyclase; MKP-1, mitogen-activated protein kinase phosphatase 1; NO, nitric oxide; NOS, nitric oxide synthase; PLA2, phospholipase A2; PP2A, protein phosphatase 2A; SHIP-1; SH2-domain-containing phosphatase 1.

the generation of arachidonic acid through stimulation of PLA2. This represents an unusual signaling pathway because arachidonic acid targets and activates the MAP kinase cascade as a downstream effector, in contrast to the mostly inhibitory effects of AT_2 on MAP kinases observed in numerous other cellular systems.

VI. SUMMARY

The intracellular signaling mechanisms triggered by the octapeptide hormone angiotensin II that lead to its pleiotropic effects in various target cells are mediated by two receptor subtypes, AT_1 and AT_2. AT_1 receptor activation is responsible for the vast majority of the cardiovascular effects of Ang II and is associated, via G-proteins, with an intricate network of calcium- and phosphorylation-sensitive effector systems. The AT_2 receptor is predominantly involved in developmental processes and is mainly coupled to intracellular phosphatases.

Glossary

aldosterone The main salt-retaining hormone; a steroid synthesized from cholesterol in the zona glomerulosa of the adrenal cortex under the control of three principal physiological activators: angiotensin II, extracellular potassium, and adrenocorticotropic hormone.

cytosolic calcium concentration $[Ca^{2+}]_c$ The concentration of free calcium ions found in the cytosol; maintained in resting cells at levels 10,000 times lower than those occurring in the extracellular medium (0.1 μM vs 1–2 mM). Changes of $[Ca^{2+}]_c$ during stimulation serve as intracellular signaling processes.

CRAC channels Calcium release-activated calcium channels located in the cell membrane; CRAC channels are activated on release of calcium from intracellular stores, thus contributing to the replenishment of these stores.

losartan Nonpeptidic, selective antagonist of the AT_1 receptor subtype; widely used to block cardiovascular effects of angiotensin II.

renin Proteolytic enzyme that is released by the kidney in response to a drop in blood pressure, sympathetic nerve activity, or decreased sodium excretion; generates angiotensin I in the circulation by cleaving the 10 N-terminal amino acids of a large a_2-globulin produced by the liver, angiotensinogen.

Anti-Inflammatory Actions of Glucocorticoids

ANN-CHARLOTTE WIKSTRÖM, JAN-ÅKE GUSTAFSSON, AND SAM OKRET
Karolinska Institutet, Huddinge, Sweden

Glucocorticoid hormones serve as important regulators of inflammatory responses. They act to repress inflammation by inhibiting an array of inflammatory mediators, such as adhesion molecules, prostaglandins, cytokines, and cytokine receptors, as well as by inducing apoptosis of certain inflammatory effector cells. Glucocorticoid effects are mediated mainly by transrepressive genomic mechanisms acting via the intracellular glucocorticoid receptor, and, to a lesser extent, possibly also by nongenomic mechanisms.

I. INTRODUCTION

Glucocorticoids (GCs) regulate and suppress nuclear factor κB (NF-κB), a major proinflammatory mediator. Synthetic GCs are often used as drugs for immunosuppression and for treating inflammatory and allergic conditions. However, adverse side effects following therapeutic use can diminish the clinical efficacy of GCs, and thus future development of more selective ligands is desirable.

II. GENE REGULATION BY GLUCOCORTICOID HORMONES

Glucocorticoids play a key role in regulating diverse physiological processes such as metabolism, salt and water balance, cellular proliferation and differentiation, inflammation, and immune responses. The anti-inflammatory and immunosuppressive actions of GCs are essential; inflammatory reactions with loss of GC production proceed in an uncontrolled way and can lead to death. The GC signal is transduced via the glucocorticoid receptor (GR), which regulates the expression of a subset of genes in both a promoter- and a tissue-specific manner. The general mechanism of GC action involves passive uptake and binding of GC to the GR, which is localized in the cytoplasm. Binding of the hormone to the receptor leads to a conformational change, dissociation of associated chaperone proteins, and translocation into the nucleus, where the GR directly or indirectly (through other transcription factors) binds to DNA in target genes. This results in enhancement or repression of gene transcription.

Stimulation of gene transcription by the GR most often involves binding of a homodimer of the hormone–receptor complex to one or more so-called GC-responsive elements (GREs), which consist of two more or less palindromic hexamers spaced by three nucleotides, usually located in the promoter

Angiotensins

NADHEIGE LOCHARD AND
TIMOTHY L. REUDELHUBER
Clinical Research Institute of Montreal

In 1898, Tigerstedt and Bergman first made a correlation between hypertension and a soluble component in kidney extracts. This pioneering work and that of many others eventually led to the biochemical description of the renin–angiotensin system, an enzymatic cascade that results in the synthesis of a family of vasoactive peptides called angiotensins. The activity of this system plays a key role in the regulation of blood pressure and fluid volume in mammals, and its inhibition has become a primary tool for the treatment of hypertension and, more recently, myocardial infarction in North America.

I. INTRODUCTION

All of the components necessary for the production of angiotensin peptides are found in the circulation (Fig. 1). Juxtaglomerular cells in the kidney release the aspartyl protease renin, as well as its enzymatically inactive precursor prorenin, into the circulation. Once there, renin acts on its only known substrate, the 60,000 Da liver-derived glycoprotein angiotensinogen, releasing the decapeptide angiotensin (1–10) (Ang I) from the amino terminus of angiotensinogen. Ang I is in turn converted to the octapeptide angiotensin (1–8) (Ang II) by the removal of two carboxy-terminal amino acids by angiotensin-converting enzyme (ACE). ACE is a metalloprotease bound to the plasma membrane of endothelial cells throughout the circulation. Ang II is the principal effector of the renin–angiotensin system (RAS) through its interaction with angiotensin (AT) receptors type 1 and type 2 (AT_1 and AT_2), members of the seven-transmembrane G-protein-coupled receptor

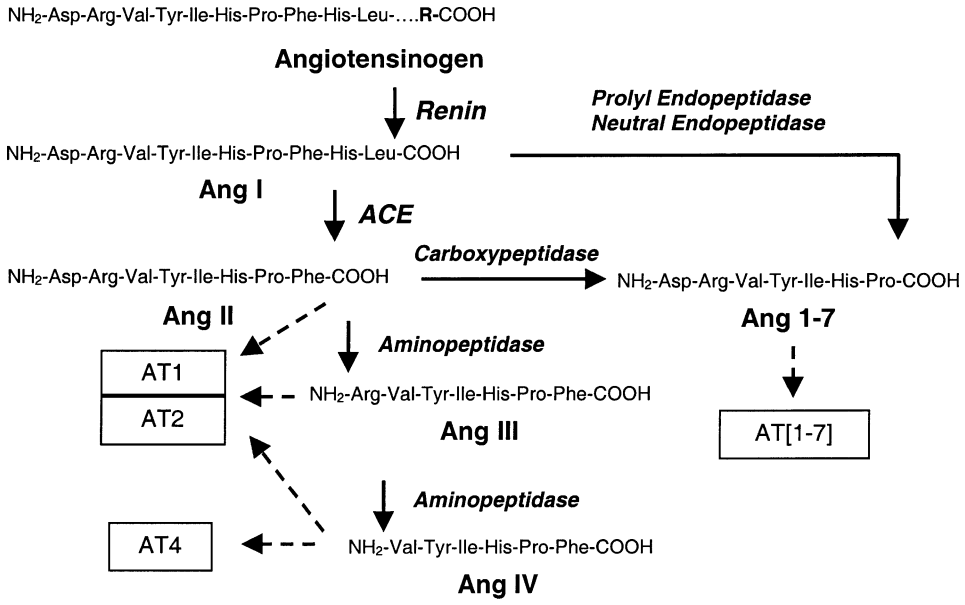

FIGURE 1 Generation of angiotensin peptides (Ang) from angiotensinogen and activation of various angiotensin receptors (AT) by angiotensin II and its metabolites.

family. A vast majority of the cardiovascular effects of Ang II are mediated by the AT_1 receptors. This activity represents the peripheral (classical) components of the RAS.

II. ALTERNATE BIOSYNTHETIC PATHWAYS AND ADDITIONAL ANGIOTENSIN PEPTIDES

In the formation of Ang II, there may exist alternate biosynthetic pathways that have important physiological functions: Hussain and colleagues have described an enzyme called chymase, which may partially substitute for ACE in the generation of Ang II in certain tissues, including the heart. In addition, other proteases, such as cathepsin D and tonin, exhibit renin-like activity *in vitro*, leading to the suggestion that Ang II could be synthesized in some tissues by a renin-independent mechanism. Recent studies by Fukamizu and colleagues lend support to this possibility: mice in which the renin gene has been inactivated by homologous recombination are unable to generate angiotensin peptides in the circulation, but still make them in the brain.

Indeed, although Ang II is the major product of the classical pathway of the RAS, this pathway also leads to the formation of other angiotensin peptides that may have biological roles distinct from those of Ang II (Fig. 1). For example, Ang I can be converted by prolyl endopeptidase (EC 3.4.21.26) and various neutral endopeptidases (NEPs) (EC 3.4.24.11, EC 3.4.24.15, and EC 3.4.24.26) to the heptapeptide Ang (1–7). The abundance of Ang (1–7) increases dramatically in animals treated with ACE inhibitors, and it has been proposed to have its own receptor through which it mediates vasodilation. Ang(1–7) has also been reported to bind and inhibit ACE, which could contribute to its role in vasodilation by acting as a natural inhibitor of the RAS. The heptapeptide Ang (2–8), or Ang III, is produced by the action of aminopeptidase A on Ang II. Aminopeptidases can act also on Ang I to generate Ang (2–10), which can in turn be converted into Ang III by ACE. Ang III binds to AT_1 and AT_2 receptors, although with reduced affinity. Ang II injected directly into the brain has been associated with increases in blood pressure, the stimulation of sympathetic nervous system (SNS) activity, stimulation of vasopressin release, and an increase in water and sodium appetite. These effects of Ang II in brain are mediated by the AT_1 receptor. Ang III in the brain can also elicit many of these responses, although higher doses are required. Because Ang III can interact with AT_1 receptors and because the brain is particularly rich in aminopeptidases, it is possible that the biologically active angiotensin peptide in brain is Ang III. Interestingly, coinjection of Ang II with aminopeptidase inhibitors dramatically reduces the response to this peptide, raising the additional possibility that Ang III is acting through a signaling pathway distinct from that used by Ang II. Aminopeptidases can further cleave Ang III to generate the hexapeptide Ang (3–8), or Ang IV. Ang IV has also been proposed to bind to a specific receptor (AT_4) distinct from AT_1 and AT_2 with a variety of resulting actions, including increasing cerebral and renal blood flow. Interestingly, very recent data suggest that the AT_4 receptor may in fact be an aminopeptidase and that the biological effects of Ang IV may be secondary to inhibition of this enzyme. Ang IV can be further degraded into smaller peptides with currently unknown functions, if any.

III. TISSUE SOURCES OF ANGIOTENSIN PEPTIDES

For many years the biological actions of the RAS were believed to be solely due to the activity of the circulating RAS components. However, in recent years evidence has accumulated that angiotensin peptides are synthesized within tissues, where they might have local actions that are distinct from the known cardiovascular effects of the RAS. These observations have changed the way that RAS is evaluated and impact the clinical management of RAS activity. The components necessary for the formation and action of Ang II have been detected in a number of tissues:

A. Brain and Pituitary

Although angiotensins do not readily cross the blood–brain barrier, all of the components of the RAS, including Ang II receptors, have been identified in brain, with the possible exception of renin. Interestingly, the fetal brain is particularly rich in AT_2 receptor, which virtually disappears after birth. The pituitary has a high concentration of Ang II per gram of tissue, which has bolstered the suggestion of local angiotensin synthesis. In the pituitary, the mRNA for renin colocalizes with Ang II in the cells (gonadotropes) that produce luteinizing hormone, whereas angiotensinogen is found in a different and as-yet unidentified cell type.

B. Heart and Blood Vessels

Although the messenger RNAs for angiotensinogen, ACE, and AT_1 and AT_2 receptors are expressed in the heart, the local synthesis of renin by the heart remains quite controversial. Angiotensin receptors have been described on both cardiac myocytes and fibroblasts. In blood vessels, ACE can be found in abundance on endothelial cells, and angiotensinogen is particularly abundant in the surrounding adipose tissue. Interestingly, although renin activity is easily measured in the lumen of blood vessels, its mRNA there is difficult to demonstrate.

C. Kidney

In addition to releasing renin into the circulation, the kidney also contains all the necessary components for the local generation of Ang II. Angiotensinogen is synthesized in the epithelial cells of the proximal tubule. ACE is present throughout the renal vasculature and Ang II receptors are found on both the basolateral and lumenal membranes of renal tubules as well as on renal blood vessels. The finding that the concentration of Ang II in renal interstitial and tubular fluid is hundreds to thousands of times higher than that found in the plasma also supports the model of local angiotensin peptide synthesis in the kidney.

D. Adrenal Gland

The adrenal gland is the tissue with the highest content of Ang II per gram of wet weight. Angiotensinogen mRNA is present in fibroblast-like cells adjacent to the adrenal capsule and in the adrenal cortex and medulla. ACE is present in the adrenal medulla and also at lower levels in the adrenal cortex. The majority of renin is present within the outer adrenal cortex and renin mRNA is present within the steroid-producing adrenocortical cells. Both Ang II AT_1 and AT_2 receptors are expressed in the outer adrenal cortex. Interestingly, the renin gene is expressed at higher levels in the fetal adrenal gland of the mouse than in any other tissue, raising the possibility that it is somehow important during fetal development.

E. Reproductive Organs

Ang I and Ang II and AT_1 receptors have been localized on Leydig cells and sperm tails. The testis expresses a unique but fully functional form of ACE (a hemienzyme) in the lumenal wall of the epididymis. All of the soluble components of RAS have been found in ovarian follicular fluid. Granulosa and theca cells contain renin and angiotensinogen and the ovary secretes large amounts of prorenin and renin, particularly during pregnancy. Prorenin, found in placental fluid in very large amounts, increases in concentration as pregnancy proceeds to term.

IV. CONCEPT OF A HYBRID CIRCULATING/TISSUE RAS

The synthesis of angiotensin peptides requires the concerted actions of two enzymes (renin and ACE) on the substrate angiotensinogen. In addition, renin is synthesized as an inactive precursor, and to be activated it must be modified by the precise proteolytic removal of its prosegment by an as-yet unidentified enzyme (or enzymes). These components must also meet in the appropriate compartments to be active. This presents a mechanistic problem, as can be illustrated by considering the cellular distribution of the components of the brain RAS. Although ACE is widely distributed in the brain, angiotensinogen is made in astrocytes and Ang II immunoreactivity has been detected primarily in neurons. Two hypotheses have been proposed to explain these findings. Angiotensinogen might be released by the astrocyte in the extracellular space, where it is converted into Ang II and subsequently internalized in neurons after binding to its specific receptors. The other possibility is that angiotensinogen is taken up by the neurons, metabolized to Ang II inside the cells, and released at the nerve endings to act on receptors in adjacent areas. In fact, there is evidence to suggest that angiotensinogen, renin, Ang I, and Ang II can be taken up by several tissue types to be further metabolized locally for the generation of bioactive peptides (Fig. 2). Specific acceptor proteins have been described for both renin and its precursor prorenin in a number of tissues. These may have the role of concentrating renin on the cell surface for local action or perhaps may be involved in renin internalization for the intracellular generation of peptides. Evidence has also accumulated that angiotensins can be formed within certain cell types for later release. For example, renin, ACE, and Ang II can all be detected in juxtaglomerular cells of the kidney afferent arteriole. Treatment of animals with ACE inhibitors causes the accumulation of Ang I in these cells, suggesting that they may contain a complete intracellular RAS pathway. Thus, it is difficult (and perhaps not so important) to distinguish between a

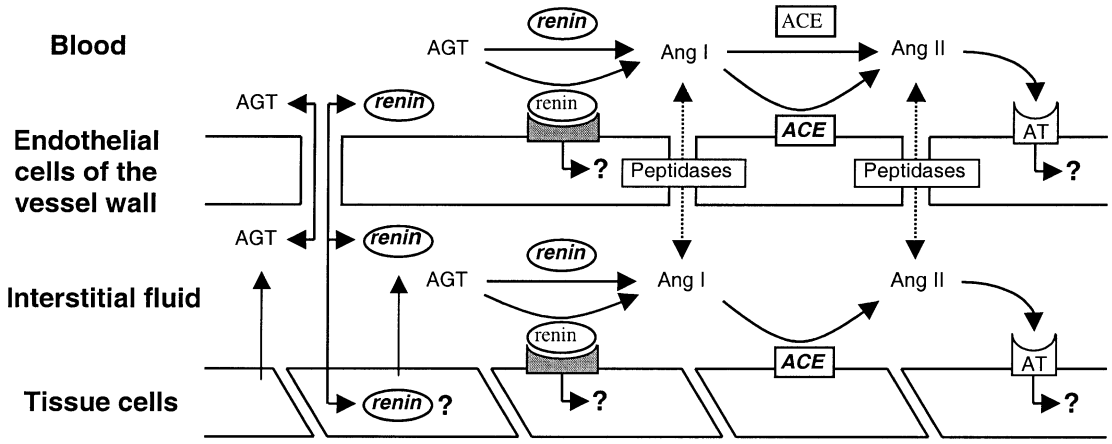

FIGURE 2 Alternative pathways of angiotensin (Ang) I and II production in tissues. Angiotensinogen (AGT), renin, Ang I, and Ang II either traverse the endothelial cell layer to the interstitial space or are produced locally to react with other components of the RAS. Renin may also bind to acceptor proteins on certain cells and either acts on the cell surface or is internalized. Ang I and II may also be metabolized by peptidases while passing through the vascular wall. Tissue Ang I and Ang II generation may occur not only in the interstitial fluid or on the cell surface, but also within cells. Binding of Ang II to the AT_1 receptor is followed by intracellular signaling.

circulating and a local RAS, because many tissues are capable of using both locally synthesized and "imported" RAS components to complete angiotensin peptide synthesis locally.

V. PROPOSED TISSUE-SPECIFIC ROLES OF ANGIOTENSIN PEPTIDES

Ang II acts on numerous tissues to affect salt and water balance and blood pressure. Tissue-specific actions of Ang II include the stimulation of drinking behavior and salt appetite (by actions on the brain), facilitation of sympathetic transmission in the central and peripheral nervous systems, stimulation of aldosterone release from the adrenal gland (which acts on the kidneys to increase sodium retention), direct effects on the kidney to increase sodium retention, stimulation of cardiac output, and vasoconstriction (Fig. 3). The Ang II responsible for these actions can be derived from the circulating renin–angiotensin system in most cases, with the possible exception of the brain, because angiotensin peptides do not readily cross the blood–brain barrier.

There are also several tissue-specific actions of angiotensin peptides that are unrelated to blood pressure regulation. Perhaps the most useful insight into this topic comes from mice, which are deficient for a functional RAS due to inactivation of genes for either angiotensinogen, renin, ACE, or AT_1 and AT_2 receptors. What is strikingly absent in mice deficient for a functional renin–angiotensin system is any apparent gross effect on reproduction and fetal development. Thus, in spite of the expression of RAS components in reproductive tissues, placenta, and fetal organs, angiotensinogen-deficient mice (thus completely devoid of a RAS) are fertile and deliver pups that are histologically normal at birth. However, these mice do display some deficiencies as they age, some of which are fairly subtle: For example, inactivation of the gene coding for the AT_2 receptor in mice leads to reduced exploratory behavior, suggesting that Ang II could affect learning through the AT_2 receptor. Ang IV may also play a unique role in the brain: although complete ablation of the RAS (by inactivation of the angiotensinogen gene) leads to a defect in the ability of mice to repair the blood–brain barrier after a cold injury, this defect can be corrected by provision of the mice with Ang IV, even in the presence of antagonists for the AT_1 and AT_2 receptors.

There are also a number of more dramatic age-related defects in mice that are entirely deficient for a functional RAS. As many as 85% of mice deficient for angiotensinogen die before weaning. This high neonatal mortality may be related to a deficiency in salt retention (perhaps due in part to a lack of Ang II-stimulated aldosterone release), because it can be largely reversed with intraperitoneal injection of saline into neonatal mice. Virtually all RAS-deficient mice also display late-stage renal defects within 3 weeks of birth, including atrophic renal papillae, mesangial expansion, dilated collecting ducts in

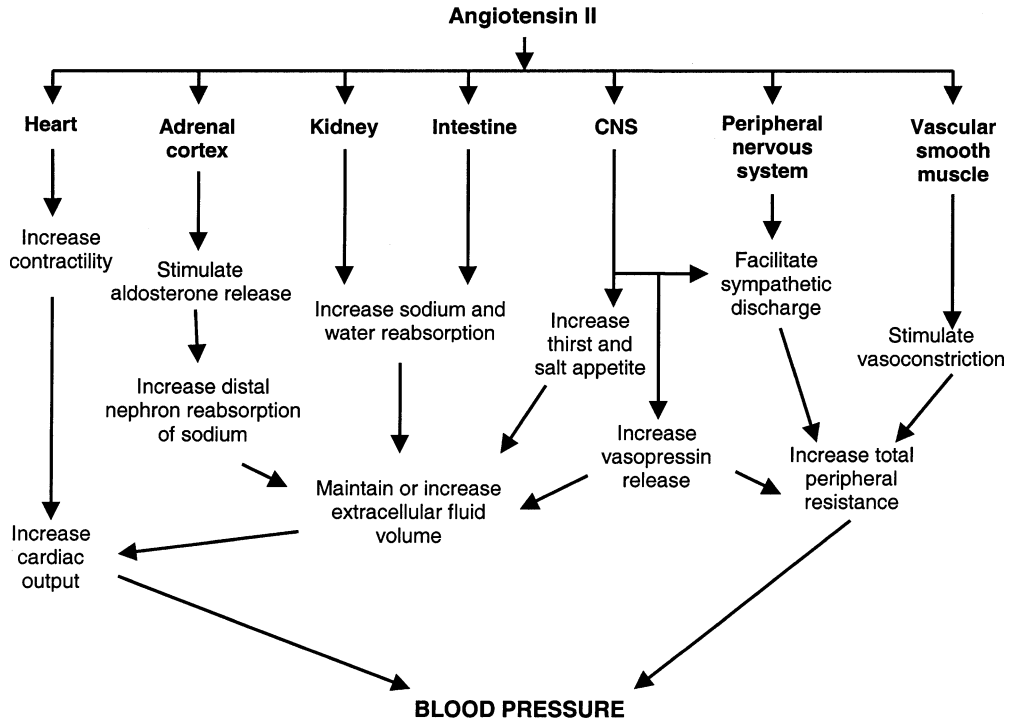

FIGURE 3 Tissue actions of angiotensin II that affect blood pressure and fluid volume.

the outer renal medulla, mild interstitial fibrosis, and hyperplasia of interlobular arteries, all of which are associated with impaired renal function. Ichikawa and co-workers have shown that RAS-deficient mice display impaired urinary peristalsis and propose that Ang II may be a necessary chemotactic or differentiation agent in this correct formation of a smooth muscle cell layer in the renal pelvis. By 7–8 weeks of age, surviving angiotensinogen-deficient mice have lower blood pressure than do their control littermates, confirming the expected role of the RAS in blood pressure modulation. Finally, mice deficient in RAS signaling are anemic, possibly due to a missing and crucial Ang II-signaling step in erythropoiesis, and exhibit a decreased immune response due to an impairment in lymphocyte activation.

VI. CONCLUSION

The concept of a circulating RAS with a role designed solely to generate the vasoactive peptide Ang II has undergone significant revision in the past two decades. It is now clear that many tissues have the capacity to generate a variety of functional angiotensin peptide hormones and that these peptides have roles beyond the regulation of salt and water balance. Because of the pleiotropic effects of angiotensin peptides, it has been very difficult to sort out their tissue-specific functions in whole animals, and although the use of homologous recombination experiments in mice have helped to rule out some proposed roles for the RAS, the dissection of the role of angiotensin peptides in learning, blood–brain barrier maintenance, erythropoiesis, immunity, and renal development may ultimately make the clinical use of RAS inhibitors safer and more effective.

Glossary

angiotensins A family of peptide hormones derived from the protein angiotensinogen.

homologous recombination A natural chromosomal recombination mechanism that has been harnessed to "knock out" genes in mice in order to test for their functional importance.

renin–angiotensin system The enzymatic cascade composed of the substrate (angiotensinogen), two processing proteases (renin and angiotensin-converting enzymes), and receptors; mediates the hormonal action of angiotensin peptides.

Angiotensin II Receptor Signaling

ALESSANDRO M. CAPPONI
University Hospital, Geneva

Angiotensin II, an octapeptide hormone, is the product of two successive enzymatic proteolytic cleavages. Angiotensin II is produced in blood and in some tissues by the action of renin and angiotensin-converting enzyme on angiotensinogen (an α_2-globulin) and angiotensin I (a decapeptide), respectively. Initially described as a hypertensive factor, angiotensin II has proved to be a remarkably pleiotropic peptide. It exerts pressor effects by acting peripherally (in vascular smooth muscle, adrenal cortex, and kidney tissues) as well as centrally, but is also involved in the regulation of metabolic pathways (in liver and adipose tissues), inflammatory responses (by macrophages), tissue growth, and developmental processes.

I. INTRODUCTION

In spite of the spectrum of different responses elicited by angiotensin II in a host of distinct tissues, only two major angiotensin (Ang II) receptor subtypes, AT_1 and AT_2, have been identified to date. The vast majority of the biological functions of the hormone are mediated through the AT_1 receptor subtype, whereas the AT_2 subtype is essentially involved in developmental and remodeling processes. Clearly, therefore, the specificity of the response within a given tissue or cell type cannot be conferred by the receptor but must rely on the intracellular signaling mechanisms activated beyond the receptor. In this respect, signal transduction events following binding of the hormone to the AT_1 receptor have been extensively studied and are fairly well understood; less is known of the downstream events triggered by activation of the AT_2 subtype.

Anti-Inflammatory Actions of Glucocorticoids

ANN-CHARLOTTE WIKSTRÖM, JAN-ÅKE GUSTAFSSON, AND SAM OKRET
Karolinska Institutet, Huddinge, Sweden

Glucocorticoid hormones serve as important regulators of inflammatory responses. They act to repress inflammation by inhibiting an array of inflammatory mediators, such as adhesion molecules, prostaglandins, cytokines, and cytokine receptors, as well as by inducing apoptosis of certain inflammatory effector cells. Glucocorticoid effects are mediated mainly by transrepressive genomic mechanisms acting via the intracellular glucocorticoid receptor, and, to a lesser extent, possibly also by nongenomic mechanisms.

I. INTRODUCTION

Glucocorticoids (GCs) regulate and suppress nuclear factor κB (NF-κB), a major proinflammatory mediator. Synthetic GCs are often used as drugs for immunosuppression and for treating inflammatory and allergic conditions. However, adverse side effects following therapeutic use can diminish the clinical efficacy of GCs, and thus future development of more selective ligands is desirable.

II. GENE REGULATION BY GLUCOCORTICOID HORMONES

Glucocorticoids play a key role in regulating diverse physiological processes such as metabolism, salt and water balance, cellular proliferation and differentiation, inflammation, and immune responses. The anti-inflammatory and immunosuppressive actions of GCs are essential; inflammatory reactions with loss of GC production proceed in an uncontrolled way and can lead to death. The GC signal is transduced via the glucocorticoid receptor (GR), which regulates the expression of a subset of genes in both a promoter- and a tissue-specific manner. The general mechanism of GC action involves passive uptake and binding of GC to the GR, which is localized in the cytoplasm. Binding of the hormone to the receptor leads to a conformational change, dissociation of associated chaperone proteins, and translocation into the nucleus, where the GR directly or indirectly (through other transcription factors) binds to DNA in target genes. This results in enhancement or repression of gene transcription.

Stimulation of gene transcription by the GR most often involves binding of a homodimer of the hormone–receptor complex to one or more so-called GC-responsive elements (GREs), which consist of two more or less palindromic hexamers spaced by three nucleotides, usually located in the promoter

region of GC-responsive genes. GR interaction with co-activators results in the establishment of contact with and regulation of the basal transcription machinery, with increased transcriptional initiation as the outcome. In addition, in most natural genes regulated by GCs, the GR establishes, and may even require, an interaction with other transcription factors binding in the proximity of the GRE, in order to allow proper GC regulation. Furthermore, in some cases the GR may even enhance gene expression without having to bind to the DNA. Instead, in these cases, enhancement occurs through a direct protein–protein interaction between the GR and other transcription factors binding to their cognate sites within the regulatory regions of the gene (Fig. 1).

As in the case of activation of gene transcription, repression of gene transcription by the GR occurs via GR binding in a DNA-dependent or -independent mechanism (Fig. 1). For a few genes, GR interaction with a so-called negative GRE seems to be required for repression to occur. This is the case for the human osteocalcin gene, the human interleukin-1β gene, and the bovine prolactin gene. It is generally thought that repression by the GR occurs by displacement of transcription factors binding to an element overlapping a GRE. However, most cases of GR-mediated repression seem to involve GR binding to other transcription factors, such as NF-κB or activator protein-1 (AP-1), which are important for regulating the transcriptional activity of genes. This involves protein–protein interactions without GR binding to DNA. This mechanism has been referred to as "tethering." In fact, repression of target genes by the GR seems to be more important than activation. This was initially suggested by G. Schütz and colleagues, who replaced the wild-type GR in a mouse with a GR mutant ($GR^{dim/dim}$), which maintains its ability to transrepress but has lost its ability to transactivate. These mice develop normally and are generally healthy, revealing that GR-mediated transactivation is not necessary for development or survival. Importantly, these mice also retain their ability to repress inflammatory reactions, suggesting that protein–protein interactions with other transcription factors, rather than GR–GRE interactions, form the basis of the anti-inflammatory activity of the GR (see also the following discussion).

III. NONGENOMIC EFFECTS

The response to glucocorticoid treatment is generally the result of genomic effects, i.e., specific direct or indirect regulation of target genes via the GR (cf. above). However, when using very high doses of

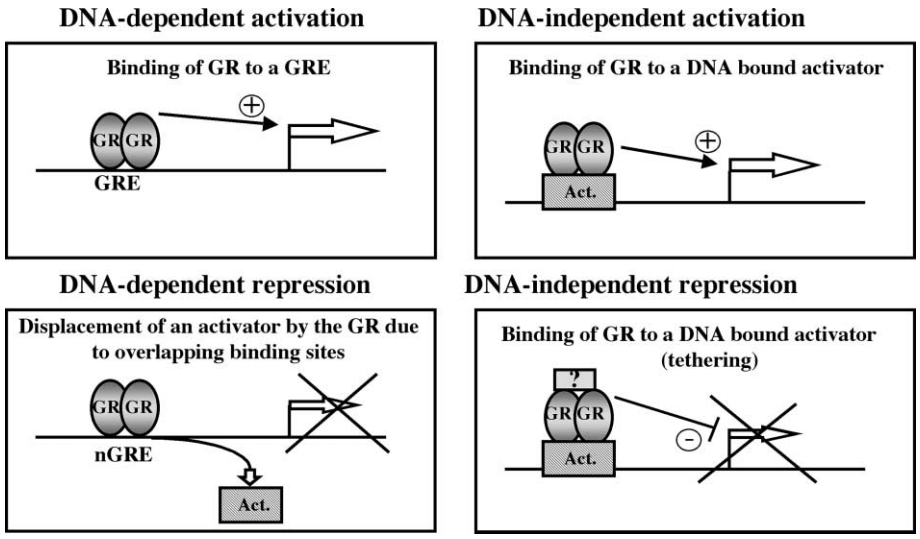

FIGURE 1 Transcriptional activation and repression of target genes by the glucocorticoid receptor (GR). Activation or repression of GR target genes can be DNA dependent or DNA independent. The classical activation of GR target genes involves binding of a GR homodimer to a glucocorticoid response element (GRE). However, the GR may also further stimulate gene expression by binding to another transcriptional activator (Act) on DNA, without binding to the DNA. Repression of gene expression can also be DNA dependent or DNA independent. In the first case, it is thought that the GR may displace binding of another transactivator due to overlapping DNA binding sites. In the latter case, the GR interacts through a protein–protein contact with another transactivator without binding to DNA (tethering) and represses gene expression. This may involve recruitment of additional unknown proteins to the complex.

GCs in acute clinical situations—for example, in severe exacerbation of multiple sclerosis or after spinal cord injury—it has been suggested that nongenomic effects are also of importance. Certain GC effects are obtained within minutes, a time span that does not allow genomic effects to take place. The rapid effects are obtained via mechanisms involving phosphorylation events, Ca^{2+} signaling, and other second-messenger systems. The existence of steroid-binding membrane receptors has been proposed, but no convincing data are yet available to support this notion. Also, a nonspecific, nongenomic effect of steroids has been proposed, whereby the GC molecule would interact directly with and thus stabilize lipophilic biological membranes.

IV. ENDOGENOUS GLUCOCORTICOIDS AS ANTI-INFLAMMATORY AGENTS

Purified GC has been available since 1936, when Kendall's compound E was synthesized in a crystalline form; the correct structure of this compound was described in 1938 by Steiger and Reichstein. Since 1946, large-scale synthesis of compound E, today called cortisone, has been possible. Long before that, in 1915, Corbett had noted that "suprarenal exhaustion" was an important parameter in the bad prognosis for patients with severe shock. In 1932, Whitehead and Smith administered adrenal extract to five patients with severe infectious disease, all of whom initially improved and four of whom survived!

Compound F (corresponding to cortisol) and compound B [corresponding to corticosterone and deoxycorticosterone (DOC)] were also used in early studies of endogenous corticoids. The endogenous steroid of primary importance in humans is cortisol, also called hydrocortisone. Cortisol and cortisone differ only in their 11-carbon substitution. Cortisol has an 11β-OH group, whereas cortisone has an 11-keto group. This difference is biologically important: cortisone is relatively inactive biologically, whereas cortisol is a biologically active molecule. These forms of GCs are interconvertible by the action of both type 1 and type 2 of the enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD1 and 11β-HSD2), which have been extensively studied during recent years. The conversion of cortisone to cortisol by 11β-HSD1 acting as an 11β-reductase exploits the substantial circulating levels of 11-keto steroids and explains the therapeutic effects of cortisone, which, when used as a drug, requires this activating metabolic step. This conversion takes place mainly in the liver, brain, and adipose tissue, which are organs expressing high levels of 11β-HSD1. Kidney 11β-HSD2, on the other hand, converts cortisol to inactive cortisone, allowing kidney-specific effects of aldosterone to be exerted.

There exists a species-dependent difference regarding which particular GC is the main active form. In rodents, the predominant active form is corticosterone, which differs from cortisol by lacking a hydroxyl group in the 17α position due to a lack of 17α-hydroxylase in rodent adrenals. This active form of GC can be rapidly converted to an inactive form by an 11β-hydroxy → 11-keto conversion catalyzed by 11β-HSD2.

Approximately 8–30 mg/day of GCs is produced in the zona fasciculata in the adrenal cortex. The serum level of cortisol varies in a diurnal pattern, depending on the sleep/wake cycle, and is related to food intake. Peak values of 280–700 nmol/liter are obtained in the morning around 8 AM, whereas after midnight and during the following 4 h serum levels are very low, sometimes not measurable even by sensitive radioimmunoassay techniques. The late-night values are usually in the range of 0–280 nmol/liter, thus there is a 5- to 10-fold variation in serum levels during 24 h. Healthy individuals tend to adhere to an individual diurnal variation and repeatedly maintain a pattern of low-, intermediate-, or high-level cortisol secretion from childhood through puberty and into adult life. Diseases such as depression, posttraumatic stress syndrome, metabolic syndrome, and even aging may lead to perturbations of the diurnal rhythms and secretion levels of GCs.

There have been attempts to exploit the endogenous diurnal rhythm of GC secretion, and studies have been performed to test if the therapeutic effect of GC administration to patients with asthma, for example, varies during the day. Timing the inhalation of a single dose of GCs to the evening, instead of the morning, leads to a better therapeutic effect. However, for oral or parenteral GC therapy this may be a dangerous approach, because administration of GCs in the morning, preferably only every second day, has been shown to be optimal in preventing development of adverse effects, especially the iatrogenic hypothalamic–pituitary–adrenal (HPA) axis depression that occurs with continued high-dose GC therapy.

Animal studies have shown that adrenalectomy is associated with an exacerbation of inflammatory responses. Metyrapone, a cortisol synthesis inhibitor, has been used to study late-phase reactions to antigen in animals. These studies show that blocking cortisol synthesis leads to an enhanced late-phase response.

The interplay of inflammation and cortisol response is complex; allergic or other types of inflammation may lead to increased levels of cortisol via HPA axis up-regulation, whereas inflammatory mediators such as histamine, interleukin-1 (IL-1), IL-6, tumor necrosis factor α (TNFα), and others lead to release of corticotropin-releasing hormone (CRH) and adrenocorticotropic hormone (ACTH), which, in turn, lead to increased levels of cortisol. Cortisol in turn can differentially down-regulate these cytokines, especially IL-1 and TNFα, whereas IL-6 seems to be more resistant to GC regulation. Some studies also indicate that certain cytokines can modify the affinity of the GR to its ligand as well as induce functional resistance to GC effects (see the following discussion).

Both excess and inadequate levels of glucocorticoids can lead to disease. Excess GC levels increase the risk for infections, whereas suboptimal levels increase the risk for inflammatory, allergic, and autoimmune diseases. The data from studies of patients with asthma, rheumatoid arthritis, systemic lupus erythematosus, and other inflammatory/autoimmune disorders and from animal model systems, suggest that the HPA axis as such may influence disease pattern and severity. Humans undergoing long-term stress have an increased susceptibility to viral infection, impaired wound healing, and a poorer response to vaccination. It has also been demonstrated in a rat experimental model by Ester Sternberg and others that endogenous GC levels and the HPA axis have an impact on disease. These studies have compared the Lewis (LEW/N) rat, which has a blunted HPA axis response and a high susceptibility to autoimmune diseases, to the histocompatible Fischer (F344/N) rat, which has a hyperactive HPA axis and a low susceptibility to the same diseases. Interference with the HPA axis, leading to low levels of circulating GCs, renders the previously resistant F344/N strain more prone to inflammatory disease, and exposure to bacterial lipopolysaccharide (LPS) results in a high mortality rate. The susceptible strain LEW/N, when transplanted with fetal hypothalamic tissue from F344/N rats, decreases its inflammatory response and can withstand LPS exposure.

In summary, there is interplay between the immune system and the neuroendocrine GC system. An HPA axis resulting in low levels of circulating GCs may predispose to inflammatory disorders. On the other hand, secretion of specific inflammatory cytokines such as IL-1, IL-6, and TNFα may affect the HPA axis and up-regulate GC secretion, which then can serve to control and down-regulate these and other cytokines and thereby maintain homeostasis and regulate the magnitude of the inflammatory response.

V. GLUCOCORTICOIDS AND SPECIFIC CYTOKINES

GCs can down-regulate expression of specific cytokines via negative regulation of promoters of cytokine genes. Several cytokines have also been reported to be down-regulated by GCs through a reduction of the half-life and the translatability of the cytokine mRNAs. Among cytokines affected by GCs are IL-1β, IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-11, IL-12, IL-13, IFN-γ, granulocyte/macrophage colony-stimulating factor (GM-CSF), and TNFα. In the case of IL-4, for instance, up-regulation by GCs has also been reported. GCs can also inhibit the synthesis of cytokine receptors such as the IL-2 receptor. GC down-regulation of the production of cytokines has secondary effects on cells that are dependent on certain cytokines for survival, i.e., eosinophils and subsets of T lymphocytes; eosinophils, for instance, when deprived of GM-CSF and IL-5, die by apoptosis.

The interplay of cytokines and GCs is complex, as exemplified by the reported down-regulation by GCs of constitutive and IL-1β-induced IL-6 in certain cell types. IL-6 in turn can up-regulate the number of GR sites per cell, as measured by a ligand-binding assay in osteoblastic cell lines, most notably in Saos-2 cells. An up-regulation of the receptor number in this case does not necessarily reflect an increased ability to respond to GCs, but may be due to an inability of the receptor to translocate to the nucleus. The cytokine IL-4, in the presence of IL-2, has been reported to decrease GR ligand affinity in T cells concomitantly with an increase in the number of GR binding sites. These changes seem to affect GR function, because the ability of a GC to inhibit the proliferation of T cells in the presence of these two cytokines is hampered. Also, IL-13 has been reported to have a similar effect, decreasing GR ligand binding affinity.

Other interleukins, e.g., IL-10, have been reported to increase the concentration of GR binding sites in human monocytes without affecting the binding affinity. These cells, when treated with IL-10, have an increased sensitivity to GCs; this effect has been suggested to be mediated via an up-regulation of the GR-stabilizing chaperone, heat-shock protein 90 (Hsp 90). A similar effect on human monocytic cells has been reported to take place when the cells are exposed to transforming growth factor-β (TGF-β), an effect involving activation of the activator protein-1

and Smad, leading to an increased number of GR sites and an enhanced ability to transactivate GRE-dependent promoters.

VI. GLUCOCORTICOID REPRESSION OF GENES INVOLVED IN INFLAMMATORY RESPONSES

As already indicated, cortisol (corticosterone in rodents) is a key molecule involved in feedback regulation of inflammatory and immune responses. The efficiency of GCs in this respect has widely encouraged their use as drugs in the treatment of inflammatory diseases or when immunosuppression is required. The cellular responses to inflammatory reactions are several, and include migration of cells to the site of inflammation (T cells and dendritic cells), expression and/or release of numerous inflammatory mediators, e.g., adhesion molecules, cytokines, and chemokines (endothelial cells, macrophages, and T cells), and proliferation (T and B cells). GC hormones repress most of these inflammatory responses. In addition, GCs may induce apoptosis of peripheral T cells. The effects are mainly mediated by the ability of GCs to repress transcription of the genes involved in the inflammatory process, e.g., those for intercellular, vascular cellular, and endothelial leukocyte adhesion molecules (ICAM-1, VCAM-1, and ELAM) and proinflammatory cytokines such as TNFα, IL-1β, IL-6, and IL-8, as well as for other molecules involved in inflammatory reactions, such as inducible nitric oxide synthase (iNOS), cyclooxygenase 2 (COX-2), GM-CSF, cytokine-induced neutrophil chemoattractant/growth-regulated oncogene (CINC/gro), and macrophage inflammatory protein-1 (MIP-1, also known as RANTES, for receptor-activated neutrophil T-cell expression and secretion).

Promoter and ablation analyses (knockouts) have identified some key transcription factors that are responsible for activation of a large part of the genes involved in inflammatory and immune reactions. These include the transcription factors NF-κB, AP-1, nuclear factor of activated T cells (NF-AT), Ca^{2+}/cAMP response element binding protein (CREB), and CCAAT/enhancer binding protein β (C/EBPβ). Indeed, mutational studies of inflammatory genes have demonstrated that the ability of GCs to repress transcription involves the binding sites for the above-mentioned transcription factors. However, these sites lack the ability to bind the GR. Instead, as previously discussed, repression occurs through a tethering mechanism by which GR interferes with the transcription factor through a direct or indirect protein–protein interaction, without actually contacting DNA. This interaction between two signaling pathways is often referred to as "crosstalk." Usually this crosstalk is mutual, meaning that the transcription factors also repress the activity of a GRE-bound GR, thus resulting in impaired transcriptional activation by the GR. It is thought that an abortive nonproductive complex is formed and is unable to maintain transcription. The best *in vivo* evidence that tethering is the main operating mechanism in the anti-inflammatory action of GC is the generation of $GR^{dim/dim}$ mice, in which the wild-type GR gene has been replaced by the gene for a GR mutant that is unable to dimerize and bind to GRE. These mice are unable to transactivate GC-responsive target genes but maintain the ability to repress target genes through the tethering mechanism.

Interestingly, these mice have a normal anti inflammatory response, measured as the ability of GCs to repress phorbol ester-induced skin or ear edema, serving as models of acute inflammation. Furthermore, TNFα release after systemic injection of lipopolysaccharide, a model of bacterial infection and subsequent systemic inflammatory response, was also repressed to a similar degree in $GR^{dim/dim}$ mice and in wild-type mice. Analysis of GC repression of cytokine gene expression in primary cells derived from the $GR^{dim/dim}$ mice [TNFα, IL-1β, IL-6, COX-2 from macrophages, or IL-2 and interferon γ (IFNγ) from T cells] confirmed the ability of the transactivation-deficient $GR^{dim/dim}$ mice to repress genes activated during the inflammatory response. These results were also obtained in the presence of a protein synthesis inhibitor, demonstrating that synthesis of a secondary protein is not required. These findings confirm a number of earlier studies based on cell transfection experiments showing that GR mutants unable to bind GRE and to transactivate may retain their ability to repress both NF-κB, AP-1, NF-AT, CREB, or C/EBPβ activity. Although DNA binding per se is not required, regions within the DNA-binding domain (DBD) of the GR seem important for the interference.

VII. MECHANISMS INVOLVED IN GLUCOCORTICOID REPRESSION OF NF-κB

The expression of most proinflammatory genes depends on the activation of NF-κB. Thus, NF-κB most likely represents the major target for the GR in the inhibition of inflammatory responses. Because of the central role of NF-κB in signal transduction in inflammatory and immunological responses, the focus here is on GC repression of this activity.

NF-κB is activated by numerous signals, including proinflammatory cytokines such as TNFα and IL-1β, viruses, viral proteins, double-stranded RNA, and phorbol esters, as well as physical and chemical stress. In nonstimulated cells, NF-κB is kept inactive in the cytoplasm in a complex with its inhibitor protein, IκBα (Fig. 2). The signal transduction pathway involved in activation of NF-κB includes stimulation of the IκB kinase (IKK) that phosphorylates Ser-32 and Ser-36 on IκBα. These phosphorylations lead to degradation of IκBα through the 26S proteasome machinery, resulting in the release of NF-κB, the translocation of NF-κB into the nucleus, and the binding to NF-κB binding sites in target genes. Through recruitment of co-activators and stimulation of the basal transcription machinery, transcriptional initiation occurs (Fig. 2). The members of the mammalian NF-κB/Rel family consist of RelA (p65), RelB, c-Rel, NF-κB1 (p50/p105), and NF-κB2 (p52/p100). The NF-κB/Rel transcription factors are characterized by a conserved stretch of 300 amino acids, the Rel homology domain (RHD), which is responsible for DNA binding and interaction with IκB. NF-κB exists as a dimer, most often a heterodimer, predominantly consisting of one p65 and one p50 protein. The GR has been shown to interact with RelA (p65) and c-Rel, whereas interaction with p50 is a matter of controversy. The physical interaction between the GR and RelA seems to involve the GR DBD and the RHD of RelA, although carboxy-terminal transactivation domains of RelA also seem to be required for a functional interference. It is not known whether the interaction between the GR and RelA proteins is direct or whether intermediary proteins are involved.

Although some previous reports based on *in vitro* experiments have suggested the formation of an abortive NF-κB/GR complex that is unable to bind DNA, more recent results from *in vivo* experiments, including *in vivo* footprinting and chromatin

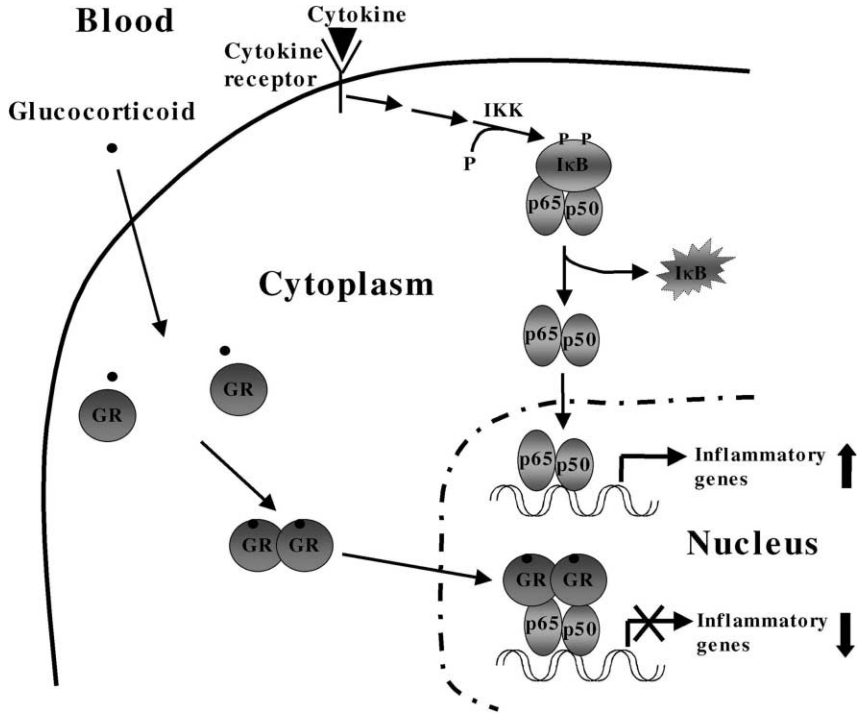

FIGURE 2 Crosstalk between nuclear factor κB (NF-κB) and glucocorticoid receptor (GR) signaling pathways. Binding of a cytokine to its membrane receptor triggers several steps that lead to activation of the NF-κB signal transduction pathway. This includes phosphorylation of NF-κB inhibitory protein IκBα in the cytosol by an IκB kinase (IKK) at Ser-32 and Ser-36. This triggers degradation of IκBα. This in turn allows the NF-κB complex (most often consisting of a p65/p50 dimer) to translocate to the nucleus, where it binds to NF-κB binding sites, usually located in the promoter region, and stimulates expression of inflammatory genes. Simultaneous administration of glucocorticoid activates the GR, which homodimerizes, translocates to the nucleus, and binds the NF-κB complex on DNA, without binding to the DNA (tethering). This interaction leads to repression of NF-κB activity and thus to reduced expression of inflammatory genes.

immunoprecipitation (ChIP) techniques, show that the GR does not disrupt NF-κB binding to its target genes or alter the assembly of the preinitiation complex formed following TNFα treatment (Fig. 2). Interestingly, GR interaction with NF-κB seems rather to interfere with the phosphorylation of Ser-2 on the carboxy-terminal domain (CTD) of RNA polymerase II, a required step for transcriptional initiation. It is not known whether the NF-κB complex harbors or brings in a kinase activity that is inhibited following GR interaction or whether the GR harbors or brings in a corepressor/phosphatase. It is also possible that the NF-κB interaction with its target sequence is slightly modulated following GR interaction. An additional level of regulation may involve GC-mediated modulation of cofactor histone acetylase activity or DNA methylation. The observation that GR tethering to transcription factors does not result in displacement from DNA is supported by earlier *in vivo* footprinting results from the collagenase I promoter. In this case, the GR tethered to the AP-1 complex did not result in AP-1 displacement from its binding site when GC repression of collagenase I expression took place. Although the GR represses both NF-κB and AP-1 activity, without displacing the factors from the target genes, recent results have indicated that the mechanisms are not completely identical.

The ability of transactivation-deficient GR mutants to repress inflammation also shows that GC induction of the NF-κB inhibitor protein, IκBα, as suggested previously, is not a major mechanism involved in the anti-inflammatory action of GCs. However, this mechanism may, to a lesser extent, contribute to the repressive mechanism in cells in which it is induced following GC administration. This is in line with the observation that IκBα induction by GCs is highly cell and tissue specific, in contrast to GC repression of NF-κB-dependent genes in most cell types and in cells not inducing IκBα in response to GCs. Finally, some GC analogues are able to induce IκBα without repressing NF-κB activity, whereas "classical" GCs affect both proteins in the same cell type. These results show that GC-mediated transrepression of NF-κB, and IκBα up-regulation, respectively, are two separate processes, the latter of which is not necessary for GC-mediated repression of NF-κB activity.

It has also been suggested that a molecular mechanism responsible for repression of NF-κB or AP-1 activity following GR activation by GC administration would involve competition for a limiting amount of a co-activator. This is supported by the mutual nature of the crosstalk between GR and NF-κB or AP-1. In this model, a limiting amount of a general co-activator—e.g., CREB-binding protein (CBP), p300, or steroid receptor co-activator-1 (SRC-1)—that binds to NF-κB or AP-1 and is required for efficient transactivation by these factors would instead bind to the activated GR, thereby reducing transcriptional activity of NF-κB or AP-1. Although some initial reports found experimental support for such a mechanism, more recent results have questioned this model. Overexpression of CBP, p300, or SRC-1 did not impair GC-mediated inhibition of the IL-6 promoter nor of a Gal/DBD/Jun fusion-dependent reporter gene. The model also does not explain the synergistic effect of GR on an AP-1 complex consisting of a c-Jun homodimer or the ability of retinoic acid receptor (RAR) to distinguish between AP-1 and NF-κB in the crosstalk. Binding of co-activators by RAR is similar to that by GR, and RAR represses AP-1 but not NF-κB. In addition, in contrast to the competition model for a limiting co-activator, most recent results have shown that GR repression of the AP-1 complex on the collagenase 3 gene is enhanced rather than repressed by an excess of co-activator, the TIF2/GRIP1. In summary, results show that although the co-activators may be limiting for transactivation, this seems not to be the case for transrepression. Furthermore, because the co-activators interact with many different transcription factors and activities, a competition model would constitute a rather nonspecific way to mediate repression. However, squelching of an unknown cofactor as an explanation for the crosstalk can still not be fully excluded.

Another possible mechanism that may be involved in the anti-inflammatory or immunosuppressive effects of GCs is a rapid GR-mediated inhibition of Jun phosphorylation and of c-Jun N-terminal kinase (JNK) activity, independent of ongoing transcription. The GR has also been reported to interfere with extracellular signal-related kinase (ERK) activity. However, there are conflicting results regarding the requirement for protein synthesis in the inhibition of mitogen-activated protein (MAP) kinase. This may simply be due to use of different investigative model systems. In cases in which ongoing protein synthesis is required for GC-mediated repression, induction of a phosphatase may be a plausible explanation. Another level of GC regulation of NF-κB activity may be exerted by the catalytic subunit of protein kinase A (PKAc). This subunit has been shown to interact with NF-κB and to phosphorylate Ser-276 of RelA. Interestingly, PKAc has also been shown to interact

with the GR in a ligand-independent way, and deletion of the conserved Ser-276 in RelA abolishes RelA repression of GR activity. Overexpression of PKAc stops GR/RelA crosstalk.

VIII. GLUCOCORTICOIDS AND T-HELPER CELL SUBSETS

The profile of an immune response is to a large extent determined by which subset of T-helper cells has been activated and, more specifically, by the balance between T_H1 and T_H2 cells. The T_H1 response is characterized by a cytokine profile that supports inflammation and preferentially activates other T cells and macrophages. A T_H2 profile is characterized by the secretion of cytokines that activate B cells and antibody-dependent immune responses. The most important cytokines secreted by T_H1 cells are IL-2, IFNγ, and IL-12, whereas T_H2 cells produce IL-3, IL-4, IL-5, IL-6, IL-10, and IL-13. In principal, these cytokines promote the development of subsets of the cells that produce them, but they can also inhibit both production of and functional effects of the opposite subset; this effect is called cross-regulation, which explains the inverse relationship between antibody production (T_H2 profile) and delayed-type hypersensitivity (T_H1 profile). T_H1 and T_H2 responses are both suppressed by regulatory T_H cells that secrete TGF-β.

Increased levels of GCs after therapeutic administration act in an immunomodulatory or immunosuppressive way, depending on the dose. When employing moderate GC levels, the balance of T_H1 and T_H2 cell subsets shifts so that T_H2 responses become predominant. GCs, norepinephrine, epinephrine, histamine, and adenosine inhibit the production of IL-12 and TNFα, which normally promote T_H1 cell development, whereas they do not affect IL-10 production and thus not T_H2 development. GCs have also been reported to target macrophages and monocytes as well as IL-1 and IL-1 receptor antagonists. The down-regulation of T_H1 cells leads to a subsequent lower production of IFNγ, IL-2, and IL-12. A down-regulation of the T_H1 response acts permissively for T_H2 responses, and some researchers have reported an up-regulation of the production of IL-4, a T_H2-type cytokine. It has also been reported that GCs down-regulate TGF-β secretion and this may serve to down-regulate both T_H1 and T_H2. Furthermore, it has been shown that memory T cells are less susceptible to inhibition by GCs, implying that GCs may be of special importance in primary responses.

The GC-induced shift to predominant T_H2 responses under stressful conditions and during GC treatment may lead to an increased susceptibility to various infections because infections are usually defeated via T_H1-dependent mechanisms; the GC-induced shift may also impact susceptibility to autoimmune, allergic, and malignant diseases.

IX. GLUCOCORTICOIDS AS THERAPEUTIC AGENTS

Due to the potent anti-inflammatory and immunosuppressive effects of GCs, they are widely used in the clinic to treat asthma, rheumatoid arthritis, systemic lupus erythematosus (SLE), dermatitis, polymyositis, glomerulonephritis, and rejection of organ transplants. The use of endogenous-type GCs as drugs is not ideal. These GCs show a high degree of binding to the serum transporter protein, cortisol-binding globulin (CBG). This renders a large fraction of the administered drug inactive. Cortisol also has a relatively rapid turnover. By chemical modifications of the original cortisol structure, it has been possible to synthesize GCs with increased stability and a low binding affinity for CBG. The substitutions have involved insertion of halogen in the C-9α position, as in fluorohydrocortisone, as well as the introduction of a double bond between C-1 and C-2, as in prednisolone and prednisone. The substituted or derived GCs show a whole spectrum of therapeutic potential, ranging from mild steroids, such as the original hydrocortisone, to very potent steroids, such as betametasone and dexametasone.

The routes of glucocorticoid administration determine the requirements for further modifications of steroidal drugs. Originally, most steroids were ingested or injected, and hydrophobic compounds were sufficient. Development of steroid succinates and phosphates enabled various kinds of parenteral and topical treatments. The need for GCs for localized treatment of the colon, in diseases such as inflammatory bowel disease, and of the lungs, as in asthma, led to further pharmaceutical steroid developments. In generating these topical steroids, the aim of the organic chemists has often been to maximize the local effect and to minimize the systemic effect of the new drug. Comparisons of the potencies of GCs that are topical anti-inflammatory (cause cutaneous "vasoconstriction") and systemic (cause depression of plasma cortisol and changes in differential white blood cell count) formulations have been performed for several of the new compounds. New types of GCs

(e.g., 16,17-acetals) have an improved topical/systemic activity ratio as compared to GCs with fluorine substitution in 9α or 6α, 9α positions.

X. ADVERSE EFFECTS OF GLUCOCORTICOID TREATMENT

When using glucocorticoids as anti-inflammatory drugs, it is important to remember that GCs do not simply regulate the inflammatory response or the immune system. In fact, they affect almost all tissues in the body, influencing energy metabolism, electrolyte and water balance, central nervous system functions, proliferation, and differentiation. Severe side effects thus result following long-term treatment with GC in chronic diseases. Adverse effects of GCs are reminiscent of the disease syndrome that can be found in patients with Cushing's disease and includes a perturbation of the HPA axis. After long-term treatment, even with moderate doses of GCs, the adrenals become atrophic and adrenal production of GCs is depressed. This necessitates specific care when tapering off GC therapy or when the treated individual is exposed to stress. Lack of adequate GC production affects the ability to cope with stress and may even be lethal in cases of severe stress. Another common adverse effect of GC therapy is osteoporosis, which can be both rapid and dramatic. Growth inhibition in children has also been claimed to occur, but recent studies show that this is a rather limited problem. Other side effects of GCs include an increased risk for opportunistic infections, muscle wasting, neuropsychiatric complications with behavioral and cognitive changes, impaired wound healing, skin atrophy, hypertension, bruises, moon face, striae (especially on the trunk), and perturbations in lipid and glucose metabolism. The latter may even lead to GC-induced diabetes. Due to these adverse effects it is recommended to regularly monitor weight, blood pressure, signs of infections, electrolyte concentration (especially Na^+ and K^+), glucose levels, serum lipid levels, and signs of osteoporosis, osteonecrosis, and cataract.

Preventive measures may be effective to address the side effects of GC therapy, especially for preventing osteoporosis. When more than 4 weeks of GC therapy is planned, dietary supplements of calcium and vitamin D are often recommended. Specific drugs, such as estradiol, bisphosphonates, raloxifen, or parathyroid hormone, may be prescribed with longer term treatment.

XI. DEVELOPMENT OF GR LIGANDS THAT DISSOCIATE ACTIVITIES

Although several severe side effects occur after long-term treatment with ingested or parenterally administered GCs, the anti-inflammatory effects are in some cases still unsurpassed, and GCs may thus be the only efficient therapy available. Because of this, there is a large degree of interest by pharmaceutical companies in developing GCs that maintain their anti-inflammatory action, but without side effects. Support for such a possibility is based on the fact that GR mutants have proved to be able to dissociate the transrepressive activity of GR, which is responsible for the anti-inflammatory activity, from the transactivating activity of GR. In fact, experimental cell studies have demonstrated the existence of synthetic GC derivatives that can dissociate GR-mediated transrepression from GR-mediated transactivation of genes. Furthermore, claims have been made that a more potent transrepressive effect is exerted by GCs such as RU24858, RU486, and ZK98299, as well as by certain topical steroids such as fluticsone propionate and budesonide, compared to the transactivating effect of these compounds. However, whether all of these compounds are efficient as anti-inflammatory agents *in vivo*, with fewer side effects, remains to be seen. Furthermore, it is not known which mechanism, transrepression or transactivation of GR target genes, is mainly responsible for the side effects of GCs.

Glossary

crosstalk The ability of various signal transduction pathways to influence the signaling processes of one another. Crosstalk often occurs via phosphorylation/dephosphorylation events or through a physical interaction, e.g., tethering.

glucocorticoid A steroid hormone produced in the adrenal cortex. Glucocorticoids bind the glucocorticoid receptor and affect cellular growth and differentiation as well as metabolic and inflammatory processes. They are essential for life and are key regulators in the stress response. The term also encompasses synthetic hormones with a similar structure and function.

glucocorticoid receptor The intracellularly located receptor for glucocorticoid hormones belongs to the family

of nuclear receptors. Acts as a ligand-activated transcription factor and binds both agonists and antagonists.

glucocorticoid response element A conserved palindromic set of nucleotides; each half-site of six conserved nucleotides is separated by three nondefined nucleotides to which the glucocorticoid receptor can bind as a homodimer via its DNA-binding domain.

nuclear factor-κB A complex of the family of Rel-related transcription factors and an important signaling molecule in inflammatory responses. NF-κB was first described to be required for B-cell-specific gene activation, but, as with all Rel-related transcription factors, it is a critical factor for the inducible expression of many different genes. NF-κB most often consists of a heterodimer between p65 (RelA) and p50.

tethering Physical interaction between two different transcription factors, forming a heteromeric complex independent of DNA binding. Tethering may also occur on the DNA at the point where one of the transcription factors is attached. This interaction often leads to a mutual repression of the transcriptional ability of either of the factors.

transactivation The ability of a factor, e.g., the glucocorticoid receptor, to induce gene expression.

transrepression The ability of a factor, e.g., the glucocorticoid receptor, to suppress gene expression.

Anti-Müllerian Hormone

RODOLFO REY* AND JEAN-YVES PICARD†

**Hospital de Niños R. Gutiérrez, Buenos Aires • †Institut National de la Santé de la Recherche Médicale Unité 493, Clamart, France*

Anti-Müllerian hormone (AMH) is involved in the differentiation of the internal genitalia in the fetus; it is produced by fetal testicular Sertoli cells and ovarian granulosa cells. AMH produced by the fetal testis induces the regression of the Müllerian ducts. Granulosa cells produce only small amounts of AMH late in fetal life, when the Müllerian ducts are no longer sensitive to the hormone. In the ovary, AMH down-regulates luteinizing hormone receptor and aromatase activities, leading to a decrease in estrogen production. AMH exerts its action by binding to a specific membrane receptor, AMHR-II, inducing the recruitment of a non-specific type I receptor and leading to the phosphorylation of Smad1, which binds to

of nuclear receptors. Acts as a ligand-activated transcription factor and binds both agonists and antagonists.

glucocorticoid response element A conserved palindromic set of nucleotides; each half-site of six conserved nucleotides is separated by three nondefined nucleotides to which the glucocorticoid receptor can bind as a homodimer via its DNA-binding domain.

Anti-Müllerian Hormone

RODOLFO REY* AND JEAN-YVES PICARD†

**Hospital de Niños R. Gutiérrez, Buenos Aires • †Institut National de la Santé de la Recherche Médicale Unité 493, Clamart, France*

Anti-Müllerian hormone (AMH) is involved in the differentiation of the internal genitalia in the fetus; it is produced by fetal testicular Sertoli cells and ovarian granulosa cells. AMH produced by the fetal testis induces the regression of the Müllerian ducts. Granulosa cells produce only small amounts of AMH late in fetal life, when the Müllerian ducts are no longer sensitive to the hormone. In the ovary, AMH down-regulates luteinizing hormone receptor and aromatase activities, leading to a decrease in estrogen production. AMH exerts its action by binding to a specific membrane receptor, AMHR-II, inducing the recruitment of a non-specific type I receptor and leading to the phosphorylation of Smad1, which binds to

Smad4, is translocated to the nucleus, and regulates target gene expression. The biological actions of AMH in fetal sex differentiation, the regulation of AMH expression, and the clinical applications of AMH are discussed.

I. INTRODUCTION

Anti-Müllerian hormone (AMH), also called Müllerian inhibiting substance (MIS) or Müllerian inhibiting factor (MIF), owes its name to its first described and best-known action during fetal male sex differentiation. The first author to suggest that a second testicular factor—apart from testosterone—should be involved in the differentiation of internal genitalia was Alfred Jost, in the late 1940s. By means of a refined fetal surgery technique, Jost castrated rabbit fetuses before the time of sex differentiation and observed that—whatever the genetic sex was—the absence of gonads resulted in a newborn with female internal and external genitalia, whereas the presence of testes resulted in newborns with male genitalia; he therefore deduced that the male gonad was the "sex differentiator." When a crystal of testosterone was implanted in a normal or castrated female or castrated male fetus, Wolffian ducts gave rise to the epididymis, vas deferens, and seminal vesicle and the external genitalia became virilized, yet the Müllerian ducts formed the Fallopian tubes, uterus, and upper portion of the vagina. Hence, Jost concluded that the fetal testis produces androgens that masculinize the genital tract and another factor, which he called "hormone inhibitrice" or "Müllerian inhibitor," that is responsible for the regression of Müllerian derivatives. More than 50 years later, the picture remains essentially the same, with a more detailed knowledge of the hormones and receptors involved in male sex differentiation (Fig. 1). In this article, we discuss the "AMH pathway" of fetal sex differentiation, as well as other more recently discovered actions of AMH, the regulatory mechanisms controlling AMH expression, and the applications of AMH in clinical practice.

II. AMH: THE HORMONE

AMH is a 140 kDa glycoprotein homodimer, composed of 550–580 amino acids depending on the species, that belongs to the transforming growth factor-β (TGF-β) superfamily of growth and differentiation factors. The maturation process of AMH involves the removal of a 24-amino-acid leader prior to secretion by Sertoli cells; although this full-length

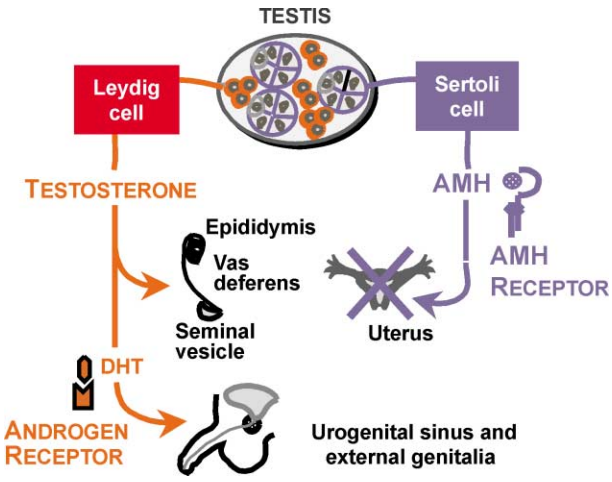

FIGURE 1 Hormonal control of male sexual differentiation. Reprinted from R. Rey and J. Y. Picard, Embryology and endocrinology of genital development. *Baillière's Clinical Endocrinology and Metabolism* **12**, 17–33. Copyright 1998, by permission of the publisher Baillière Tindall.

secreted dimer has some active potential, to be fully active, it must be cleaved—most probably in target organs—at a monobasic site located 109 amino acids upstream from the C-terminus. The resulting 25 kDa C-terminal dimeric fragment is the bioactive moiety, whereas the 110 kDa N-terminal dimeric fragment is inactive. However, the presence of the N-terminal fragment in the medium significantly enhances the bioactivity of the C-terminal domain.

The gene for AMH has been cloned in human and several other mammalian and nonmammalian species. It is composed of five exons and four introns spanning approximately 2.8 kb and maps to chromosome 19, band 19p13.3 in the human and to different autosomes in other species. The human AMH promoter lacks a classical TATA-box and exhibits several transcription initiation sites, in contrast to what is observed in the bovine, rat, and mouse genes, which contain a canonical TATA element and a single transcription initiation site. Although more than 3 kb of the 5′-flanking region of the AMH gene have been sequenced, only the proximal promoter region has been functionally studied. Response elements for GATA-4, steroidogenic factor-1 (SF-1), and the SRY-related factor SOX9 are present in a sequentially conserved manner in several mammalian species within the 280 bp proximal promoter of AMH. The importance of the existence of a gene coding for a ubiquitously expressed spliceosome protein, SAP62, 762 bp upstream of the transcriptional start site of the human AMH gene and 328 bp upstream of the mouse gene, remains to be elucidated.

III. AMH RECEPTORS

Like most glycoprotein hormones, AMH was expected to have a membrane-bound receptor in its target cells. Members of the TGF-β superfamily usually signal through a receptor complex formed by two serine/threonine kinase proteins, named type I and type II receptors according to their molecular weight. The type II receptor, of higher molecular weight, is responsible for ligand binding. Not all of the corresponding type I receptors have been identified yet. Furthermore, most type I receptors can interact with more than one type II receptor and can therefore be involved in signaling different members of the superfamily.

The specific type II receptor for AMH (AMHR-II) is a single-transmembrane domain serine/threonine kinase encoded by a gene of 8.2 kb, arranged in 11 exons and 10 introns, mapping to chromosome 12, band q13, in the human. Of the 573 amino acids that form the receptor, 17 correspond to the signal peptide (5′ sequences of exon 1), 127 to the extracellular domain (3′ sequences of exon 1 and exons 2 and 3), 26 to the transmembrane domain (exon 4), and 403 to the intracellular domain (exons 5 to 11), which bears the serine/threonine kinase activity. AMHR-II has also been cloned in other mammalian species. In the rabbit and the dog, two splice variants exist: the full-length protein and a shorter variant, owing to an alternative splicing resulting in skipping of exon 2. The presence of exon 2 is essential: In humans, a splice mutation leading to the lack of exon 2 results in a nonfunctional receptor.

At least two type I receptors, also involved in intracellular signaling of bone morphogenetic proteins (BMPs) and activin, have been reported to have the capacity to transduce AMH action on AMHR-II. ALK2 (activin receptor-like kinase 2), also known as ActR-IA, and ALK3, also known as BMPR-IA, and ALK6, also known as BMPR-IB, are nonspecific type I serine/threonine kinases with a single transmembrane domain, present in AMH target cells, which are recruited by AMHR-II upon binding of AMH.

IV. BIOLOGICAL ACTIONS OF AMH

AMH, produced by the fetal testis, provokes the regression of Müllerian ducts in the male fetus. The period of Müllerian duct sensitivity to AMH is limited: In the human, AMH is secreted from the end of the seventh week and acts on its target organ during the following week. By the end of the eighth week, the fate of the Müllerian ducts has already been determined: If no AMH has been produced by then, the uterus and Fallopian tubes will develop, whereas withdrawal of AMH after the eighth week will not stop Müllerian duct regression.

AMH is produced by testicular Sertoli cells and ovarian granulosa cells. Sertoli cells secrete AMH from the time of fetal testicular differentiation, but granulosa cells begin to express AMH only in late fetal life in mammals, when Müllerian ducts are no longer sensitive to the hormone. In birds, AMH is produced by the fetal ovaries at early stages although in lower amounts than in males, which may explain the sexual dimorphism in the evolution of Müllerian derivatives. In all species, the testes secrete significantly higher levels of AMH than the ovaries until puberty. Then, AMH production decreases in Sertoli cells and sex differences are no longer observed in AMH levels in the adult until menopause, when the ovaries cease to produce AMH.

AMH binds to its specific receptor, AMHR-II, present on mesenchymal cells surrounding the Müllerian duct epithelium (Fig. 2A), with a relatively high dissociation constant (approximately 2.5 nM); this explains why AMH must be at a high level to be active, behaving as a local factor. In Jost's experiences and in human pathology, the existence of only one functional testis during fetal life results in the regression of the homolateral Müllerian duct and the development of a Fallopian tube and a hemi-uterus on the side where there is insufficient or no testicular tissue. At variance with this is the observation in bovine and ovine fetuses of "freemartinism," consisting of AMH-like effects in a female twin to a male fetus. A clear explanation of this particular phenomenon is still lacking.

The effects observed in female freemartin fetuses and in transgenic female mice chronically overexpressing AMH confirm that the AMH receptor signaling pathway is present in the target organs of both sexes and that male-specific regression of Müllerian ducts in fetal life is due to the sex differences in AMH gonadal secretion. AMHR-II expression begins in mesenchymal cells of the cranial end of Müllerian ducts in early fetal life and subsequently spreads caudally. In clear correlation with AMHR-II temporal expression is the pattern of regression of Müllerian ducts. When AMH binds to its type II receptor, mesenchymal cells produce an as yet unknown signal that induces apoptosis in the neighboring epithelial cells of Müllerian ducts, followed by basal membrane disruption and epithelial–mesenchymal transformation, which

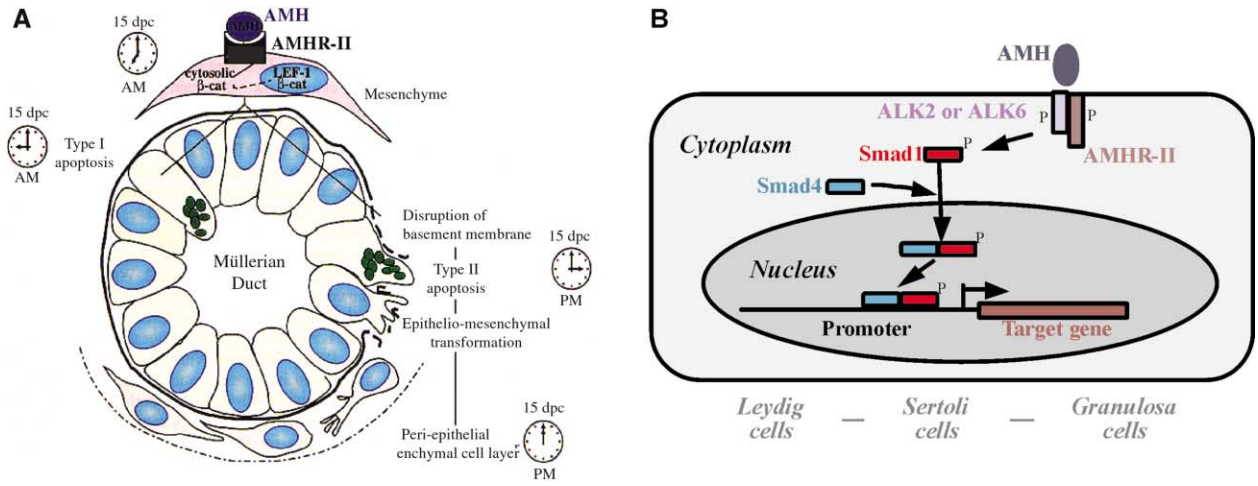

FIGURE 2 (A) Mechanism of action of AMH in Müllerian ducts. Modified from S. Allard, *et al.* Molecular mechanisms of hormone-mediated Müllerian duct regression: Involvement of β-catenin. *Development* **127**, 3349–3360. Copyright 2000, by permission of The Company of Biologists Ltd. (B) Mechanisms of action of AMH in Sertoli, Leydig, and granulosa cells. Modified from J. Massagué. TGFβ signal transduction. *Annual Review of Biochemistry* **67**, 753–791. Copyright © 1998 by permission of the publisher Annual Reviews, www.AnnualReviews.org.

finally results in Müllerian duct regression (Fig. 2A). The expression of AMHR-II is regulated by SF-1 and Wnt-7a.

Naturally occurring mutations in AMH or AMHR-II and transgenic mice in which these genes have been knocked out clearly indicate that the essential role of AMH is the regression of the uterus and Fallopian tube anlagen in the male fetus (see Section VI). However, AMHR-II is also expressed in granulosa cells of the ovary and Sertoli and Leydig cells of the testis. In the female gonad, AMH down-regulates LH receptor and aromatase activities, inducing a decrease of estrogen production. An excess of AMH (e.g., in freemartins or in transgenic mice overexpressing AMH) provokes a dramatic reduction of ovarian size owing to a decrease in germ cell number and a depletion of ovarian follicles; cord-like structures resembling Sertoli-cell-only seminiferous tubules may subsequently appear. In the testis, AMH exerts a negative effect on Leydig cell differentiation from mesenchymal precursors and decreases the expression of steroidogenic enzymes, mainly cytochrome P450 17α-hydroxylase/C17–20 lyase (P450c17), resulting in lowered testosterone production. Transgenic male mice chronically overexpressing AMH may have Leydig cell hypoplasia and decreased androgen levels, which can result in hypovirilization. Conversely, transgenic mice with null mutations of AMH or AMHR-II develop a hyperplasia of Leydig cells. As in granulosa cells, aromatase activity is also decreased in Leydig and Sertoli cells exposed to AMH. The mechanism of action of AMH has recently been described (Fig. 2B): In granulosa and Sertoli cells, AMH binding to AMHR-II induces the recruitment of a nonspecific type I receptor, ALK2 or ALK6, resulting in the phosphorylation of Smad1, which—upon binding to Smad4—is translocated to the nucleus and regulates target gene expression.

V. REGULATION OF AMH PRODUCTION

The need for sex-specific expression of AMH during a short critical period of sensitivity to the hormone in order for normal sex differentiation to occur suggests that AMH expression is tightly regulated. In mammals, but not in birds, SOX9 seems to be one of the most important activators of AMH expression in the fetal testis. SF1 and GATA-4 synergistically increase SOX9-induced AMH expression. All three of these factors have binding elements on the AMH promoter. GATA-4, WT-1 (Wilms' tumor suppressor-1), and DAX-1 (dosage-sensitive sex-reversal, adrenal hypoplasia, critical region on the X chromosome, gene 1), which do not bind to the AMH promoter, can also indirectly influence AMH expression. GATA-4 and WT-1 always function as enhancers, whereas DAX-1 acts as a repressor of AMH transcription, via interactions with SOX9 or SF-1.

While these transcription factors regulate baseline AMH expression, androgens, follicle-stimulating hormone (FSH), and primary spermatocytes influence

production in Sertoli cells. When intratesticular testosterone concentration increases in the male gonad, AMH is down-regulated, provided that the androgen receptor is expressed at sufficient levels in Sertoli cell nuclei. This is why testicular AMH production decreases during normal puberty in males. In the fetus and newborn, as in patients with androgen insensitivity, the lack of activity of the androgen receptor prevents testosterone from inhibiting AMH expression in Sertoli cells. FSH is capable of enhancing AMH production, but its effect is observed only when the inhibitory effect of testosterone, which is largely predominant in normal puberty, is absent. Independently of testosterone, the entry of germ cells into meiosis is also followed by AMH down-regulation. Although the molecular events responsible for hormonal and cellular regulation of testicular AMH output need further investigation, serum AMH appears to be a reliable marker of FSH and androgen effects on Sertoli cells as a well as of meiotic entry of male germ cells.

VI. PERSISTENT MÜLLERIAN DUCT SYNDROME

The persistent Müllerian duct syndrome (PMDS) is a rare form of internal male pseudo-hermaphroditism in which the Fallopian tubes and uterus are present, indicating a failure in the AMH-dependent sex differentiation pathway. In these patients, external genitalia have normal male characteristics, proof that the androgen-dependent pathway is intact. PMDS should be distinguished from other forms of male pseudo-hermaphroditism with alterations in androgen synthesis or action resulting in ambiguous or female external genitalia. In PMDS, the Müllerian derivatives are generally discovered unexpectedly during surgical correction of cryptorchidism and/or inguinal hernia. Two different anatomical forms have been described: In the most common presentation, one testis descends into the scrotum and drags the homolateral Fallopian tube, the uterus, and consequently the contralateral Fallopian tube and testis. Less frequently, both testes remain in ovarian position embedded in the broad ligament.

PMDS is an autosomal recessive condition resulting from a lack of production of AMH or a resistance to AMH in target organs. The former, known as AMH-negative PMDS, is due to mutations in both alleles of the AMH gene: These patients represent approximately 50% of all PMDS cases and have undetectable serum AMH levels. Resistance to AMH, or AMH-positive-PMDS, is due to mutations in AMHR-II, present in nearly 40% of the cases. Serum AMH is normal or high. Except for a 27 bp deletion in exon 10 of AMHR-II, responsible for almost 20% of PMDS cases, there are no hotspots in the AMH or AMHR-II genes, and mutations have been found along the entire length of both genes (Fig. 3). In approximately 10% of the PMDS cases described, no mutation has been found, suggesting that mutations in a type I receptor, in components of the transduction cascade, or in the proteolytic enzyme involved in AMH processing may also be responsible for this syndrome. Mice models for PMDS have been obtained by transgenic engineering: Gene knockout of either AMH or AMHR-II results in the same phenotype. PMDS has also been described as a naturally occurring condition in two strains of dogs.

VII. CLINICAL APPLICATIONS OF AMH

As a marker of the existence of functional Sertoli cells, determination of serum AMH is extremely useful in boys with nonpalpable gonads (Fig. 4): Before puberty, undetectable serum AMH is highly indicative of anorchia, except for rare cases of AMH-negative PMDS. Serum AMH may also be used to estimate the functional mass of Sertoli cells in prepubertal boys: Low serum AMH is found in patients with small, dysgenetic testes, and elevated AMH has been detected in rare cases of prepubertal Sertoli cell hyperplasia. Because AMH production is normally low in the first 10–15 days following birth, determination of serum levels may not be informative in this period of life. The advantage of AMH over androgens during the rest of childhood is that no human chorionic gonadotropin stimulation test is necessary.

Intersex disorders in patients with an XY lineage may result from gonadal dysgenesis affecting both the tubular and the interstitial compartments of the testes or from a dissociated tubular–interstitial dysfunction in which only one compartment is affected. The existence of ambiguous or female external genitalia indicates that the androgen pathway of sex differentiation is impaired. Low testosterone production may result from either gonadal dysgenesis or mutations affecting Leydig cell differentiation or steroidogenesis. AMH determination is useful in these cases, because serum levels are low in patients with gonadal dysgenesis but normal or high if the condition is due to an isolated defect of the androgen pathway (Fig. 4 and Table 1). In intersex patients with normal or high levels of both testosterone and AMH, androgen

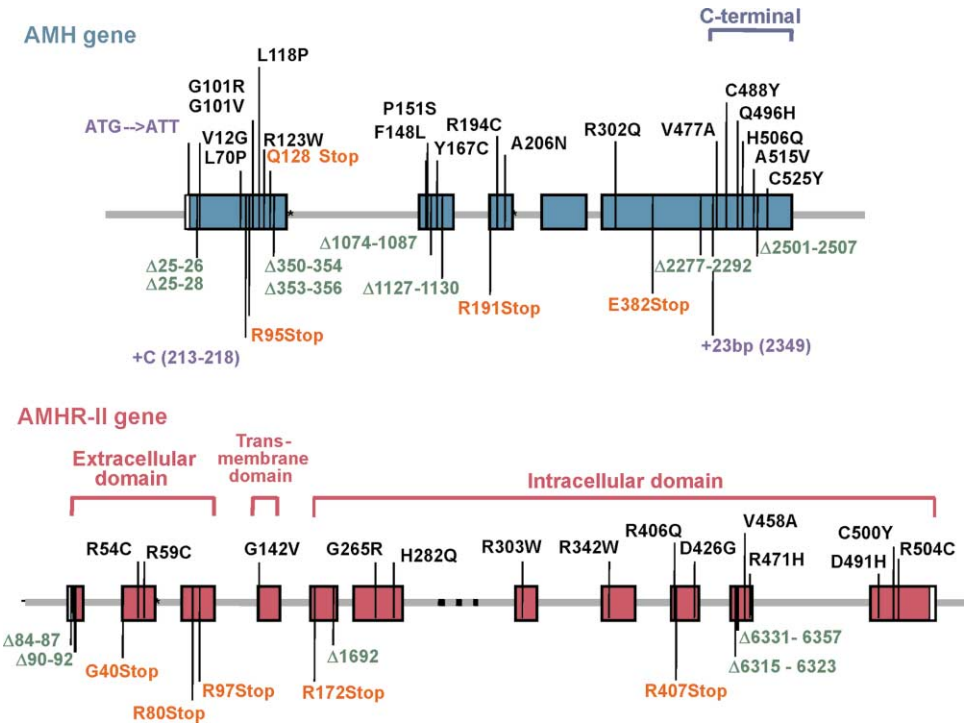

FIGURE 3 Mutations in human genes for AMH and AMHR-II responsible for the persistent Müllerian duct syndrome. From C. Belville, N. Josso, and J. Y. Picard. Persistence of Müllerian derivatives in males. *American Journal of Medical Genetics* **89**, 218–223, 1999. Copyright © 1999. insensitivity is the most probable etiology (Fig. 4 and Table 1). The ovary produces very low quantities of AMH. The detection of serum AMH levels over 100 pmol/liter is clearly indicative of the existence of testicular tissue in XX patients. Congenital adrenal hyperplasia can be ruled out, and a diagnosis of true hermaphroditism or XX male should be considered.

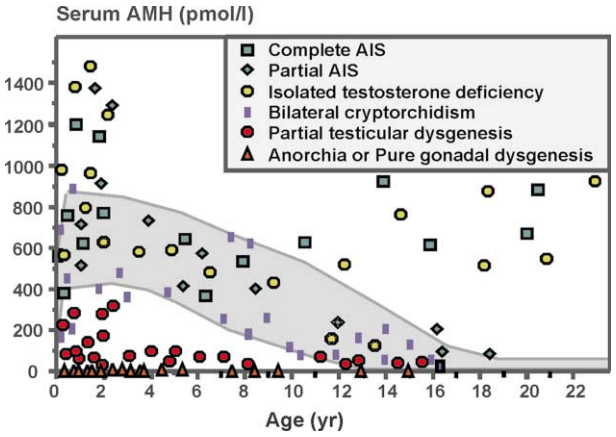

FIGURE 4 Serum AMH in patients with intersex disorders and/or abnormal testicular function. AIS, androgen insensitivity syndrome. The shaded area represents normal values of serum AMH

Because it is a reliable marker of androgen concentration within the testis, serum AMH is useful in the follow-up of patients treated for precocious puberty or hypogonadotropic hypogonadism. High serum AMH is indicative of low androgen production by Leydig cells; a decrease in serum AMH suggests that the intratesticular concentrations of androgens and Sertoli cell expression of the androgen receptor reach pubertal levels.

Sertoli and granulosa cells may originate sex-cord stromal tumors that conserve AMH expression. Immunohistochemical study of biopsies using anti-AMH antibodies proves useful in the identification of these tumors. Furthermore, the serum level of AMH correlates with tumor progression and is a reliable marker of the success of surgical treatment or chemotherapy (Fig. 5). Since granulosa cell tumors are frequently observed postmenopause or require bilateral ovariectomy—both situations resulting in no detectable AMH in serum—the determination of AMH using an ultrasensitive enzyme-linked immunosorbent assay represents a powerful tool for the early detection of recurrences.

TABLE 1 Diagnosis of Intersex Disorders Based on Serum AMH and Testosterone Levels in Patients with a 46,XY Karyotype

	External genitalia			
	Female		Ambiguous	
	High testosterone	Low or undetectable testosterone	High testosterone	Low testosterone
Normal or high AMH	Complete AIS	Leydig cell aplasia; severe steroidogenic enzyme deficiency	Partial AIS	Leydig cell hypoplasia; mild steroidogenic enzyme deficiency
Low or undetectable AMH		Pure gonadal dysgenesis		Partial gonadal dysgenesis

Note. AMH and testosterone levels are considered high, normal or low, compared to those observed in normal age-matched boys. AIS, androgen insensitivity syndrome.

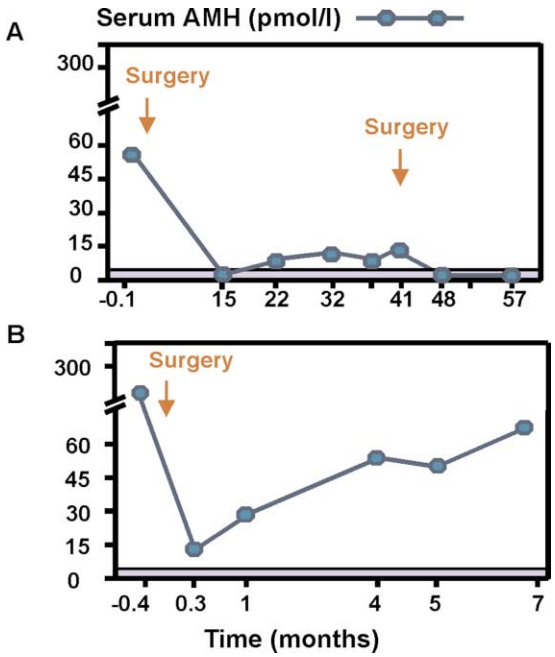

FIGURE 5 Serum AMH in female patients with granulosa cell tumors. In Patient A, surgical removal of the tumor was initially successful, and AMH levels became undetectable; however, the tumor recurred and could be detected by serum AMH determination before clinical manifestations became apparent. In Patient B, a complete surgical removal of the tumor could not be achieved. The shaded area represents expected values in postmenopausal or bilaterally ovariectomized women. Time 0 indicates the moment of surgery. Reprinted from Long, W. Q., Ranchin, V., Pautier, P., Belville, C., Denizot, P., Cailla, H., Lhommé, C., Picard, J. Y., Bidart, J. M., and Rey, R. VIII. SUMMARY

AMH is produced by testicular Sertoli cells and ovarian granulosa cells. As soon as the testes differentiate in the fetus, Sertoli cells secrete large amounts of AMH, inducing the regression of Müllerian ducts, the anlagen of the uterus and Fallopian tubes, after binding to a specific membrane receptor, AMHR-II. Mutations in the genes coding for AMH or AMHR-II result in males with a uterus. In mammals, granulosa cells secrete only low quantities of AMH from late fetal life, when Müllerian ducts are no longer sensitive to the hormone. AMH also acts as a moderator of the activities of granulosa and Leydig cells, which also express AMHR-II. Owing to its specificity of expression, AMH is a useful serum marker of Sertoli and granulosa cell function under normal and pathological conditions.

Glossary

dissociated tubular–interstitial testicular dysfunction Disorder of gonadal development affecting only one gonadal compartment.

fetal sex differentiation In mammals, although defined from the time of fertilization by the existence of a heterogametic (XY) or homogametic (XX) chromosome pair, the sex of the embryo remains indistinguishable during the first stages of development. When the testis differentiates, it begins to secrete AMH, responsible for the regression of Müllerian ducts, and androgens, which virilize the external and internal genitalia. In the absence of the secretion or action of these hormones, the genitalia acquire a female phenotype.

gonadal dysgenesis Disorder of gonadal development affecting all gonadal compartments.

granulosa cells Somatic cells of the ovary that form the ovarian follicles, in which germ cells are embedded.

hermaphroditism The existence of testicular and ovarian tissue in one individual.

Leydig cells Somatic cells of the testes secreting testosterone after stimulation by luteinizing hormone or chorionic gonadotropin.

Müllerian ducts Paired ducts, formed of epithelial cells surrounded by mesenchymal cells, present in male and female embryos before sexual differentiation. Also known as paramesonephric ducts. In the male fetus, they degenerate under AMH action; in the female fetus, they give rise to the Fallopian tubes, the uterus, and the upper third of the vagina.

pseudo-hermaphroditism Disorder characterized by the existence of female or ambiguous genitalia in individuals with male gonads, or vice versa.

Sertoli cells Somatic cells of the testes that form the seminiferous tubules where the germ cells giving rise to the gametes are embedded. The tissue surrounding the seminiferous tubules is called interstitial tissue and contains Leydig cells.

transforming growth factor-β (TGF-β) The first isolated member of a family of factors controlling the growth, differentiation, and death of most tissues in invertebrates and vertebrates.

Apoptosis

DEREK LE ROITH* AND MICHAEL KARAS†

**National Institutes of Health, Maryland • †Cambrex Bioscience, Maryland*

Apoptosis is an essential process in the development and homeostasis of multicellular organisms. In embryogenesis, apoptosis ensures the correct development of organisms, counteracting proliferation by removing unnecessary cells. In adults, apoptosis is also crucial in counteracting unrestricted proliferation as well as in the cyclic growth and involution of endocrine-dependent tissues. Apoptotic cell death differs from necrotic cell death in that specific, characteristic morphological changes occur, including the following: There are changes within the nucleus, in particular, chromatin condensed as DNA is degraded into small nucleosomal fragments. Changes occur in specific organelles, in particular, in the mitochondria, where apoptosis uncouples electron transport from ATP synthesis, leading to an increase in reactive oxygen species and a decrease in transmembrane potential. Changes at the plasma membrane lead to cell shrinkage and the formation of membrane protuberances that enclose cellular debris, become apoptotic bodies, and are subsequently engulfed by phagocytic cells.

I. CELLULAR EVENTS IN APOPTOSIS

Apoptotic cell death is crucial for both normal development and homeostasis of multicellular organisms. During embryonic development, apoptosis counteracts proliferation by removing unnecessary cells to ensure proper organogenesis. In the adult, apoptosis is important mainly in counteracting unrestricted (i.e., neoplastic) proliferation and in the cyclic involution of many endocrine-dependent tissues. Apoptosis is distinct from necrotic death in that (1) characteristic and specific morphological changes occur and (2) energy synthesis and protein synthesis are required in the dying apoptotic cell, to regulate specific genes and biochemical pathways.

The morphology of apoptosis involves changes within the nucleus, within specific organelles (most notably, the mitochondria), and within the plasma membrane. In what was once considered to be the hallmark of apoptosis, the chromatin condenses within the nucleus, as DNA is degraded first into large 30 to 50 kb fragments and then into smaller nucleosomal fragments of 180–200 bp. These nuclear alterations, however, are not a *sine qua non* of apoptosis, as their inhibition fails to block cell death.

Apoptosis leads to uncoupling of electron transport from ATP synthesis in the mitochondria, thereby leading to an increase in reactive oxygen species (ROS) and a decrease in transmembrane potential. These changes precede the nuclear changes described above and can occur in the absence of nuclear changes in apoptotic cells. Different members of the bcl-2 family of proteins oppose or promote cell survival under apoptotic conditions, as described in more detail below. The identification of bcl-2 family members in mitochondrial membranes suggests that mitochondrial changes are not merely the end result of apoptosis but are involved in the apoptotic cascade itself.

Changes in the plasma membrane and cytoskeleton lead to cell shrinkage and to the formation of membrane protuberances or "blebs." As apoptosis proceeds, these blebs of membrane enclosing cellular debris detach and become "apoptotic bodies," which are then engulfed by neighboring phagocytic cells. These changes are relatively easy to observe with light microscopy. However, the rapid time course of the apoptotic process, which is complete within a few hours, makes it difficult to identify a significant number of apoptotic cells at any given time. This problem is further compounded *in vivo*, where apoptotic rates are probably even slower than under experimental conditions *in vitro* and where the close proximity of phagocytic cells within normal tissue facilitates the rapid clearance of apoptotic cells. The loss of membrane asymmetry causes translocation of the phospholipid phosphatidyl serine from the internal leaflet to the outer surface, where it serves as a recognition marker for apoptotic cells by phagocytes.

II. DETECTION METHODS

DNA fragmentation, long considered a characteristic feature of apoptosis, is often determined by the identification of a 200 bp DNA ladder with gel electrophoresis and, more recently, by enzyme-linked immunosorbent assay kits based on antibodies to histone–DNA complexes. However, these methods are not quantitative (i.e., one cannot determine the percentage of cells actually undergoing apoptosis in the population being assayed) and give only a rough qualitative estimate, at best. The alternative quantitative method is to stain DNA in ethanol-fixed cells and then analyze the DNA content by flow cytometry, using fluorescent dyes, such as propidium iodide, that intercalate into DNA. In this approach, apoptotic cells are characterized by a reduced (sub-G1) DNA content as compared to cells in the G1 phase of the cell cycle.

This analysis must be done carefully, so that true apoptotic nuclei (with a DNA content within 1 log of cells in G1) will be distinguished from smaller apoptotic bodies. The method is presumed to give the ratio of normal cells to apoptotic cells. However, it has recently been shown that necrosis, particularly when induced by ROS, also results in DNA fragmentation. Thus, an accurate analysis of apoptosis requires excluding necrotic death by other means (e.g., morphological analysis). Another widely used technique detects breaks in the DNA. The deoxynucleotidyl transferase (TdT)-mediated dUTP-biotin nick-end labeling, or TUNEL, assay utilizes TdT to label the 3′-ends of breakpoints in double-stranded DNA and can be used both for flow cytometry and for *in situ* labeling. TUNEL is the preferred method for detecting apoptosis *in vivo*, primarily due to the lack of technically feasible alternatives.

As mitochondrial dysfunction is an early common event in the apoptotic cascade, a number of methods analyze mitochondrial function to detect apoptosis. A popular and simple assay is the MTT assay, which is based on the ability of mitochondria to convert soluble yellow tetrazolium salt into blue formazan. This enables the quantification of viable cells. The MTT assay does not distinguish between apoptosis and necrosis per se, but it can be effectively used to quantify cell death when apoptosis has been confirmed by other methods. However, it is not suitable for use *in situ* or *in vivo*. Another method is based upon the uptake in live cells of fluorescent mitochondrion-selective dyes, such as rhodamine 123 or $DiOC_6$, which is dependent on mitochondrial membrane potential. This method can be used both in flow cytometry and in fluorescence microscopy, where necrotic cells can be excluded with the use of plasma membrane nonpermeable DNA dyes. Various mitochondrion-selective dyes have recently been modified so that they can be fixed, thereby enabling *in situ* staining.

An alternative method detects the loss of asymmetry of phospholipids in the plasma membrane of apoptotic cells. Annexin V is a calcium-dependent phospholipid-binding protein that, when conjugated to a fluorescent dye, can be used to label apoptotic cells where it recognizes phosphatidyl serine moieties that have been translocated to the outer surface of the cell membrane. When propidium iodide is included in this assay, it can concurrently detect necrotic cells that have lost membrane integrity. Annexin V–FITC is an ideal assay to measure apoptosis in living cultured cells, as it simultaneously allows rapid and quantitative detection of normal, apoptotic, and necrotic cell populations. However, annexin V–FITC is nearly impossible to apply in an *in vivo* setting.

III. BIOCHEMICAL ASPECTS

Elucidation of the biochemical processes involved in apoptosis has been facilitated by the genetic analysis of development in *Caenorhabditis elegans*. In this nematode, which is made up of 1090 adult cells, 131 specific cells undergo apoptosis during embryonic development. Genes that either promote apoptosis (such as ced-3) or prevent apoptosis (such as ced-9) in *C. elegans* have mammalian homologues that encode related gene families. The cloning of ced-3 led to the discovery of a novel class of the caspase proteases, which cleave proteins after aspartic acid residues and seem to operate in an enzymatic cascade. Some caspases are apically activated by so-called "death molecules" [e.g., caspase-8 activation by Fas and other tumor necrosis factor-related molecules and others act as downstream effectors of various apoptotic events, such as cleavage of poly(ADP ribose) polymerase, lamin, actin, and other molecules]. Ced-9 is related to the bcl-2 family of proteins. Current models of the regulation of apoptosis suggest that the balance between members of the Bcl-2 family plays a critical role in determining whether a cell survives or activates the cell death machinery. Several members of the Bcl-2 family (Bcl-2, Bcl-xL, MCL-1, A1, and BAG-1) appear to promote survival, whereas others (Bcl-xS, BAD, BAX, and BAK) promote apoptosis. The balance between hetero- and homodimerization of the various Bcl-2 family proteins is thought to be critical in determining cell fate.

Caspase proteins not only are evolutionarily conserved, but also seem to universally operate in a similar way in most cell types that have been studied. In contrast, the role played by other proteins in the apoptotic cascade is more restricted. Bcl-2, for example, is not required for embryonic development. Bcl-2 can block apoptosis induced by a wide variety of stimuli, including chemotherapeutic agents, γ and UV radiation, and overexpression of *myc* or *p53*, but this protein plays little or no role in other apoptotic processes, such as the negative selection of thymocytes. Even in *C. elegans*, genes that are involved in the apoptotic pathway of specific subtypes of the 131 cells that are eliminated during embryogenesis, such as *egl-1*, which is involved in the apoptosis of hermaphrodite-specific neurons, have been cloned. By controlling the genes involved in the common steps of the apoptotic pathway in specific cell types, such a

gene can control apoptosis within a specific cell type or differentiation step. The mammalian homologues of egl-1 contain Bcl-2 homology region 3 domains. These domains are involved in protein–protein interactions, but the specific role they play in the cellular control of apoptosis remains to be determined.

Within the endocrine system, cyclic growth and involution as well as homeostasis of hormone-dependent target organs require tight cellular control of susceptibility to apoptosis. For example, in the murine reproductive tract, gonadectomy induces apoptotic cell death, which is dependent upon Fas neo-expression and is preceded by down-regulation of BCL-2; ovarian follicle atresia results from granulosa cell apoptosis, which is preventable by estrogens and FSH; apoptotic regression of decidual zones in the implanted uterine is hormone dependent and correlates with an increase in bax and a decrease in bcl-2. The emerging paradigm is that hormones can act on target cells not only by stimulating proliferation, but also by preventing apoptosis. It is interesting to note that hormones with a high level of anti-apoptotic activity, such as insulin-like growth factor-I, epidermal growth factor, platelet-derived growth factor, and nerve growth factor, activate specific cognate receptors, yet these receptors share strikingly similar functional activity and downstream signal transduction pathways. The receptors for each of these hormones possess intrinsic tyrosine kinase activity. Upon ligand binding, these receptors become self-activated by autophosphorylation. Shortly thereafter, three major signal transduction pathways are activated, including phosphatidylinositol 3′-kinase (PI-3 kinase), mitogen-activated protein kinase, and the stress-activated protein kinases p38 and JNK. The PI-3 kinase pathway is considered to play a major role in the anti-apoptotic activity of tyrosine kinase receptors. Activation of these receptors induces phosphorylation of the 85 kDa regulatory subunit of PI-3 kinase, thereby recruiting it to the membrane. Phosphorylation of phosphoinositides within the membrane then recruits pleckstrin homology domain-containing proteins, such as AKT, a serine–threonine protein kinase, and phosphtatidylinositol(3,4,5)triphosphate-dependent kinases. The assembly of these proteins within the same microdomain facilitates the phosphorylation of AKT at the two sites, which results in activation of the AKT molecule. The activated AKT then phosphorylates the mitochondrial pro-apoptotic protein BAD on Ser136. Phosphorylated BAD then forms a complex with 14-3-3 protein, which sequesters BAD and prevents its pro-apoptotic actions.

Although our knowledge of a complex network of pathways regulating apoptosis is much more advanced than it was a decade ago, it is still far from complete. Mapping of the human genome and other genomes, as well as rapid development of modern technologies, such as microarray analysis, will dramatically improve our understanding of the mechanisms underlying apoptotic death.

Glossary

apoptosis Decision by a cell to die.

Bcl family of proteins Some members of this protein family prevent apoptosis.

caspase proteins When activated, these proteins mediate cell death.

programmed cell death The process by which cells actually die.

Apoptosis Gene Knockouts

JAMES K. PRU AND JONATHAN L. TILLY
Massachusetts General Hospital and Harvard Medical School

The cell death pathway of apoptosis is fundamental to sex determination and the embryonic development of reproductive organs, as well as to the normal reproductive and endocrine functions of the gonads, reproductive tract, and accessory reproductive tissues in postnatal life. Recent investigations have documented that germ cells and somatic cells of female reproductive tissues possess an evolutionarily conserved cohort of "cell death genes" that ultimately determine cell fate in response to physiological or pathological stimuli. However, much of the current knowledge regarding the role of apoptosis in female reproductive tissue development and function stems from studies that characterize the expression of genes known to coordinate and execute apoptosis. Although it is important to continue to understand when, and in what circumstances, these genes are expressed, it is equally important to distinguish between those genes that are correlatively or redundantly expressed from those that are functionally required for apoptosis to occur. This article reviews what is currently known of the principal intracellular pathways responsible for initiating and executing apoptotic cell death in vertebrate species, then discusses several published reports in which gene inactivation was used to identify functional, or in some cases dispensable, components of the cell death machinery in somatic cells and germ cells of the female reproductive system.

I. OVERVIEW OF APOPTOSIS

In most cell types, the process of apoptosis can be broken down into six phases that are arguably characterized by a decreasing level of complexity as the cell becomes progressively more committed to apoptosis (Fig. 1). In the signal transduction phase (phase I), a physiological or pathological stimulus (or stimuli) for death is relayed across the plasma membrane of the cell. The signal(s) conveyed by these stimuli is amplified and integrated through alterations in the activity of a wide spectrum of second messengers and signal transduction networks, including the phosphatidylinositol 3′-kinase (PI-3K)/Akt, p53, sphingomyelin, and c-jun N-terminal kinase (JNK) pathways. This amplification step can be initiated, for example, by the binding of a "death ligand," such Fas ligand (Fas_L) or tumor necrosis factor α (TNFα), to its cognate "death receptor." Alternatively, an inadequate level of growth ("survival") factor support from the extracellular environment can serve as a potent stimulus for engaging the machinery of apoptosis in many cell types. Pro-apoptotic signal transduction cascades can also be set in motion by oxidative stress or other damage to the cell, usually at the level of the plasma membrane, cytoskeleton or DNA. In most situations, the signaling cascades of phase I then initiate phase II (Fig. 1), in which activation of one or more pro-apoptotic members of the Bcl-2 family (Table 1) containing only the Bcl-2 homology domain 3 ("BH3-only") motif occurs.

At least 14 BH3-only proteins (Bad, Bid, Bim, Hrk/DP5, Nix, Noxa, MAP-1, Blk, Bik/Nbk, Bmf, Nip3/Bnip3, PUMA/Bbc3, Bcl-G_{short}, 2′-5′oligoadenylate synthase) have been identified in mammalian species to date (Table 1). Interestingly, the involvement of any given BH3-only protein in apoptosis appears to be dictated primarily by the stimulus for cell death. For example, Bad is a target for phosphorylation by the growth factor-coupled PI-3K/Akt cell survival pathway, and in its phosphorylated state Bad lacks cell death-promoting activity. If cells are exposed to inadequate levels of growth factor support, the absence of PI-3K/Akt signal transduction (phase I) thus permits Bad to exist in a nonphosphorylated or "active" state (phase II; BH3-only activation). As a consequence, hypophosphorylated Bad translocates to mitochondria where it interferes with the function of anti-apoptotic Bcl-2 family members (see below and Table 1). Activation of Bid occurs by a completely different mechanism involving a two-step process. The first is proteolytic cleavage of the inactive cytosolic protein by caspase-8, a signal transduction component coupled to ligand-activated death receptors. Truncated Bid is then myristolated as a means to promote translocation of this now "activated" protein to mitochondria where it functions with other pro-apoptotic Bcl-2 family members (see below and Table 1) to induce cell death.

In addition to these examples of BH3-only protein activation by the absence or presence of endocrine

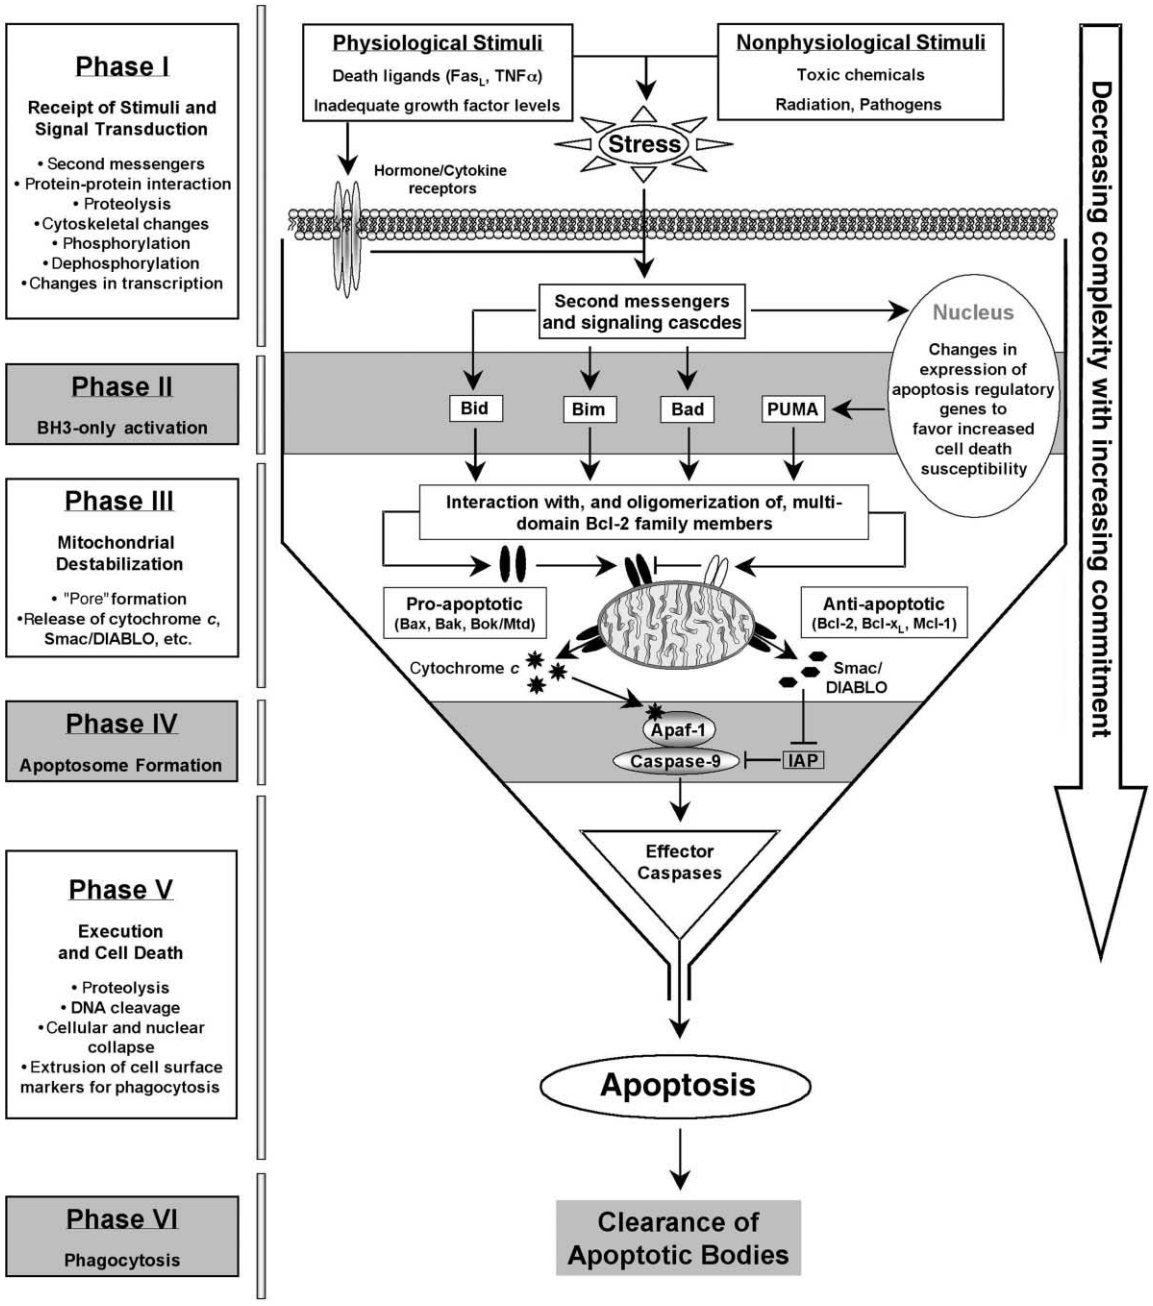

FIGURE 1 Schematic diagram depicting the principal components of the six major phases of apoptosis in mammals. See text and bibliography for additional details.

signals, BH3-only proteins are recruited into action by a number of pathological insults, albeit by different mechanisms once again. For instance, DNA damage resulting from exposure of cells to ionizing radiation or various chemicals activates p53 and, if the genomic damage is irreparable, apoptosis. Recently, *noxa* and *puma/bbc3*, two transcriptionally regulated BH3-only members of the Bcl-2 family, were cloned as being p53-responsive genes involved in the apoptotic cell death response to DNA damage. As a final example of the diversity of mechanisms through which phase II of apoptosis can be set in motion, the Bim protein is normally sequestered to microtubules by its interaction with the LC8 component of the dynein motor complex. However, disorganization or disruption of the cytoskeleton by

growth factor deprivation or chemical agents (e.g., Taxol) leads to a rapid release of Bim from the dynein motor complex into the cytoplasm. This activated form of Bim then translocates to mitochondria where the protein antagonizes the function of anti-apoptotic Bcl-2 family members (see below and Table 1).

Once activated, BH3-only proteins trigger phase III, or the mitochondrial destabilization phase, of apoptosis (Fig. 1) by facilitating the ability of pro-apoptotic Bcl-2 family members containing two or more Bcl-2-homology domains—the so-called "multidomain" pro-apoptotic members (e.g., Bax, Bak, and Bok/Mtd; Table 1)—to form "pores" in the outer mitochondrial membrane. In some cases (e.g., Bid), the destabilization of mitochondria can occur as a direct result of BH3-only proteins causing the oligomerization of pro-apoptotic multidomain members of the Bcl-2 family into pore-forming complexes. Alternatively, some BH3-only family members, such as Bad, Bim, and PUMA/Bbc3, function by direct interaction with anti-apoptotic Bcl-2 family members, such as Bcl-2, Bcl-x_{long}, Mcl-1, and Bcl-w, anchored in the mitochondria. The latter scenario leads to a functional "sequestration" of anti-apoptotic Bcl-2 family members, allowing for pro-apoptotic multidomain family members to assume their pore-forming conformation. In either situation, a spectrum of cell death-promoting factors, including cytochrome *c*, Smac/DIABLO, apoptosis-inducing factor, and endonuclease-G, are released from mitochondria during phase III, presumably through pores created by pro-apoptotic Bcl-2 family members.

Importantly, the release of cytochrome *c* into the cytoplasm heralds the initiation of phase IV of apoptosis, during which time the protein functions as an essential co-factor in the formation of the "apoptosome" (Fig. 1). The apoptosome is a high-molecular-weight complex composed of many molecules of an adapter protein termed apoptotic protease-activating factor-1 (Apaf-1) and the pro-form of caspase-9. It is currently believed that the assembly of the apoptosome provides for an induced proximity model of autocatalytic or transcatalytic processing of procaspase-9 to the active enzyme. Interestingly, in nonapoptotic cells or in those cells not yet committed to die, a family of gene products referred to as inhibitor of apoptosis proteins (IAP) function to prevent premature or unwanted activation/activity of caspase-9. However, this survival checkpoint can be overridden by Smac/DIABLO released from the mitochondria during phase III, which dissociates IAP from caspase-9. Once freed from IAP-mediated constraint, caspase-9 rapidly activates phase V, or the execution phase (Fig. 1), of apoptotic cell death.

During this near-final phase of apoptosis, the pro-forms of a number of cell death effector caspases, such as caspase-2, -3, -6, and -7, are processed to form active enzymes by the apoptosome containing caspase-9 or by one another. These effector caspases then attack a wide spectrum of homeostatic and structural proteins within the cell, producing the morphological and biochemical characteristics of apoptotic cells and essentially sealing the cell's fate. Once cellular dissolution and fragmentation have occurred, phase VI of apoptosis is engaged. During this final step in the process, the membrane-bound vesicles containing the pieces of the dead cell are rapidly removed by phagocytosis to prevent an inflammatory response characteristic of pathological ("necrotic") cell death.

II. APOPTOSIS GENE KNOCKOUTS AND THE MAMMARY GLAND

It has long been recognized that apoptosis occurs in the mammary gland of numerous mammalian species during weaning-induced involution of the tissue, and that hormones and cytokines play important roles as either survival factors (e.g., progesterone, glucocorticoids, and insulin-like growth factor-1/IGF-1) or death factors (e.g., transforming growth factor-β and Fas_L) in coordinating mammary epithelial cell fate. In addition, important roles for BH3-only proteins (Bad), multidomain pro-apoptotic members of the Bcl-2 family (Bax, Bak, and Bcl-x_{short}), multidomain anti-apoptotic members of the Bcl-2 family (Bcl-2, Bcl-x_{long}, and Bcl-w), mitochondrial cytochrome *c* release, and caspases in controlling or executing mammary gland involution have been proposed. Unfortunately, many of these observations regarding the intracellular mediators of apoptosis in mammary epithelial cells remain correlative at present.

There are, however, four published examples of gene knockouts affecting mammary gland involution that have provided insight into functionally important components of at least phase I and phase III of apoptosis in this tissue. First, through the use of *lpr/lpr* mice, which are defective in the expression of the death receptor Fas, and *gld/gld* mice, which lack expression of Fas_L, in 2000, Song *et al.* demonstrated that both Fas and its ligand play important roles in apoptosis associated with the remodeling of post-lactational mammary tissue. At day 1 postweaning,

TABLE 1 Representative Members of the Mammalian BCL-2 Family

Family member[a]	BH domains	Species studied[b]	Cellular localization in inactive state	Mechanism of BH3-only activation	Stimulus for BH3-only activation	Bcl-2-like interacting partner[c]
Pro-apoptotic						
Multidomain						
Bak	1, 2, 3	h, m, o, p, r, s	Mitochondria, ER[d]	NA	NA	Bid, Bax, Bcl-2, Bcl-X_{long}
Bax	1, 2, 3	h, m, o, p, r, s	Mitochondria, ER, nucleus	NA	NA	Bid, Bax, Bcl-2, Bcl-X_{long}
Bcl-G_{long}	2, 3	h	Cytoplasm	NA	NA	NA
Bcl-rambo	1, 2, 3, 4	h	Mitochondria	NA	NA	NA
Bcl-x_{short}	2, 3, 4	h, m, o, r	Mitochondria	NA	NA	Nrh
Bok/Mtd	1, 2, 3	h, m, r	Mitochondria	NA	NA	Mcl-1, Bcl-X_{long}, Bcl-2
Diva/Boo[e]	1, 2, 3, 4	m	Perinuclear membranes	NA	NA	Apaf-1[f]
BH3-only						
2′-5′ Oligoadenylate synthase	3	h, m	Perinuclear	Transcription	Interferon-β	Bcl-2, Bcl-x_{long}
Bad	3	b, h, m, p, r	Cytosol	Dephosphorylation	Growth factor deprivation	Bcl-x_{long}, Bcl-w
Bcl-G_{short}	3	h	Mitochondria, heavy membranes	Unknown	Unknown	Bcl-2, Bcl-x_{long}
Bid	3	h, m, p, r	Cytosol	Proteolysis and myristolation	Death receptor activation, calpains	Bax, Bak
Bik/NBK	3	h	Mitochondria	Phosphorylation	Unknown	Bcl-2, Bcl-w, Bcl-x_{long}
Bim	3	d, h, m, p, r	Microtubules	Cytoskeletal alterations	Cytokine deprivation, γ-irradiation, Taxol	Bcl-2, Bcl-x_{long}
Blk[g]	3	m, r	Mitochondria	Unknown	Unknown	Bcl-2, Bcl-x_{long}
Bmf-1	3	h, m	Microfilaments	Cytoskeletal alterations	Anoikis, DNA damage, cytokine deprivation	Mcl-1, Bcl-w, Bcl-2, Bcl-x_{long}

Hrk/DP5	3	h, m, r	Mitochondria	Transcription	Calcium flux, DNA damage, cytokine deprivation	Bcl-2, Bcl-x_{long}
Map-1	3	h, m	Mitochondria	Unknown	Unknown	Bcl-2, Bax, Bcl-x_{long}
Nip3/Bnip3	3	h, m	Mitochondria	Transcription	Hypoxia	Bcl-2, Bcl-x_{long}, Nip3/Bnip3
Nix	3	h, m	Mitochondria	Transcription	Hypoxia	Bcl-2, Bcl-x_{long}, Nix
Noxa	3	h, m	Mitochondria	Transcription	DNA damage	Bcl-x_{long}
PUMA/Bbc3	3	h, m	Mitochondria	Transcription	DNA damage, glucocorticoids, growth factor deprivation	Bcl-2, Bcl-x_{long}
Anti-apoptotic						
Multidomain						
Bcl-2	1, 2, 3, 4	h, m, o, p, r, s	Mitochondria, ER, nucleus	NA	NA	Hrk, Bcl-x_{long}, Bcl-2, Map-1
Bcl-B	1, 2, 3, 4	h	Mitochondria, cytosol	NA	NA	NA
Bcl-x_{long}	1, 2, 3, 4	h, m, o, p, r	Mitochondria	NA	NA	Bcl-G_{short}, Bcl-2, Noxa, Bax
Bcl-w	1, 2, 3, 4	h, m	Mitochondria	NA	NA	Bik, Bcl-x_{long}, Bcl-2
Bfl-1/A1	1, 2, 3, 4	h, m, p	Unknown	NA	NA	Unknown
Mcl-1	1, 2, 3, 4	h, m, p, r	Mitochondria	NA	NA	Bmf-1, Bcl-w, Bcl-2, Bcl-x_{long}
Nrh[b]	1, 2, 3, 4	h	Mitochondria, nuclear envelope	NA	NA	Bcl-x_{short}
Boo/Diva[e]	1, 2, 3, 4	m	Perinuclear membranes	NA	NA	Apaf-1[f]

[a] Except for Bcl-x and BCI-G, this list does not include numerous splice variants of various members.
[b] b, bovine; d, dog; h, human; m, mouse; o, ovine; p, nonhuman primate; r, rat; s, swine.
[c] Representative interactions, most of which were deduced from cell-free or yeast two-hybrid assays that may not be reflective of what occurs *in vivo*.
[d] ER, endoplasmic reticulum.
[e] Depending on the study and cell type, this member can be pro- or anti-apoptotic.
[f] Apaf-1 is a component of the apoptosome (phase IV).
[g] Blk (Bik-like killer) may be the mouse orthologue of human Bik/NBK.
[h] Nrh is a human orthologue of mouse Boo/Diva and avian NR-13.

mammary glands of wild-type mice showed high levels of expression of Fas, Fas_L, and the effector caspase, caspase-3, coincident with the initiation of apoptosis in the tubular and alveolar epithelia. In comparison, there were no apoptotic cells detected in mammary glands of either *lpr/lpr* or *gld/gld* mice examined in parallel at day 1 postweaning.

The next two examples of gene knockouts affecting cell death in the mammary gland underscore the importance of transcriptional events in the process. The first of these studies reported that a loss of p53 significantly delays involution of the mammary gland through the first 5 days postweaning, with the mammary epithelial area in mutant mice being as much as 60% larger than that of wild-type controls. Interestingly, however, by day 7 postweaning, there were no apparent differences in the mammary tissues of wild-type versus *p53*-null female mice, suggesting that the delay in epithelial cell apoptosis caused by p53 deficiency was eventually compensated for by as yet unknown mechanisms. The second of these studies utilized Cre recombinase–*lox*P technology to generate a conditional knockout of the gene encoding the transcription factor, signal transducer and activator of transcription 3 (Stat3), only in the mammary gland. In these animals, weaning-induced involution of mammary tissue was significantly delayed due to a marked decrease in epithelial cell apoptosis. In screening for potential targets of Stat3, in 1999 Chapman *et al.* noted no alteration in p53, Bcl-x_{long}, or Bax levels in the mammary glands of mutant mice. However, the induction of IGF-binding protein-5 (IGFBP5) expression that normally accompanies mammary gland involution was completely absent in *Stat3*-null mammary tissue analyzed in parallel. Given the likely role of IGF-1 as a survival factor for mammary epithelial cells, these findings suggest that the reduced incidence of mammary epithelial cell apoptosis in these mutant mice is due, at least in part, to increased or sustained availability of IGF-1 resulting from the lack of IGFBP5 expression.

In the fourth and final example of apoptosis gene knockouts affecting mammary gland involution, the Cre recombinase–*lox*P system was used to conditionally inactivate the gene encoding Bcl-x, a principal regulator of phase III of apoptosis, only in mammary epithelium. No differences were observed in the proliferation or differentiation of ductal and alveloar epithelial cells in mammary glands of wild-type versus *bcl-x*-conditional knockout mice during pregnancy or lactation. However, weaning-induced epithelial cell apoptosis and tissue remodeling were greatly accelerated in *bcl-x*-null mammary glands, highlighting the importance of this specific Bcl-2 family member in mammary epithelial cell survival. Interestingly, simultaneous deletion of the gene encoding Bax, a pro-apoptotic multidomain member of the Bcl-2 family, did not alter the accelerated rate of apoptosis caused by Bcl-x deficiency in postweaning mammary epithelial cells. Therefore, as predicted from *in vivo* studies of Bcl-2 family member interactions in mouse mammary tissue, it is likely that Bcl-x interacts with other pro-apoptotic multidomain members of the family, such as Bak, to regulate mammary epithelial cell fate.

III. APOPTOSIS GENE KNOCKOUTS AND THE OVARY

The ovary is a hotbed of cell death activity, essentially from the point of its genesis during fetal life until the time of its senescence in adulthood. In the germ line, apoptosis claims up to 99.9% (depending upon the species) of the oocytes produced by gametogenesis, either directly or indirectly, following the apoptotic death of granulosa cells during atresia of maturing follicles. In addition, apoptosis of the ovarian surface epithelium has been implicated as a key step in the release of the egg at ovulation. Moreover, structural involution of the corpus luteum, at the end of each estrous cycle or pregnancy, clearly involves apoptosis. In light of this information, it is perhaps not surprising that the power of using apoptosis gene knockouts to study reproductive function is best exemplified in the ovary, where loss of phase I, III, and V components of the apoptosis pathway has been studied in detail. In addition, three cell populations—oocytes, granulosa cells, and luteal cells—have been examined with respect to the impact of a given apoptosis gene knockout on ovarian function. Thus, these studies have provided invaluable insight into not only the involvement of a specific apoptosis regulatory gene in the ovary but also the existence of cell lineage-specific pathways for executing ovarian cell death. As with the discussion of mammary epithelial cell death above, evaluation of the literature on apoptosis gene knockouts and the ovary will begin with phase I components and move progressively toward phase V.

Similar to the epithelium of the mammary gland, the Fas/Fas_L system appears to play a key role in signaling apoptosis in multiple cell types in the ovary. Mutant mice with aberrant expression of Fas (*lpr/lpr*) or lacking expression of Fas_L (*gld/gld*)

exhibit a spectrum of ovarian abnormalities, including irregularities in follicle development. In particular, female *lpr/lpr* mice have increased numbers of secondary follicles and decreased numbers of antral follicles, as well as exhibit attenuated apoptosis in both oocytes and granulosa cells following Fas activation. Furthermore, reduced numbers of corpora lutea (*lpr/lpr*) and defective luteolysis (*gld/gld*) have been described in these mutants. Gene knockout mice lacking TNF receptor 1 (TNFR1), another death receptor, also show a spectrum of ovarian phenotypes. For example, prior to puberty *TNFR1*-null females have a heightened response to exogenous gonadotropin stimulation, as reflected by a significantly larger than normal ovulatory response to hormonal priming. With increasing age, however, reproductive performance declines precipitously in TNFR1-deficient females, with only 40% of mutant females exhibiting estrous cyclicity by 6 months of age. Unfortunately, given the pleiotropic nature of the actions of TNFα in various cell types, it remains to be established whether the alterations in female reproductive function resulting from TNFR1 deficiency are related, either directly or indirectly, to defective apoptosis.

Another component of phase I that has been examined in detail, at least in oocytes, by gene inactivation is the role of the ceramide-generating enzyme, acid sphingomyelinase (ASMase). Ceramide is a pro-apoptotic second messenger that, in many cell types, serves a crucial role in transducing stress stimuli. The mechanisms by which ceramide is believed to act are diverse and include super-aggregation ("capping") of death receptors, activation of JNK, and facilitation of Bax-induced mitochondrial destabilization. Recent studies have shown that female *ASMase* gene knockout mice possess roughly twice as many oocytes at birth as wild-type sisters, suggesting that ASMase-generated ceramide regulates the death of oocytes during fetal ovarian development. This postulate was confirmed by studies with cultured fetal ovaries that showed that the high incidence of oocyte apoptosis in wild-type female gonads starved of hormonal support *ex vivo* was greatly attenuated in ASMase-deficient fetal ovaries cultured in parallel. Moreover, *ASMase*-null oocytes treated with the chemotherapeutic drug doxorubicin are resistant to apoptosis, providing evidence that the defect in apoptosis caused by ASMase deficiency is cell autonomous in nature. Unfortunately, there are no published reports showing whether granulosa or luteal cells lacking ASMase show similar defects in the signaling of apoptosis.

Despite the generation of several BH3-only family member knockouts, including mice lacking Bid and Bim, no studies have yet been published on ovarian phenotypes caused by deficiency of these or other phase II components. However, the ovarian "consequences" in mutant mice that do not express various multidomain Bcl-2 family members (phase III) have been described. The first of these studies reported that inactivation of the anti-apoptotic *bcl-2* gene caused a significant reduction in the number of oocyte-containing primordial follicles in the ovaries of young adult female mice. These data, which suggest that Bcl-2 serves an important survival function in the female germ line, have been supported by experiments to accomplish the opposite—that is, the generation of mice with increased expression of Bcl-2 in oocytes. Using two different promoters to drive *bcl-2* gene expression in oocytes, Morita *et al.* and others described a survival advantage for transgenic oocytes.

The second multidomain knockout studied in the context of ovarian development and function is the Bax-deficient mouse. In the first report on the generation of these mice, the investigators described "a marked accumulation of unusual atretic follicles" in the ovaries of *bax*-null females that "contained numerous atrophic granulosa cells that presumably failed to undergo apoptosis." Our laboratory has since confirmed that Bax-deficient granulosa cells are indeed defective in their capacity to undergo apoptosis (unpublished data). More importantly perhaps is the pronounced resistance of Bax-deficient oocytes to apoptosis induced by diverse stimuli. For example, postnatal loss of primordial and primary follicles, an event driven by death of the oocyte, is significantly reduced in *bax*-mutant female mice, leading to a dramatic prolongation of ovarian function into very advanced chronological age. In addition, a number of pathological stimuli known for their ovotoxic effects, including chemotherapeutic drugs and environmental toxicants, fail to trigger oocyte depletion and ovarian failure in the absence of functional Bax protein. Finally, an interesting story is emerging on the role of Bax in fetal ovarian germ cell death, with involvement of the protein in oocyte demise apparently dependent upon the stimulus for cell death.

This latter point can be prefaced by an overview of the third and final multi-domain mutant to be discussed, a *bcl-x* hypomorph. Conventional gene knockout of *bcl-x* leads to embryonic lethality at approximately day 12. This hurdle in studying the functional importance of Bcl-x to ovarian development was overcome somewhat serendipitously

following the insertion of a neomycin cassette into the *bcl-x* promoter at a site important for germ cell-specific expression of the gene. Consequently, in mutant mice with two hypomorphic alleles, *bcl-x* expression was reduced in the germ line at embryonic day 12.5. Subsequent germ cell development was considerably impaired, leading to the birth of females with significantly reduced numbers of primordial and primary follicles in their ovarian reserves. Interestingly, simultaneous inactivation of the *bax* gene in *bcl-x* hypomorphic females rescued germ cell development and restored a normal level of follicle endowment, providing clear evidence that a cell death "rheostat" based on the opposing actions of anti- and pro-apoptotic Bcl-2 family members exists *in vivo*. However, despite these and other data implicating Bax as a key determinant of female germ cell death in developing fetal ovaries, Bax deficiency does not rescue fetal oocytes from death due to meiotic defects. As such, more than one cell death pathway must exist for the deletion of female germ cells.

At present, there are no published data indicating how a loss of apoptosome function, resulting from either Apaf-1 or caspase-9 deficiency, impacts on apoptosis in the ovary. Studies of mice lacking various phase V components have, however, provided evidence that a divergence in the apoptosis-signaling pathway occurs in ovarian germ cells and somatic cells at this step. In oocytes, knockout of the *caspase-2* gene provides oocytes with resistance to death induced by both physiological (e.g., cytokine starvation) and pathological (e.g., chemotherapy) stimuli. On the other hand, granulosa cell death and maturing follicle atresia occur normally in the absence of caspase-2. By comparison, mutant mice lacking caspase-3 show a dramatic defect in the ability of granulosa cells to execute apoptosis, both *in vivo* and *in vitro*, without a corresponding defect in oocyte death driven by either developmental cues or pathological insults. As such, these data suggest the existence of cell lineage-selective, if not cell lineage-specific, pathways of apoptosis execution in the ovary. Of additional note, a very recent study has reported that caspase-3 is required for cell death during luteal regression, underscoring the probable conservation of caspase-3 function in the granulosa cell lineage even after the process of luteinization.

As a final point of discussion and, to some degree, integration, a novel apoptosis-signaling pathway that utilizes gene transcription to kill oocytes has been recently identified. It was determined that treatment of oocytes with 9,10-dimethylbenz[*a*]anthracene (DMBA), a toxic chemical found in tobacco smoke and in the environment as a by-product of fossil fuel combustion, induces *bax* gene transcription as well as an accumulation of *bax* mRNA and Bax protein. Importantly, the induction of *bax* expression, and the resultant initiation of apoptosis, in oocytes involves DMBA-driven activation of the aromatic hydrocarbon receptor (AHR), a transcription factor of the *Per–Arnt–Sim* gene family. Furthermore, oocytes of mutant mice lacking either the AHR or Bax are completely resistant to DMBA-induced apoptosis. Given this information, it is not surprising that *Ahr*-null female mice are born with approximately twofold more primordial follicles than normal, suggesting that the AHR serves as a key phase I regulator of oocyte death in both physiological and pathological situations.

If one considers, however, the principles discussed herein regarding the coordinated and stepwise progression of apoptosis through phases I–V, it is unlikely that the up-regulation of a single gene, such as *bax*, by the DMBA-activated AHR triggers oocyte death. In fact, in such a paradigm of transcription-dependent cell death, one would envisage wholesale, modular changes in the expression of genes that function in the various phases of apoptosis. For example, because of the supple nature of the genome (i.e., genomic plasticity), could exposure of oocytes to DMBA increase the expression of genes encoding ASMase (phase I), Apaf-1 or caspase-9 (phase IV), and death effector caspases (phase V), in addition to multiple Bcl-2 family members (phases II and III)? An understanding of such complex events may one day help facilitate the development of therapeutic strategies to preserve female germ cells, regulate the endocrine function of the ovaries, and, perhaps, improve the quality of life for women.

Glossary

apoptosis A form of physiological ("programmed") cell death characterized at the light and electron microscopic levels by separation of the cell from its neighboring cells and/or its extracellular matrix, a loss of cell volume, chromatin condensation and margination along the nuclear envelope (pyknosis), and the final budding and fragmentation of the cell into plasma membrane-bound vesicles that are cleared by phagocytosis.

Bcl-2 family A group of structurally and/or functionally related proteins that can either promote or prevent cell death and are considered to be the primary regulators of apoptosis via their actions at the level of intracellular organelles, particularly mitochondria.

caspases A cohort of cysteine aspartic acid-specific proteases that function either as initiators (e.g., caspase-8 and -9) or as executioners (e.g., caspase-2, -3, -6, and -7) of the apoptotic cell death program in vertebrates.

gene knockout A mutant mouse line generated by targeted disruption (inactivation) of a specific gene, generally through homologous recombination, to examine the functional significance of that gene product in cell, tissue, or organ function.

Apoptosis, Glucocorticoid-Induced

RHEEM D. MEDH*, E. BRAD THOMPSON†, AND E. AUBREY THOMPSON†

**California State University, Northridge • †University of Texas Medical Branch, Galveston*

Glucocorticoids (GCs) play a vital role in maintaining normal metabolism, regulating various physiological processes, and overcoming several forms of stress. Because of their diverse actions, naturally occurring as well as synthetic glucocorticoids are commonly used as therapeutic agents for various disorders. In a number of physiological and therapeutic instances, induction of or protection from apoptosis is a critical aspect of GC action. Apoptosis is a form of suicidal cell death that has now been recognized as being an integral part of physiological cell turnover and helps maintain the dynamic state of cellular homeostasis. It is an energy-requiring process

typically involving altered expression or function of key cell proliferation/death genes. Excessive or defective apoptosis has been implicated in a number of diseases, provoking the development of therapeutic strategies targeting any physiological imbalance in the process. In this article, we briefly outline the mechanism of action of GCs, identify specific physiological targets of GC-evoked apoptosis, and cite examples of therapeutic applications in which GC regulation of apoptosis is relevant to its therapeutic efficacy. Finally, we present a concise review of the mechanisms of GC-evoked apoptosis, based on the extensive literature from studies on thymocytes and leukemic lymphoblasts.

I. MECHANISM OF GLUCOCORTICOID ACTION

Glucocorticoids (GCs) modulate their actions via binding to a specific intracellular GC receptor (GR), which upon ligand binding is released from the complex of cytoplasmic proteins to which it is bound in the inactive state. The GR has been shown to be essential for GC-evoked apoptosis. The classical model of GR action postulates that the activated GR is translocated to the nucleus, where it regulates transcription of a finite set of genes via GC-response elements (GREs) on target genes. Recent studies have demonstrated that this model is rather simplistic, and GR-dependent transcriptional regulation is modulated by precise interactions of the GR with "co-regulatory" proteins and involves the formation of a "transcriptosome" complex, which includes basal transcription factors (such as TBP and TFIID) and either co-activators (such as CBP and other histone acetylases) or co-repressors (such as NcoR and other histone deacetylases). Most natural GR target genes contain complex GREs, termed GC-response units, that bind multiple transcription factors either cooperatively or competitively. GR also modulates physiological processes by cross talk with other signal transduction pathways and secondary transcriptional and posttranscriptional effects.

II. GC-EVOKED APOPTOSIS IN REPRODUCTIVE TISSUES

GCs impact on normal cell turnover in several other tissues, as evidenced in experimental rodent models, in cell cultures, and in humans. In the prostate, glucocorticoids, in conjunction with androgens, stimulate glandular epithelial cell proliferation and prevent apoptosis. The relevance of GCs in the process is apparent in castration (androgen withdrawal)-induced prostate involution, which is inhibited by high doses of GCs. By a process that involves the GR, GCs prevent a castration-induced increase in the apoptotic genes TRPM-2, c-*fos*, and hsp 70. Testicular germ cells are prone to stress-induced apoptosis, mediated by increased secretion of GCs and resulting in suppression of testosterone levels. GCs modulate the cyclic pattern of epithelial cell proliferation and involution in the mammary gland in synergy with estrogens, progesterone, prolactin, and insulin. Using immortalized mammary cell culture models, GC deprivation has been shown to trigger apoptosis. Involution of postlactation mammary gland is caused by apoptotic loss of epithelial cells owing to a fall in levels of lactogenic hormones, including GCs.

III. EFFECTS OF GCs ON BONE TURNOVER

In the skeletal system, GCs influence the production and function of paracrine and autocrine factors including hormones and cytokines secreted by bone cells, the net effect being increased bone resorption and decreased bone volume and density. The primary target of GC action in the bone seem to be osteoblasts, which modulate bone formation and mineralization and eventually become osteocytes and undergo apoptosis. GCs have been shown to induce osteoblast apoptosis and repress osteocalcin, insulin-like growth factor-1, and type I collagen synthesis, all implicated in preosteoblast differentiation and proliferation. Impaired osteoblastogenesis secondarily represses osteoclastogenesis, thereby resulting in diminished bone turnover and remodeling. In addition, GCs promote osteocyte apoptosis, a primary cause of osteonecrosis (a misnomer, since the cells are actually dying via apoptosis rather than necrosis) in isolated portions of bone after administration of pharmacological doses of GCs. Indeed GC-induced bone resorption is a major cause of osteoporosis, often manifested following GC administration for inflammatory disease or disorders of immune function. Paradoxically, GCs are effective therapeutic agents for chronic inflammatory diseases of the bone, such as rheumatoid arthritis. Rheumatoid arthritis is associated with neutrophil activation, infiltration, and apoptosis at the inflamed joint. GCs prevent bone erosion by inhibiting pro-inflammatory neutrophil function including apoptosis.

IV. GC-MEDIATED REGULATION OF THYMOCYTE SELECTION AND LEUKOCYTE APOPTOSIS

Early studies demonstrated that GCs evoke thymic involution and affect the development of a normal immune system. During development, immature T-cells are subjected to a rigorous selection process in the thymus, allowing survival of cells with precisely defined properties. Double-positive, immature thymocytes that do not express functional T-cell receptors apoptose via a default pathway mediated by GCs. T-cells that do express functional T-cell receptors escape this pathway but are further subjected to negative selection if their receptors recognize self-antigen/MHC complexes with high avidity. GCs influence the TCR avidity "threshold" that distinguishes between cells that survive (low avidity) and those that die (high avidity). Indeed, in experimental models, apoptosis triggered by receptor-mediated T-cell activation is antagonized by GCs; deprivation of GC lowers the threshold of avidity beyond which negative selection ensues. GCs also affect the death of circulating leukocytes including neutrophils, eosinophils, and T- and B-lymphoid cells by mechanisms that are not clearly understood.

Because of their apoptotic actions, GCs are powerful therapeutic agents for a number of disorders, including autoimmune disorders, allergies, asthma, inflammatory diseases, and several forms of leukemia. GCs are effective components of multiagent combination therapy for ALL and CLL, where therapeutic efficacy is linked to the presence of functional GC. Eosinophil infiltration of bronchial mucosa causes many of the pathological features of asthma, including blockage of lung airways. GC-evoked apoptosis of eosinophils is instrumental in their ability to facilitate clearance of lung airways and reduce inflammation in asthma. Similarly, eosinophilia-associated allergic inflammation is also alleviated by GC-mediated eosinophil apoptosis. In autoimmune diseases, such as rheumatoid arthritis and lupus, GCs are effective therapeutic agents because of their ability to reduce the numbers of $CD4^+$ and $CD8^+$ thymocytes via apoptosis (see Fig. 1).

V. MECHANISMS OF GC-EVOKED THYMOCYTE APOPTOSIS

GC-evoked thymocyte apoptosis has been extensively studied and has facilitated a better understanding of the molecular pathway for apoptosis. Morphological

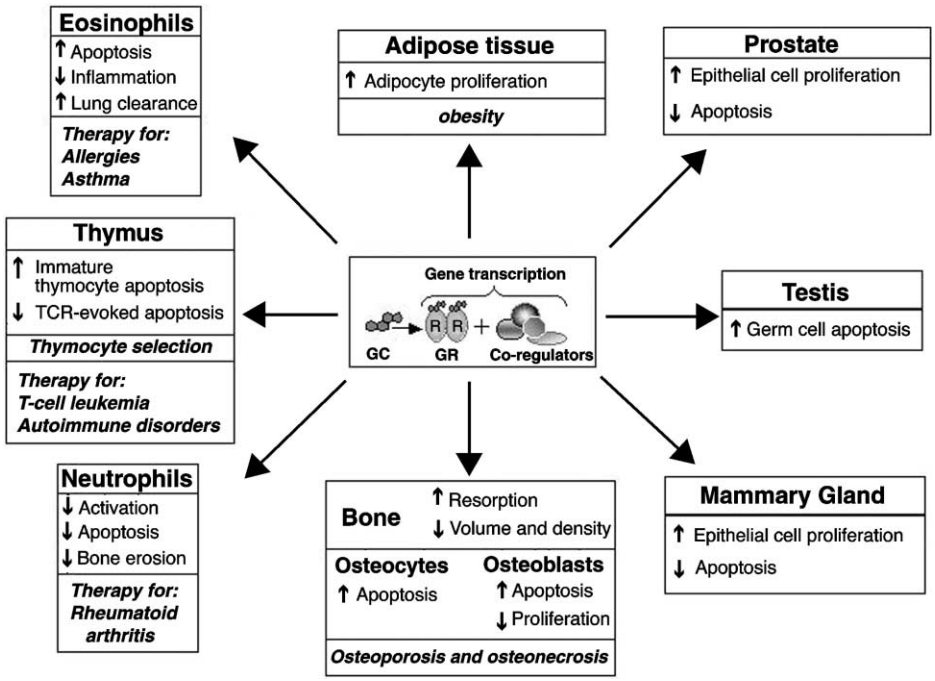

FIGURE 1 Targets of GC-evoked apoptosis and examples of therapeutic applications in which GC regulation of apoptosis occurs.

and biochemical changes associated with GC-evoked apoptosis include cell shrinkage, chromatin condensation, membrane flipping and blebbing, DNA fragmentation, and formation of apoptotic bodies. Researchers have been studying the molecular changes that precede these irreversible manifestations of apoptosis. It has become apparent that several overlapping or redundant pathways are simultaneously activated by GCs, all of which eventually culminate in protease activation, degradation of target substrates, and subsequent cell death (Fig. 2).

A. Alterations in Gene Expression

GC-mediated regulation of certain genes seems to play a vital role in evoking thymocyte/lymphoid cell apoptosis. One of the early effects is the down-regulation of expression of the proto-oncogene c-*myc*, which has been implicated as a decisive event triggering the apoptotic machinery. In GC-sensitive leukemic CEM-C7 cells constitutively expressing ectopic c-*myc*, apoptosis is significantly delayed. c-*myc* levels are not repressed in GC-resistant lymphoid cell lines or in GC-resistant thymocytes from NOD mice, providing a strong correlation between GC-evoked apoptosis and c-*myc* suppression. In murine P1798 cells, however, GC-evoked c-*myc* suppression is not sufficient to trigger an apoptotic response; a simultaneous depletion of the G1 cyclin, cyclin D3, is necessary. Indeed, GC-evoked apoptosis of leukemic cell lines is accompanied by growth arrest in the G1 phase of the cell cycle, which is thought to require regulation of cyclin–cyclin-dependent kinase (cdk) complex formation. GC-mediated lymphoid cell growth arrest/apoptosis is associated with up-regulation of the cdk inhibitor $p27^{kipI}$ and down-regulation of various cyclins, effectively blocking cdk activity.

The proto-oncogene c-*jun*, a component of the transcription factor AP-1, is up-regulated in association with GC-evoked apoptosis of lymphoid cells and may alter GR function via AP-1-mediated cross talk. AP-1 is also known to activate protein kinase C isoforms, some of which have been implicated as being pro-apoptotic. Another second messenger, cAMP, promotes GC-mediated thymocyte apoptosis by as yet unidentified mechanisms The classic path of cAMP signaling is through activation of protein kinase A, leading to modulation of gene transcription via phosphorylation of cAMP-response element-binding protein (CREB) and recruitment of CREB-binding protein (CBP) to alter gene expression of cAMP-responsive genes. Both CREB and CBP are known to interact with GR as components of the GR co-regulatory complex.

B. GC-Mediated Activation of Signaling Pathways

Induction of genes mentioned in the previous section is also accompanied by activation of multiple signal transduction pathways, including those activated via

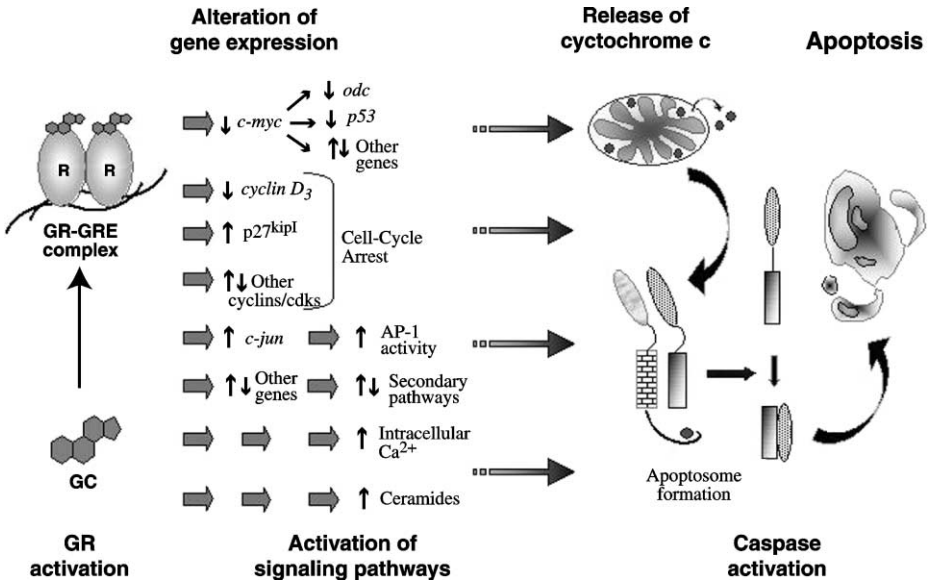

FIGURE 2 Signaling pathways that are activated by GCs, eventually leading to protease activation, degradation of target substrates, and subsequent apoptosis.

protein kinases C and A. GCs elevate cytosolic Ca^{2+} levels by depleting intracellular stores and trigger the activation of nuclear Ca^{2+}-dependent endonuclease(s), facilitating the accompanying DNA fragmentation. Ca^{2+} may also exert its effects on thymocyte apoptosis via calmodulin-mediated activation of the Ca^{2+}-dependent protein phosphatase, calcineurin. GC-evoked apoptosis has been shown to generate ceramides via the sequential production or activation of the phosphoinosotide-specific phospholipase C, diacyl glycerol (DAG), protein kinase C, and acidic sphingomyelinase (aSMase). This process is dependent on GR, since RU 38486 can block the induction of aSMase production by dexamethasone (a synthetic glucocorticoid) in correlation with inhibition of apoptosis. This pathway is also linked to activation of the JNK/SAPK cascade, as demonstrated in stress-induced apoptosis of leukemic U937 cells. aSMase activation appears to mediate downstream activation of caspases, since inhibition of intermediate steps in the pathway blocks caspase activation in parallel with the prevention of apoptosis.

C. Protease Activation

Proteases are believed to be the ultimate mediators of irreversible changes in apoptosis. Members of the caspase family of aspartate-specific cysteine proteases have been implicated as the executioners of apoptosis in the lymphoid system. Caspase activity can be detected in immature double-positive thymocytes that are subject to apoptotic selection, but not in double-negative or mature thymocyte populations that are generally resistant to GC-evoked apoptosis, indicating that caspases act as apoptotic effectors. In recent years, mice generated by targeted disruption of individual caspase genes have provided important, although preliminary, information on their role in normal thymocyte development and selection. Mice deficient in caspase 1, 2, 3, or 9 exhibit normal development and distribution of thymocyte subpopulations, suggesting either that caspase activation is not essential for thymocyte selection or that there is redundancy in their action. Thymocytes from caspase 3 knockout mice are normal, whereas those from caspase 9 knockout mice exhibit a delayed death response to dexamethasone. In CEM cells, GC-evoked apoptosis is dependent on the activity of a member of the caspase 3 subfamily, but not on caspase 1 or its homologues, which are involved in Fas/Fas L-mediated apoptosis. Cell-surface differences in the recruitment of individual caspases have been reported in different subsets of isolated normal mouse T-lymphocytes and T-cell lines when triggered to undergo apoptosis by the same stimulus. Thus, great diversity exists in the recruitment of individual caspases by various apoptotic pathways. Other proteases, such as calpain, granzyme A, and proteosomes, also mediate apoptosis; however, details of their role in the process have not been forthcoming.

D. Mitochondrial Events

Loss of mitochondrial transmembrane potential and release of cytochrome c have been implicated as early events in apoptosis triggered by various agents; however, the precise mechanisms by which these events occur are still being debated. Also, in the case of GC-evoked lymphoid cell apoptosis, mitochondrial changes seem to be important for the activation of caspases; however, there is little information on the upstream events that trigger membrane permeability transition and loss of mitochondrial membrane potential. The release of cytochrome c is thought to recruit pro-caspases and adapter proteins to form an apoptosome, which activates initiator caspases via autocatalysis, setting on the caspase cascade that goes on to activate effector caspases, such as caspase 3, the final executioner in the process of cell death. The anti-apoptotic protein, Bcl-2, which acts via binding to the outer mitochondrial membrane and preventing cytochrome c release, is able to delay but not prevent GC-evoked lymphoid cell apoptosis, again suggesting that independent pathways may eventually lead to cell death.

VI. SUMMARY

Glucocorticoid hormones play an important role in normal tissue turnover and cellular homeostasis, in addition to their widely recognized contribution to the regulation of metabolic processes, ion transport, and stress responses. GC-induced cytostatic or lytic action in several tissues has been exploited for therapeutic intervention in diseases such as autoimmune disorders and leukemia. Paradoxically, this aspect of GC action in tissues such as bone is a contraindication for high-dose GC therapy. Studies on the lymphoid cell system have provided insights into the mechanisms of GC-evoked apoptosis. In modulating their action, GCs engage GRs, which may alter the expression of key genes either autonomously or via cross talk with other signaling pathways. GC-evoked apoptosis appears to require suppression

of proliferative genes, such as c-*myc* and *cyclin D3*, and up-regulation of proteins, such as $p27^{kipI}$ and c-Jun. DAG-, Ca^{2+}-, ceramide-, and aSMase-mediated signaling processes are activated and are believed to contribute to the apoptosis process. Indeed, there is increasing evidence that GCs trigger multiple, seemingly independent pro-apoptotic pathways in parallel, ultimately culminating in protease activation and the collapse of cellular machinery, which brings about irreversible apoptotic cell death. Much needs to be learned about the precise sequence of events that modulate GC-evoked apoptosis in lymphoid and other systems.

Glossary

apoptosis A genetically programmed process of cellular suicide characterized by cell shrinkage, membrane blebbing, nuclear condensation, and formation of membrane-bound cell fragments or "apoptotic bodies" that are engulfed by phagocytic cells.

avidity The total strength of an interaction between two multivalent surfaces.

caspases Family of aspartate-specific cysteine proteases that have been implicated in apoptosis.

glucocorticoid receptor Intracellular protein that binds with high specificity to glucocorticoids to form a hormone–receptor complex that is translocated to the nucleus and interacts with specific DNA sequences on target genes to elicit a transcriptional response.

major histocompatability complex (MHC) A set of membrane glycoproteins that present intracellular peptides to T-cells. MHC molecules are also involved in antigen processing and host defense.

osteoblasts Bone-forming cells derived from stromal mesenchymal cells and rich in alkaline phosphatase, collagens I and V, and other bone-specific proteins.

osteoporosis A progressive systemic skeletal disease characterized by low bone mass and deterioration of bone tissue, causing increased bone fragility and susceptibility to fracture.

T-cell selection The process that T-cells undergo during cell proliferation that eliminates potentially self-reactive cells and favors the survival of those cells that can recognize foreign antigens.

Appetite Regulation, Neuronal Control

SUZANNE M. APPLEYARD
Oregon Health and Science University, Portland

Obesity is a major health problem in the United States today. Twenty to thirty percent of Americans are obese, leading to a rapid increase in diseases associated with obesity, such as heart disease, diabetes, and stroke. The development of obesity is due to an upset in energy homeostasis, the balance between energy intake and energy expenditure. There has been an explosion of research in this field over the past decade, leading to the discovery of many new hormones and neurotransmitters involved in the regulation of food intake. This article provides a brief overview of the various brain regions implicated in the regulation of food intake; the main focus will be on the hypothalamic peptides and hormonal regulation of food intake. However, the regulation of food intake is a complex process and the final output is likely to be due to an integration of the effects of each of the hormones and transmitters, involving all of the brain regions discussed in this article.

I. BRAIN REGIONS INVOLVED IN APPETITE REGULATION

A. Hypothalamus

The hypothalamus is the primary brain region involved in the regulation of food intake (see Fig. 1). Lesions to the ventromedial hypothalamus (VMH) including the arcuate nucleus lead to an animal that is severely obese and hyperphagic, whereas lesions to the lateral hypothalamus (LH) cause a lean and hypophagic phenotype. Conversely, electrical stimulation of the VMH inhibits food intake, whereas electrical stimulation of the LH stimulates food intake. These experiments led to the dual-center model suggested by Stellar in the 1950s, which stated that the lateral hypothalamus served as a feeding center and the ventromedial nucleus as a satiety center. Extensive research in this area has refined this hypothesis from specific "centers" of the brain controlling food intake to the notion of discrete neuronal pathways capable of integrating satiety signals and responding to changing fuel needs. Multiple hypothalamic nuclei play a role in this complex regulation of food intake and energy homeostasis (Fig. 1).

The arcuate nucleus of the hypothalamus (ARC) is located near the median eminence, where the blood–brain barrier is weakest and can therefore "sense" circulating levels of peripheral hormones and the levels of nutrients in the blood. Lesions to the arcuate nucleus lead to hyperphagia and obesity, suggesting that this region is critical for the appropriate regulation of food intake and appetite. Neurons with cell bodies in this region are sensitive to the levels of circulating regulators of energy homeostasis, such as leptin, insulin, and glucose. Many peptides and other neuroregulators are expressed in the arcuate nucleus. Two of the most widely studied groups of neurons in the ARC are the leptin-sensitive neuropeptide

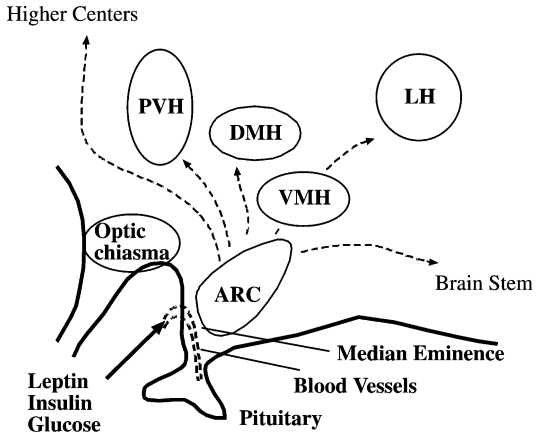

FIGURE 1 Schematic diagram of the role of the hypothalamus in appetite regulation. The arcuate nucleus lies directly above the median eminence, with its weak blood–brain barrier. Circulating satiety factors enter through the median eminence and regulate the activity of neurons within the arcuate nucleus. These neurons send projections to other hypothalamic nuclei as well as other brain regions involved in the regulation of appetite. The different hypothalamic nuclei are extensively interconnected, including projections back to the arcuate nucleus from its downstream targets. Therefore, hypothalamic regulation of food intake involves integration of the activity of numerous neuronal populations within the different nuclei. ARC, arcuate nucleus; PVH, paraventricular hypothalamus; DMH, dorsal medial hypothalamus; LH, lateral hypothalamus; VMH, ventromedial hypothalamus.

Y (NPY) and pro-opiomelanocortin (POMC) neurons. The ARC has reciprocal connections with many regions of the hypothalamus, including the dorsomedial hypothalamus (DMH), VMH, LH, and paraventricular hypothalamus (PVH). ARC neurons also project to other brain regions involved in energy homeostasis, including the nucleus of the solitary tract (NTS), central nucleus of the amygdala, nucleus accumbens, and cerebral cortex.

The LH also plays a major role in the regulation of food intake and energy homeostasis. Lesions to the lateral hypothalamus cause hypophagia and weight loss, whereas stimulation leads to hyperphagia. The LH receives inputs from the arcuate nucleus and other regions implicated in the regulation of appetite. The LH also sends extensive projections throughout the brain, including monosynaptic projections to the cerebral cortex and NTS. The main transmitters expressed in the lateral hypothalamus are melanin-concentrating hormone (MCH), orexins (hypocretins), and the endogenous opioid dynorphin. The LH receives inputs from the leptin-sensitive NPY and POMC neurons of the ARC. However, leptin receptors are expressed in the LH, suggesting that leptin may also have direct effects. In addition, many neurons in the LH are directly sensitive to changes in glucose levels.

The DMH receives inputs from both the lateral hypothalamus and the ventromedial hypothalamus and sends projections to the PVH, and is therefore a potentially important relay pathway for the neuroendocrine functions. Leptin and insulin receptors are also located in the DMH, indicating that this region may be involved in mediating the feedback effects of these hormones. However, rats with lesions to the DMH show normal body composition and weight, respond normally to body weight-regulatory challenges, and have normal efficiency of food utilization.

The PVH is also involved in the regulation of food intake. The PVH receives extensive projections from many regions including the ARC, LH, DMH, and NTS. Injections of many appetite-regulating neurotransmitters have potent effects when injected into the PVH, including NPY, α-melanocortin-stimulating hormone (αMSH), galanin, monoamines, and opioids. Neurons located in the PVH express oxytocin, vasopressin, thyroid-releasing hormone (TRH), and corticotropin-releasing hormone (CRH).

The VMH is also thought to act as a satiety center. As outlined above, lesions to the VMH lead to hyperphagia and weight gain, whereas stimulation inhibits feeding. The VMH also has reciprocal connections with the PVH, LH, and DMH and has a high level of leptin receptor expression.

B. Nucleus of the Solitary Tract

The NTS is a brainstem nucleus that is an important relay site for information from peripheral satiety signals to central sites. It also functions as a pathway relaying compensatory signals from the brain to peripheral targets. Many of these signals lead to changes in energy homeostasis, such as changes in autonomic functions. Vagal afferents from both the gastrointestinal tract and the abdominal viscera terminate in the NTS along with gustatory information from the oral cavity. The NTS also receives projections from the hypothalamus, amygdala, and nucleus accumbens, regions of the brain integral in the regulation of feeding. The NTS and the adjacent region, the area postrema, have weak blood–brain barriers and have access to circulating hormones and other regulators of feeding in much the same way as the arcuate nucleus of the hypothalamus. The NTS is also an important site of action of satiety factors released following a meal, such as cholecystokinin (CCK), that act to induce meal termination. Some of the inhibitory effects of the gastrointestinal tract on food intake do not require hypothalamic influences, as food intake is reduced even when connections between the forebrain and the hindbrain are severed.

C. Other Brain Regions

The hypothalamus and brainstem are thought to be the primary integration sites for peripheral satiety signals; however, other "higher" centers are proposed to be important for the appropriate control of food intake and appetite. The amygdala, nucleus accumbens, caudate putamen (dorsal striatum), and cortex all receive and/or send inputs from and/or to the hypothalamus. Lesions to the amygdala result in hyperphagia and weight gain, although the nucleus and the mechanisms involved have not been definitively identified. The nucleus accumbens is thought to mediate some of the rewarding or "hedonic" aspects of food intake. The caudate putamen and cortex are also proposed to mediate some of the behavioral changes that regulate food intake through their connections with the hypothalamus.

II. LEPTIN AND INSULIN

Leptin is a 15 kDa protein that is secreted by adipocytes. The finding that the profound obesity and hyperphagia of the ob/ob mouse were due to a mutation in the leptin gene led to the proposal that

leptin acted as an inhibitor of food intake and promoted a negative energy balance. Injection of leptin into rodents potently inhibited food intake, and leptin was proposed to be the adiposity feedback signal that was released from the fat to signal the brain to decrease energy intake and reduce weight. Consistent with this hypothesis, plasma leptin levels are proportional to total fat content, and leptin enters the CNS at levels that correlate with circulating concentrations. Furthermore, leptin receptors are expressed in regions of the brain involved in energy homeostasis, and administration of leptin directly into the brain reduces food intake. However, the role of leptin in the regulation of food intake and energy homeostasis is more complicated than acting as a simple adiposity feedback signal. Leptin is also thought to indicate the nutritional health of the organism, as it is a required permissive signal for many endocrine functions including the development of puberty and normal fertility. Indeed, given the affinity of leptin for its receptor and the circulating levels in a normal rodent, a decrease in circulating leptin levels may be a more physiologically important signal than is an increase brought about by weight gain. The arcuate nucleus is a major site of action for the effects of leptin. Leptin receptors are highly expressed in this region and injections of leptin specifically into the arcuate potently inhibit food intake. Conversely, ablations of the arcuate attenuate the hypophagic effects of a generalized intracerebroventricular (icv) injection of leptin. Leptin receptors are found on the majority of arcuate NPY and POMC neurons, and these neurons are proposed to play a major role in transducing circulating leptin and insulin levels into a neuronal response.

Insulin is a pancreatic hormone that is released into the blood. In addition to its effects on glucose homeostasis, insulin inhibits food intake. It is thought that insulin reduces appetite by acting in the brain as icv injections of insulin inhibit food intake. The levels of insulin correlate with the degree of adiposity of the organism in a manner similar to the correlation shown by leptin. Furthermore, insulin receptors are expressed in regions of the brain involved in energy homeostasis, and, like leptin, insulin modulates the activity of hypothalamic and NTS neurons.

III. NPY AND MELANOCORTIN SYSTEM

A. Neuropeptide Y

NPY is one of the most potent stimulators of food intake known. The primary hypothalamic site of synthesis of NPY is arcuate neurons that project throughout the hypothalamus and the rest of the brain. In addition to increasing food intake, NPY promotes weight gain by reducing sympathetic nervous system outflow to brown adipose tissue, which increases energy efficiency, decreases the metabolic rate, and promotes energy saving. The effects of NPY therefore promote a positive energy balance and weight gain, and chronic central administration of NPY leads to obesity. Both the production and the release of NPY are altered by changes in energy balance, suggesting that the NPY system plays an important physiological role in the regulation of appetite and weight homeostasis. Interestingly, however, NPY knockout mice have normal growth, food intake, and refeeding following a fast. Furthermore, they have normal responses to diet-induced obesity, chemically induced obesity, and many genetic types of obesity. However, NPY deficiency partially decreases the obesity seen in ob/ob mice, suggesting that NPY is important for the weight phenotype seen in leptin-deficient mice. NPY-deficient mice are also more sensitive to the effects of leptin, suggesting that NPY may have a tonic inhibitory effect on leptin's actions.

NPY receptors are members of the G-protein-coupled family of receptors and five major subtypes have been described. Studies with antagonists suggest that NPY receptors 1 and 5 are the main receptors involved in the stimulation of food intake, although the putative autoreceptors NPY receptors 2 and 4 are also highly expressed in the hypothalamus, including on both arcuate NPY and POMC neurons. Paradoxically, mice lacking the NPY1, NPY2, or NPY5 receptors have mild obesity phenotypes and varying degrees of hyperphagia. The failure to see a lean phenotype after the removal of a potent stimulator of feeding such as NPY suggests that the pathways involved in the control of food intake, like other hypothalamic systems, are sufficiently redundant to compensate for the loss of a major signaling system.

B. Melanocortins

The melanocortins αMSH and γMSH are the products of the pro-opioimelanocortin gene. POMC is a pro-hormone that is differentially processed into multiple bioactive peptides; in arcuate neurons, the main products of the POMC gene are αMSH, γMSH, and the endogenous opioid β-endorphin. αMSH is a potent inhibitor of food intake when administered centrally. There are five types of melanocortin receptors described to date, MCR1–5. The feeding effects of αMSH are mediated predominately by

the MC4 receptor as an αMSH-like agonist does not decrease feeding in mice genetically engineered not to express the MC4 receptor. αMSH also increases sympathetic outflow to brown adipose tissue, thereby increasing energy expenditure, and together with decreased food intake leads to a negative energy balance and weight loss. The critical role of the melanocortins in the appropriate regulation of both food intake and energy balance is evident in mice with disrupted melanocortin signaling. Mice that either lack the MC4 receptor or overexpress an antagonist of the melanocortin receptor are severely hyperphagic and obese. Mice lacking the MC3 receptor display a milder obesity phenotype and have increased adiposity. However, these mice appear to be mildly hypophagic and the major phenotype of the mice is an alteration in the regulation of energy utilization. Interestingly, the anorexia/cachaxia associated with cancer is attenuated by melanocortin receptor antagonists and absent in MC4 knockout mice, providing evidence that the melanocortins may mediate the decreased appetite seen in chronic illnesses. The essential role of the melanocortins is also apparent in humans. Independent studies have demonstrated that approximately 5% of childhood-onset obesity is associated with mutations in the MC4 receptor, making it the most common monogenic form of human obesity described to date. Mutations in the *POMC* gene also lead to a severe early onset form of human obesity.

C. Pro-Opiomelanocortin and Neuropeptide Y Neurons

Two of the main groups of neurons with their cell bodies in the arcuate nucleus are POMC and NPY neurons. These neurons are thought to act as the primary integration site of signals from peripherally circulating hormones and central signals involved in energy homeostasis. POMC neurons co-express cocaine- and amphetamine-regulated transcript (CART), whereas NPY neurons co-express agouti gene-related peptide (AGRP), an endogenous antagonist of the melanocortin receptors. NPY and POMC neurons project to many of the same regions, including the PVH, LH, and NTS. In addition to their opposing effects on food intake, NPY and αMSH have opposing effects on downstream target neurons, and the NPY and POMC neurons have been proposed to be the primary site of action of both leptin and insulin on food intake and energy homeostasis. Leptin is proposed to lead to a negative energy balance and decreased food intake by increasing the activity of POMC neurons and inhibiting NPY neurons (see Fig. 2). Conversely, decreasing the activity of the POMC neurons and increasing the activity of the NPY neurons lead to positive energy balance and increased food intake. Cross talk is thought to occur between the POMC and the NPY neurons. One mechanism of interaction functions via the endogenous antagonist of melanocortin receptors, AGRP, which is co-expressed in NPY neurons. AGRP is a potent activator of food intake and its actions are thought to occur primarily through the blockade of a basal inhibitory melanocortin tone. Therefore, the release of the NPY and AGRP peptides from NPY neurons has direct effects on downstream targets through the actions of NPY and indirect effects through inhibition of effects of any MSH released from POMC neurons. NPY and POMC neurons are also thought to have direct effects on each other's activities, which would also modulate the release of peptides from the opposing neuron. NPY and POMC neurons both express receptors for leptin; however, different responses are produced. Leptin turns on the expression of the immediate-early genes, c-fos and soc3, in POMC neurons. In contrast, leptin activates only socs3 expression in NPY neurons. Activation of c-fos is generally associated with an excitation of neurons, whereas soc3 expression is turned on

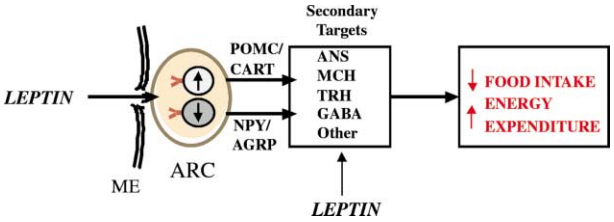

FIGURE 2 Leptin-regulated melanocortin and NPY circuits influence food intake and body weight. Leptin produces its effects on food intake and energy homeostasis in part through activation of the POMC and inhibition of the NPY neurons in the ARC. Potential downstream targets of these neurons include TRH and GABA neurons in the PVH, MCH neurons in the LH, and other targets in the hypothalamus, brainstem, and other brain regions. The ultimate consequence of activation of POMC neurons is a decrease in food intake. As NPY and AGRP tend to stimulate food intake and energy homeostasis, the ultimate consequence of inhibition of the NPY neurons will again be inhibition of food intake and increased energy expenditure. POMC, pro-opiomelanocortin; CART, cocaine- and amphetamine-regulated transcript; NPY, neuropeptide Y; AGRP, agouti gene-related peptide; ANS, autonomic nervous system; MCH, melanin-concentrating hormone; TRH, thyroid-releasing hormone; GABA, gamma-aminobutyric acid; ME, median eminence; ARC, arcuate nucleus.

following cytokine receptor activation regardless of whether the effects on the neuron are excitatory or inhibitory. The immediate-early gene expression therefore suggests that leptin activates POMC neurons and inhibits NPY neurons. Indeed, electrophysiological recordings in the ARC have shown that leptin increases the activity of POMC neurons and decreases the activity of NPY neurons. Therefore, leptin acts to decrease food intake by both decreasing the release of the orexegenic peptides NPY and AGRP and increasing the release of the anorexegenic peptide αMSH. The downstream targets of the POMC and NPY neurons are less well understood. However, several possible targets are emerging. Both NPY and melanocortins have been shown to produce their effects on food intake and energy homeostasis following injections into the PVN. TRH neurons in the PVN express MC4 receptors and TRH expression is regulated by melanocortins. Furthermore, leptin's effects on TRH expression are mediated at least in part by the melanocortin system, although leptin has also been shown to have some direct effects on TRH expression. Regulation of TRH and other PVN neurons would regulate both the pituitary and the thyroid axes and provide one mechanism by which leptin and the melanocortin system may modulate both food intake and energy homeostasis. Other potential downstream targets of both the POMC and the NPY neurons are the MCH and orexin neurons discussed below. POMC and NPY neurons have many other projection sites including those involved in the regulation of autonomic functions, and it is likely that these multiple downstream targets act in concert to mediate the effects of both melanocortins and NPY on appetite.

IV. OREXIGENIC FACTORS

A. Melanin-Concentrating Hormone

MCH is expressed exclusively in the lateral hypothalamus, which sends projections to other brain regions involved in appetite regulation, including monosynaptic connections throughout the cortex and NTS. MCH is a potent stimulator of food intake following intracerebroventricular injection. Fasting or removal of leptin increases MCH mRNA levels and these are restored to normal levels following food intake or leptin administration. Targeted disruption of the MCH gene leads to mice that are hypophagic and lean, demonstrating a critical role for MCH in both food intake and weight homeostasis. Conversely, overexpression of MCH in transgenic mice leads to increased food intake and promotes obesity. MCH neurons have been proposed to be part of a secondary relay system for the actions of leptin and insulin and are hypothesized to be targets of the NPY and melanocortin neurons. MCH has also been shown to suppress the release of TRH from downstream target neurons. The finding that mice lacking MCH are lean contrasts with the lack of an obesity phenotype observed in the NPY-deficient mice and suggests a lack of redundancy at the level of the MCH neurons in the regulation of food intake and energy homeostasis.

B. Orexins (Hypocretins)

Orexin A and B, or hypocretin 1 and 2, named by the two groups who simultaneously discovered them, are expressed in neurons with cell bodies in the LH and DMH. Orexin-positive neurons send projections to regions involved in appetite regulation, including projections that synapse on NPY neurons in the ARC. Conversely, ARC NPY neurons send projections that synapse on orexin-positive cells in the LH. Orexins have been shown to increase food intake when administered centrally. However, orexins also increase general arousal, and targeted deletion of the orexin gene in mice causes narcolepsy. The effects of the orexins on food intake may therefore be due to indirect effects on general arousal rather than a direct effect on food intake. Further studies are required to determine the exact role of the orexins in appetite regulation.

C. Galanin

Galanin neurons are located as several discrete populations in the ARC, DMH, and PVN and innervate multiple areas of the hypothalamus and other brain regions involved in food intake. Central injections of galanin peptide into the PVN, LH, VMH, NTS, and central nucleus of the amygdala all stimulate feeding in rats. Galanin neurons have synaptic links with both NPY and POMC neurons, and galanin gene expression is increased by fasting, suggesting a role for this neuropeptide in appetite regulation. However, the food intake stimulated by galanin is much less robust than that stimulated by NPY and no obvious weight phenotype has been reported in galanin knockout mice.

D. Endogenous Opioids

Several members of the endogenous opioids have been described, along with three main types of opioid

receptor, the μ, δ, and κ receptors. β-endorphin is processed from the POMC pro-hormone and is therefore predicted to be released from the POMC neurons along with the melanocortins at many regions critical for the regulation of food intake and energy homeostasis. β-endorphin has affinity for all three opioid receptor subtypes. Dynorphin is an endogenous opioid with high affinity for the κ opioid receptor and affinity for the μ opioid receptor. Dynorphin is highly expressed in the lateral hypothalamus where it is co-localized in orexin neurons. Met- and Leu-enkephalin have the highest affinity for δ opioids and μ opioid receptors. Met- and Leu-enkephalin are expressed in the hypothalamus as well as other brain regions involved in the regulation of appetite, including the nucleus accumbens, the amygdala, and the NTS. Injections of opioid agonists, including β-endorphin and dynorphin, stimulate food intake, predominately through the μ and κ opioid receptors. Conversely, opioid antagonists inhibit food intake, suggesting that there is a basal tone of endogenous opioids that stimulates food intake. Furthermore, opioid receptor antagonists attenuate NPY-induced, galanin-induced, and fast-induced food intake. However, given the promiscuous pharmacology of the endogenous ligands, it is hard to determine which of the endogenous opioids mediates these effects. In addition to potentially having direct effects on food intake, endogenous opioids are thought to mediate some of the rewarding aspects of food intake. However, mice that lack dynorphin or enkephalin have not been reported to have abnormal body weights and mice lacking β-endorphin have an unexpected mild increase in body weight.

E. Ghrelin

Ghrelin was first identified as an endogenous ligand for the growth hormone secretagogue receptor; however, it has recently been found to have orexegenic properties as well and is thought to act as an integrator of growth and energy needs. Ghrelin is produced in the stomach and is proposed to stimulate food intake via the hypothalamus when an increase in energy intake is needed. Consistent with this hypothesis, ghrelin stimulates food intake when administered both peripherally and centrally. The central injection of ghrelin produces a more robust and sustained food intake than a peripheral injection, and ghrelin has been proposed to have a central mode of action. As predicted for an energy deficiency signal, mRNA levels of ghrelin in the stomach, and circulating blood levels, are increased by fasting and decreased by feeding. Interestingly, caloric intake, and not stomach expansion, appears to decrease circulating levels of ghrelin. The effects of ghrelin can be long term, as subcutaneous injections of ghrelin twice daily for 2 weeks stimulated body weight gain and increased fat mass with no change in lean mass. Anti-ghrelin antibodies reduce fast-induced food intake when administered either peripherally or centrally, suggesting a tonic ghrelin tone.

The GHS or ghrelin receptor is highly expressed in the arcuate nucleus and the ventromedial hypothalamus, and ghrelin stimulates arcuate neurons and the expression of immediate-early gene products such as c-fos in the arcuate nucleus. Fifty percent of the arcuate neurons expressing the GHS receptor are NPY/AGRP neurons; ghrelin treatment increases both NPY and AGRP expression but the mRNA levels of POMC are unchanged. Pretreatment with NPY1 receptor antagonists attenuates the effects of ghrelin on food intake, consistent with the orexigenic effect of ghrelin being mediated by NPY/AGRP neurons. Ghrelin still has effects on feeding in NPY-deficient mice, suggesting that other transmitters (potentially AGRP) also contribute to the orexigenic effects of ghrelin. Leptin and ghrelin appear to have antagonistic actions on the regulation of food intake and weight homeostasis, and co-administration of ghrelin attenuates the effects of leptin.

F. Endogenous Cannabinoids

The endogenous cannabinoids, anandamide and 2-arachidonoyl glycerol, are found in the hypothalamus, and injections of cannabinoid agonists stimulate food intake, suggesting a role for cannabinoids in the regulation of appetite. Pharmacological studies suggest that the orexigenic effects of cannabinoids are mediated by the centrally expressed CB_1 receptor. Furthermore, chronic treatment with a CB_1 receptor antagonist inhibits food intake and decreases weight, although these effects last for less than a week. Consistent with the pharmacology, mice lacking the CB_1 receptor have reduced food intake following fasting. However, nonfasted CB_1 receptor knockout mice have normal food intake. Acute leptin administration reduces the levels of the endogenous cannabinoids. Conversely, the levels of the endogenous cannabinoids are increased in the hypothalamus in ob/ob and db/db mice and Zucker rats, animal models with defective leptin signaling, suggesting that the cannabinoids may mediate some of the effects of leptin.

G. Dopamine

Dopamine has been proposed to contribute to the rewarding aspects of food intake. Both pharmacological depletion and genetic depletion of dopamine result in profound feeding deficits. However, dopamine deficiency also results in impaired movement and locomotion, and therefore, interpretation of these results is complicated. More recent studies specifically restoring dopamine in the caudate putamen of dopamine-deficient mice restored feeding. In contrast, rescue of dopamine specifically in the nucleus accumbens of dopamine-deficient mice restored exploratory behavior, but not feeding. This study separates the locomotive and feeding effects of the dopamine-deficient mice and suggests that depletion of dopamine in the caudate putamen is primarily responsible for the hypophagia phenotype in dopamine-deficient mice. This was somewhat of a surprise given the role of the nucleus accumbens in mediating the rewarding aspects of food intake. The mechanisms underlying the effects of dopamine on food intake remain to be established.

H. Other Orexigenic Factors

Glucocorticoids stimulate an increase in food intake. Furthermore, many of the hypothalamic effects of leptin and insulin are opposed by glucocorticoids. Thyroid hormone and growth hormone also stimulate food intake. However, the mechanism by which the increase in food intake occurs is not known and may be indirect. Thyroid hormone effects may be indirect due to compensation for increased metabolic rate, whereas the effects of growth hormone may occur through growth hormone-releasing hormone.

V. ANOREXIGENIC FACTORS

A. Glucagon-like Peptide 1

Glucagon-like peptide 1 (GLP-1) is a gastrointestinal peptide that is released in response to food intake. GLP-1 plays an important role in glucose homeostasis and augments glucose-induced insulin secretion and inhibits glucagon secretion. However, GLP-1 is also proposed to act as a satiety factor. Consistent with this hypothesis, peripheral administration of GLP-1 inhibits food intake. In addition to being produced in the intestine, GLP-1 is expressed at hypothalamic sites, the caudal portion of the nucleus of the solitary tract, and the forebrain. Central administration of GLP-1 inhibits food intake through actions in the hypothalamus, including the PVH. Conversely GLP-1 antagonists stimulate feeding in satiated rats. GLP-1 antagonists also attenuate the effects of both leptin and CCK to inhibit food intake. Leptin has been shown to increase hypothalamic GLP-1 levels and to activate GLP-1 neurons in the NTS, providing further evidence of a role for GLP-1 in food intake and energy homeostasis. However, mice lacking the GLP-1 receptor do not show any feeding abnormalities.

B. Cocaine- and Amphetamine-Regulated Transcript

Cocaine- and amphetamine-regulated transcript is a recently discovered hypothalamic peptide that is co-expressed in POMC neurons, although its expression is not restricted to these neurons. CART neurons are known to project to many sites important for appetite regulation. Furthermore, injections of CART inhibit food intake, and CART expression is regulated by changes in leptin levels, suggesting a role for this peptide in the regulation of energy homeostasis. However, mice deficient in CART have minimal changes in food intake and energy homeostasis, suggesting that although CART has effects on food intake and energy homeostasis, its effects are redundant in that the system appears to be able to compensate for the absence of CART.

C. Corticotropin-Releasing Hormone

Cell bodies of CRH are expressed predominately in the PVN, a major site of action for appetite-regulating drugs. CRH has diverse effects and is the primary hypothalamic hormone that stimulates ACTH release from the pituitary, ultimately leading to the release of corticosterone from the adrenal gland. Injections of CRH centrally decrease food intake, including NPY-induced food intake. CRH also promotes a negative energy balance by stimulating energy expenditure, by increasing thermogenesis via sympathetic pathways. CRH levels are regulated by leptin, suggesting a role for CRH in mediating the effects of leptin. Another member of the CRH family is urocortin, which is more potent at suppressing food intake than CRH. The effects of both urocortin and CRH are mediated by CRHR1 or CRHR2 receptors. However, the weights and basal food intake of both CRHR1 and CRHR2 knockout mice are normal.

D. Serotonin

Serotonin (5HT)-expressing neurons have their cell bodies in the brainstem and project widely in the brain including the hypothalamus. The 5HT or

serotonin system is the primary target of drugs currently used to treat obesity. Dexfenfluramine and other diet drugs increase 5HT signaling and inhibit food intake. Serotonin turnover is increased by leptin, and mice lacking the 5HT2c receptor have increased food intake and increased weight. The obesity seen in these mice is mild, however, and leptin still inhibits food intake, suggesting that this receptor signaling pathway is not critical for the actions of leptin. More studies are required to determine the exact role of the serotonin system in weight homeostasis.

E. Noradrenaline

The PVH receives a dense catecholaminergic innervation from the caudal medulla relaying predominately visceral sensory information. Many of the catecholaminergic neurons from the NTS co-express NPY. Injections of noradrenaline (NE) into the PVH stimulate food intake, supporting a role for this transmitter in the regulation of appetite. Furthermore, NE levels are regulated by changes in leptin levels and therefore appear to be sensitive to changes in energy state.

F. Cholecystokinin

CCK was the first gut peptide identified to be a satiety factor. Injections of CCK produce a rapid onset inhibition of food intake that is short-lived. The satiety effects of peripherally administered CCK require an intact vagal nerve and are believed to be mediated through the NTS. Physiologically, CCK is secreted by the gut after a meal, and its release stimulates CCK receptors located on the vagal nerve. Vagal afferents terminate on neurons in the NTS believed to regulate appetite and energy homeostasis. CCK has synergistic effects with leptin on both food intake and c-fos expression in the NTS, area postrema, and PVH. Two subtypes of CCK receptors have been identified: CCK_A and CCK_B. CCK_A receptor-specific antagonists block the anorexic effects of CCK, suggesting that it is mediated primarily through the CCK_A receptor. Furthermore, CCK_A receptor antagonists have been shown to attenuate refeeding following food deprivation. Interestingly, rats that lack the CCK_A receptor have a mild type of obesity, whereas CCK_A receptor knockout mice do not. CCK is also expressed in the brain, suggesting that there are direct actions of CCK centrally as well as through modulation of the vagal afferents. Indeed, injections of CCK directly into either the NTS or the hypothalamus inhibit food intake.

G. Other Anorexigenic Factors

Cytokines such as interleukins [interleukin-1 (IL-1) and interleukin-6 (IL-6)], tumor necrosis factor-α, ciliary neurotrophic factor, and leukemia inhibitory factor have all been shown to inhibit food intake. The mechanism remains to be established but may involve actions on insulin and leptin sensitivity and regulation of the melanocortin system. Interestingly, IL-6 knockout mice have a late onset obesity, although the cause is not yet established. The peptide bombesin reduces food intake in rodents, and mice lacking the bombesin-3 receptor become obese, suggesting that this peptide may also be important in regulating food intake. Furthermore, histamine is also thought to be an appetite suppressor through actions at the H_1 receptor. Enterostatin is a pentapeptide, produced in the gut, that also reduces food intake in rodents and reduces hunger ratings in humans. Interestingly, it appears to selectively reduce fat intake.

VI. SUMMARY

The regulation of appetite and food intake is a complex process. It involves a coordinated response to many orexigenic and anorexigenic factors in multiple brain regions (Table 1). Significant progress has occurred over the past decade, including the discovery of the adipostatic hormone leptin and some of the pathways required for its actions. Leptin produces its effects, in part, by a coordinated action

to simultaneously activate POMC and inhibit NPY neurons in the ARC to alter food intake and energy homeostasis. Downstream targets of the NPY and POMC neurons include specific neurons in the PVN, LH, NTS, and other brain regions. However, there are still many "black boxes" and it is likely that some critical appetite factors remain to be discovered. Furthermore, as is the case with other functions regulated by the hypothalamus, there appears to be some redundancy between these appetite factors.

Given the tremendous health impact of obesity in the world, elucidating the pathways and mechanisms involved in the regulation of energy homeostasis is essential to understanding more about this problem and for the development of novel therapeutic tools. Disruptions of these pathways clearly have a large impact on food intake and energy homeostasis, as illustrated by monogenic mutations resulting in severe obesity. However, the epidemic of obesity in recent years probably reflects more changes in lifestyle, particularly in food intake and exercise. This illustrates the importance of emotional and other influences on food intake that may modulate the pathways involved in energy homeostasis discussed in this article.

Glossary

anorexigenic A compound that inhibits or decreases food intake.

cachexia A state of malnutrition associated with disease and consisting of a combination of anorexia, increased metabolic rate, and wasting of lean body mass.

db/db mice Mice that are deficient in the leptin (ob) receptor.

knockout A mouse with a gene that has been specifically targeted (or "knocked out") so that the protein is no longer made.

ob/ob mice Mice that are deficient in the hormone leptin.

orexigenic A compound that stimulates or increases food intake.

thermogenesis Process that occurs in the brown adipose tissue of rodents. Heat is generated and energy expended. It is a major determinant of metabolic rate in rodents.

Aromatase and Estrogen Insufficiency

EVAN R. SIMPSON

Monash Medical Centre, Australia

Endogenous estrogens are formed from androgenic steroids by the action of the enzyme aromatase, which is a member of the cytochrome P450 superfamily, and encoded by the CYP19 gene. In humans, aromatase expression and hence estrogen biosynthesis occur in a number of tissue sites including ovary, placenta, fetal liver, adipose, bone, and brain. Analysis of the phenotypes of humans with natural mutations of the aromatase gene, as well as mice in which the gene has been inactivated by targeted disruption, has revealed a number of new and unexpected roles for estrogens in both males and females. These include roles in bone mineralization, lipid and carbohydrate metabolism, and spermatogenesis in the male. This article will briefly summarize the present and sometimes contradictory state of knowledge regarding the diverse roles that are played by the products of the aromatase reaction and point to future directions that may help to clarify these issues.

I. INTRODUCTION

Models of estrogen insufficiency have revealed new and often unexpected roles for estrogens in both males and females. These models include natural mutations of the aromatase gene in humans and one man with a mutation in the estrogen receptor-α (ERα) gene, as well as the various mouse knockout (KO) models, namely, the ERαKO and ERβKO mice, the ERα/ERβ double KO mouse, as well as the aromatase knockout (ArKO) mouse.

Some of these roles for estrogen are nonsexually dimorphic and apply equally to males and females, for example, the role of estrogens in bone metabolism as well as in carbohydrate and lipid metabolism. Indeed, in the context of its role in male germ cell development, estradiol can appropriately be considered an androgen.

Estrogens are synthesized from C19 androgenic precursors by means of the aromatase enzyme, which is the product of the CYP19 gene. Aromatase is a member of the P450 gene superfamily, which has over 600 members in approximately 100 families; CYP19 is the sole member of family 19.

The human CYP19 gene was cloned some years ago when it was shown that the coding region spans nine exons beginning with exon II. Upstream of exon II are a number of alternative exons I that are spliced in the 5′-untranslated region of the transcript in a tissue-specific fashion (Fig. 1). Thus, placental transcripts contain at their 5′-end a distal exon, I.1, which is localized at least 40 kb upstream from the start of translation in exon II. This is because placental expression is driven by a powerful distal promoter upstream of exon I.1. On the other hand, transcripts in ovary and testes contain at their 5′-end a sequence that is immediately upstream of the translational start site. This is because expression of the gene in the gonads utilizes a proximal promoter, promoter II. By contrast, transcripts in adipose tissue contain yet another distal exon located at least 20 kb upstream of the start of translation, exon I.4. Splicing of these untranslated exons to form the mature transcript occurs at a common 3′-splice junction that is upstream of the translational start site. This means that although transcripts in different tissues have different 5′-termini, the coding region and thus the protein expressed in these various tissue sites are always the same. However, the promoter regions upstream of each of the several untranslated first

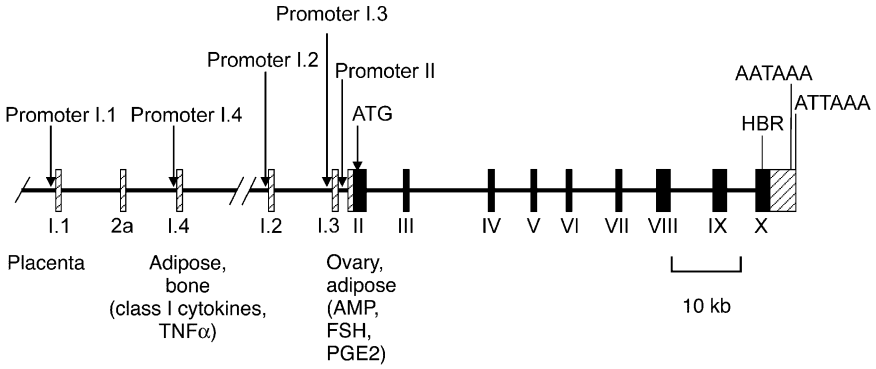

FIGURE 1 Diagram of the structure of the human aromatase gene showing the arrangement of the various untranslated first exons and their associated promoters.

exons have different cohorts of response elements, and so regulation of aromatase expression in each tissue that synthesizes estrogens is different. Thus, the gonadal promoter binds the transcription factors Ca^{2+}/cyclic AMP-response element-binding protein and Sp-1, and so aromatase expression in gonads is regulated by cyclic AMP and gonadotropins. On the other hand, adipose promoter I.4 is regulated by class I cytokines, such as interleukin-6 (IL-6), IL-11, and oncostatin M, as well as by tumor necrosis factor α. Thus, the regulation of estrogen biosynthesis in each tissue site of expression is unique.

II. AROMATASE DEFICIENCY IN HUMANS

Aromatase deficiency appears to be a rare condition and there have been 10 mutations reported to date, affecting seven females and three males, one of whom is a child (Fig. 2). The phenotypes of these individuals will be summarized in this article as will the findings on the phenotype of ArKO mice created by disruption of the CYP19 gene, which encodes aromatase.

With the exception of the first reported case, namely, the Japanese patient, all of the mutations thus far identified are single base-pair changes giving rise to single amino acid substitutions and in one case a premature stop codon (Fig. 2). The mutation in the Japanese patient is a single base change that destroyed an exon–intron splice junction, giving rise to continued read-through of an extra 87 bases to a cryptic intron–exon splice junction within the intron, resulting in an in-frame insertion of 29 amino acids within the coding region. It should be pointed out that both siblings in the New York family were homozygous for the condition, which would suggest that the mutation does not cause any diminished likelihood of implantation or any serious problem with embryonic or fetal development. Apart from the Californian patient and the Swiss patient, who are compound heterozygotes, all of the subjects are homozygous for the mutation in question and are the products of consanguineous relationships. In most cases, it was the mother who presented, during the third trimester, complaining of virilization resulting in facial hair and acne. These symptoms subsided after delivery. In the cases of female newborns, they present with pseudo-hermaphroditism with clitoromegaly and hypospadias in varying degrees of severity. This virilization of both mother and fetus is a consequence of the inability of dehydroepiandrosterone of fetal adrenal origin to be converted to estrogens by the placenta, with its consequent peripheral conversion to androgens. These individuals then present again at the time of puberty with primary amenorrhea, failure of breast development, hypergonadotropic–hypogonadism, and cystic ovaries. Subsequent estrogen supplementation leads to regression of these symptoms.

In addition, two men have been reported with this condition. In each case, childhood development was uneventful. Each presented in their late twenties with tall stature due to sustained linear growth through puberty as a consequence of failure of epiphyseal fusion. They also had severely delayed bone age, resulting in osteopenia and undermineralization.

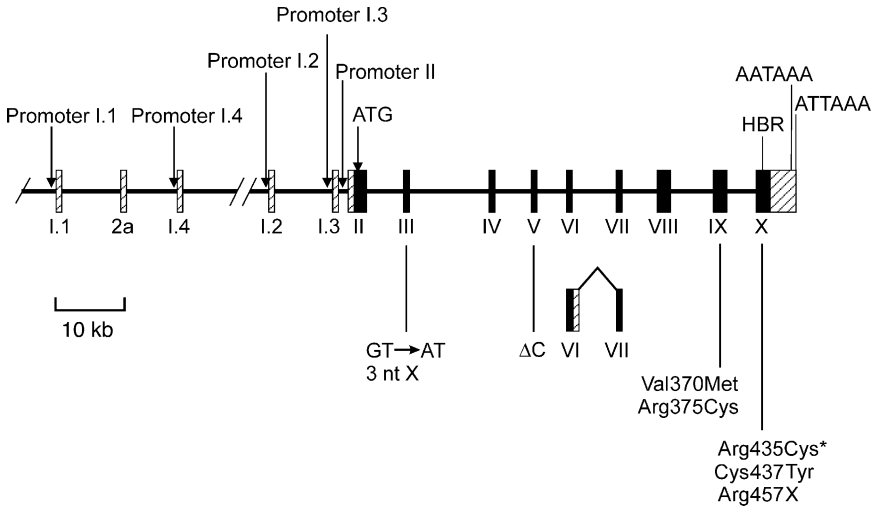

FIGURE 2 Known mutations in the CYP19 gene that give rise to estrogen insufficiency in humans. The mutations in the Swiss compound heterozygote case are not included.

TABLE I Plasma Hormone Levels in the Male Patient with CYP19 Deficiency

Δ^4A	335	ng/dl	30–263
T	2015	ng/dl	200–1200
5α-DHT	125	ng/dl	30–85
E1	<7	pg/ml	10–50
E2	<7	pg/ml	10–50
FSH	28.3	mU/ml	5.0–9.9
LH	26.1	mU/ml	2.0–9.9
Glucose	70	mg/dl	70–105
Insulin	52	μU/ml	5–25
GH	<0.5	ng/ml	0.5–4.2
IGF-I	203	ng/ml	182–780

Analysis of the plasma hormone levels of the New York male patient (Table 1) revealed undetectable estrogens and very high circulating androgens. Circulating follicle-stimulating hormone and luteinizing hormone (LH) were also elevated, indicative of an important role for estrogens in the negative feedback regulation of gonadotropins in males, as in females. Presumably, in the case of males, this estrogen is normally derived from local aromatization of testosterone within brain sites. The patient was 204 cm tall at the age of 24 years and had testes that were 35 ml in volume. Unfortunately, no semen sample was available so it was impossible to gauge his sperm count or sperm viability. He was unmarried and had no offspring. However, his testicular volume and hormonal profile would indicate the likelihood that he had functioning testes as far as their capacity to synthesize steroids was concerned.

The fetal testes synthesize anti-Müllerian hormone and testosterone, the former causing regression of the Müllerian structures and the latter causing virilization of the male external genitalia (Fig. 3). Classically this action of testosterone is thought to be achieved by conversion to 5α-dihydrotestosterone due to the activity of 5α-reductase. However, more recently it has become evident that there are several sites in the testes that are capable of converting testosterone to estrogens. This is because the enzyme aromatase, responsible for the conversion of androgens to estrogens, has been reported to be present at a number of sites within the testes including the Leydig cell and also germ cells at various stages of development. Additionally, both the α and the β isoforms of the estrogen receptor have been reported to be present at several sites. Furthermore, the levels of estradiol in the semen and rete fluid are greater than those circulating in the plasma of females. These considerations give rise to the concept that estrogens play a role in the function of the testes.

The second male patient was from a family in southern Italy and presented at the age of 28 years with tall stature, infertility, and skeletal pain. He was found to have open epiphyses and a bone age of 14.8 years. Treatment with testosterone for 8 months failed to result in any improvement of his condition, whereas treatment with transdermal estradiol for 6 months restored his bone density to within the normal range and eliminated his other symptoms. In contrast to the New York patient, this individual had a testicular volume of 8 ml and was infertile. Testicular biopsy revealed that his seminiferous tubules had little or no sperm present and gamete development appeared to be arrested at the spermatocyte level. Again in contrast to the New York patient, his circulating testosterone levels were not elevated and were reduced dramatically on administration of estradiol. These results might suggest a relationship between aromatase deficiency and testicular dysfunction. Unfortunately for this concept though, the individual has a brother with azoospermia but who is homozygous for the normal active aromatase gene. These observations suggest that the fertility problem in these men may be independent of the aromatase deficiency in this family. Thus, the study of these two men with aromatase deficiency has failed to elucidate the role of estrogens in male fertility and suggests that, at the very least, there is variable penetrance of the phenotype. The phenotypes of these men may be compared with that of the one known male with a mutation in the estrogen receptor-α isoform, who also presented with a failure of epiphyseal closure and undermineralized bones, but who has reduced sperm count and sperm motility.

In addition to the bone and fertility phenotypes outlined above, individuals with aromatase deficiency have a lipid and carbohydrate phenotype, namely, truncal obesity, hypertriglyceridemia, elevated low-density lipoprotein levels, and insulin resistance. These symptoms all subside on treatment with estrogen (Table 1).

III. THE AROMATASE KNOCKOUT MOUSE

To gain further insight into the physiological role of estrogens, a mouse was created in which the aromatase gene was disrupted by homologous recombination (Fig. 4). Studies of these mice are indicative of a dramatic bone phenotype, with shortened femur length and reduction in all of the indices of bone mineralization. Because circulating

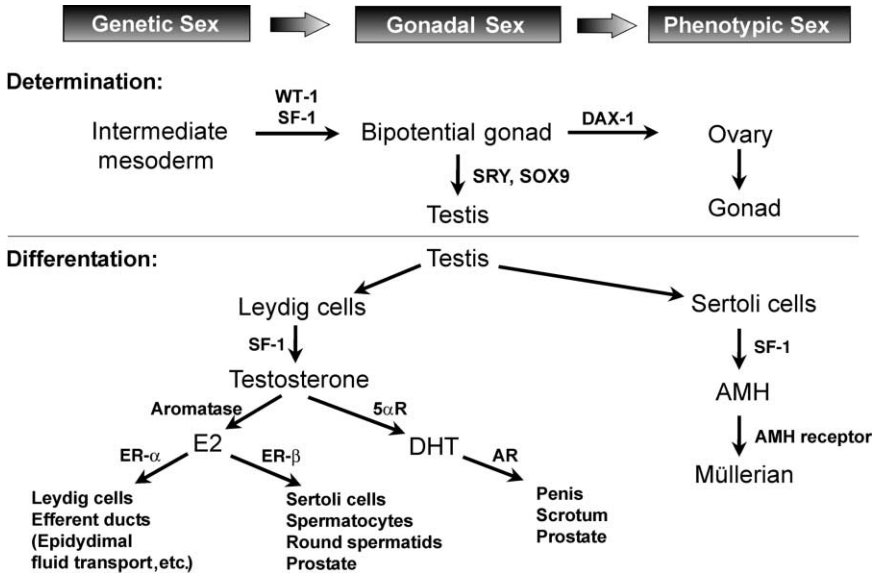

FIGURE 3 Factors involved in testicular differentiation.

estradiol levels in wild-type as well as ArKO male mice are below the level of detection, this would indicate that the source of estrogens maintaining bone mineralization in the wild-type mice is likely to be local production within the bone itself or at other extragonadal sites.

Examination of the morphology of the ovaries of mice at the age of 10–12 weeks (Fig. 5) revealed a striking phenotype in that the ovaries contained a number of follicles that showed signs of antral information but appeared arrested prior to ovulation. No corpora lutea were present but the follicles had abundant granulosa cells displaying some mitotic figures. The stroma was hyperplastic, indicative of the high circulating LH levels and some pyknotic figures were present, perhaps indicative of follicular atresia. At later ages, cystic hemorrhagic follicles were present, coincident with an infiltration of macrophages and collagen deposition in the interstitium. By 1 year of age, there were no secondary or antral follicles in ArKO ovaries and atresia was widespread in the remaining primary follicles.

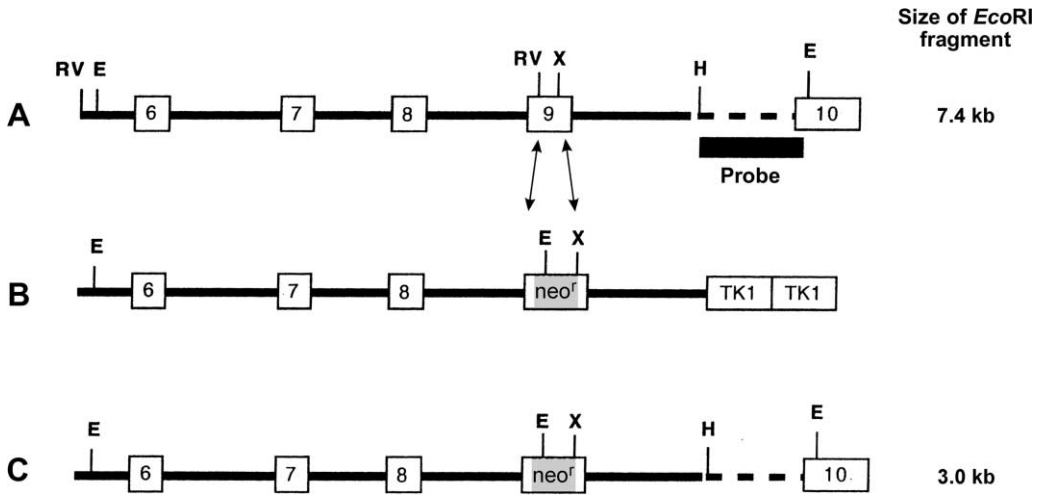

FIGURE 4 Diagram of part of the structure of the wild-type mouse CYP19 gene (A), the targeting vector (B), and the disrupted gene (C).

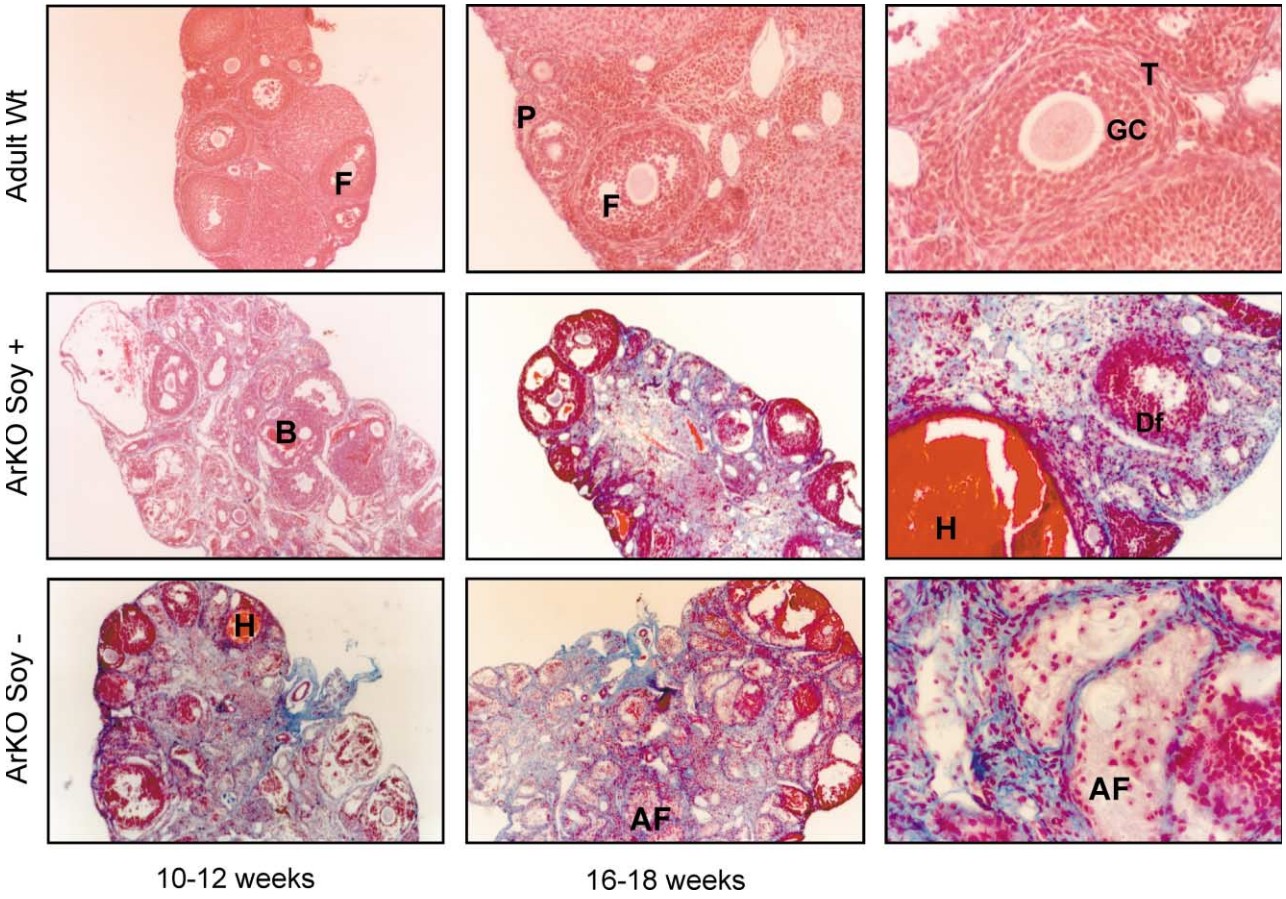

FIGURE 5 Optical micrographs of ovaries of adult wild-type mice (top row), ArKO mice on a regular chow diet (middle row), and ArKO mice on a soy-free diet (bottom row). The right-hand panels of the ArKO ovaries are higher magnifications of parts of the central panels to show details. F, follicle; P, primordial follicle; T, theca; GC, granulosa cells; H, hemorrhagic cyst; Df, dying follicle; AF, abnormal follicle.

Examination of the testes of male mice at a similar age showed no obvious phenotypes and these males were fertile (data not shown). However, with increasing age, the numbers of litters they sired diminished compared with their wild-type littermates. Disruptions to spermatogenesis commenced at 4–5 months and became more progressive with advancing age. Spermatogenesis was primarily arrested at early spermiogenic stages, as characterized by an increase in apoptosis and the appearance of multinucleated cells, and there was a significant reduction in round and elongated spermatids, but no changes in Sertoli cells and earlier germ cells. In addition, Leydig cell hyperplasia/hypertrophy was evident, presumably as a consequence of increased circulating LH. These findings suggest that local expression of aromatase, at least in mice, is essential for spermatogenesis and indicate a direct action of estrogen on male germ cell development and, thus, fertility. These results are in contrast to those of ERKO mice in which the seminiferous tubules had grossly distended lumens with no sign of sperm. This is apparently due to failure of fluid transfer across the epithelium of the efferent ductules, resulting in increased pressure and back-up of fluid into the seminiferous tubules. By contrast, the ER-β knockout mice display no detectable testicular phenotype. These differences in phenotype of the various models of lack of estrogen representation are not readily explicable in terms of the current level of understanding. These are several possibilities, including the presence of endogenous estrogenic substances other than the products of the aromatase reaction non-ligand-mediated pathways of estrogen receptor activation

and pathways of estrogen action other than via the known receptors.

Another phenotype developed by these mice, similar to the situation with humans carrying a natural mutation in the CYP19 gene, is a lipid and carbohydrate phenotype. ArKO mice, both male and female, develop a progressive increase in abdominal adiposity, involving both the gonadal and the infrarenal fat deposits. This is associated with increased plasma triglycerides and cholesterol, insulin resistance, and hyperleptinemia. Hepatic steatosis is also present. Interestingly, the increased adiposity is not accompanied by a marked increase in body weight. This is because there is a corresponding decrease in lean body mass, most likely skeletal muscle, which is associated with a decrease in activity. This adiposity phenotype is reversed dramatically within 3 weeks on administration of estradiol in the form of implants. A similar phenotype has been reported for the ERαKO mice, so these two models are in accordance as far as this phenotype is concerned.

IV. CONCLUSIONS

Models of estrogen insufficiency, whether they be natural mutations in humans or targeted gene disruptions in mice, are revealing new and often unsuspected roles for estrogens in both males and females. In some cases, consistency is observed between the animal models, such as the adipose phenotype of the ArKO and ERαKO mice. On the other hand, the studies conducted so far on aromatase-deficient males have not served to throw light on the role of estrogens in male reproduction. This is because of the conflicting phenotypes of the two men with aromatase deficiency, as well as the apparent discrepancies between the phenotype of the ArKO mice and that of the ERαKO mice. This issue can be resolved only by more extensive characterization of the phenotypes of these animals at the cellular and molecular levels. There is also a pressing need to identify other men with aromatase deficiency.

Glossary

aromatase A microsomal enzyme complex that catalyzes the conversion of testosterone to estradiol.

exon The portion of the DNA sequence in a gene that contains the codons that specify the sequence of amino acids in a polypeptide chain, as well as the beginning and end of the coding sequence.

phenotype The appearance or other characteristics of an organism, resulting from the interaction of its genetic constitution with the environment, as opposed to its underlying hereditary determinants, or genotype.

pseudo-hermaphroditism A condition in which an individual has sexual organs of only one sex but has either genital openings or external tissue exhibiting one or more traits of the opposite sex.

spermatogenesis The process by which undifferentiated male germ cells form into mature spermatozoa.

Auxin

LAWRENCE J. HOBBIE
Adelphi University, Garden City, New York

Auxins are a class of plant hormones that display a common set of biological activities. As originally defined, an auxin was a substance that could promote elongation in certain tissues. Now a spectrum of auxin effects are known, including promotion of lateral root formation, induction of cell division in callus tissue in conjunction with cytokinins, and induction of ethylene biosynthesis. A variety of natural and synthetic compounds possessing these activities have been identified.

I. HISTORY, STRUCTURES, AND APPLICATIONS

The existence of a mobile signal that controlled a plant's response to gravity was first postulated by Ciesielski in 1872. Charles Darwin and his son Francis suggested in 1881 that a transported substance was important for plants' response to light. In the 1920s, Went devised a method of capturing this substance and quantifying its biological activity, which led to the determination of the chemical structure of the first known auxin in the 1930s. Subsequent studies of auxins have focused on their physiological roles, biosynthesis and degradation, and cellular mechanism of action. Auxins are found in all vascular plants and have also been identified in green and brown algae, making it likely that they have been used as signaling molecules throughout plant evolution.

The major naturally occurring auxin is indole-3-acetic acid (IAA; IUPAC: indol-3-yl-acetic acid), a weak acid with a pK_a of 4.75. Several other naturally occurring compounds with auxin activity have also been identified in various plant species, including 4-chloroindole-3-acetic acid and indole-3-butyric acid (Fig. 1). These other compounds have a high level of auxin activity, but it is unclear whether they have intrinsic auxin activity or are active only after their enzymatic conversion to IAA. Auxins are localized primarily to the cytoplasm and the chloroplasts in plant cells.

A large number of synthetic compounds with auxin activity have been produced (Fig. 2), some of which are more stable than IAA, which is subject to

Auxin

LAWRENCE J. HOBBIE
Adelphi University, Garden City, New York

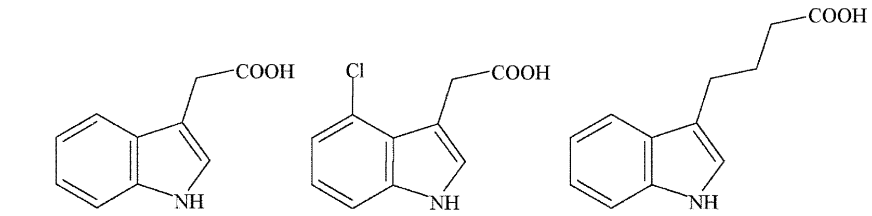
Auxins are a class of plant hormones that display a common set of biological activities. As originally defined, an auxin was a substance that could promote elongation in certain tissues. Now a spectrum of auxin effects are known, including promotion of lateral root formation, induction of cell division in callus tissue in conjunction with cytokinins, and induction of ethylene biosynthesis. A variety of natural and synthetic compounds possessing these activities have been identified.

I. HISTORY, STRUCTURES, AND APPLICATIONS

The existence of a mobile signal that controlled a plant's response to gravity was first postulated by Ciesielski in 1872. Charles Darwin and his son Francis suggested in 1881 that a transported substance was important for plants' response to light. In the 1920s, Went devised a method of capturing this substance and quantifying its biological activity, which led to the determination of the chemical structure of the first known auxin in the 1930s. Subsequent studies of auxins have focused on their physiological roles, biosynthesis and degradation, and cellular mechanism of action. Auxins are found in all vascular plants and have also been identified in green and brown algae, making it likely that they have been used as signaling molecules throughout plant evolution.

The major naturally occurring auxin is indole-3-acetic acid (IAA; IUPAC: indol-3-yl-acetic acid), a weak acid with a pK_a of 4.75. Several other naturally occurring compounds with auxin activity have also been identified in various plant species, including 4-chloroindole-3-acetic acid and indole-3-butyric acid (Fig. 1). These other compounds have a high level of auxin activity, but it is unclear whether they have intrinsic auxin activity or are active only after their enzymatic conversion to IAA. Auxins are localized primarily to the cytoplasm and the chloroplasts in plant cells.

A large number of synthetic compounds with auxin activity have been produced (Fig. 2), some of which are more stable than IAA, which is subject to



Indole-3-acetic acid (IAA) | 4-Chloroindole-3-acetic acid | Indole-3-butyric acid

FIGURE 1 Structure of three naturally occurring auxins.

degradation by light and by plant enzymes. Among the synthetic auxins, a few have been widely used as herbicides, including picloram, 2,4,5-trichlorophenoxy-acetic acid (2,4,5-T), and 2,4-dichlorophenoxy-acetic acid (2,4-D). Auxins are also used in horticulture to promote fruit set and root development of cuttings. In assays involving exogenous application to plants, "active" auxins generally show effects at submicromolar levels. The common structural requirement for auxin activity, based on a comparison of active and inactive auxin analogues, seems to be a negatively charged carboxyl group, linked at an approximate distance of 0.5 nm to a planar aromatic ring that possesses a fractional positive charge.

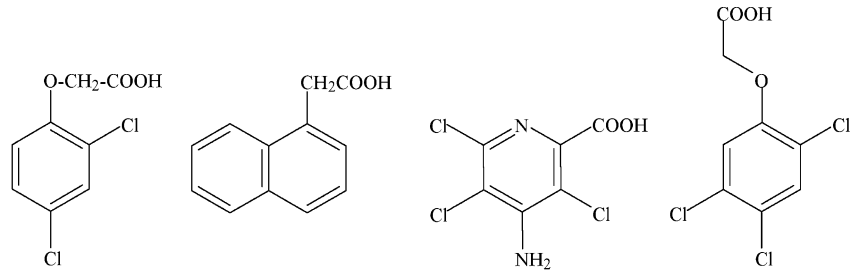
II. BIOCHEMISTRY

A. Techniques

For decades, the only methods available for quantifying auxin were bioassays, with the most widely used bioassay being the curvature test. In this assay, an agar block containing a sample is placed on one side of an *Avena sativa* coleoptile from which the tip has been excised, with the resulting curvature being measured. Comparison with the effects of known amounts of IAA allowed the auxin activity in the sample to be quantified. More recently, quantitative chemical analysis has become standard: Gas chromatography–mass spectrometry techniques incorporating stable isotope-labeled internal standards permit precise determination of IAA levels present in samples and correction for losses during purification.

B. IAA Biosynthesis

IAA biosynthesis studies are challenging because IAA concentrations are generally very low (tens to hundreds of nanograms per gram of tissue) compared to other compounds, such as tryptophan, that can be converted to IAA by nonenzymatic processes or by



2,4-Dichlorophenoxyacetic acid (2,4-D) | 1-Naphthaleneacetic acid (1-NAA) | 4-Amino-3,5,6-trichloropicolinic acid (picloram) | 2,4,5-Trichlorophenoxyacetic acid (2,4,5-T)

FIGURE 2 Structures of four synthetic auxins. 2,4-D and 2,4,5-T were the major components of Agent Orange, used as a defoliant by American forces during the Vietnam War.

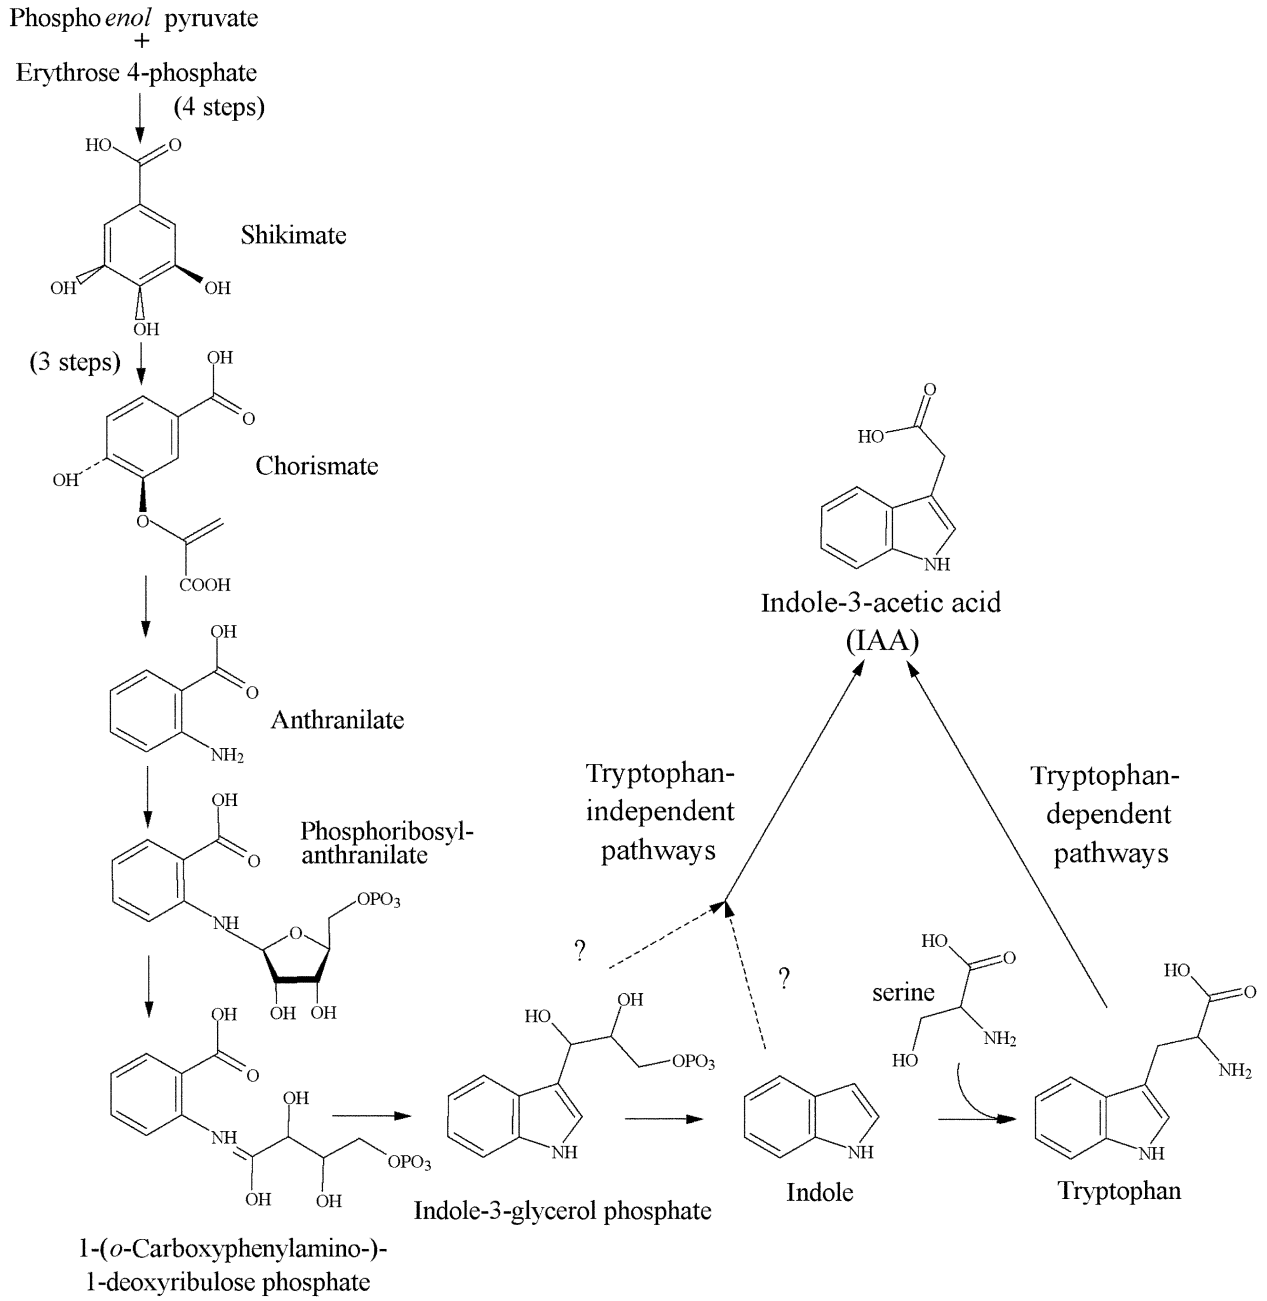


FIGURE 3 Overview of the pathways of IAA biosynthesis in plants. The enzymes catalyzing the reactions leading to tryptophan biosynthesis are found in the chloroplast. From Buchanan, B.B., Gruissem, W., and Jones, R.L. 2000. "Biochemistry and Molecular Biology of Plants." Copyright American Society of Plant Physiologists.

bacterial enzymes. Furthermore, extraction destroys enzyme compartmentation, which may also cause nonphysiological reactions to occur. Because of this, the final several steps leading to IAA biosynthesis are still not known with certainty.

IAA biosynthesis is believed to occur predominantly in the growing shoot tip and in the young leaves. The biosynthesis of IAA appears to proceed through several different routes, broadly divided into tryptophan-dependent and tryptophan-independent

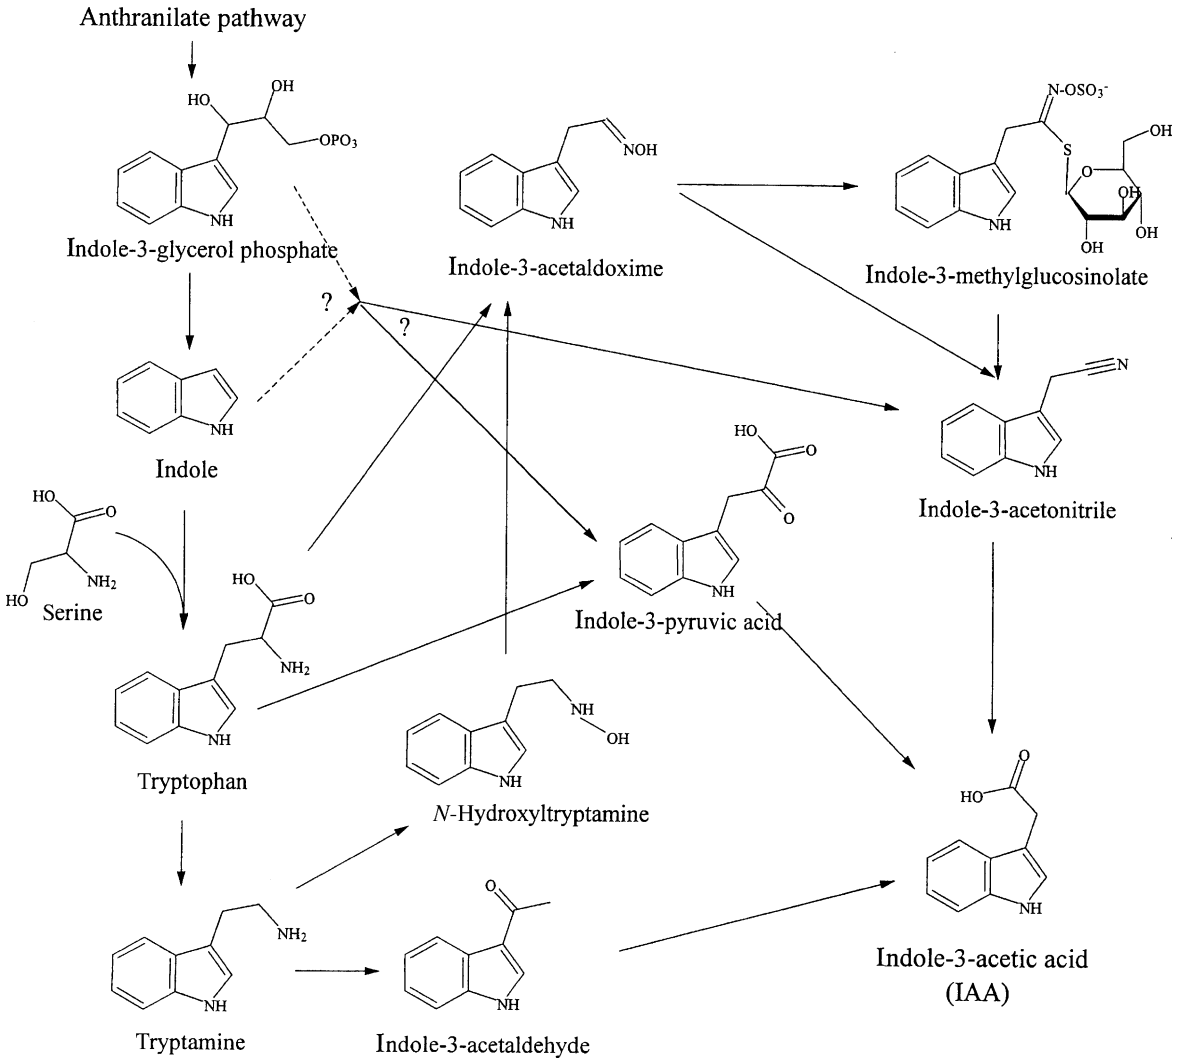

FIGURE 4 Possible pathways of tryptophan-dependent and tryptophan-independent biosynthesis in plants. It is unclear whether indole or indole-3-glycerol phosphate is the IAA precursor in tryptophan-independent biosynthesis. Reprinted with permission from the *Annual Review of Plant Physiology & Plant Molecular Biology*, Volume 48, ©1997 by Annual Reviews,www.AnnualReviews.org.

pathways. The ultimate precursor is chorismate, which is converted into anthranilate and then subsequently into indole, tryptophan, and related molecules (Fig. 3). Tryptophan can be converted to IAA through one of three possible pathways (Fig. 4). One pathway is via indole-3-pyruvic acid and indole-3-acetaldehyde (likely to be important in tomato shoots). In a second pathway, tryptamine is the intermediate between tryptophan and indole-3-acetaldehyde; alternatively, in *Arabidopsis thaliana*, one pathway may proceed from tryptamine through *N*-hydroxyltryptamine and then to indole-3-acetaldoxime and eventually to IAA. A third pathway (important in only a subset of plants, including the mustards, grasses, and bananas) leads from tryptophan to indole-3-acetaldoxime to indole-3-acetonitrile and then to IAA. A branch of this third pathway proceeds from indole-3-acetaldoxime to indole-3-methylglucosinolate and then to indole-3-acetonitrile.

IAA biosynthesis independent of tryptophan has been demonstrated in plants using mutants of corn (*orange pericarp*) and *Arabidopsis* (*trp2* and *trp3*) blocked in tryptophan synthesis. Possible pathways are shown in Fig. 4. Probable precursors are indole-3-glycerol phosphate or indole, which could be

converted to either indole-3-pyruvic acid or indole-3-acetonitrile and then to IAA. It is likely that different IAA biosynthetic pathways are important in different species, in different tissues, and at different developmental stages. For example, carrot cultures, maize, and *Arabidopsis* seedlings may use both tryptophan-dependent and -independent pathways. *Phaseolus vulgaris* seedlings appear to use primarily tryptophan-dependent pathways, whereas tryptophan-independent pathways are important in *Lemna gibba* (duckweed), maize endosperm, and oat coleoptiles.

C. IAA Degradation and Inactivation

IAA is most likely degraded by oxidation, either of free IAA or of its conjugates. In maize, IAA degradation proceeds via conversion to oxindole-3-acetic acid, which is then further oxidized and conjugated to glucose. In contrast, in maize root tips, oxidative decarboxylation (removal of the carboxyl side chain) appears to be an important route of IAA degradation. In tomato and *Vicia faba*, IAA–aspartate is the target of oxidation and is conjugated to sugars as a means of deactivation.

Peroxidases were long thought to be the primary enzymes involved in IAA degradation. Recent evidence suggests that, although peroxidases are powerful IAA-degrading enzymes *in vitro*, they are unlikely to play a role *in vivo*, perhaps because of compartmentation.

D. IAA Conjugation

Most of the IAA is conjugated to other molecules, either via ester linkages to *myo*-inositol or sugars (such as glucose) or via amide linkages to amino acids or peptides. For example, maize endosperm, one of the best-studied tissues in this regard, contains IAA–glucose, IAA–*myo*-inositol, IAA–*myo*-inositol-galactose, and IAA–*myo*-inositol-arabinose, among other conjugates. IAA conjugates are believed to possess auxin activity only after hydrolysis, which releases free IAA. IAA conjugates have at least three functions. First, they may serve as a storage form of IAA. In maize seeds, for example, IAA conjugates stored in the endosperm move to the shoot following germination and are deconjugated to release free IAA. Second, conjugates are important in the regulation of IAA levels. For example, many mutant and transgenic plants that overproduce IAA have greatly increased levels of conjugates, thereby moderating the increase in levels of free IAA. Third, production of the conjugate IAA–aspartate is likely to be the first step in the inactivation and degradation of IAA in a variety of plants. Enzymes that carry out the conjugation and deconjugation reactions are beginning to be identified.

III. POLAR AUXIN TRANSPORT

IAA is transported from its sites of synthesis and storage to other tissues throughout the plant. Auxin transport can occur either via the phloem or by a cell-to-cell pathway called polar auxin transport. Polar auxin transport requires energy and proceeds at a rate of 5 to 20 mm/h. Two routes of polar auxin transport are known. In the first, found in the shoot and central cylinder of the root, auxin travels down the shoot and into the root through parenchyma cells associated with the vascular tissue. In the second, auxin is transported from the root tip back to the root elongation zone in the epidermal and cortical tissues. Both routes are believed to use a similar mechanism and similar protein transporters.

The mechanism of polar auxin transport is explained by the chemiosmotic hypothesis, first proposed in the 1970s. According to this model, polar IAA transport is driven by chemical and electrical gradients across the cell membrane and results primarily from directional IAA efflux out of the basal side of cells. A further feature of the model is that IAA enters cells through two mechanisms: active uptake, probably by co-transport with protons, and diffusion. IAA that enters cells deprotonates in the neutral environment of the cytoplasm and, as a charged molecule, can no longer diffuse across the plasma membrane. IAA^- will therefore tend to accumulate in cells. Efflux carriers localized to the basal side of the cell enable IAA^- to move down the electrochemical gradient and out of the cell. It then enters the next cell below it and similarly effluxes out through the basal side. This polar efflux causes IAA to move unidirectionally down a file of cells.

Genetic approaches using *Arabidopsis* have led to the identification of transmembrane proteins likely to be important for auxin transport; their properties thus far are consistent with the chemiosmotic hypothesis. The AUX1 protein, a putative IAA uptake carrier, acts primarily in the root. The protein sequence shows similarity to amino acid transporters and consists of 485 amino acids, predominantly

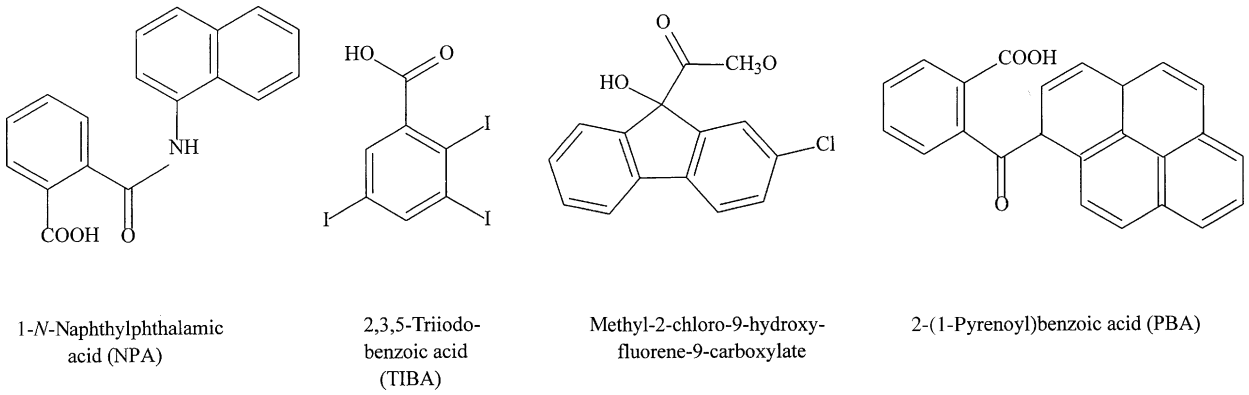

FIGURE 5 Compounds that specifically inhibit polar auxin transport.

hydrophobic, with up to 11 transmembrane domains. Genes for three other proteins with significant similarity to AUX1 have been identified in *Arabidopsis*. Proteins of the PIN family (at least 14 family members in *Arabidopsis*) are strong candidates for the efflux carriers. PIN1 is a highly hydrophobic, multiple-membrane-spanning protein. It is localized to the basal side of xylem parenchyma cells, which is consistent with the chemisosmotic hypothesis and with a role in apical-to-basal polar auxin transport. The PIN2/EIR1/AGR1/WAV6 protein is localized on the upper membrane of epidermal and cortical cells in the root elongation zone, where it could function in IAA redistribution during root gravitropic response. The asymmetric cellular distribution of the PIN1 protein requires a functional membrane trafficking system; disruption of vesicle traffic with inhibitory chemicals or mutations in the *GNOM/EMB30* gene, believed to encode a key component of trafficking, destroys the localization pattern of PIN1 protein.

Many compounds that specifically inhibit polar auxin transport have been identified (Fig. 5). Most of these inhibitors of polar auxin transport have diverse effects on plants, including blocking gravitropic responses and inhibiting growth. The best-characterized such inhibitors are 1-naphthylphthalamic acid (NPA) and 2,3,5-triiodobenzoic acid (TIBA). These compounds have been shown to block auxin efflux; TIBA may compete directly with IAA at the efflux carrier, whereas NPA and related compounds (called phytotropins) are postulated to bind to a regulatory subunit of the efflux carrier. In either case, inhibition of auxin efflux increases cytoplasmic auxin concentrations. Recently, it has been suggested that phytotropins could act by blocking general vesicle trafficking, thereby disrupting the dynamic basal localization of the efflux carrier. A number of endogenous flavonoids act similarly to NPA, suggesting that plants may use flavonoids to regulate polar auxin transport.

Polar auxin transport has been shown to regulate many developmental processes including inhibition of growth of axillary buds in shoots, promotion of growth of lateral roots, regulation of embryonic polarity, regulation of shoot meristem function and organization, and regulation of vascular tissue development.

IV. PHYSIOLOGICAL AND DEVELOPMENTAL ROLES

A. Auxin and Embryogenesis

Auxin plays a key role in several aspects of plant embryogenesis. For example, inhibitors of polar auxin transport prevent normal embryo development in carrot somatic embryos and block separation of the cotyledons in cultured *Brassica juncea* embryos. Treatment of cultured *B. juncea* embryos with exogenous auxin causes various developmental abnormalities, including nonseparated cotyledons and arrested ball-shaped embryos. Expression patterns of the PIN1 putative auxin efflux carrier in *Arabidopsis* embryos suggest that auxin is channeled to the central provascular cells and to the presumptive root pole. Indeed, localized activation of an auxin-responsive promoter has been found in the future root region of early *Arabidopsis* embryos, suggesting that there is in fact a high auxin concentration in

these cells. Three *Arabidopsis* mutants affected in auxin response (*monopteros*, *bodenlos*, and *auxin-resistant6*) have defects in early embryogenesis, leading to similar defects affecting development of the hypocotyl, root, and cotyledons. Thus, genetic, physiological, and molecular evidence indicates that local patterns of auxin transport and accumulation are likely to regulate the establishment of bilateral symmetry and development of the root, hypocotyl, and vascular tissue.

B. Auxin and Vascular Development

Auxin is believed to be a critical determinant of the differentiation and connectivity of vascular tissue. The auxin canalization hypothesis states that auxin flow through provascular tissue promotes its differentiation into vascular tissue, which increases auxin flow through these cells. The positive feedback between auxin flow and vascular development results in channeling of auxin flow to a small set of connected cells, ensuring the continuity necessary for proper function of the vascular system. This hypothesis is supported by the effects of experimental perturbation of auxin flow by wounding or auxin transport inhibitors. Further support comes from defects in vascular tissue formation and alignment seen in various auxin-related mutants of *Arabidopsis*. A direct correlation between vascular development and IAA concentration has been observed in the trunks of Scots pine and hybrid aspen, where IAA concentration is highest in the vascular cambium.

C. Auxin and Root Development

Auxin produced in the shoot and transported to the root has been suggested to be essential for proper root development. A high concentration of auxin has been localized to the cells around the root tip in maize and *Arabidopsis* seedlings. Blockage of auxin accumulation by either genetic or chemical means causes changes in the patterning of cells in the root. Auxin may regulate the cell cycle in cells of the root quiescent center through actions on ascorbic acid and ascorbic acid oxidase.

D. Auxin and Lateral Roots

Lateral roots are produced when cells in the pericycle, the layer of cells surrounding the central vascular cylinder, begin to divide, form additional cell layers that push through the outer cell layers of the primary root, and ultimately organize a second root meristem. Many lines of evidence indicate that lateral root development is promoted by transported auxin. Increasing the auxin concentration in roots causes increased lateral root formation. Approaches that have been used to increase auxin levels include mutations, transgene expression, and exogenous application of auxin to the entire root or to the stump of a severed root. Conversely, reducing auxin levels or response in the primary root leads to a decreased number of lateral roots. This is accomplished by inhibition of polar auxin transport at the root–shoot junction or by mutation-induced reductions in auxin response. Auxin appears to stimulate the division of the pericycle cells that initiate lateral root development and may also be required at the later stage of outgrowth.

E. Auxin and Apical Meristem Function

Auxin is produced in the apical region of the growing shoot and seems likely to play an important role in the proper functioning of this organ. Reduced auxin transport out of the *Arabidopsis* shoot apex due to treatment with auxin transport inhibitors or genetic defects that reduce auxin transport or response (*pin1*, *pid*, and *mp* mutants) all result in pin-shaped inflorescence meristems lacking any floral organs. Mutations in the *ETTIN* gene, an auxin-response factor (see below), affect floral patterning. These observations indicate that normal auxin transport and response in the apical meristem area are essential for proper floral development.

Auxin has also been found to affect the proper initiation and arrangement of leaves on a shoot, called phyllotaxy. Auxin may play a role in determining the species-specific phyllotactic patterns, perhaps via auxin transport patterns. Characteristic pathways of auxin transport in the meristem could lead to local auxin maxima in specific positions relative to the meristem and existing organs. Evidence in support of this model includes the observation that application of IAA to tomato and *Arabidopsis* apices can induce initiation of lateral organs and that defects in phyllotaxy can result from disruptions in auxin transport.

F. Auxin and Control of Branching

An axillary bud, the precursor of a branch or lateral shoot, is formed at the junction between a leaf and

the stem. The shoot apex tends to inhibit outgrowth of axillary buds, a phenomenon called apical dominance. Removal of the shoot tip leads to growth of these buds to produce lateral shoots. Application of auxin to a decapitated shoot inhibits bud outgrowth, but this auxin effect can be blocked by inhibitors of polar auxin transport. These observations led to the model that auxin produced by the shoot apex and transported in a polar manner down the shoot inhibits the development and outgrowth of lateral shoots. However, this theory remains controversial. Decreased auxin levels in axillary buds would have been expected after decapitation, but were not in fact observed in several species. In contrast, many auxin-related mutants display changes in the degree of shoot branching. Mutants with reduced auxin response frequently have increased numbers of secondary shoots or of lateral branches, consistent with the involvement of auxin in apical dominance. It is likely that auxin regulates outgrowth of axillary buds indirectly rather than directly, perhaps by affecting levels of another growth regulator.

G. Auxin and Fruit Development

Fertilization and fruit development seem to involve auxin at many steps. For example, pollen, seed endosperm, and embryos all produce auxin. In many species, including tomato and pineapple, auxin can induce fruit development in the absence of fertilization (parthenocarpy). Expression of bacterial auxin biosynthetic genes induces parthenocarpy in transgenic eggplant, tomato, and tobacco.

H. Auxin and Elongation Growth

Application of exogenous auxin has long been known to induce elongation of excised stem or coleoptile sections. The initial rapid phase of this elongation is thought to be due to acid-induced growth (see Section V.D). A later phase of slower elongation probably proceeds by a different mechanism involving new protein synthesis. The importance of auxin in *in vivo* elongation growth has been supported by the dwarf phenotypes of many mutants with reduced auxin responses and transgenic plants with reduced auxin levels. In addition, application of auxin to intact pea plants induces stem elongation *in vivo*.

I. Auxin and Tropisms

IAA was originally discovered using an assay based on plant responses to light (phototropism). Auxin has since been implicated in response to gravity (gravitropism) as well. The general mechanism proposed for auxin's involvement in tropistic responses is called the Cholodny–Went model. Under uniform illumination, auxin is distributed evenly across the growing region of the shoot. When a shoot is exposed to light coming from only one side, auxin becomes asymmetrically distributed across the growing region of the shoot and accumulates to higher concentrations on the side away from the light, causing the cells on the dark side to elongate more than those on the light side. This results in the shoot bending toward the light, thus producing the phototropic response.

The mechanism for shoot gravitropic responses is postulated to be similar to that described for phototropism. In roots, where auxin tends to inhibit cell elongation, auxin accumulates on the lower side in roots oriented perpendicularly to gravity, causing these cells to elongate less and the root to bend toward gravity.

Studies of cell growth, auxin distribution, and auxin transport in shoots and roots generally support the Cholodny–Went model, although some aspects remain controversial or poorly understood. Mutations affecting auxin response or auxin transport pathways frequently cause defects in responses to light and gravity, as does treatment with auxin transport inhibitors, confirming auxin's role in these tropisms.

The mechanisms by which tropic stimuli are transduced into asymmetric auxin distributions are not yet understood. Perception of the initial stimulus is presumed to result in lateral auxin transport and/or localized destruction, synthesis, or breakdown of IAA conjugates. In the root, both lateral auxin transport and the root tip-to-elongation zone transport pathway through the epidermal cells are likely to be important, because auxin transport inhibitors block normal root gravitropism. The PIN2 putative efflux carrier and the AUX1 putative influx transporter are likely participants in gravistimulus-induced lateral redistribution of auxin in roots. Both proteins localize to the epidermal and cortical cells in the root elongation zone, to which transported auxin from the root apex would be directed, and defects in the respective genes encoding either protein cause agravitropic roots in *Arabidopsis*.

J. IAA Interactions with Other Hormones

Auxin interacts with other known plant hormones in often complex ways to regulate many physiological and developmental processes. One of the best understood interactions is the induction of ethylene biosynthesis by auxin, which occurs because auxin induces expression of the enzyme involved in the rate-limiting step in ethylene biosynthesis, ACC synthase. Auxin-induced ethylene triggers a wide variety of effects, including promoting abscission (the shedding of leaves, flowers, and fruit), inhibition of bud growth, and inhibition or promotion of flowering (depending on the species). Ethylene in turn has been observed to inhibit auxin transport.

A second class of hormones with which auxin interacts is the cytokinins. In some processes, the interactions are antagonistic. For example, the ratio of cytokinins to auxins in plant tissue culture media controls whether roots or shoots are produced by callus tissue (a high auxin ratio leads to root growth, and a high cytokinin ratio leads to shoot growth). An antagonism between auxin and cytokinin also seems to control growth of axillary buds (lateral shoots): Auxin inhibits and cytokinin promotes this outgrowth. In other processes, the interactions are synergistic. For example, both hormones seem to be required to produce cell division in tissue cultures of many plant species.

K. Involvement of IAA in Microorganisms' Association with Plants

Many microorganisms whose life cycles include growth on plants have evolved to synthesize IAA as a way of manipulating their hosts. The best characterized are a number of bacteria that infect plants, including *Pseudomonas syringae* pv *savastonoi*, *Agrobacterium tumefaciens* (the cause of crown gall), *Agrobacterium rhizogenes* (the cause of hairy root disease), and *Erwinia herbicola* pv *gypsophila*. Bacteria most commonly synthesize IAA via the intermediates indole-3-acetamide and indole-3-pyruvate. The *iaaM* gene (from *Ag. tumefaciens*) encodes tryptophan monooxygenase, which converts tryptophan to indole-3-acetamide (IAM). IAM can then be converted, by the product of the *Ag. tumefaciens iaaH* gene or by endogenous plant hydrolases, into IAA. Various genes transferred from *Ag. rhizogenes* to the host plants also alter auxin metabolism and response.

Rhizobium and related species form nitrogen-fixing nodules on the roots of plants of the Leguminosae. Induction of the root cortical cell divisions that lead to nodule formation may involve IAA. Treatment of host plant roots with inhibitors of polar auxin transport, in the absence of bacteria, induces formation of empty nodules. Signaling molecules produced by the bacteria, called lipo-chitin oligosaccharides, have been found to produce local accumulation of auxin in roots of clover, probably by local inhibition of auxin transport.

V. AUXIN SIGNAL TRANSDUCTION

Cellular responses to auxin include cell division (e.g., in the root pericycle when lateral roots are initiated), cell differentiation (e.g., in provascular cells that become vascular tissue), and cell elongation (e.g., in tropic responses). The molecular mechanisms of cellular auxin response are still being elucidated, but several key themes have emerged. The importance of transcriptional control proteins and the involvement of ubiquitin-mediated protein degradation in auxin response now seem clear. Evidence for the involvement of phosphorylation events and membrane signaling in auxin response is also growing.

A. Auxin-Binding Proteins

Auxin signaling is presumed to begin with auxin binding to a receptor. Although a number of auxin-binding proteins have been identified, there is still no undisputed auxin receptor with a well-understood mechanism of action. The best-characterized auxin-binding protein is called auxin-binding protein 1 (ABP1), which has been identified and cloned in maize, *Arabidopsis,* and many other species. ABP1 is a protein of approximately 22 kDa that is initially synthesized with a signal sequence, indicating that it is co-translationally inserted into the endoplasmic reticulum. Following cleavage of the signal sequence, most of the protein is retained in the lumen of the endoplasmic reticulum via its C-terminal Lys-Asp-Glu-Leu (KDEL) sequence. A small amount of the protein may reach the plasma membrane and cell wall. ABP1 specifically binds IAA and active auxin analogues with relatively high affinity (K_d for IAA = 3.2 μM). Many lines of evidence support ABP1's role as an auxin receptor. For example, anti-ABP1 antibodies inhibit or mimic auxin-induced electrophysiological changes in protoplasts.

ABP1-derived peptides mimic auxin-induced electrophysiological changes. Overexpression of ABP1 induces auxin-dependent cell expansion in transgenic tobacco. ABP1 knockout mutants in *Arabidopsis* are lethal, with the homozygotes arresting at the early embryo stage, lacking the normal patterns of cell elongation. However, skepticism persists about ABP1's relevance as an auxin receptor because the protein lacks any obvious functional domains by which it might transmit a signal. Although it seems clear that ABP1 is important for auxin-regulated cell elongation, there may well be other auxin receptors involved in mediating other auxin responses.

B. Auxin-Induced Genes: The Aux/IAA Genes

Auxin application to plants alters the expression of many genes. At least four families of genes whose expression is rapidly induced by auxin have been identified in plants: the Small Auxin Up RNAs (SAURs), the GH3 family, the ACC synthase family, and the Aux/IAA family. Of these, the Aux/IAA genes have the best-characterized role in auxin response. The Aux/IAA proteins are encoded by large multigene families in both monocots and dicots. Transcription of most of the Aux/IAA genes is specifically induced in response to auxin and not to other hormones. In most cases, induction is detectable within 4 to 30 min after auxin treatment, although some of the genes are induced more slowly. The proteins encoded by these genes share four small domains of homology separated by variable regions that differ greatly in size, accounting for the 19 to 39 kDa range of predicted protein sizes. Aux/IAA proteins share two key characteristics of many regulatory proteins: They are localized to the nucleus and are short-lived. Direct tests show that some Aux/IAA proteins act as repressors of gene expression from auxin-inducible promoters. However, the Aux/IAA proteins most likely act not by binding DNA directly, but by interacting with other proteins (primarily auxin regulatory factors, or ARFs; see below) that bind DNA. This interaction occurs through domains 3 and 4 of the proteins, which are found in both the Aux/IAA proteins and the ARFs. Many auxin-response mutants in *Arabidopsis* have been found to have mutations in the Aux/IAA genes, confirming the significance of the Aux/IAA genes in auxin response. The Aux/IAA proteins may also play an important role in plants' responses to light.

C. Auxin-Response Factors

Analysis of the promoters of auxin-induced genes led to identification of conserved DNA sequence motifs that mediate auxin induction, called auxin-responsive elements or AuxREs. The minimal AuxRE identified in the promoter of the GH3 gene is 11 bp in length and includes the sequence TGTCTC. In the promoters of Aux/IAA genes, two conserved elements were identified, one of which contains the essential sequence TGTCCCAT.

The protein auxin-response factor 1 (ARF1) was first isolated by its ability to bind to and activate expression at a highly auxin-responsive synthetic promoter. ARF1 contains an N-terminal DNA-binding domain and two short C-terminal domains that are homologous to domains 3 and 4 of the Aux/IAA proteins. Subsequently, other ARFs were identified, and it is now known that the ARFs comprise a multigene family. The ARF proteins can dimerize with themselves, with other ARFs, or with Aux/IAA proteins, through binding of domains 3 and 4. *In vivo* evidence for the significance of the ARFs in auxin response has come from the phenotypes of mutants in three of the ARF genes. Mutants in the *MONOPTEROS/ARF5* gene are affected in auxin-related processes: Strong *mp* alleles are homozygous lethal, lacking a root and hypocotyl after germination and having severe defects in vascular development. Weak *mp* alleles also show defective vasculature combined with reduced levels of auxin transport in inflorescence stems. *ARF3* has been identified as *ETTIN*, mutations in which lead to defects in floral development. Mutations in *ARF7/NPH4/MSG1* alter tropic responses in the hypocotyl and reduce auxin sensitivity in the leaf and hypocotyl. It has been proposed that ARFs regulate a variety of downstream genes that are important in auxin-regulated processes such as vascular differentiation. DNA binding by ARFs can either activate or repress transcription from auxin-regulated promoters, depending on the ARF. ARF activity could be controlled by dimerization with other ARFs or with Aux/IAA proteins, which might act to prevent ARFs from binding to promoters.

D. Auxin and Membranes

Auxin has dramatic effects on the electrophysiology of plant cells. Both intact cells and protoplasts (plant cells with the cell walls removed) hyperpolarize

(develop a more negative membrane potential) within 10–30 min after treatment with active auxins. This response is primarily due to rapid activation of the plasma membrane H^+-ATPase. This protein pumps protons out of the cytoplasm and into the cell wall and extracellular space, resulting in acidification of the cell wall and alkalinization of the cytoplasm. Auxin-induced increases in H^+-ATPase activity appear to involve both activation of existing transporters and induction of increased expression of the H^+-ATPase gene. According to the acid growth hypothesis, this auxin-induced cell wall acidification is the primary mechanism by which auxin induces cell elongation. Cell wall acidification leads to cell wall "loosening," perhaps through activation of cell wall-modifying enzymes. Turgor pressure then stretches the cell wall and the cell expands, producing the rapid elongation as seen, for example, in stem or coleoptile sections immersed in auxin solutions.

Auxin affects membrane physiology in other ways as well. The effects on potassium channels seem to be especially important. In *V. faba* guard cells, which respond to auxin by an increase in turgor and subsequent stomatal opening, active auxins at concentrations up to 10 μM rapidly (within less than a second) produce an increased inward flow of potassium through potassium channels. Outward-directed potassium channels are also activated by auxins. Effects on ion channels have been demonstrated at the level of gene expression also. In maize coleoptiles, for example, auxin increases expression of an inward-directed potassium channel that appears to be necessary for continued elongation growth.

Ions and lipids known to be involved in other signal transduction pathways have also been implicated in auxin action, including calcium, phosphatidylinositols, and the products of phospholipase A_2. Definitive evaluation of the importance of these for auxin signal transduction awaits further studies.

E. Ubiquitin Pathway of Protein Degradation

Regulated protein degradation is important in many aspects of cell physiology, including progression through the cell cycle. Studies of *Arabidopsis* mutants with altered auxin responses have implicated the ubiquitin pathway in auxin response.

Ubiquitin is a highly conserved, 76-amino-acid protein that is found in all eukaryotes. It is covalently attached to target proteins to mark these proteins for degradation. Ubiquitin-activating enzyme (E1) activates ubiquitin and then transfers it to ubiquitin-conjugating enzyme (E2), which together with ubiquitin ligase (E3) attaches ubiquitin to lysines on specific target proteins. Multiubiquitin chains are formed on target proteins through continued action of the pathway. Ubiquitinated proteins are then, most commonly, targeted to the 26S proteasome, a large multisubunit cytoplasmic protease that degrades the target proteins and recycles the ubiquitins. Of the several known types of E3 ubiquitin ligases, one in particular has been implicated in auxin action. This is the multisubunit SCF^{TIR1} complex, composed of the proteins SKP1 (ASK1 in *Arabidopsis*), cullin/Cdc53, RBX1, and the F-box protein TIR1. The protein cullin is itself modified by attachment of a ubiquitin-like protein called RUB1; this modification is necessary for cullin activity. RUB1 is activated and then attached by the action of at least three enzymes: A dimer called AXR1/ ECR1 activates RUB1, and then the RUB-Conjugating Enzyme RCE1 attaches RUB1 to cullin. *Arabidopsis* plants with mutations in components of SCF^{TIR1} and in the RUB1 activation and conjugation pathway have been identified, and all of them confer altered auxin responses on the plants. Likely targets for auxin-regulated ubiquitin-mediated degradation are the rapidly turned-over proteins of the AUX/IAA family. Altered stability of these proteins could lead to changes in activity of the ARF transcription factors and thereby to changes in gene expression. Although it is unlikely that only auxin signal transduction requires this pathway, it does seem to play a critical role in auxin response.

F. Protein Kinases and Auxin Signal Transduction

Several lines of evidence suggest that protein kinases may be involved in auxin signaling, but as yet the pathway is unclear. In experiments using transiently transfected maize protoplasts, expression of a tobacco mitogen-activated protein kinase kinase kinase (MAPKKK) called NPK1 blocked auxin induction of an auxin-regulated promoter. Further experiments in *Arabidopsis* suggested the MAPKKK may normally function in stress response. Thus, the effects of auxin signal transduction may be opposed by stress-induced pathways. A MAP kinase activity that is very rapidly induced by auxin treatment has been identified in *Arabidopsis* root culture. The *RCN1* gene, which regulates auxin transport, encodes a protein phosphatase subunit, and the *PINOID* gene, which when mutated causes defects

in auxin transport, is a serine/threonine kinase. One model suggests that phosphorylation and dephosphorylation activities controlled by auxin may regulate degradation of the AUX/IAA proteins by the ubiquitin pathway.

VI. SUMMARY

Decades of research have shown that auxin is important in almost every aspect of plant development and physiology. Levels of free auxin are regulated by the interplay of pathways of biosynthesis, degradation, and conjugation. Distribution of auxin throughout the plant also requires polar auxin transport, whose molecular basis is at last becoming clear. Cellular auxin responses depend at least in part on transcriptional regulatory proteins that are encoded by multigene families and that show significant posttranslational regulation of activity via degradation and dimerization. Modern approaches combining many techniques are finally yielding insights into the complexity of auxin biochemistry, physiology, and cell biology.

Glossary

Arabidopsis thaliana A small member of the mustard family (Brassicaceae), commonly used as a model system for plant genetics, physiology, and molecular biology.

coleoptile The outermost sheathing leaf of a grass seedling, which serves as a protective sheath for the leaf plumule and shoot apical meristem.

hypocotyl The stem like axis between the seed leaf or leaves and the root in an embryo or seedling.

protein kinase An enzyme that adds a phosphate group to a target, usually as a means to control the activity of the target.

signal transduction The series of biochemical reactions that transform a signal (such as hormone binding to a receptor) into a cellular response (such as cell elongation or cell division).

tropism A growth response that is directionally oriented with respect to the stimulus.

Bombesin-like Peptides

ELIOT R. SPINDEL
Oregon National Primate Research Center

The entire bombesin-like peptide family includes the gastrin-releasing peptide subfamily, the neuromedin B subfamily, and the bombesin-related peptide family. Three bombesin-like peptide receptors are known to function in mammals. In conjunction with their peptide ligands, these receptors play roles in a wide array of activities in the brain, lungs, esophagus, and intestinal tract.

I. INTRODUCTION

The bombesin-like peptides were initially characterized in frog skin; then subsequently found to be widely distributed in mammals. Bombesin occurs in frogs of the *Bombina* species, and related peptides such as ranatensin occur in other amphibian species. Soon after its isolation, bombesin was found to have many potent central nervous system (CNS) effects in mammals, including effects on temperature regulation, grooming and scratching behaviors, appetite, heart rate, and gastric acidity regulation. Outside of the CNS, bombesin is a potent secretagogue for gastrin and other gastrointestinal hormones, a secretagogue for pancreatic exocrine secretion, and a stimulus for gastrointestinal (GI) growth. Early studies of bombesin used radioimmunoassays to establish that bombesin-like immunoreactivity (BLI) is widespread in brain, lung, and GI tract tissues. This prompted a search for mammalian homologues of bombesin; in 1979, McDonald *et al.*, using gastrin release as a bioassay, isolated a 27-amino-acid peptide from porcine gut. This peptide and bombesin had a similar C-terminus, thus the peptide was named gastrin-releasing peptide (GRP). In 1983, a second mammalian bombesin-like peptide, neuromedin B (NMB), was isolated from porcine spinal cord by Minamino *et al.* (Fig. 1). GRP was initially considered the mammalian homologue of bombesin, but when it was discovered that frogs have both GRP and bombesin it became clear that GRP and bombesin are in different subfamilies of the bombesin-like peptides. The bombesin-like peptides can be divided into three subfamilies—the GRP family, the NMB family, and the bombesin-related peptide (BRP) family (Fig. 1). At present, the BRP subfamily has been characterized only in amphibians but also likely occurs in mammals.

The two mammalian bombesin-like peptides, GRP and NMB, each have their own cognate receptors. The GRP and NMB receptors belong to the same seven-membrane-spanning domain superfamily and are highly homologous. BB4, a receptor for one form of frog bombesin (Phe-13 bombesin), has been cloned and is phylogenetically distinct from the GRP and NMB receptors. BRS-3, a third receptor for bombesin-like peptides, was cloned by Battey and co-workers from rat testes and by Gorbulev *et al.*, from pregnant guinea pig uterus. The affinity of this receptor for the known bombesin-like peptides is very weak, indicating that its endogenous ligand remains to be characterized. This receptor is most homologous to the frog BB4 receptor, suggesting that the ligand for the BRS-3 receptor will belong to the BRP subfamily.

Physiologically, the key functions of the bombesin-like peptides involve autonomic regulation, GI function, appetite control, and growth regulation. Bombesin-like peptides are also expressed in a variety of cancers and may be autocrine growth factors for cancers.

II. AMPHIBIAN BOMBESIN-LIKE PEPTIDES

The initial characterization of the bombesin-like peptides in frog skin and later detection in mammals are similar to the discovery of sauvagine, a corticotropin-releasing hormone (CRH)-like compound found in frog skin; the characterization of sauvagine led to the characterization of urocortin. Peptides in frog skin are located in cutaneous granular glands (Fig. 2) that are surrounded by smooth muscle. α-Noradrenergic stimulation causes contraction of the smooth muscle, resulting in secretion of the contents within the glands. These glands also contain multiple other peptides and nonpeptide compounds

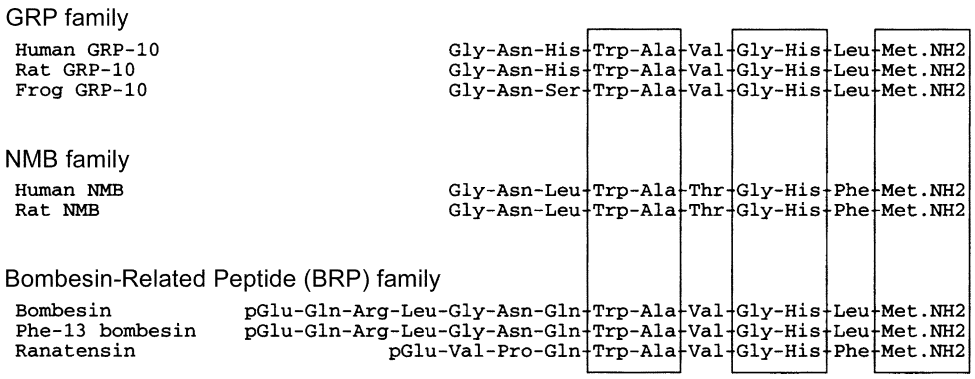

FIGURE 1 Representative members of each of the three subfamilies of bombesin-like peptides. Bombesin and ranatensin are amphibian; gastrin-releasing peptide (GRP) and neuromedin B (NMB) are mammalian. GRP-10 is the C-terminal decapeptide of GRP and contains the full biological activity of GRP. The grouping into families is based on phylogenetic analyses of prohormones.

that have been the sources of many pharmaceuticals. For example, the compound epibatidine, a highly potent nicotinic agonist, is found in these glands.

Different species of frogs have slightly different variants of bombesin-like peptides. For example, the peptide ranatensin (Fig. 1) comes from the frog *Rana pipiens*, whereas bombesin comes from the frog *Bombina orientalis*. Phylogenetic analysis of the mRNAs and prohormones that encode the peptides, however, shows that all the frog skin peptides are related and can be grouped in the same subfamily. Frogs also contain in their brain and gut GRP-like and NMB-like peptides that are distinct from the bombesin-related peptides in their skin. Within a given frog species, multiple forms of bombesin-related peptides occur in skin. For example, in *B. orientalis*, there are three forms of bombesin in skin, differing only by one or two amino acids but

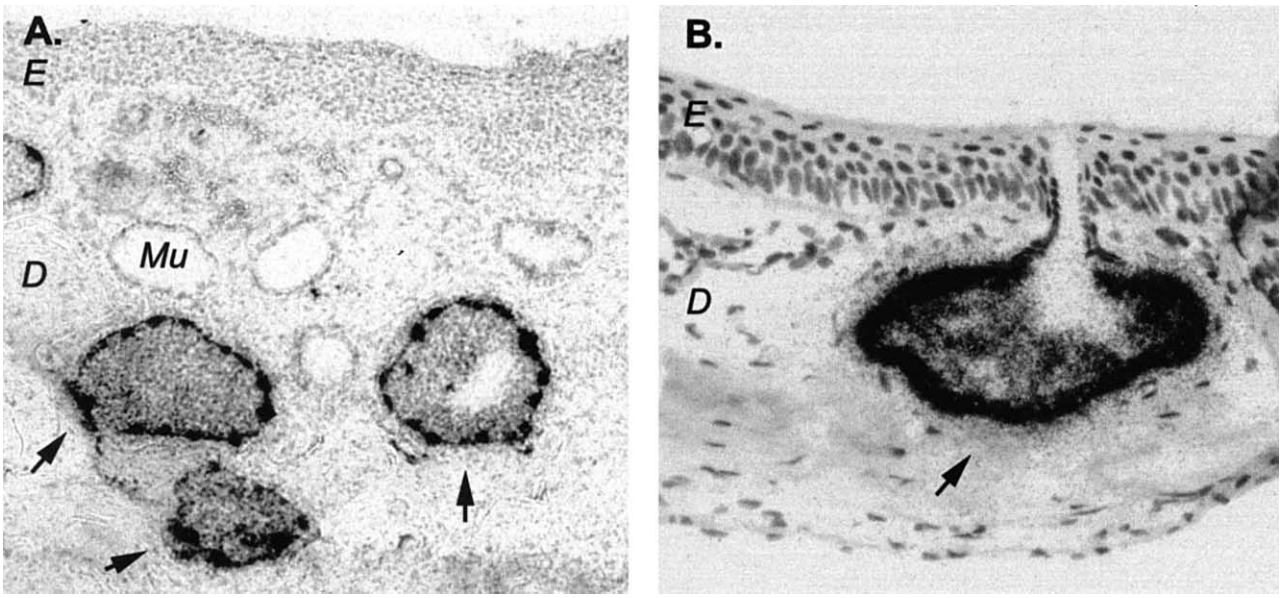

FIGURE 2 Bombesin-like peptide mRNA expression in frog skin. (A) Low-power view showing ranatensin mRNA expression in cutaneous granular glands in the skin of *Rana pipiens* (100 ×). (B) Higher power view showing bombesin expression in the skin of *Bombina orientalis* (200 ×). E, Epidermis; D, dermis; Mu, mucus gland; arrows point to peptide-containing glands.

arising from distinct genes. The frog *Phyllomedusa sauvagei* has two bombesin-related skin peptides, Phe-8 phyllolitorin and Leu-8 phyllolitorin, which differ by only a single amino acid. Interestingly, these two different peptides arise by RNA editing of a single gene transcript. The presence of multiple forms of bombesin-related peptides in frog skin is significant because it suggests that if these peptides occur in humans, they may similarly occur in multiple forms.

The three families of bombesin-like peptides in frogs all have distinct receptors. The frog GRP receptor is related to the mammalian GRP receptor and the frog NMB receptor is related to the mammalian NMB receptor; the BB4 class of receptors for the frog skin bombesin-related peptides has been cloned. It appears that there are multiple subtypes of BB4 receptors in frogs corresponding to the multiple subtypes of bombesin-related peptides in frogs. Phylogenetic analysis shows that the amphibian BB4 receptor is closest to the mammalian BRS-3 receptor. This raises the possibility that the BRS-3 receptor is the mammalian homologue of the BB4 receptor; if so, when the ligand for the BRS-3 receptor is discovered, it will be the mammalian counterpart of the frog skin bombesin-related peptides.

III. RECEPTORS FOR BOMBESIN-LIKE PEPTIDES

The receptors for the bombesin-like peptides are highly homologous seven-transmembrane, G-protein-linked receptors sharing an overall homology of 50–60% at the amino acid level. Each bombesin-like peptide has its own cognate receptor, but to date multiple subtypes for each receptor have not been identified. The most commonly used nomenclature for the bombesin-like peptide receptors is the NMB receptor, GRP receptor, BRS-3 receptor, and BB4 receptor. These receptors have also been assigned numbers and can also be, respectively, called the BB1, BB2, BB3, and BB4 receptors. The distributions of the specific receptors are related to the functions and distributions of their ligands (see later).

The GRP receptor, cloned in 1989 by Spindel and co-workers and by Battey and co-workers, was the first bombesin-like peptide receptor identified; subsequently, the remaining receptors were cloned, and careful pharmacology by Jensen and co-workers laid out the affinity of the receptors. Each receptor has the highest affinity for its cognate ligand in the range of 1–5 n*M* and has varying degrees of affinity for the other receptors. The BB4 receptor is least selective and the BRS-3 receptor is most selective. The approximate affinities of each receptor for the canonical bombesin-like peptides is shown in Table 1. Mutational analysis has shown that ligand affinity is controlled by a small number of key amino acid residues in each receptor. For example, in the GRP receptor, selectivity for GRP over NMB is controlled by two amino acid residues in the third extracellular domain. Highly specific antagonists such as [D-F_5-Phe^6,D-Ala^{11}]Bn(6–13)*O*-Me (BIM26226), 3-phenylpropanoyl-His^{20},D-Ala^{24}, Pro^{26}, Psi^{26,27}, Phe^{27} GRP(20–27) (BW2258U89), and [D-Phe^6]bombesin(6–14) ethylamide (readily available from commercial sources) have been developed for the GRP receptor, and selective antagonists for the NMB receptor, such as PD168368, are beginning to be developed. No selective antagonists for the BRS-3 and BB4 receptor have yet been described. Agonists are less selective, although design of a selective agonist for the BRS-3 receptor, [D-Tyr^6,(*R*)-Apa^{11}, Phe^{13}, Nle^{14}]Bn(6–14), has recently been described.

The bombesin receptors are all G-protein linked utilizing $G_{\alpha q}$ and $\beta\gamma$ to activate phospholipase C-β to hydrolyze phosphatidylinositol 4,5-bisphosphate (PIP_2) to for diacylglycerol (DAG) and inositol 1,4,5-trisphosphate ($InsP_3$). DAG, in turn, activates protein kinase C (PKC), and $InsP_3$ leads to increased

TABLE 1 Affinities of Bombesin-like Peptides for the Four Bombesin Receptor Subtypes[a]

Receptor	GRP	NMB	Bombesin	Phe-13 Bn	Nle-Bn(6–14)
GRP	2.5[b]	200	2.5	1	1
NMB	150	2[b]	25	1	2.5
Human BRS-3	>10,000	5000	>10,000	7000	2.5
Frog BB4	25	25	10	1[b]	1

[a]Nle-Bn(6–14), [D-Phe^6, β-Ala^{11}, Phe^{13}, Nle^{14}]Bn(6–14). Phe-13 Bn, Phe-13 bombesin. Affinities averaged from data of Nagalla *et al.* (1995), Mantey *et al.* (1997), and Katsuno *et al.* (1999).

[b]Cognate ligand–receptor interactions.

intracellular calcium. Activation of PKC and the increase in intracellular calcium lead to increases in gene transcription and cell growth. Activation of all of the bombesin-like receptors leads to cell growth and hence to the role of bombesin-like peptides as autocrine growth factors. (The role of bombesin-like peptides in neoplastic growth is discussed further in Section IV). The bombesin receptors also lead to activation of the small GTPases such as Rho and Rac, which provides another pathway for gene activation. The three mammalian bombesin receptors have all been knocked out, which has helped clarify the specific physiologic roles of each peptide.

IV. GASTRIN-RELEASING PEPTIDE

Gastrin-releasing peptide was the first mammalian bombesin-like peptide discovered. After it was discovered that amphibian bombesin stimulates the release of gastrin in mammals, gastrin release was used as a bioassay and a 27-amino-acid peptide was isolated from porcine stomach by McDonald and coworkers (Fig. 3). Subsequently, GRP has been isolated from multiple species, ranging from sharks, frogs, and mice to humans. The C-terminus of GRP is highly conserved across all species, the amino terminus less so. GRP circulates in two forms, a large form of 27 to 29 amino acids and a truncated 10-amino-acid form (GRP-10; Fig. 3). Both forms have roughly similar affinities for the receptor and the significance of the two forms is not clear, although GRP may be more resistant to proteolytic cleavage.

Like most neuropeptide hormones, GRP is processed from a larger prohormone. The amino acid sequence of GRP immediately follows the signal peptide and following the sequence of GRP is a C-terminal extension peptide of unknown function. GRP is cleaved from the prohormone by prohormone convertases and the C-terminus is amidated by the action of peptidylglycine α-amidating monooxygenase (PAM). Cleavage of GRP to GRP-10 is adjacent to a single arginine residue that is conserved in all known GRPs. Cleavage at the C-terminus of GRP is adjacent to two basic amino acids in all sequenced GRP prohormones.

A. Distribution

GRP is widely distributed in the brain, lung, and GI tract. In humans, the highest levels of GRP are found in fetal lung and in small-cell lung carcinoma (SCLC). In the developing lung, GRP is found in pulmonary neuroendocrine cells (PNECs) and the highest levels occur from 14 to 30 weeks of gestation. GRP can be detected in PNECs as early as 10 weeks into gestation, and RNA levels in 20-week fetal lungs are more than 200-fold higher than in full-term lungs. In humans, increased levels of GRP are also found in bronchopulmonary dysplasia and chronic obstructive pulmonary disease (COPD). In the gut, GRP is located primarily in intrinsic neurons, where it regulates gastrointestinal hormone release, pancreatic enzyme secretion, and smooth muscle contraction. In the brain, GRP is widely distributed. Highest levels of GRP are found in the hypothalamus (with highest levels in the suprachiasmatic nucleus and medial preoptic nucleus), the brain stem (with highest levels in the nucleus of the lateral solitary tract and the parabrachial nucleus), and the hippocampus, amygdala, and dentate gyrus. The distribution of the GRP receptor follows the terminal fields of GRP-containing neurons in the brain and closely tracks that of GRP.

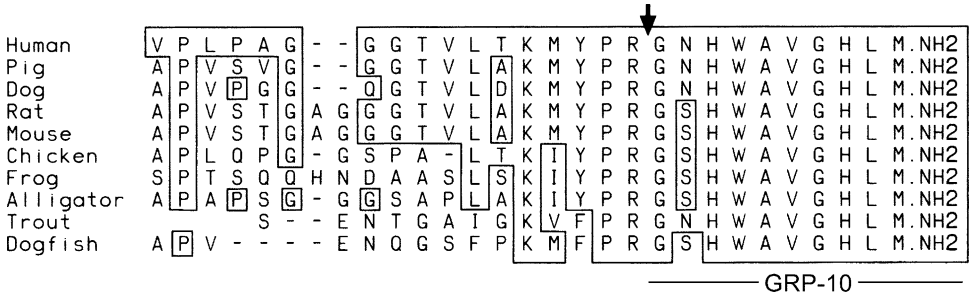

FIGURE 3 Sequences of gastrin-releasing peptides from various species. Amino acid identities with human gastrin-releasing peptide (GRP) are boxed. The GRP-10 sequence is underlined, and the arrow indicates the monobasic cleavage site for generation of GRP-10.

B. Central and Peripheral Functions of GRP

GRP in the brain plays a key role in autonomic function, having regulatory effects on thermoregulation, heart rate, activity, acid secretion, appetite, and energy balance. GRP stimulates acid secretion through a complex mix of central and peripheral effects, although peripheral mechanisms dominate. Consistent with this, both central and peripheral administration of GRP antagonists will lower acid secretion in both animals and humans. In the GI tract, GRP is released from intrinsic neurons, acting as a paracrine hormone to stimulate the release of many different GI hormones and to control GI motility. For example, GRP released from neurons in the stomach stimulates release of gastrin and somatostatin and GRP released in the pancreas stimulates release of exocrine enzymes. The effect of GRP on gastric smooth muscle contraction is abolished in the GRP knockout, showing this is mediated specifically by the GRP receptor.

In analyzing the central actions of GRP, given the overlapping affinities of ligands for the GRP and NMB receptor, the use of receptor knockout animals has been particularly important. Bombesin-like peptides have profound effects on thermoregulation, leading to decreases in body temperature when animals are injected with GRP or NMB and placed in the cold. Analysis with GRP and NMB knockout animals shows that the response to GRP is abolished in GRP receptor knockout animals and that much of the response to NMB is also blocked in GRP receptor knockout animals. This indicates that most of the effect of bombesin-like peptides on thermoregulation is mediated by the GRP receptor, although a small portion is mediated by the NMB receptor. GRP receptor (GRP-R) knockout mice also show significant changes in behavior, with increased motor activity in the knockouts and increased aggressive social behaviors, suggesting that GRP circuits affect these behaviors.

GRP also appears to play a key role in regulating development of memory for fear. Studies by Shumyatsky and co-workers have shown high levels of GRP in the amygdala and have demonstrated that development of memory to adverse conditioned stimuli is significantly increased in GRP knockout mice. This has significant implications for the possible role of GRP in anxiety and in mental disorders.

C. GRP and Appetite

Administration of bombesin-like peptides leads to decreased food intake. This is observed after both central and peripheral administration of the peptides, although peptides are more potent when administered into the brain, suggesting a central mechanism. Animals given bombesin cease eating sooner than normal and ingest smaller amounts of offered nutrients, suggesting an effect on satiety. Humans given bombesin similarly experience less hunger and an earlier feeling of fullness. This effect is mediated by the GRP receptor, because the effect of bombesin or GRP on appetite is eliminated in GRP receptor knockout animals and is unchanged in NMB receptor knockout mice. Chronic administration of bombesin to mice does not cause weight loss, perhaps because of development of tolerance. The effect of chronic administration of bombesin or GRP on human weight has not been reported.

D. GRP in Normal and Neoplastic Lung

GRP is expressed in high levels in developing primate lung tissue. GRP is localized in pulmonary neuroendocrine cells and GRP receptors are expressed in airway epithelial cells. GRP stimulates mitogenesis in airway epithelial cells, thus GRP is a paracrine growth factor for the developing lung. GRP also stimulates surfactant expression in the developing lung, thus it also plays a role in lung maturation. At the same time, excessive GRP secretion may play a role in the pathogenesis of bronchopulmonary dysplasia (BPD), because levels of GRP are increased in lungs from BPD patients and GRP is increased in urine in infants preceding the onset of BPD. Preliminary data from a baboon model of the disease suggest that antibodies against bombesin may prevent development of the most severe symptoms of BPD. The mechanism linking GRP to BPD is unknown, but likely involves stimulation of inappropriate and disordered lung growth.

In 1985, Minna and co-workers made the key observation that many small-cell lung carcinomas express GRP, express GRP receptors, and respond to GRP with growth. Thus, it was proposed that GRP is an autocrine growth factor for small-cell lung carcinoma. Consistent with this hypothesis, it was demonstrated that in a number of models, GRP antagonists or monoclonal antibodies to bombesin could slow tumor growth. Although GRP and GRP receptor expression is most common in SCLC, expression is also seen in non-small-cell lung carcinomas (NSCLCs). Clinical trials with a1nti-GRP antibodies and antagonists have been performed but have only proved helpful to a very

limited patient population. Clinical studies with broad-spectrum neuropeptide antagonists that block GRP receptors as well as other neuropeptide receptors are ongoing and may yield new therapeutic approaches. Other cancers, such as pancreatic and colon cancer, express GRP receptors and thus may also be targets for therapies that target the GRP receptor. Because a relatively large percentage of SCLC express GRP, measurement of GRP prohormone in blood has been used as tumor marker for SCLC.

V. NEUROMEDIN B

Neuromedin B was initially isolated by Minamino and co-workers in 1983 from porcine spinal cord. Neuromedin B circulates in both a large 32-amino-acid form (NMB-32) and a nonapeptide form (NMB; Fig. 1). The relation between NMB-32 and NMB is similar to that of GRP and GRP-10, with the sequence of NMB-32 immediately following the signal peptide in the NMB prohormone and a single monobasic cleavage for the cleavage of NMB from NMB-32. In all species analyzed to date, the sequence of the nonapeptide form of NMB is identical.

The receptor for NMB is highly homologous to the GRP receptor, with only a few amino acids conferring selectivity for NMB over GRP in the receptor. Signal transduction mechanisms for the NMB receptor are the same as for the GRP receptor. The original evidence for a distinct NMB receptor came from studies of ligand binding in the esophagus by Jensen and co-workers, which showed clearly different affinities for GRP and NMB. The esophagus remains one of the few peripheral tissues with a distinct role for NMB. Specific nonpeptide NMB receptor antagonists have been recently developed (PD16838 and PD165929).

A. Distribution

In the brain, NMB has a distribution distinct from that of GRP. Highest levels are found in the olfactory cortex, substantia nigra, and somatosensory regions, including the principal sensory nucleus of the brain stem, reticular formation, and central raphe. High levels are also found in the trigeminal nucleus and dorsal root ganglion. NMB is also present in the pituitary and is found in nerves innervating the esophagus and intestines. Like GRP, NMB occurs in some small-cell lung carcinomas.

B. Central and Peripheral Functions of NMB

Analyses of GRP and NMB receptor knockout mice have revealed remarkably few functions for NMB. Most effects of injected NMB are abolished in the GRP receptor knockout mouse, indicating that most effects of NMB are mediated by NMB cross-reacting with the GRP receptor. These studies have demonstrated that NMB appears to have no specific effect on appetite or contraction of the gut and only a small effect on thermoregulation. In fact, the NMB receptor knockout mouse shows remarkably little phenotype, with no changes in activity, appetite, or social behavior, as is observed in the GRP knockout. The NMB knockout does show mild changes in stress responses mediated by serotoninergic neurons, consistent with localization of NMB in dorsal raphe neurons. Characterized distinct functions for NMB to date are primarily localized to the esophagus, where NMB affects contractility and motility, and to sensory functions in the peripheral nervous system. In the pituitary, NMB may modulate thyroid-stimulating hormone (TSH) secretion. In the subset of SCLCs that express NMB, NMB also appears to be an autocrine growth factor for SCLCs, although expression of NMB by SCLCs occurs less frequently compared to GRP expression.

VI. BRS-3

The BRS-3 receptor remains the intriguing mystery of the bombesin-like peptide family. The BRS-3 receptor was cloned by Battey and co-workers from a testes library and by Gorbulev and co-workers from a uterus library prepared from pregnant guinea pigs. The endogenous ligand for the BRS-3 receptor is unknown. Although none of the known natural bombesin-like peptides have much affinity for the BRS-3 receptor, the BRS-3 receptor is clearly a receptor for bombesin-like peptides based on its high homology to the other bombesin-like peptide receptors. This relationship is further confirmed by the fact that mutation of four amino acids in the BRS-3 receptor increases affinity for GRP 100-fold. Signal transduction mechanisms for the BRS-3 receptor are similar to those for the other bombesin-like peptide receptors.

Although the endogenous ligand for the BRS-3 receptor is unknown, the synthetic bombesin-like peptide [D-Tyr^{6}, Ala^{11}, Phe^{13}, Nle^{14}]Bn(6–14) has nanomolar affinity for the BRS-3 receptor (Table I). [D-Tyr^{6}, Ala^{11}, Phe^{13}, Nle^{14}]Bn(6–14) also has nanomolar affinities for all of the known

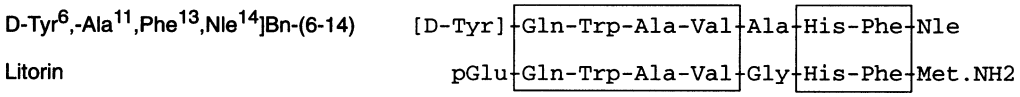

FIGURE 4 Relationship between a synthetic BRS-3 agonist and the frog bombesin-like peptide litorin. Boxed residues show conservation between the two peptides. Nle, Norleucine.

bombesin-like peptides. [D-Tyr^6, -Ala^{11}, Phe^{13}, Nle^{14}]Bn(6–14) shows significant homology to the frog skin peptide litorin, which suggests that the BRS-3 ligand resembles one of the known frog skin bombesin-like peptides (Fig. 4). Derivatives of [D-Tyr^6, Ala^{11}, Phe^{13}, Nle^{14}]Bn(6–14) that are more selective for BRS-3 have been developed and will be valuable tools in defining the function of the BRS-3 system.

The BRS-3 receptor has a highly limited distribution; it is expressed in the uterus, in the testes, and in the hypothalamus. Levels of expression in the uterus increase during pregnancy. In the hypothalamus, BRS-3 expression is found in the paraventricular, arcuate, striohypothalamic, and dorsal hypothalamic nuclei and in the lateral preoptic areas and the lateral and posterior hypothalamic nuclei.

A. Central and Peripheral Functions of BRS-3

What makes the BRS-3 receptor so interesting is that, despite the limited distribution of BRS-3, BRS-3 knockout mice show metabolic defects and become obese. In contrast to the GRP knockouts, which show defects in appetite control and satiety, the BRS-3 knockout shows abnormalities in energy regulation. BRS-3 knockout mice develop mild obesity, mild hypertension, decreased glucose tolerance, elevated levels of insulin, and reduced metabolic rate. BRS-3 mice also show increased levels of leptin. Exact details of how the BRS-3 receptor mediates these changes remain to be determined, although it has been proposed that the changes may be secondary to changes in glucose metabolism. Clearly, investigation into this pathway will be facilitated by identification of the BRS-3 ligand.

VII. SUMMARY

There are three known mammalian bombesin-like peptide receptors, the GRP receptor, NMB receptor, and the BRS-3 receptor. GRP is distributed in the brain, gut, and lung and regulates autonomic function, appetite, lung development, and GI hormone secretion. GRP also affects both normal and neoplastic lung growth. NMB is distributed in the brain and esophagus, but the functions of NMB remain poorly characterized. The endogenous ligand for the BRS-3 receptor has not yet been characterized, but may be related to the bombesin-like peptides that occur in frog skin. The BRS-3 receptor is involved in energy balance and its further study may provide new therapeutic approaches to obesity.

Glossary

bombesin-related peptides Members of the bombesin-like peptide subfamily; phylogenetically related to amphibian bombesin and to date have been found only in frogs.

bronchopulmonary dysplasia Chronic lung disease that can occur in premature infants; characterized by abnormal lung structure, tachypnea, and continuing need for supplemental oxygen.

peptidylglycine α-amidating monooxygenase Enzyme that synthesizes the amino-terminal amide group on neuropeptides through use of the nitrogen from the adjacent glycine residue.

prohormone Protein precursor to the active peptide hormone; must be proteolytically cleaved and enzymatically processed to yield the active hormone.

pulmonary neuroendocrine cells Airway epithelial cells that secrete a variety of neuropeptides, growth factors, and amines; may also be involved in oxygen sensing.

RNA editing Process of making posttranscriptional changes in the RNA sequence by enzymatic mechanisms; in a classic example, this process is involved in the formation of different forms of the glutamate receptor.

Bone Morphogenetic Proteins

DI CHEN, MING ZHAO, AND GREGORY R. MUNDY
University of Texas Health Science Center

Bone morphogenetic proteins, composed of ~400–525 amino acids, comprise one subset of the transforming growth factor-β superfamily. They are closely related structurally to other subsets, but are distinguished by a capacity to stimulate ectopic bone formation in rodents. After binding to their receptors, they play a role in bone and cartilage development.

I. DISCOVERY OF BMPS

Bone morphogenetic proteins (BMPs) are members of the transforming growth factor-β (TGF-β) superfamily. BMPs were originally identified from bone matrix using an ectopic bone formation assay. The activity of BMPs was first identified in the late 1950s, but the proteins responsible for bone induction remained unknown until the purification of bovine BMP-3 (osteogenin) and cloning of human BMP-2 and -4 in the late 1980s. The purification of BMPs was completed using the rat ectopic bone formation assay. This assay involves combining the sample containing the unknown protein to be assayed with demineralized rat bone matrix, which has been treated with dissociative agents such as guanidine and urea to remove all of the endogenous BMP activity. This combination is then implanted subcutaneously in rats, and after 1–2 weeks, formation of new cartilage and bone is detected histologically. Using this bioassay, BMPs were purified and sequenced. Purifying growth regulatory factors present in trace amounts in bone tissue to homogeneity using a slow and cumbersome *in vivo* bioassay was an amazing feat.

To determine the biological activities of each individual BMP member, a cloning approach was

Bone Morphogenetic Proteins

DI CHEN, MING ZHAO, AND GREGORY R. MUNDY
University of Texas Health Science Center

Bone morphogenetic proteins, composed of ~400–525 amino acids, comprise one subset of the transforming growth factor-β superfamily. They are closely related structurally to other subsets, but are distinguished by a capacity to stimulate ectopic bone formation in rodents. After binding to their receptors, they play a role in bone and cartilage development.

I. DISCOVERY OF BMPS

Bone morphogenetic proteins (BMPs) are members of the transforming growth factor-β (TGF-β) superfamily. BMPs were originally identified from bone matrix using an ectopic bone formation assay. The activity of BMPs was first identified in the late 1950s, but the proteins responsible for bone induction remained unknown until the purification of bovine BMP-3 (osteogenin) and cloning of human BMP-2 and -4 in the late 1980s. The purification of BMPs was completed using the rat ectopic bone formation assay. This assay involves combining the sample containing the unknown protein to be assayed with demineralized rat bone matrix, which has been treated with dissociative agents such as guanidine and urea to remove all of the endogenous BMP activity. This combination is then implanted subcutaneously in rats, and after 1–2 weeks, formation of new cartilage and bone is detected histologically. Using this bioassay, BMPs were purified and sequenced. Purifying growth regulatory factors present in trace amounts in bone tissue to homogeneity using a slow and cumbersome *in vivo* bioassay was an amazing feat.

To determine the biological activities of each individual BMP member, a cloning approach was

taken to obtain molecular clones corresponding to each of the proteins present in the purified extract. Based on the BMP sequence information, oligonucleotide probes were synthesized and used to screen bovine genomic libraries. Once bovine genes corresponding to the proteins were obtained, they were then used to obtain human cDNA clones encoding each protein within the extract. A large number of clones were identified by this strategy. All of the BMPs have homologous amino acid sequences. To date, around 20 BMP family members have been identified and characterized.

II. CHEMICAL STRUCTURE OF BMPS

BMPs are 30- to 38-kDa homodimers that are synthesized as prepropeptides of approximately 400–525 amino acids. The mature C-terminal region of 100–140 amino acid residues is released from a propeptide region by cleavage at an Arg-X-X-Arg sequence. The secretion of the C-terminal mature segment is as a dimer, sometimes disulfide linked. Although homodimers are considered the standard form, there are natural heterodimers with similar bioactivity. It has been reported that a heterodimer composed of BMP-4 and BMP-7 is a potent inducer of mesoderm. All BMPs have similar sequences, including seven similarly spaced cysteine residues located in the mature region of the proteins. Six of seven cysteine residues on each BMP subunit form three intrachain disulfide bonds, with the remaining residue forming an interchain bridge to create the dimer. Many of the BMPs are glycosylated in both the mature and the propeptide regions, as determined by biochemical characterization and the presence of appropriate carbohydrate addition sites in the presumed amino acid sequence. Unlike TGF-β, secreted BMP proforms apparently do not form latent complexes with their mature counterparts. There is considerable cross-species bioactivity for the BMPs. The BMPs have been grouped into subsets based on amino acid sequence homology. The groupings are suggested to be as follows: (1) BMP-2 and BMP-4, (2) BMP-3 and BMP-3b, (3) BMP-5, BMP-6, BMP-7, and BMP-8, (4) BMP-9 and BMP-10, (5) BMP-12, BMP-13, and BMP-14, and (6) BMP-11 and growth/differentiation factor 8 (GDF-8).

The production of BMPs by recombinant methods has allowed the activities of each molecule to be investigated *in vitro* and *in vivo*. These recombinant BMPs have been produced using both a mammalian cell expression system and an *Escherichia coli* expression system. BMPs have been implicated in a variety of functions. BMPs induce the formation of both cartilage and bone. During the process of bone formation, BMPs create a rudimentary environment that is conducive to the development of functional bone marrow. In addition, BMPs play a role in a number of nonosteogenic developmental processes. BMP-2 can direct the development of neural crest cells into neuronal phenotypes, and BMP-4 and BMP-7 specifically induce a sympathetic adrenergic phenotype. BMP-4 and GDF-8 give direction to somite development by inhibiting the process of myogenesis. BMPs also appear to be responsible for normal dorsal/ventral patterning. BMP-4 specifies the development of ventral structures (e.g., skin from ectoderm and connective tissue/blood from mesoderm). Dorsal structures (nervous system and muscle) apparently appear when BMP-4 signals are interrupted through the activities of binding proteins. In the limb bud, and as part of the fibroblast growth factor 4 (FGF-4) and sonic hedgehog (Shh) interaction, BMP-2 apparently inhibits limb bud expansion and induces the formation of chondrocyte and osteoblast precursors.

III. RECEPTORS FOR BMPS

BMPs signal through serine/threonine kinase receptors that are composed of type I and type II subtypes. Three type I receptors have been shown to bind BMP ligands, including type IA and IB BMP receptors [BMPR-IA (ALK-3) and BMPR-IB (ALK-6)] and type IA activin receptor (ActRIA or ALK-2). Three type II receptors for BMPs have also been identified and they include type II BMP receptor (BMPR-II) and types II and IIB activin receptors (ActRII and ActRIIB). Whereas BMPR-IA, BMPR-IB, BMPR-II, and ActRIA are specific to BMPs, ActRII and ActRIIB are also signaling receptors for activins. These receptors are expressed differentially in various tissues. Ligand–receptor cross-interactions are observed among the BMP, activin, and TGF-β receptor family members.

IV. SIGNAL TRANSDUCTION PATHWAY

For the TGF-β family, ligands bind to type II receptors in the absence of type I receptors. Type I receptors can bind ligands only in the presence of type II receptors. However, BMPs bind weakly to the type I receptors in the absence of type II receptors. In the presence of type II receptors, the binding of BMPs

to type I receptors is accelerated. The type II BMP receptor kinase transphosphorylates the G_s domain in the type I receptor, which leads to activation of the type I receptor kinase. Type II receptor is a primary binding protein for ligands, and the type I receptor acts as an effector in signal transduction. This notion is supported by the observation that mutation of glutamine to aspartic acid in the G_s domain of the type I BMP receptor results in a receptor with a constitutively activated kinase. In these mutants, signals are transduced from the type I BMP receptor in the absence of ligand and type II BMP receptor.

The type I BMP receptor substrates include a recently identified protein family, the Smad proteins, which play a central role in the relay of BMP signals from the receptor to target genes in the nucleus. Smad1, Smad5, and Smad8 are phosphorylated by BMP receptors in a ligand-dependent manner. After release from the receptor, Smad proteins associate with the related protein Smad4, which acts as a shared partner. This complex translocates into the nucleus and participates in gene transcription with other transcription factors.

Activation of specific genes by Smads is conducted by interaction with specific DNA-binding proteins. One of the transcription factors that interact with Smad1 has been identified as a homeodomain DNA-binding protein, Hoxc-8. Hoxc-8 serves as a transcriptional repressor for osteopontin gene transcription. Interaction of Smad1 with Hoxc-8 relieves the repressive activity of Hoxc-8 and activates osteopontin gene transcription. Another protein, which interacts with Smad1 and Smad5 in the nucleus, is core-binding factor α1 (Cbfα1). Cbfα1 is an osteoblast-specific transcription factor and plays a central role in osteoblast differentiation and bone formation. Targeted disruption of Cbfα1 in mice reveals that Cbfα1 expression is absolutely required for bone development *in vivo*. A complete lack of both endochondral and intramembranous ossification, with an absence of mature osteoblasts throughout the body, is observed in homozygous Cbfα1-deficient mice.

V. DISORDERS ASSOCIATED WITH BMPS

Studies of naturally occurring mutations of BMPs and BMP receptors have shown that BMPs also play important roles in several inherited diseases. Disruption of the gene for BMP-5 in mice results in short ears and a wide range of skeletal defects, including reductions in long bone width and the size of several vertebral processes and an overall lower body mass. Mutations in growth/differentiation factor-5 (GDF-5; also named CDMP-1 and BMP-11) genes result in brachypodism in mice and chondrodysplasia in humans. The BMP-5 and GDF-5 genes are localized to chromosome 2 in mice and to chromosome 20 in humans. GDF-5 has been shown to bind to BMPR-IB specifically, and null mutations in the BMPR-IB gene cause a skeletal phenotype similar to that observed in GDF-5 mutant mice.

Fibrodysplasia ossificans progressiva (FOP) is an extremely rare and disabling genetic disorder characterized by congenital malformations of the great toes and by progressive heterotopic endochondral ossification in predictable anatomical patterns. Mutations in the *noggin* gene, which encodes a BMP-binding protein, have been found in FOP patients and linked to the FOP disease. In addition, ectopic expression of BMP-4 is also found in FOP patients. Familial primary pulmonary hypertension is a rare autosomal dominant disorder that has been mapped to chromosome 2q33. Monoclonal plexiform lesions of proliferating endothelial cells in pulmonary arterioles are the characteristic phenotype of this disease. These lesions lead to elevated pulmonary artery pressure, right ventricular failure, and death. Genotyping multiple families with this disorder has shown that BMPR-II mutations are found in these patients. Mutations in GDF-9 and GDF-9b genes have been found in patients with premature ovarian failure and polycystic ovary syndrome. Overexpression of BMP-2, -4, -5, and BMPR-IA is associated with malignancy of the oral epithelium, and overexpression of BMP-3 has been described in prostate cancer cells. Mutations in the BMPR-IB gene are associated with increased ovulation rates in Booroola Mérino ewes and in sheep. Female mice deficient in BMPR-IB are infertile due to a constellation of defects, including irregular estrous cyclicity, impaired pseudopregnancy response, severe defects in cumulus cell expansion, and insufficient uterine endometrial gland development.

VI. NULL MUTATIONS OF BMP LIGANDS AND RECEPTORS

To understand the roles of BMP ligands and BMP receptor signaling in embryonic development and in postnatal life, null mutations of BMP ligands and BMP receptors have been created and phenotypic changes in these animal models have been extensively studied. Mice deficient for BMP-2 and BMP-4 are

nonviable. Homozygous BMP-2 mutant embryos die between days 7.0 and 10.5 of gestation and have defects in cardiac development, manifested by the abnormal development of the heart in the exocoelomic cavity. Homozygous BMP-4 mutant embryos die between days 6.5 and 9.5 and show little or no mesodermal differentiation. BMP-7-deficient mice die shortly after birth because of poor kidney development. Histological analysis of mutant embryos at several stages of development reveals that metanephric mesenchymal cells fail to differentiate, resulting in a virtual absence of glomerulus in newborn kidneys. In addition, BMP-7-deficient mice have eye defects that appear to originate during lens induction. BMP-6-deficient mice are viable and fertile and show no overt defects in tissues known to express BMP-6 mRNA. BMP-6 is mainly expressed in hypertrophic cartilage. Because BMP-2 and BMP-6 are coexpressed in this tissue, BMP-2 may functionally compensate in BMP-6 null mice. Growth/differentiation factor-8 (GDF-8, myostatin) is expressed specifically in developing and adult skeletal muscle. During early stages of embryogenesis, GDF-8 expression is restricted to the myotome compartment of developing somites. At later stages and in adult animals, GDF-8 is expressed in many different muscles throughout the body. GDF-8 null mutant mice are significantly larger compared to wild-type mice and show a large and widespread increase in skeletal muscle mass.

Null mutation of the BMPR-IA gene causes embryonic lethality in mice. Animals die at embryonic day 9.5. Homozygous mutants with morphological defects are first detected at day 7.0. No mesoderm forms in the mutant embryos, suggesting that BMPR-IA is essential for the inductive events that lead to the formation of mesoderm during gastrulation. Mice lacking BMPR-IB are viable and exhibit defects in the appendicular skeleton. In BMPR-IB-deficient mice, proliferation of prechondrogenic cells and chondrocyte differentiation in the phalangeal region are markedly reduced. In adult mutant mice, the proximal interphalangeal joint is absent and the phalanges are replaced by a single rudimentary element, but the distal phalanges are unaffected. The lengths of the radius, ulna, and tibia are normal, but the metacarpals/metatarsals are reduced. The appendicular defects in BMPR-IB mutant mice resemble those seen in mice homozygous for the GDF-$5^{bp\text{-}j}$ null allele of the GDF-5 locus. Because GDF-5 has been shown to play a critical role in cartilage formation and binds BMPR-IB with high affinity, these results suggest that BMPR-IB plays a nonredundant role in cartilage formation *in vivo*. BMP ligands may utilize multiple type I receptors to mediate their signaling during bone formation. This hypothesis is supported by observations in BMPR-IB and BMP-7 double mutant mice. In the double mutant, severe appendicular skeletal defects have been observed in the forelimbs and hindlimbs. The ulna is nearly absent and the radius is shortened. Because BMP-7 binds efficiently to both BMPR-IB and ActRIA, it is conceivable that BMPR-IB and ActRIA play important synergistic or overlapping roles in bone formation *in vivo*.

VII. PHYSIOLOGIC ROLES OF BMPS

Physiologic roles of BMPs and BMP receptor signaling on normal bone formation have also been studied. Injection of BMP-2 locally over the surface of calvariae of mice induces periosteal new bone formation on the surface of calvariae of mice without a prior cartilage phase. Systemic administration of BMP-6 increases trabecular bone volume and bone formation rates in mice. In the transgenic mice that express a dominant-negative truncated BMPR-IB driven by the osteoblast-specific type I collagen promoter, the bone mineral density, the static bone volume, and the dynamic bone formation rates are decreased, suggesting that BMP receptor signaling plays an important role in normal postnatal bone formation.

VIII. BMPS AS POTENTIAL THERAPIES

The osteoinductive capacity of BMPs has been demonstrated in preclinical models, and the efficacy of BMPs for the treatment of orthopedic and dental patients is now being evaluated in clinical trials. The clinical applications of recombinant BMP-2 and BMP-7 are being studied most extensively. Many of the animal models used to evaluate the capacity of BMPs to heal bone defects have utilized critical-sized defects. In these animal models, bone defects are large enough that they will not heal without a therapeutic intervention. This setting facilitates analysis of the ability of a BMP to induce bone. Recombinant human BMP-2 combined with a variety of matrices has been shown to heal defects in a canine mandibular defect model. Healing of long bone critical-sized defects by BMP-2 has been demonstrated in several species, including rats, rabbits, dogs, sheep, and nonhuman primates. The implantation of BMP-7 containing bovine collagen matrix preparations restored large

diaphyseal segmental defects in monkeys, rabbits, and dogs, leading to the regeneration of new bone that is fully functional biologically and biomechanically. Osteochondral defects are the common end point for several types of joint diseases, such as degenerative arthritis, infection, and trauma. Preparations of BMP-7 in conjunction with a type I collagen carrier induces autologous cells and repairs iatrogenic osteochondral defects in rabbits. These results suggest that BMP-7 may be useful in articular cartilage repair. Both BMP-2 and BMP-7 have been shown to induce new dentine formation and have a potential application as a substitute for root canal surgery.

Glossary

bone formation Comprises distinct processes involving osteoblast proliferation, differentiation, and mineralization at sites of prior resorption. Two types of bone are formed in humans: bone formed immediately after a cartilage phase in growing long bones at epiphyses (endochondral bone formation) and bone formed on periosteal surfaces in calvarial and scapular bones (intramembranous bone formation). Cellular events in bone formation are regulated by ambient concentrations of transforming growth factor-β superfamily members as well as by other growth regulatory factors.

bone morphogenetic protein receptors Serine/threonine kinase receptor complexes of type II and type I components, responsible primarily for ligand binding and signal transduction, respectively.

Smads Signal transduction molecules in the bone morphogenetic protein signal transduction pathway; responsible for transmitting the signal generated by ligand binding to the receptor through the cytoplasm to the nucleus in order to activate specific gene expression.

transforming growth factor-β superfamily Large group of structurally related peptides present in the bone matrix and other tissues.

Brain-Derived Neurotrophic Factor

DEVIN K. BINDER

University of California, San Francisco

Brain-derived neurotrophic factor is a protein that is active in components of the central nervous system, particularly the hippocampus. It is important in maintaining viability and function of hippocampal and cerebral cortical neurons, axons, and dendrites. Because of its role in synaptic transmissions, brain-derived neurotrophic factor is of great interest for possible therapeutic applications in neurodegenerative and neuropsychiatric disorders.

I. INTRODUCTION

Brain-derived neurotrophic factor (BDNF) is a member of the neurotrophin family of neurotrophic factors. Originally purified from pig brain, it was shown to have survival-promoting action on a subpopulation of dorsal root ganglion neurons. There is a strong homology between the amino acid sequences of BDNF and nerve growth factor (NGF), the first neurotrophin described for its trophic (survival- and growth-promoting) effects on sensory and sympathetic neurons. Since the discovery of NGF in the early 1950s by Rita Levi-Montalcini and Viktor Hamburger and the discovery of BDNF by Yves Barde and colleagues in 1982, other members of the neurotrophin family have been discovered, including neurotrophin-3 (NT-3) and neurotrophin-4/5 (NT-4/5). Each factor appears to have a distinct profile of trophic effects on subpopulations of peripheral nervous system (PNS) and central nervous system (CNS) neurons.

II. STRUCTURE

The mature form of human BDNF has been mapped to chromosome 11 and shares about 50% amino acid identity with human NGF, NT-3, and NT-4/5. The structure of each neurotrophin contains three elements: (1) a signal peptide following the initiation codon, (2) a pro-region containing an N-linked glycosylation site and a proteolytic cleavage site for furin-like pro-protein convertases, followed by the mature sequence, and (3) a distinctive three-dimensional structure containing two pairs of antiparallel β-strands and cysteine residues in a cystine knot motif. Mature neurotrophins are noncovalently linked homodimers with molecular mass about 28 kDa. Dimerization appears essential for NT receptor activation.

III. SIGNALING

Each neurotrophin binds one or more high-affinity receptors [the trk receptors] ($K_d \sim 10^{-11}$ M). The trk proteins are transmembrane receptor tyrosine kinases (RTKs) homologous to other RTKs, such as the epidermal growth factor (EGF) receptor and insulin receptor family. Signaling by receptor tyrosine kinases involves ligand-induced receptor dimerization and dimerization-induced trans-autophosphorylation. Receptor autophosphorylation on multiple tyrosine residues creates specific binding sites for intracellular target proteins, which bind to the activated receptor via SH2 domains. For the neurotrophin family, these target proteins have been shown to include PLC-γ1 (phospholipase C), p85 (the noncatalytic subunit of phosphatidylinositol 3-kinase), and Shc (SH2-containing sequence); activation of these target proteins can then lead to a variety of intracellular signaling cascades such as the Ras–mitogen-activated protein (MAP) kinase cascade and phosphorylation of the cyclic AMP response element binding protein (CREB). Binding specificity is conferred via the juxtamembrane immunoglobulin (Ig)-like domain of the extracellular portion of the receptor in the following pattern: trkA is the high-affinity receptor for NGF (with low-affinity binding by NT-3 in some systems), trkB is the high-affinity receptor for BDNF and NT-4/5 (with lower affinity binding by NT-3), and trkC is the high-affinity receptor for NT-3.

All of the neurotrophins bind to the low-affinity neurotrophin receptor, designated $p75^{NTR}$ ($K_d \sim 10^{-9}$ M). $p75^{NTR}$ has a glycosylated extracellular region involved in ligand binding, a transmembrane region, and a short cytoplasmic sequence lacking intrinsic catalytic activity. It is related to proteins of the tumor necrosis factor receptor (TNFR) superfamily. Neurotrophin binding to $p75^{NTR}$ is linked to several intracellular signal transduction pathways, including nuclear factor-κB (NF-κB), Jun kinase, and sphingomyelin hydrolysis. $p75^{NTR}$ signaling mediates biologic actions distinct from those of the high-affinity trk receptors, notably the initiation of programmed cell death (apoptosis).

IV. LOCALIZATION, TRANSPORT, AND RELEASE

BDNF mRNA as well as the mRNA encoding the high-affinity receptor for BDNF (trkB) have a widespread distribution in the central nervous system. In parallel, BDNF protein immunoreactivity is also widespread, and is localized in neuronal cell bodies, axons, and dendrites. Like BDNF mRNA, constitutive BDNF protein expression is particularly high in the hippocampus, where the mossy fiber axons of dentate granule cells display intense BDNF immunoreactivity.

Unlike the classical target-derived trophic factor model in which neurotrophins such as NGF are retrogradely transported, there is now abundant evidence that BDNF is also anterogradely transported in the brain. Biochemical studies demonstrate that endogenous BDNF may be packaged in a releasable vesicular pool, and recent evidence indicates that neurotrophins are released acutely following neuronal depolarization.

V. BDNF AND DEVELOPMENT

The classical view of neurotrophin function, derived initially from studies of NGF, includes effects on growth and survival of neurons, and indeed BDNF has been shown to be necessary for the survival of some neurons during vertebrate development. Certain peripheral sensory neurons, especially those in vestibular and nodose-petrosal ganglia, depend on the presence of BDNF, as demonstrated by the loss of these sensory neurons in BDNF knockout mice (lacking both alleles for BDNF). Unlike NGF effects, with BDNF knockout, sympathetic neurons are not affected, nor are motor neuron pools. BDNF knockout mice fail to thrive, demonstrate lack of proper coordination of movement and balance, and ultimately die by 3 weeks of age. Conversely, provision of BDNF or other neurotrophins to peripheral nerves during development enhances outgrowth.

BDNF is abundantly expressed in the central nervous system, especially in the hippocampal formation, cerebral cortex, and amygdaloid complex. Its expression increases in the early postnatal period and then stays high into adulthood, consistent with a continuous role in the mature CNS. *In vitro* and *in vivo* studies have demonstrated that BDNF has survival- and growth-promoting actions on a variety of CNS neurons, including hippocampal and cortical neurons. Lack or blockade of BDNF leads to death of certain identified forebrain neurons (thalamic neurons).

VI. BDNF GENE REGULATION

Many stimuli have been shown to alter BDNF gene expression in both physiologic and pathologic states. Physiologic stimuli are known to increase BDNF mRNA content. For example, light stimulation increases BDNF mRNA in the visual cortex, osmotic stimulation increases BDNF mRNA in the paraventricular hypothalamic nucleus, and whisker stimulation increases BDNF mRNA expression in the somatosensory barrel cortex. Electrical stimuli that induce long-term potentiation (LTP) in the hippocampus, a cellular model of learning and memory, increase BDNF and NGF expression. Even physical exercise has been shown to increase NGF and BDNF expression in hippocampus.

This physiologic alteration in BDNF gene expression may be very important in the development of the brain. For example, there is an exciting body of work implicating BDNF in activity-dependent development of the visual cortex. Provision of excess BDNF or blockade of BDNF signaling leads to abnormal patterning of ocular dominance columns during a critical period of visual cortex development. This suggests a role for BDNF in the patterning of axonal arborizations from the lateral geniculate nucleus (LGN; a part of the thalamus) to the visual cortex during development. BDNF expression can also be regulated by neurotransmitters and hormones. For example, glutamate receptor agonists induce, whereas γ-aminobutyric acid type A ($GABA_A$) receptor agonists inhibit, BDNF expression.

Pathologic states are also associated with alteration in BDNF gene expression. For example, seizures dramatically up-regulate BDNF mRNA. Increased BDNF expression is seen after hypoxia/ischemia and hypoglycemic coma, whereas reduced BDNF expression is associated with stress.

VII. BDNF AND SYNAPTIC PLASTICITY

A great deal of evidence now indicates that BDNF and its high-affinity receptor trkB, in addition to modulating neuronal survival and differentiation, are also critically involved in modulation of synaptic transmission. Recent studies have demonstrated that BDNF is transported anterogradely in CNS neurons,

is released on neuron depolarization, and triggers rapid intracellular signals and action potentials in central neurons. Direct activity-dependent pre- to postsynaptic transneuronal transfer of BDNF has recently been demonstrated using fluorescently labeled BDNF.

BDNF has an enormous range of physiologic actions at both developing and mature synapses, enhancing or reducing transmission at excitatory and inhibitory synapses by both pre- and postsynaptic mechanisms. Overall, the evidence favors a role for BDNF causing increased excitability both by strengthening of excitatory (glutamatergic) synapses and by weakening of inhibitory (GABAergic) synapses. Application of BDNF potentiates synaptic transmission both *in vitro* and *in vivo*. Incubation of hippocampal or visual cortical slices with trkB inhibitors inhibits LTP, and hippocampal slices from BDNF knockout animals exhibit impaired LTP induction that is restored by reintroduction of BDNF.

VIII. BEHAVIORAL AND DISEASE ASSOCIATIONS

A. Learning and Memory

Learning and memory depend on persistent selective modification of synapses between CNS neurons. Because BDNF appears to be critically involved in activity-dependent synaptic strengthening of the sort observed in the long-term potentiation model, there is great interest in its role as a molecular mechanism of learning and memory. The hippocampus, which is required for many forms of long-term memory in humans and animals, appears to be an important site of BDNF action. Indeed, rapid and selective induction of BDNF expression in the hippocampus during contextual learning has been demonstrated, and function-blocking antibodies to BDNF and/or knockout of forebrain trkB signaling in mice impair spatial learning.

B. Neurodegenerative Diseases

The idea that degenerative diseases of the nervous system may result from insufficient supply of neurotrophic factors has generated great interest in BDNF as a potential therapeutic agent. Many reports have documented evidence of decreased expression of BDNF in cases of Alzheimer's and Parkinson's diseases. Selective reduction of BDNF mRNA in the hippocampus has been reported in Alzheimer's disease specimens and decreased BDNF protein has been demonstrated in the substantia nigra in Parkinson's disease, areas that degenerate in these diseases. BDNF promotes survival of all major neuronal types affected in Alzheimer's and Parkinson's diseases, such as hippocampal and neocortical neurons, cholinergic septal and basal forebrain neurons, and nigral dopaminergic neurons. Interestingly, recent work has implicated BDNF in Huntington's disease as well. Huntingtin, the protein mutated in Huntington's disease, up-regulates BDNF transcription, and loss of huntingtin-mediated BDNF transcription leads to loss of trophic support to striatal neurons, which subsequently degenerate in the hallmark pathology of the disorder. In all of these disorders, provision of BDNF or increasing endogenous BDNF production may conceivably be therapeutic if applied in the appropriate spatiotemporal context.

C. Epilepsy

The discovery that limbic seizures increase mRNA levels for nerve growth factor led to the idea that seizure-induced expression of neurotrophic factors may contribute to the lasting structural and functional changes underlying epileptogenesis. Recent *in vitro* and *in vivo* findings implicate BDNF in the cascade of electrophysiologic and behavioral changes underlying the epileptic state. BDNF mRNA and protein are markedly up-regulated in the hippocampus by seizure activity in animal models, and infusion of anti-BDNF agents or use of BDNF knockout mice inhibits epilepsy in animal models. Conversely, overexpression of BDNF in transgenic mice leads to spontaneous seizures. The hippocampus and closely associated limbic structures are thought to be particularly important in the pro-epileptogenic effects of BDNF, and, indeed, increased BDNF expression in the hippocampus is found in specimens from patients with temporal lobe epilepsy. It is hoped that understanding of the hyperexcitability associated with BDNF in epilepsy animal models may lead to novel anticonvulsant or antiepileptic therapies.

D. Pain

BDNF also may play an important neuromodulatory role in pain transduction. BDNF is synthesized by spinal cord dorsal horn neurons and is markedly up-regulated (along with NGF) in inflammatory injury to peripheral nerves. Application of BDNF in

experimental studies acutely sensitizes nociceptive afferents and elicits hyperalgesia. Central pain sensitization is an activity-dependent increase in excitability of dorsal horn neurons leading to a clinically intractable condition termed "neuropathic pain" in which normally nonpainful somatosensory stimuli (touch and pressure) become exquisitely painful (allodynia). Electrophysiological and behavioral data demonstrate that inhibition of BDNF signal transduction inhibits central pain sensitization.

E. Depression

BDNF signaling may also be involved in affective behaviors. Environmental stresses (e.g., immobilization) that induce depression also decrease BDNF mRNA. Conversely, physical exercise is associated with decreased depression and increased BDNF mRNA. Existing treatments for depression are thought to work primarily by increasing endogenous monoaminergic (i.e., serotonergic and noradrenergic) synaptic transmission, and recent studies have shown that effective antidepressants increase BDNF mRNA in the brain. Exogenous delivery of BDNF promotes the function and sprouting of serotonergic neurons in adult rat brains. Thus, new pharmacologic strategies are focused on the potential antidepressant role of BDNF.

IX. SUMMARY

Since the purification of BDNF in 1982, a great deal of evidence has pointed to its central roles in neuronal morphology, development, physiology, and pathology. Aside from its importance in neural development and regeneration, BDNF appears essential to molecular mechanisms of synaptic plasticity. Basic activity-related changes in the central nervous system are thought to depend on BDNF modification of synaptic transmission, especially in the hippocampus and neocortex. Pathologic levels of BDNF-dependent synaptic plasticity may contribute to conditions such as epilepsy and chronic pain sensitization; conversely, application of the trophic properties of BDNF may lead to novel therapeutic options in neurodegenerative diseases and perhaps even in neuropsychiatric disorders.

Glossary

γ-aminobutyric acid Amino acid neurotransmitter; the major inhibitory neurotransmitter in the central nervous system.

glutamate Amino acid neurotransmitter; the major excitatory neurotransmitter in the central nervous system.

hippocampus Curved, elongated ridge [(Gk) "sea horse"] in the medial temporal lobe of the brain; thought to be responsible for consolidation of short-term memories and their conversion to long-term memories; also involved in spatial learning. Hippocampal morphology is markedly altered in epilepsy (in which certain hippocampal neurons die and others sprout aberrant connections) and Alzheimer's disease (in which there is degeneration of hippocampal neurons).

long-term potentiation Cellular model of learning and memory that uses stereotyped *in vitro* or *in vivo* stimulation of defined neural pathways to elicit long-term increases in synaptic strength; thought to be a general model for how brain synapses are altered by experience and learning.

neurotrophin One of a family of growth factors that includes nerve growth factor, brain-derived neurotrophic factor, neurotrophin-3, neurotrophin-4/5 (NT-4/5), neurotrophin-6, and neurotrophin-7. All have been shown to have growth- or survival-promoting actions on subpopulations of peripheral or central nervous system neurons.

$p75^{NTR}$ Low-affinity receptor for all neurotrophins; linked to distinct intracellular signal transduction pathways; may modulate neurotrophin binding to trk receptors.

synaptic plasticity General term for a variety of alterations in synapses, both strengthening and weakening; may involve alterations in neurotransmitter receptors, neurotransmitter release, or propensity for activation of intracellular second messengers. Brain-derived neurotrophic factor has particularly strong effects on synaptic plasticity in a variety of systems.

thalamus Deep brain structure involved in processing and transmitting peripheral sensory information to the cerebral cortex. The lateral geniculate nucleus of thalamus receives visual input from the retina and transmits it to the visual cortex in the occipital lobe.

tropomyosin receptor like kinases (trk) High-affinity receptors for neurotrophins, including trkA (binds nerve growth factor and neurotrophin-3 with lower affinity), trkB (binds brain-derived neurotrophic factor, neurotrophin-4/5, and neurotrophin-3 with lower affinity), and trkC (binds neurotrophin-3); linked to a variety of intracellular signal transduction pathways.

Brassinosteroids

JIANMING LI

University of Michigan, Ann Arbor

Brassinosteroids are a group of polyhydroxylated plant steroids that are ubiquitous in the plant kingdom. These compounds elicit a variety of responses that affect plant growth and development and are now widely recognized as a new class of major plant hormones.

I. INTRODUCTION

Brassinosteroids, first isolated from *Brassica napus* L., are the focus of extensive biochemical studies. Cell cultures of *Catharanthus roseus* (periwinkle) have been used to examine brassinosteroid (BR) biosynthesis; data from those studies, coupled with the recent discovery and molecular genetic/ metabolic characterization of BR-deficient and BR-insensitive dwarf mutants in *Arabidopsis*, pea, and tomato plants, have provided strong evidence for essential roles of BRs in plant growth and development.

II. STRUCTURAL FEATURES AND PHYSIOLOGICAL ACTIVITIES

Brassinolide, a potent plant growth stimulator, was the first BR isolated; it was discovered in rape (*B. napus*) pollen in 1979, and its structure was determined by X-ray crystallography and spectroscopic analysis to be (22*R*,23*R*,24*S*)-2α,3α,22,23-tetrahydroxy-24-methyl-*B*-homo-7-oxa-5α-cholestan-6-one (Fig. 1). So far, more than 40 brassinolide analogues, collectively known as BRs, have been identified and characterized from many different plant species, including 37 angiosperms, 5 gymnosperms, a pteridophyte (*Equisetum arvense*), and an alga (*Hydrodictyon reticulatum*). BRs have been isolated from almost every plant tissue, although immature seeds and pollen contain the highest concentrations of the steroids. When applied exogenously to intact plants or to explants at nanomolar to micromolar concentrations, BRs can induce a variety of physiological responses, including seed germination, pollen tube growth, stem elongation, leaf unrolling and bending, root growth inhibition, vascular differentiation, microtubule reorientation, proton pump activation, induction of ethylene biosynthesis, altered gene expression, and stress response modulation.

All naturally occurring BRs have a common 5α-cholestane skeleton with different substitutions in the A/B rings and the side chain (Fig. 1). Whereas the variations in the A ring mainly come from the presence and/or orientations of hydroxyl groups at the C-1, C-2, and C-3 positions, the modifications of the B ring are produced by C-6 oxidation, giving rise to 6-deoxo, 6-oxo, or 7-oxalactone steroids. Based on the degree of alkylation of the side chain, BRs can also be grouped into C_{27}, C_{28}, and C_{29} steroids.

Brassinosteroids

JIANMING LI

University of Michigan, Ann Arbor

Brassinosteroids are a group of polyhydroxylated plant steroids that are ubiquitous in the plant kingdom. These compounds elicit a variety of responses that affect plant growth and development and are now widely recognized as a new class of major plant hormones.

I. INTRODUCTION

Brassinosteroids, first isolated from *Brassica napus* L., are the focus of extensive biochemical studies. Cell cultures of *Catharanthus roseus* (periwinkle) have been used to examine brassinosteroid (BR) biosynthesis; data from those studies, coupled with the recent discovery and molecular genetic/ metabolic characterization of BR-deficient and BR-insensitive dwarf mutants in *Arabidopsis*, pea, and tomato plants, have provided strong evidence for essential roles of BRs in plant growth and development.

II. STRUCTURAL FEATURES AND PHYSIOLOGICAL ACTIVITIES

Brassinolide, a potent plant growth stimulator, was the first BR isolated; it was discovered in rape (*B. napus*) pollen in 1979, and its structure was determined by X-ray crystallography and spectroscopic analysis to be (22*R*,23*R*,24*S*)-2α,3α,22,23-tetrahydroxy-24-methyl-*B*-homo-7-oxa-5α-cholestan-6-one (Fig. 1). So far, more than 40 brassinolide analogues, collectively known as BRs, have been identified and characterized from many different plant species, including 37 angiosperms, 5 gymnosperms, a pteridophyte (*Equisetum arvense*), and an alga (*Hydrodictyon reticulatum*). BRs have been isolated from almost every plant tissue, although immature seeds and pollen contain the highest concentrations of the steroids. When applied exogenously to intact plants or to explants at nanomolar to micromolar concentrations, BRs can induce a variety of physiological responses, including seed germination, pollen tube growth, stem elongation, leaf unrolling and bending, root growth inhibition, vascular differentiation, microtubule reorientation, proton pump activation, induction of ethylene biosynthesis, altered gene expression, and stress response modulation.

All naturally occurring BRs have a common 5α-cholestane skeleton with different substitutions in the A/B rings and the side chain (Fig. 1). Whereas the variations in the A ring mainly come from the presence and/or orientations of hydroxyl groups at the C-1, C-2, and C-3 positions, the modifications of the B ring are produced by C-6 oxidation, giving rise to 6-deoxo, 6-oxo, or 7-oxalactone steroids. Based on the degree of alkylation of the side chain, BRs can also be grouped into C_{27}, C_{28}, and C_{29} steroids.

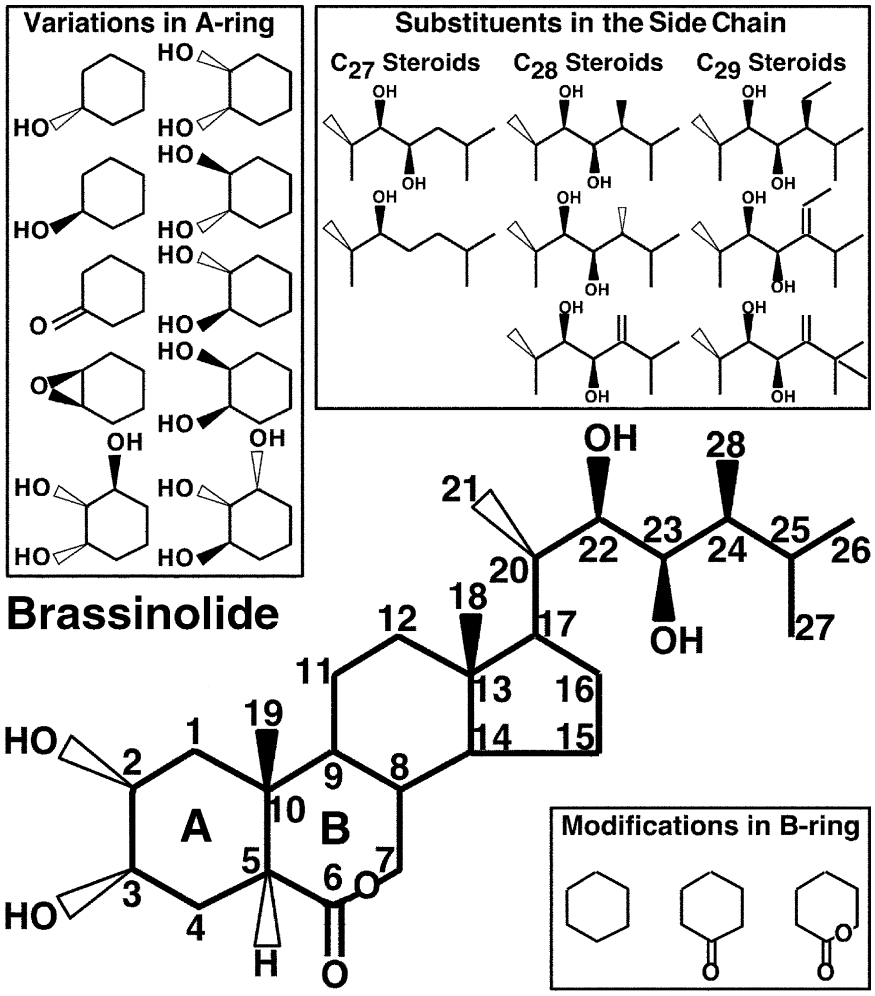

FIGURE 1 Brassinolide structure and structural variations.

Most BRs isolated so far contain a 24*R*-methyl group, but steroids containing a 24*S*-methyl, 24-methylene, 24*R*-ethyl, 24-ethylidene, 24-methylene-25-methyl, or no substitution at C-24 also exist in nature. Almost all natural BRs contain *R*-oriented vicinal hydroxyls at positions C-22 and C-23. Structure-activity evaluation of various synthetic brassinolide analogues concluded that the biological activities of BRs depend on the presence of the following functional groups: (1) A/B trans-fused ring junction, (2) α-oriented vicinal hydroxyls at C-2 and C-3, (3) 6-oxo or 7-oxalactone functionality in ring B, (4) alkylation at the C-24 position, and (5) a 22*R*,23*R*-vicinal diol moiety. Among the natural BRs, brassinolide and castasterone, two C_{28} steroids with a 24*R*-methyl group, are the most widely distributed steroids in the plant kingdom and have the strongest biological activities.

III. BIOSYNTHESIS AND METABOLISM

Brassinolide is synthesized from campesterol, a common plant sterol that has the same carbon skeleton as that found in brassinolide (Fig. 2). The first step of the reaction is conversion of campesterol to campestanol via three intermediates; 24*R*-methylcholest-4-en-3β-ol, 24*R*-methylcholest-4-en-3-one, and 24*R*-methyl-5α-cholestan-3-one. The resulting campestanol is then converted to castasterone through either of two alternative routes: the early and late C-6 oxidation pathways, depending on whether the oxidation at C-6 occurs before or after

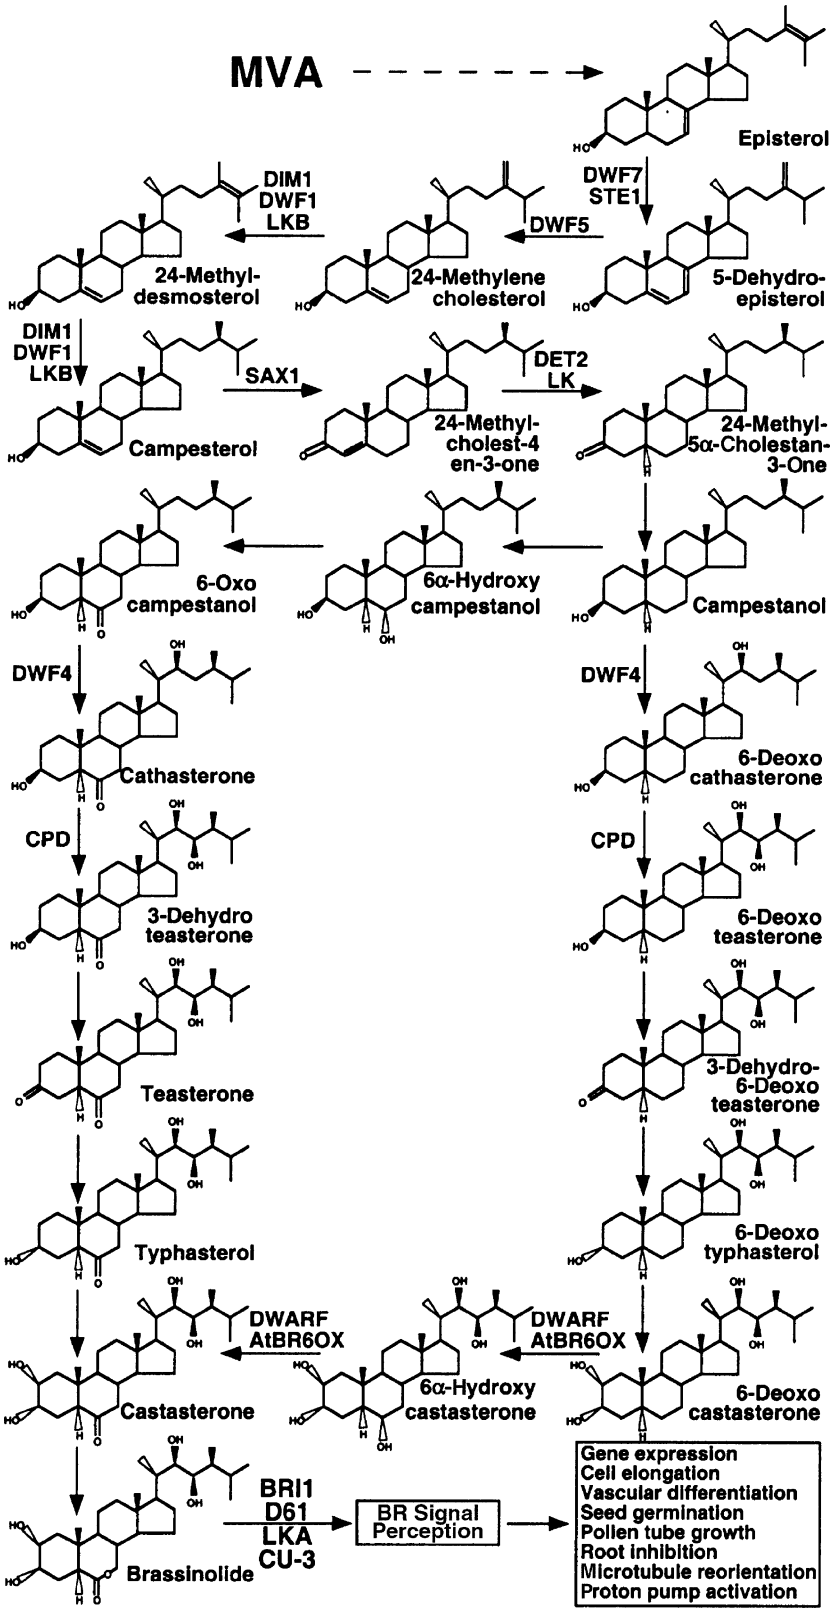

FIGURE 2 Proposed biosynthetic pathways of brassinolide and proteins involved in brassinosteroid biosynthesis and signal perception. Genes involved are shown alongside the reaction arrows. MVA, mevalonic acid.

the introduction of vicinal hydroxyls at C-22 and C-23 of the side chain. In the early C-6 oxidation pathway, campestanol is oxidized at the C-6 position to produce 6α-hydroxycampestanol and 6-oxocampestanol; the latter is then modified by two consecutive hydroxylation reactions at positions C-22 and C-23, yielding cathasterone and teasterone, respectively. Teasterone undergoes 3-epimerization to become typhasterol, involving an inversion from 3β-hydroxyl to 3α-hydroxyl via a 3-oxo intermediate. The introduction of an additional hydroxyl group at the C-2α position of typhasterol leads to the formation of castasterone. In the late C-6 oxidation pathway, the reactions from campestanol to 6-deoxocastasterone exactly mirror those between 6-oxocampestanol and castasterone in the early C-6 oxidation pathway. 6-Deoxocastasterone is then oxidized at the C-6 position to yield castasterone, via 6-hydroxycastasterone, to connect the two parallel routes. Finally, the 6-oxo group of castasterone is further oxidized via a Baeyer-Villiger-type oxidation to produce a lactone group, yielding brassinolide. Although the initial metabolic study of BR biosynthesis was conducted using cultured cells of *C. roseus*, which can produce high levels of BRs, various intermediates of the proposed pathways have also been identified in many other plant species. Gas chromatography–mass spectrometry analyses of metabolites of *C. roseus* and *Arabidopsis* plant cells fed with deuterium-labeled intermediates have confirmed most of the enzymatic steps.

Further support for the proposed BR biosynthetic pathways has come from molecular genetic and/or biochemical studies of many BR-deficient *Arabidopsis*, pea, and tomato mutants. These mutants are characterized by dwarf stature, darker green coloration with short petioles and rounder, epinastic leaves, reduced male fertility, delayed flowering and senescence, and varying degrees of de-etiolation in the dark; these mutants can be normalized to wild-type phenotypes by exogenous application of BRs, and their characteristics can be mimicked by treating normal plants with brassinazole, a highly specific BR biosynthesis inhibitor. The cabbage-like dwarfs have furnished indisputable evidence that BRs are essential for normal plant growth and also have provided much needed materials for testing the hypothesized BR biosynthetic pathways and a powerful means for identifying BR biosynthetic enzymes.

The *sax1* mutants of *Arabidopsis* are defective in the oxidation and isomerization of 3β-hydroxy-$\Delta^{5,6}$ precursors to 3-oxo-$\Delta^{4,5}$ steroids, and the *SAX1* gene is postulated to encode a 3β-hydroxyl steroid dehydrogenase that catalyzes the first step of the campesterol to campestanol conversion. Both the *Arabidopsis det2* mutant and the pea *lk* mutant are defective in the formation of campestanol. Careful metabolic analysis has indicated that the reduction of 24-methylcholest-4-en-3-one to 24-methylcholestan-3-one is blocked in the *det2* and *lk* mutants. The cloned *DET2* gene was found to encode a plant homologue of mammalian steroid 5α-reductases and the *det2* mutation could be complemented by transgenic expression of human steroid 5α-reductase genes. The *Arabidopsis dwf4* mutant is defective in 22α-hydroxylation, whereas the *Arabidopsis cpd* and the tomato *dumpy* mutants are blocked in the 23α-hydroxylation steps, resulting in strong dwarf phenotypes that can be rescued only by 22α- and 23α-hydroxylated BRs, respectively. These results provide strong genetic support for previous physiological data indicating that the vicinal hydroxyls are essential for the biological activities of BRs. The *DWF4* and *CPD* genes both encode cytochrome P450 monooxygenases that share significant sequence homology to mammalian steroid hydroxylases. The tomato *dwarf* mutant is defective in the formation of castasterone, resulting in dwarfism as a consequence of inhibited stem elongation and leaf expansion. The *DWARF* gene and its *Arabidopsis* orthologue, *AtBR6ox*, encode cytochrome P450 enzymes that can catalyze the C-6 oxidation of 6-deoxocastasterone, yielding castasterone, and may also catalyze the conversion of other 6-deoxo BRs to the corresponding 6-oxo BRs, thus linking the late C-6 oxidation pathway to the early C-6 oxidation pathway at multiple positions.

In addition to genes specifically involved in BR biosynthesis, several other genes are involved in the synthesis of sterol precursors to BR biosynthesis (Fig. 2), including *DWF7/STE1*, *DWF5*, and *DIM1/DWF1* from *Arabidopsis* and *LKB* from pea plants. Mutations in these genes impart a weak BR-deficient dwarf phenotype that can be rescued by exogenous BR application. Biochemical analysis of endogenous sterols from the mutants revealed that *dwf7/ste1*, *dwf5*, and *dim1SQ4/dwf1/lkb* mutants are blocked in the dehydrogenation of episterol to 5-dehydroepisterol, the conversion of 5-dehydroepisterol to 24-methylenecholesterol, and the reduction of the $\Delta^{24(28)}$ double bond, respectively. All three *Arabidopsis* genes have been cloned and found to encode a sterol C-5-desaturase, a sterol

Δ^7-reductase, and a FAD-dependent oxidoreductase, respectively.

Like many other plant hormones, the activities of BRs are often modulated by further metabolic reactions. O-Glucosylation at the existing hydroxyl groups and/or new hydroxylation are important mechanisms for deactivating plant steroids. Natural 23-*O*-β-glucopyranosyl and 3-*O*-β-glucopyranosyl BRs have been identified. Exogenous BRs, when fed into tomato cell cultures, are converted to 25β--D-glucopyranosyloxy and 26β-D-glucopyranosyloxy BRs in a process involving hydroxylation and subsequent glucosylation at C-25 and C-26, respectively. An activation tagging screening involving transferred DNA (T-DNA, derived from *Agrobacterium tumefaciens*) identified an *Arabidopsis* cytochrome P450 gene, *BAS1*; elevated expression of *BAS1* led to an increased production of 26-hydroxybrassinolide with reduced accumulation of brassinolide, giving a phenotype similar to BR-deficient mutants. This is the first genetic evidence that further hydroxylation on the side chain could serve as an inactivation mechanism to regulate BR activities. Plants also contain other mechanisms for deactivating BRs, including sulfonation of the C-22 hydroxyl group by a sulfotransferase and catabolic side chain degradation by a multistep metabolic process. BRs can also be conjugated with fatty acids. Exogenous BRs are esterified at the 3β position with lauric acid, myristic acid, or palmitic acid, and two natural fatty-acid-conjugated BRs have been identified in lily anthers. It is thought that these acylated BRs might function as storage forms of BRs, which would be released as free BRs in response to developmental and environmental signals.

IV. SIGNAL PERCEPTION AND MOLECULAR RESPONSES

In animals and insects, steroid action is mediated mainly by intracellular steroid receptors; these receptors function as ligand-dependent transcriptional factors that regulate gene expression. Although BRs are structurally similar to animal/insect steroids and are known to affect gene expression, no similar nuclear receptor has been found in plant systems. The completely sequenced *Arabidopsis* genome did not yield a single gene that encodes a homologue of animal and insect intracellular steroid receptors. It is thought that plants might use a different receptor system to detect the presence of steroid hormones.

Several genetic screens for BR signaling mutants have led to the identification of the *Arabidopsis* gene *BRASSINOSTEROID-INSENSITIVE 1* (*BRI1*), which encodes a protein with sequence homology to leucine-rich-repeat (LRR) receptor-like kinases. Mutations in the *BRI1* gene result in a phenotype that is indistinguishable from the severe BR-deficient phenotype, except that it cannot be rescued by BR application. Interestingly, *bri1* mutants accumulate high levels of brassinolide and brassinolide biosynthetic precursors, with the most severely affected alleles promoting the highest levels of brassinolide, suggesting that *BRI1* is necessary for homeostasis of steroid hormones. BRI1 consists of an extracellular domain with 25 tandem LRRs disrupted by a 70-amino-acid island between the 21st and 22nd LRRs, a single transmembrane α-helix, and a cytoplasmic domain having the serine/threonine kinase signatures. Sequence analysis of many *bri1* mutant alleles shows that both the LRR-containing extracellular domain, especially the 70-amino-acid island, and the cytoplasmic kinase are essential for BR signaling. The BR-insensitive dwarf mutants have also been identified in other plant species, including tomatoes (*cu-3*), peas (*lka*), and rice (*d61*). The *lka* and *d61* mutants have been found to contain mutations in their respective *BRI1* homologues.

The *Arabidopsis* BRI1 protein is localized in the plasma membrane and can function as a serine/threonine kinase *in vitro*. In addition, the extracellular domain of BRI1 can confer dose-dependent BR responsiveness to Xa21, a similar LRR-containing receptor kinase of rice involved in disease resistance. Moreover, transgenic *Arabidopsis* plants overexpressing the *BRI1* gene show higher BR sensitivity and stronger brassinolide binding activity that can be co-immunoprecipitated with the receptor kinase. Interestingly, brassinolide treatment stimulates autophosphorylation of BRI1 proteins. This finding led to a hypothesis that BR binding to BRI1, either directly or indirectly, stimulates the kinase activity of the BRI1 protein, which in turn activates a signaling cascade to control a variety of BR-regulated processes, including gene expression and cell elongation.

The first BR-regulated gene, *BRU1*, to be isolated from BR-treated elongating soybean epicotyls encodes a protein exhibiting 48–74% sequence identity to various xyloglucan endotransglycosylases (XETs), which are implicated in cell wall growth. An increase in *BRU1* message levels correlates with the extent of stem elongation and with increases in plastic extensibility of the cell wall in response to BR

treatment, suggesting that BRs may promote cell elongation by regulating gene expression and/or activities of cell-wall-modifying enzymes. Such a hypothesis is supported by the identification of similar BR-regulated *XET* genes in *Arabidopsis*, rice, and tomato plants. BRs can also exert their effects on cell elongation by regulating the orientations of cortical microtubules. Genes encoding β-tubulins, a component of microtubules, and an actin effector protein, which controls polymerization of actins that associate with microtubules, have been found to be regulated by the plant steroids.

BR-regulated gene expression may also control other BR-regulated physiological processes. The BRI1-mediated feedback inhibition of *CPD* gene expression is involved in homeostasis of the steroid hormones. BRs are also known to induce the expression of an aminocyclopropane-1-carboxylate synthase gene, which might be responsible for BR-stimulated ethylene biosynthesis. Other BR-regulated genes include *CDC2b*, an *Arabidopsis* cyclin-dependent kinase gene involved in cell division, a tomato invertase gene that plays a role in controlling source/sink balance and carbohydrate metabolism, and several *B. napus* genes that encode heat-shock proteins, which are implicated in thermotolerance.

Despite intensive studies of BRI1 and identification of many BR-regulated genes, virtually nothing is known about how the BR signal, once transmitted to a cell via BRI1, is transduced in the cytosol and reaches the nucleus, where it affects gene regulation. It also remains to be determined whether all known BR-regulated processes require a BR-regulated gene expression event.

Glossary

leucine-rich repeats Tandem repeats of a versatile protei–protein interaction domain that often consists of 24 residues with a consensus sequence, LxxLxxLxx-LxLxxNxxxGxIPxx, where x represents any amino acid.

T-DNA activation tagging A novel mutagenesis method utilizing transferred DNA (T-DNA). T-DNA is derived from *Agrobacterium tumefaciens* and is used to introduce multiple copies of a viral transcriptional enhancer element randomly into a plant genome, resulting in transcriptional activation of a plant gene that is near the introduced T-DNA.

xyloglugan endotransglycosylase A cell-wall-modifying enzyme that cleaves xyloglucan polymers internally and then religates the newly generated ends to other xyloglucan ends.

Calcitonin

DAVID M. FINDLAY* AND PATRICK M. SEXTON†
*University of Adelaide, Australia • †Howard Florey Institute of Experimental Physiology and Medicine, University of Melbourne

Calcitonin is a protein that is synthesized in the mammalian thyroid gland. Both calcitonin and its receptors are found in many mammalian cell types and tissues, and calcitonin is a potent inhibitor of osteoclast-mediated bone resorption. Understanding the chemistry and mechanisms of action of calcitonin led to its use in treatment of various bone disorders, and further analysis of its diverse roles may lead to additional clinical applications.

I. INTRODUCTION

Calcitonin (CT) is a 32-amino-acid peptide synthesized in mammals by the C cells of the thyroid gland. CT was discovered because of its ability to lower the concentration of plasma calcium. This hypocalcemic response was found to be due principally to a potent inhibitory action of CT on osteoclast-mediated bone resorption and it is this action that underlies its use clinically in the treatment of bone disorders, including Paget's disease, osteoporosis, and hypercalcemia due to malignancy. Receptors for CT were subsequently identified as members of the large family of seven-membrane-spanning, G-protein-coupled receptors. Since the initial discovery of CT, expression of CT and its receptors has been demonstrated in many cell types and tissues other than bone. This suggests additional, biologically diverse roles for CT, including functions in brain and kidney and in cell differentiation and tissue morphogenesis.

II. CHEMISTRY

CT belongs to a family of molecules that are structurally related but biologically diverse, comprising calcitonins of various species, calcitonin gene-related peptides (CGRPs), amylin, and adrenomedullin. The CT sequence has been determined for many species and shows considerable divergence, with the common features being that all sequences contain 32 amino acids, a carboxy-terminal proline amide, and a disulfide bridge between cysteine residues at positions 1 and 7 (Fig. 1). Based on their amino acid s]equence homologies, CTs from different species are classified into three groups. The first is the artiodactyl group, which includes porcine, bovine, and ovine CT; within this group each CT differs by four amino acids. The second group is the primate/rodent group, which includes human and rat CT, and these differ within the group by two amino acids. The third group is the teleost/avian group, which includes salmon, eel, goldfish, and chicken CT, each differing within the group by four amino acids. The order of biological potency of the CTs, with respect to a hypocalcemic response, is teleost $\geq$ artiodactyl $\geq$ human, although absolute biological activities vary considerably among different animal species.

Studies of substituted, deleted, and otherwise modified CTs have provided considerable information regarding structure/activity relationships of the CT molecule. For example, stabilization of the N-terminal ring structure, by substitution of the disulfide bridge with an ethylene linkage or an acetylenic bridge, leads to greatly improved stability of the salmon calcitonin (sCT) molecule and retention of biological potency. Despite this, analogues of sCT that lack the ring structure can retain full potency, in terms of hypocalcemic activity. However, the N-terminal amino acids are critical for the agonist activity of CT. Progressive truncation of this region of sCT leads to generation of, first, weak or partial agonists and, then, with deletion of six or seven amino acids, to peptides with antagonist activity. Deamidation of the amino terminus can increase the potency of CT peptides *in vivo*, perhaps by increasing their resistance to degrading endopeptidases. Modifications of CT peptide length from the C-terminal end, either by deletion or elongation, are poorly tolerated. Additionally, the C-terminal amide is required, with the COOH-form having markedly reduced activity. The lower *in vivo* potency of human CT (hCT), compared with teleost CTs, is due partly to

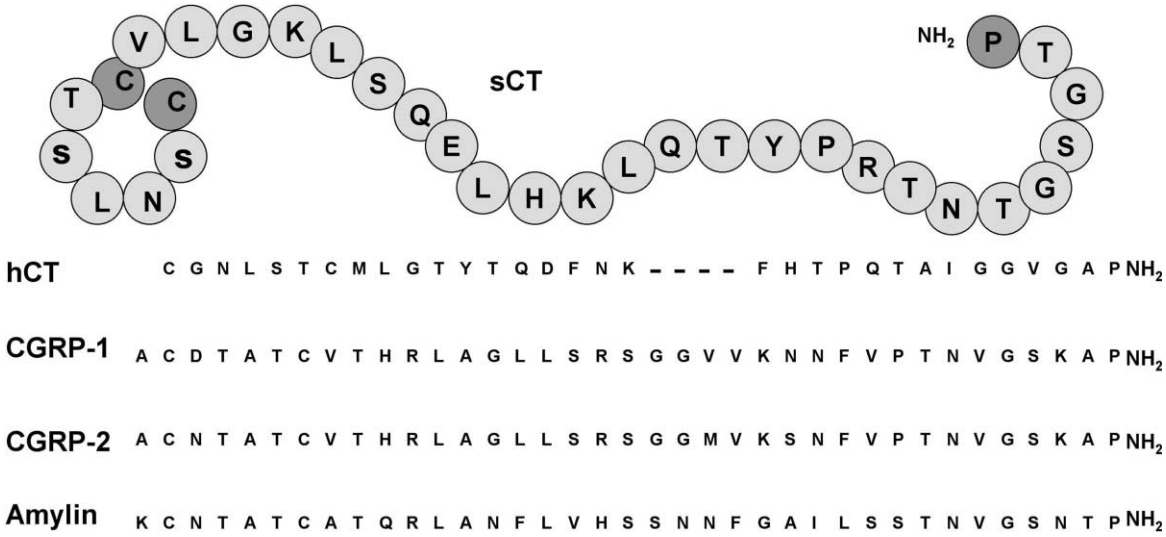

FIGURE 1 Primary amino acid sequence of salmon calcitonin (sCT), human calcitonin (hCT), calcitonin-related gene peptide-1 and -2 (CGRP-1 and -2), and amylin. Note the homologies between the peptides, and the cysteine (C) residues, which form the disulfide-bonded ring structure at the N-terminus of each molecule. The C-terminal proline residue in each case is amidated, which is important for activity.

its increased rate of metabolic degradation and clearance, contributed to by the methionine in position 8, which is susceptible to oxidation.

Circular dichroism studies indicate that sCT exhibits considerable secondary structure in the presence of lipid, and predicts the generation of an amphipathic α-helix between residues 8 and 22, in proximity to the cell membrane. The less potent human CT has reduced propensity to form this secondary structure. In addition, amino acid substitutions that enhance the formation of an α-helix between residues 8 and 16 also increase the hypocalcemic potency of the peptide. However, modifications of residues in the 8–22 sequence that alter the ability of sCT or hCT to form a helical secondary structure have yielded conflicting results in terms of the biological significance of this structure, which may be explicable on the basis of differences between CT receptor (CTR) subtypes. In rat tissues, two CTR subtypes have been described: the first, designated CT-H (for helical), displays high-affinity interaction only for peptides with a strong potential to form helical secondary structure; the other, designated CT-L (for linear), is capable of high-affinity interaction with both helical and nonhelical peptides. Following cloning of the rat C1a and C1b CTR isoforms, it was found that the CT-L and CT-H subtypes corresponded to the C1a and C1b receptors, respectively (see Section VI).

III. BIOSYNTHESIS

A. Sites of Production

Elevation of circulating calcium concentrations stimulates CT release from the C cells of the thyroid, and low serum calcium levels inhibit release. Sensitivity by thyroidal C cells to circulating calcium levels appears to be mediated by the same extracellular calcium-sensing receptor that is found in parathyroid cells. The basal concentration of hCT in human blood in normal individuals is very low (<10 pg/ml). Size fractionation analysis of CT extracted from plasma and tissues demonstrates the presence of multiple immunoreactive forms of CT. In addition to the CT monomer (~ 3500 Da), a number of high-molecular-weight forms exist in certain situations. These forms probably correspond to precursor molecules and dimers and other aggregates of the CT molecule and are largely inactive biologically. In several pathological states, such as CT-secreting tumors, circulating levels of CT are increased. Conditions of stress, such as some chronic lung problems, burns, acute pancreatitis, and certain infections/inflammatory conditions, are characterized by high circulating levels of large molecular-weight forms of CT.

CT synthesis also occurs in extrathyroidal sites. For example, assays using specific anti-hCT serum have detected hCT-like immunoreactivity (hCT-i) in the blood and urine of patients after total

thyroidectomy. In fact, significant amounts of CT have been found in many human tissues. Thyroid and prostate gland contain the highest levels of hCT-i and significant amounts are also extractable from the gastrointestinal tract, thymus, bladder, lung, and central nervous system (CNS). The physiological role of CT in these extraskeletal tissues is not known. However, CT-producing cells in extrathyroidal sites do not appear to respond to elevations in serum calcium, suggesting that CT produced in these sites is not involved in calcium homeostasis.

Both hCT-i and salmon CT-i (sCT-i) have been found in the CNS of vertebrate and invertebrate species, the latter again consistent with roles for CT unrelated to osteoclast inhibition. hCT-i is detectable in human cerebrospinal fluid, and in extracts of postmortem human brain. In addition, low levels of material immunologically similar to sCT-i are found in the hypothalamus, which also contains high densities of CT receptors. Release of a sCT-like peptide from cultured rat anterior pituitary cells has been described, and a cell line derived from a mouse pituitary carcinoma produces abundant sCT-i activity. Calcitonin receptors are present in the intermediate pituitary, thus calcitonin-like material present at this site may act as a paracrine regulator in this tissue. In accord with this, both anti-sCT and anti-hCT antisera were shown to significantly increase the release of prolactin from cultured anterior pituitary cells, presumably by neutralizing the effects of endogenously produced CT.

B. Calcitonin Gene Products

The human calcitonin gene is located in the p14 *qter* region of chromosome 11. Like several other small peptide hormones, CT is synthesized as part of a larger precursor protein, of 136 amino acids. The DNA sequence of the human calcitonin gene predicts that the hormone is flanked in the precursor by N- and C-terminal peptides. Two forms of the C-terminal flanking peptide (CCP-I and CCP-II), which differ in their last eight amino acids, are produced by alternative splicing of the human CT mRNA primary transcript, such that part of exon 4 splices to exon 5. The alternative donor site is absent in rat, rabbit, chicken, and sCT mRNA sequences. CCP-I is the form found predominantly, although CCP-II is also present in the plasma and thyroidal tissues of both normal and medullary thyroid carcinoma (MTC) patients. CCP-I, also termed "katacalcin," does not influence serum calcium levels and has no known bioactivity. However, measurement of serum katacalcin levels, together with CT and CGRP concentrations, is a useful marker for diagnosis of MTC. The N-terminal flanking peptide of procalcitonin contains 57 amino acids; although a stimulatory action on osteoblast proliferation has been proposed for this peptide, this claim is controversial.

It has been found that the calcitonin gene transcript actually encodes two distinct peptides that arise by tissue-specific alternative splicing of the primary mRNA transcript. The primary mRNA transcript is spliced almost exclusively to calcitonin mRNA in the thyroid, and to a mRNA encoding a calcitonin gene-related peptide in the nervous system. However, aberrant expression of CGRP is commonly seen in medullary thyroid carcinoma. The calcitonin/CGRP gene was one of the first recognized examples of a cellular gene exhibiting alternative, tissue-specific processing and has served as an important paradigm to study the molecular mechanisms of RNA splicing. Processing of the premessenger RNA to the calcitonin mRNA transcript involves usage of exon 4 as a 3′ terminal exon, with concomitant polyadenylation at the end of exon 4. Processing to produce the CGRP mRNA involves the exclusion of exon 4 and direct ligation of exon 3 to exon 5, with polyadenylation at the end of exon 6.

The CT gene family consists of four known genes, CALC-I, CALC-II, CALC-III, and CALC-IV, that contain nucleotide sequence homologies. CALC-I is the only gene that produces CT. CALC-I and CALC-II genes produce two different forms of CGRP, CGRP-1 and CGRP-2, respectively, which differ from each other by three amino acids. CALC-III is thought to be a pseudogene, producing neither peptide, and CALC-IV produces another molecule of the CT-related peptide family, amylin.

IV. METABOLISM

Calcitonin is rapidly cleared from the circulation at a rate that depends on the species of calcitonin, the route of administration, and the preparation of administered peptide. This clearance has implications for the use of CT clinically, and CT is usually injected intramuscularly in vehicles that maintain useful serum levels for 4–8 h after injection. Degradation of the CT molecule into inactive fragments occurs in various organs, with the kinetics and sites of inactivation being different for different species of CT. The hypocalcemic activity of CT is reduced by

incubation *in vitro* in serum at 37°C, with relative rates of loss in the following order: porcine CT > human CT = rat CT > salmon CT ≫ chicken CT. For salmon CT, the half-life of elimination from plasma *in vivo* is about 90 min and the metabolic clearance rate is around 200 ml/min. Incubation of CT with extracts of liver, kidney, or spleen showed that hypocalcemic activity was lost most rapidly in liver and kidney extracts due to a thermolabile degrading factor, with different rates of degradation for different CTs. The primary sites of CT degradation are extravascular, mainly in the liver for porcine CT and mainly in the kidney for human and salmon CT. Impaired renal function results in delayed elimination of human and salmon CT.

V. BIOLOGICAL ACTIONS

A. Bone Actions of Calcitonin

The first discovered and best understood physiological role of CT is its ability to potently inhibit bone resorption. This role is probably most relevant at times of stress on skeletal calcium conservation, such as pregnancy, lactation, and growth, when bone remodeling by osteoclasts and consequent release of calcium stores in bone need to be tightly regulated to prevent unnecessary bone loss. Evidence for a role of CT during growth, when the rate of bone turnover is high, is that the calcium-lowering effect of CT in the rat is strongly evident in young animals and becomes less marked with increasing age of the animals. In normal adult humans, even quite large doses of CT have little effect on serum calcium levels, because the process of bone resorption is a slow one in maturity. However, in pathologies characterized by increased bone turnover—for example, thyrotoxicosis, metastatic bone disease, or Paget's disease—CT treatment acutely inhibits bone resorption, which results in a lowering of plasma calcium. The lack of overt effects on serum calcium levels in maturity may indicate that the role of CT in bone is that of a regulator of the bone resorptive process, whatever the rate of resorption. Thus, CT probably should not be regarded primarily as a "calcium-regulating hormone," but as a regulator of bone resorption. CT is the only hormone known to be capable of inhibiting resorption by a direct action on bone. Evidence in support of an important physiological role for endogenous CT in protecting against bone loss comes from experiments showing that treatment with parathyroid hormone in parathyroidectomized (CT-deficient) rats caused more loss of cancellous bone than in intact (CT-replete) rats.

In addition to the hormonal activity of CT in regulating bone resorption, it is clear that many factors produced locally in bone also regulate this process. Key molecules that have central roles in bone resorption have recently been identified. Osteoclast formation and resorptive function both depend on the interaction of a molecule that is a receptor activator of NF-κB ligand (RANKL) with its cognate receptor, RANK. RANK is located on the cell surface of osteoclast precursors and mature osteoclasts. A soluble receptor-like molecule, termed osteoprotegerin (OPG), is synthesized in bone, and is a natural antagonist of RANKL. OPG can interfere with the RANKL–RANK interaction to inhibit both osteoclast formation and bone resorption. Overexpression of OPG in mice results in an osteopetrotic phenotype, due to reduced osteoclast numbers. Conversely, OPG knockout mice develop extensive osteoporosis associated with an increased number of osteoclasts. Because injection of RANKL into mice produces rapid increases in serum calcium levels, it appears that OPG tonically modulates the rate of osteoclast activity. As yet, the relative roles of CT and OPG in bone resorption are not known.

The inhibition of bone resorption by CT can be explained by a direct action on osteoclasts. Calcitonin treatment of resorbing osteoclasts has a profound effect on cell morphology, resulting in rapid loss of osteoclast ruffled borders, characteristically present at the resorption site, reduced cytoplasmic spreading, and decreased release of lysosomal enzymes. CT infused into rats results in an immediate reduction in the rate of excretion of hydroxyproline, consistent with the action of the hormone to inhibit the breakdown of bone collagen. The other means by which CT could inhibit resorption is through inhibition of osteoclast formation. However, the experimental data relating to such an action are conflicting, with several reports showing CT inhibition of osteoclast-like cell formation in bone marrow cultures of human, baboon, and mouse origin, and other studies, using more physiological concentrations of CT, showing no reduction in osteoclast formation.

B. Renal Actions of Calcitonin

CT has been reported to have several effects in the kidney. These include an increase in the urinary excretion rate of sodium, potassium, phosphorus, chloride, and magnesium. Salmon CT was much more

potent than porcine or human CT when administered subcutaneously into rats. A transient increase in calcium excretion, due probably to inhibition of renal tubular calcium reabsorption, has not usually been regarded as an important effect of CT, although recent observations link it to the calcium-lowering effect of CT in hypercalcemic patients with metastatic bone disease, in addition to inhibition of osteolysis by CT. Calcitonin receptors have been demonstrated clearly in the kidney, and a further action on the kidney is to enhance 1-hydroxylation of 25-hydroxyvitamin D in the proximal straight tubule of the kidney by stimulating the expression of 25-hydroxyvitamin D 1α-hydroxylase. These results suggest that CT is involved in the regulation of vitamin D production.

C. Central Actions of Calcitonin

In addition to their presence in kidney and bone, CTRs are also abundant in the central nervous system (CNS). Central administration of CT generates potent effects that include analgesia and inhibition of appetite and gastric acid secretion. The centrally mediated actions of CT correlate well with the location of CT binding sites. The periaqueductal gray is important in central regulation of pain, and CT binding within this region is likely to be involved in CT-induced analgesia, although other brain regions have also been implicated. The recent identification of mouse CTR mRNA in serotonergic neurons, which are known to project into the spinal cord, forming a descending inhibitory system against pain transmission, also strongly supports a central analgesic role for CT. Administration of CT in clinical situations of bone pain can be very effective in ameliorating the pain symptoms. The hypothalamic binding parallels the multiple hypothalamic actions of CT, which include modulation of hormone release, decreased appetite, gastric acid secretion, and intestinal motility. There are also high densities of receptors in the subfornical organ (SFO), the vascular organ of the lamina terminalis (VOLT), and the area postrema, which, as circumventricular organs, are directly accessible to thyroidally derived, blood-borne CT. The area postrema is likely to contribute similarly to the anorexia of peripherally administered CT. The SFO and VOLT are involved in fluid and electrolyte homeostasis and thus are potential targets for CT-induced alteration in drinking behavior. Salmon calcitonin, when injected into the lateral part of the paraventricular nucleus of the hypothalamus, significantly reduced sleep duration and profoundly affected sleep cycles, producing prolonged insomnia, major reduction of slow-wave sleep, and a long period of alternation of rapid eye movement (REM) sleep and wakening.

D. Other Actions of Calcitonin

Using various experimental approaches, CT and its receptors have been identified in a large number of other cell types and tissue sites, suggesting multiple roles for the CT/CTR. CTR binding sites include kidney, brain, pituitary, testis, prostate, spermatozoa, lung, and lymphocytes, as well as cancer-derived cells from lung, breast, pituitary, bone (osteoclastoma, osteogenic sarcoma), and embryonal carcinoma. There is evidence consistent with the involvement of CT in cell growth and differentiation and in tissue development and remodeling. CT appears to be important both for blastocyst implantation and for development of the early blastocyst. In addition, embryonic expression of the mouse CTR, and of a lacZ construct driven by the CTR promoter, suggest that CTRs may play important roles in morphogenesis. Reports that CT treatment of human breast cancer cells inhibited cell proliferation, together with the reported mitogenic action of CT in certain prostate cancer cell lines, support a role for CT in the modulation of cell proliferation. Recently, CT was found to inhibit profoundly the growth of cells overexpressing human CTR, causing an accumulation of cells in the G_2 phase of the cell cycle, which is associated with a prolonged increase in $p21^{WAF1/CIP1}$ expression and a sustained activation of the p42/44 mitogen-activated protein (MAP) kinase proteins. CT may also have a role in cell survival, and has been shown to be protective of drug-induced apoptosis in osteoblast-like and osteocyte-like cells and prostate cancer cell lines, and to promote the survival of osteoclasts. On the other hand, CT has been found to potentiate neuronal death due to oxygen and glucose deprivation.

As already stated, specific high-affinity receptors for CT have been demonstrated in a number of cancer cell lines and CT has been found to be a potent inhibitor of the growth of human breast cancer cells *in vitro*. A study of CTR in surgically obtained human breast cancers identified receptor mRNA production in all cases examined. CTR expression by tumors possibly represents a recapitulation of fetal expression, and it was recently reported that the CTR is expressed in several fetal tissues in the mouse, including the developing mammary gland, although it is absent in the same tissues postnatally. There are no

data on the developmental expression of the CTR in humans, but it is reasonable to speculate that CTR expression in certain tumors represents a reappearance of fetal expression.

VI. MECHANISMS OF ACTION

A. Receptors

CT is known to act by binding to receptors on the plasma membrane of responsive cells. Our knowledge of the molecular basis of CT action, both in terms of ligand-binding and post-binding events, has been greatly assisted by the cloning of the CTR gene from several species. The first receptor cloned, in 1991, was the porcine CTR, which was isolated by expression cloning from a cDNA library derived from a renal epithelial cell line. Subsequently, human, rat, mouse, rabbit, and guinea pig CTR cDNAs were isolated. Analysis of the proteins translated from the CTR DNA sequences revealed that these receptors comprise approximately 500 amino acids and belong to the class II (family B) subclass of G-protein-coupled receptors, which also includes the receptors for other peptide hormones such as secretin, parathyroid hormone (PTH), glucagon, glucagon-like peptide-1, vasoactive intestinal polypeptide, pituitary adenylate cyclase-activating peptide, and gastric inhibitory peptide. The human CTR gene is located on chromosome 7 at 7q21.3. In the mouse it is in the proximal region of chromosome 6, and in chromosomal band 9q11–q12 in the pig, which is homologous to the 7q location in humans. The CTR gene, like the genes for other class II G-protein-coupled receptors, is complex, comprising at least 14 exons with introns ranging in size from 78 nucleotides to >20,000 nucleotides. The total receptor gene is estimated to exceed 70 kb in length. In organization and size, the human CTR gene is similar to the pig CTR gene, although some interspecies differences in organization do occur. For instance, in the pig, the intracellular domain 1 (I1) insert is generated by selective use of alternate splice sites located in exon 8, whereas in humans the I1 insert occurs on a separate exon.

B. Receptor Isoforms

Receptor cloning shows the existence of multiple receptor isoforms that arise from alternative splicing of the CTR gene. The human receptor has been most extensively studied and at least five splice variants have been described. Differential splicing at the amino terminus of the coding sequence leads to either a potential additional upstream ATG translation start site or a deletion of the first 47 amino acids. However, the two most common human CTR variants arise by alternative splicing in the sequence encoding intracellular domain 1 (Fig. 2). Of these, the most common of the I1 variants leads to a 16-amino-acid insert in the first intracellular loop of the human CTR (I_{1+}). An alternative small exon may also be spliced into this region, leading to termination of the protein in this domain (I_{1ter}). Alternate splicing to yield a 16-amino-acid insert form of I1 also occurs in the pig CTR. However, splicing of the pig CTR primary transcript differs slightly from that in the human transcript, in that the insert arises from alternate splicing within exon 8 of the pig gene, whereas the insert is encoded by a separate exon in the human. Evidence exists for the presence of the I1 truncated form of the receptor only in the human CTR.

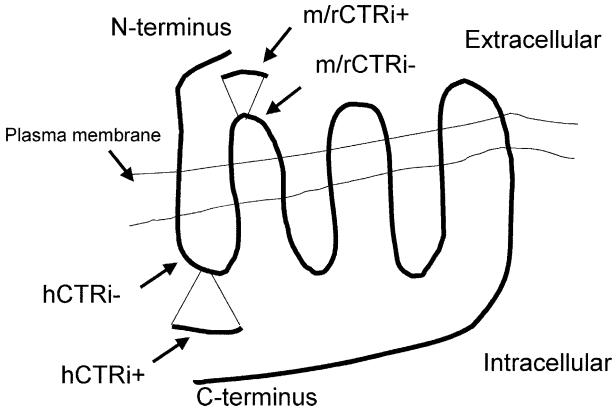

FIGURE 2 Diagrammatic representation of the calcitonin receptor (CTR). The receptor is shown spanning the cell membrane, with the N-terminal domain extracellular and the C-terminal domain intracellular. The mouse and rat CTRs are expressed as two predominant isoforms that differ by the exclusion (m/rCTRi −) or inclusion (m/rCTRi +) of a 37-amino-acid insert in the first putative extracellular loop of the receptor. The human CTR is expressed as two predominant isoforms that differ by the exclusion (hCTRi −) or inclusion (hCTRi +) of a 16-amino-acid insert in the first putative intracellular loop of the receptor.

Different splice variants have been identified in the CTRs of other species. In rodents, alternate splicing leads to two receptor isoforms (termed C1a and C1b); these differ by the presence (C1b; E_{2+}) or absence (C1a) of an additional 37 amino acids in the second extracellular (E) domain (Fig. 2). In rabbits, alternate splicing can lead to deletion of the exon encoding most of the seventh transmembrane domain. In the case of the human, rodent and rabbit receptors, the

insert-negative form of the CTR is the predominant isoform.

Alternative splicing of the CTRs has consequences for receptor function. For example, C1b variants show a loss of affinity for CT peptides that have a low propensity to form an α-helical secondary structure, such as hCT, whereas peptides with strong helical secondary structure, such as sCT, maintain high affinity at this receptor. In the case of the human CTRs, the receptor isoform containing a 16-amino-acid insert displays similar affinity for peptides to the I_{1-} variant but has dramatically reduced ability to signal intracellularly. Presence of the 16-amino-acid insert leads to complete loss of CT-induced intracellular calcium mobilization and profoundly reduced stimulation of cAMP production in response to CT.

The physiological significance of the multiple CTR isoforms remains to be established. However, receptor isoforms are differentially expressed in different cell types, suggesting that alternative splicing is highly regulated and that receptor variants do have physiological roles. For example, the level of expression of the I_{1+} isoform is relatively high in human ovary and placenta, and the rodent C1b receptor isoform is widely expressed in the CNS. The C1b receptor has only very weak affinity for the thyroidally derived form of CT (rat or human) and thus may act as a receptor for endogenous sCT-like peptides that have been found in neural tissues. Alternate splicing thus produces CTR variants with altered function.

It has recently been found that changes in receptor function can also be achieved by interaction between the CTR and proteins of a newly recognized family called receptor activity-modifying proteins (RAMPs). To date, three RAMPs, RAMP1, RAMP2, and RAMP3, have been identified. These proteins are single-transmembrane-spanning proteins that act to modify receptor processing, glycosylation, and presentation on the cell surface. Interactions between CTRs, and several closely related receptors, and RAMPs can alter ligand specificity. For example, in the case of the human CTR, which alone binds amylin with low affinity, RAMP3 enables these receptors to interact with amylin with greatly increased affinity (Fig. 3). This finding is of great interest because it has not been possible to identify the amylin receptor as a

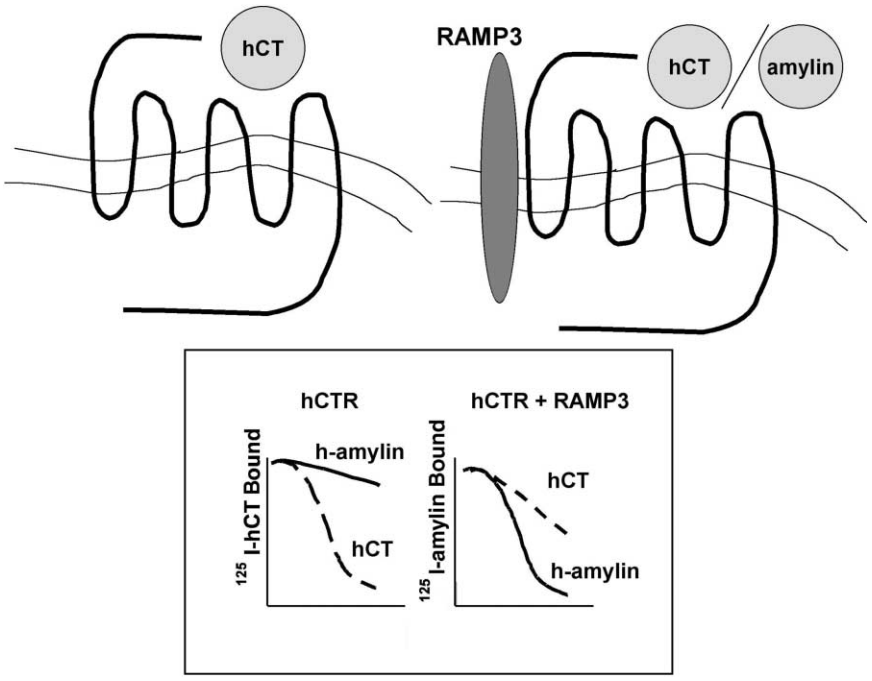

FIGURE 3 Schematic model of altered ligand recognition by the calcitonin receptor due to receptor interaction with RAMP protein. The model shows that expression of the human CTR (hCTR) alone leads to high-affinity interaction with human calcitonin (hCT) and poor interaction with amylin, as shown by the relative ability of these peptides to compete for binding of ^{125}I-labeled hCT (lower panel). The co-expression of RAMP3 with hCTR leads to an amylin receptor "phenotype" that can bind either hCT or amylin, as shown by the competitive binding of ^{125}I-labeled amylin and unlabeled amylin.

unique gene product. Thus, RAMPs present a novel mechanism for alteration or generation of receptor phenotype, and regulation of RAMPs may be important in the regulation of the physiological response to the CT family of peptides.

C. CTR Signaling

The molecular mechanisms by which CTRs signal inside cells to produce cellular effects are still being elucidated. However, the signaling pathways appear to depend on the cell type as well as on the animal species. As with most other G-protein-coupled receptors, the CTR can couple to multiple members of the guanosine triphosphate (GTP)-regulated G-protein family (Fig. 4). In many cell types, activation of the CTR results in its ability to interact with G_s, which leads, in turn, to activation of adenylate cyclase and elevated intracellular levels of cyclic adenosine monophosphate (cAMP). The action of CT in osteoclasts to inhibit bone resorption is accompanied by increased cAMP levels. In addition, both forskolin, which directly activates adenylate cyclase, and dibutyryl cAMP, which elevates intracellular cAMP independent of adenylate cyclase action, inhibit bone resorption. Calcitonin also stimulates adenylate cyclase activity in kidney, with the pattern of CT responsiveness paralleling the distribution of CTRs in this tissue. Calcitonin induction of cAMP has now been documented in a large number of cultured CTR-bearing cells, including LLC-PK1 pig kidney cells, and in cancers of lung, breast, and bone. Receptor cloning and expression studies have confirmed that cAMP production is an important component of CTR-mediated signaling in many cell types.

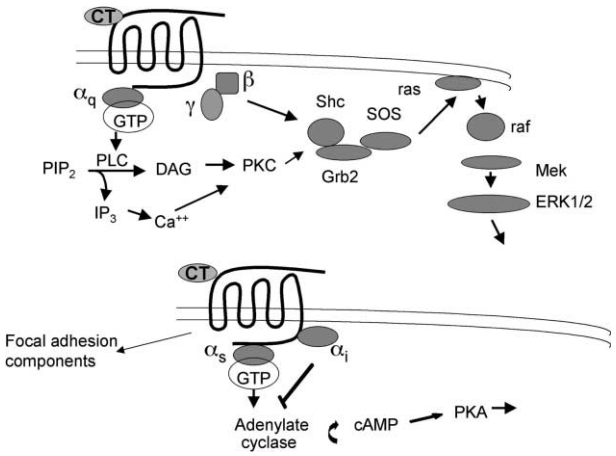

FIGURE 4 Signaling capability of the CTR, showing some of the major intracellular signaling pathways that are activated on binding of CT to the CTR. Ligand binding causes a conformational change in the receptor that enables it to bind to (and to activate, by allowing the binding of GTP) a number of heterotrimeric G-proteins. These G-proteins then dissociate into α and βγ subunits, which act as adapter molecules that in turn bind and activate effector molecules, such as phospholipase C (PLC) and adenylate cyclase. Downstream pathways activated include those involving protein kinase C (PKC), protein kinase A (PKA), mitogen-activated protein kinase (extracellular signal-related kinase, ERK), and components of the focal adhesions.

Activation of the insert-negative isoforms of the CTR can also induce mobilization of intracellular calcium. In osteoclasts, there is evidence that signaling through both cAMP and intracellular calcium is important in CT action. Inhibition of osteoclast-mediated bone resorption by CT can be mimicked by dibutyryl cAMP and phorbol esters or blocked by protein kinase inhibitors. Thus, coupling of the CTR to different G-proteins can activate adenylate cyclase as well as phospholipase C. In the latter case, coupling of the CTR to G_q can lead to increased intracellular triphosphate levels and thence to increased cytosolic calcium, which, together with co-liberated diacylglycerol, activates protein kinase C. In brain tissue, CT apparently couples primarily to G-proteins other than G_s, based on the limited evidence of activation of adenylate cyclase in neural tissue. In hepatocytes, CT-induced activation of adenylate cyclase has not been shown, but CT, even at very low concentrations, is capable of increasing cytosolic calcium, and CT-induced differentiation of early rat embryos is dependent on intracellular calcium mobilization. In LLC-PK1, pig kidney cells, CT can induce changes mediated by either cAMP or intracellular calcium, in a cell-cycle-dependent manner. Finally, expression of cloned receptors in several cell types has conclusively shown that CTRs of human, rat, and porcine origin are capable of signaling through both cAMP- and calcium-activated second-messenger systems. Study of cell lines expressing different CTR levels has suggested that the magnitude of this response is proportional to the receptor density, a common finding also in other receptor systems. This phenomenon has been described, for example, for the thyrotropin-releasing hormone and PTH receptors, so that relative receptor density in target tissues can influence the signaling pathways that are activated in particular cells.

An interesting "calcium-sensing" function of the CTR has been reported, whereby CTR-bearing cells are rendered sensitive to extracellular calcium in terms of increased cytosolic calcium. Thus, CT treatment of CTR-bearing cells, in the presence of

extracellular calcium, initiates a sustained rise in intracellular calcium level, the extent of which is dependent on the concentration of the extracellular calcium. Because osteoclasts, which express high levels of CTR, are reportedly exposed to calcium concentrations as high as 26 m*M* during bone resorption, this phenomenon may have particular relevance for this cell type. In fact, CT and extracellular calcium can both cause intracellular calcium transients in isolated osteoclasts and, interestingly, CT and extracellular calcium greatly augment the signal produced by either agent alone.

In addition to cAMP- and Ca^{2+}-mediated signaling, CTR-mediated activation of the MAP kinase (MAPK) pathway was also recently described (Fig. 4). Rapid or sustained activation of MAPK has been observed under different circumstances, the former apparently involving both G_i and G_q mechanisms. Evidence for coupling of CTRs to G_i was seen in cells overexpressing the C1b CTR isoform, in which pertussis toxin enhanced the cAMP response to CT. The means by which CTR activation leads to MAPK activation requires further examination, and, in particular, consideration of a possible role for βγ G-protein subunits, as is commonly the case for other G-protein-coupled receptors. There is also evidence that CT can influence cell attachment mechanisms by modulating components of focal adhesions and the cytoskeleton. CT can induce phosphorylation of the focal adhesion-associated protein, human enhancer of filamentum 1 (HEF 1), paxillin, and focal adhesion kinase (FAK), and the association of these latter two proteins with HEF 1. This effect of CT requires cell attachment and the integrity of the cytoskeleton, and involves c-Src. CT treatment of cells can thus result in complex effects on cell attachment mechanisms, although it is not yet clear how these *in vitro* results relate to the actions of CT *in vivo*.

D. Receptor Regulation

The cell surface expression of receptors is, in general, tightly regulated, and both the absolute amount of cell surface receptor and the affinity of the receptor for ligand can be modulated. The CTR is subject to regulation both by CT (homologous regulation) and by other agents (heterologous regulation). Calcitonin-induced CTR down-regulation has been demonstrated in various transformed CTR-expressing cell lines, primary kidney cell cultures and osteoclasts. The CT-induced loss of CTRs in osteoclasts has been proposed as a mechanism to account for the well-known loss of responsiveness by patients to CT on repeated administration clinically. This refractoriness has been termed "escape." Down-regulation of the CTR is mediated by specific loss of cell surface receptors, which occurs by an energy-dependent internalization of the ligand–receptor complex. Prevention of lysosomal degradation also prevents loss of cell surface receptors, indicating that the principal internalization pathway involves processing of the receptor–ligand complex into lysosomes and subsequent degradation of the receptor. Prevention of lysosomal recycling does not influence receptor levels, suggesting that the CTRs are unlikely to be recycled. Down-regulation of CTRs *in vivo* has been observed in the kidney, in animals chronically administered CT and in animals with CT-secreting tumors. Down-regulation of CTRs is accompanied by desensitization of responses to CT, in particular activation of adenylate cyclase. This presumably occurs via uncoupling of the CTR from G-proteins.

Acutely, down-regulation of receptors is not mimicked by activators of either protein kinase A (PKA) or protein kinase C (PKC), and may be dependent on G-protein receptor kinases. The intracellular C-terminal tail of the CTR is subject to phosphorylation by second messenger-dependent and second messenger-independent kinases following agonist activation of the receptor, and it has been shown that integrity of the C-terminal tail is important for cellular internalization of the CTR. However, the mechanisms of CTR expression by homologous down-regulation appear to be cell-type dependent. For example, in mouse or rat osteoclasts, a potent down-regulation of CTR mRNA appears to be mediated by a cAMP-dependent mechanism (Fig. 5), in addition to down-regulation of the receptor by internalization. The mechanism of CT-induced receptor mRNA loss in osteoclasts is due principally to destabilization of receptor mRNA. The 3′-untranslated regions of mouse and rat CTR mRNAs contain four AUUUA motifs, as well as other A/U-rich domains and a large number of poly(U) regions. Such motifs, commonly found in cytokines and oncogenes, function as signals for rapid mRNA inactivation. Interestingly, CTR regulation in human osteoclasts differs from that in mice in that receptor down-regulation and CT-induced receptor mRNA loss appear to be due to PKC-mediated events, rather than involving cAMP (Fig. 5). In nonosteoclastic cells, regulation of the CTR was found to be mechanistically distinct from that in osteoclasts. In a number of cell types, CTR down-regulation was cAMP-independent and did not involve reduced CTR

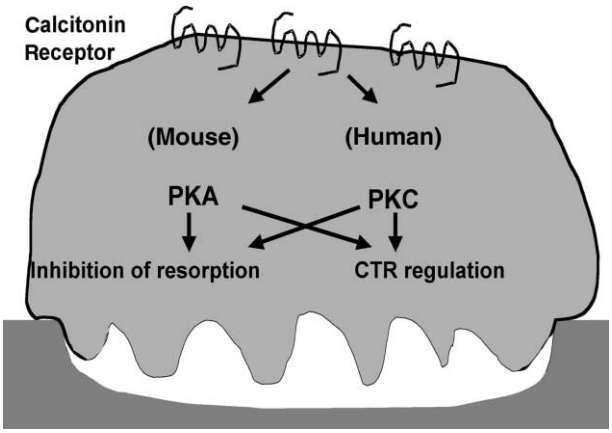

FIGURE 5 Species specificity of CTR-mediated signaling in osteoclasts. Mammalian osteoclasts express abundant CTRs and CT is a potent inhibitor of osteoclast resorptive activity. CT also causes rapid and prolonged down-regulation of the CTRs in osteoclasts. However, the signaling pathways activated in osteoclasts are species specific, with inhibition of osteoclast activity and CTR regulation due primarily to PKA activation in mouse osteoclasts and due primarily to activation of PKC in human osteoclasts.

mRNA levels. It has now been found that the CTR gene in the mouse has at least three promoters and that one of these, P3, appears specific for osteoclasts. Different promoter usage may provide a mechanism for the tissue-specific regulation of the CTR.

An additional interesting aspect of CT-induced CTR regulation in osteoclasts is that glucocorticoid treatment can substantially prevent the loss of CTRs. In the mouse, glucocorticoid treatment was shown by nuclear run-on analysis to increase transcription of the CTR gene. It is worth noting that clinical evidence suggests that glucocorticoids, when administered with CT, might prevent to some extent the CT-induced resistance to its own action. It is also worth noting that the degree of internalization of human CTRs appears to be isoform specific, with the I_{1+} variant being resistant to internalization. Thus, the regulation of receptors, and consequently peptide responses, may also vary according to the level of specific receptor isoforms present in each tissue.

Heterologous regulation of the CTR by other agents has also been found. As previously indicated, in mouse and human osteoclast cultures, glucocorticoids increase the level of cell surface CTR expression following up-regulation of receptor mRNA levels; this is an effect mediated at the level of transcription. Similarly, the CT-mediated decrease in cell surface receptors and mRNAs is attenuated by dexamethasone. Increased production of CTRs in response to glucocorticoid stimulation also occurs in the human T47D breast cancer cell line, which requires cortisol for expression of CTRs, suggesting that this may be a common regulatory mechanism for induction of CTR expression. Transforming growth factor-β (TGF-β) also increases CTR levels in human blood monocyte cultures; this is perhaps related to induction of cellular differentiation toward the osteoclast lineage. As with homologous CTR regulation, responses to heterologous agents are cell-type specific. Thus, in UMR106-06 cells, TGF-β reduces the cell surface CTR levels. CTR expression is an early marker for differentiation of cells toward osteoclasts, and indeed is considered the most reliable marker for monitoring osteoclast differentiation. Thus, factors that induce osteoclasts induce CTRs as part of this process. A recent example of this is the combination of macrophage colony-stimulating factor (M-CSF) and the soluble osteoclast differentiation factor, RANK ligand, which can induce CTR expression in human or mouse monocytes or mouse spleen cells, secondary to promotion of osteoclast differentiation.

VII. SUMMARY

There is much yet to learn about the actions and role of CT. It will be important to better understand the physicochemistry of CT–CTR interactions, and the pharmacokinetics of CT, so that small-molecule CT mimetics and more potent, differently delivered, longer acting forms of the molecule can be designed to control bone resorption and turnover. An understanding of the actions of CT in inflammation and stress, in the CNS, in blastocyst implantation and development, in cancer, and in cell growth and morphogenesis could well have interesting and unexpected consequences. The recent recognition that the CTR can also interact with other peptides by collaborating with RAMPs provides additional complexity to CT physiology. The study of calcitonin in and well beyond its role as a calcium-regulating and bone-sparing hormone will continue to provide insights of biological interest and of importance in our understanding of health and disease.

Glossary

calcitonin A 32-amino-acid peptide hormone produced by the C cells of the thyroid. Immunologically similar molecules have also been identified in other tissues, suggesting additional local autocrine or paracrine actions of calcitonin.

G-proteins Family of intracellular proteins that act as linking molecules or adapters to link receptors to effector molecules. G-Proteins are heterotrimers of $\alpha\beta\gamma$ subunits and are activated by receptor binding, which enables them to bind GTP and to dissociate into α and $\beta\gamma$ subunits, which in turn activate molecules such as adenylate cyclase and phospholipase C. Activation is terminated by hydrolysis of GTP to GDP.

isoforms Different but related forms of protein molecules. Different isoforms of the calcitonin receptor arise by differential splicing of the primary mRNA transcript. This means that the CTR mRNA, which is transcribed from a single gene, can be further processed (spliced) to remove portions of mRNA that correspond to particular exons of the CTR gene. The different mRNA species then code for proteins that contain or exclude portions of the receptor, and this has functional consequences.

osteoclasts Large, multinucleated cells that are responsible for the resorption of bone in the cycle of bone turnover that comprises bone removal and bone formation. Osteoclasts are sensitive to CT, which rapidly and potently inhibits their bone-resorbing activity.

receptor A protein molecule that recognizes and binds its cognate ligand with high affinity and specificity. The calcitonin receptor is a cell surface receptor with extracellular domains that interact with the calcitonin molecule (ligand). The intracellular domains interact with intracellular signal transduction molecules to translate ligand binding into cellular actions.

G-proteins Family of intracellular proteins that act as linking molecules or adapters to link receptors to effector molecules. G-Proteins are heterotrimers of $\alpha\beta\gamma$ subunits and are activated by receptor binding, which enables them to bind GTP and to dissociate into α and $\beta\gamma$ subunits, which in turn activate molecules such as adenylate cyclase and phospholipase C. Activation is terminated by hydrolysis of GTP to GDP.

isoforms Different but related forms of protein molecules. Different isoforms of the calcitonin receptor arise by differential splicing of the primary mRNA transcript. This means that the CTR mRNA, which is transcribed from a single gene, can be further processed (spliced) to remove portions of mRNA that correspond to particular exons of the CTR gene. The different mRNA species then code for proteins that contain or exclude portions of the receptor, and this has functional consequences.

osteoclasts Large, multinucleated cells that are responsible for the resorption of bone in the cycle of bone turnover that comprises bone removal and bone formation. Osteoclasts are sensitive to CT, which rapidly and potently inhibits their bone-resorbing activity.

receptor A protein molecule that recognizes and binds its cognate ligand with high affinity and specificity. The calcitonin receptor is a cell surface receptor with extracellular domains that interact with the calcitonin molecule (ligand). The intracellular domains interact with intracellular signal transduction molecules to translate ligand binding into cellular actions.

Calcium Signaling

STANKO S. STOJILKOVIC

National Institute of Child Health and Human Development, Maryland

Calcium acts as both an extracellular (first) and an intracellular (second) messenger in biological systems. Intracellular calcium signals are generated by activation of ionic channels and pathways in plasma membrane, endoplasmic and sarcoplasmic reticula, mitochondria, and cell nuclei. Calcium signals vary with respect of their spatial and temporal characteristics and frequency and amplitude coding. Calcium functions are versatile and universal in living systems: triggering life at fertilization, controlling cell division and differentiation, modulating the subsequent activity of cells, and ultimately signaling apoptosis.

I. INTRODUCTION

Over 100 hormones and neurotransmitters, acting on their respective receptors and receptor channels, relay their signals by altering intracellular calcium concentrations ($[Ca^{2+}]_i$). For the generation of intracellular Ca^{2+} signals, cells depend on pathways that facilitate calcium release (i.e., Ca^{2+} mobilization) from the endoplasmic reticulum (ER) and the sarcoplasmic reticulum (SR) and/or calcium influx across the plasma membrane. Calcium mobilization occurs in both nonexcitable and excitable cells and is mediated through Ca^{2+} channels that are associated with intracellular organelles. These channels belong to two major classes: inositol 1,4,5-trisphosphate ($InsP_3$)-sensitive receptor channels ($InsP_3Rs$) and ryanodine-sensitive calcium release channels (RyRs). The phospholipase C-controlled production of $InsP_3$ is essential in the initiation of Ca^{2+} release through $InsP_3Rs$, and this family of enzymes is controlled by several G-protein-coupled receptors as well as by some members of tyrosine kinase receptors. $InsP_3$-controlled Ca^{2+} release is also commonly associated with Ca^{2+} influx; Ca^{2+} release predominates during the early phase of agonist stimulation, whereas Ca^{2+} entry is essential during sustained agonist stimulation. In nonexcitable cells, Ca^{2+} influx occurs through store-operated Ca^{2+} channels. In excitable cells, these channels may also be expressed and act in conjunction with voltage-gated calcium channels (VGCCs). RyRs are expressed in the ER and SR membranes and are sensitive to the plant alkaloid ryanodine, after which they are named. At the present time, it is unknown whether they operate as intracellular ligand-gated channels. However, $InsP_3$-induced Ca^{2+} release and action potential (AP)-driven Ca^{2+} influx through VGCCs signal the release of intracellular Ca^{2+} through RyRs, a process known as Ca^{2+}-induced Ca^{2+} release.

Calcium influx can also occur independently of the status of calcium release pathways. There are two major mechanisms by which receptors control calcium influx: VGCCs and external ligand-gated channels. VGCCs are highly selective for Ca^{2+} and are opened by a decrease in the electrical potential across the plasma membrane (V_m), which is the membrane depolarization. In excitable cells, this pathway is typified by the firing of Ca^{2+}-dependent APs. Cells can fire APs spontaneously and/or in response to receptor activation. Hormones can also inhibit spontaneous electrical activity and associated Ca^{2+} signals. In general, receptors can modulate firing of APs directly, by $\beta\gamma$-subunits of G-proteins, or indirectly, by intracellular messengers activated by these receptors. Receptor-induced modulation of AP-driven Ca^{2+} entry is characterized by changes in AP amplitude, duration, or firing frequency; all of which alter Ca^{2+} influx. On the other hand, ligand-gated receptor channels, including nicotinic acetylcholine receptor channels, glutamate receptor channels, and adenosine 5′-triphosphate (ATP) receptor channels, require the binding of an extracellular ligand to open the channel pore. Many of these channels are permeable to Ca^{2+}, but also conduct other ions to control membrane excitability.

Spontaneous and agonist-induced Ca^{2+} signals can exhibit different spatial and temporal patterns. Calcium signals can be localized within the cytoplasm, such as those driven by electrical activity, but it can also be propagated within the cell (intracellular Ca^{2+} waves) or between cells (intercellular Ca^{2+} waves) to produce more global Ca^{2+} signals. Some cells respond to agonist stimulation with nonoscillatory rises in $[Ca^{2+}]_i$, whereas others respond with oscillatory increases in $[Ca^{2+}]_i$. The complexity of the temporal and spatial organization of Ca^{2+} signals is in accord with the numerous intracellular Ca^{2+} functions, including control of mitochondrial metabolism, "packaging" in the trans-Golgi network, exocytosis of secretory vesicles, and control of gene expression in the nucleus.

II. RECEPTOR-CONTROLLED CALCIUM MOBILIZATION

In nonexcitable cells, receptor-controlled Ca^{2+} mobilization is the major pathway for Ca^{2+} signaling. This pathway is also operative in excitable cells. In both cell types, calcium-mobilizing receptors coupled to G_q/G_{11} (gonadotropin-releasing hormone [GnRH], thyrotropin-releasing hormone [TRH],

angiotensin II, endothelin, vasopressin receptors, etc.), as well as several receptors coupled to pertussis-toxin-sensitive G_i (luteinizing hormone, dopamine D2, serotonin 5HTlc, muscarinic m2, formyl-methionyl-leucyl-phenylalanine receptors, etc.), activate phospholipase C-β, whereas tyrosine kinase receptors activate phospholipase C-γ. Both enzymes hydrolyze membrane-associated phosphatidylinositol 4,5-bisphosphate to increase the production of $InsP_3$ and diacylglycerol. Diacylglycerol remains in the plasma membrane, where it acts on protein kinase C, whereas $InsP_3$ rapidly diffuses into the cytosol to release Ca^{2+} from a fraction of the nonmitochondrial stores containing $InsP_3Rs$.

Purification and functional reconstitution of $InsP_3Rs$ demonstrate that the binding sites for $InsP_3$ are on the same protein that makes up the Ca^{2+} release channels. This channel is composed of four similar subunits forming a four-leaf clover-like structure, the center of which makes the Ca^{2+}-selective channel. Three subtypes of these receptor channels have been identified and most cells express multiple isoforms of $InsP_3Rs$. These channels are common for all cells and are localized in the ER membrane, nuclear membrane, and possibly the plasma membrane in some cell types. Functionally reconstituted purified $InsP_3Rs$ respond to $InsP_3$ with an increase in the probability of the open state due to a large conformational change. The release of Ca^{2+} is electrically compensated by an inward potassium flux. The $InsP_3$ binding sites are located within the first 788 residues of the N-terminus of each subunit. In addition to $InsP_3$, cytosolic Ca^{2+} is the major messenger controlling InP_3R gating. Investigation of the single-channel function of type 1, type 2, and type 3 $InsP_3R$ has revealed isoform-specific properties in terms of isoform sensitivity to $InsP_3$ and Ca^{2+}. Several other factors also modulate the activity of IP_3Rs, including lumenal calcium, protein kinase A, protein kinase C, calcium/calmodulin-dependent protein kinase II, adenine nucleotides, and pH.

Activation of $InsP_3$-dependent Ca^{2+} mobilization is associated with depletion of the ER calcium pool, and Ca^{2+} entry through Ca^{2+}-conducting channels is essential to sustaining agonist-induced Ca^{2+} spiking and refilling of intracellular Ca^{2+} pools on termination of receptor activation. The mechanism of activation of voltage-insensitive Ca^{2+} influx pathways has been termed "capacitative calcium entry," indicating that intracellular Ca^{2+} stores prevent entry when they are charged (filled by Ca^{2+}), but promote entry as soon as the stored Ca^{2+} is discharged (released). Because depletion of the ER Ca^{2+} stores is followed by the influx of Ca^{2+} into the cell, the channels involved in such influx are termed "store-operated Ca^{2+} channels" (SOCCs). At the present time, the nature of these channels and the mechanism of their regulation in response to store depletion are unknown. The fruit fly *trp* gene and its mammalian counterparts have been considered to encode components of SOCCs. Others have proposed CaT1 protein as a constituent of the ion-conducting pore of SOCCs. According to one theory, a diffusible signal (calcium influx factor) is released from the ER during store depletion and binds to and activates SOCCs. The other model proposes that depletion of Ca^{2+} stores leads to a conformation change in $InsP_3Rs$, which can then bind to SOCCs (Fig. 1).

In excitable cells, calcium-mobilizing receptors, including GnRH, bradykinin, opioid, substance P, ATP, adrenergic, TRH, and angiotensin II receptors, also stimulate or inhibit voltage-gated Ca^{2+} influx by altering the V_m. During the initial receptor activation, agonist-induced release of Ca^{2+} from the ER opens Ca^{2+}-activated K^+ or Cl^- channels that hyperpolarize the membrane. This in turn inhibits AP firing and the associated Ca^{2+} influx, preventing a lethal increase in $[Ca^{2+}]_i$. The depletion of the ER calcium pool terminates activation of these channels, frequently leading to depolarization of cells and activation of voltage-gated calcium influx. Several channels have been implicated in sustained receptor-induced depolarization of cells, including non-elective cationic channels and SOCCs, and M-type voltage-dependent K^+ channels (Fig. 1).

III. RECEPTOR-CONTROLLED VOLTAGE-SENSITIVE CALCIUM INFLUX

Stimulation of Ca^{2+} influx through VGCCs is the major pathway for Ca^{2+} signaling in excitable cells. VGCCs are large multisubunit proteins that span the plasma membrane to provide a Ca^{2+}-selective pathway into the cytosol. Biophysical and pharmacological studies have identified multiple subtypes of VGCCs that can be distinguished by their ion selectivity, single-channel conductance, pharmacology, metabolic regulation, and tissue localization. Consistent with functional studies, molecular cloning has identified several genes that encode different VGCC subtypes. The first Ca^{2+} channel was purified from skeletal muscle, a highly enriched source of L-type Ca^{2+} channels. Purification of the channel identified five subunits, including a large α_1 subunit and four smaller ancillary subunits, α_2, β, γ, and δ.

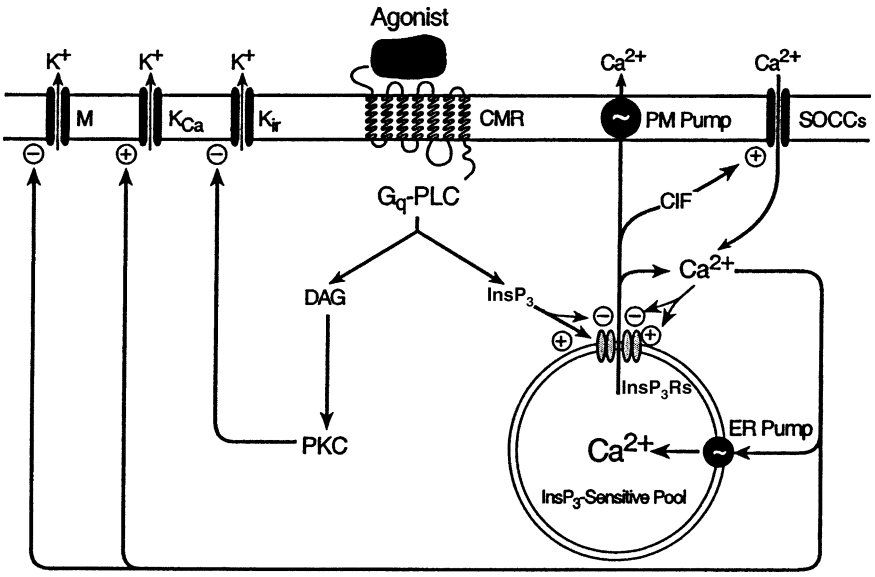

FIGURE 1 A calcium-mobilizing receptor (CMR) and calcium signaling. Activation of cell surface receptors by peptide hormones results in the production of inositol 1,4,5-trisphosphate ($InsP_3$) via G-protein and phospholipase C (PLC). $InsP_3$ binds to its receptors ($InsP_3Rs$) on the endoplasmic reticulum (ER), resulting in release of Ca^{2+} and a diffusible signal, the calcium influx factor (CIF). Ca^{2+} acts as a coagonist in the control of $InsP_3R$ permeability. When the receptor is occupied by $InsP_3$, low concentrations of calcium facilitate Ca^{2+} release from the ER, and subsequently the elevated $[Ca^{2+}]_i$ inhibits $InsP_3Rs$. During prolonged occupation of the receptor, $InsP_3$ may also inhibit $InsP_3Rs$. CIF binds to and activates store-operated calcium channels (SOCCs) on the plasma membrane (PM). An alternative model proposes that release of Ca^{2+} from the ER leads to a conformation change in the $InsP_3R$, which can then bind to SOCCs (not shown). In excitable cells expressing CMRs, discharge of Ca^{2+} from the ER activates Ca^{2+}-controlled potassium channels (K_{Ca}), leading to a transient hyperpolarization of cells. During sustained agonist stimulation, calcium inhibits M-type potassium channels, an action that depolarizes cells and facilitates voltage-gated Ca^{2+} influx. Protein kinase C (PKC)-mediated inhibition of spontaneously active inward rectifier potassium channels (K_{ir}) has similar effects on voltage-gated Ca^{2+} influx. Finally, in excitable cells expressing SOCCs, activation of these channels leads to depolarization of cells and facilitation of voltage-gated Ca^{2+} influx. DAG, diacylglycerol.

The α_1 subunit consists of four homologous repeats, each one composed of six transmembrane segments. Located within the α_1 subuint are the voltage sensor, gating machinery, channel pore, and multiple protein kinase A- and C-dependent phosphorylation sites. Since the first α_1 subunit was cloned from skeletal muscle, at least seven isoforms have been identified, including α_{1S}, α_{1C}, α_{1D}, α_{1B}, α_{1A}, α_{1E}, and α_{1G}.

Voltage-gated Ca^{2+} channels serve two major functions in excitable cells; one is to generate and/or shape action potentials and the other is to allow Ca^{2+} influx during the transient depolarization. Membrane depolarization increases the probability that VGCCs will open, whereas membrane hyperpolarization decreases this probability. In some cells, VGCCs account entirely for the upstroke of an AP. In other cells, voltage-gated Na^+ and Ca^{2+} channels contribute to the upstroke of the AP. In spontaneously quiescent cells, G-protein-coupled receptors can initiate AP firing by depolarizing cells. In spontaneously firing cells, G protein-coupled receptors can further depolarize cells and stimulate AP-driven Ca^{2+} entry, as well as inhibit it by hyperpolarizing cells. Receptor-mediated stimulation and inhibition of AP firing can be regulated by direct actions on VGCCs and/or indirectly through other plasma membrane ionic channels. In general, G_q/G_{11}-coupled receptors can modulate voltage-gated Ca^{2+} influx via $[Ca^{2+}]_i$/protein kinase C-dependent pathways; G_i/G_o-coupled receptors modulate via $\beta\gamma$ dimers and G_s-coupled receptors modulate via cAMP/protein kinase A signaling pathways (Fig. 2).

A. Direct Modulation of Voltage-Gated Calcium Influx

Receptors modulate the gating properties of VGCCs by two pathways. Inhibition of VGGCs is controlled by the fast membrane-delimited pathway, in which the $\beta\gamma$ dimer of the G_i/G_o protein is a direct

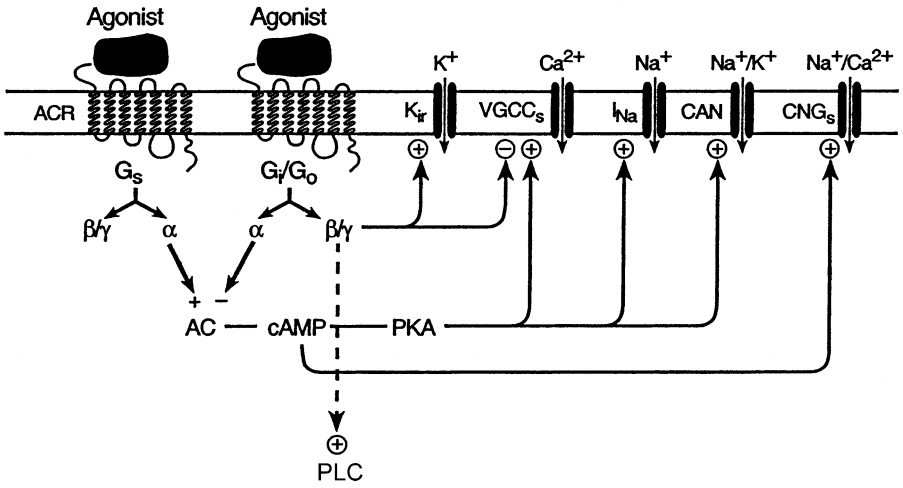

FIGURE 2 Adenylyl cyclase-coupled receptor (ACR) and calcium signaling. ACRs modulate voltage-gated Ca^{2+} influx by the direct actions of G-protein subunits on plasma membrane inward rectifier potassium (K_{ir}) and voltage-gated calcium channels (VGCCs), as well as through protein kinase A (PKA)-dependent phosphorylation of VGCCs, tetrodotoxin-insensitive sodium channels (I_{Na}), and nonselective cationic channels. In cells expressing cyclic nucleotide-gated channels (CNGs), cAMP mediates the action of G_s-coupled receptors. In addition to "classical" G_q/G_{11}-coupled Ca^{2+}-mobilizing receptors, G_i-coupled receptors can also stimulate PLC, leading to production of inositol 1,4,5-trisphosphate and facilitation of Ca^{2+} release from the endoplasmic reticulum (see Fig. 1).

intermediate between the plasma membrane receptor and VGCCs. In the second pathway, diffusion of cytoplasmic messengers mediates the stimulatory action of the G-protein-coupled receptor. The essential structural elements required for G-protein modulation are found in VGCCs, supporting the direct action of G-proteins. Inhibition of the Ca^{2+} channel (N- and P/Q-types) mediated by βγ dimer is a time- and voltage-dependent process. A fraction of the total Ca^{2+} channels open much more slowly and require larger depolarization to open; this produces a slowing of the activation kinetics and a reduction in the current amplitude. The G-protein-dependent inhibition of these channels can be reversed by hormones acting through the protein kinase C pathway. Facilitation of Ca^{2+} influx through L-type VGCCs can occur by protein kinase A-dependent phosphorylation of the α_1 and/or β subunits. On the other hand, protein kinase C-dependent phosphorylation leads to inhibition of voltage-gated calcium influx. Cytosolic calcium also inactivates L-type calcium channels and facilitates P/Q-type Ca^{2+} channels, both in a calmodulin-dependent manner.

B. Indirect Modulation of Voltage-Gated Calcium Influx

The most well-characterized mechanism by which G-protein-coupled receptors indirectly modulate voltage-gated Ca^{2+} influx is that mediated through activation/inhibition of inward rectifier potassium (K_{ir}) channels. In general, inhibition of K_{ir} depolarizes the membrane to increase excitability, whereas activation hyperpolarizes the membrane to decrease excitability. These channels are susceptible to modulation by a wide range of hormones and neurotransmitters that exert their actions via G-zproteins directly or via several different intracellular messenger pathways, including protein kinases A and C, intercellular ATP, and pH. In pituitary melanotrophs and lactotrophs, dopamine activates K_{ir} channels via the fast membrane-delimited pathway to hyperpolarize the membrane, causing a cessation of AP firing and a decrease in $[Ca^{2+}]_i$ and hormone secretion. Like dopamine, somatostatin stimulates K_{ir} channels via a βγ dimer to reduce membrane excitability and GH secretion in pituitary somatotrophs. On the other hand, in pituitary corticotrophs, corticotropin-releasing factor inhibits the K_{ir} via protein kinase A-dependent pathways to increase AP frequency and associated Ca^{2+} entry. TRH can also inhibit K_{ir} channels in GH3 cells and pituitary lactotrophs, presumably via the protein kinase C pathway, leading to an increase in membrane excitability (Fig. 3). G-Protein-coupled receptors can also modulate voltage-gated Ca^{2+} influx via tetrodotoxin (TTX)-sensitive and -insensitive Na^+ channels, Na^+/Ca^{2+}-conducting ligand-gated channels, and nonselective

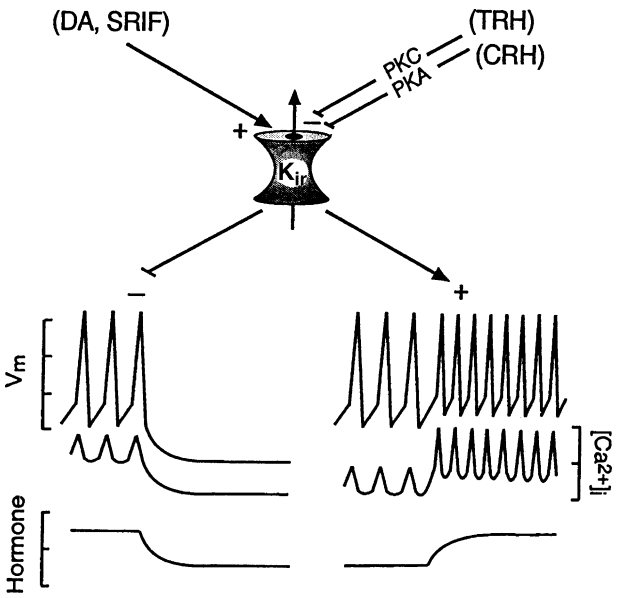

FIGURE 3 Receptor-controlled inward rectifier potassium current (K_{ir}) and membrane excitability. A number of receptors negatively coupled to adenylyl cyclase stimulate type 3 K_{ir} channels, leading to membrane hyperpolarization and abolition of spontaneous electrical activity, a decrease in $[Ca^{2+}]_i$, and a concomitant decrease in hormone secretion. Calcium-mobilizing receptors and those positively coupled to adenylyl cyclase inhibit type 1 and type 2 K_{ir} channels in a protein kinase C (PKC)- and protein kinase A (PKA)-dependent manner, leading to depolarization of cells and an increase in action potential frequency, which increases $[Ca^{2+}]_i$ and augments hormone secretion. DA, dopamine; SRIF, somatotropin release-inhibiting factor; TRH, thyrotropin-releasing hormone; CRH, corticotropin-releasing hormone.

cationic channels. For example, in pituitary somatotrophs growth hormone-releasing hormone (GHRH) activates TTX-insensitive Na^+ channels via a cAMP/protein kinase A signaling pathway, leading to cell membrane depolarization and an increase in AP frequency and $[Ca^{2+}]_i$.

IV. CALCIUM MOBILIZATION THROUGH RYANODINE RECEPTOR CHANNELS

RyRs were originally identified as Ca^{2+} release channels expressed in the SR of skeletal muscle fibers and cardiac myocytes, where they play a central role in excitation–contraction coupling. These channels are also expressed in neurons, chromaffin cells, sea urchin eggs, and several nonexcitable cell types. Mammalian tissues express three isoforms: RyR_1 is expressed predominantly in skeletal muscle, RyR_2 is expressed in cardiac muscle, and RyR_3 has a wide tissue distribution, including the endocrine cells. RyR_1 and RyR_2 channels display a 66% identity, whereas the RyR_3 channel is much shorter. Like the $InsP_3Rs$, RyRs are tetramers, with a large N-terminal region forming heads, and a C-terminal region that forms the Ca^{2+}-selective channel. Although these channels are frequently co-expressed with $InsP_3Rs$, the physiological importance of their co-expression and their variable density within the cells are still largely unclear.

Cytosolic Ca^{2+} is a major regulator of RyRs; at low concentrations, Ca^{2+} promotes release, whereas higher concentrations are inhibitory. However, inhibition of RyRs by high $[Ca^{2+}]_i$ is somewhat controversial, because it requires $[Ca^{2+}]_i$ to be in the millimolar concentration range, which is not reached under physiological conditions. The ability of Ca^{2+} to stimulate its release from the ER/SR via RyRs is called "Ca^{2+}-induced Ca^{2+} release." This process is of fundamental importance for coordinating the elementary Ca^{2+} release events into Ca^{2+} spikes and waves. Unlike $InsP_3Rs$, RyRs can release Ca^{2+} in response to an increase in $[Ca^{2+}]_i$, without any other change in the concentration of second messengers. This is crucial for excitation–contraction coupling. For example, in cardiac cells, Ca^{2+} entry through dihydropyridine-sensitive channels activates RyRs to induce a further increase in $[Ca^{2+}]_i$. In skeletal muscle cells, the dihydropyridine receptors act primarily as voltage sensors to activate RyRs directly in response to V_m depolarization. In neuroendocrine and endocrine cells, activation of RyRs coincides with stimulation of phospholipase C signaling pathway, but also can be coupled with electrical activity, for example, in pancreatic beta cells. In addition to Ca^{2+}, there are numerous other endogenous modulators of RyRs. These include, ER/SR Ca^{2+}, cytosolic pH, Mg^{2+} and other cations, Cl^- and other anions, nucleotides, cyclic adenosine 5′-diphosphate ribose, several protein kinases, calmodulin, and other Ca^{2+}-binding proteins.

V. CALCIUM INFLUX THROUGH EXTRACELLULAR LIGAND-GATED CHANNELS

Extracellular ligand-gated receptor channels differ from other Ca^{2+}-conducting plasma membrane channels in three respects. First, their activation depends on the delivery and binding of a ligand to the extracellular domain. Second, termination of their activities requires removal of the ligand, which is usually mediated by a specific pathway for ligand degradation and/or uptake. Third, they are not highly

selective for Ca^{2+}, but conduct other ions as well. Because ligand-gated channels are generally activated by neurotransmitters, they are also known as neurotransmitter-controlled channels. However, some of these channels can be controlled through hormonal transmission, i.e., a ligand for a particular receptor channel can be colocalized with hormones in secretory vesicles and cosecreted on cell activation. Once released, the ligand can act in an autocrine and/or paracrine manner.

There are two classes of ligand-gated channels, the excitatory cation-selective receptor channels, operated by acetylcholine, glutamate, 5-hydroxytryptamine (5-HT), and ATP, and the inhibitory anion-selective receptor channels, activated by γ-aminobutyric acid (GABA) and glycine. Structural information obtained by cDNA cloning of ligand-gated receptor channels has led to the identification of several families of evolutionarily related proteins. The $5\text{-}HT_3$, GABA, and glycine receptor channels possess structural features similar to those of the nicotinic acetylcholine receptor channel, hence these receptors can be grouped as one family. These channels are composed of five subunits (pentamers), each of which contributes to the ionic pore. Each subunit has a large extracellular amino-terminal region followed by four hydrophobic putative membrane-spanning segments and an extracellular carboxyl terminus.

Glutamate receptor channels (GluRs) are traditionally divided into three major subtypes: (1) the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), (2) kainate (KA), and (3) *N*-methyl-D-asparate (NMDA) receptor channels. Molecular cloning revealed numerous subunits for each receptor group. For NMDA receptor channels, NR1 and NR2A–NR2D subunits have been established. For the non-NMDA receptor channels, GluR1–GluR4 denote the AMPA-sensitive family, whereas GluR5–GluR7, KA1, and KA2 denote the kinate subclass. The molecular diversity of GluRs is further increased by variants created by alternative splicing and RNA editing. All GluR subunits contain four hydrophobic segments, labeled as M1-M4, but their M2 segment forms a pore-loop structure, entering and exiting the cell membrane from the intracellular side. The M2 amino acids line the inner channel pore, and specific residues in this segment determine the ion selectivity of the channel. These receptor channels are expressed in neural cells and in neuroendocrine and excitable endocrine cells.

The ATP-gated channels, termed "P2X receptor channels" (P2XRs), have only two putative transmembrane domains, with the amino- and carboxyl-termini facing the cytoplasm. Seven cDNAs $P2X_1$–$P2X_7$, have been expressed individually in different expression systems. There is 35–50% identity and 50–65% similarity in amino acid sequences between pairs of P2XRs, whereas the recombinant receptors characterized differ among themselves with respect to the action of ATP analogues, the desensitization rate, and the effectiveness of antagonists. As with nicotinic and glutamate channels, functional diversity of P2X channels is generated by subunit multimerization. It is believed that functional channels are tetramers and that both hetero- and homotetramers account for the native receptor channels. In contrast to acetylcholine receptor channel and GluRs, P2XRs have been identified in both excitable and nonexcitable cells.

Because of their permeability to Na^+ and Ca^{2+}, the majority of ligand-gated channels act as a Ca^{2+} influx pathway and as a modulator of AP-driven Ca^{2+} influx. In pituitary gonadotrophs, for example, activation of P2XRs drives Ca^{2+} into the cell to initiate AP firing in quiescent cells or to increase AP frequency and associated Ca^{2+} entry in spontaneously active cells. Because ATP is cosecreted with other neurotransmitters or hormones, it may bind to its receptors to amplify agonist-induced Ca^{2+} signals and secretory responses by further increasing AP-driven Ca^{2+} entry. Activation of $GABA_A$ receptor channels in GnRH-secreting neurons also depolarizes the membrane to increase membrane excitability. Unlike P2XRs, however, activation of $GABA_A$ receptor channels increases the membrane permeability to chloride ions, which diffuse out of the cell to depolarize the membrane. In other cells, $GABA_A$ receptors decrease excitability due to hyperpolarization of the plasma membrane. The mechanisms of desensitization of ligand-gated channels and hormonal control of this process are incompletely characterized.

VI. CALCIUM SIGNALING PATTERNS

A. Localized Calcium Signals

Analysis of images obtained by confocal microscopy of individual cells loaded with Ca^{2+}-sensitive fluorescent dyes makes possible the visualization of localized events in Ca^{2+} signaling. These events occur in the vicinity of a single channel or a small group of channels and consist of a brief opening of the channels and a concomitant rise in local $[Ca^{2+}]_i$ of about 2 μm in diameter; these are termed sparks (in cells expressing RyRs) and blips and puffs (in cells expressing $InsP_3Rs$). At subthreshold agonist

concentrations, the two major factors for the generation of localized Ca^{2+} signals are the site of action of the primary stimulus and the density of Ca^{2+}-mobilizing receptors in the plasma membrane. The focal and discrete injection of an agonist close to one region of the cell leads to a localized rise in $[Ca^{2+}]_i$ near the region of stimulation. Similarly, the initial rise of $[Ca^{2+}]_i$ in oocytes occurs at the point of sperm entry. In pancreatic acinar cells, the $InsP_3Rs$ are predominantly localized in a zone with secretory granules, providing localized Ca^{2+} signals independent from the regions of stimulation by agonist. Depolarization-driven Ca^{2+} entry also forms several types of localized increases in $[Ca^{2+}]_i$ close to the plasma membrane. At the mouth of an open VGCC, $[Ca^{2+}]_i$ can reach hundreds of micromoles, and such a signal is analogous to the blips generated by the activation of a single $InsP_3R$. These highly localized peaks are transient, with a time scale faster than that of Ca^{2+} binding to its buffers, and are relevant for colocalized processes, such as exocytosis. Conversely, the synchronized activity of several VGCCs can generate bumps, or quantum emission domains, which are localized Ca^{2+} signals that are analogous to sparks and puffs.

B. Global Calcium Signals

The elementary calcium events may be arrested and remain local Ca^{2+} signals, or they may trigger the spread of Ca^{2+} throughout the cytoplasm to form global Ca^{2+} signals. Both Ca^{2+} release and Ca^{2+} influx can make the transition from local to global signals. Depending on the cell type, Ca^{2+} waves propagate at 5–100 μm/s. The pattern of $InsP_3Rs$ and RyRs distribution and the size of cells are critical for wave propagation. In $InsP_3R$-dependent wave propagation, the "priming" of cells with $InsP_3$ is required for wave initiation, whereas Ca^{2+} serves as both a positive and a negative feedback element. Depolarization-induced global signals result form the synchronized activity of VGCCs and RyRs, whereby the opening of RyRs is tightly coupled to AP firing.

C. Oscillatory vs Nonoscillatory Calcium Signals

There is an enormous heterogeneity of $[Ca^{2+}]_i$ signals from one cell type to another. Among cells operated by Ca^{2+}-mobilizing receptors, some respond to agonist stimulation by the generation of sinusoidal oscillations, in which agonist concentration regulates the amplitude but not the frequency of Ca^{2+} transients. In other cells, discrete $[Ca^{2+}]_i$ transients or spikes can be observed above a constant baseline level, and this pattern of $[Ca^{2+}]_i$ oscillations is referred to as baseline spiking. Here, the agonist concentration regulates the frequency, but not the spike amplitude. In some cells, both oscillatory patterns are observed, depending on the agonist concentration. Other cells respond with monophasic or biphasic nonoscillatory Ca^{2+} signals in response to agonist stimulation. Monophasic $[Ca^{2+}]_i$ responses are characterized by the generation of a single spike increase in $[Ca^{2+}]_i$. Conversely, biphasic $[Ca^{2+}]_i$ signals can be characterized by the generation of a single transient increase in $[Ca^{2+}]_i$ followed by a sustained increase in $[Ca^{2+}]_i$ of lower amplitude.

D. Intraorganelle Calcium Signals

Except for the ER and SR, where the mechanism of Ca^{2+} release into and uptake from the cytosol is quite well established, Ca^{2+} fluxes across membranes of other organelles are much less understood. New results are emerging, especially on nuclear and mitochondrial Ca^{2+} transport and regulation. The nuclear membranes share many features with that of the ER, including expression of $InsP_3Rs$ and Ca^{2+}-ATPase in the outer membrane, and $InsP_3$ and cADP-ribose-regulated channels in the inner nuclear membrane. Because the inositol lipid cycle also takes place in the nucleus, Ca^{2+} can enter the nucleus directly from perinuclear stores, but can also diffuse from the cytosol through the nuclear pore complex, a large multiprotein structure that provides direct exchange between the cytoplasm and the nucleoplasm. Although research on the control of transport through the pore complex is far from complete, it seems clear that the opening of the pore is regulated by the state of depletion in the perinuclear Ca^{2+} stores. Mitochondria possess their own sophisticated Ca^{2+} efflux/influx systems that are unique compared to the mechanisms taking place at the membranes of the ER and nucleus. Calcium influx occurs via a Ca^{2+} uniporter that is very fast and does not require energy for its operation. Calcium efflux from the mitochondria via two electroneutral antiporters, $2Na^+/Ca^{2+}$ and $2H^+/Ca^{2+}$, requires energy in the form of ATP hydrolysis. Sodium-dependent transport dominates in muscle and neuroendocrine tissues, and sodium-independent transport dominates in the liver and kidney. The mitochondrial system for handling Ca^{2+} constitutes an active element in the formation of Ca^{2+} waves and oscillations, and it can also regulate transient $[Ca^{2+}]_i$ changes, induced by either V_m-controlled or Ca^{2+}-mobilizing processes.

E. Intercellular Calcium Waves

In addition to intracellular Ca^{2+} signals, waves of $[Ca^{2+}]_i$ can flow through connected cells to coordinate the cellular activity of a tissue. Intercellular Ca^{2+} waves are characterized by an increase in $[Ca^{2+}]_i$ that crosses cell borders into neighboring cells through direct or indirect contact with the stimulated cell. Intercellular Ca^{2+} waves can be initiated *in vitro* by electrical or mechanical stimulation of a single cell or by focal application of hormones or neurotransmitters. Once initiated, waves travel complex routes for several hundred micrometers at rates of 15 to 25 μm/s. Intercellular Ca^{2+} waves have been observed in dissociated cell and organotypic cultures of many tissues, including the heart, brain, pituitary, kidney, liver, mammary gland, and lens epithelium. They have also been observed *in situ* using glial cells in acutely isolated rat retinas. Two pathways mediate intercellular Ca^{2+} waves: the movement of cytosolic messengers between connected cells via gap junctions and extracellular diffusion of messenger molecules, such as ATP.

VII. CALCIUM-CONTROLLED CELLULAR MACROMOLECULES AND PROCESSES

A. Calcium-Controlled Enzymes

Calcium can indirectly, by binding to specific intracellular proteins, control the activity of a number of enzymes. In all nonmuscle and smooth muscle cells, calmodulin is the predominant Ca^{2+} binding protein. A related Ca^{2+} binding protein, known as troponin C, dominates in skeletal muscle. The calcium–calmodulin complex controls over 20 intracellular enzymes that participate in regulation of several intracellular functions, such as cyclic nucleotide and glycogen metabolism, secretion, motility, Ca^{2+} transport, and cell cycle. Many of these enzymes are inhibited in an intramolecular manner, and the calcium–calmodulin complex releases this inhibition. Activated calmodulin can bind directly to the effector protein and modulate its activity or can act indirectly through a family of calcium–calmodulin-dependent protein kinases and phosphatases. The kinase family includes myosin light chain kinase, phosphorylase kinase, calmodulin kinase I, calmodulin kinase II, extracellular factor-2 (EF-2) kinase, and calmodulin kinase IV. A number of other enzymes are directly controlled by cytosolic Ca^{2+}. For example, mammalian cells express a family of several closely related protein kinase C isoenzymes, many of which require Ca^{2+} for activation. Cytosolic Ca^{2+} also participates in the control of phospholipases C, D, and A_2. Several members of the adenylyl cyclase family of enzymes are also sensitive to changes in $[Ca^{2+}]_i$. Subtypes 5 and 6 of these enzymes are inhibited by elevation in $[Ca^{2+}]_i$ in a calmodulin-independent manner. The activity of three other members of this family of enzymes, subtypes 1, 3, and 8, is facilitated by the rise in $[Ca^{2+}]_i$ in a calmodulin-dependent manner. Several members of other enzyme families participating in cyclic nucleotide metabolism, i.e., nitric oxide synthase, guanylyl cyclases and phosphodiesterases, are also $[Ca^{2+}]_i$ sensitive.

B. Calcium-Controlled Channels

A rise in $[Ca^{2+}]_i$ is an effective signal for activation and/or inhibition of several plasma and ER membrane calcium channels. The role of Ca^{2+} in control of $InsP_3Rs$ and RyRs has already been discussed. SOCCs are also sensitive to $[Ca^{2+}]_i$, and both calcium-dependent activation and inactivation of these channels have been observed. The conductivity of L- and P/Q-types calcium channels is also altered by $[Ca^{2+}]_i$ in a calmodulin-dependent manner. In addition to Ca^{2+}-selective channels, other ionic channels are controlled or modulated by $[Ca^{2+}]_i$. These include several potassium, chloride, and nonspecific channels, all of which are known to be Ca^{2+}-activated channels.

C. Fertilization, Development, and Apoptosis

Calcium plays important roles in fertilization and embryonic development. At fertilization, the sperm interacts with the egg to trigger Ca^{2+} oscillations. These oscillations last for several hours and may be critical in triggering the enzymes involved in the cell division cycle. The mechanism of these oscillations is not well defined, but it is likely that $InsP_3$ is involved in their generation. Also, a prolonged period of Ca^{2+} signaling, similar to that during fertilization, is an important growth signal for many cells, including normal immune cells and cancer cells exhibiting unlimited growth. During development, cells also use Ca^{2+} signaling pathways to regulate development. For example, the rise in $[Ca^{2+}]_i$ contributes to body axis formation, organ development, cell migration, and formation of neuronal circuits. The finding that alterations in intracellular Ca^{2+} homeostasis are commonly observed in necrosis and apoptosis is consistent with a view that elevated $[Ca^{2+}]_i$, especially if maintained for long periods, can be

cytotoxic. Necrosis is usually accompanied by prolonged nonoscillatory elevations in $[Ca^{2+}]_i$. In contrast, apoptosis represents a more orderly program of cell death. A wide variety of candidate molecules could be involved in the Ca^{2+}-sensitive apoptotic process. These include calmodulin-dependent kinase/phosphatase, Ca^{2+}-sensitive proteases such as calpain and nuclear scaffold protease, Ca^{2+}-activated endonuclease, and transglutaminase.

D. Exocytosis

In endocrine cells and neurons, regulated exocytosis is triggered by an elevation in $[Ca^{2+}]_i$. A rise in $[Ca^{2+}]_i$ is a critical step in the process of exocytosis, which is accomplished by rapid, Ca^{2+}-regulated fusion of neurotransmitter- or hormone-filled vesicles with the plasma membrane. Once the fusion is complete, the components of secretory vesicles are selectively recovered by endocytosis. Secretory vesicles are regenerated by a recycling pathway, and the final stages of this pathway include the recruitment, docking, and ATP-dependent priming of the secretory vesicles, in preparation for the next cycle of exocytosis. Distinct factors are required for sequential docking, ATP-dependent priming, and Ca^{2+}-dependent triggering (fusion) reactions. For example, phospholipids may contribute to the priming, but not to the fusion, whereas Ca^{2+} is required for both steps in exocytosis. Although exocytosis is a highly specialized process, the molecules involved in this process are related to those that mediate the targeting and fusion of transport vesicles in other intracellular membrane trafficking pathways. Among the identified cytosolic Ca^{2+} sensors, synaptotagmin I has been the most thoroughly characterized. Synaptotagmin I is a presynaptic vesicle protein that has two repeats of cytoplasmic calcium domain (C2A and C2B), each sharing homology with the C2 regulatory domain of protein kinase C. These domains mediate Ca^{2+}-regulated interaction with liposomes and the plasma membrane protein syntaxin, suggesting the underlying mechanism for synaptic vesicular docking and fusion to the plasma membrane. Over 50 C2 domain sequences have been identified, several of which have been implicated in exocytosis, including the synaptotagmin isoforms, rabphilin, doc2, and munc13-1.

E. Nuclear Functions

The transcriptional activity of several genes is controlled by $[Ca^{2+}]_i$. Calcium can directly modulate transcriptional activity, but it can also act through individual Ca^{2+}-sensitive proteins that serve as molecular decoders of intracellular Ca^{2+} signals. For example, both Ca^{2+} and cAMP can be involved in the regulation of c-*fos* transcription via calcium- and cAMP-dependent phosphorylation of the dimeric transcription factor, Ca^{2+}/calmodulin response element binding protein (CREB). It is interesting that Ca^{2+} exhibits stimulatory and inhibitory actions on c-*fos* expression that depend on $[Ca^{2+}]_i$. The $[Ca^{2+}]_i$ dose dependence of c-*fos* transcription and mRNA accumulation is bell-shaped, with facilitation at low $[Ca^{2+}]_i$ and inhibition at high $[Ca^{2+}]_i$. It is also likely that different genes require different $[Ca^{2+}]_i$ thresholds for their activation.

F. Mitochondrial Functions

Calcium regulates several mitochondrial dehydrogenase enzymes involved in oxidative ATP synthesis, including pyruvate dehydrogenase, isocitrate dehydrogenase, and α-ketoglutaric dehydrogenase. Calcium regulates these enzymes in the range of 0.2–2 μM concentration. It has been suggested that increases and decreases in $[Ca^{2+}]_i$ are translated into parallel changes in the concentration of mitochondrial Ca^{2+}. Accordingly, V_m-dependent and calcium-mobilizing-dependent mitochondrial $[Ca^{2+}]$ spiking occurs in intact hepatocytes. Furthermore, each Ca^{2+} spike in cytosol is sufficient to cause a transient increase in mitochondrial $[Ca^{2+}]$, which is then associated with a transient activation of Ca^{2+}-sensitive mitochondrial dehydrogenases. This action also triggers sustained activation of mitochondrial metabolism as long as the spiking frequency is higher than 0.5/min. In contrast, sustained low-amplitude $[Ca^{2+}]_i$ response and the slow, partial elevations in $[Ca^{2+}]_i$ are ineffective in increasing mitochondrial $[Ca^{2+}]$ and dehydrogenase activities. These observations are further supported by findings in chromaffin cells and isolated mitochondria, in which an increase in $[Ca^{2+}]_i$ to about 500 nM is required to activate calcium electrogenic uniport.

VIII. CONCLUSIONS

Calcium is the most versatile and universal intracellular messenger. In contrast to other intracellular messengers, Ca^{2+} signals can be generated by activation of many different ionic channels and other pathways expressed in the plasma membrane, ER/SR, mitochondria, and nucleus. Calcium can terminate and/facilitate its intracellular messenger functions by modulating the activity of several enzymes and channels participating in control of

calcium influx and mobilization. Calcium can also modulate cellular function by activating enzymes involved in signal transduction, such as adenylyl and guanylyl cyclases, phosphodiesterases, and protein kinase C. In addition to intracellular messenger functions, Ca^{2+} also acts as a first messenger, participating in cellular Ca^{2+} homeostasis and several other processes, by controlling a number of extracellular Ca^{2+}-sensing receptors. This results in the incredible diversity and versatility of Ca^{2+} signals, which differ in term of their spatial/temporal organization and amplitude coding. Spatial organization includes not only local and global Ca^{2+} signals within the cytosol, but also the intraorganelle and intercellular Ca^{2+} signals. Such a variety of Ca^{2+} signals and patterns, and the pathways involved in their generation, provides a framework for understanding the universality of Ca^{2+}, the agent that signals for new life at the stage of fertilization and is used during embryonic development and cell differentiation. All differentiated cells can use the same Ca^{2+} signaling patterns over and over again, but at any time point they preserve the ability to switch to a pattern of signaling that will activate the program that leads to cell death.

Glossary

adenylyl cyclases Integral membrane protein enzymes that colocalize with regulatory G_s- and G_i-proteins and catalyze formation of cAMP at the inner surface of a membrane. cAMP acts as a messenger for protein kinase A, cyclic nucleotide channels, and phosphodiesterases.

G-protein-coupled receptors A large variety of hormones, neurotransmitters, and chemokines regulate cellular function via cell surface receptors that are coupled to guanine nucleotide-binding regulatory proteins (G-proteins). Heteromeric G-proteins regulate ion channels directly, by binding of their $\beta\gamma$ dimers to channels, or indirectly by activating several intracellular messengers, including calcium, protein kinases, cyclic nucleotides, and nitric oxide.

ion channels Macromolecular pores in cell membranes; play a central role in cell excitability, calcium signaling, and transport of small molecules. At rest, the channels remain closed, blocking ion entry into the cell. A group of voltage-gated channels can rapidly activate in response to a change in membrane potential, allowing ions to flow through the aqueous pore of the channel. The direction of ion flow is determined by an electrochemical gradient. After only a few milliseconds, or even as long as several hundred milliseconds, the channels inactivate and the flow of ions is again blocked. Inactivated channels cannot be activated to the conducting state until their inactivation block is removed. Another group of channels, ligand-gated receptor channels, require a ligand to become activated. Once activated, these channels desensitize, i.e., reduce or completely block ion conductance, although ligand is present, and removal of ligand is required for their return to resting state. Ligand-gated receptor-channels can be expressed in plasma membranes (extracellular), but also in the endoplasmic reticulum and the nuclear membranes (intracellular).

phospholipase C Inositol phospholipid-specific phospholipase C is the enzyme family that generates several phosphoinositide-derived messenger molecules, including inositol 1,4,5-trisphosphate ($InsP_3$) and diacylglycerol. $InsP_3$ is a ligand for calcium receptor channels expressed in the endoplasmic reticulum and nuclear membranes ($InsP_3$ receptor channels). Diacylglycerol and/or calcium activate protein kinase C, a family of serine/threonine protein kinases.

Calmodulin

MARCIA A. KAETZEL AND JOHN R. DEDMAN
University of Cincinnati

Calmodulin is a major sensor and mediator of changes in intracellular Ca^{2+} concentrations. In 1883, Sir Sidney Ringer provided the first reports relating tissue function to calcium. He demonstrated that calcium was necessary for normal contraction of the isolated frog heart. Calcium, therefore, was recognized as an essential component of physiological salines.

I. CALCIUM: A REGULATORY ION

The primary regulatory role of calcium in biological systems including fertilization, development, adhesion, secretion, growth, motility, chemotaxis, division, differentiation, and phagocytosis is well established. Ca^{2+} has also been associated with a number of diseases, in particular, disorders of the muscular and nervous systems in which calcium plays an important role in contraction and neurotransmitter release. The understanding of calcium action has proven to be a complex topic and has required the inspiration and insight of many individuals from broadly distinct fields of expertise. Calcium is not like other metal ions involved in biological activities, such as K^+ and Na^+, which produce electrogenic membrane potentials, nor is it like manganese, magnesium, and zinc, which act as enzyme co-factors involved in the catalysis of metabolic intermediates.

Early studies characterizing intracellular Ca^{2+} action used model systems such as the glycerinated muscle fiber. Calcium could be regulated and contraction and glycogenolysis monitored. It was found that calcium was active at micromolar levels and was rapidly sequestered from the cytosol. Calcium channels and pumps were identified using isolated enclosed vesicles through which the movement of $^{45}Ca^{2+}$ was monitored. Convincing evidence for the movement of calcium into and out of cells using the isotopic method proved difficult since the element is in a dynamic state of flux between the various intracellular organelles, the cytoplasm, and the extracellular fluids.

To monitor real-time Ca^{2+} movements in living cells, calcium indicators were developed by Roger Tsien. Since the free acids of these fluorescent indicators are not membrane-permeable, they were made permeable by esterification of the free carboxyl acid groups. Once in the cytosol, multiple cellular esterases de-esterify the probe, trapping it within the cell. Fluorescent Ca^{2+} indicators have provided valuable insights into the "calcium signal." The intracellular resting calcium level is approximately 100 nM free calcium. Cell stimulation by a variety of agents causes a transient rise in intracellular calcium (400–800 nM) lasting from milliseconds to a few minutes. The amplitude of the signal varies from tissue to tissue and may be related to the type of stimulation. Cells must convert this common regulator, calcium, into a multifunctional signal in order to achieve a variety of cellular functions. The sensing, mediation, and ultimate discrimination of the intracellular calcium signal at the molecular level will provide valuable insight into understanding the broader aspects of the role of calcium in organ, tissue, and cellular function.

II. DISCOVERY OF CALMODULIN

The identification of calmodulin as a calcium-binding entity and mediator was a process that took several years, and thus, no single experiment can be singled out as the key in the discovery. In 1957, Hodgkin and Keynes postulated the existence of intracellular calcium receptors, due to the fact that $^{45}Ca^{2+}$ microinjected into the squid axon was not freely mobile in an electric field. In 1970, Cheung reported a putative protein activator of cyclic nucleotide phosphodiesterase. In the same year, Kakiuchi reported a calcium-activated phosphodiesterase and

Calmodulin is a major sensor and mediator of changes in intracellular Ca^{2+} concentrations. In 1883, Sir Sidney Ringer provided the first reports relating tissue function to calcium. He demonstrated that calcium was necessary for normal contraction of the isolated frog heart. Calcium, therefore, was recognized as an essential component of physiological salines.

I. CALCIUM: A REGULATORY ION

The primary regulatory role of calcium in biological systems including fertilization, development, adhesion, secretion, growth, motility, chemotaxis, division, differentiation, and phagocytosis is well established. Ca^{2+} has also been associated with a number of diseases, in particular, disorders of the muscular and nervous systems in which calcium plays an important role in contraction and neurotransmitter release. The understanding of calcium action has proven to be a complex topic and has required the inspiration and insight of many individuals from broadly distinct fields of expertise. Calcium is not like other metal ions involved in biological activities, such as K^+ and Na^+, which produce electrogenic membrane potentials, nor is it like manganese, magnesium, and zinc, which act as enzyme co-factors involved in the catalysis of metabolic intermediates.

Early studies characterizing intracellular Ca^{2+} action used model systems such as the glycerinated muscle fiber. Calcium could be regulated and contraction and glycogenolysis monitored. It was found that calcium was active at micromolar levels and was rapidly sequestered from the cytosol. Calcium channels and pumps were identified using isolated enclosed vesicles through which the movement of $^{45}Ca^{2+}$ was monitored. Convincing evidence for the movement of calcium into and out of cells using the isotopic method proved difficult since the element is in a dynamic state of flux between the various intracellular organelles, the cytoplasm, and the extracellular fluids.

To monitor real-time Ca^{2+} movements in living cells, calcium indicators were developed by Roger Tsien. Since the free acids of these fluorescent indicators are not membrane-permeable, they were made permeable by esterification of the free carboxyl acid groups. Once in the cytosol, multiple cellular esterases de-esterify the probe, trapping it within the cell. Fluorescent Ca^{2+} indicators have provided valuable insights into the "calcium signal." The intracellular resting calcium level is approximately 100 nM free calcium. Cell stimulation by a variety of agents causes a transient rise in intracellular calcium (400–800 nM) lasting from milliseconds to a few minutes. The amplitude of the signal varies from tissue to tissue and may be related to the type of stimulation. Cells must convert this common regulator, calcium, into a multifunctional signal in order to achieve a variety of cellular functions. The sensing, mediation, and ultimate discrimination of the intracellular calcium signal at the molecular level will provide valuable insight into understanding the broader aspects of the role of calcium in organ, tissue, and cellular function.

II. DISCOVERY OF CALMODULIN

The identification of calmodulin as a calcium-binding entity and mediator was a process that took several years, and thus, no single experiment can be singled out as the key in the discovery. In 1957, Hodgkin and Keynes postulated the existence of intracellular calcium receptors, due to the fact that $^{45}Ca^{2+}$ microinjected into the squid axon was not freely mobile in an electric field. In 1970, Cheung reported a putative protein activator of cyclic nucleotide phosphodiesterase. In the same year, Kakiuchi reported a calcium-activated phosphodiesterase and

the involvement of a protein modulator that enhanced the calcium sensitivity. Soon afterward, Wang showed that the protein modulator was a calcium-binding protein and that the true activator of cyclic nucleotide phosphodiesterase was the complex of calcium and the protein activator. Subsequent studies revealed that the protein activator, calmodulin (CaM), was present in all mammalian tissues and in all species of the major phyla examined. It was clear, however, that the levels of calmodulin did not correlate directly with the levels of its only known target, cyclic nucleotide phosphodiesterase. Brain adenylate cyclase was soon shown to be regulated by the calcium–calmodulin complex. Over the next few years, calcium–calmodulin was shown to regulate the red cell Ca^{2+} pump, myosin light chain kinase (MLCK), a brain protein kinase, CaM kinase II (CaMKII), plant NAD kinase, muscle phosphorylase kinase, and microtubule disassembly. Antibody localization studies suggested that calmodulin is a dynamic component of the mitotic apparatus, a finding consistent with the elevated levels of intracellular calcium seen in the polar regions of the mitotic spindle. Characterization of calmodulin established that intracellular free calcium translates its signal through high-affinity, selective receptors.

III. CALMODULIN GENOMICS

From its early discovery, the most striking features of calmodulin were its ubiquitous occurrence in eukaryotes and structural conservation; calmodulin isolated from a coelenterate was an effective activator of human enzymes. Calmodulins from vertebrates, invertebrates, and plants have very few sequence differences. All plant CaM contains a cysteine at position 27; CaM from animal phyla lacks cysteines. Invertebrate CaM sequences are characterized by a serine at position 148 in place of alanine in vertebrates. All vertebrate species express an identical protein, making calmodulin one of the most highly conserved proteins known in nature. More interesting, mammals are unique in that they have three distinct CaM genes (I, II, and III), located on different chromosomes with unique promoters. These three genes have different intron–exon structures and different exon sequences and collectively produce six distinct mRNA species. This arrangement would suggest an evolutionary opportunity to permit differential expression of CaM isoforms in order to allow for discrete changes in enzyme regulation. All six unique CaM mRNAs, however, translate into identical proteins. This consequence suggests that the evolutionary pressure of a protein to appropriately sense and mediate the many actions of intracellular Ca^{2+} disallowed any, even modest, changes in the sequence and structure of the protein. Each gene can, however, be dynamically regulated, producing six differentially expressed mRNAs. Differential message induction signals, stability, and cellular targeting contribute to the accurate expression of CaM as physiologically required.

IV. CA^{2+}-MODULATED MOLECULAR ANATOMY

Parvalbumin was the first high-affinity Ca^{2+}-binding protein structure to be solved by X-ray crystallography. A helix-loop-helix ("EF-hand") composed of six precisely positioned amino acids in the 12-residue loop coordinate the Ca^{2+} ion. This structural motif has been found in numerous proteins including troponin C, S-100, and CaM. The crystal analysis of Ca^{2+}–CaM revealed a "dumbbell" structure, that is, two globular domains linked by a flexible α-helix. In the absence of micromolar Ca^{2+}, the E-F α-helices are nearly parallel in a closed conformation. Ca^{2+} binding to the 12-residue loop causes the E-F α-helices to move perpendicular to each other, creating an open conformation that promotes a flexible pocket to bind target proteins.

V. TARGET SITES FOR CALMODULIN BINDING

The extreme structural conservation of CaM between phyla predicted a similar conservation in the binding site of the target protein. The CaM-binding component of MLCK was identified using limited proteolysis. It is a 17-residue amphipathic α-helical peptide. This peptide is an effective competitive inhibitor of CaM-activated enzymes. Analysis of co-crystals of Ca^{2+}–CaM and the MLCK peptide revealed a compact conformation. The globular domains individually grasped the binding peptide like a vice. As additional CaM-binding sites were identified from other target proteins, it became clear that sequence conservation was not rigidly maintained. The binding motif is typically hydrophobic and basic in nature. In many cases, large hydrophobic residues are precisely spaced at positions 1-16, 1-8-14, or 1-5-10. Isolation of high-affinity CaM-binding peptides using a bacteriophage display library identified peptides that contained a trytophan–proline combination, a binding motif not found in nature. Comparison of the 3-D structures of Ca^{2+}–CaM–MLCK peptide (1-8-14)

and Ca^{2+}–CaM–CaMKII peptide (1-5-10) demonstrated that although CaM is highly conserved in sequence, it is structurally flexible. This adaptability is due to the linker α-helix and the high concentration of malleable methionines present on the binding surfaces.

The CaM-binding site of many target enzymes is adjacent to an autoinhibitory domain. Ca^{2+}–CaM binding derepresses the active site. This activation is reversed as intracellular levels fall below 800 nM Ca^{2+}. An additional class of CaM-binding site includes the "IQ motif." This motif begins with an isoleucine–asparagine followed by two precisely spaced arginines and a terminal hydrophobic anchor, IQxxxRxxxxRxxF/V. Many of these target proteins bind CaM in the absence of Ca^{2+} and allow CaM to remain anchored during unstimulated periods. The highly adaptive nature of CaM binding suggests that caution should be exercised when identification of target proteins is based primarily on sequence motifs. Binding of CaM should change the activity or property of the putative target; CaM and the target should co-localize, and disruption of the binding motif in gene knock-in studies should modify cellular function.

VI. DISCRIMINATION OF THE CA^{2+}–CALMODULIN SIGNAL

Major mechanisms of mediation of the intracellular Ca^{2+} signal include protein modification through MLCK, phosphorylase kinase, Ca^{2+}–CaM-dependent protein kinases I, II, and IV, and calcineurin (protein phosphatase 2B). MLCK is a dedicated protein kinase and is the major mediator of smooth muscle contraction via thick filament regulation. Several kinases can reduce the affinity of Ca^{2+}–CaM for MLCK including protein kinase A (PKA), protein kinase C (PKC), CaMKII, and p21-activated kinase (PAK). In nonmuscle cells, MLCK regulates myosin II, which, in turn, modifies focal adhesion, cell morphology, contraction, cell locomotion, mitosis, and secretion.

CaM kinase II comprises a family of multifunctional kinases that are encoded by four genes, α, β, γ, and δ. Each can be alternatively spliced. Although it is found in all tissues, CaMKII is a major protein in neurons. Ca^{2+}–CaM binding causes catalytic activation including autophosphorylation at threonine-286. This phosphorylation markedly decreases the dissociation rate for Ca^{2+}–CaM and causes persistence of activity. Dephosphorylation occurs with protein phosphatase 1. Many cells exhibit oscillations in Ca^{2+} levels. CaM kinase II is capable of decoding this frequency modulation. For example, efficiency of synaptic transmission is characteristic of long-term potentation (LTP), which is developed by repeated depolarization of postsynaptic spines associated with an influx of Ca^{2+}. CaMKII is localized in these dendritic spines and demonstrates changes in the level of threonine-286 phosphorylation depending on the duration, amplitude, and frequency of the nerve stimulation. Mutation of threonine-286 to alanine allows Ca^{2+}–CaM activation of the enzyme but not autophosphorylation. Mice containing this mutation are deficient in LTP and display learning disabilities. Primary substrates for CaM kinase II at the postsynaptic density are the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor (potentiation of current), the *N*-methyl-D-aspartate (NMDA) receptor (increasing Ca^{2+} entry), and neuronal nitric oxide synthase (inhibition). CaM kinase II also regulates Ca^{2+} levels through the phosphorylation of the L-type Ca^{2+} channel, inositol 1,4,5-trisphosphate (IP_3) receptor, phospholamban, and the Ca^{2+} pump.

Calcineurin, protein phosphatase 2B, is a major Ca^{2+}–CaM-binding protein in neural tissues and is broadly distributed in other tissues. It is the only phosphatase regulated by Ca^{2+}–CaM. Calcineurin contains a binuclear Fe^{3+}–Zn^{2+} metal center. Oxidation of the Fe^{3+} causes catalytic inactivation even in the presence of Ca^{2+}–CaM. This activation is reversed by an associated enzyme, superoxide dismutase. This modulation allows for the coupling of Ca^{2+} modulation to the redox state of cells. Substrate specificity is narrow and includes protein phosphatase inhibitor 1, PKA regulatory subunit, nuclear factor of activated T cells (NF-AT), neurogranin, synapsin 1, and phosphorylase kinase. Phosphatase activity is not inhibited by protein phosphatase inhibitor-1 or -2, okadaic acid, calyculin, or microcystin. Calcineurin, however, is a target for the immunosuppressive drugs FK506 and cyclosporin A (CsA). When bound to their respective binding proteins, FKBP12 and cyclophilin A, FK506 and CsA inhibit phosphatase activity.

VII. CA^{2+}–CALMODULIN REGULATION OF ION CONDUCTANCES

Elegant studies by Kung and colleagues with swimming mutants of Paramecium first identified an

in vivo role for CaM. Paramecia avoid undesirable environments by entering a "tumble" and changing the direction in which they are swimming. The ciliates were mutated and examined for their ability to respond to harmful stimuli. Many of the mutant animals displayed an exaggerated or a diminished response. These mutant paramecia showed no change in growth rate, secretion, or excretion. Electrophysiological measurements identified changes in Ca^{2+}-dependent Na^+ currents (underreactors) and Ca^{2+}-dependent K^+ currents (overreactors). Furthermore, reconstitution studies identified CaM as the defective gene product with individual single point mutations. Na^+ current mutants had substitutions of conserved amino acids in the N-terminal lobe of the CaM dumbbell, whereas the overreactors (defective K^+ currents) had substitutions in the C-terminal lobe. No mutations were found in the central helix. These studies established that each lobe has a distinct cellular role, which, in turn, modifies behavior. Recent reports have shown a unique regulatory mechanism for CaM. CaM binds individual, inactive K^+ channel subunits in the absence of Ca^{2+} through an IQ motif. Membrane depolarization allows an influx of Ca^{2+}, which causes the CaM to dimerize the channel subunits and increase K^+ conductance. This process is reversed as Ca^{2+} levels are reduced.

In 1978, Brehm and Eckert characterized a voltage-gated Ca^{2+} channel in Paramecium. The channel demonstrated a rapid opening with a slow inactivating decay. This inactivation was Ca^{2+} dependent. This conductance was observed in cardiac and smooth muscle and in neurons. Recently it was shown that this L-type channel was regulated by CaM. CaM is tethered to the channel via an IQ motif, a Ca^{2+}-independent interaction. Channel inactivation requires Ca^{2+} binding to the CaM. The NMDA receptor, a ligand-gated Ca^{2+} channel, also demonstrates Ca^{2+}–CaM-dependent inactivation. This negative feedback mechanism is very efficient. Ca^{2+} enters the cell to activate many Ca^{2+}–CaM target proteins and then feeds back to terminate the stimulus.

VIII. CA^{2+}–CALMODULIN REGULATION OF TRANSCRIPTION

The two primary pathways of regulating gene transcription by Ca^{2+}–CaM are through the phosphorylation and dephosphorylation of the transcription factors Ca^{2+}/cyclic AMP-response element (CRE)-binding protein (CREB), and NF-AT. CREB resides in the nucleus. Several kinases including RSK2, PKA, PKC, and CaM kinase I, II, and IV can phosphorylate CREB at serine-133. This modification causes dimerization, binding to CRE, and recruitment of the transcriptional co-activator, CREB-binding protein. This complex then cooperates with other transcription factors, such as ELK, which promote transcription. This assembly process can be prevented or reversed by dephosphorylation of serine-133 or phosphorylation at serine-142 by CaM kinase II. This is another example of feedback regulation of a Ca^{2+}–CaM-mediated pathway.

T lymphocytes produce cytokines [interleukin-2 (IL-2), IL-3, and IL-4] in response to antigen binding. Activation of T cells elevates intracellular Ca^{2+} levels. The response is blocked by the immunosuppressive drugs FK506 and CsA. Activated T cells contain a transcription factor within the nucleus (NF-AT). In unstimulated cells, this protein resides in the cytosol in a phosphorylated state, yet remains transcriptionally competent. This stimulus transcription pathway is well defined. T-cell receptor binding elevates IP_3 levels, which elevate Ca^{2+}–CaM levels, which activate calcineurin. Dephosphorylation of NF-AT conceals a nuclear export signal (NES) and exposes a nuclear import signal. NF-AT enters the nucleus, combines with other transcription factors, and promotes gene transcription. Protein kinases including glycogen synthase kinase-3, JUN N-terminal kinase, and MEKK1 rephosphorylate NF-AT and expose the NES, and NF-AT exits the nucleus. NF-AT is a family of transcription factors that function in a similar manner in virtually all tissues including heart and neurons.

IX. SUMMARY

Our knowledge of the many properties of the intracellular Ca^{2+} signal continues to evolve. The resting intracellular ionized Ca^{2+} level is approximately 100 nM. Cell stimulation by a variety of agents causes a transient rise in intracellular free Ca^{2+} (400–800 nM); the increase is variable, lasting for milliseconds to minutes. The amplitude of the Ca^{2+} spike also varies from tissue to tissue. The elevation in Ca^{2+} may be uniform throughout a cell or a group of cells or may be highly localized to specific regions of individual cells. In many cellular systems, the Ca^{2+} signal occurs as a wave, beginning at a discrete initiation site and then moving across the cell. Ca^{2+} oscillations of various frequencies and amplitudes are influenced by cell stimuli.

TABLE 1 Major Calmodulin Target Proteins

CyclicAMP phosphodiesterase
Adenylate cyclase
Plasmalemma Ca^{2+} pump
Nitric oxide synthase
NAD kinase
Phosphorylase kinase
Myosin light chain kinase
Nonmuscle myosins I, II, and V
Calmodulin-dependent protein kinases I–IV
Protein phosphatase 2B (calcineurin)
NMDA receptor
L-type Ca^{2+} channel
SR Ca^{2+} release channel (RYR1)
IP3 receptor
Ca^{2+}-activated K^+ channel

The major sensor and mediator of intracellular Ca^{2+} is a highly conserved protein, calmodulin. Ca^{2+} binding causes conformational changes that allow this mediator to bind numerous target proteins. Major calmodulin target proteins are listed in Table 1. The diverse activities regulated by Ca^{2+}–CaM reflect the interplay of major cellular functions including cyclic nucleotide metabolism, redox state, transcription, membrane potential, nitric oxide synthesis, and contraction. Although the calcium–calmodulin pathway is common in all eukaryotic cells, the target proteins are the discriminators of the calcium regulatory signal. The localization, expression, and posttranslational modifications of the calmodulin target proteins dictate the ultimate cellular response to external stimuli. Isolation and functional characterization of individual target proteins will continue to expand the understanding of Ca^{2+}–CaM action in more precise terms.

Glossary

Ca^{2+} signal Ca^{2+} indicator dyes have shown intracellular free Ca^{2+} to be maintained at 100 nM. Stimulation of cells by hormones, cytokines, or membrane depolarization causes a transient elevation (400–800 nM) in cytosolic free Ca^{2+}. This Ca^{2+} signal regulates numerous cellular functions.

calcineurin (protein phosphatase 2B) A calmodulin target protein that dephosphorylates proteins including enzymes and transcription factors in a Ca^{2+}-dependent manner.

calmodulin An intracellular Ca^{2+}-binding protein that acts as a sensor and mediator of the Ca^{2+} signal by binding and regulating specific target proteins.

calmodulin-regulated kinases Enzymes that are activated by Ca^{2+}–calmodulin during the Ca^{2+} signal.

calmodulin target proteins Enzymes, ion pumps, and channels that bind calmodulin and change their activity in a Ca^{2+}-dependent manner.

Cancer Cells and Progrowth/Prosurvival Signaling

GIRISH V. SHAH AND MAURIZIO CHIRIVA-INTERNATI
Texas Tech University Health Sciences Center

Cancer cells represent a process of increased cell growth and decreased cell attrition. Changes in biological regulatory systems that lead to cancer and tumors are mediated by expression of mitogenic peptides and growth factors and/or by mutations in receptors or signal transduction pathway components. Elucidation of the signaling mechanisms that promote cancer cell growth is key to regulating and reversing tumorigenic processes.

I. INTRODUCTION

At a cellular level, cancer is characterized by several paradigms: unregulated proliferation, whereby mechanisms controlling the cell cycle and/or programmed cell death are lost; loss of differentiated phenotype; and acquisition of the ability to evade host defenses, to invade, and to metastasize. These changes allow cancer cells to grow unchecked in the absence of extracellular growth-stimulating signals and to overcome growth-inhibitory signals and host immune responses. It has been suggested that malignant transformation of a normal cell results from a stepwise accumulation of mutations in proto-oncogenes and tumor suppressor genes. These mutations are known to modulate oncogenic signals that stimulate anchorage-independent proliferation, rearrangement of the cytoskeleton, inhibition of apoptosis, and promotion of survival. Because cancer arises as a consequence of unregulated cell growth and survival, it is critical to understand the role of normal mitogens such as hormones and growth factors in growth and survival, and how they activate specific interconnecting signaling pathways that regulate cell growth and apoptosis.

II. GROWTH FACTORS AND THEIR RECEPTORS

Usually, growth factors (GFs) are secreted locally in an organ to regulate the growth of target cells in a paracrine/autocrine fashion. GFs or their receptors are often overexpressed in many cancers, and these can continuously stimulate the growth of cancer cells. Likewise, overexpression of GF receptors can cause a cancer cell to become hyperresponsive to ambient GF levels that normally would not trigger cell proliferation. There is growing evidence for up-regulated epidermal growth factor receptor (EGFR) signaling in formation and progression of human cancers. For example, the epidermal GF receptor EGFR/erb B (or Her2/neu) is overexpressed in stomach, brain, ovarian, and breast cancers. Additionally, gross overexpression or structural alteration of GF receptors can elicit ligand-independent signaling. Truncated EGFRs, which are found in various human cancers, lack much of their cytoplasmic domain but are constitutively active. Extracellular matrix receptors or integrins also activate mitogenic signaling, and cancer cells are known to increase the expression of the types of integrins that transmit progrowth signals.

A. GF Signaling

Normally, GF signaling pathways are activated on binding of a ligand to its receptor. The receptor undergoes ligand-induced dimerization and cross-phosphorylation (Fig. 1). Phosphorylation of tyrosine sites in the receptor leads to recruitment of intracellular docking proteins (such as Grb2, Shc, and Nck), followed by their formation of a complex with the guanine nucleotide exchange factor (GEF) Sos. These docking proteins create a molecular scaffold from which subsequent signals emanate. For example, the guanine nucleotide exchange factor Sos binds to Grb2, which interacts with Ras protein. Ras serves as a molecular switch in the plasma membrane that alternates between an inactive guanosine diphosphate (GDP)-bound state to an active guanosine triphosphate (GTP)-bound state. Binding of GTP to Ras leads to conformational changes and causes activation of downstream effectors such as

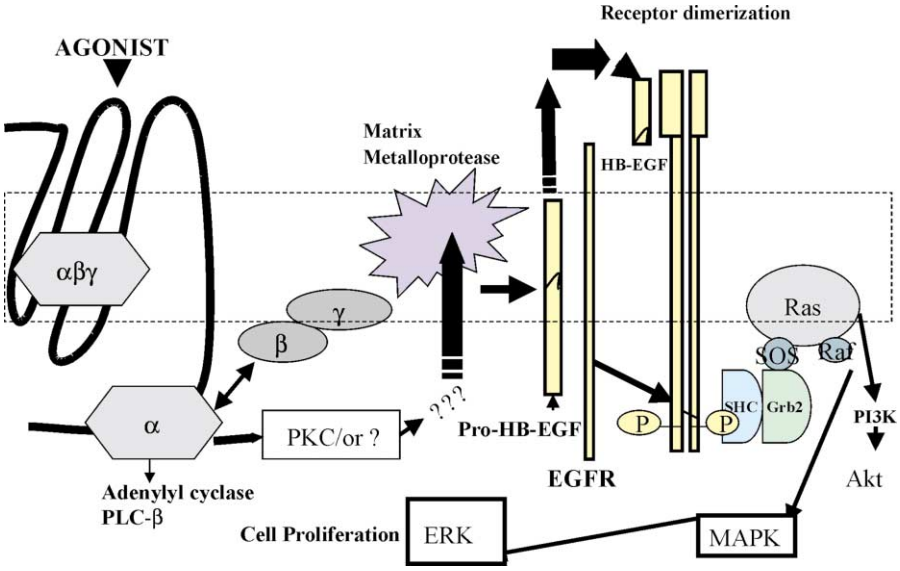

FIGURE 1 G-Protein-coupled receptor-mediated cell proliferation via transactivation of epidermal growth factor receptor (EGFR). Several G-protein-coupled receptors, such as those for endothelin, thrombin, or muscarinic cholinergics, activate a matrix metalloprotease, which in turn cleaves pro-heparin-binding EGF (pro-HB-EGF), causing it to shed mature HB-EGF. The released HB-EGF binds to EGFR, activating the receptor tyrosine kinase-mediated Ras/Raf/mitogen-activated protein kinase (MAPK) pathway. ERK, extracellular signal-related kinase; PI3K, phosphatidylinositol 3-kinase; PKC, protein kinase C; PLC-β, phospholipase C-β.

Raf and mitogen-activated protein kinases (MAPKs). In addition to activation of the Ras/Raf/MAPK pathway, GF receptor may also activate other pathways, perhaps involving PLC-γ, phosphatidylinositol 3-kinase (PI3K), Syp, and Src.

III. PARACRINE/AUTOCRINE PEPTIDES

Recent studies suggest that solid tumors involved in breast, lung, prostate, and colorectal cancers synthesize and secrete numerous neuropeptides, such as thrombin, bombesin, calcitonin, bradykinin, substance P, endothelin, neurotensin, serotonin, gastrin, and cholecystokinin. Receptors for these peptides are also expressed in human cancers. Although these peptides serve as neurotransmitters or modulators in the central nervous system, they can serve as potent mitogens for poorly differentiated cancer cells. Current evidence supports the notion that growth of the tumors is also driven by multiple autocrine and paracrine loops involving the neuropeptides. These structurally diverse signaling peptides exert their effects on cell proliferation by binding to their specific G-protein-coupled receptors (GPCRs) on the surface of their target cells (Fig. 2).

A. GPCR (Heptahelical) Receptor Family

The family of GPCR (heptahelical) receptors comprises over 1000 members and displays a common structural motif consisting of seven transmembrane domains. A diverse array of external stimuli, such as hormones, neurotransmitters, phospholipids, photons, odorants, taste ligands, and growth factors, can activate a specific receptor of this family to transduce signals in the cytoplasm of target cells. There is compelling evidence for the role of GPCRs in many human neoplasias, including small-cell lung carcinoma, thyroid carcinoma, colon carcinoma, prostate cancer, gastric hyperplasia and carcinoma, and pancreatic carcinoma. These carcinomas express wild-type GPCRs that are persistently stimulated by tumor-released agonists in an autocrine or paracrine fashion. In addition, activating mutations in GPCRs have been identified in various tumors. For example, *mas* oncogene, which encodes a putative GPCR, was initially cloned using standard transfection by virtue of its ability to induce tumors in mice. Subsequently, serotonin 1c; muscarinic m1, m3, and m5; and adrenergic α1 receptors were shown to transform contact-inhibited cultures of rodent fibroblasts when persistently activated. However, the mechanisms whereby GPCRs regulate cell proliferation are not completely understood.

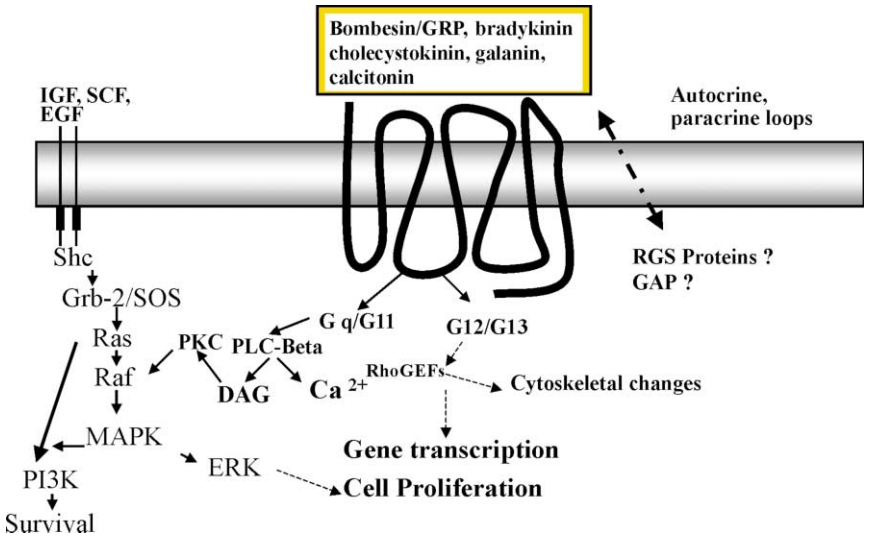

FIGURE 2 Neuropeptide-induced cell proliferation. Activation of G-protein-coupled receptors by neuropeptide ligands leads to the activation of appropriate G-proteins. Activation of G_q- or G_{11}-coupled receptors activates downstream effectors such as protein kinase C (PKC). Protein kinase C can directly activate Raf/mitogen-activated protein kinase (MAPK) to stimulate cell proliferation or differentiation (depending on the cell types). On the other hand, activation of G_{12}- or G_{13}-coupled receptors causes the activation of Rho guanine nucleotide exchange factor (GEF) GTPases, which then activate the cascades that induce changes in the cytoskeleton. Activation of G-protein-coupled receptors can be modulated by membrane proteins such as regulators of G-protein signaling (RGS proteins) or GTPase-activating proteins (GAPs). Growth factors, on the other hand, activate Raf/MAPK through receptor tyrosine kinase-stimulated activation of Ras. Ras may also induce the survival pathway through the activation of phosphatidylinositol 3-kinase (PI3K). DAG, diacylglycerol; EGF, epidermal growth factor; ERK, extracellular signal-related kinase; IGF, insulin-like growth factor; PLC-β, phospholipase C-β; SCF, stem cell factor.

IV. GTP-BINDING PROTEINS

Heterotrimeric GTP-binding proteins (G-proteins) are composed of three subunits, α, β, and γ. In a resting state, G-protein exists as the GDP-bound α-subunit complexed with the β- and γ-subunits. The β- and γ-subunits are tightly bound and are commonly referred to as the $G_{\beta,\gamma}$ subunit. In a typical G-protein-coupled signaling pathway, ligand-activated receptor catalyzes the exchange of GDP for GTP bound to the α-subunit, followed by the dissociation of the GTP-α and $G_{\beta,\gamma}$ subunits. The GTP-α subunit then activates its respective effector molecule–for example, stimulating or inhibiting adenylyl cyclase (in the case of αs or αi). The $G_{\beta,\gamma}$ subunit also activates the same or different effector molecules. Hydrolysis of bound GTP to GDP by intrinsic GTPase of the α-subunit leads to a conformational change, which terminates its interaction with the effector molecule. The GDP-α, thus freed, recombines with the $G_{\beta,\gamma}$ subunit and the newly formed GDP-αβγ heterotrimer reenters the signaling cycle. Modulation of this basic signaling pathway may be accomplished by signaling modulators such as GPCR kinases, regulators of G-protein signaling (RGS proteins), and effectors with intrinsic GTPase-activating protein (GAP) activity). Other signaling molecules, such as nonreceptor tyrosine kinases (RTKs), protein kinase C, ADP-ribosylases, and lipid transferases, also modulate this process by modifying GPCRs and/or G-proteins.

The subunits of G-proteins display a wide range of heterogeneity. To date, 17 α-subunits, 5 β-subunits, and 12 γ-subunits have been identified and cloned. The heterogeneity of α-subunits has been used to define and classify the G-proteins. The α-subunits with 50% or greater homogeneity are grouped into four distinct classes or subfamilies, i.e., G_s, G_i, G_q, and G_{12}. Although this classification is rather arbitrary, a functional similarity between the members of a subfamily is observed. For example, members of the G_s subfamily stimulate adenylyl cyclase, whereas those of the G_i subfamily inhibit this activity. Members of the G_q family interact with phospholipase C-β, whereas those of G_{12} regulate small GTPases. G_s and G_i proteins also regulate ion channels, certain phosphatases, and phosphodiesterases. In addition, $G_{\beta,\gamma}$ subunits regulate certain ion channels, phospholipase C, and phosphatidylinositol

3-kinases. Cells expressing the constitutively active form of $G_{\alpha s}$ display translocation of PKC-ζ molecules in membrane fractions, which suggests a role for $G_{\alpha s}$ in activation of this enzyme. Regulation of G-protein-mediated signal transduction is further complicated by the heterogeneity of effector molecules. For example, several isoforms of adenylyl cyclases and phospholipase C have been identified, and they are distributed in a cell-specific manner.

Although GPCRs have traditionally been linked to tissue-specific fully differentiated cell functions, increasing evidence suggests that GPCRs also play an important role in cell proliferation and cellular transformation. For example, activating mutations of subunits αs and αi are found in a subset of endocrine tumors. Furthermore, *gsp* oncogene, which mutationally activates the $G_{\alpha s}$ subunit, causes endocrine cell hyperplasia and induces tumors in human pituitary gland and thyroid. Activating mutations have also been identified in $G_{\alpha i2}$ (*gip*2 oncogene) in a subset of ovarian sex chord stromal tumors and adrenocortical tumors. Mutants of different α-subunit proteins, when expressed in diverse cell lines, demonstrate an increase in cell growth. For example, constitutive expression of $G_{\alpha s}$ causes a dramatic increase in the rate of prostate cancer cell proliferation and tumorigenicity. Similar actions of several other α-subunits, such as $G_{\alpha i1}$, $G_{\alpha i2}$, $G_{\alpha o}$, $G_{\alpha 16}$, $G_{\alpha z}$, $G_{\alpha 12}$, and $G_{\alpha 13}$, have been demonstrated in other systems.

V. MAJOR PROGROWTH/PROSURVIVAL SIGNALING PATHWAYS

A wide array of mitogenic GFs, hormones, and neuropeptides activate their specific receptors to induce survival and growth of their target cells. However, most of these receptors generally use one or multiple common intracellular signaling pathways to produce biological effects. Among existing signaling pathways, three pathways have taken a center stage in the transduction of progrowth/prosurvival signals: (1) the Ras/Raf/mitogen-activated protein kinase pathway, (2) the JAK/Stat pathway, and (3) the phosphoinositol 3-kinase/Akt pathway.

A. Ras/Raf/MAPK Pathway

The Ras/Raf/MAPK pathway plays a dominant role in the processes of cell proliferation and differentiation and may also activate survival pathway in some cell types. The available evidence suggests that the Ras/Raf/MAPK-mediated growth signaling pathway is up-regulated in about 25% of all human tumors. As many as half of the cases of human colon carcinoma bear the mutant *ras* oncogene, which allows persistent release of mitogenic signals even in the absence of upstream regulators.

RTK receptors, GPCRs, and progrowth integrins stimulate cell proliferation by activating the Ras/Raf/MAPK pathway. Interestingly, the pathways of GPCR and RTK-mediated MAPK activation are convergent in many cases. It has been shown that stimulated GPCRs rapidly activate matrix metalloproteases, thus releasing heparin-binding EGF (HB-EGF) from its precursor protein (Fig. 1). These proteases are activated through either protein kinase C-dependent or -independent pathways, depending on the stimulus, and in a cell-specific manner. Shed HB-EGF then acts as a ligand to transactivate EGFR, which leads to RTK-mediated activation of the Ras/Raf/MAPK pathway. Metalloprotease inhibitor BB94 inhibits bombesin- and 12-*O*-tetradecanoylphorbol 13-acetate (TPA)-induced transactivation of EGFR in PC3 human prostate, breast, and colon carcinoma cell lines. Treatment of Rat1 cells with GPCR agonists such as endothelin-1, lysophosphatic acid, or thrombin rapidly phosphorylates EGFR or the Her2 receptor. Moreover, agonist-induced MAPK-activation in these cells can be attenuated by the addition of EGFR inhibitor tyrophostin AG1478 or the expression of a dominant-negative EGFR mutant. Activation of this pathway has been demonstrated in several cell types, including human keratinocytes, mouse astrocytes, PC12 cells, and vascular smooth muscle cells. GPCR-induced EGFR transactivation has been shown to occur via pertussis toxin (PTX)-sensitive and -insensitive pathways, and EGFR inhibition strongly attenuates G_q- and G_i-induced MAPK activation in COS-7 cells. G_{13}-Coupled receptors have also been shown to cause EGFR transactivation. Moreover, $G_{\beta,\gamma}$ dimers may also activate Ras proteins, but this pathway has not been completely delineated. Receptors coupled to G_q or G_{12} may activate the Raf/MAPK pathway in a Ras-independent manner by activating protein kinase C, which can directly activate Raf (Fig. 2). The Ras/Raf/MAPK mitogenic cascade is linked to other signaling pathways through cross-talking connections, which enable various mitogenic ligands to produce multiple biological effects.

Ligands that activate cell proliferation via the MAPK pathway also induce prosurvival signals in several cases. A direct interaction of Ras protein with PI3K may enable growth signals to evoke survival

signals concurrently within the cells. For example, deletion of the cytoplasmic tail in granulocyte-macrophage colony-stimulating factor (GM-CSF) receptor in BaF3 cells abrogates interlukin-2 (IL-2)-induced activation of the Ras/Raf/MAPK pathway. However, overexpression of activated Ras in these cells rescues this defect, supporting IL-3-induced survival. It is conceivable that Ras transformation may activate PI3K in this system. However, overexpression of downstream effectors of Ras does not affect PI3K activity, but suppresses cell death. Moreover, inhibition of MAPK activation with dominant-negative mutants suppresses IL-3-dependent survival in BaF3 cells. Several targets of MAPK activity in the survival pathway have been proposed, including the family of 90-kDa ribosomal S6 kinases (Rsks); Rsks protect the cells from death through phosphorylation of BAD (so named because it is a member of the Bcl-2 family, and is an agonist causing cell death) at Ser-136 in multiple tissues. In other Ras/MAPK survival studies, evidence points to a role of the anti-apoptotic proteins of the Bcl-2 gene family in mediating survival.

B. JAK/Stat Signaling Pathway

The Janus family of kinases (JAKs) plays a major role in transducing the signal from cytokine receptors to a family of signal transduction/activation of transcription (Stat) factors. Members of this relatively small family of proteins serve both as transducers of cytoplasmic signals and as nuclear transcription factors, thereby directly converting a stimulus at the cell surface to an alteration in the genetic program. Stats are unique among transcription factors in possessing an SH2 domain that regulates their dimerization and activation via tyrosine phosphorylation. Seven mammalian Stat family members (Stat1–Stat6, with Stat5A and Stat5B encoded in distinct genes) have been molecularly cloned and may represent all Stats in mammalian cells. Aberrant Stat signaling has been suggested to contribute to malignant transformation by promoting cell cycle progression and/or cell survival.

The JAK/Stat pathway is activated by the binding of a specific ligand to its receptor (Fig. 3). Activation of the receptor induces its own dimerization, which is followed by phosphorylation of the receptor and activation of receptor-associated JAK family kinases. The activated JAKs, in turn, phosphorylate the receptor cytoplasmic tails on tyrosine, providing docking sites for the recruitment of monomeric Stats. JAKs then phosphorylate the recruited Stat proteins on tyrosine, inducing their dimerization, nuclear translocation, and DNA binding. In some cases, other tyrosine kinases (TKs), such as Src family kinases, are also involved in Stat activation. There is a very high correlation between the activation of Stat3 by Src and oncogenic transformation. Activation of Stats by other TK families, such as Lck and v-Fps in oncogenic transformation, has also been reported. JAK1 and v-Src cooperate in activation of Stat3 in transformation of NIH 3T3 fibroblasts. Constitutive Stat3 DNA-binding activity induced by Src oncoprotein results in malignant transformation. In contrast, attenuation of Stat3 signaling by the expression its of dominant-negative forms blocks the transforming ability of Src. However, co-expression of dominant-negative Stat3 together with Ras does not activate Stat3 and does not block Ras-induced transformation. The expression of cyclin D1, which associates with cdk4 or cdk6 and controls the progression of cell cycle from G_1 to S phase, is elevated in Stat3-expressing cells. MAP kinase 1/2 can modulate the transcriptional activity of Stat3 by phosphorylating Ser-727. Additionally, v-Src-induced activation of Stat3 is also modulated by p38 and the c-Jun N-terminal kinase/stress-activated protein kinase (JNK/SAPK) pathway. Activation of GPCRs such as angiotensin II and melanocyte-stimulating hormone receptors also activates Stat1, Stat2, and Stat3. The presence of mutant active melanocortin receptors has been demonstrated, raising the possibility that mutant GPCRs expressed in diseases may activate Src and Stat3 to induce morphological changes and neoplastic transformation.

In addition to proliferative and transforming effects, the JAK/Stat pathway also transduces cytokine-mediated survival signals in several cell types. Knockout studies of the Stat family reveal that Stat3 may have a role in cell survival. Stat3 activation is required for GM-CSF-dependent cell survival in BaF-BO3 cell lines, and the cells expressing dominant-negative Stat3 are apoptotic even in the presence of GM-CSF. Downstream effectors of Stat-mediated survival are unclear, but when the survival is apparent, increased Bcl-2 protein expression has been reported. However, there is no evidence to suggest the direct role of Stat activity in Bcl-2 induction. In some models, Stat activation leads to cell cycle arrest and cell death. Stat1 has been reported to trigger cell death through the expression of caspase-1. This apparent contradiction is probably the consequence of at least four JAK isoforms and seven Stat molecules, which may be activated by several cytokines and have distinct DNA-binding properties.

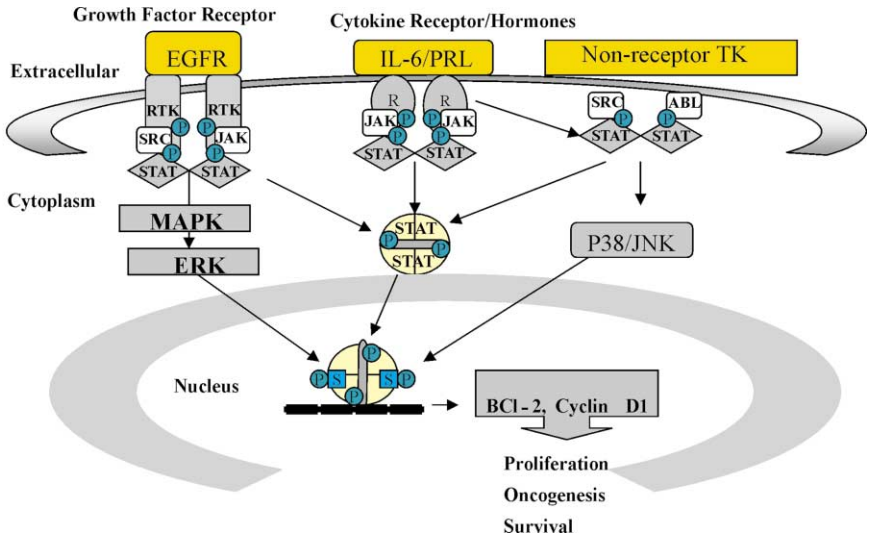

FIGURE 3 JAK/Stat signaling. Stat signaling is activated by various ligands, including growth factors, hormones, cytokines, or nonreceptor tyrosine kinases (TKs). However, the cellular mechanisms of activation may be different. For example, the binding of interleukin-6 (IL-6) with its receptor causes receptor dimerization and activation of JAKs. JAKs then phosphorylate IL-6 receptors, which enables the IL-6 receptors to recruit and dock monomeric Stats. JAKs then phosphorylate tyrosine residues of Stats, which causes dimerization of Stat proteins. Dimerized Stats are translocated to the nucleus, where they bind to DNA and activate genes associated with cell proliferation and malignant transformation. Receptors for hormones such as prolactin (PRL) or growth hormone also activate this pathway in a similar manner. Epidermal growth factor receptor (EGFR)–receptor tyrosine kinase(RTK)can either directly phosphorylate Stats or can act indirectly through activation of JAKs or Srcs. Nonreceptor TKs such as Src or Abl can also phosphorylate Stats in the absence of ligand-induced receptor activation. ERK, extracellular signal-related kinase; JNK, c-Jun N-terminal kinase; MAPK, mitogen-activated protein kinase.

C. PI3-Kinase Signaling Pathway and Cell Proliferation/Survival

Many receptors, including those for growth factors [insulin-like growth factor-I, platelet-derived growth factor (IGF-I, PDGF)], brain-derived neurotrophic factors, neuroendocrine peptides (bradykinin, calcitonin, adrenaline, gastrin), cytokines (IL-3, IL-2), and integrins, transmit survival as well as growth signals through the PI3K pathway. Receptor-induced activation of PI3K activity is biphasic, and only the late phase of activation (3–7 h) is required for cell proliferation.

Eight mammalian PI3Ks have been identified and classified into three main groups on the basis of sequence homology, in *vitro* substrate preference, and method of activation and regulation. Humans express four class I enzymes, which are referred to as Ia and Ib on the basis of their mechanism of activation. The class Ia group consists of classical p110α and two other closely related enzymes, p110β and p110δ. The α and β isoforms are ubiquitous whereas δ isoform expression is more restricted. All class Ia enzymes constitutively associate with the p85 regulatory/adapter subunit to form a heterodimeric complex. At least eight adapter isoforms, encoded by three different genes, have been identified. A majority of the RTK-coupled receptors activate class Ia PI3-kinases through the binding of SH2 domains that are found in all p85 isoforms, although the binding and duration of the resulting signal may vary (Fig. 4). Insulin and PDGF receptors activate PI3-kinase strongly, whereas EGFR has a weak and inconsistent effect. The class Ib group consists of the p110γ catalytic subunit, which associates with the p101 adapter subunit. GPCRs activate class Ib PI3Ks by releasing $G_{\beta,\gamma}$ subunits. It has been suggested that $G_{\beta,\gamma}$ docks on and activates the catalytic subunit of PI3K (Fig. 4).

PI3Ks catalyze the phosphorylation of inositides on the 3 position of the inositol head group. At least four 3-phosphorylated inositol lipids (PIPs) have been identified *in vivo*. These lipids bind to specific binding proteins, which either act as effectors or transmit the PI3K signal onward. PIPs have been described as lipid messengers because they serve as binding sites for proteins that possess a pleckstrin homology (PH) domain. One such protein is c-Akt (also identified as

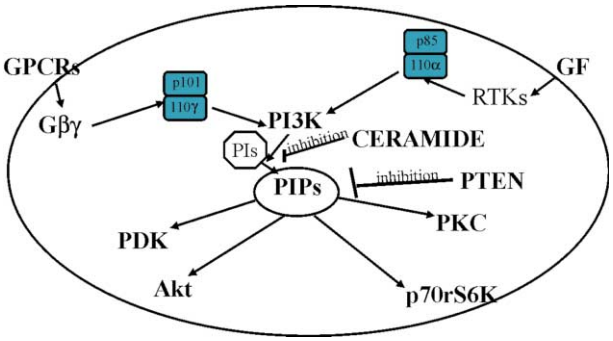

FIGURE 4 Activation of phosphatidylinositol 3-kinase (PI3K) by G-protein-coupled receptors (GPCRs) and receptor tyrosine kinases (RTKs). GPCRs as well as RTKs activate PI3K, and ceramide can inhibit this process. PI3K catalyzes the phosphorylation of inositides (PIs). Phosphoinositides (PIPs) can activate downstream targets such as phosphoinositide-dependent kinase (PDK), Akt, p70rS6K, and protein kinase C (PKC). The phosphatase/tensin (PTEN) homologue can attenuate PIP action by dephosphorylating the PIPs.

protein kinase B), which is related to protein kinases A and C. Binding of the Akt PH domain to the phospholipids results in Akt translocation to the plasma membrane and phosphorylation at two critical residues, Thr-308 and Ser-473. Phosphorylation at Thr-308 is achieved through additional kinases, such as phosphatidylinositol-dependent kinase 1, which also contains a PH domain and requires PI3K activity for membrane localization. The enzyme that phosphorylates Ser-473 has yet to be identified, but a role for Ca^{2+}/calmodulin-dependent protein kinase or cyclic adenosine monophosphate (cAMP)-dependent protein kinase has been suggested. Regulation of Akt function is controlled both by localization to the membrane, which is dependent on available PIPs, and by the level of its phosphorylation. The generation of 3′-phosphoinositols is counterbalanced by lipid phosphatases that dephosphorylate PIPs. The evidence has shown that a phosphatase/tensin (PTEN) homologue that dephosphorylates PIPs and inhibits PI3-kinase activity is inactivated in a majority of prostate tumors and PC cell lines (Fig. 4).

Studies employing relatively specific chemical inhibitors of PI3K (Wortmannin or LY294002) and, more recently, studies using cells transfected with vectors that encode an active or dominant-negative PI3K have led to the identification of several signaling enzymes in addition to Akt, which further amplify the signal initiated by PI3K. These enzymes include the phosphoinositide-dependent kinase (PDK), p70 ribosomal S6 kinase, and possibly protein kinase C. Each of these enzymes are serine/threonine protein kinases that play critical roles in regulating gene expression, cell growth, cell survival, and cell differentiation in response to a number of stimulants. Many of the receptor tyrosine kinases that stimulate PI3K have been localized to microdomains in the plasma membrane that are rich in lipids, including sphingomyelin and cholesterol. More importantly, the microdomains contain ceramide, which, at high levels, may interrupt PI3K signaling.

D. Akt in Cell Survival Signaling

Inhibition of PI3K activity is sufficient to induce cell death even in the presence of survival factors. However, this death can be overcome by constitutive Akt activity. In some cases, the expression of dominant-negative forms of Akt induces apoptosis. Although Akt is a major, if not the sole, effector of PI3K-induced survival, the precise mechanism by which Akt suppresses death is not yet elucidated. Several Akt identified targets may promote cell survival; however, no one substrate or model has emerged as the clear candidate.

The current understanding of Akt targets can be sorted into essentially two categories: proteins directly involved in signal transduction and enzymes of glucose metabolism (Fig. 5). Among the former is BAD, a pro-apoptotic member of the Bcl-2 family. Akt phosphorylates BAD at Ser-136. When phosphorylated, BAD is sequestered in the cytoplasm by 14-3-3 proteins, unable to heterodimerize with and inactivate the anti-apoptotic protein, Bcl-xL. Overexpression of BAD alone commits a cell to death, but the cell may be rescued by co-expression of activated Akt. However, Akt is incapable of protecting cells expressing BAD with a Ser-136 → Ala mutation. Clearly, Akt can mediate growth factor-dependent survival by reversing the apoptotic activity of BAD. However, this may not be the only mechanism of Akt protection, because Akt-dependent survival can be observed in cells that do not contain BAD. This suggests that Akt-mediated survival is likely to involve other mechanisms in these cells.

In *Caenorhabditis elegans*, a homologous PI3K pathway regulates development and longevity. Mutations in Daf-2 (mammalian insulin receptor homologue) or AGE-1 (mammalian PI3K homologue) lead to developmental arrest at the dauer larval stage. This phenotype can be suppressed by mutations of the Daf-16 allele. Searches for mammalian orthologues of the Forkhead transcription factor Daf-16 have revealed three members to date, AFX,

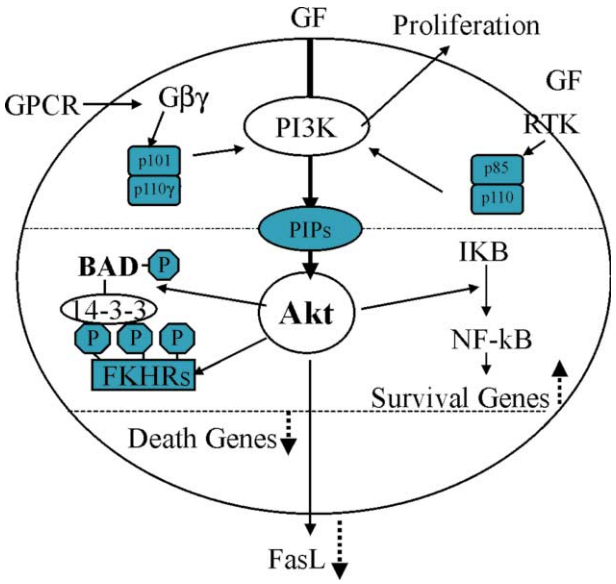

FIGURE 5 Induction of survival by Akt. Akt regulates survival through phosphorylation of multiple targets involved in the regulation of apoptosis. For example, Akt inhibits apoptosis through regulation of transcription of NF-κB as well as Forkhead family members (FKHRs) by controlling their phosphorylation. Akt also phosphorylates BAD (a Bcl-2 homologue). Phosphorylated forms of BAD and FKHRs are retained by 14-3-3 proteins in the cytoplasm and are thereby prevented from translocating to the nucleus, where they can activate death genes. Akt also down-regulates Fas ligand (FasL). GF, growth factor; IκB, inhibitor κB; PIPs, phosphoinositides; RTK, receptor tyrosine kinase.

FKHR, and FKHRL1. As with BAD, in the presence of survival factors, Forkhead proteins are phosphorylated and retained in the cytosol by 14-3-3 proteins, suggesting a general role of 14-3-3 proteins in Akt-induced inhibition. Nonphosphorylatable mutants of FKHRL1 induce apoptosis in a variety of cell lines, whereas expression of Forkhead mutants with aspartic acid residues to mimic phosphorylation renders cells resistant to death. Transcriptional activity is required for Forkhead function; mutants unable to bind DNA are unable to induce cell death even in the absence of growth factors. When dephosphorylated, Forkhead transcription factors migrate to the nucleus, where they bind insulin response sequences. Among other targets, the Fas ligand (FasL) promoter contains a binding site for FKHRL1. In the absence of survival signals, Forkhead activity leads to FasL expression, which then migrates to the cell surface and activates the Fas-mediated cell death cascade. In fact, FKHRL1-dependent death can be abated in the presence of antibodies that block Fas activation. Consistent with this model, PTEN heterozygous mice develop a lethal polyclonal autoimmune disorder similar to that of Fas-deficient mice. Fas-mediated apoptosis is impaired in PTEN(+/−) mice, but apoptosis can be restored in the presence of PI3K inhibitors. Moreover, PTEN knockout studies reveal high concentrations of PIPs and a concomitant hyperactivation of Akt. Although inactivating mutations of PTEN render cells resistant to apoptosis, overexpression of wild-type PTEN sensitizes the cells to death following their detachment from the extracellular matrix. This potentially explains the frequency of PTEN mutations in late-stage, invasive tumors. Induction of NF-κB by Akt has been reported. Akt survival function in response to platelet-derived growth factor and tumor necrosis factor requires the activation of NF-κB transcriptional activity. Gene targets of the transcription factor NF-κB include a prosurvival member of the Bcl-2 family, A1, and the inhibitors of apoptosis proteins.

VI. CROSSTALK BETWEEN SIGNALING PATHWAYS

There is considerable evidence for crosstalk between different signaling pathways, and the Src family of kinases may play an important role in this process. c-Src is a member of the Src family of cytoplasmic tyrosine kinases; these kinase are involved in various cellular processes such as proliferation, migration, and differentiation. They are 52- to 62-kDa proteins with several domains, including a catalytic domain, a regulatory domain, and SH2 and SH3 binding domains. The inactive form of c-Src is phosphorylated at Tyr-527 and interacts with its own SH2 domain to mask its catalytic domain. Its activation causes dephosphorylation of Tyr-527, enabling its catalytic domain to interact with other substrates.

Src kinases seem to play an important role in GPCR-induced MAPK activation. Agonist-induced activation of the β-adrenergic receptor (β-AR) causes rapid recruitment of β-arrestin 1 and c-Src. Blocking of β-arrestin 1/c-Src interaction impairs β-AR-induced MAPK activation in 293 cells as well as in other cell systems. A similar role for the β-arrestin 1/c-Src complex in several other systems has been reported. There is also evidence that GPCRs may directly activate c-Src. For example, treatment of normal mesangial cells with endothelin-1 stimulates autophosphorylation of pp60 v-Src. Overexpression of pp60 c-Src in C3H10T1/2 mouse fibroblasts potentiates the intracellular accumulation of cyclic AMP on stimulation of the β-adrenergic receptor.

Recent evidence has shown that pp60 c-Src phosphorylates the tyrosine residues of $G_{\alpha s}$ at positions 37 and 377. Because Tyr-37 is located near the site of $\beta\gamma$ binding, it is likely that phosphorylation of Try-37 would modulate GDP dissociation and GTP activation. Overexpression of c-Src kinase (CSK), which inhibits c-Src activation, impairs $G_{\beta,\gamma}$-mediated tyrosine phosphorylation of EGFR and Shc.

VII. TUMOR ESCAPE FROM HOST DEFENSE

The immune system is charged with the function of cancer surveillance and has an ability to clear genetically altered cells that have undergone malignant transformation. However, tumor cells develop an ability to avoid this clearance and survive, grow, and metastasize. The mechanisms by which cancer cells escape host immune responses vary among different types of cancers and even within different cancers of a particular type. Generally, tumors accomplish escape by a host of mechanisms, including down-regulation of expression of surface antigens [such as major histocompatibility complex class I (MHC-I) antigens]; increased secretion of immunosuppressive cytokines [such as transforming growth factor-β (TGF-β), IL-10, or vascular endothelial growth factor (VEGF)]; generation of variants of tumor antigens, thereby affecting the ability of immune cells to recognize tumor cells; and overexpression of Fas ligand, which interacts with immune T cells and induces their apoptosis. These actions significantly reduce the ability of immune cells to recognize tumor cells, to associate with them, and to induce cytotoxic response. The tumors that are more efficient in inducing all these responses are more aggressive than those that inefficiently evade the immune response.

VIII. SUMMARY

Tumor growth occurs because of the increased expression of mitogenic peptides or growth factors. Growth can also be caused by mutations in the receptors for mitogens or growth factors or in the components of signal transduction pathways. Such changes promote increased cell growth and decreased cell attrition. Most of the mitogenic signals generated as a result of these changes are mediated by Ras/Raf/MAPK, JAK/Stat, and/or PI3K/Akt signaling pathways. This is supported by studies showing that a majority of human cancers display persistent activation of one or more of these pathways. Tumor cells can also evade the host immune system by secreting various proteins, which may either confuse or kill the natural killer cells of the immune system. Further understanding of these mechanisms will contribute to a better understanding of the processes associated with tumor growth, and will provide novel approaches to regulate and reverse the growth of cancers.

Glossary

G-protein-coupled (heptahelical) receptors A family of transmembrane receptor proteins that activate G-proteins in response to activation by a specific ligand.

phosphoinositide 3-kinases A group of lipid kinases that phosphorylate the 3 position of the inositol ring of inositol phospholipids. They have been shown to interact with growth factors, hormones, and oncogene products to activate diverse signal transduction pathways. They also play a key role in mediating anti-apoptotic, i.e., prosurvival, actions.

tyrosine kinases A group of transmembrane proteins with tyrosine-specific phosphorylating activity. The extracellular domain of receptor tyrosine kinases serves as a receptor for agonists, such as growth factors and hormones. The binding of a specific ligand to the extracellular domain of the receptors turns on the kinase activity of their catalytic domain, which is located on the cytoplasmic side of the membrane. Nonreceptor tyrosine kinases lack an extracellular binding domain, and they are activated by phosphorylation of their tyrosine residues.

CC, C, and CX_3C Chemokines[1]

RONALD L. RABIN

Center for Biogenics Evaluation and Research, U. S. Food and Drug Administration, Maryland

The CC chemokines (β-chemokines) constitute a large family of chemoattractant peptides in which the first (N-terminal) two of the four conserved cysteines are adjacent. As in the other major chemokine subfamily, the CXC chemokines, the first pair of cysteines lies within the first 10 amino acids of the mature peptide, and there are disulfide bonds between cysteines 1 and 3 and between cysteines 2 and 4. All non-CXC chemokines are presumed to play a role in adaptive immunity and are involved in the immune response or in development and homeostasis.

I. INTRODUCTION

There are currently 28 human CC chemokines, which have been assigned systematic names consisting of "CCL" (CC ligand) followed by the number that is in the designation for the corresponding human gene. CC chemokine family members signal only through chemokine receptors with the prefix "CCR" and do not share receptors with the CXC, C, or CX_3C families of chemokines. There are three non-CXC, non-CC chemokines. Two are C (γ) chemokines in which one of the pair of N-terminal region cysteines and one of the downstream cysteines are absent, and one is a CX_3C (δ) chemokine in which 3 amino acids separate the first and second cysteines. The receptor for the C chemokines (XCL1 and XCL2) is XCR1 and the receptor for CX_3CL1 is CX3CR1. Table 1 shows the systematic and common names, gene alias accession numbers, and receptors for the CC, C, and CX_3C chemokines.

All non-CXC chemokines have a presumptive role in adaptive immunity and participate either in the response to immunological challenge and inflammation or in homeostasis. Those in the latter group are important for the organization of secondary lymphoid organs—spleen, lymph nodes, and mucosal-associated lymphoid tissue (MALT).

Three features distinguish the non-CXC chemokines from their CXC counterparts. Although neutrophils migrate toward many of the CXC chemokines, the role of CC family members in neutrophil migration in humans is minimal. Second, although only one CXC chemokine can bind to more than one receptor (CXCL8 binds CXCR1 and CXCR2), seven pro-inflammatory CC chemokines signal through two or three receptors. This promiscuity has impeded attempts to define precise roles for CC chemokines in immune function. Third, although most of the CXC chemokine family members can either enhance or inhibit angiogenesis, CCL2, CCL11, and CX_3CL1 are the only non-CXC chemokines shown to be pro-angiogenic, and none have been reported to inhibit angiogenesis.

All chemokine receptors are seven-transmembrane domain proteins that are coupled to G- proteins (7TMDGPCR). Of the four classes of heterotrimeric G-proteins, G_i-proteins are those best documented as coupling to chemokine receptors and being essential for chemotaxis. G-protein activation leads to signaling through phospholipase Cβ, phosphatidylinositol-3-kinase-γ, and protein kinase C. The endpoints of these cascades can include chemotaxis, respiratory burst, degranulation, and enhanced cell adhesion. It is important to note that the consequences of signaling can vary according to cellular context. For example, whereas freshly isolated monocytes and lymphocyte subsets express receptors for CCL5 (RANTES) and all receptor-bearing cells can migrate toward CCL5,

Adapted from P. M. Murphy, *et al*., International Union of Pharmacology. XXII. Nomenclature for Chemokine Receptors. *Pharmacol. Rev.* **52**, 145, 2001, with permission from the corresponding author. The systematic names refer only to human chemokines. However, the accession numbers and common names for putative mouse orthologues are included. CCL6, CCL9, and CCL12 lack known human orthologues; the standard name is reserved for a potential human counterpart. In many cases, the same common name applies to human and mouse counterparts, but species-specific names are sometimes used to convey substantially different properties, such as a major difference in sequence (e.g., human I-309 versus mouse TCA-3) or length (e.g., mouse JE versus MCP-1). The number in the systematic name for each chemokine matches that in an alias for the corresponding human gene name, and the roots for gene names correspond to protein roots as follows: SCYA = CCL; SCYB = CXCL; SCYC = XCL; and SCYD = CX3CL, where SCY denotes small cytokine; A, B, C, and D denote the chemokine classes in the gene locus; and L signifies "ligand" in the root of the protein name. Thus, for example, SCYA1 is a gene alias for the human chemokine CCL1. Accession numbers are from the SwissProt database, when available; NA, not available in any database. Also listed are the two nonsignaling chemokine-binding proteins D6 and Duffy antigen receptor (DARC).

only the monocytes respond to CCL5 with a global calcium flux.

The genes for 14 of the 28 non-CXC chemokines are clustered in one of two subregions of chromosome 17 (Table 2). The others are scattered over six chromosomes, although in three instances, pairs of genes for homologous chemokines that share a common receptor are adjacent to each other. These patterns suggest that both dispersion and duplication *in situ* are responsible for generating the gene family.

The chemokines are discussed in groups, first, according to the class of chemokine (CC, C, and then CX_3C), second, by their roles in either homeostasis or response to immune challenge, and third, according to similarities in chromosome localization, protein structure, function, and receptor usage, all of which are typically correlated (see Table 2).

TABLE 2 Chromosomal Organization of CC, C, and CX_3C Chemokines

Chromosome (subregion)	Chemokine (common name)
2	CCL20 (MIP-3α)
5	CCL28
7	CCL24 (eotaxin-2)
	CCL26 (eotaxin-3)
9	CCL19 (ELC)
	CCL21 (SLC)
	CCL27 (CTACK)
16	CCL17 (TARC)
	CCL22 (MDC)
17 (MIP subregion)	CCL4 (MIP-1β)
	CCL3 (MIP-1α)
	CCL18 (DC-CK1)
	CCL23 (MPIF-1)
	CCL15 (leukotactin)
	CCL14 (HCC-1)
	CCL16 (HCC-4)
	CCL5 (RANTES)
17 (MCP subregion)	CCL1 (I-309)
	CCL13 (MCP-4)
	CCL8 (MCP-2)
	CCL11 (eotaxin)
	CCL7 (MCP-3)
	CCL2 (MCP-1)
19	CCL25 (TECK)
1	XCL1 (lymphotactin-1)
	XCL2 (lymphotactin-2)
16	CX_3CL1 (fractalkine)

Note. The chemokines are listed first according to the chromosomal location of their gene, and from top to bottom, with decreasing distance from the centromere. The most common nonsystematic name is given in parentheses.

II. CC CHEMOKINES

A. Structural Features

The secondary and tertiary structures of the CC and CXC chemokines are similar. The N-termini that lead to the first cysteine are elongated, limited in flexibility by the first two cysteines, and except for CCL5, unstructured in solution. After the first two cysteines, there is a loop of approximately 10 residues, the so-called N-loop, followed by a single turn 3_{10} helix, three anti-parallel β-strands that form a β-pleated sheet, and an α-helix at the C-terminus. Each of the β-strands and the α-helix is connected by the 30's, 40's, and 50's loops, named for their position in the peptide sequence. The third and fourth cysteines are in the 30's and 50's loops, respectively. Naturally produced chemokines are usually glycosylated, but recombinant proteins that lack glycosylation retain their *in vitro* biological activity. The α-helix and C-terminus contain basic residues that bind to glycosylaminoglycans (GAGs), such as heparin and chondroitin sulfate.

The two disulfide bonds and hydrophobic interactions between the C-terminal helix and the β-sheet are critical for chemokine structure. Several CC chemokines have additional cysteine residues, in one case within the N-loop and in the other cases C-terminal to the fourth conserved cysteine.

Some chemokines multimerize at concentrations necessary for X-ray crystallography and nuclear magnetic resonance (NMR); and quaternary structure is where CXC and CC chemokines differ. The CXC chemokines tend to contain hydrophobic residues along the first β-strand, which is their point of contact. By contrast, CC chemokines have hydrophobic residues surrounding the first two cysteines, and their point of contact is along the extended N-terminus.

The relevance of dimers in chemokine function is controversial. Mutant proteins that cannot dimerize are active *in vitro* and compete well for receptor with wild-type proteins. On the other hand, chemokines are frequently "presented" to circulating leukocytes bound to GAGs on the surface of endothelial cells, which would be expected to lead to oligomerization *in vivo*. Oligomerization of ligands raises the possibility of receptor oligomerization. Dimerization of 7TMDGPCR has been shown in a number of systems including those for chemokine receptors and may result in activation of signaling molecules usually associated with other types of cytokine receptors, such as the Janus kinases. Heterodimerization of CCL3 (MIP-1α) and CCL4 (MIP-1β) has also been

reported, suggesting the possibility of receptor heterodimerization. Finally, GAG-mediated multimerization of CCL5 has been reported to lead to activation of *Src* kinase family members independent of 7TMDGPCR signaling.

B. CC Chemokines with a Role in Homeostasis of the Adaptive Immune System

1. CCL19 (ELC) and CCL21 (SLC)—Chromosome 9

The structure of CCL19 is typical for CC chemokines. However, CCL21 has a 30-amino-acid, highly basic, C-terminal extension that interacts with GAGs on high endothelial venule cells. An additional pair of cysteines in the extension of CCL21 may form a disulfide bond.

CCL19 is expressed at high levels in the thymus medulla including endothelial venules and in lymph nodes by dendritic cells (DCs). Expression is increased by the inflammatory cytokines tumor necrosis factor α (TNFα) and interferon-γ (IFN-γ). CCL21 is also expressed in thymus, but much less than CCL19. CCL21 is expressed in the high endothelial venules that direct migration of cells into lymphoid organs. These two chemokines bind only to CCR7.

By definition, homeostatic migration occurs in the absence of inflammation and allows lymphocytes to survey secondary lymphoid tissue for antigen. This includes migration from the blood across specialized high endothelial cells into lymph nodes and presumably migration within the tissue itself. CCL19 and CCL21 provide this function for naive T cells and a subset of memory T cells that surveys secondary lymphoid tissues for recall antigens. Both of these chemokines trigger rapid integrin-mediated arrest of lymphocytes under flow conditions, emphasizing their importance in migration from the microvasculature. In addition, DCs express CCR7 when they begin to migrate through lymphatics and into the T-cell zones of lymph nodes. Thus, CCL19 and CCL21 are "compartment" chemokines that direct a variety of cell types to T-cell zones of lymphoid organs.

Neutralization of CCL19 in mice results in reduced numbers of T cells in spleens of newborn mice due to defective thymocyte emigration. In the *plt* (paucity of lymph node T cells) mouse, which fails to express both CCL19 and CCL21 in lymphoid organs, naive T cells and DCs do not home into the T-cell areas of lymph nodes, Peyer's patches, and the white pulp of the spleen.

C. CC Chemokines with Pro-inflammatory Roles in Adaptive Immunity

1. CCL20 (MIP-3α)—Chromosome 2

CCL20 is expressed in thymus, in lymph nodes, and at high levels in epithelium associated with MALT. Inflammatory cytokines and lipopolysaccharide (LPS) induce the expression of CCL20 by peripheral blood mononuclear cells (PBMCs), endothelial and epithelial cells, monocyte and macrophage cell lines, and neutrophils.

CCL20 binds only to CCR6, which is expressed on B cells, a subset of memory T cells, and immature DCs, all of which migrate toward CCL20. Of note, CCL20 is highly active on resting memory T cells, which suggests that this chemokine may be important for their recruitment to inflammatory sites early in an immune response. In addition, of the five CC chemokines that reportedly reversibly arrest hematopoiesis *in vitro*, CCL20 is the only one that does not bind to CCR1.

Although no knockout (KO) mice for CCL20 have been described, CCR6KO mice show a defect in mucosal antibody production. CCL20 expression levels are high in models of allergen-induced pulmonary inflammation, and when CCR6 KO mice are used in these models, pulmonary inflammation is reduced.

In humans, CCL20 is expressed in affected tissues in a variety of autoimmune diseases, such as psoriasis, rheumatoid arthritis, and type I diabetes—all consistent with the role for this chemokine in mediating the migration of memory T cells.

2. CCL28—Chromosome 5

CCL28 is expressed in secondary lymphoid organs and at high levels in mucosal epithelium. CCL28 signals through CCR10, which is also the receptor for CCL27. CCR10 is expressed on skin-derived Langerhans' cells and on T cells infiltrating into skin (see section on CCL27, below).

3. CCL11 (Eotaxin)—Chromosome 17, CCL24 (Eotaxin-2), and CCL26 (Eotaxin-3)—Chromosome 7

CCL11 was discovered as a result of a systematic search for eosinophil chemotactic factors in bronchoalveolar lavage fluid in a guinea pig asthma model. Despite the relatively low level of sequence identity among the "eotaxins" (34–38%), they all bind to the receptor CCR3, which is expressed at high levels on eosinophils and basophils.

A variety of cell types express CCL11, including epithelial and endothelial cells, smooth muscle cells,

mast cells, and macrophages. All the eotaxins are expressed in response to interleukin-4 (IL-4) or IL-13, two cytokines that are associated with the type 2 response and that signal through the transcription factor STAT6. However, CCL11 and CCL24 are constitutively expressed in some tissues, and expression of CCL11 is also enhanced by the inflammatory cytokines TNFα or IL-1β. CCL26 expression is limited to vascular endothelium and fibroblasts.

The eotaxins are potent eosinophil and basophil chemoattractants. They also trigger calcium flux, actin polymerization, and eosinophil effector functions including respiratory burst, Leukotriene C4 (LTC4) production, adhesion molecule activation, release of eosinophil granule cationic proteins and preformed IL-4, and internalization of CCR3. CCR3 is a co-receptor for some human immunodeficiency virus-1 (HIV-1) isolates, and CCR3 ligands block CCR3-mediated infection *in vitro*.

CCL11-deficient mice have reduced levels of eosinophils in the intestine compared with wild-type controls, demonstrating that CCL11 is critical for basal trafficking of eosinophils into tissue. Studies using these mice to address the role of CCL11 in allergen-induced eotaxin recruitment into the lung have yielded discrepant results, suggesting that the role of CCL11 in this context is dependent on the strain of mice used. By contrast, CCL11 is critical for allergen-induced eosinophilic gastrointestinal inflammation, since CCL11-deficient mice show no pathology in that model.

CCL11, CCL24, and CCL26 are important either individually or together in diseases that are mediated by eosinophils and are associated with atopy, since CCR3 is the dominant receptor mediating eosinophil recruitment. Human studies have shown an association of type 2 diseases with CCL11, which is elevated in serum in patients with atopic dermatitis and in nasal lavage fluid from patients with allergic rhinitis. Furthermore, asthmatics who are homozygous for a variant of CCL11 (A23T) have lower levels of plasma CCL11 and better lung function than asthmatics who lack the mutation. Since expression of the eotaxins is regulated differently, they may have nonredundant roles *in vivo*, despite sharing a receptor.

4. CCL27 (CTACK)—Chromosome 9

CCL27 is constitutively expressed by keratinocytes, and expression is increased by TNFα and IL-1β and decreased by IL-10. Fibroblasts in inflamed skin also express CCL27. CCL27 binds only to CCR10, which is also the receptor for CCL28. CCR10 is frequently co-expressed with the skin homing molecule cutaneous lymphoid antigen (CLA) on memory T cells, and all T cells invading the skin are $CCR10^+$, suggesting that CCL27 and CCR10 may be important for supporting the inflammatory response in skin and that blockade may attenuate inflammatory skin disease.

5. CCL17 (TARC) and CCL22 (MDC)—Chromosome 16

Both CCL17 and CCL22 are highly expressed in thymus and to a lesser extent in lungs, intestines, skin (by keratinocytes), and secondary lymphoid tissue (by DCs and macrophages). IL-4 and IL-13 enhance and IFN-γ inhibits the expression of CCL22.

Both CCL17 and CCL22 signal only through CCR4, which is expressed on thymocytes, monocytes, activated natural killer (NK) cells, and DCs. CCR4 is also expressed on a subset of memory CD4 T cells, including Th2 cells, on those that express CLA (see section on CCL27, above), and on CD4 regulatory T cells, a newly defined subset that suppresses the immune response.

Expression of CCL22 in the thymus suggests a role in directing the migration of thymocytes during maturation. In murine models, antibody blockade of CCL17 or CCL22 attenuates ovalbumin-induced asthma, consistent with a role for these chemokines in the type 2 response. Concordantly, levels of CCL17 are high in the serum and sputum of asthmatics, and both CCL17 and CCL22 are elevated in patients with atopic dermatitis.

6. CCL3 (MIP-1α) and CCL4 (MIP-1β)—Chromosome 17, MIP Subregion

CCL3 is expressed constitutively in the bone marrow, including by osteoblasts, and is induced during inflammation. Bacterial toxins, viral infections, TNFα, IFN-γ, IL-1β, and IL-6 are some of the stimuli that induce the expression of CCL3 and/or CCL4 *in vitro* from multiple cell types including monocytes/macrophages, DCs, and epithelial cells. In addition, IL-10, IL-4, and transforming growth factor-β attenuate the inflammation-induced expression of these two chemokines.

CCL3 signals through CCR1 and CCR5. CCR5 is the primary receptor for CCL4. Neutrophils, eosinophils, and T cells express CCR1, although CCL3 is not a chemotactic factor for human neutrophils. NK cells and subsets of resting memory T cells, including some but not all Th1 cells, express CCR5. Monocytes express both CCR1 and CCR5.

In vitro, CCL3 induces the chemotaxis of CCR1- or CCR5-expressing cells, stimulates adhesion and integrin expression, and may increase IL-2 secretion and proliferation by T cells in response to antigen receptor stimulation. CCL4 is a chemoattractant for CCR5-expressing cells and also activates NK cells to kill tumor cells *in vitro*. Both of these chemokines are expressed in inflamed tissues in mice and humans.

Expression of CCR5 on Th1 cells and induction of CCR1 expression on T cells by IFN-α suggest a role for CCL3 and CCL4 in cell-mediated immunity. Mice treated with monoclonal antibodies against CCL3 or that are CCL3-deficient have an impaired inflammatory response and decreased pathology from viral infections, decreased survival after infection with *Cryptococcus neoformans*, delayed allograft rejection, and attenuated development of experimental autoimmune encephalitis. Mice treated with antibodies to CCL4 have decreased responses to endotoxemia and hapten-induced contact hypersensitivity.

The demonstration that CCL3 and CCL4 (and CCL5) block *in vitro* infection by macrophage-tropic strains of HIV-1 was crucial for the discovery that CCR5 is the major co-receptor used by HIV-1 for fusion and entry. In fact, HIV-1-infected patients with higher levels of circulating CCL3 and CCL4 have an improved prognosis. CCL5 analogues have been used to study the effect of CCR5 blockade on HIV-1 infection, as have "intrakines" containing CCL3 that trap CCR5 in the endoplasmic reticulum to render cells resistant to HIV-1. Clinical studies of CCR5 blockers with the goal of treating HIV-1 infection are under way.

CCL3 reversibly arrests hematopoiesis *in vitro* and was investigated as an agent to protect the bone marrow from toxicity of cancer chemotherapeutics. Unfortunately, to date, the human studies have shown little benefit. CCL15, CCL16, and CCL23 also bind to CCR1 and arrest hematopoiesis.

Inhibition of CCL3 and CCL4 is being explored in animal models of autoinflammatory diseases in which local levels are elevated—rheumatoid arthritis, for example—but has not been tested in humans.

7. CCL5 (RANTES)—Chromosome 17, MIP Subregion

CCL5 expression is induced by IFN-γ, TNFα, or IL-1 in T cells, fibroblasts, macrophages, epithelial cells, and endothelial cells. In addition, CCL5 protein is found in eosinophil granules and is released upon exposure to IFN-γ.

CCR1, CCR3, and CCR5 all function as receptors for CCL5. Thus, CCL5 produces signals in monocytes, macrophages, T-cell subsets, DCs, eosinophils, basophils, and microglia. In addition to its chemoattractant activity, CCL5 stimulates eosinophils to secrete eosinophil cationic protein and stimulates basophils to release histamine.

Mononuclear cells in CCL5 KO mice migrate less to sites of cutaneous hypersensitivity and T cells from these mice proliferate less *in vitro* in response to mitogens and specific antigens. The effects of CCL5 overexpression in animal models or challenge in humans vary with the anatomic site and type of challenge. Intratracheal challenge of Sprague–Dawley rats with CCL5-expressing adenovirus showed enhanced monocyte recruitment to the lung by approximately 50-fold, although CCL5 challenge to nasal mucosa of allergic patients induced eosinophil influx. CCL5 is expressed in lungs of patients with chronic eosinophilic pneumonia, suggesting that CCL5 has a role in eosinophil-induced pathology and that CCL5 blockade may be beneficial in treatment of atopic diseases, including asthma.

CCR5 is the major HIV-1 co-receptor, and CCL5 is an effective inhibitor of CCR5-mediated infection *in vitro*. Since increased transcription of the CCL5 gene due to polymorphisms in its promoter is associated with delayed progression of HIV-1 disease, CCR5 blockade with CCL5 or its derivatives may be an effective strategy for prevention of HIV-1 entry into cells. Clinical trials of modified CCL5 proteins to block HIV transmission are under way.

8. CCL18 (DC-CK, PARC)—Chromosome 17, MIP Subregion

CCL18 is constitutively expressed by DCs in secondary lymphoid organs and by alveolar macrophages in lung. Expression can be induced by IL-4, IL-10, IL-13, and LPS and inhibited by IFN-γ.

CCL18 attracts naive resting T cells and naive tonsil B cells and thus may participate in primary T-cell and B-cell activation in secondary lymphoid tissue. Since CCL18 is also expressed at high levels in hypersensitivity pneumonitis and by macrophages in atherosclerotic plaques, it may have a role in chronic inflammation as well, presumably by targeting cells other than naive lymphocytes.

9. CCL23 (MPIF-1, CKβ8-1) and CCL15 (Leukotactin-1)—Chromosome 17, MIP Subregion

CCL15 and CCL23 are similar in many respects. They share $>80\%$ identity, have unusually long amino-termini, 31 and 49 amino acids, respectively, possess an extra pair of (presumably bonded) cysteines,

and are transcribed from genes with four exons, one more than the other CC chemokine family members.

There are, however, distinct differences between these two chemokines. CCL23 is the only chemokine with an alternative splice variant in which amino-terminal amino acids are deleted. In addition, although both are expressed in response to IL-4 and LPS, TNFα and IFN-γ also stimulate CCL15 expression, and although both CCL15 and CCL23 signal through CCR1, CCL15 also uses CCR3. Thus, although both chemokines attract monocytes, lymphocyte subsets, and neutrophils, only CCL15 attracts eosinophils.

CCL15 is expressed by leukocytes and is found in the adrenal gland, pancreas, heart, intestine, and liver. CCL15 is also found in atherosclerotic plaques. CCL23 is expressed in pancreas, skeletal muscle, and bone and is chemotactic for osteoclast precursors, suggesting a role in bone remodeling. In addition, the genes for CCL15 and CCL14 (see below) are separated by 14 kb, and bicistronic transcripts are found in colon and liver.

10. CCL14 (Hemofiltrate CC Chemokine-1, HCC-1) and CCL16 (HCC-4)—Chromosome 17, MIP Subregion

CCL14 was purified initially from hemofiltrate collected from patients with chronic renal failure. Two variants lacking the first two and four amino acids of the amino terminus are more potent than the parent protein. In addition to bicistronic transcripts with CCL15 in colon and liver, monocistronic transcripts for CCL14 are found in all tissues examined except brain and placenta. Leukocytes do not express CCL14. The reason for the high levels of CCL14 in normal plasma and for its elevation during chronic renal failure is unknown.

The C-terminus of CCL16 is approximately 20 amino acids longer than most other CC chemokines. CCL16 is expressed in liver and by monocytes, T cells, and NK cells. CCL16 expression is increased by the anti-inflammatory cytokine IL-10.

Both of these chemokines primarily signal through CCR1. CCL16 also binds to CCR2, CCR5, and CCR8. The required concentrations for induction of chemotaxis by CCL16 are 10- to 100-fold higher than those for other chemokines, and CCL16 cannot block CCR5-mediated HIV-1 infection *in vitro*.

In its secreted form, CCL14 binds only to CCR1. However, serine proteases that are found, for example, in tumor cell supernatants, cleave the amino-terminal eight amino acids, resulting in a chemokine that binds to CCR3 and CCR5. Since binding of the cleaved form of CCL14 internalizes CCR5, *in vitro* infection with CCR5-dependent strains of HIV-1 is blocked.

The roles for these chemokines in immunity are unclear. CCL14 protects mice challenged with LPS, and tumors that express this CCL16 are rejected more readily than nonexpressers.

11. CCL1 (I-309)—Chromosome 17, MCP Subregion

CCL1 is expressed by T cells, mast cells, and, in response to LPS or inflammatory cytokines, by monocytes and macrophages. CCL1 signals through CCR8, the only chemokine to do so. CCR8 is expressed on thymocytes, on monocytes, and, similar to CCR4, on Th2 and CD4 regulatory T cells. Thus, like CCR4 and its ligands, CCR8 and CCL1 may have a role in type 2-mediated (allergic) diseases and in preserving the balance between appropriate and overexuberant or misdirected immune responses.

12. CCL2 (MCP-1), CCL7 (MCP-3), CCL8 (MCP-2), and CCL13 (MCP-4)—Chromosome 17, MCP Subregion

These four chemokines are collectively referred to as the "MCPs". Their expression is induced by inflammatory cytokines, such as IL-1, TNFα, IFN-γ, IL-6, and IL-4, in many different cell types including fibroblasts, endothelial cells, smooth muscle cells, monocytes/macrophages, and keratinocytes. Expression of the MCPs is attenuated by glucocorticoids, estrogen, progesterone, and by IL-4, IL-10, IL-13, and TGFβ.

All of the MCPs target CCR2, and all but CCL2 signal through CCR3. In addition, CCL7 and CCL8 signal through CCR1 and CCL8 signals through CCR5, and can inhibit HIV-1 infection *in vitro*. CCR2 is expressed by monocytes, by NK cells, and by subsets of memory CD4 T cells.

The MCPs are best characterized as chemoattractants for monocytes, but they also attract subsets of resting or activated memory CD4 T lymphocytes, NK cells, and DCs. Since CCR3 is expressed on eosinophils and basophils, these cells are targets for all MCPs except CCL2. In addition, the MCPs may modulate the immune response independently of their effects on migration, by increasing type 2 polarization of T cells, stimulating secretion of IL-1 and IL-6 by monocytes, and, in the case of the CCR3 ligands, stimulating basophils to release histamine.

CCL2 has been extensively studied in murine models. Mice transgenic for CCL2 show an accumulation of monocytes in uninflamed tissues. Genetic deletion of CCL2 results in the lack of migration of monocytes after intraperitoneal thioglycollate challenge and decreased ability to mount type 2 responses. CCL2 blockade attenuates murine models of asthma, arthritis, and glomerulonephritis.

In humans, CCL2 is expressed in many pathologic tissues and states, including rheumatoid arthritis synovia, asthma, idiopathic pulmonary fibrosis, psoriasis, multiple sclerosis, and HIV-1 dementia. Plasma levels of CCL2 are elevated in sepsis, congestive heart failure, and acute myocardial infarction. CCL2 is expressed in atherogenic plaques, and atherogenic mice cross-bred to CCR2 KO mice are rescued from atheroma formation. Also interesting are reports that CCL2 expression is decreased by estradiol, perhaps contributing to the differences in the incidence of vascular disease between males and females. Taken together, the animal models and human studies suggest that CCL2 blockade may be an effective therapy for inflammatory diseases and arteriosclerosis.

13. CCL25 (TECK)—Chromosome 19

CCL25 is unusually long (142 amino acids) due to the unique C-terminus, which is 40 amino acids longer than that of most other chemokines. CCL25 is highly expressed in thymus by DCs and epithelial cells and in small intestinal epithelium. CCR9 is the unique receptor for CCL25 and is highly expressed on $CD4^+$ $CD8^+$ thymocytes. Two observations suggest a role for CCR9 in mucosal immunity. First, $CCR9^+$ T cells co-express the $\alpha4\beta7$ integrin, which mediates homing into mucosal sites. Second, CCL25 attracts cells that secrete IgA, an antibody isotype that confers humoral protection at mucosal sites.

CCR9 KO mice are grossly normal, but competition experiments using $CCR9^{-/-}$ and $CCR9^{+/+}$ chimeric bone marrow suggest a role for migration of T-cell progenitors to or in the thymus. These mice also reveal a role for CCR9 in the generation of intraepithelial γ/δ T cells.

III. C AND CX_3C CHEMOKINES

A. XCL1 (Lymphotactin α) and XCL2 (Lymphotactin β)—Chromosome 1

XCL1 is an unusual chemokine with only one disulfide bond. The C-terminal extension of XCL1 is conserved across species and contains six hydrophobic and six uncharged polar amino acids (mostly threonine). The NMR structure reveals the conserved chemokine fold of a three-stranded anti-parallel β-sheet and C-terminal α-helix, with disordered N- and C-termini. The C-terminus is necessary for chemokine activity. The XLC1 and XLC2 genes are adjacent on chromosome 1 and the proteins differ by two amino acids.

XCL1 is produced by prothymocytes, activated CD8 T cells, Th1 T cells, γδ epidermal T cells, and mast cells. XCL1 signals through XCR1 and is a chemoattractant for T cells and NK cells *in vitro* and *in vivo*.

XCL1 can induce anti-tumor immunity in mice synergy with IL-2. There is also evidence that XCL1 may have a role in graft rejection and T-cell-mediated autoimmunity and as a vaccine adjuvant.

B. CX_3CL1 (Fractalkine)—Chromosome 16

CX_3CL1 is a 373-amino-acid type 1 transmembrane protein, of which the N-terminal 76 amino acids comprise the chemokine domain and 241 amino acids include a mucin stalk, which is followed by a transmembrane domain and an intracellular domain. A cleaved soluble form can also be produced. CX_3CL1 is unique in having 3 amino acids between the first two conserved cysteines. Although the CX_3CL1 gene is located between the genes for CCL17 and CCL22, CX_3CL1 does not share any more homology with them than with the other CC chemokines.

CX_3CL1 is expressed by neurons, macrophages, dendritic cells, and inflamed endothelial cells. It signals through CX3CR1 and is a chemoattractant for T cells, monocytes, and NK cells. The transcription factor p53 is expressed in injured cells, functions as a tumor suppressor, and induces the expression of CX_3CL1, thus suggesting a role for this chemokine in recruiting cytotoxic cells and eliminating cells that might undergo malignant transformation. CX_3CL1 also signals through CX3CR1 on neurons, but its function in the central nervous system is unknown. CX3CL1 is unique among chemokines in being able to mediate arrest of cells under conditions of flow by direct interaction, without G protein signaling. In addition, CX3CR1 is a co-receptor for HIV-1 and functions as a binding site for the envelope protein of the respiratory syncytial virus. CX_3CL1 can block the CX3CR1-mediated entry of these viruses *in vitro*.

CX3CR1 is preferentially expressed on Th1 T cells, and CX3CL1 is found in lesions of psoriasis, a type 1 autoimmune disease. Inhibiting CX_3CL1 activity prevented leukocyte infiltration in a rat model of crescentic glomerulonephritis, and CX_3CR1 KO

mice required less immunosuppression to prevent cardiac allograft rejection.

Acknowledgment

I wish to thank Dr. Joshua Farber for editing and reviewing the manuscript.

Glossary

adaptive immunity A limb of the immune system that responds slowly and that depends on interactions between components of pathogens and antigen-specific T-cell or B-cell receptors. Adaptive immunity improves qualitatively and quantitatively with continued or repeated exposure to pathogen antigens. B and T cells are the primary cells of the adaptive limb.

antigen Literally, any molecule that binds antibody. Frequently used to refer to any foreign molecules that stimulate an adaptive immune response.

dendritic cells Specialized bone marrow-derived cells that present antigen to T cells and are important for the primary immune response that results in naive to memory T-cell transition.

innate immunity A limb of the immune system that responds quickly and that does not depend on interactions between components of pathogens and antigen-specific T-cell or B-cell receptors. The neutrophil is the quintessential innate immune cell.

integrins Heterodimeric molecules on the surface of leukocytes that mediate strong adhesion between cells, including adhesion between leukocytes and endothelial cells, which is necessary for proper trafficking. Integrins that are activated have increased affinity for their ligands, which are members of the immunoglobulin superfamily.

memory B or T cells B or T cells (or their descendants) that have been activated by their cognate antigen and undergone phenotypic changes resulting in a lower activation threshold and the capability to migrate into peripheral tissues in addition to (or rather than) secondary lymphoid organs.

naive B or T cells Mature B or T cells that have never been activated by their cognate antigen. Naive cells can migrate only into secondary lymphoid organs and have a higher threshold for activation than memory cells.

primary lymphoid organs Sites of lymphocyte development and maturation. In humans, these are the bone marrow (B cells, NK cells) and thymus (T cells).

secondary lymphoid organs Sites of primary stimulation of B and T cells by specific antigen. These include, among others, lymph nodes, spleen, and Peyer's patches.

Th1 Memory CD4 T cells that secrete IFN-γ, and not IL-4 or IL-5, and direct an adaptive response to intracellular pathogens such as viruses. Th1 cells guide a "type 1" response, which is important for most host defense and is implicated in autoimmune diseases such as multiple sclerosis and rheumatoid arthritis.

Th2 Memory CD4 T cells that secrete IL-4, IL-5, and IL-13, and not IFN-γ. These Th2 cytokines are important for B cells to divide, mature, and produce antibodies and for response to some parasites, particularly helminths. Th2 cells guide a "type 2" response, which is implicated in allergic diseases and asthma.

Cholecystokinin (CCK)

RODGER A. LIDDLE
Duke University Medical Center

Cholecystokinin (CCK), a peptide hormone, is produced and secreted by endocrine cells of the upper small intestine following food ingestion. CCK is the major hormone responsible for stimulating pancreatic enzyme secretion and gallbladder contraction. CCK promotes satiety, delays gastric emptying, potentiates insulin secretion, and may regulate bowel motility; CCK may also play a role in learning and memory, anxiety, analgesia, and thermoregulation.

I. INTRODUCTION

Cholecystokinin (CCK) was discovered by Ivy and Oldberg in 1928 when they recognized that intestinal extracts could stimulate gallbladder contraction in dogs; the substance responsible for this action was named cholecystokinin ["cholecyst" (gallbladder); "kinin" (to move)]. In 1943, Harper and Raper noted that a similar extract, which they named "pancreozymin," stimulated pancreatic enzyme secretion. It was not until CCK was purified and its amino acid sequence determined by Mutt in 1968 that it was proved that CCK and pancreozymin were identical, both possessing the ability to stimulate the gallbladder and the pancreas. The original name, cholecystokinin, is the term commonly used today.

Over the past three decades, CCK has been found to have many other biological effects in experimental animals and in human study participants and patients. One of the most noteworthy actions of CCK is its ability to induce satiety and thus reduce food intake. Until the development of reliable assays for measuring blood levels of CCK, the physiological effects of CCK remained controversial. However, it has now been shown in humans that physiological levels of CCK stimulate gallbladder contraction and pancreatic enzyme secretion, inhibit gastric emptying, potentiate insulin secretion, and reduce food intake. Although it is not yet proved physiologically, CCK may regulate bowel motility and, in certain species, may promote pancreatic growth. Less well described but fascinating actions of CCK include effects on learning and memory, anxiety, analgesia, and thermoregulation.

In the small intestine, CCK is produced by discrete endocrine cells within the mucosa. However, CCK is even more abundant in the brain and is found in peripheral nerves innervating the intestine, where it functions as a neurotransmitter.

II. MOLECULAR FORMS

The original CCK peptide isolated from the intestine was a tritriacontapeptide (CCK-33). Several larger and smaller molecular forms of CCK have since been found in human and animal intestine, brain, and blood. The biologically active region of CCK resides in its carboxyl terminus and all forms of CCK possesses an identical carboxyl five-amino-acid sequence (-Gly-Trp-Asp-Met-Phe-NH_2) (Fig. 1). This region is common to gastrin, thus gastrin has some CCK-like activity (albeit weak) and CCK shares some weak gastrin-like activity. The amino acid sequence shared by the two hormones has made it difficult to develop assays for CCK because antibodies directed against the biologically active region of CCK may cross-react with gastrin. This problem is accentuated by the finding that circulating levels of gastrin are 10- to 100-fold greater than those of CCK.

CCK is produced from a single gene that encodes a 115-amino-acid preprohormone. By posttranslational processing, molecular forms of CCK ranging in size from 4 to 83 amino acids have been identified in tissues and blood. However, the major molecular forms of CCK are CCK-8, CCK-33, and CCK-58. In humans, the CCK gene is located in the 3q12–3pter region of chromosome 3. CCK expression is both tissue specific and developmentally regulated. In the intestine, the CCK gene is expressed prenatally; after birth, expression is regulated primarily by ingestion of foods that stimulate CCK secretion. In the central nervous system, stimuli regulating neuronal CCK gene transcription include growth factors, second messengers such as cyclic adenosine monophosphate

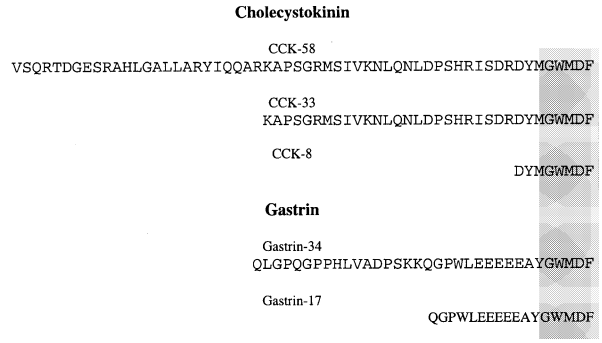

FIGURE 1 Amino acid sequences of the common molecular forms of CCK and gastrin. All biologically active forms of CCK and gastrin share an identical carboxyl-terminal pentapeptide sequence (shaded area).

(cAMP), the neurotransmitter dopamine, and hormones such as estrogen.

III. DISTRIBUTION

Cholecystokinin cells are flask-shaped cells that are scattered throughout the mucosa of the small intestine. The concentration of CCK cells is greatest in the proximal small intestine and diminishes in a gradient fashion toward the distal jejunum and ileum. CCK cells arise from progenitor cells in the intestinal crypts and, along with enterocytes, migrate up the villus. Residing in the mucosa, the apical surface of CCK cells is open to the lumen of the intestine. Here cells can actually "sample" lumenal contents such as food and releasing factors. These enteroendocrine cells also possess microvilli that increase the exposed surface area, thus allowing greater exposure to potential stimuli.

Like other gastrointestinal hormones, CCK is a "brain–gut" peptide, meaning that the transmitter is found in both the central nervous system and the intestine. In the brain, CCK is highly concentrated in the striatum, hippocampus, and cerebral cortex. The CCK-containing neurons may also synthesize dopamine. Such nerves have been shown to extend to the limbic forebrain and ventromedial hypothalamus, where they may participate in controlling food intake. CCK has been demonstrated to modulate dopamine release, dopamine-mediated reward, and receptor binding and function. These actions have implications for a role for CCK in drug abuse and neurologic and psychiatric disease.

CCK is prevalent in peripheral nerves of the gastrointestinal tract. It is most abundant in nerves innervating the colon, with fewer CCK-containing nerves in the ileum. In these locations CCK is present in myenteric and submucosal plexi, where ganglionic bodies are innervated. CCK is also abundant in the vagus nerve and celiac plexus. In the intestine, CCK stimulates acetylcholine release and causes smooth muscle contraction. Postganglionic CCK-containing neurons also terminate around the islets of Langerhans, where CCK may stimulate islet hormone secretion, e.g., insulin and glucagon release.

IV. CCK RECEPTORS

CCK exerts its biological actions by binding to specific receptors on its target tissues. Gastrointestinal CCK receptors reside on tissues of the pancreas, gallbladder, stomach, lower esophageal sphincter, ileum, and colon. In the nervous system, CCK receptors are abundant in the brain and on some peripheral nerves. Two types of CCK receptors have been identified. CCK-A (alimentary) receptors are the primary CCK receptor and mediate most of the effects of CCK in the gastrointestinal tract. The CCK-B (brain) receptor is identical to the gastrin receptor and is the major CCK receptor subtype in the nervous system. It is also abundant in the stomach. Both receptors are G-protein-coupled, seven-membrane-spanning proteins, but arise from different genes.

CCK receptor antagonists have been extremely useful in pharmacological and physiological studies to define the physiological role of CCK. The first CCK receptor antagonists useful for *in vitro* studies were cyclic nucleotide analogues (e.g., dibutyryl cGMP). Subsequently, amino acid derivatives (e.g., CR-1409), carboxyl-terminal CCK analogues, and substituted benzodiazepines (e.g., devazepide) were developed and were used *in vivo*. Clinical studies have shown that CCK receptor antagonists inhibit CCK- and meal-stimulated gallbladder contractions, accelerate gastric emptying, and induce hunger (i.e., reverse satiety), indicating that CCK has important physiological roles in each of these processes.

V. CHOLECYSTOKININ RELEASE

CCK is secreted from specialized endocrine cells of the mucosa (known as I cells) into the extracellular space, where CCK is taken up into the bloodstream. It is by this mechanism that circulating CCK reaches distant target tissues such as the pancreas and gallbladder. Enteric endocrine cells package CCK in secretory granules that are stored along the basolateral surface of the cell, thus allowing CCK to be secreted into the interstitium when the cell is

stimulated. *In vivo*, ingested proteins and fat are the major dietary stimulants of CCK release. However, in some species, including humans, and in cell preparations *in vitro*, partially digested nutrients such as amino acids and peptides and fatty acids are potent releasers of CCK, indicating that these components directly interact with the CCK cell.

Circulating blood levels of CCK average approximately 1 p*M* in the fasting state and increase to between 5 and 8 p*M* after eating. Postprandial levels remain elevated for 3–5 h as food empties from the stomach into the upper small intestine. Gastric distention does not influence CCK release. Although fat and protein are the primary stimulants of CCK, carbohydrate has a modest effect on secretion.

It is well recognized that inactivation of protease activity in the lumen of the small intestine of rodents stimulates CCK release and pancreatic exocrine secretion. This phenomenon, known as negative feedback control of CCK release, also applies to other species, including humans. Thus, CCK release is controlled in part by the presence or absence of pancreatic enzymes in the intestine (Fig. 2). This concept indicates that intestinal releasing factors are secreted into the intestine and stimulate CCK secretion. When pancreatic enzymes are present in the intestine, these CCK-releasing factors are inactivated; however, when pancreatic enzymes are inhibited or pancreatic secretion is reduced, these CCK-releasing factors are active and stimulate CCK secretion. Similarly, ingestion of a meal causes temporary binding of trypsin and other digestive enzymes, thus CCK-releasing factors are available to stimulate CCK secretion. To date, a human counterpart of the rodent CCK-specific releasing factor has not been identified.

VI. BIOLOGICAL ACTIONS OF CCK

CCK is the major hormonal regulator of gallbladder contraction. Coincident with this effect, CCK also relaxes the sphincter of Oddi, which also promotes bile secretion into the intestine. In humans, the predominant CCK receptor type in the pancreas is CCK-B. In most species, CCK-A receptors predominate in the pancreas, and CCK is a potent stimulant of pancreatic secretion. Therefore, in humans, although CCK stimulates pancreatic secretion, its role may be limited.

At physiological blood concentrations that typically occur after a meal, CCK delays gastric emptying; this may be important in the influence CCK has on

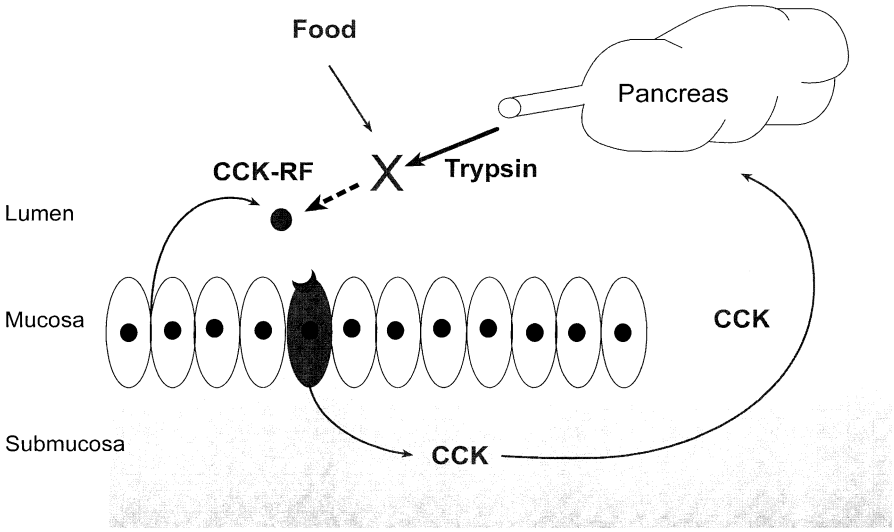

FIGURE 2 Model for regulation of cholecystokinin (CCK) release by an intralumenal CCK-releasing factor (CCK-RF). One or more CCK-RFs stimulate intestinal CCK secretion. CCK-RF is normally secreted in the intestinal lumen, where it is exposed to pancreatic enzymes. Under basal conditions, CCK-RF is inactivated by even small amounts of enzyme; however, following a meal, food competes for enzyme binding, allowing CCK-RF to interact with CCK cells, stimulating hormone secretion. CCK in the circulation stimulates pancreatic secretion, which, following digestion of food, restores CCK-RF and CCK secretion to basal levels. Modified from Liddle, R. A. (1995). Regulation of cholecystokinin secretion by intralumenal releasing factors. *Am. J. Physiol. Gastrointest. Liver. Physiol.* **269**, G319–G327.

reducing food intake and inducing satiety. Due to CCK effects on gallbladder contraction, pancreatic secretion, and gastric emptying, CCK coordinates many digestive processes and plays an important role in the ingestion and digestion of a meal. Although it has been shown that CCK causes relaxation of the lower esophageal sphincter and promotes intestinal motility, it appears that these effects are neural rather than hormonal. CCK receptors have been found on some gastrointestinal and lung cancers, but it is unknown whether CCK plays a role in human cancer growth.

VII. CLINICAL USES OF CHOLECYSTOKININ

CCK is used along with secretin as a test of pancreatic function. In patients with pancreatic insufficiency, low levels of pancreatic juice are recovered following intravenous injection of these hormones. CCK can also be used clinically to stimulate gallbladder contraction and is helpful in radiographic testing of gallbladder function. For diagnostic purposes, CCK has facilitated the collection of bile and pancreatic juices for cytological examination. Therapeutically, CCK injections have been administered to patients who are unable to eat (e.g., parental alimentation) in order to stimulate gallbladder contraction. This therapy has been effective in reducing gallbladder sludge and in preventing gallstone formation.

Low blood levels of CCK have been reported in patients with celiac disease, in bulimia nervosa, and in conditions that delay gastric emptying. The defect in celiac disease is likely due to reduced CCK secretion from diseased small intestinal mucosa. The cause of abnormal CCK responses in bulimia is unknown but may be related to alterations in gastric emptying, because normal postprandial CCK release is dependent on delivery of food from the stomach to the small intestine. It is not known whether CCK deficiency contributes to any specific pathological consequences. There are no known diseases of cholecystokinin excess.

Glossary

gastrin Gastrointestinal polypeptide hormone produced by G cells of the gastric antrum; stimulates gastric acid secretion.

G-protein-coupled receptor A family of cell surface receptor proteins consisting of seven transmembrane regions. The intracellular region interacts with GTP-binding proteins, which, on ligand binding, transduce signals within the cell, leading to a cellular response (e.g., secretion, motility, and growth).

microvilli Finger-like extensions along the apical surface of intestinal mucosal cells. On enterocytes, microvilli increase the absorptive surface of the cell; on endocrine cells, microvilli allow potential stimuli greater exposure to their targets (e.g., receptors).

myenteric plexus Also known as Auerbach's plexus; a system of nerves and ganglia lying within the longitudinal and circular muscle layers of the intestine. Nerves of the myenteric plexus innervate numerous targets, including the myenteric externa, mucosa, and sympathetic prevertebral ganglia.

sphincter of Oddi Muscular region surrounding the distal ends of the common bile duct and pancreatic duct as they enter the duodenum. When constricted, this sphincter prevents flow of bile and pancreatic juice into the duodenum and restricts reflux of duodenal contents back into the bile and pancreatic ducts.

submucosal plexus Network of nerves and small ganglia found in the submucosa of the intestine. It is composed of outer and inner layers and transmits secretomotor and vasodilator stimuli to the mucosa. Primary sensory nerves are contained in this plexus, which also communicates with the myenteric plexus.

Co-activators and Corepressors for the Nuclear Receptor Superfamily

BRIAN G. ROWAN* AND BERT W. O'MALLEY†
*Medical College of Ohio • †Baylor College of Medicine

Groups of nuclear-receptor-interacting proteins that regulate the degree of receptor-dependent target gene transcription have been recently identified. These proteins, termed coregulators (both co-activators and corepressors), achieve this effect through multiple mechanisms, including stabilization of nuclear receptors and the basal transcription machinery at the promoter; recruitment of proteins with a variety of enzymatic activities; covalent modification of histones, activators, and other coregulators; and, possibly, turnover of activators and other proteins at the promoter.

I. INTRODUCTION

The discovery, structure, and mechanisms of action of the major groups of nuclear receptor coregulators, highlighting both similarities and differences among many of these molecules, are described in this article. Current mechanistic models by which coregulators modulate nuclear receptor action are presented. Tables 1 and 2 summarize some of the major coregulators and their effects. A comprehensive discussion of all nuclear receptor coregulators is beyond the scope of this article, and the reader is referred to recent review articles listed in the bibliography.

A. The Nuclear Receptor Superfamily

Nuclear receptors constitute a superfamily of ligand-dependent transcription factors that mediate the pleiotropic physiological effects of steroids, retinoids, and other lipophilic ligands through modulating expression of multiple target genes. Nuclear receptors are modular proteins that contain an N-terminal domain (NTD), a centrally located DNA-binding domain (DBD), a dimerization region, a hinge region, a nuclear localization sequence, and a carboxyl-terminal ligand-binding domain (LBD). In addition there are two transcriptional activation functions, activation function-1 (AF-1) and activation function-2 (AF-2), that mediate the gene regulatory functions of the receptor. AF-2 is located in the carboxyl terminus of the protein, is ligand dependent, and contains the major interaction regions for the nuclear receptor coregulators (see later), whereas AF-1 is located in the amino terminus and is ligand independent (Fig. 1).

B. Type I and Type II Nuclear Receptors

Nuclear receptors are broadly classified as either type I or type II receptors. The steroid receptors include the estrogen receptor (ER), progesterone receptor (PR), glucocorticoid receptor (GR), androgen receptor (AR), and mineralocorticoid receptor (MR). Type II receptors include the thyroid hormone receptor (TR) vitamin D receptor (VDR), all-*trans*-retinoic acid receptor (RAR), and 9-*cis*-retinoic acid receptor (RXR). Grouping as type I or II is based on evolutionary conservation and receptor location in the unliganded state. A third category, the type III

Co-activators and Corepressors for the Nuclear Receptor Superfamily

BRIAN G. ROWAN* AND BERT W. O'MALLEY†
*Medical College of Ohio • †Baylor College of Medicine

Groups of nuclear-receptor-interacting proteins that regulate the degree of receptor-dependent target gene transcription have been recently identified. These proteins, termed coregulators (both co-activators and corepressors), achieve this effect through multiple mechanisms, including stabilization of nuclear receptors and the basal transcription machinery at the promoter; recruitment of proteins with a variety of enzymatic activities; covalent modification of histones, activators, and other coregulators; and, possibly, turnover of activators and other proteins at the promoter.

I. INTRODUCTION

The discovery, structure, and mechanisms of action of the major groups of nuclear receptor coregulators, highlighting both similarities and differences among many of these molecules, are described in this article. Current mechanistic models by which coregulators modulate nuclear receptor action are presented. Tables 1 and 2 summarize some of the major coregulators and their effects. A comprehensive discussion of all nuclear receptor coregulators is beyond the scope of this article, and the reader is referred to recent review articles listed in the bibliography.

A. The Nuclear Receptor Superfamily

Nuclear receptors constitute a superfamily of ligand-dependent transcription factors that mediate the pleiotropic physiological effects of steroids, retinoids, and other lipophilic ligands through modulating expression of multiple target genes. Nuclear receptors are modular proteins that contain an N-terminal domain (NTD), a centrally located DNA-binding domain (DBD), a dimerization region, a hinge region, a nuclear localization sequence, and a carboxyl-terminal ligand-binding domain (LBD). In addition there are two transcriptional activation functions, activation function-1 (AF-1) and activation function-2 (AF-2), that mediate the gene regulatory functions of the receptor. AF-2 is located in the carboxyl terminus of the protein, is ligand dependent, and contains the major interaction regions for the nuclear receptor coregulators (see later), whereas AF-1 is located in the amino terminus and is ligand independent (Fig. 1).

B. Type I and Type II Nuclear Receptors

Nuclear receptors are broadly classified as either type I or type II receptors. The steroid receptors include the estrogen receptor (ER), progesterone receptor (PR), glucocorticoid receptor (GR), androgen receptor (AR), and mineralocorticoid receptor (MR). Type II receptors include the thyroid hormone receptor (TR) vitamin D receptor (VDR), all-*trans*-retinoic acid receptor (RAR), and 9-*cis*-retinoic acid receptor (RXR). Grouping as type I or II is based on evolutionary conservation and receptor location in the unliganded state. A third category, the type III

TABLE 1 Partial Listing of Major Nuclear Receptor Co-activators[a]

Co-activator	Effect on nuclear receptors
SRC family of HAT enzymes	Interact with and co-activates nuclear receptors; possess HAT activity; synergize with CBP in co-activation; SRC-1 and SRC-3 null mice exhibit partial hormone resistance
CBP/p300 HAT enzymes	Interact with and co-activate nuclear receptors; possess HAT activity; synergize with SRC family in co-activation
P/CAF HAT enzyme	Interacts with nuclear receptors, CBP/p300, and SRC family; possesses HAT activity
E3 ubiquitin–protein ligases	E6-AP interacts with and co-activates nuclear receptors independent of ubiquitin ligase activity
Kinases	TIF1α interacts with and co-activates nuclear receptors; possesses kinase activity
Protein methyltransferases	CARM1 and PMRTs interact with carboxyl terminus of SRC family proteins; synergize with SRC family in co-activation; possess methyltransferase activity; methylate histones and CBP
RNA co-activator	SRA is an RNA transcript that interacts with the AF-1 region and co-activates type I receptors; interacts with SRC family proteins
TRAPs/DRIPs	Complex of proteins that interact with and co-activate thyroid and vitamin D receptors

[a]Abbreviations: SRC, steroid receptor co-activator; HAT, histone acetyltransferase; CBP, Ca^{2+}/cAMP response element-binding protein; P/CAF, p300/CBP-associated factor; E6-AP, E6-papillomavirus-associated protein; TIF1α, transcription intermediary factor-1α; CARM1, co-activator-associated arginine methyltransferase 1; PMRT, protein arginine N-methyltransferase; SRA, steroid receptor RNA activators; AF-1, activation function-1; TRAP, thyroid hormone receptor-associated protein; DRIP, vitamin D receptor-interacting protein.

receptors, contains the largest number of receptors and includes all of the orphan receptors, i.e., receptors with ligands or modes of regulation that were not known at discovery. In the absence of ligand, type I steroid receptors reside in an inactive complex with heat-shock proteins and immunophilins in either the cytoplasm or the nucleus. Ligand binding results in a receptor conformational change that facilitates dissociation from the inactive complex and association with a dimeric partner. Liganded steroid receptor dimers bind to hormone-responsive element (HRE) sequences in the promoter of steroid receptor target genes. Referred to now as the "activated" form, steroid receptors recruit co-activator proteins (see later) that further facilitate receptor interaction with the promoter and stabilize the basal transcription machinery, resulting in gene transcription (Fig. 2). In contrast to type I receptors, unliganded type II receptors are bound to DNA at HREs and often repress basal transcription of target genes through association with corepressor proteins (see later and Fig. 3). The activation mechanisms for type I and type II receptors are described in detail in later sections. The type III receptors also use similar co-activators/corepressors, but their specific actions are not discussed herein.

TABLE 2 Partial Listing of Major Nuclear Receptor Corepressors[a]

Corepressor	Effect on nuclear receptors
N-CoR/SMRT	Interacts with and corepresses unliganded type II nuclear receptors; represses the partial agonist activity of mixed antagonists for type I nuclear receptors
SUN-CoR	Interacts with and corepresses unliganded TR and RevErb; interacts with N-CoR and SMRT
TRUP	Inhibits transactivation of TR and RAR

[a]Abbreviations: N-CoR, nuclear receptor corepressor; SMRT, silencing mediator for retinoid and thyroid hormone receptors; SUN-CoR, small ubiquitous nuclear coreceptor; TRUP, thyroid hormone receptor uncoupling protein; TR, thyroid hormone receptor; RAR, retinoic acid receptor.

C. Discovery of Nuclear Receptor Coregulators

Early biochemical studies had identified proteins that interacted with type I steroid receptors in a ligand-dependent manner. These proteins were subsequently cloned using yeast two-hybrid screens from a variety of cDNA libraries and are now referred to as co-activators based on their ability to enhance receptor-dependent gene transcription. Similarly, early biochemical studies identified proteins that interacted with unliganded type II nuclear receptors and presumably facilitated gene silencing. These proteins

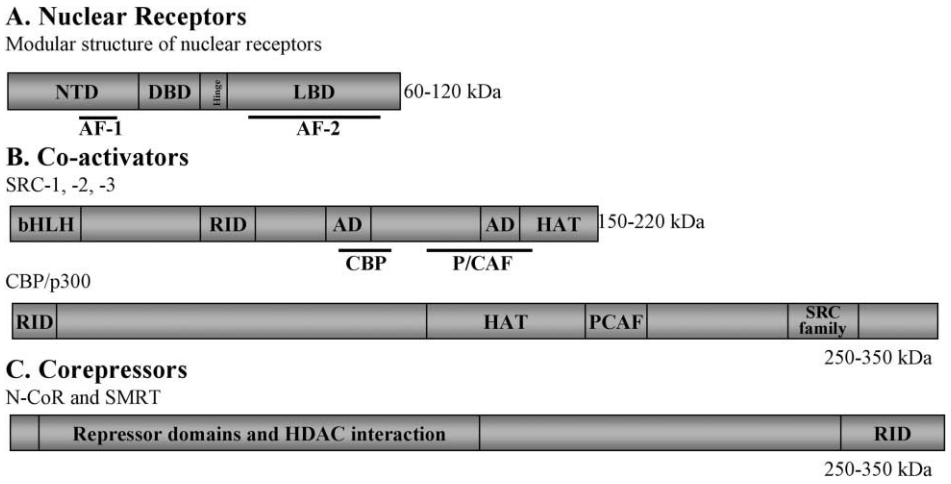

FIGURE 1 Domain structure of receptors, co-activators, and corepressors. (A) Nuclear receptors consist of an N-terminal domain (NTD) containing the ligand-independent activation function-1 (AF-1), a DNA-binding domain (DBD), a hinge region, and a ligand-binding domain (LBD) containing a ligand-dependent activation function-2 (AF-2). (B) The steroid receptor co-activator (SRC) family and CBP/p300 represent major co-activators for the nuclear receptor superfamily. The SRC family members contain a basic helix-loop-helix (bHLH) domain in the amino terminus, the major receptor interaction domain (RID) containing LXXLL motifs in the central region of the protein, activation domains (ADs), histone acetyltransferase (HAT) activity, and domains for interaction with CBP and P/CAF. CBP/p300 contains a RID, HAT activity, and domains for interaction with P/CAF and SRC family members. (C) Nuclear receptor corepressor (N-CoR) and silencing mediator for retinoid and thyroid hormone receptors (SMRT) are representative of the major nuclear receptor corepressors. These proteins contain repressor domains that interact with histone deacetylases (HDACs) and a RID containing LXXI/HIXXXI/L motifs.

were subsequently cloned using a variety of procedures and are now termed corepressors. The major groups of co-activators and corepressors are described in the following section in a way that illustrates the functional and structural diversity and similarities among many of these molecules.

II. NUCLEAR RECEPTOR CO-ACTIVATORS

A. SRC Family of Co-activators

Cloning and characterization of the first authenticated co-activator for the nuclear receptor superfamily were accomplished with the identification of

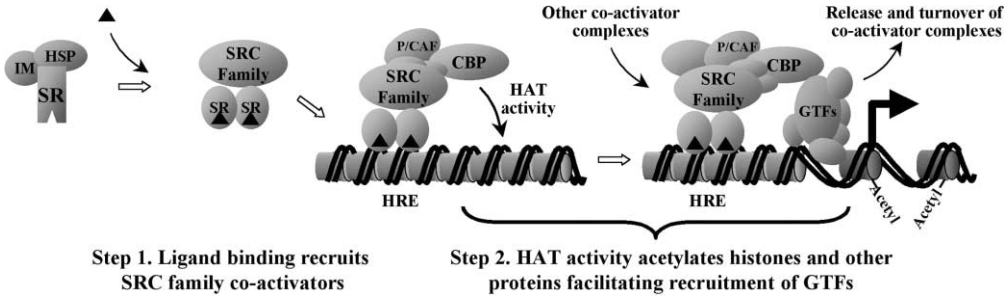

FIGURE 2 Type I steroid receptor activation of gene transcription: a two-step model (for receptors for estrogen, progesterone, glucocorticoid, androgen, and mineralocorticoid). An unliganded steroid receptor (SR) resides in an inactive complex with heat-shock protein (HSP) and immunophilin (IM). Ligand binding dissociates receptors from HSP and IM; then receptors dimerize and recruit a SR co-activator (SRC) to the promoter (step 1). SRCs possess histone acetyltransferase (HAT) activity and recruit other HATs that acetylate histones, creating a more open chromatin conformation that facilitates binding of general transcription factors (GTFs) (step 2), allowing transcription initiation to proceed. It is hypothesized that other co-activator complexes (thyroid hormone-associated proteins/vitamin D receptor-interacting proteins) are recruited subsequent to the SR co-activators and are released and degraded from the promoter in an as-yet undetermined temporal pattern.

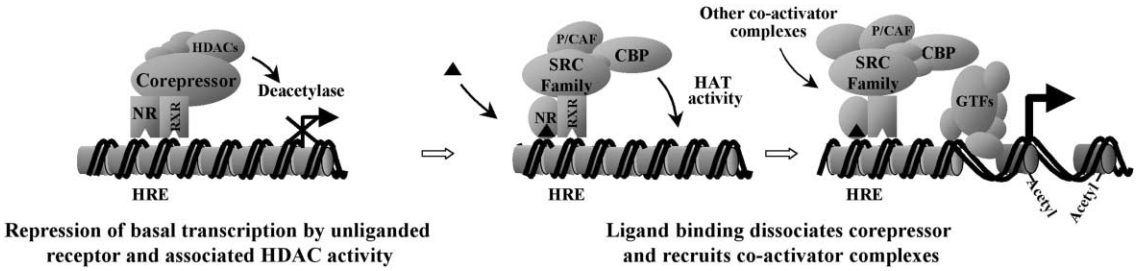

FIGURE 3 Type II nuclear receptors: repression of basal transcription by unliganded receptors and transcriptional activation following ligand binding (for thyroid, retinoic acid, and vitamin D receptors). An unliganded type II nuclear receptor (NR) binds the hormone -responsive element (HRE) predominantly as a heterodimer with retinoid X receptor (RXR) and recruits corepressor proteins with associated histone deacetylases (HDACs). HDACs deacetylate histones, resulting in a closed local chromatin structure, thereby silencing low-level basal gene transcription. Ligand binding to type II receptors changes receptor conformation, resulting in dissociation of corepressors and recruitment of co-activators with associated HAT activity. SRC, Steroid receptor co-activator; CBP, Ca^{2+}/cAMP response element-binding protein; P/CAF, p300/CBP-associated factor; GTF, general transcription factor.

steroid receptor co-activator-1 (SRC-1). SRC-1 and other co-activators were discovered using yeast two-hybrid screens of cDNA libraries with the hormone-bound steroid receptor LBD as bait. SRC-1 interacts with nuclear receptors in a ligand-dependent manner and, in general, steroid receptor antagonists that block receptor-dependent gene transcription prevent the interaction of receptor with SRC-1. SRC-1 co-activation was demonstrated in cotransfection assays in which PR-negative cells were transfected with an expression vector for PR, an HRE-containing reporter gene, and cotransfected either with or without an expression vector for SRC-1. Expression of SRC-1 in cells resulted in enhancement of progesterone-dependent reporter gene activity. Although SRC-1 interacts with and co-activates most nuclear receptors, it has a limited ability to co-activate unrelated transcription factors. Subsequent to the discovery of SRC-1, independent laboratories identified two other nuclear receptor co-activators that shared extensive sequence homology to SRC-1 and exhibited similar functional properties with respect to nuclear receptor co-activation. These co-activators, termed TIF2 (GRIP1 and NcoA-2, referred to here as SRC-2) and RAC3 (ACTR, AIB1, P/CIP, and TRAM, referred to here as SRC-3), established an important gene family of co-activators for the nuclear receptor superfamily members that are broadly expressed in mammalian tissues. Because the SRC family and most coregulators lack a DNA-binding function, coregulators must be recruited to the promoter through the interaction with DNA-bound nuclear receptors.

Mutational analysis and biochemical assays have defined several important domains and an enzymatic activity for the SRC family (Fig. 1). The major receptor interaction domain (RID) for all three SRC family members contains several highly conserved LXXLL motifs, where L is leucine and X is any other amino acid. These motifs interact with LBD hydrophobic regions that are exposed on ligand binding and likely adopt an amphipathic α-helical conformation. The LXXLL motif is also conserved in a number of unrelated nuclear receptor coregulators, including Ca^{2+}/cAMP response element-binding (CREB)-binding protein (CBP/p300), E6 papillomavirus-associated protein (E6-AP), receptor-interacting protein-140 (RIP140), transcription intermediary factor-1 (TIF1), and components of the TR-associated protein complex. Two activation domains (ADs) that are important for interaction with other activators and/or the basal transcription machinery mediate SRC-1 function. A histone acetyltransferase (HAT) activity is present in the carboxyl terminus of SRC-1, giving the SRC family the potential to modify promoter function through covalent modifications of histones and other locally recruited transacting factors. However, the SRC acetylase activity is likely targeted more to the other proteins in the complex than to histone. In addition, the carboxyl terminus contains domains that interact with two very strong HATs, CBP and p300/CBP-associated factor (P/CAF), bringing additional HAT activity to the promoter for direct histone modification and chromatin remodeling. Indeed, the SRC family has been shown to interact functionally with CBP to enhance steroid receptor gene activation synergistically.

A two-step model for type I steroid receptor induction of gene expression incorporates the

discovery of the SRC family in which (1) the liganded receptor recruits SRC co-activators that can (2) open up local chromatin structure through their intrinsic or associated HAT activity and contribute to the stabilization of the preinitiation complex at the promoter (Fig. 2). The *in vivo* significance of co-activators for nuclear receptor action was recently reported for the SRC family. Generation of mice with targeted deletions in SRC-1 and SRC-3 exhibited limited steroid insensitivity. The partial, but not full, hormone resistance phenotype in the SRC knockout models may be explained by functional redundancy among SRC co-activators, as illustrated by a compensatory elevation in the expression of SRC-2 in the SRC-1 null mice.

B. CBP/p300

CBP and the related orthologue p300 function as co-activators for a large and diverse collection of transcription factors, including members of the nuclear receptor superfamily. CBP possesses HAT enzymatic activity and has domains for interaction with nuclear receptors, all three SRC family members, and P/CAF (Fig. 1). Furthermore, CBP functionally interacts with SRC co-activators to co-activate ER- and PR-dependent gene transcription synergistically in cotransfection assays. However, the physical interaction between SRC co-activators and steroid receptors is by comparison stronger than the interaction between CBP with steroid receptors. Further data indicate there is a sequential recruitment of, initially, a stable complex between the liganded type I steroid receptors and SRC co-activators, followed by recruitment of CBP/p300 and other factors (Fig. 2). Both CBP and p300 null mice exhibit embryonic lethality, possibly indicating the global importance of CBP/p300 to many types of transcription factors.

C. E3 Ubiquitin-Protein Ligases: E6-AP and RPF-1

Another group of co-activators that bring an entirely different enzymatic function to the promoter are the E3 ubiquitin-protein ligases E6-AP and retina-derived POU domain factor-1 (RPF-1). E6-AP and RPF-1 physically and functionally interact with type I receptors to co-activate target gene transcription, and co-expression of both proteins synergistically enhances transcription. Although both proteins possess ubiquitin ligase activity and are essential components of the ubiquitin proteolysis pathway, the enzymatic activity of E6-AP is dispensable for its co-activation function. The E3 ubiquitin-protein ligases may be involved in ubiquitination and turnover of nuclear receptor complexes at the promoter, providing another potential mechanism of gene regulation by co-activators.

D. Protein Methyltransferases: CARM1 and PRMTs

The recently discovered co-activator-associated arginine methyltransferase 1 (CARM1) and protein arginine N-methyltransferases (PRMTs) contribute yet another enzymatic activity to the promoter region of nuclear receptor responsive genes. Both CARM1 and PRMTs enhance the transcriptional activity of nuclear receptors, not through a direct physical interaction with receptors but through binding to the carboxyl terminus region of the SRC family of co-activators. Indeed, the presence of an SRC co-activator is prerequisite for CARM1 and PRMTs co-activation of nuclear receptors and for the synergistic enhancement of gene transcription when both proteins are co-expressed. Furthermore, unlike E6-AP enzymatic activity, the methyltransferase enzymatic activity of CARM1 and PRMTs is required for full co-activator function. Co-activator function may be due in part to methylation of histones H3 and H4 by CARM1 and PRMTs, respectively.

E. SRA

A novel, recently identified co-activator for type I steroid receptors possesses two unique properties: (1) interaction with the amino terminus AF-1 domain of nuclear receptors rather than with the AF-2 domain and (2) function as an RNA transcript rather than as a protein. The steroid receptor RNA activator (SRA) brings a new level of complexity to nuclear receptor-mediated transcription through its novel mechanism and its somewhat restricted pattern of expression. SRA is expressed predominantly in the brain and in tumor tissues. SRA exists in a complex with SRC-1 and may aid in recruiting RNA-binding proteins to steroid receptors at the promoter.

F. TRAPs/DRIPs

Biochemical studies identified a multiprotein complex that is composed of TR-associated proteins (TRAPs) or vitamin D receptor-interacting proteins (DRIPs); the complex interacts with the liganded LBD of the TR and the VDR. Interestingly, the TRAP/DRIP complex contains no HAT activity and is distinct from SRC-containing complexes. Components of TRAP/DRIP interact with and stabilize components

of the general transcription machinery at the promoter, allowing continuous transcription to occur. Similar to the SRCs, one component of the TRAP/DRIP complex, TRAP 220/DRIP 205, contains LXXLL motifs and interacts with the LBD of nuclear receptors in a manner similar to that of SRC co-activators. TRAP 220/DRIP 205 serves as a platform for binding of other components of the TRAP/DRIP complex. The common sites for interaction of TRAP/DRIP and SRC complexes with nuclear receptors suggest a competition between the two complexes for receptor binding. However, emerging data now favor a stepwise recruitment of co-activator complexes to nuclear receptors at the promoter. The current model proposes that the SRC complex is recruited first to remodel chromatin, followed by exchange of the SRC complex with the TRAP/DRIP complex. It is envisioned that the TRAP/DRIP complex stabilizes components of the general transcription factor machinery at the promoter, providing for sustained transcription over time.

III. NUCLEAR RECEPTOR COREPRESSORS

Selected type II nuclear receptors such as TR and RAR silence basal transcription of target genes in the unliganded state. This was the basis for identification of corepressor proteins that selectively interact with unliganded type II receptors at the promoter of receptor-silenced genes. Relatively fewer examples of nuclear receptor corepressors have been described when compared to the more than thirty nuclear receptor co-activators.

A. N-CoR and SMRT

Biochemical and cloning strategies led to independent discoveries of two highly homologous proteins that interact with the unliganded TR and RAR. Nuclear receptor corepressor (N-CoR) and silencing mediator for retinoid and thyroid hormone receptor (SMRT) are corepressors for nuclear receptors as well as for a wide variety of unrelated transcription factors. This unrestricted ability of N-CoR and SMRT to corepress many types of transcription factors may be reflected in the embryonic lethal phenotype of N-CoR (−/−) mice. Similar to co-activators, mutational analysis identified several RIDs in the carboxyl terminus of N-CoR/SMRT that contain an extended hydrophobic motif of the consensus sequence LXXI/HIXXXI/L, where L, I, and H are leucine, isoleucine, and histidine, respectively, and X is any amino acid (Fig. 1). These motifs likely bind to similar regions in the LBDs of type II receptors, as do the co-activators LXXLL motifs. Presumably the extra length of the corepressor hydrophobic motif precludes binding to the liganded receptor yet is permissive for binding to the unliganded receptor. The amino termini of N-CoR and SMRT contain transferable repressor domains that mediate interaction with a variety of histone deacetylases (HDACs). In opposition to the manner in which certain co-activators bring HAT activity to the promoter, N-CoR and SMRT recruit HDACs to the promoter, resulting in deacetylation of histones and other proteins, culminating in a more closed local chromatin conformation that represses basal transcription. On ligand binding, an LBD conformational change promotes dissociation of corepressor proteins and recruitment of HAT-containing co-activator complexes, relieving the repression at the promoter and allowing transcriptional activation to proceed (Fig. 3). Although first identified as proteins that facilitate gene silencing of unliganded TR and RAR, N-CoR and SMRT have also been shown to interact with antagonist-occupied ER and PR and to block the partial agonist activity of mixed antagonists.

B. Other Corepressors

Although N-CoR and SMRT appear to be the major corepressors for the nuclear receptor superfamily, several other corepressors may also play an important role in gene silencing. Thyroid receptor uncoupling protein (TRUP) appears to have a different mode of action, compared to N-CoR and SMRT. In blocking ligand-dependent activation of gene transcription by TR and RAR, TRUP appears to reduce DNA binding by TR:RXR (retinoid X receptor) and RAR:RXR heterodimers. Small ubiquitous nuclear corepressor (SUN-CoR) is a 16-kDa nuclear protein that represses basal transcription of TR and the orphan nuclear receptor RevErb. Although unrelated to N-CoR, SUN-CoR interacts with N-CoR and SMRT. It is likely that many additional nuclear receptor corepressors will be identified in the coming years.

IV. SUMMARY/PERSPECTIVES

The discovery of nuclear receptor coregulators and associated proteins has provided a mechanistic explanation for the long-recognized phenomenon of transcriptional activation and gene silencing exhibited by selected members of the nuclear receptor superfamily. The competing nature of limiting cellular HAT and HDAC activities that are recruited by co-activators and corepressors, respectively, is

instrumental in balancing gene repression to gene activation. In addition to HAT and HDAC activities, other coregulators bring a diversity of structural and enzymatic features to receptor-dependent promoters, illustrating the complexity of gene transcription mechanisms. Functional redundancies as well as synergy among coregulators add to this complexity, providing for a fine-tuning of gene expression.

As investigators delve further into the turnover of protein complexes at the promoter, the temporal aspects of co-activator and corepressor complex recruitment, and the tissue-specific, receptor-specific, and ligand-specific coregulators, the model for nuclear receptor gene transcription will necessarily expand. Further challenges will be to describe the role of coregulators at complex promoters and promoters that lack HREs, the detailed tissue- and developmental-specific expression patterns of coregulators, the hormonal regulation of coregulator expression, the promising role of coregulators in directing the action of partial agonists, and the role that membrane signaling pathways play in modulating coregulator activity. The integration of all of these parameters is required to fully understand the complex role of coregulators in nuclear receptor gene transcription.

Glossary

co-activator A biomolecule (predominantly protein) that interacts with transcription factors to enhance transcription factor-dependent target gene transcription.

corepressor A biomolecule (predominantly protein) that interacts with transcription factors to repress basal gene expression and to block transcription factor-dependent target gene activation.

histone acetylase A protein with enzymatic activity that results in covalent acetylation of histones and other proteins.

histone deacetylase A protein with enzymatic activity that results in removal of acetyl groups from histones and other proteins.

nuclear receptor superfamily An evolutionarily conserved family of ligand-dependent transcription factors.

Colony-Stimulating Factor-1 (CSF-1)

XU-MING DAI AND E. RICHARD STANLEY
Albert Einstein College of Medicine, New York

Colony-stimulating factor-1 (CSF-1) is the primary regulator of mononuclear phagocytic lineage cells, including monocytes, tissue macrophages and osteoclasts. As one of a group of four growth factors defined by their ability to stimulate hematopoietic progenitor cells to form colonies of mature progeny cells in semisolid culture media, colony-stimulating factor-1, also known as macrophage CSF, may play a role in atherosclerosis, glomerulonephritis, Alzheimer's disease, and in some myeloproliferative diseases and neoplasms.

I. INTRODUCTION

The primary regulator of cells of mononuclear phagocytic lineage, colony-stimulating factor-1, promotes differentiation of the committed but undifferentiated monoblast precursor to the mature, terminally differentiated cell; CSF-1 supports the survival, proliferation, and function of all cells of the lineage. It also regulates the function of cells of the female reproductive tract. CSF-1 is synthesized by a variety of different cell types, including fibroblasts, endothelial cells, bone marrow stromal cells, osteoblasts, keratinocytes, astrocytes, myoblasts, thyrocytes, adipocytes, liver parenchymal cells, mesothelial cells, and uterine epithelial cells. Ovarian granulosa cells, oviduct epithelium, and uterine epithelial cells synthesize large amounts of CSF-1 during pregnancy under the control of a variety of female steroid hormones. The effects of CSF-1 are mediated by the CSF-1 receptor (CSF-1R) that is expressed on osteoclasts and tissue macrophages and their progenitors, as well as on embryonic cells, decidual cells, and trophoblastic cells. The reported CSF-1-producing cells and CSF-1R-bearing cell types are summarized in Table 1. CSF-1 appears to be involved in several disease states, including atherosclerosis, glomerulonephritis, and Alzheimer's disease, in some pathological pregnancy states, and, via autocrine or paracrine regulation, in the development or progression of myeloproliferative diseases, leukemias, and neoplasms of the ovary, uterus, and breast, for which elevated serum levels of CSF-1 are a tumor marker.

TABLE 1 CSF-1-Producing and CSF-1R-Bearing Cells

CSF-1-producing cells	CSF-1R-bearing cells
Endothelial cells	Monocytes
Fibroblasts	Tissue macrophages
Monocytes	Kupffer cells
T cells	Langerhans cells
B cells	Neurons
Osteoblasts	Microglia
Bone marrow stromal cells	Peripheral B cells
Mesothelial cells	Osteoclasts
Liver parenchymal cells	Trophoblastic cells
Keratinocytes	
Myoblasts	
Astrocytes	
Adipocytes	
Ovarian granulosa cells	
Grandular cells of uterus	
Oviduct epithelium	
Uterine epithelial cells	
Other epithelial cells	

II. CSF-1 GENOMIC ORGANIZATION, GENE EXPRESSION, BIOSYNTHESIS, AND STRUCTURE

CSF-1 cDNAs have been cloned from several species, including humans, mice, rabbits, rats, cows, and cats. Sequence comparison indicates that the CSF-1 gene is highly conserved. The human CSF-1 gene, located on chromosome 1p13–p21, spans approximately 21 kb and is composed of 10 exons. The genomic organization of the human CSF-1 gene, the posttranscriptional differential splicing of CSF-1 messenger RNA, and the biosynthesis of various forms of CSF-1 protein are summarized in Fig. 1.

Through differential mRNA splicing and posttranslational proteolytic processing and modification, mouse and human CSF-1s are each expressed in three forms: a secreted glycoprotein (80–100 kDa), a secreted chondroitin sulfate-containing proteoglycan (130–160 kDa), and a biologically active membrane-spanning cell surface glycoprotein form (68–86 kDa). All of these forms are homodimeric and highly glycosylated with N- and O-linked oligosaccharides. The cell surface form is involved in local regulation and the proteoglycan form may be sequestered to particular tissue matrices to function locally. The specific functions and biological significance of these various forms of CSF-1 are currently under intensive investigation both *in vivo* and *in vitro*.

At least four types of mature CSF-1 mRNAs have been isolated. Differential splicing at exon 6 in the coding region gives rise to mRNAs encoding either

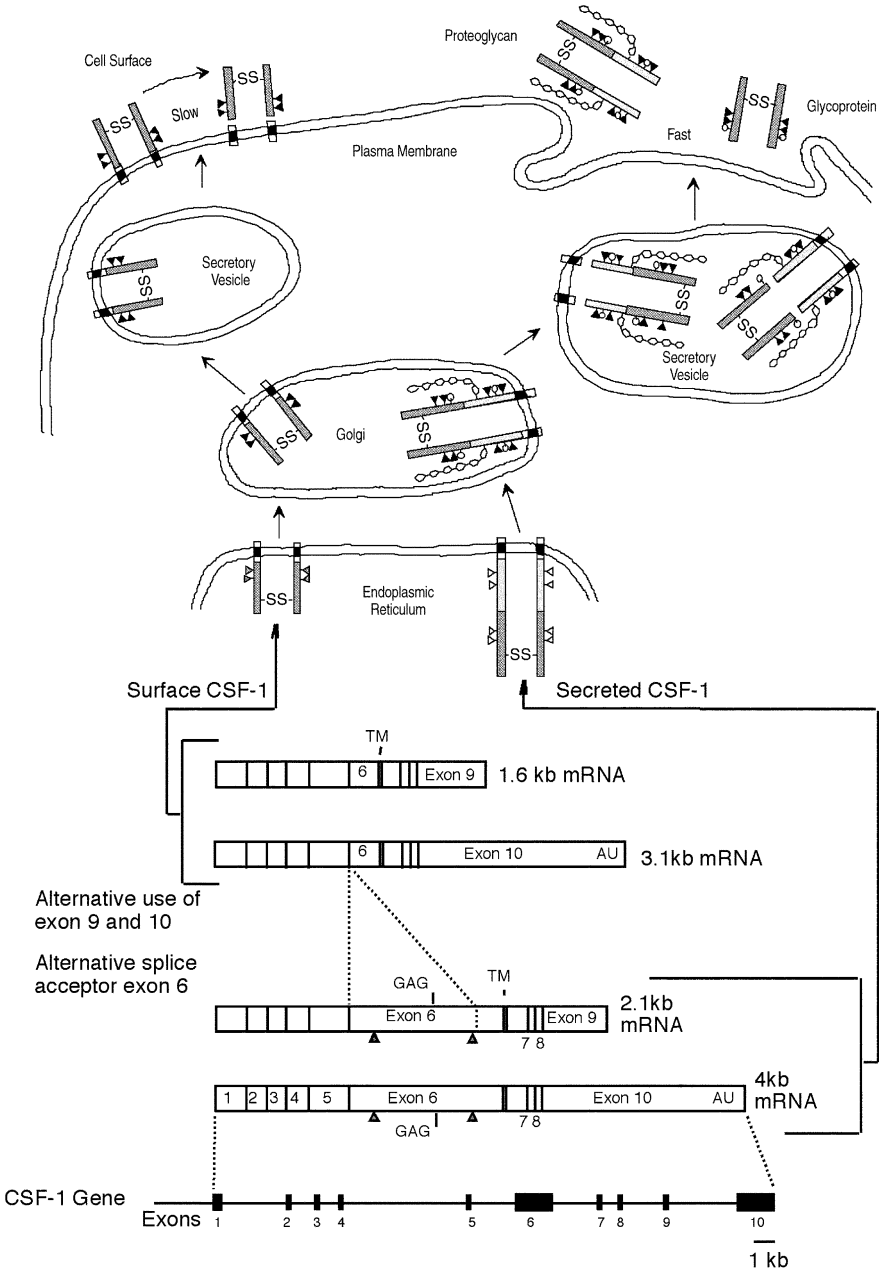

FIGURE 1 CSF-1 genomic organization, expression, and structure. The CSF-1 gene is localized to human chromosome 1p13–p21 and mouse chromosome 3. The bottom half of the diagram shows the intron–exon structure and four representative human cDNA clones that have been sequenced. Similar mouse clones have been isolated. Exons 1–10 and the transmembrane (TM) domain are indicated. The 4- and 2.1-kb mRNAs arise from alternative usage of untranslated regions (AU) encoded by exons 9 and 10, the latter exon encoding putative mRNA instability sequences. The 1.6- and 3.1-kb mRNAs are products of a splicing reaction that results in the use of a short form of exon 6. The approximate intracellular proteolytic cleavage sites (arrowheads) and the chondroitin sulfate glycosaminoglycan addition site (GAG) are also shown. The top half of the diagram shows the processing of CSF-1 homodimers encoded by both the short and long coding regions. Hatched regions represent those present in the mature secreted or released glycoprotein forms whereas both hatched and filled regions are present in the major secreted proteoglycan form. N-Linked (filled arrowheads) and O-linked (open circles) glycosylation sites, the chondroitin sulfate chain (linked, open hexagons), and the transmembrane domain (filled region) are shown. Reproduced from Stanley (1998), with permission.

secreted or cell surface CSF-1 and there is alternative use of exon 9 and 10 in the 3′ untranslated region. These exons may confer differential stability to the CSF-1 mRNA. The CSF-1 gene is expressed either constitutively (usually at low levels) or is induced in response to a variety of factors during development or in pathophysiological states. Interferon γ (IFNγ), tumor necrosis factors (TNFα and TNFβ), interleukin-1 (IL-1), IL-3, IL-4, granulocyte/macrophage colony-stimulating factor (GM-CSF), and bacterial lipopolysaccharide (LPS) induce CSF-1 production by monocytes, endothelial cells, fibroblasts, T cells, and polymorphonuclear leukocytes.

The N-terminal 149 amino acids of the full-length CSF-1 precursor, which is highly conserved in all biologically active forms of CSF-1, are necessary and sufficient for *in vitro* biological activity. The crystal structure of this region reveals that the CSF-1 monomer has an antiparallel four-α-helical bundle/antiparallel β-ribbon structure, similar to the structure of other cytokines, e.g., GM-CSF. The CSF-1 dimer is formed by the disulfide bonding of two monomers end to end, yielding a very flat, elongated structure.

III. CSF-1 RECEPTOR, SIGNAL TRANSDUCTION, AND CELLULAR RESPONSE

The unique, high-affinity CSF-1R is encoded by the c-*fms* protooncogene. The CSF-1R gene is localized to human chromosome 5q33.3 and to mouse chromosome 18. The human CSF-1R gene is 58 kb long and is composed of 21 introns and 22 exons. Exon 1 encodes untranslated sequences and is 26 kb upstream of exon 2, which encodes the signal peptide. Gene transcription occurs in a tissue-specific fashion from two distinct promoters. In human placental trophoblast, transcription is initiated upstream of exon 1. In macrophages, it is initiated immediately upstream of exon 2. The receptor possesses a highly glycosylated extracellular ligand-binding domain (493 amino acids), a hydrophobic transmembrane domain (25 amino acids), an intracellular tyrosine kinase domain (436 amino acids) interrupted by a kinase insert domain (73 amino acids), and a C-terminal tail (Fig. 2). The extracellular domain of the CSF-1R is characteristic of members of the immunoglobulin gene superfamily.

Signaling by the CSF-1R is initiated by the binding of the divalent CSF-1 dimer ($K_d = 0.1$ n*M*) to the CSF-1R, which stabilizes a dimerized receptor–ligand complex; this results in the activation of the kinase domain and autophosphorylation of the receptor on the multiple tyrosine residues that serve as binding sites for SH2 and protein tyrosine-binding domain-containing downstream signaling proteins, including Src, p85/phosphatidylinositol 3-kinase (PI3K), and Cbl. These and other, primarily cytosolic, proteins become tyrosine phosphorylated. These events are followed by CSF-1R extracellular domain disulfide bonding and further tyrosine phosphorylation, serine phosphorylation, and Cbl-regulated multiubiquitination of the receptor, all of which precede internalization and intralysosomal destruction of the receptor–ligand complex. The juxtamembrane region of the CSF-1R has been implicated in internalization. The C-terminal tail of the CSF-1R, presumably via the binding of Cbl to Tyr-974, has been shown to regulate signal transduction negatively. Its truncation, in conjunction with point mutations in the extracellular domain of the v-*fms* product (encoded by the Susan McDonough strain of feline sarcoma virus), leads to ligand-independent signaling and transforming activity. The major CSF-1R signaling pathways, the signaling molecules involved, and the cellular response to each signaling pathway in myeloid cells are summarized in Fig. 2.

In vitro experiments with cultured primary bone marrow-derived macrophage (BMM) and CSF-1-responsive macrophage cell lines, such as BAC1.2F5 and RAW246, have shown multiple cellular effects of CSF-1. These include the stimulation of cell proliferation, survival, differentiation, and protein synthesis, and inhibition of protein degradation. Macrophages are also induced to undergo morphological changes, including spreading and extension of lamellipodia and formation of ruffles on the cell surface, followed by cell polarization and increased motility. The small G-proteins and protein tyrosine phosphatase-ϕ are involved in mediating these effects. In addition, CSF-1-enhanced invasiveness of CSF-1R-expressing macrophage and carcinoma cell lines has been shown in a human amniotic basement membrane invasion assay. This response may be correlated with the enhancement of breast cancer metastasis by CSF-1 and macrophages in animal model systems. CSF-1 has also been shown to prime macrophages to respond to other stimuli, such as LPS, by releasing cytokines (TNFα, IL-1, and IL-6), and to stimulate the synthesis and surface expression of the macrophage scavenger receptor and to maintain the expression of CD36, an oxidized low-density lipoprotein (LDL) scavenger receptor. In addition, trophoblasts, decidual cells, microglia, and CD5 + B lymphocytes are all responsive to CSF-1 stimulation *in vitro*. Multiple signaling pathways activated by CSF-1 stimulation induce the expression of the cyclin

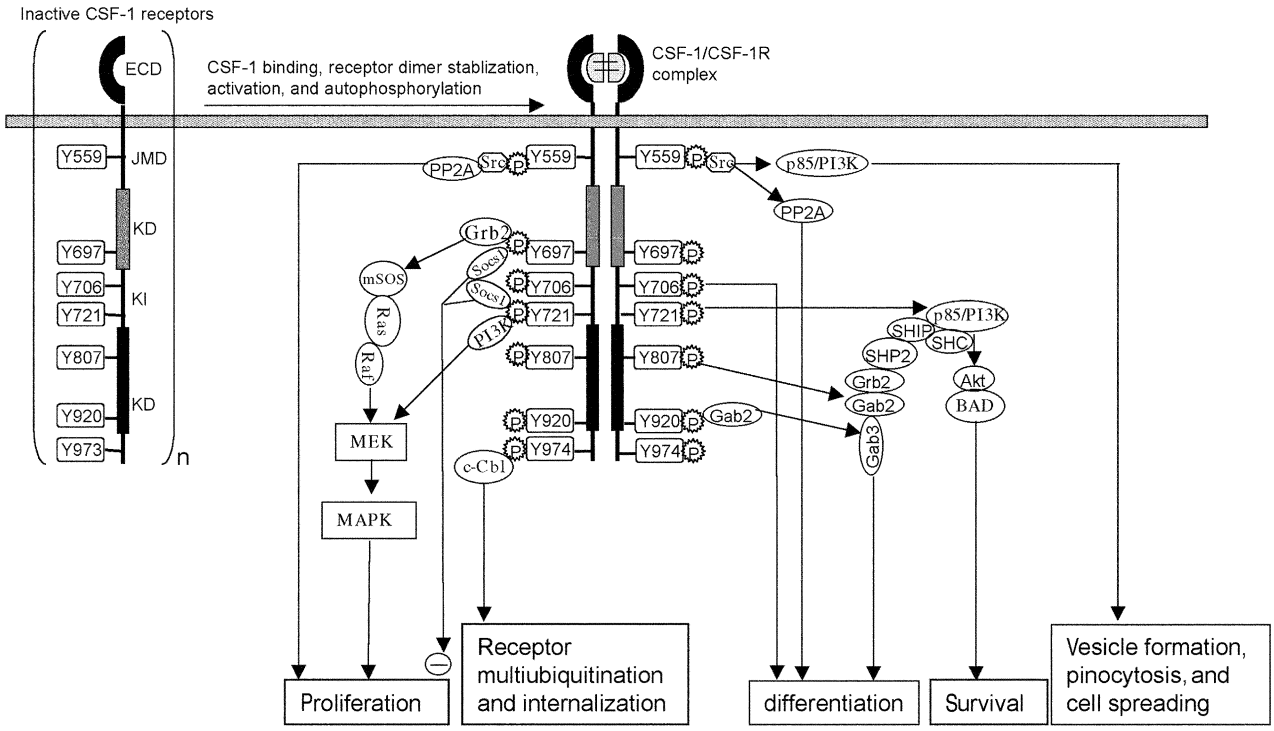

FIGURE 2 CSF-1/CSF-1 receptor signaling pathways and cellular responses to CSF-1. The CSF-1 homodimer binds to the extracellular domain (ECD) of the CSF-1R to form a CSF-1/CSF-1R complex, leading to activation of the kinase domain (KD) and phosphorylation of the receptor in specific tyrosine residues. These phosphorylated tyrosine residues create binding sites for Src homology region 2 (SH2) domain and protein tyrosine-binding domain-containing signaling molecules that may also become tyrosine phosphorylated and that regulate cell proliferation, differentiation, survival, and spreading, as well as the CSF-1R multiubiquitination, internalization, and lysosomal degradation. JMD, Juxtamembrane domain; KI, kinase insert domain.

D1 and D2 genes in the macrophage proliferative response, and CSF-1-induced protein phosphatase 2A gene expression is similarly required for cell cycle progression. CSF-1 induces myeloid lineage differentiation by activating differentiated cell-specific gene expression [e.g., the urokinase plasminogen activator (uPA) gene] through the action of transcription factors such as PU.1 and Ets/activator protein 1(AP-1) elements. During the course of differentiation, CSF-1R gene expression is also up-regulated by these transcription factors.

IV. CSF-1 BIOLOGY

Circulating CSF-1 is believed to be synthesized by endothelial cells lining the small blood vessels. Of the circulating CSF-1 (half-life 10 min), 94% is cleared by CSF-1R-mediated endocytosis and by intracellular degradation by liver Kupffer cells and splenic macrophages, only 5% being filtered through the kidney. This clearance mechanism represents a coarse negative feedback control on macrophage production, whereby the number of sinusoidally located end cells determines the steady-state concentration of circulating growth factor. In addition, many different cell types synthesize CSF-1 locally, including osteoblasts and epithelial cells of the female reproductive tract. By virtue of local synthesis of the long-lived cell surface CSF-1 and of localized sequestration of the secreted proteoglycan CSF-1, both of these forms may participate in short-range regulation of target cells.

The phenotypes of mice homozygous for the inactivating mutation in the CSF-1 gene, *osteopetrotic* (*op*, $Csf1^{op}$), and the phenotypes of gene targeted $Csf1r^{-}/Csf1r^{-}$ mice are similar (Table 2). These mice are osteopetrotic and toothless due to a deficiency in osteoclasts. Mouse $Csf1^{op}/Csf1^{op}$ phenotypes were all readily corrected by transgenic expression of full-length CSF-1. Though many of the overt phenotypes of these mice are significantly corrected by restoration of circulating CSF-1, failure to rescue several phenotypes by daily injection with human recombinant CSF-1 (Table 3) indicates that CSF-1 also acts

TABLE 2 Shared Phenotypes of *Csf1 ^{op}/Csf1 ^{op}* and *Csf1r $^{-}$/Csf1r $^{-}$* Mice

Toothlessness	Female reproductive defects
Reduced weight	Extended estrus cycle
Reduced postnatal viability[a]	Reduced pregnancy rate
Osteopetrosis[a]	Reduced post-implantation survival
Osteoclast deficiency[a]	Abnormal mammary gland development[b]
Reduced bone marrow cellularity	Failure of lactating mammary gland development
Reduced numbers of tissue macrophages[a]	Male reproductive defects
Reduced dermal thickness	Reduced testosterone production
Reduced auditory and visual processing	Reduced mating capability
Spontaneous emphysema[b]	Reduced numbers of viable sperm

[a]Phenotype more severe in *Csf1r $^{-}$/Csf1r $^{-}$* than in *Csf1 ^{op}/Csf1 ^{op}*.
[b]Phenotype not studied in *Csf1r $^{-}$/Csf1r $^{-}$* mice.

locally. Studies in *Csf1^{op}/Csf1^{op}* mice have established the central role of CSF-1 in the regulation of osteoclast progenitor cell differentiation, tissue macrophage production, and various biological functions. *Csf1r^{-}/Csf1r^{-}* mice have some more severe phenotypes than do *Csf1^{op}/Csf1^{op}* mice (Table 2). These data indicate that all CSF-1 functions are mediated by CSF-1 receptor and there are some CSF-1-independent effects of the CSF-1R.

Initially CSF-1 alone was shown to stimulate cultured murine bone marrow progenitor cells to form colonies of macrophages. Subsequent studies conclusively proved the central role of CSF-1 in the supporting mononuclear phagocyte proliferation, differentiation, and survival. CSF-1 also synergizes with cytokines (stem cell factor, IL-1, IL-3, and IL-6) that act on multipotent cells to stimulate the differentiation of multipotent hematopoietic cells into cells

committed to the mononuclear phagocytic lineage. With osteoprotegerin ligand, CSF-1 is required for *in vitro* generation of osteoclasts from their monocytic precursors. CSF-1 also appears to play a role in regulating osteoclast function by increasing survival, cell size, and multinucleation and by stimulating motility and spreading. Recently, CSF-1 was identified as a growth factor for mouse primary stromal initiating cells, which are defined by their ability to support the proliferation of B and myeloid lineage cell lines and which are not hematopoietic. This suggests that CSF-1, together with other necessary cytokines, could participate in the establishment of a functional hematopoietic microenvironment.

Local CSF-1 expression in the mouse female reproductive tract coincides with CSF-1R expression. CSF-1 regulates the estrus cycle, pregnancy rate, postimplantation embryonic viability, and branching morphogenesis of the developing and lactating mammary gland. Although CSF-1 is not absolutely required at any stage during pregnancy, it affects many stages and, if assessed by their ability to produce viable offspring beyond weaning, *op/op* females are almost completely infertile. CSF-1 regulates the development of testicular macrophages that normally contact the testosterone-producing Leydig cells. Associated with an absence of these testicular macrophages, male $Csf1^{op}/Csf1^{op}$ mice have a low libido, abnormal Leydig cell morphology, and reduced testosterone levels. Recently, CSF-1 and its major target cells in the central nervous system, microglia, have been shown to play a role in establishing the feedback sensitivity to circulating steroid hormones in the hypothalamus. This may partly explain the reproductive defects in $Csf1^{op}/Csf1^{op}$ mice.

The CSF-1R is predominantly expressed in mononuclear phagocytes and their progenitors and cells of the female reproductive tract. Thus, the pleiotropic nature of the $Csf1^{op}/Csf1^{op}$ phenotype suggests that one group of broadly distributed target cells, the macrophages, plays important regulatory roles in tissues (Fig. 3). Tissue macrophages that require CSF-1 for their development are found primarily in tissues undergoing rapid morphogenesis or tissue remodeling. A current hypothesis to explain the broad biological effects of CSF-1 is that CSF-1

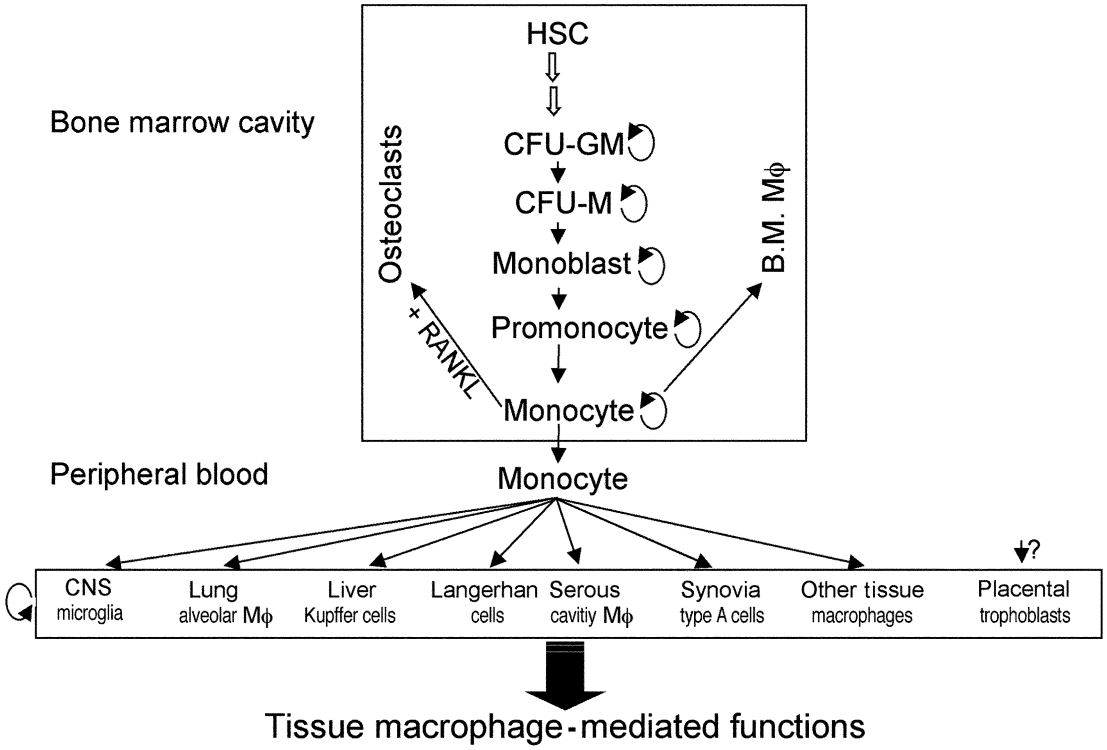

FIGURE 3 Regulation of mononuclear phagocyte production by CSF-1. CSF-1 is the primary regulator of mononuclear phagocytes. In combination with other hematopoietic growth factors, CSF-1 supports multipotent progenitor differentiation to CSF-1-dependent bone marrow colony-forming cells *in vitro*; in combination with RANKL, CSF-1 is able to support osteoclast differentiation both *in vivo* and *in vitro*. regulates the development of cells (macrophages and osteoclasts) that have important trophic and/or scavenger roles for the development and/or function of the tissue in which they reside (Fig. 4).

V. CSF-1 AND THE CSF-1R IN DISEASES

In normal adults, the reported average serum level of CSF-1 is about 4.46 ± 1.33 ng/ml and the range is from 1.7 to 8.4 ng/ml. Serum CSF-1 levels are significantly elevated during pregnancy. Compared with adults, CSF-1 levels are higher in the newborn infant. Increased circulating CSF-1 has been associated with many human diseases and local CSF-1 expression is also believed to be either pathological or protective in various states.

A. Neoplasms

Viral oncogenic forms of *fms* cause feline fibrosarcomas. The 5′ end of the CSF-1R is used approximately 20% of the time as an integration site for Friend murine leukemia virus-induced mouse myeloid leukemias. Autocrine regulation by CSF-1 is a characteristic of all irradiation-induced leukemias in SJL/J mice and of some *myc* retrovirus-induced mouse tumors. Transfection of ovarian cancer cells with CSF-1 cDNA enhances their tumorigenicity in nude mice, with the formation of invasive metastases. In polyoma middle T-antigen-induced mammary tumors in mice, CSF-1, via its action on tumor-associated macrophages, promotes mammary carcinoma progression and metastasis. In addition, mouse CSF-1 antisense treatment suppresses the growth of metastatic human tumor xenografts in mice.

Circulating levels of CSF-1 are elevated in patients with myeloid and lymphoid malignancies and carcinomas of the ovary, endometrium, breast, head, and neck and in prostatic cancer with bone metastasis. In the metastases of epithelial ovarian tumors, overexpression of the CSF-1 receptor in addition to epithelial cell-derived CSF-1 is associated with poor prognosis and decreased survival. High levels of CSF-1 in the ascites of these patients correlate with advanced presentation and poor outcome. Furthermore, tyrosine phosphorylated forms of the CSF-1R (pTyr-809 and pTyr-723) are detectable in a significant proportion of ovarian tumors. pTyr-809 is associated with enhanced local invasiveness and pTyr-723 is associated with enhanced metastatic potential. Their expression is correlated with a highly significant decrease in survival and increased risk of recurrence. The activated CSF-1R may be used as a predictor of poor outcome in advanced epithelial ovarian carcinoma. The more invasive human breast cancer cell lines express elevated CSF-1, CSF-1 receptor, and uPA. The CSF-1R is also expressed in prostatic carcinoma cells. Assignment of the GM-CSF, CSF-1, and CSF-1R genes to a specific region of human chromosome 5 provides evidence for linkage of a family of genes regulating hematopoiesis and for their involvement in the deletion (5q) in myeloid disorders. In some cases of human myeloid leukemias, the CSF-1 and CSF-1R genes are simultaneously and stably expressed.

These studies suggest that there is not only autocrine/paracrine growth control by CSF-1 in selected human neoplasias but also an indirect enhancing effect of CSF-1 stimulation of tumor-associated macrophages in tumor progression and metastasis.

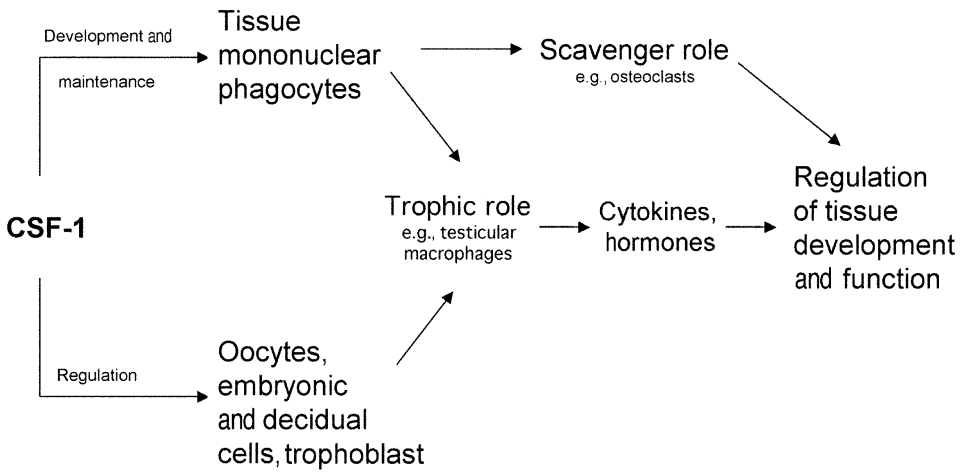

FIGURE 4 Regulation by CSF-1 of target cells that have trophic and/or scavenger roles in tissues. Reproduced from Stanley (1998), with permission.

B. Atherosclerosis

Monocyte-derived macrophage accumulation and their transformation into lipid-laden foam cells after taking up modified lipoproteins in the arterial intima represent the initial atherosclerotic cellular lesion. In low-density lipoprotein receptor-null or apolipoprotein E-null mice, the $Csf1^{op}$ mutation has protective effects on the development of atherosclerosis, despite the inhibitory effect of CSF-1 on cholesterol clearance. CSF-1 also enhances vascular plaque rupture by triggering apoptosis of vascular smooth muscle cells. A reduction of the CSF-1 expression is a potential mechanism underlying the reduction of neointimal proliferation by intracoronary brachytherapy. Increased CSF-1 levels are correlated with the increased aortic calcification index and the elevated atherosclerosis in the hemodialysis patient.

C. Glomerulonephritis

Glomerular and interstitial macrophage accumulation is one of the major inflammatory aspects of most types of human glomerulonephritis. The increase of both locally produced and circulating CSF-1 has been shown to be correlated with enhanced monocyte infiltration, the local proliferation of macrophages and their activation, and glomerular injury and proteinuria. In particular, the renal tubular epithelium is a major site of production of CSF-1 during experimental renal injury. The ectopic expression of CSF-1 in the kidneys of autoimmune MRL-Fas^{lpr} mice causes local tissue injury accompanied by extensive macrophage infiltration. A proinflammatory role of CSF-1 has been assumed. In addition, based on the experiments carried out with a drug-induced hypercholesterolemia rat model, a preventive role of CSF-1 on the progression of lipid-induced nephrotoxicity in diabetic nephropathy has been proposed.

D. Alzheimer's Disease

In Alzheimer's disease (AD), inflammation mediated by microglia plays an important role in neuron injury and cognitive decline. CSF-1 and its receptor are involved in the inflammatory process. There is increased expression of the CSF-1R and CSF-1 in both human AD brain and transgenic mouse AD models. Both *in vitro* and *in vivo* studies have proved the powerful proliferative and proinflammatory effects of CSF-1 on microglia. CSF-1 also augments β-amyloidal-induced interleukin-1, interleukin-6, and nitric oxide production by microglial cells.

E. Other Diseases

Elevated serum CSF-1 levels have been found in following chemotherapy treatment and in several other human pathological states, such as preeclampsia in pregnant patients, infection, hepatic injury, hemophagocytic syndrome, thalassemia, and ischemic heart disease, indicating a possible role of CSF-1 in these diseases. In addition, low maternal serum CSF-1 levels in the first trimester have been associated with unexplained recurrent abortion. Also, low levels of CSF-1, or lack of sufficient increase of serum CSF-1 after the first trimester, have been strongly associated with adverse pregnancy outcome, including low body weight or preterm delivery, severe gestational hypertension, and preeclampsia. In contrast, other studies have shown that placental and blood levels of CSF-1 are higher in preeclampsia than in normal pregnancies. The specific roles of CSF-1 in pregnancy need to be further defined.

F. Potential Therapeutic Applications

Preclinical studies have shown encouraging potential therapeutic applications of CSF-1, including its use in the treatment of infections and malignancies, to accelerate hematopoietic recovery following chemotherapy or bone marrow transplantation, to reduce the risk of atherosclerosis, and to improve fertility.

Administration of pharmacological doses of recombinant human CSF-1 in mice and nonhuman primates has been shown to result in (1) an increase of up to 10-fold in the circulating monocyte concentration, (2) an increase in macrophage numbers in certain areas of the periphery, (3) a stimulation of the cycling of bone marrow progenitors for granulocytes, macrophages, megakaryocytes, and erythrocytes, and (4) stimulation of natural killer (NK) cell activity and macrophage/monocyte antibody-dependent cellular cytotoxicity to protect against lethal *Escherichia coli* and *Candida* infections and to reduce tumor metastases and increase survival of mice bearing melanomas. CSF-1 administration to hyperlipidemic rabbits or cynomolgus monkeys rapidly lowers blood cholesterol levels by enhancing the clearance of lipoproteins containing apolipoprotein B-100 via both LDL receptor-dependent and -independent pathways. CSF-1 increases the uptake of acetylated LDL into macrophages by up-regulating scavenger receptors

and stimulates the efflux of free LDL from macrophages by up-regulating both the LDL receptor and cholesterol ester hydrolase. Exposure-based safety evaluations show that recombinant human CSF-1 is free of toxicity at all tested dosages, except for a transient decrease of platelet counts (thrombocytopenia). Thrombocytopenia is the major dose-related adverse effect of CSF-1 administration. It has been reported to happen to all the species studied. No effect of CSF-1 administration has been found on thrombocytopoiesis. The thrombocytopenia is thought to be due to the increased monocyte/macrophage activity causing shortened platelet survival.

The innate immune system consists largely of professional phagocytes of the granulocyte and monocyte lineages [polymorphonuclear leukocytes (PMLs), circulating monocytes, and tissue-based macrophages], which play a critical role in host recognition of, and responses to, bacterial, fungal, and parasitic pathogens. CSF-1 enhances the cytotoxicity, superoxide production, phagocytosis, chemotaxis, and secondary cytokine production by macrophages. It has been shown to augment the *in vitro* antifungal activity of monocytes/macrophages against both conidia and hyphae of *Aspergillus fumigatus*, partly via enhancement of oxidation-dependent mechanisms. Therapeutic effects of CSF-1 in combination with a systemic antifungal agent (amphotericin B; fluconazole) have been shown in both mouse and rat systemic fungal infection models. The effects of CSF-1 administration have also been reported to suppress the acute virus-induced myocarditis and the infiltration of glomerular macrophages in lipid-induced nephrotoxicity.

Clinical trials with CSF-1 have mainly been based on its specificity for mononuclear phagocytic cells. In the reported phase I and phase II trials, CSF-1 has been used in the adjunctive treatment of infectious complications during neutropenia, for example, the treatment of patients with invasive fungal infections after bone marrow transplantation.

Because elevated serum CSF-1 levels or local production are involved in some chronic pathological processes, the development of effective CSF-1/CSF-1R antagonists is another potential area of application. For example, *in vitro* experiments showed that CSF-1 increased the frequency of human immunodeficiency virus (HIV) infection in monocyte-derived macrophages, the amount of HIV mRNA expression per infected cell, and the level of proviral DNA expressed per infected cell. An autocrine/paracrine mechanism in sustaining HIV replication in macrophages was proposed. In addition, CSF-1 is involved in the undesired recruitment of macrophages to the site of transplanted kidney allografts and plays a pathogenic role in acute rejection. CSF-1 could be a potential target for immunosuppression in kidney transplantation patients. Potential therapeutic approaches could involve the use of anti-CSF-1R antibodies, CSF-1R extracellular domain or anti-sense RNA to CSF-1, and the CSF-1R. Indeed, as indicated earlier, blocking host synthesis of CSF-1 with anti-CSF-1 antisense in mice bearing metastatic human embryonic and colon carcinoma xenografts has been shown to block tumor progression and improve survival.

VI. SUMMARY

CSF-1 is the primary regulator of the differentiation, proliferation, and functioning of mononuclear phagocytic lineage cells, including monocytes, tissue macrophages such as skin Langerhans cells, liver Kupffer cells, bone osteoclasts and neuronal microglia. All CSF-1 function is mediated by a high-affinity receptor (CSF-1R) encoded by the c-*fms* protooncogene. Abnormal CSF-1/CSF-1R regulation is involved in a variety of disease states. CSF-1 is of potential diagnostic and therapeutic significance in disease management.

D.).

Glossary

colony-stimulating factors Group of four growth factors defined by their ability to stimulate hematopoietic progenitor cells to form colonies of mature progeny cells in semisolid culture media. CSF-1 supports formation of macrophage colonies, granulocyte CSF supports formation of granulocyte colonies, granulocyte/macrophage CSF supports formation of colonies of granulocytes and macrophages, and interleukin-3, also known as multilineage CSF, supports formation of colonies containing cells derived from multiple lineages.

mononuclear phagocytic lineage Term used to describe the lineage of the colony-stimulating factor-1-responsive hematopoietic precursor of macrophage → monoblast → promonocyte → monocyte → macrophage. Mononuclear phagocytes generally include tissue

macrophages, microglia, Kupffer cells, Langerhans cells, synovial type A cells, and osteoclasts. These cells are derived from common hematopoietic precursors and their differentiation is regulated by CSF-1.

osteopetrosis bone imbalance disorder characterized by accumulation of excessive bone mass resulting from a reduction in bone resorption relative to bone formation.

Corpus Luteum: Regression and Rescue

ANTHONY J. ZELEZNIK
University of Pittsburgh School of Medicine

luteal cell proliferation, survival, and steroid production. The steroidogenic cells of the corpus luteum cease to proliferate and this is associated with the decline in the expression of proliferating cell nuclear antigen (PCNA). Rescue of the corpus luteum by hCG is not associated with either the resumption of steroidogenic cell proliferation or the expression of PCNA. Likewise, hCG does not appear to dramatically increase mRNA levels for the enzymes involved in progesterone production. Rather, it seems that the rescue of the corpus luteum during early pregnancy is the result of the extremely high concentrations of hCG in blood that serve to maximally stimulate progesterone production by the aging corpus luteum until the placenta assumes the principal burden of progesterone production for the remainder of pregnancy.

Glossary

human chorionic gonadotropin A glycoprotein hormone similar to LH that is produced by the trophoblast cells of the early embryo and placenta.

luteinizing hormone A glycoprotein hormone produced by the anterior pituitary gland.

luteolysis The cessation of progesterone production at the end of a nonfertile menstrual cycle.

luteotropin Any substance that stimulates the function of the corpus luteum.

Corpus Luteum in Primates

RICHARD L. STOUFFER

Oregon National Primate Research Center, Oregon Health & Science University

The corpus luteum is the endocrine tissue in the ovary of mammals that differentiates from the mature follicle after ovulation has occurred. The corpus luteum plays two key roles during the reproductive life of primates, including women. First, with its limited functional tenure during the ovarian/menstrual cycle, reproductive potential and cyclicity are maintained. Second, with its timely rescue during the fertile cycle, early pregnancy is sustained until sufficient placental function is acquired.

I. INTRODUCTION

A key feature of ovarian function in mammalian species is the development of the corpus luteum from the ovulatory follicle and its subsequent role in producing hormonal factors, notably progesterone, that are essential for the initiation and maintenance of pregnancy. Considering the importance of this process, the species differences in the structure, function, lifespan, and regulation of the corpus luteum are remarkable. Important differences between the corpus luteum of typical laboratory animals, such as rats, mice, and rabbits, and that of domestic animals limit our understanding of the control of the primate corpus luteum but certainly provide a strong rationale for further studies.

Primates are among the species that have ovarian cycles with "long luteal phases," i.e., the corpus luteum differentiates after ovulation and functions for a sufficient period of time to permit movement of the early embryo through the oviduct, preparation of the

uterus for implantation, and embryo attachment plus trophoblast invasion into the endometrium. If the oocyte released after ovulation is not fertilized and/or implantation does not occur, the functional lifespan of the corpus luteum is limited to approximately 2 weeks, corresponding to the luteal phase of the menstrual cycle. Luteolysis near the end of the menstrual cycle typically occurs before the developing placenta can initiate local processes (e.g., progesterone production) to keep the uterus in a quiescent, supportive state throughout pregnancy. Thus, a critical interval in early pregnancy is when the conceptus signals to the mother (i.e., maternal recognition of pregnancy) that intrauterine pregnancy is occurring, the primate corpus luteum is "rescued" from impending regression, and luteal function is extended until essential activities are replaced by placental function (i.e., the luteal–placental shift).

The following sections address our current understanding, or lack thereof, of the processes controlling the development, function, and lifespan of the primate corpus luteum.

II. DEVELOPMENT OF THE CORPUS LUTEUM

Differentiation of the corpus luteum from the wall of the ovulatory follicle (Fig. 1) involves two pivotal events. One is the conversion of granulosa cells lining the inside of the wall into luteal cells (sometimes referred to as granulosa-luteal cells). In the preovulatory follicle, the granulosa cells are small and display limited steroidogenic activity, primarily converting androgen to estrogen by aromatization. During luteinization, the granulosa cells hypertrophy and acquire increased quantities of lipid droplets and cellular organelles (e.g., smooth endoplasmic reticulum and mitochondria with lamellar cristae) associated with steroidogenesis. The second event is the disruption of the basement membrane between the avascular granulosa and vascular theca cell compartments, followed by proliferation and migration of vascular elements into the luteinizing granulosa layer. Luteal angiogenesis is so extensive that approximately half of all cells comprising the corpus luteum are endothelial or perivascular cells in sinusoidal capillaries adjacent to steroidogenic luteal cells. The fate of follicular theca cells during development of the primate corpus luteum is controversial. Some follicular theca cells may degenerate or be absorbed into the surrounding stroma, but there is little evidence that they disperse into the luteal parenchyma as theca luteal cells, which is typical of many nonprimate species. Others remain as paraluteal cells (Fig. 1)

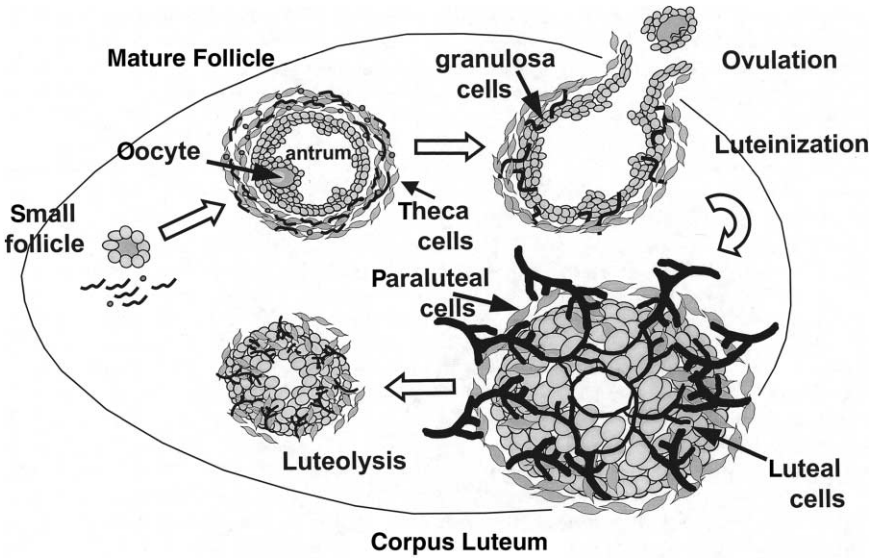

FIGURE 1 Tissue remodeling and angiogenesis associated with conversion of the ovulatory follicle into the corpus luteum in primates. In the mature follicle, vascularization (black blood vessels) is limited to the theca cell layers. A basement membrane separates the theca from the avascular granulosa cell layer, which encloses the oocyte and a fluid-filled antrum. Near the time of ovulation, the basement membrane breaks down and angiogenesis occurs in the granulosa layer. Granulosa-derived luteal cells hypertrophy but remain generally segregated from theca-derived paraluteal cells found around the outside of and along infoldings in the corpus luteum. At luteolysis, both the luteal cells and the microvasculature degenerate. Adapted from Hazzard and Stouffer (2000), with permission.

clustered along the periphery and within infoldings of the luteal gland. By day 6–7 after ovulation, the corpus luteum is well developed, with the antrum of the antecedent follicle replete with luteinized steroidogenic cells and the vascular elements connected to venules running from the center back through the luteal tissue to veins outside the gland.

It is generally accepted that the midcycle surge of gonadotropins, particularly luteinizing hormone (LH), secreted by the anterior pituitary is the stimulus for periovulatory events in the primate follicle. The duration of the LH surge in primates (~48 h) is considerably longer than that in nonprimates (e.g., 4–8 h in rodents and rabbits). Recent evidence suggests that surge requirements vary for periovulatory events, with resumption of oocyte maturation requiring less LH exposure than that for optimal luteal development. Why primate follicles appear to require such a prolonged LH surge, particularly for luteinization, remains unknown. It could be related to their predominant reliance on LH as a luteotropic hormone, whereas other species rely on other pituitary hormones (e.g., prolactin in rodents) or local factors (e.g., estrogen in rabbits) as primary luteotropins.

Both granulosa and theca cells of the preovulatory follicle contain LH receptors, and it is generally believed that the surge levels of LH act via receptor–adenylate cyclase-coupled, cyclic AMP (cAMP)-mediated intracellular pathways to modulate gene transcription and consequent changes in cellular levels of enzymes or proteins. Such events produce transient changes related to ovulation and luteinization or stable changes related to luteal cell phenotype. Recent studies using controlled ovarian cycles, where events can be examined at precise time intervals after exposure to an ovulatory gonadotropin bolus, are providing insight into the kinetics and array of changes occurring in the luteinizing follicle. For example, granulosa cell proliferation is inhibited early (within 12 h) during the gonadotropin surge, in association with suppressed expression of mRNAs for key promoters of cell cycle progression (e.g., cyclin B1) and increased expression of cell cycle inhibitors (e.g., the cyclin-dependent kinase inhibitors $P21^{Cip1}$ and $P27^{Kip1}$). The ability of luteinizing granulosa cells to bind low-density lipoprotein (LDL) and to convert LDL-derived cholesterol to progesterone increases markedly after the gonadotropin surge and is associated with increased expression and/or activity of LDL receptor, StAR, P450 side-chain cleavage enzyme (P450scc), and 3β-hydroxysteroid dehydrogenase (3β-HSD). A major action of the LH surge is to promote further differentiation of granulosa cells into the progesterone-producing luteal cells.

Another action of the midcycle gonadotropin surge is to modulate the production of paracrine or autocrine factors and follicular/luteal sensitivity to hormones or local factors. In primates, as well as nonprimates, the LH surge induces the expression of one isoform of cyclooxygenase (COX-2) with a resulting increase in prostaglandin (PG) levels in follicular fluid of ovulatory follicles. Since elevated PG levels occur in various species ~10 h before follicle rupture, there is speculation that this event controls the timing of ovulation in mammals. Whether COX-2 expression is important for luteinization is unclear. Another important action of the LH surge is to promote the production of angiogenic factors, such as vascular endothelial growth factor (VEGF; notably VEGF-A) and angiopoietin (Ang; particularly Ang-1), by luteinizing granulosa cells. Systemic or intrafollicular injection of VEGF-neutralizing agents into monkeys around the time of ovulation impairs angiogenesis/vascular function and progesterone secretion by the developing corpus luteum. The data are consistent with the concept that angiogenic factors produced by luteinizing granulosa cells, in direct response to LH, act in a paracrine manner to promote the development and maturation of new blood vessels in the corpus luteum. The LH surge also markedly alters the expression of steroid hormone receptors, and presumably local steroid action, in the primate follicle. Whereas estrogen receptors (ERβ) are suppressed, progesterone receptors (PRs) are induced in luteinizing granulosa cells concomitant with their increased ability to produce progesterone. Progesterone produced in the early response to the LH surge is essential for ovulation and luteinization to occur in primate follicles (Fig. 2). The cellular mechanisms of progesterone action are under investigation, but it is likely that this steroid promotes the expression/activity of specific proteases (e.g., matrix metalloproteinases, MMP-1) and their endogenous inhibitors (e.g., TIMP-1) to regulate the tissue remodeling that is critical for ovulation or luteinization. In addition, progesterone may act as an anti-atretic, pro-differentiative factor in the ovulatory follicle. The LH surge also modulates the production, sensitivity, or action of growth factors, such as the insulin-like growth factor-binding proteinsystem, in the developing corpus luteum.

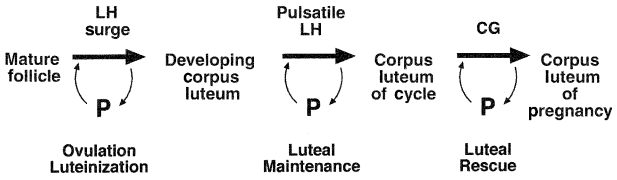

FIGURE 2 Schematic of the hypothesis that the luteotropic actions of LH during the menstrual cycle and CG in early pregnancy involve at least two mechanisms: (1) a direct action on luteinizing follicle and luteal cells and (2) an indirect action via stimulation of luteal progesterone (P) and P receptor expression. Thus, both endocrine (LH and CG) and local (P) factors are essential for the development and maintenance of the primate corpus luteum.

III. FUNCTION OF THE CORPUS LUTEUM

The primate corpus luteum synthesizes and secretes remarkable amounts of progesterone, the steroid hormone that is essential for the initiation and maintenance of pregnancy. Localization of P450-SCC and 3β-HSD protein and enzyme activity to granulosa luteal cells and paraluteal cells indicates that both can contribute this hormone, although the former is a much more numerous cell population. However, the primate corpus luteum produces at least three other substances that may have endocrine functions during the menstrual cycle or early pregnancy. Moreover, they appear to originate from specific luteal cell types.

Unlike in many nonprimate species, the luteal tissue of monkeys, apes, and humans produces significant amounts of estrogen. Immunohistochemical studies indicate that P450-C17, the enzyme catalyzing androgen synthesis, is confined to the theca layer of preovulatory follicles and the paraluteal cells in the corpus luteum. In contrast, P450-aromatase, the enzyme converting androgen to estrogen, is found in the granulosa layer of the follicle and luteal cells in the central parenchyma of the corpus luteum. These findings suggest that a two-cell model for estrogen synthesis, similar to that proposed for the follicle, is retained in the primate corpus luteum. Paraluteal cells may synthesize androgens that diffuse or are carried by the local microvessels to granulosa luteal cells where they serve as a precursor for estrogen production.

Compartmentalization of luteal cell activities is not limited to steroidogenesis; it involves two peptide or protein hormones, inhibin and relaxin. Whereas inhibin (primarily inhibin B) production typically ends following the LH surge in many species, the primate corpus luteum synthesizes and secretes significant amounts of inhibin A. Investigators report immunostaining for inhibin subunits primarily in granulosa luteal but not paraluteal cells; these cells likely produce other members of the inhibin receptor family, including the binding proteins follistatin and follistatin-related gene product, that neutralize inhibin/activin activity. Relaxin is also produced by the primate corpus luteum, with levels becoming detectable by the late luteal phase of the menstrual cycle, concomitant with relaxin immunostaining in granulosa luteal cells. Although their presence in the circulation has led to speculation regarding endocrine actions [e.g., inhibin control of pituitary follicle-stimulating hormone (FSH) secretion or relaxin stimulation of uterine growth or pituitary GH/prolactin secretion], such roles await verification. Nevertheless, it is likely that they locally modulate follicular or luteal function, e.g., inhibin suppression of FSH or LH actions in the ovary.

It is generally accepted that the low levels of LH circulating during the luteal phase of the menstrual cycle are required for normal function of the primate corpus luteum. The function and lifespan of the corpus luteum end abruptly at any stage of the luteal phase if LH support is compromised. To date, LH remains the only luteotropic hormone identified during the menstrual cycle. A possible regulatory role for prolactin, a luteotropic hormone in some species, remains unsubstantiated in primates despite considerable investigation. Participatory roles for other hormones, notably those regulating cell metabolism (e.g., GH or insulin), require further investigation.

Although pituitary LH appears to be the essential luteotropin, its precise actions in maintaining the structure and function of the primate corpus luteum are ill defined. Primate luteal tissue contains specific LH–chorionic gonadotropin (CG)-binding sites that belong to the G-protein-coupled family of membrane receptors that contain seven-transmembrane domains and activate primarily the adenylate cyclase system. cAMP generated by this signal transduction system acts as an intracellular "second messenger" to elicit LH's biologic effects. LH and cAMP stimulate the production of progesterone and estrogen by primate luteal cell preparations. However, the population(s) of luteal cells that are targets for LH action is controversial. Initial evidence from domestic animals suggested that the "small" luteal cells of putative theca origin respond acutely to LH with enhanced progesterone secretion, whereas "large" luteal cells of granulosa cell origin did not respond to LH while producing large amounts of progesterone. However, since small and large cells from corpora

lutea of the natural cycle contain equal numbers of LH-binding sites, a role for LH in large luteal cells of nonprimates, including rodents, cannot be ruled out. Investigations in nonhuman primates suggest that large—not small—cells respond to LH–CG and cAMP with enhanced progesterone production in a stage-dependent manner. Comparable studies on human luteal cells are difficult to interpret due to the need to use proteases for tissue dispersion. The data generally support the concept that large luteal cells produce greater amounts of progesterone than small luteal cells, but their origin (granulosa vs theca) and LH responsiveness may be species-dependent and vary during the luteal lifespan.

It is unclear how acute actions of LH to stimulate progesterone production relate to chronic actions to sustain the structure and function of the corpus luteum. It is likely that other substances produced by the corpus luteum act to modulate, and perhaps mediate, the actions of LH in controlling luteal development and function. Examples include lipid derivatives (prostaglandins and leukotrienes; see following section), peptides/proteins, and the steroid hormones themselves. The corpus luteum of certain species, notably, nonhuman primates and humans, express PRs throughout the luteal phase of the reproductive cycle and into early pregnancy. This contrasts with other species, such as rodents and rabbits, in which luteinizing granulosa cells express PR for only a short interval (12–72 h) around ovulation. Recent reports suggest that the local actions of progesterone include promotion of luteal cell differentiation while preventing cell degeneration (via apoptosis), perhaps by sustaining luteal sensitivity to, or production of, luteotropic factors (e.g., via LH receptor synthesis or enhanced ratio of luteotropic:luteolytic PG production) and preventing luteal sensitivity to, or production of, luteolytic factors (e.g., via inhibition of estrogen receptor expression or sequestration and action of immune cells). Since luteal PR expression is sustained in species in which LH is the primary luteotropin, it appears that the effects of LH–CG involve at least two mechanisms: (1) a direct, acute action on luteal cells to promote progesterone production and (2) an indirect, chronic action via the local effects of progesterone to promote luteal structure and function (Fig. 2).

IV. REGRESSION OF THE CORPUS LUTEUM

The factors responsible for the regression of the primate corpus luteum near the end of the menstrual cycle remain an enigma. In many nonprimate species, luteolysis is controlled by prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) secreted by the uterus near the end of the ovarian cycle; prevention or neutralization of this luteolytic signal, e.g., via hysterectomy (removal of the uterus), prolongs the luteal lifespan. However, in primates, the demise of the corpus luteum is not the result of a luteolytic signal from the uterus, since hysterectomy does not alter cyclic ovarian function in monkeys or women.

Research has focused on mechanisms involving three substances: one endocrine (LH) and two local (estrogen and $PGF_{2\alpha}$) factors. LH is secreted in a pulsatile manner by the pituitary, and since the frequency of LH pulses declines by the midluteal phase, investigators proposed that this apparent reduction in luteotropic support causes luteolysis. However, subsequent studies demonstrated that the length of the luteal lifespan was *not* altered if the frequency of LH pulses was not allowed to decline [by giving exogenous gonadotropin-releasing hormone (GnRH) pulses at frequent intervals] or if the frequency of LH pulses was prematurely reduced in the early luteal phase. While this hypothesis appears untrue, considerable evidence supports the concept that the corpus luteum becomes less sensitive to LH as its lifespan progresses during the menstrual cycle. The causes for the apparent reduction in luteal sensitivity to LH and its role in controlling luteal lifespan remain unclear.

The lack of a uterine or pituitary role in controlling luteal regression led investigators to propose "self-destruct" mechanisms whereby local factors synthesized in the ovary or corpus luteum initiate luteolysis near the end of the menstrual cycle. Based on the unique ability of primate luteal tissue to synthesize estrogen, plus reports that systemic or local delivery of estradiol into the monkey and human corpus luteum induces premature luteolysis, it was proposed that estrogen was the local luteolytic factor. However, subsequent studies led to the perception that exogenous estrogen did not directly induce luteolysis, but suppressed luteal function via its potent negative feedback inhibition of pituitary LH secretion. Unsuccessful efforts to detect appreciable levels of the classical genomic estrogen receptor, ER-α, further reduced enthusiasm for a local luteolytic action of estrogen. However, the recent discovery that the primate corpus luteum expresses the β isoform of ER, plus evidence from the monkey model that ER-β expression is highest at the time of luteal regression, indicates that the issue of local estrogen action in primate luteal tissue warrants reevaluation.

Because the primate corpus luteum synthesizes PGs, including the PG that is the luteolysin in nonprimates, a self-destruct scenario similar to that described for estrogen was envisioned for $PGF_{2\alpha}$. Early *in vivo* studies with exogenous $PGF_{2\alpha}$ or its analogues yielded variable results, in part due to rapid metabolism, stage-specific sensitivity of the corpus luteum, or high levels of endogenous PGs in luteal tissue. However, intraluteal administration of $PGF_{2\alpha}$ induces premature luteolysis in monkeys and women. Evidence for anti-gonadotropic effects of $PGF_{2\alpha}$ on primate luteal cells *in vitro*, plus the presence of PG receptors in luteal tissue, supports a direct action of $PGF_{2\alpha}$ in the corpus luteum of the menstrual cycle. Nevertheless, it has been difficult to substantiate a physiologic role for endogenous $PGF_{2\alpha}$ in the initiation of luteolysis. Administration of general inhibitors of PG synthesis (cyclooxygenase blockers) either orally or intraluteally to monkeys did not extend the luteal lifespan as one would expect if it prevented the synthesis and action of a luteolytic PG. In fact, intraluteal infusion caused premature luteolysis; these results support the *in vitro* evidence that other PGs of the E, I, and D series have stimulatory or steroidogenic actions in the corpus luteum. Thus, it is possible that the functional lifespan of the primate corpus luteum is influenced by a balance between luteotropic and luteolytic PGs, with PGE or PGI promoting luteal function and, as the tissue becomes responsive to PGF, the latter inhibiting luteal function. It is also possible that other arachidonate products, such as the leukotrienes or epoxide derivatives, influence luteal function.

Although the luteolytic signal(s) remains elusive, cellular and molecular approaches are providing new insight into the processes controlling luteal structure and function. The corpus luteum consists of dynamic populations of luteal and nonluteal cells whose numbers and characteristics change as the luteal lifespan progresses. It appears that there is a loss of large steroidogenic luteal cells as the primate corpus luteum ages. Since it was suggested that small luteal cells differentiate into large cells in response to LH, the decline could be related to a reduction in luteal differentiation or alternatively the onset of luteal degeneration. Likewise, there is a decline in small cell, and then large cell, responsiveness to PGE_2 and LH–CG as the monkey corpus luteum ages. Thus, the declining steroidogenic output is due, at least in part, to changes in cell populations and their responsiveness to luteotropic factors. Changes in luteal vasculature may also be critical during luteolysis (Fig. 1); the volume density of blood vessels declines during luteal regression in many species, including humans. Large portions of luteal capillary beds degenerate during luteolysis, although larger vessels are maintained perhaps to assist in resorption of the luteal mass. Although the mechanisms remain unclear, it is hypothesized that the balance between angiogenic factors that stabilize vessels (VEGF, angiopoietin-1) and those that destabilize vessels (angiopoietin-2) shifts in the corpus luteum at luteolysis. Finally, local actions of resident or migrating immune cells, including macrophages and T-lymphocyte subsets, may contribute to endothelial and luteal cell destruction during luteolysis via humoral or nonhumoral mechanisms. Whether molecular pathways such as the generation of highly toxic reactive oxygen species or initiation of apoptosis play key roles in luteolysis in primates, as proposed in other species, awaits further investigation.

V. RESCUE OF THE CORPUS LUTEUM

It is widely accepted that CG secreted by the implanting embryo and syncytiotrophoblast of the placenta is responsible for rescuing the primate corpus luteum from its impending demise at the end of the menstrual cycle and extending luteal function in early pregnancy (Fig. 3). Passive or active immunization of nonhuman primates and women against CG produces infertility despite normal ovulatory menstrual cycles. Moreover, administration of human chorionic gonadotropin (hCG) to mimic the patterns and levels of endogenous CG in early pregnancy elicits changes in the corpus luteum that are characteristic of maternal recognition of pregnancy: (1) the lifespan of the corpus luteum is extended and timely menstruation does not occur, (2) circulating levels of progesterone increase transiently and then decline as the time of the luteal-placental shift approaches, and (3) nonsteroidogenic activities, including relaxin and inhibin A production, also increase. Thus, CG in the absence of any other embryonic factors is capable of rescuing the corpus luteum of early pregnancy.

Although CG can be first detected, initially in utero-ovarian blood and then in the general circulation, around the time of implantation, the patterns and duration of CG and luteal progesterone secretion vary among primate species. In humans and apes, CG levels peak in the first trimester of pregnancy and then decline, but remain at substantial levels throughout gestation. However, in baboons and Old World monkeys, CG levels decline to undetectable levels by midpregnancy. In New World monkeys, CG levels

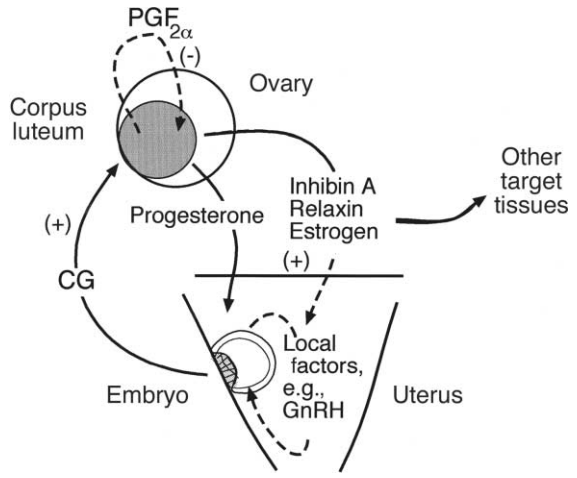

FIGURE 3 Endocrine and local mechanisms during rescue of the primate corpus luteum at pregnancy initiation. Solid arrows indicate established pathways, whereas dotted arrows indicate proposed pathways. Embryo-derived CG, likely produced in response to local GnRH or other factors, prevents the timely luteal regression at the end of the menstrual cycle. CG may prevent the action of local luteolytic factors, e.g., $PGF_{2\alpha}$. Thus, the corpus luteum continues to produce progesterone (and other putative hormones), which sustains intrauterine pregnancy until the luteal–placental shift. Reprinted from Stouffer and Hearn (1998), with permission.

do not peak until midpregnancy and decline just before parturition. In humans, apes, and Old World monkeys, CG increases serum progesterone levels above those observed during the menstrual cycle. In women, luteal progesterone production remains elevated for 2–3 weeks and the luteal-placental shift does not occur until the sixth week of pregnancy. In contrast, luteal progesterone production in Old World monkeys is enhanced for only a short interval (~4 days) before declining, despite continued increases in circulating CG. In these monkeys, the luteal-placental shift occurs by the third week of pregnancy. In New World monkeys, circulating progesterone levels at pregnancy initiation are simply maintained at concentrations observed during the ovarian cycle. The time of the luteal–placental shift is not well defined in these animals.

CG not only extends the progestational function of the corpus luteum, it promotes other activities even when progesterone production may be declining. These include the synthesis of the estrogens estradiol and estrone, which remain at elevated levels in monkeys even when progesterone levels begin to decline. They also include relaxin and inhibin A. That the corpus luteum is the primary source of inhibin in early pregnancy is confirmed by evidence from women lacking endogenous luteal function, in which circulating inhibin levels failed to rise through 4–6 weeks of pregnancy (maintained by exogenous progestin therapy) compared to normal gestation. Thus, early pregnancy can be considered the final interval of luteal differentiation in primates—a process that starts with the LH surge at ovulation and ends with CG secretion postimplantation. Although progesterone of luteal origin is essential for the maintenance of early pregnancy in primates, the roles of other luteal products, including estrogen, relaxin, and inhibin A, await clarification.

It remains unclear how production of another LH-like hormone, i.e., CG, rescues the primate corpus luteum of early pregnancy. CG is a glycoprotein hormone that is structurally similar to LH; the α-subunits are identical and there is remarkable similarity (up to 85% homology) in the first 114 amino acids of the LHβ- and CGβ-subunits. However, CG is unique due to the presence of a 24- to 31-amino-acid extension to the C-terminus of CGβ and different carbohydrate moieties attached to both subunits. These differences markedly increase CG's circulating half-life and, hence, bioactivity. Nevertheless, research in nonhuman primates and humans supports the concept that both pituitary LH and placental CG share a common receptor and activate similar cAMP-mediated pathways in gonadal cells. Indeed, the effects of administered CG so closely resemble those of pituitary LH that, because of its availability, hCG is used clinically in place of LH to promote a number of ovarian events, including ovulation and corpus luteum function. Very recently, Zeleznik reported that exogenous LH is capable of mimicking CG's action in early pregnancy. Continuous administration of increasing amounts of recombinant human LH or hCG beginning around the expected time of implantation increased progesterone levels and prevented timely luteolysis during the menstrual cycle in rhesus monkeys. These data, plus those from *in vitro* studies on primate ovarian cells, indicate that the actions of LH and CG are comparable; i.e., CG's ability to rescue the primate corpus luteum in the presence of circulating LH support is not due to a unique activity intrinsic to the CG molecule.

It is possible that CG provides an incremental increase in luteotropic support that prevents the luteolytic process. Because of differences in secretion patterns and circulating half-life between LH and CG, there are qualitative and quantitative differences in the gonadotropin milieu at pregnancy initiation. The intermittent pulses of LH secretion translate into

intervals of gonadotropin support and withdrawal during the mid- to late luteal phase that correspond positively with luteal steroidogenic activity. Since CG has a much longer half-life than LH and is produced in exponentially increasing amounts, CG circulates continuously and ultimately rises to levels that obscure any LH pulse. Thus, the conceptus offers uninterrupted (as opposed to episodic) and increasing levels of luteotropic support for the corpus luteum. Whether this change in luteotropic support prevents a luteolytic signal from occurring or bypasses the signal to prevent luteal regression is unknown.

For ethical and practical reasons, there has been little research on the cellular and molecular changes during CG rescue of the corpus luteum in early pregnancy. Models simulating early pregnancy via exogenous CG exposure provide some insight. Morphologic studies identified changes in granulosa luteal cells suggestive of the rapid use of steroid precursors and/or reduced storage of precursors (fewer lipid droplets) for steroid synthesis and increased production of secretory proteins (more membrane-bound granules). In contrast, paraluteal cells displayed changes suggestive of increased steroid precursor accumulation (more lipid droplets) and steroidogenesis (agranular endoplasmic reticulum). The increased luteal mass and steroidogenic activity are not, however, accompanied by a renewal of angiogenesis in the corpus luteum. The marked decline in endothelial cell proliferation that occurs around luteolysis is not prevented by CG. However, this does not rule out the possibility that CG has other effects on the vasculature, either directly or via vascular-specific factors, to influence vessel function or blood flow.

CG exposure results in divergent changes in luteal expression of mRNAs and proteins involved in steroid and peptide hormone production. CG may transiently stimulate progesterone production in the monkey corpus luteum by enhancing the uptake and availability of cholesterol stores (e.g., LDL) for existing steroidogenic machinery, not by stimulating key enzymatic steps (e.g., P450-scc or 3β-HSD). However, early time points (1–3 days of CG exposure) are needed to evaluate this issue. In contrast, CG markedly increases the expression and/or enzyme activity for androgen (P450-c17) and estrogen (P450-aromatase) production in the corpus luteum. With the discovery of two relaxin genes, H1 and H2, in human, it was noted that only the H2 gene is expressed by the corpus luteum, especially in pregnancy. Although transcriptional and/or posttranscriptional control of relaxin expression likely occurs in the corpus luteum, whether CG directly regulates these processes is unknown. There are no reports of acute stimulation of relaxin mRNA or protein production by CG in primate luteal tissue or cells *in vitro*.

Consideration of direct versus indirect effects of CG action must take into account the dynamics of LH–CG receptor–effector systems in primate luteal cells. Unlike in rodent systems where exposure to a large bolus of LH or CG results in the loss or "down-regulation" of gonadotropin receptors, the scenario in primate luteal tissue during exposure to high, rising levels of CG appears somewhat different. Although many of the LH–CG receptors appear occupied, there is a remarkable constancy in the total receptor population—the number of unoccupied sites declines and the number of occupied sites increases with the duration and level of CG exposure. Nevertheless, homologous desensitization of the adenylate cyclase system becomes apparent, as cAMP production in response to LH or CG, but not PGE, PGI, or forskolin, becomes severely impaired. It is possible that the uncoupling of LH–CG receptors from cAMP production is an important step in the transient progestational response of the corpus luteum to CG in early pregnancy. However, the continued response to paracrine factors, including luteotropic PGs or progesterone itself, may promote luteal structure and function. As such, it is noteworthy that a blockade of progesterone production causes structural regression of the corpus luteum despite continued exposure to rising levels of CG during simulated early pregnancy in rhesus monkeys.

VI. SUMMARY AND CLINICAL RELEVANCE

Although our knowledge of the function and control of the primate corpus luteum has increased significantly in the past decade, further studies are needed. A better understanding of the interactions between gonadotropins and local factors, between cell types, and between molecular pathways in luteal cells is required to elucidate the processes controlling the development, function, and lifespan of the corpus luteum during the menstrual cycle and early pregnancy (Fig. 4). Further progress is essential for evaluating and treating the pathophysiology leading to luteal dysfunction, including recognized disorders such as luteinized unruptured follicle syndrome, short or insufficient luteal phases, or the consequences of ovarian hyperstimulation syndrome occurring during the luteal phase and early pregnancy in assisted reproductive technology protocols. A better understanding of the endocrine, cellular, and molecular defects that lead to abnormal luteal function carries

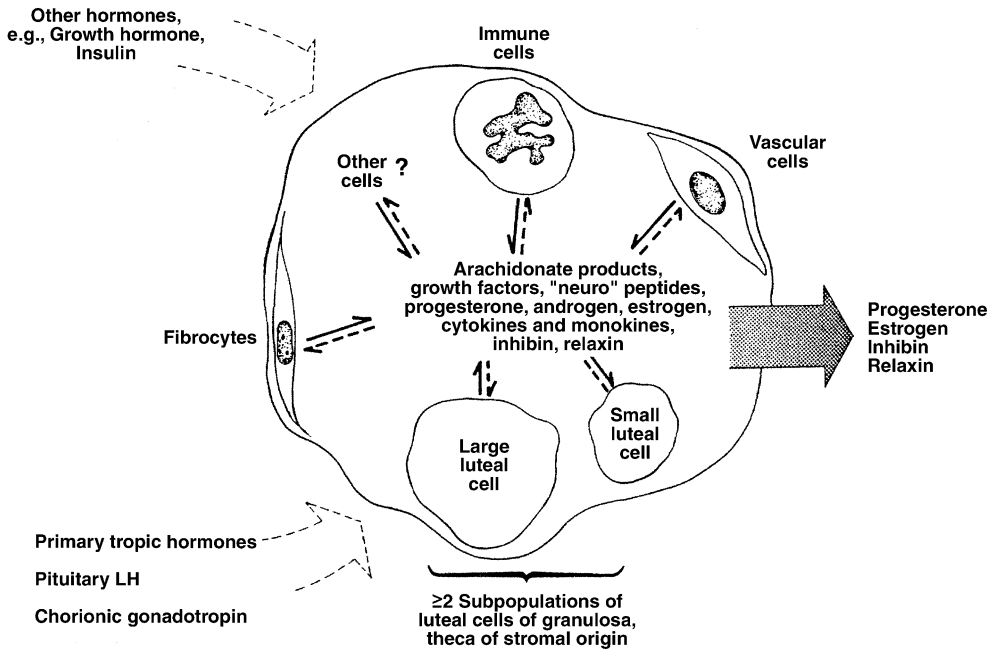

FIGURE 4 Conceptual summary of the multiple cell types in the primate corpus luteum and their many products that may serve as autocrine and paracrine regulators of luteal function or as classical hormones. Solid arrows denote secretion, whereas dotted arrows denote local action on target cells. Hormones from the pituitary, placenta, and other endocrine glands that act on the corpus luteum to regulate function or lifespan are also represented. Adapted from Stouffer (1996), with permission.

with it the hope of ameliorating or preventing the infertility, recurrent miscarriage, or serious side effects (e.g., fluid imbalance) inherent in these disorders. Likewise, the ephemeral nature of the corpus luteum offers unique opportunities for studying processes such as tissue differentiation and degeneration, angiogenesis, and inflammatory/immune response in the healthy adult, which can complement concepts arising from research during embryogenesis or pathologic states.

Glossary

corpus luteum The endocrine gland in the ovary of primarily mammals that differentiates from the mature follicle after the ovulatory surge of pituitary gonadotropic hormones.

luteal peptide/protein production The synthesis and secretion of nonsteroid hormones, notably inhibin A and relaxin, by the primate corpus luteum.

luteal–placental shift The transfer of critical hormonal functions from the corpus luteum to the placenta during gestation; thereafter, the corpus luteum is not essential for maintaining intrauterine pregnancy.

luteal steroidogenesis The synthesis and secretion of steroid hormones, notably progesterone and estrogens, by the primate corpus luteum.

luteinization The processes whereby the corpus luteum differentiates from the somatic cells of the follicle wall, including conversion of granulosa cells to luteal cells and neovascularization of the luteinizing granulosa layer.

luteolysis The processes whereby the corpus luteum regresses near the end of the nonfertile menstrual cycle or, presumably, after the luteal–placental shift in early pregnancy.

luteolytic factors Putative local substances, such as prostaglandin $F_{2\alpha}$, that cause regression of the corpus luteum.

luteotropic hormones Blood-borne factors, particularly luteinizing hormone from the pituitary gland and chorionic gonadotropin from the placenta, that promote the structure and function of the primate corpus luteum.

Corticotropin-Releasing Hormone (CRH)

DAVID T. BREAULT AND JOSEPH A. MAJZOUB
Harvard Medical School

Corticotropin-releasing hormone (CRH) is the major regulator of the hypothalamic-pituitary-adrenal axis and plays a role in the normal development of the adrenal, brain, and lung. In addition, CRH, and the family of CRH-related peptides, may have regulatory roles in a number of other systems, including the gastrointestinal system, the immune system, the autonomic nervous system, the reproductive system, and behavior.

I. INTRODUCTION

CRH derives its name from its role in the anterior pituitary, where it mediates the release of corticotropin (ACTH) leading to the release of adrenocortical steroids. In addition, CRH controls the secretion of β-endorphin and other proopiomelanocortin (POMC)-derived peptides from the anterior pituitary. CRH is the major hypothalamic activator of the hypothalamic–pituitary–adrenal (HPA) axis. In addition, CRH is an important mediator of the stress response, which integrates endocrine, autonomic, immunologic, and behavioral reflexes. Beyond its role as an endocrine hormone, increasing evidence suggests a role for CRH in the regulation of gastrointestinal and reproductive function.

Recently, a family of CRH-related peptides (CRH-RPs) has been identified. These factors likely play a role in integrating multiple aspects of the stress response. Both CRH and CRH-related peptides interact with two different transmembrane, G-protein-coupled cell surface receptors, CRH-R1 and CRH-R2, which differ in their patterns of tissue distribution. In addition, the binding affinities for CRH and the various CRH-RPs to the two receptors differ considerably and likely contribute to the different actions of these peptides.

II. ANATOMIC DISTRIBUTION

CRH has been localized to the nerve cell bodies in and near the dorsomedial parvicellular division of

macrophages, microglia, Kupffer cells, Langerhans cells, synovial type A cells, and osteoclasts. These cells are derived from common hematopoietic precursors and their differentiation is regulated by CSF-1.

osteopetrosis bone imbalance disorder characterized by accumulation of excessive bone mass resulting from a reduction in bone resorption relative to bone formation.

Corpus Luteum: Regression and Rescue

ANTHONY J. ZELEZNIK
University of Pittsburgh School of Medicine

In primate menstrual cycles, the luteal phase begins with the ovulation of the graafian follicle and the transformation of the ruptured follicle into a corpus luteum. In menstrual cycles in which pregnancy does not occur, the corpus luteum must regress in order for a new cycle to be initiated; however, if fertilization and implantation do occur, the lifespan of the corpus luteum must be extended until the placenta becomes the principal source of progesterone needed to sustain the pregnancy. The extant knowledge regarding the physiological and cellular mechanisms responsible for the regression of the corpus luteum at the end of nonfertile menstrual cycles and its rescue during early pregnancy is examined in this article.

I. OVERVIEW OF THE LUTEAL PHASE

The primate menstrual cycle consists of a follicular phase during which an ovarian follicle and its enclosed oocyte mature in preparation for ovulation and fertilization. The luteal phase commences upon the ovulation of the graafian follicle and the transformation of the ruptured follicle into a corpus luteum. The major steroid produced by the ovary during the follicular phase is estrogen, which is responsible for the proliferation of the uterine endometrium. The major steroid produced during the luteal phase is progesterone, which is responsible for the transformation of the proliferative endometrium into the secretory endometrium, a change that is absolutely required for the implantation of the fertilized oocyte and the successful initiation and maintenance of pregnancy.

In menstrual cycles in which pregnancy does not occur, the luteal phase lasts 14–16 days, following which the production of progesterone by the corpus luteum ceases and menstruation occurs. The regression of the corpus luteum at the termination of nonfertile menstrual cycles is essential for the initiation of a new cycle because the secretory products of the corpus luteum (estrogen, progesterone, and inhibin) act to suppress follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion, which, in turn, inhibits the development of a preovulatory follicle. By contrast, in menstrual cycles in which successful fertilization and implantation occur, the lifespan of the corpus luteum must be prolonged until the placenta assumes the major burden of producing progesterone and sustaining pregnancy. For successful reproduction and preservation of the species, the primate corpus luteum must have the ability to determine when to die and when to live beyond its typical lifespan.

Fig. 1 illustrates the patterns of LH secretion, luteal cell steroidogenic capacity, and serum progesterone levels during a typical luteal phase. Fig. 1A shows that LH secretion by the pituitary gland is pulsatile in nature, owing to the intermittent secretion of gonadotropin-releasing hormone (GnRH) by the hypothalamus. During the early luteal phase of the menstrual cycle, LH pulses occur at a frequency of approximately one pulse every hour. However, as the luteal phase continues, the frequency of LH pulses diminishes to one pulse every 4 to 8 h during the mid to late luteal phase. This decline in LH pulse frequency is the result of a direct action of progesterone on the hypothalamus to reduce the frequency of GnRH secretory episodes.

Fig. 1B summarizes the results of *in vitro* studies designed to investigate the secretory capacity of the corpus luteum. The secretion of progesterone on a per cell basis appears to be highest during the early luteal phase and progressively declines as the corpus luteum ages. Likewise, the expression of mRNAs for the major enzymes involved in progesterone production also appears to be highest in the newly formed corpus luteum and declines thereafter. As illustrated in

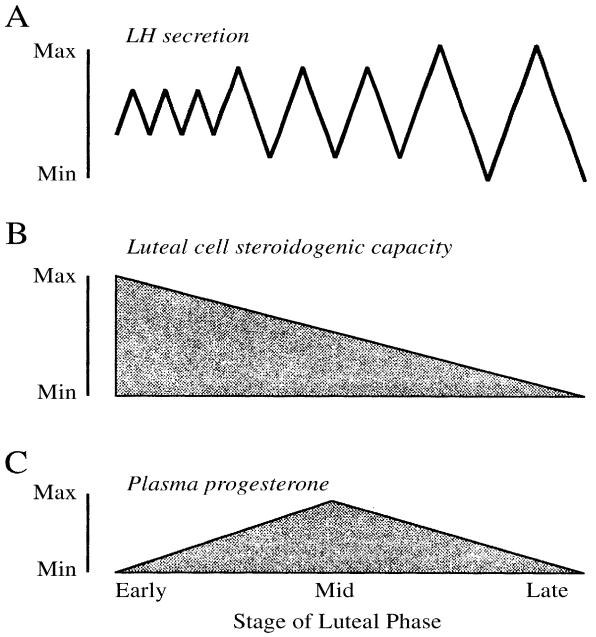

FIGURE 1 Pattern of LH secretion (A), luteal cell steroid production (B), and serum progesterone levels (C) throughout the luteal phase of the nonfertile menstrual cycle. Details are presented in the text.

Fig. 1C, the secretory activity of the corpus luteum, as reflected by serum progesterone levels, is low during the early luteal phase, rises and peaks during the midluteal phase, and declines thereafter. The discrepancy between the absolute steroidogenic capacity and serum progesterone levels during the early luteal phase is likely due to the fact that the vascular supply to luteal cells in the early luteal phase is not completely formed, hence the delivery of cholesterol via low-density lipoproteins to the luteal cells is limiting.

II. THE ROLE OF LH IN LUTEAL FUNCTION

During the final stages of follicular development, the granulosa cells of the maturing follicle acquire LH receptors on their cell surface and the expression of the LH receptor is carried over to luteal cells following ovulation. The presence of circulating LH is obligatory for the functioning of the corpus luteum. As depicted in Fig. 2, when macaque monkeys are treated with a GnRH antagonist (which blocks pituitary LH secretion), there is a rapid and sustained fall in serum progesterone production by the corpus luteum and premature menstruation ensues. These results as well as those of many other similar studies have convincingly demonstrated that LH is the major luteotropin of the primate menstrual cycle.

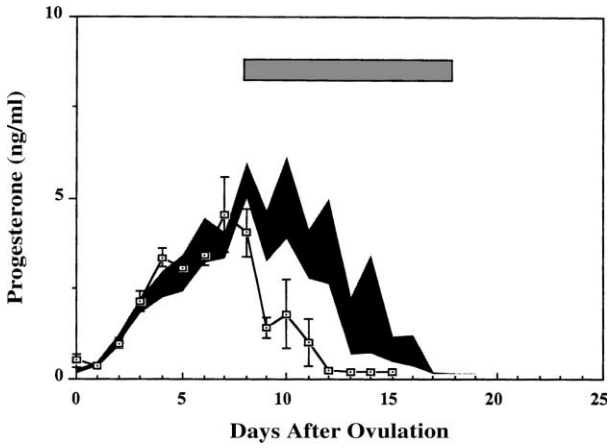

FIGURE 2 Effect of a GnRH antagonist on progesterone production by the corpus luteum. Macaque monkeys were treated with a GnRH antagonist during the midluteal phase of the menstrual cycle as shown by the shaded rectangle at the top of the graph. Serum progesterone concentrations declined to undetectable levels over a period of 3 days following the beginning of the antagonist treatment, and premature menstruation occurred.

III. LH SECRETION AND THE REGRESSION OF THE CORPUS LUTEUM

Because LH is absolutely required for the production of progesterone by the corpus luteum, it would be reasonable to think that the regression of the corpus luteum could be caused by the reduction in LH pulse frequency that occurs during the mid through late luteal phase of the menstrual cycle, as depicted in Fig. 1. However, this is not the case. Women who lack the ability to produce GnRH and monkeys whose endogenous GnRH secretion is terminated by lesions in the hypothalamus fail to undergo menstrual cycles due to the absence of FSH and LH secretion. However, menstrual cycles can be restored by the administration of exogenous GnRH at a frequency of one pulse per hour. In these subjects, the frequency of LH pulses during the luteal phase is maintained at one pulse per hour (i.e., there is no decline in LH pulse frequency during the late luteal phase), yet corpus luteum regression occurs at the expected time without any decline in LH pulse frequency. Similarly, a premature reduction in LH pulse frequency to one pulse every 8 h during the early luteal phase does not result in premature luteal regression.

IV. LUTEAL RESPONSIVENESS TO LH

Given the aforementioned finding that luteal regression during nonfertile menstrual cycles occurs in the presence of an apparently unchanging LH stimulus, the next likely explanation for luteal regression is that as the corpus luteum ages, it becomes increasingly unresponsive to the ambient circulating levels of LH. This possibility was tested by infusing LH into macaque monkeys whose endogenous LH secretion was blocked with a GnRH antagonist. As shown in Fig. 2, treatment with a GnRH antagonist results in premature luteal regression. As shown in Fig. 3, when exogenous LH was infused into GnRH antagonist-treated animals, the luteolytic effects of the GnRH antagonist were overcome. However, the functional lifespan of the corpus luteum was not prolonged beyond its normal length, despite the fact that circulating LH levels in these LH-infused animals were approximately 10 times greater than those normally encountered during the spontaneous luteal phase. The finding that the lifespan of the corpus luteum is not prolonged in the presence of markedly elevated LH levels provides strong evidence that the regression of the corpus luteum of nonfertile menstrual cycles is due to an age-related reduction in LH responsiveness of the aging

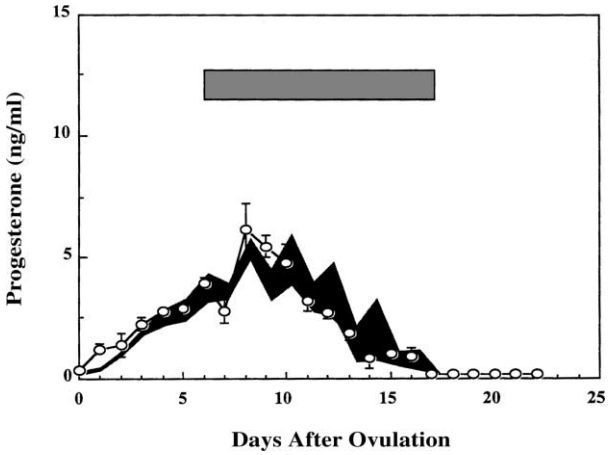

FIGURE 3 Effect of a continuous infusion of luteinizing hormone on the corpus luteum. Macaque monkeys were treated with a GnRH antagonist exactly as shown in Fig. 2. In addition, they received a continuous infusion of LH on the days indicated by the shaded rectangle at the top of the graph. The LH treatment overrode the luteolytic effect of the GnRH antagonist but did not prolong the functional lifespan of the corpus luteum.

corpus luteum such that it can no longer respond adequately to the ambient concentrations of LH in the blood.

V. RESCUE OF THE CORPUS LUTEUM DURING EARLY PREGNANCY

In menstrual cycles during which successful fertilization and implantation occur, the lifespan of the corpus luteum and its progesterone-secreting ability must be prolonged until the placenta becomes the principal source of progesterone. In humans, this amounts to a period of approximately 4 weeks beyond the normal lifespan of the corpus luteum. The lifespan of the corpus luteum is prolonged by the production of human chorionic gonadotropin (hCG) by the trophoblast cells of the embryo. hCG is a glycoprotein hormone that shares extensive structural homology with LH. Functionally, both hCG and LH bind to the same cell surface receptor and both stimulate cyclic AMP (cAMP) and progesterone production by luteal cells. The principal difference between LH and hCG is that during early pregnancy, circulating hCG concentrations are at least 100 times greater than those of LH. These high hCG concentrations are able to overcome the diminished responsiveness of the corpus luteum to LH and thereby extend the functional lifespan of the corpus luteum.

VI. CELLULAR MECHANISMS INVOLVED IN THE REGRESSION AND RESCUE OF THE PRIMATE CORPUS LUTEUM

The fact that the corpus luteum of the menstrual cycle has a highly reproducible 14- to 16-day lifespan among both humans and subhuman primates suggests that the timely regression of this tissue is internally programmed. Furthermore, programmed cell death (apoptosis) is well documented in the ovary as atresia of follicles manifests all the hallmarks of apoptosis. Despite the attractiveness of apoptosis as a cellular mechanism for luteal regression in primates, the extant data do not indicate widespread apoptosis, as reflected by histological evidence of DNA fragmentation of luteal cells during the process of luteal regression. Although some cells within the corpus luteum exhibit DNA fragmentation, they constitute only a small minority of the regressing tissue. Furthermore, although the anti-apoptotic protein BCL-2 is expressed in the corpus luteum, its level of expression does not seem to change markedly either during the regression of the corpus luteum or during its rescue by hCG.

An interesting possibility is that the microvascular vascular support of the corpus luteum may decline as the corpus luteum ages, which could contribute to the decline in function and subsequent death of the luteal parenchymal cells by depriving them of blood-borne nutrients and oxygen. Evidence continues to accumulate that vascular endothelial growth factor (VEGF) plays an important role in both the development of blood vessels that occurs during the formation of the corpus luteum and the stabilization of the luteal microvasculature thereafter. Moreover, VEGF production appears to decline during the late luteal phase, and treatment of women with hCG increases both VEGF and the endothelial cell mass of the corpus luteum. Thus, VEGF and its effects on the luteal vasculature could be involved in both luteal regression and luteal rescue.

In addition to changes in the luteal vasculature, it appears that during the process of luteinization (formation of the corpus luteum), luteal cells undergo terminal differentiation, which predestines them to regress. In addition, the process of luteinization is associated with loss of the cAMP-dependent nuclear transcription factor CREB (cAMP response element-binding protein), which controls the expression of some cAMP-regulated genes. Because the corpus luteum is absolutely dependent on LH (and its second messenger cAMP), the loss of CREB expression could remove a subset of luteal cell genes that participate in

luteal cell proliferation, survival, and steroid production. The steroidogenic cells of the corpus luteum cease to proliferate and this is associated with the decline in the expression of proliferating cell nuclear antigen (PCNA). Rescue of the corpus luteum by hCG is not associated with either the resumption of steroidogenic cell proliferation or the expression of PCNA. Likewise, hCG does not appear to dramatically increase mRNA levels for the enzymes involved in progesterone production. Rather, it seems that the rescue of the corpus luteum during early pregnancy is the result of the extremely high concentrations of hCG in blood that serve to maximally stimulate progesterone production by the aging corpus luteum until the placenta assumes the principal burden of progesterone production for the remainder of pregnancy.

Glossary

human chorionic gonadotropin A glycoprotein hormone similar to LH that is produced by the trophoblast cells of the early embryo and placenta.

luteinizing hormone A glycoprotein hormone produced by the anterior pituitary gland.

luteolysis The cessation of progesterone production at the end of a nonfertile menstrual cycle.

luteotropin Any substance that stimulates the function of the corpus luteum.

Corpus Luteum in Primates

RICHARD L. STOUFFER

Oregon National Primate Research Center, Oregon Health & Science University

The corpus luteum is the endocrine tissue in the ovary of mammals that differentiates from the mature follicle after ovulation has occurred. The corpus luteum plays two key roles during the reproductive life of primates, including women. First, with its limited functional tenure during the ovarian/menstrual cycle, reproductive potential and cyclicity are maintained. Second, with its timely rescue during the fertile cycle, early pregnancy is sustained until sufficient placental function is acquired.

I. INTRODUCTION

A key feature of ovarian function in mammalian species is the development of the corpus luteum from the ovulatory follicle and its subsequent role in producing hormonal factors, notably progesterone, that are essential for the initiation and maintenance of pregnancy. Considering the importance of this process, the species differences in the structure, function, lifespan, and regulation of the corpus luteum are remarkable. Important differences between the corpus luteum of typical laboratory animals, such as rats, mice, and rabbits, and that of domestic animals limit our understanding of the control of the primate corpus luteum but certainly provide a strong rationale for further studies.

Primates are among the species that have ovarian cycles with "long luteal phases," i.e., the corpus luteum differentiates after ovulation and functions for a sufficient period of time to permit movement of the early embryo through the oviduct, preparation of the

Corticotropin-Releasing Hormone (CRH)

DAVID T. BREAULT AND JOSEPH A. MAJZOUB
Harvard Medical School

Corticotropin-releasing hormone (CRH) is the major regulator of the hypothalamic-pituitary-adrenal axis and plays a role in the normal development of the adrenal, brain, and lung. In addition, CRH, and the family of CRH-related peptides, may have regulatory roles in a number of other systems, including the gastrointestinal system, the immune system, the autonomic nervous system, the reproductive system, and behavior.

I. INTRODUCTION

CRH derives its name from its role in the anterior pituitary, where it mediates the release of corticotropin (ACTH) leading to the release of adrenocortical steroids. In addition, CRH controls the secretion of β-endorphin and other proopiomelanocortin (POMC)-derived peptides from the anterior pituitary. CRH is the major hypothalamic activator of the hypothalamic–pituitary–adrenal (HPA) axis. In addition, CRH is an important mediator of the stress response, which integrates endocrine, autonomic, immunologic, and behavioral reflexes. Beyond its role as an endocrine hormone, increasing evidence suggests a role for CRH in the regulation of gastrointestinal and reproductive function.

Recently, a family of CRH-related peptides (CRH-RPs) has been identified. These factors likely play a role in integrating multiple aspects of the stress response. Both CRH and CRH-related peptides interact with two different transmembrane, G-protein-coupled cell surface receptors, CRH-R1 and CRH-R2, which differ in their patterns of tissue distribution. In addition, the binding affinities for CRH and the various CRH-RPs to the two receptors differ considerably and likely contribute to the different actions of these peptides.

II. ANATOMIC DISTRIBUTION

CRH has been localized to the nerve cell bodies in and near the dorsomedial parvicellular division of

the paraventricular nucleus (PVN) of the hypothalamus. These neurons send a rich fiber plexus to the median eminence and other hypothalamic and midbrain targets. These neurons are largely controlled by serotoninergic input from the amygdala and hippocampus of the limbic system and brainstem regions involved in autonomic functions. CRH expression has also been localized in many other parts of the central nervous system including the cerebral cortex, limbic system, cerebellum, brainstem, and spinal cord. It is also present in the adrenal medulla and sympathetic ganglia of the autonomic nervous system (Fig. 1).

III. GENE AND PROTEIN STRUCTURE

The CRH gene is composed of two exons and an 800 bp intron and is highly conserved among species. The entire protein-coding region is contained in the second exon. Human CRH is processed from a prepro-CRH molecule 196 amino acids in length, which contains a hydrophobic signal sequence, required for secretion, at its amino-terminal end. The middle of the molecule contains 124 amino acids of unknown function. The carboxyl-terminal end of prepro-CRH contains the 41-amino-acid sequence of the mature peptide hormone, separated from the amino-terminus by a protease-sensitive basic residue. Amidation of the carboxyl-terminus of CRH is required for biological activity. Human CRH, rat CRH, and mouse CRH have amino acid sequence identity, and ovine CRH differs by only 7 amino acid residues.

The promoter region of the CRH gene contains several putative *cis*-regulatory elements including a cyclic AMP (cAMP)-response element (CRE), activator protein-1 sequences, and glucocorticoid-response elements. The intron contains a restrictive element-1 sequence that binds restrictive element silencing transcription factor and that functions to restrict CRH expression to neuronal cells (Fig. 2).

IV. REGULATION OF EXPRESSION

The stimulation and inhibition of CRH expression by cAMP-dependent protein kinase A and glucocorticoids, respectively, are mediated by changes in CRH gene transcription. Stimulation occurs following the cAMP-induced phosphorylation of cAMP regulatory element-binding (CREB) protein, which binds to the CRE located in the CRH promoter and recruits the transcriptional activator, CREB-binding protein to the transcriptional apparatus. Experimental evidence suggests that glucocorticoid-mediated repression of CRH transcription results from a direct interaction between the activated cAMP-dependent transcription factor CREB and the activated glucocorticoid receptor. Transcription factor-mediated changes in chromatin structure, likely working through tissue-specific regulatory elements in the CRH gene, contribute to tissue-specific regulation. The brain serves as an example of tissue-specific glucocorticoid responsiveness. Glucocorticoids have a negative

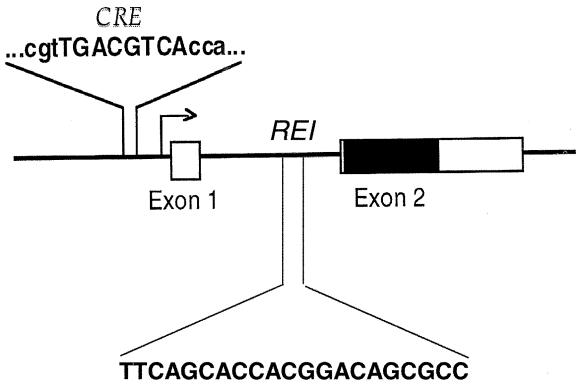

FIGURE 2 Structure of the CRH gene. Depicted are the two exons (rectangles) with the single intervening intron. The intron contains a restrictive element-1 (RE1) sequence at its 3′-end. The promoter contains a canonical cAMP-response element (CRE). The bent arrow depicts the transcription initiation site. The black area within exon 2 denotes the portion of the gene that encodes prepro-CRH.

regulatory effect on CRH gene transcription in the PVN where negative feedback regulation on the HPA axis occurs. However, in the amygdala, a brain region involved in the behavioral stress response, glucocorticoids increase CRH expression.

V. REGULATION OF CRH SECRETION

A number of neurotransmitters have been implicated in both the positive and the negative regulation of CRH release. Acetylcholine, norephinephrine, histamine, and serotonin increase hypothalamic CRH release, and γ-aminobutyric acid inhibits it. Additional factors that have been implicated in the regulation of CRH release include angiotensin, vasopressin, neuropeptide Y, substance P, atrial natriuretic peptide, activin, melanin-concentrating hormone, β-endorphin, and possibly CRH itself. In addition, cytokines such as interleukin-1β (IL-1β), tumor necrosis factor, eicosanoids, and platelet-activating factor have all been shown to activate the HPA axis by increasing hypothalamic CRH expression (see below).

VI. RECEPTORS

CRH binds to sites in the anterior lobe of the human pituitary, which correlate with the distribution of corticotrophs. CRH receptors in the anterior pituitary gland are low-capacity, high-affinity receptors, with a K_d for CRH binding of approximately 1 nM. To date, two CRH receptor genes have been identified in humans and other mammals, with a third gene described in the catfish. Both receptors consist of seven-transmembrane regions and are coupled to adenylate cyclase via G_s. Both receptors have at least one additional isoform resulting from an alternate splicing event.

The tissue distribution of the type 1 and type 2 receptors varies considerably. CRH-R1 is expressed throughout the brain, being concentrated in anterior pituitary corticotrophs. The distribution of the CRH-R2 splice variants, in contrast, is quite distinct. CRH-R2 α is expressed exclusively in the brain, being more widely distributed than CRH-R1. CRH-R2 β is expressed primarily in the periphery, with the highest levels found in heart and skeletal muscle. The distinct localization of these receptor types suggests they may have functionally different roles.

CRH-R1 binds and is activated by both CRH and urocortin (see below). This receptor mediates the actions of CRH at the corticotroph as well as some aspects of the behavioral stress response, including fear and anxiety. CRH-R2 binds urocortin with over 20-fold higher affinity, compared with CRH (see below). Experimental evidence suggests that this receptor may be involved in blood pressure control, consistent with its anatomic localization.

Mice deficient in CRH-R1 and CRH-R2 have provided important clues to help define their functional roles, with CRH-R1 mediating and CRH-R2 attenuating behavioral stress responses. Studies employing specific agonists and antagonists further suggest that CRH-R2 likely mediates pro-anxiety as well as anxiolytic behaviors in a brain region-specific manner. CRH-R2 has been shown to reduce feeding behavior and decrease gastrointestinal motility.

VII. SIGNAL TRANSDUCTION

CRH, acting via the type 1 CRH receptor, stimulates adenylate cyclase activity, increasing cAMP levels in anterior pituitary corticotrophs. CRH stimulates ACTH release via the cAMP-protein kinase A pathway, which is responsible for both the increase in POMC transcription and peptide synthesis and the rise in intracellular calcium resulting in ACTH secretion. Forskolin, a direct stimulator of adenylate cyclase activity, and 8-bromo-cAMP, a cAMP analogue, both markedly stimulate ACTH release and increase CRH-stimulated ACTH release. CRH mediates its stimulation of POMC transcription via the POMC CRH-responsive element.

VIII. CRH-BINDING PROTEIN

The CRH-binding protein (CRH-BP) was first inferred from studies in pregnant humans in whom a high level of immunoreactive CRH was detected in peripheral blood. Levels as high as 10 ng/ml have been documented during pregnancy, which is 10 to 100 times higher than CRH levels in the hypophyseal portal system. The presence of CRH-BP is thought to block the effects of CRH in the pregnant mother, thus preventing or attenuating the activation of her HPA axis. The role of CRH-BP is not fully understood, though its intracellular distribution in corticotrophs and its association with neurons both synthesizing CRH and regulating its release suggest that it may serve to modulate the effects of CRH. In addition to humans, it is expressed in great apes, who also have high levels of CRH during pregnancy, and in the rat. In humans, it is synthesized in liver, placenta, and brain, but in rat, its expression is restricted to the brain.

IX. ROLE IN PHYSIOLOGY

The HPA axis has a role in mediating the actions of many physiologic systems. Major actions include the following: (1) influencing the fetal development of major organ systems, including lung, liver, and gut; (2) metabolic functions, including the maintenance of normal blood glucose levels during the fasting state via glycogenolysis and gluconeogenesis; (3) modulation of immune function; and (4) maintenance of cardiovascular tone. In response to all forms of stressful stimuli, the HPA axis is called upon to exert the "fight or flight" response, which is mediated through each of the above actions. For example, hypoglycemia stimulates a counterregulatory response involving the HPA axis, which results in gluconeogenesis and lipolysis. Additional examples include hypovolemia and hemorrhage, both of which result in direct stimulation of the HPA axis. In addition, CRH, acting both directly and via the HPA axis, has a role in regulating a number of neuroendocrine functions including (1) behavioral activity; (2) food intake; (3) reproduction; (4) growth regulation; and (5) autonomic functions (Fig. 3).

A. Endocrine System

CRH is the key factor in the HPA axis leading to the release of ACTH, which acts on the adrenal cortex to release glucocorticoids and other steroid hormones, including androgens and to a lesser extent aldosterone. CRH can also directly stimulate glucocorticoid release from the adrenal gland. Vasopressin, co-synthesized along with CRH in hypothalamic PVN neurons, acts in concert with CRH to stimulate ACTH secretion.

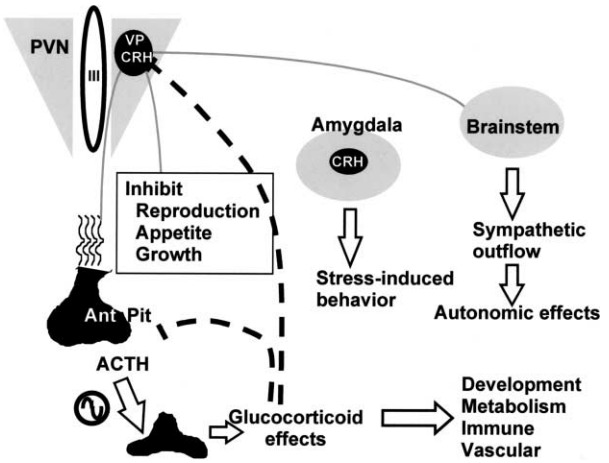

FIGURE 3 Actions of CRH and the HPA axis. CRH in the PVN, acting as a hormone, is released at the median eminence, and transported by the hypophyseal portal system to the anterior pituitary, where, in conjunction with vasopressin (VP), it stimulates the synthesis and secretion of ACTH in a circadian manner. ACTH enters the systemic circulation, where it acts in the adrenal to stimulate steroidogenic enzymes to synthesize cortisol. Cortisol has multiple actions, including those in development, metabolism, immune function, and vascular regulation. Hypothalamic CRH may also have direct actions in inhibiting reproduction, appetite, and growth. CRH (or other CRH-RPs) in the amygdala and brainstem may participate in the stress response by stimulating stress-related behaviors and activation of the autonomic nervous system, respectively.

As with other endocrine systems, this axis is organized and regulated through a series of negative feedback loops. The negative regulation of glucocorticoids on CRH and ACTH release represents long and short feedback loops, respectively. The ability of ACTH from the pituitary to inhibit CRH release is another example of a short feedback loop.

The circadian rhythm is generated in the suprachiasmatic nucleus. Signals are sent via efferent inputs to the PVN, which modulates CRH release. In response, ACTH is secreted in a pulsatile fashion, which gives rise to a corresponding rise in glucocorticoid levels. In humans, peak hormonal levels are seen in the early morning hours. In rodents and other nocturnal animals, the peak occurs in the evening. CRH is required for the presence of this rhythm, as CRH-deficient mice have a very low or absent rhythm in cortisol secretion. However, the

rhythm is restored by infusion of constant amounts of CRH into these animals, indicating that variation in CRH is not required for rhythm generation.

The precise role for the circadian rhythm has not been fully established. Some human data suggest that the rhythm in some way modulates the early morning rise in plasma glucose. It has also been postulated that the daily rise in CRH and ACTH helps prevent adrenocortical apoptotic cell death, which would result without the tropic input of ACTH. It is possible that this daily rise is sufficient to allow the adrenal cortex to maintain an adequate functional reserve, which may be required to respond to a stressful stimulus, while not allowing the excessive ACTH stimulation that would result in Cushing's syndrome (see below).

B. Gastrointestinal System

The stimulation of colonic motility is a common response to a variety of stressors. This gastrointestinal response to stress, as measured by defecation in rodent studies, can be mimicked by CRH infusion into either the brain or the periphery and is blocked by CRH-R1 antagonists (see below). Its administration induces bowel emptying by increasing colonic motility and it inhibits gastric acid secretion and gastric emptying. Indirectly, as part of the neuroendocrine stress response, CRH also inhibits feeding behavior even in food-deprived experimental animals. It is possible that one of the CRH-RPs, such as urocortin or urocortin III, rather than CRH, is the endogenous peptide that mediates these gastrointestinal actions.

C. Immune System

There is increasing evidence that the neuroendocrine system and the immune system work together in the regulation of both the stress response and the immune response. CRH is thought to have both direct and indirect effects on the immune system. Indirectly, CRH may down-regulate inflammation through the release of glucocorticoid, whereas a direct, pro-inflammatory action of CRH may occur in peripheral tissues. These direct actions are not fully understood but may include mast cell degranulation, nitric oxide-dependent vasodilation, enhanced vascular permeability, leukocyte proliferation, and cytokine release by activated leukocytes. Further support for a direct effect comes from experimental animal systems in which subcutaneous inflammation gives rise to immunoreactive CRH within leukocytes, monocytes, macrophages, fibroblasts, endothelial cells, epidermal cells, and synovial membrane-lining cells. These studies have been extended to show that CRH antiserum decreases the inflammatory response.

The integration of the neuroendocrine and immune responses to stress relies on the balancing effects of multiple factors. Several such factors, including CRH and IL-1, have been shown to manifest both stimulatory and inhibitory potential. IL-1, produced by stimulated macrophages and monocytes, serves as a potent pro-inflammatory compound. In contrast, IL-1 has also been shown to act centrally, by directly stimulating the HPA axis, to increase the secretion of CRH and ACTH, leading to increased levels of anti-inflammatory glucocorticoid. These dual actions of IL-1 and CRH to mediate both pro- and anti-inflammatory responses may illustrate a fundamental regulatory mechanism integrating the immune system with the HPA axis.

D. Autonomic Nervous System

As part of the fight or flight response to stress, CRH has direct effects on the autonomic nervous system. Experimental evidence suggests that CRH activates, via the locus ceruleus within the brainstem, the sympathetic nervous system. Central administration of CRH results in rapid increases in the plasma concentration of norepinephrine and epinephrine. These increases are followed by an increase of plasma glucose and glucagon and are associated with an increase in heart rate, respiratory activity, and oxygen consumption. In addition, CRH, via stimulation of ACTH and cortisol production, results in the conversion of norepinephrine to epinephrine in the adrenal medulla. This is likely mediated by the stimulation within the medulla of phenylethanolamine *N*-methyltransferase.

E. Behavioral Effects

As an important integrator of the stress response, CRH and CRH-RPs (see below) have been implicated as mediators of behavioral responses to stress. CRH and urocortin III are present within the amygdala, an area of the brain that mediates behaviors associated with fear and anxiety, such as decreased exploration and appetite. Consistent with this idea, CRH-R1-deficient mice exhibit decreased anxiety-related behaviors. However, CRH-deficient mice have normal behavioral stress responses that are blocked by a CRH-R1-specific antagonist, suggesting that another CRH-RP, acting through the CRH-R1 receptor, is anxiogenic. Linear growth is also decreased in response to chronic stress. Whether this is due to

the decrease in food intake observed with stress or to an independent mechanism, possibly involving CRH or a CRH-RP, is not known.

In humans, dysregulation of CRH may be involved in mental illnesses such as major depression, posttraumatic stress disorder, anorexia nervosa, and panic disorder. For this purpose, CRH-R1 receptor antagonists are currently being tested in clinical trials.

F. Reproductive System

There is considerable evidence that stress has a major negative effect on reproduction. As part of the neuroendocrine response to stress, CRH has been implicated as a major inhibitor of reproductive function in both sexes. Intense or prolonged stress, for example, has been shown to inhibit gonadotropin secretion. Additional central effects include attenuation of sexual behavior. However, CRH-deficient mice have normal stressor-induced inhibition of reproductive function, indicating that CRH is not absolutely required for this function.

Placental CRH production is found only among primates, being derived from the synciotrophoblasts. It is secreted into both the maternal and the fetal circulations (Fig. 4). During the second half of gestation, both humans and chimpanzees show an exponential rise in maternal CRH blood levels. The fetal concentration of CRH is approximately 1/10 that found in the maternal circulation. The role of placental CRH is not clear but it may function in the initiation of parturition and/or in the regulation of fetal development. Unlike hypothalamic CRH, which is inhibited by cortisol (as part of a negative feedback loop), rising levels of cortisol secreted by the fetal adrenal appear to stimulate placental CRH. Placental CRH, via the umbilical vein, enters the fetal circulation and may stimulate fetal ACTH release to cause a further increase in fetal cortisol release, thus completing a positive feedback loop. This may explain in part the marked, 10- to 100-fold rise in maternal CRH levels that occur in the last part of human pregnancy. The rise in fetal cortisol is also required for the proper maturation of lung, liver, bowel, and other tissues. The stimulation of fetal ACTH by placental CRH would also promote the synthesis and secretion of fetal dehydroepiandrostenedione sulfate, which is the obligate precursor for estradiol produced by the placenta. Estradiol is necessary for the production of placental oxytocin and prostaglandins, which are the major effectors of uterine contraction during labor and delivery. The concomitant stimulation of both fetal cortisol and dehydroepiandrosterone would thus couple the glucocorticoid effects on fetal organ maturation with the timing of parturition, of obvious benefit for postnatal survival.

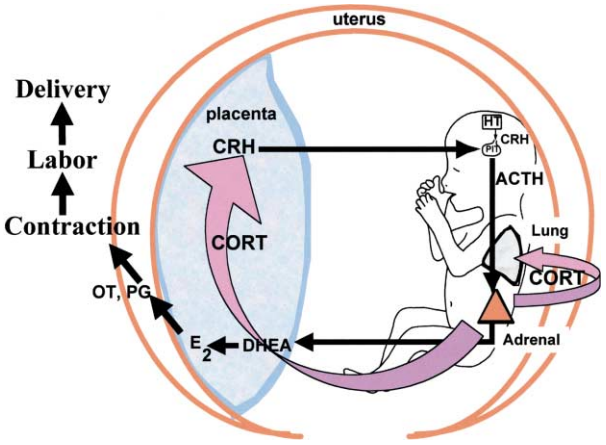

FIGURE 4 CRH and the placental-fetal unit. Placental CRH travels via the umbilical vein to the fetus, where it stimulates the pituitary to release ACTH. ACTH travels to the fetal adrenal, where it stimulates the production of cortisol (CORT) and dehydroepiadrosterone (DHEA) sulfate. Cortisol promotes the maturation of fetal lung and other organs and also feeds back, via the umbilical artery, to the placenta, where it stimulates a further rise in CRH. In the placenta, DHEA is converted to estradiol (E_2). Estradiol stimulates oxytocin (OT) and prostaglandin (PG) activity, leading to uterine contraction, labor, and delivery.

G. Fetal Development

The HPA axis is the first endocrine system to develop. In humans, the axis is active by the eighth week of gestation and is under negative feedback control by glucocorticoids at that time (as evidenced by fetuses with genetic enzymatic blockade of adrenal steroidogenesis). A number of developing organ systems, including the central nervous system, lung, and gut, appear to require the early presence of the HPA axis for normal development.

Hypothalamic CRH may not be responsible for the initial activation of the HPA axis, as corticotroph development occurs normally in the complete absence of CRH. It is intriguing that extrahypothalamic sources of CRH are present at time periods preceding hypothalamic CRH expression. For example, fetal lung in the mouse produces CRH immediately preceding the surge in fetal glucocorticoid levels. This rise in glucocorticoid levels is required for pulmonary differentiation and postnatal survival. It is unclear whether lung CRH plays a significant paracrine or endocrine role in this process.

X. PATHOPHYSIOLOGY

A. CRH Excess

Ectopic CRH secretion from a variety of different human tumors results in Cushing's syndrome due to the overproduction of ACTH and glucocorticoid. Clinical characteristics include central obesity, muscle wasting and weakness, facial plethora, glucose intolerance, thinning of skin with purple striae, osteopenia, easy bruising, excessive hair growth, and hypertension. In children, glucocorticoid excess also results in growth failure. CRH overproduction is probably not the cause of the most common form of Cushing's syndrome, termed Cushing's disease, which is due to a primary neoplasm of corticotroph cells in the anterior pituitary.

An experimental model of CRH excess in mice exhibits clinical features similar to those of Cushing' syndrome, including truncal obesity, hair loss, thin skin, and brittle bones, and in addition manifests altered leukoctye counts and increased anxiety-like behaviors.

B. CRH Deficiency

CRH deficiency, also referred to as secondary adrenal insufficiency, results in adrenal atrophy with impaired glucocorticoid production. A mouse model of complete CRH deficiency results in mice with small adrenal glands and a severely deficient hormonal response to stress. The adrenal insufficiency resulting from long-term glucocorticoid therapy may be due in part to continued suppression of hypothalamic CRH secretion as well as pituitary ACTH.

In general, the clinical features associated with glucocorticoid insufficiency are dependent on whether the CRH levels are low or high. When CRH levels are high, as in primary adrenal failure, characteristic findings include anorexia, weakness, excessive fatigue, weight loss, decreased fertility, and hyperpigmentation. Secondary adrenal insufficiency, as with isolated CRH deficiency, typically does not show these findings. This observation is further underscored by the phenotype of CRH-deficient mice; despite low basal glucocorticoid levels and an impaired stress response, these mice have normal longevity, fertility, food consumption, body composition, and activity level.

XI. CRH-RELATED PEPTIDES

Since its discovery in 1981, CRH has been postulated to mediate both the hormonal and the behavioral responses to stressful stimuli. Several lines of evidence have suggested that CRH is not the sole mediator of the stress response and have led to the identification of CRH-like molecules in rodents and humans (Fig. 5). Before the discovery of CRH, two previously discovered CRH-RPs, urotensin in the fish and sauvagine in the frog, hinted at the possibility of finding other CRH-RPs in mammals.

A. Urocortin

When CRH was initially identified, it was considered to be homologous to fish urotensin and amphibian sauvagine. The later identification of factors more closely related to CRH in these species prompted the search for the mammalian homologue to urotensin. These efforts led to the discovery of urocortin, a 122-amino-acid propeptide that undergoes a cleavage event to form the mature 40-amino-acid peptide.

FIGURE 5 CRH and related peptides. Alignment of the peptide sequences of mouse CRH (mCRH), mouse urocortin (mUCN), mouse urocortin II (mUCNII), mouse urocortin III (mUCNIII), human urocortin III (hUCNIII), pufferfish CRH-related peptide (pfCRH-RP), frog sauvagine (SVG), and fish urotensin (URO) is shown. Identity is indicated by a black background. Urocortins II and III are closely related to pufferfish CRH-related peptides, but are not closely related to CRH or urocortin.

Urocortin was first cloned in rat and shares 45% sequence identity with rat CRH. Rat urocortin and human urocortin are 95% identical within the mature peptide region.

Urocortin's primary site of expression is the Edinger-Westphal nucleus, although it is found at scattered sites throughout the brain, including the hypothalamus and pituitary. In addition, it is found in human placenta and fetal membranes. Like CRH, it binds to CRH-BP with high affinity, suggesting that its functions may be modulated by the binding protein. Urocortin binds to all CRH receptors with a higher affinity than does CRH and binds to CRH-R2 β receptor with 40-fold higher affinity. Urocortin serves as a potent ACTH secretagogue (although due to its restricted anatomic distribution it is unlikely to be an important regulator of ACTH release) and appears to mediate some stress-induced behaviors including increased anxiety and possibly anorexia. It may also be involved in sodium and water balance.

The identification of urocortin established that CRH was not the sole mediator of the stress response. It further raised the possibility that urocortin may mediate some of the behaviors previously attributed to CRH. The search for additional CRH-RPs that might be involved in regulating the stress response has led to the identification of two additional factors.

B. Urocortin II

Based on the above observations, the existence of additional CRH-like molecules was proposed and subsequently identified based on sequence homology to CRH, urocortin, and CRH-like factors identified in lower species. Searching the public DNA database, urocortin II (also termed stresscopin-related peptide) was recently identified based on its similarity to consensus amino acid sequences of known CRH-RPs. It encodes a 38-amino-acid peptide that is a selective CRH-R2 agonist with no affinity for CRH-R1. It is expressed in the hypothalamic magnocellular neurons of the paraventricular and supraoptic nuclei. Based on experimental data, it may be involved in appetite suppression, without a role in more generalized behavioral responses.

A search of the human DNA database (see below) led to the discovery of the human orthologue of urocortin II, stresscopin-related peptide. In addition to the functions described for urocortin II, the expression profile of stresscopin-related peptide was extended to include peripheral tissues such as the heart and gut.

C. Urocortin III

Using a two-part search strategy of the human DNA database, a third CRH-like peptide was identified and named stresscopin (also termed urocortin III). Human urocortin III encodes a 161-amino-acid prepropeptide with a mature peptide product of 40 amino acids. Receptor studies show selective CRH-R2 binding. Behavioral studies in mice demonstrate that urocortin III, as with urocortin II, results in suppression of appetite, decreased gastric emptying, and decreased heat-induced edema. Consistent with the lack of binding to CRH-R1, urocortin II and III have essentially no role in mediating ACTH release and elevation of glucocorticoid levels. A broad tissue survey demonstrates urocortin III expression in brain, gastrointestinal tract, adrenal, pancreas, thyroid, skeletal muscle, cardiac muscle, and spleen.

Corticotropin-Releasing Hormone Pharmacology

ROBERT F. QUINTOS, SARAH C. COSTE, AND MARY P. STENZEL-POORE

Oregon Health and Science University, Portland

Corticotropin-releasing hormone (CRH) produced in the hypothalamus is the primary activator of the hypothalamic–pituitary–adrenal axis and the central mediator of the neuroendocrine response to stress. CRH and a family of receptors and other peptides represent a central and peripheral nervous system regulatory network of components that act in concert to respond to stressors. Within this network, each regulatory component has a unique distribution and pharmacology.

I. INTRODUCTION

Harris first proposed in 1950 the theory that pituitary action on the adrenal cortex was regulated by the hypothalamus. He had demonstrated that electrical stimulation of the hypothalamus activated the adrenal cortex, and based on this finding hypothesized that on stimulation, the hypothalamus activated the pituitary via factors released into the hypophyseal circulation. Five years later, the presence of these hypothalamic factors was confirmed by demonstrating increased corticotropin secretion by the pituitary *in vitro*. Over the next several years, a number of purified hypothalamic extracts and natural substances, such as vasopressin, norepinephrine, and angiotensin II, were shown to release adrenocorticotropic hormone (ACTH), but none of these mediators demonstrated characteristics that were consistent with being the primary corticotropin-releasing factor. Corticotropin-releasing hormone (CRH) was isolated and sequenced 25 years later.

II. CRH STRUCTURE AND GENE EXPRESSION

In 1981, Vale and colleagues reported the isolation and amino acid sequence of ovine CRH (Fig. 1). In addition, they demonstrated the potency of CRH stimulation of ACTH release from anterior pituitary cells.

A. Localization

CRH is widely distributed throughout the brain and in peripheral body organs and tissues (Table 1). CRH-specific immunoreactivity reveals a wide distribution throughout the central nervous system, with high densities of CRH-positive neurons within the parvocellular region of the paraventricular nucleus, lateral hypothalamus, and locus coeruleus. Additionally, dense CRH fiber networks have been detected in the lateral septum, central nucleus of the amygdala, median eminence, stria terminalis, pituitary, and medial vestibular nucleus. This localization is consistent with the physiological role that CRH plays in regulating both the autonomic and the neuroendocrine response to stress. In the periphery, CRH mRNA is expressed in a wide variety of tissues as well, including the lung, heart, gut, kidney, adrenal gland, testis, ovary, pituitary, and spleen.

Corticotropin-Releasing Hormone Pharmacology

ROBERT F. QUINTOS, SARAH C. COSTE, AND MARY P. STENZEL-POORE

Oregon Health and Science University, Portland

Corticotropin-releasing hormone (CRH) produced in the hypothalamus is the primary activator of the hypothalamic–pituitary–adrenal axis and the central mediator of the neuroendocrine response to stress. CRH and a family of receptors and other peptides represent a central and peripheral nervous system regulatory network of components that act in concert to respond to stressors. Within this network, each regulatory component has a unique distribution and pharmacology.

I. INTRODUCTION

Harris first proposed in 1950 the theory that pituitary action on the adrenal cortex was regulated by the hypothalamus. He had demonstrated that electrical stimulation of the hypothalamus activated the adrenal cortex, and based on this finding hypothesized that on stimulation, the hypothalamus activated the pituitary via factors released into the hypophyseal circulation. Five years later, the presence of these hypothalamic factors was confirmed by demonstrating increased corticotropin secretion by the pituitary *in vitro*. Over the next several years, a number of purified hypothalamic extracts and natural substances, such as vasopressin, norepinephrine, and angiotensin II, were shown to release adrenocorticotropic hormone (ACTH), but none of these mediators demonstrated characteristics that were consistent with being the primary corticotropin-releasing factor. Corticotropin-releasing hormone (CRH) was isolated and sequenced 25 years later.

II. CRH STRUCTURE AND GENE EXPRESSION

In 1981, Vale and colleagues reported the isolation and amino acid sequence of ovine CRH (Fig. 1). In addition, they demonstrated the potency of CRH stimulation of ACTH release from anterior pituitary cells.

A. Localization

CRH is widely distributed throughout the brain and in peripheral body organs and tissues (Table 1). CRH-specific immunoreactivity reveals a wide distribution throughout the central nervous system, with high densities of CRH-positive neurons within the parvocellular region of the paraventricular nucleus, lateral hypothalamus, and locus coeruleus. Additionally, dense CRH fiber networks have been detected in the lateral septum, central nucleus of the amygdala, median eminence, stria terminalis, pituitary, and medial vestibular nucleus. This localization is consistent with the physiological role that CRH plays in regulating both the autonomic and the neuroendocrine response to stress. In the periphery, CRH mRNA is expressed in a wide variety of tissues as well, including the lung, heart, gut, kidney, adrenal gland, testis, ovary, pituitary, and spleen.

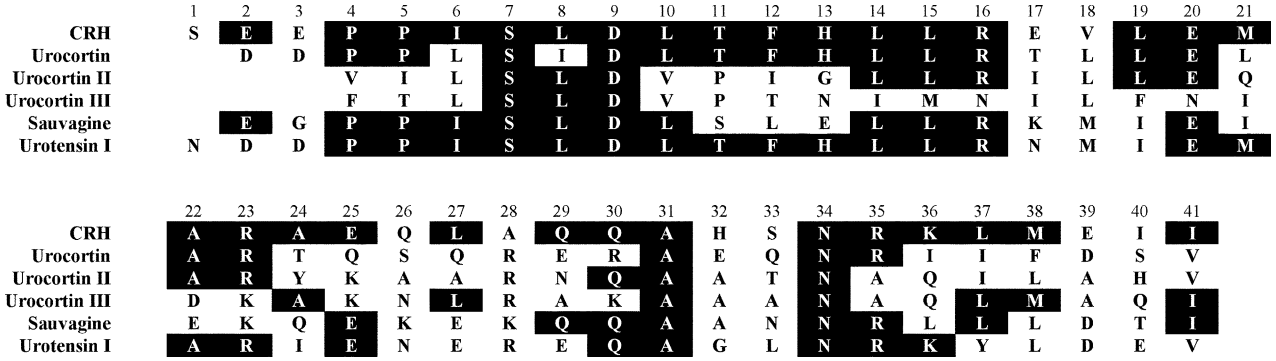

FIGURE 1 Alignment of amino acid sequences of corticotropin-releasing hormone (CRH)-related peptides. Mammalian (mouse) sequences are shown for CRH and the urocortins. Sequences of amphibian sauvagine and teleost urotensin are shown for comparison. Homologies to CRH are highlighted in black.

B. Structure and Peptide Processing

The structure and nucleotide sequence of CRH are conserved across species. The CRH gene is located on chromosome 8 (8q13) in the human genome and on chromosome 3 in the mouse and is organized as two exons separated by a single intron. The first exon encodes the majority of the 5′-untranslated region of the mRNA and the second exon contains the entire prohormone sequence.

CRH is produced in an inactive form as a 21-kDa, 196-amino-acid precursor, preproCRH, which undergoes several processing steps to yield the mature active protein (Fig. 2). Within the parvocellular neurons of the hypothalamic paraventricular nucleus, this large precursor undergoes cleavage at

TABLE 1 Tissue Distribution of CRH and Related Peptides

	Central nervous system			
Peptide	Cortical	Subcortical	Brain stem	Periphery
CRH	Wide distribution, greatest in piriform cortex	Parvocellular region of the paraventricular nucleus, lateral hypothalamus, lateral septum, central nucleus of the amygdala, median eminence, stria terminalis, medial vestibular nucleus, bed nucleus of stria terminalis, ventromedial nucleus	Locus coeruleus, central gray, lateral parabrachial nucleus, lateral reticular nucleus, all layers of cerebellum	Pituitary, adrenals, testis, ovary, gut, heart, lung, and spleen
Ucn	External cortical layer, dentate gyrus of hippocampus	Lateral septum, lateral superior olivary nucleus, supraoptic nucleus, and lateral hypothalamus	Edinger–Westphal nucleus, interpeduncular nucleus, sphenoid nucleus, periaqueductal gray, medial vestibular nucleus, autonomic and motor nuclei of the brain stem	Thymus, spleen, stomach, gut, kidney, testis, liver, and heart
Ucn II	Meninges	Paraventricular, supraoptic and arcuate nucleus of the hypothalamus, focus coeruleus	Motor nuclei of the brain stem and spinal ventral horn	Heart, adrenals, and peripheral blood
Ucn III	Meninges	Median preoptic nucleus, bed nucleus of the stria terminalis, anterior and lateral hypothalamus, anterior periventricular nucleus, medial amygdaloid nucleus	Superior paraolivary nucleus	Skin and small intestine

the C-terminal dibasic site, Lys^{153}-Arg^{154}, to yield a 43-residue peptide. Current opinion holds that prohormone convertases (PCs) are responsible for this initial processing step, and a number of PCs have been implicated. Following cleavage, the C-terminal lysine residue is removed by the enzyme carboxypeptidase H, thereby exposing the carboxyl group of a glycine residue. The glycine residue is subsequently converted into an amide by peptidylglycine α-amidating monooxygenase, rendering the mature peptide. The fully processed active CRH(1–41) is then secreted into the portal circulation.

CRH is a distinct 41-residue peptide, but contains regions homologous to other known peptides, e.g., angiotensinogen in mammals and the nonmammalian peptides sauvagine and urotensin I. Moreover, like its nonmammalian counterparts, the secondary structure of CRH consists of a long internal helix spanning 25 amino acids, which then joins a seven-peptide α-helical C-terminal fragment. Though relatively small, the length of this terminal α-helix is essential for maintaining the secondary structure (Fig. 3).

C. Determinants of Affinity

The entire COOH-terminal region in CRH is required for full potency, as evidenced by a 100-fold decrease in potency following deletion of the COOH-terminal free acid. However, as alluded to previously, the primary determinant of receptor affinity in this region appears to be the α-helical secondary structure rather than the exact chemical identities of the residues. Experimental alterations in various residues in this region have little effect on affinity, as long as the α-helix is preserved. In contrast, modifications in the N-terminal portion beyond the first two or three residues alter the potency of the peptide in ACTH release but maintain its receptor affinity.

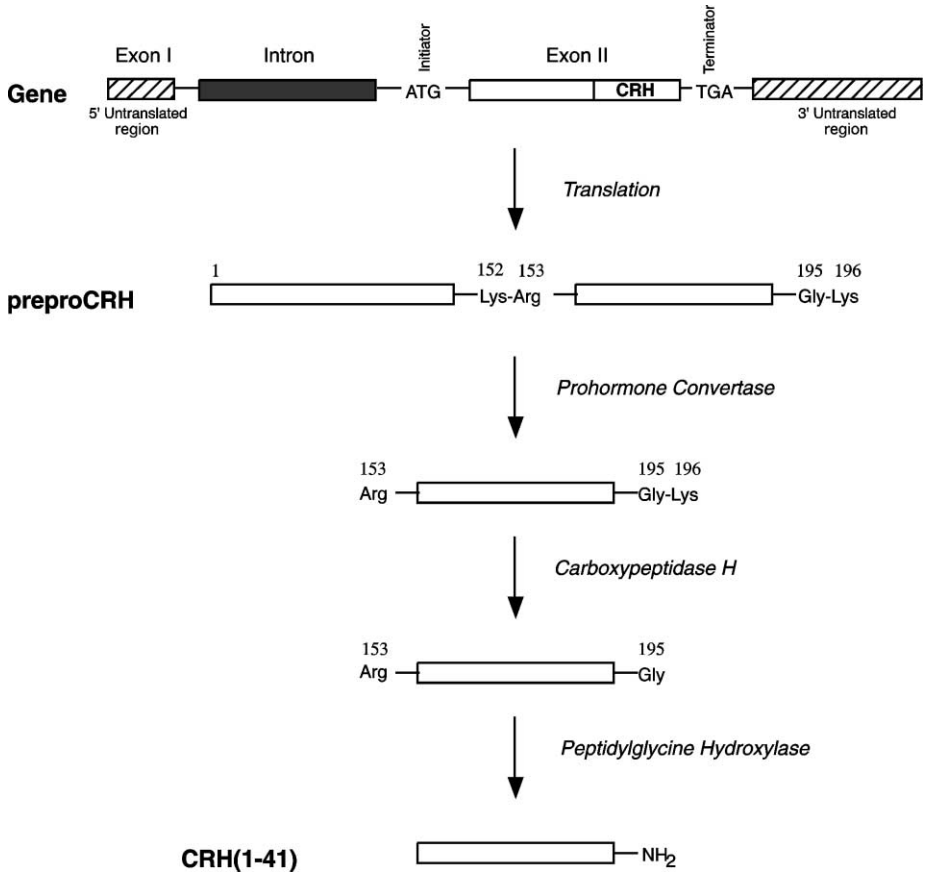

FIGURE 2 Translation and processing of corticotropin-releasing hormone (CRH). PreproCRH undergoes two major posttranslational processing events to yield a mature, bioactive peptide. First, prohormone convertases cleave the precursor at a dibasic moiety (Lys-Arg) that precedes the beginning of the mature peptide. Second, a C-terminal amino acid (Lys) is cleaved by carboxypeptidase H, and the exposed Gly residue is modified by a peptidylglycine α-amidating monooxygenase, resulting in a C-terminal carboxamide group and the mature peptide.

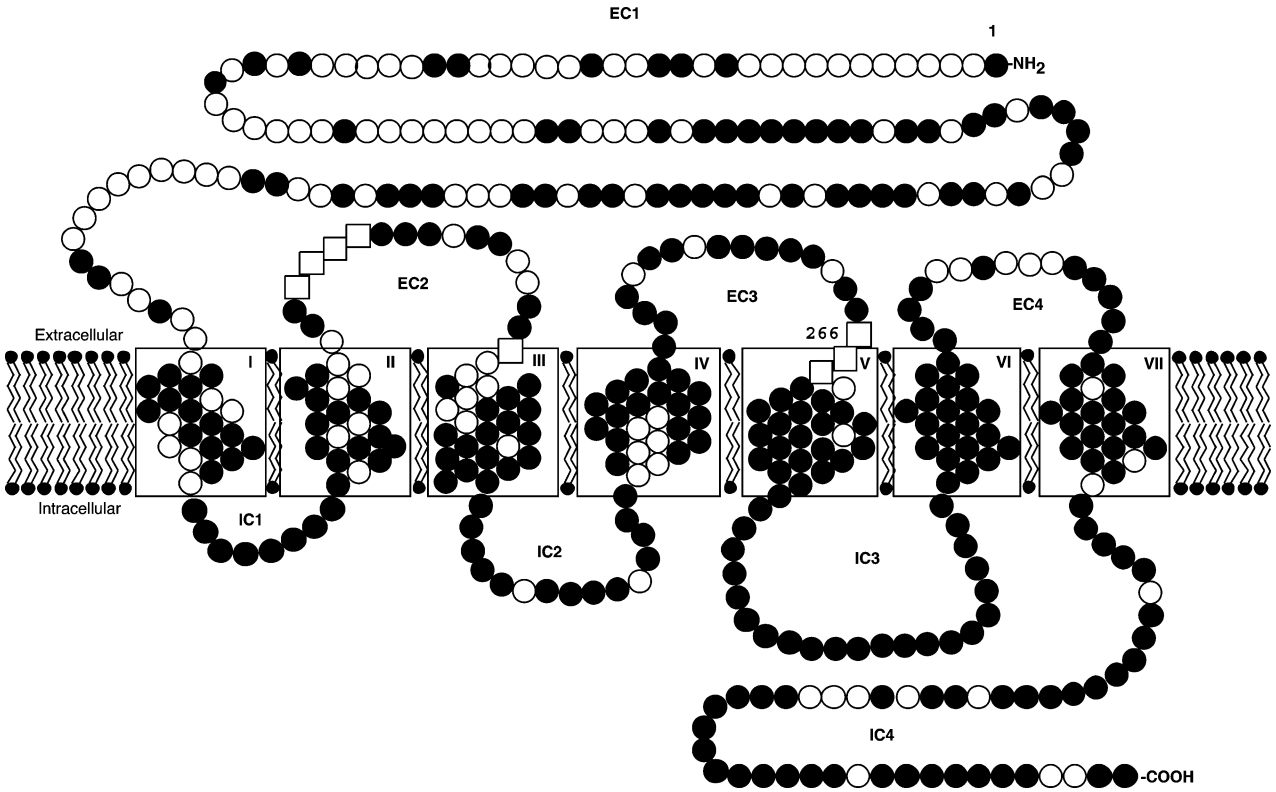

FIGURE 3 Schematic model of the human CRH-R1 and CRH-R2 receptors. Solid symbols represent conserved amino acids, open symbols represent divergent residues. Amino acids important for high-affinity CRH binding are represented by squares. Residue numbering is based on the sequence of human CRH-R1. EC, Extracellular; IC, intracellular. Transmembrane regions are indicated by Roman numerals.

Specifically, amino acids 4–8 are essential for receptor activation, because their deletion renders the peptide essentially inactive. Additionally, cleavage of these first few residues significantly affects CRH receptor binding. This detrimental effect on CRH affinity is most likely related to disruption of its secondary structure. Modifications that stabilize the α-helical configuration in these nonbinding truncated forms confer binding ability to these peptides and have led to the development of potent CRH antagonists, such as ovine α-helical CRH(10–41) and rat/human α-helical CRH(9–41), both of which are truncated α-helical structures.

III. CRH RECEPTORS 1 AND 2

A. Genetics

Currently, two major types of CRH receptors have been cloned and characterized. These receptors, CRH-R1 and CRH-R2, belong to the family of G-protein-coupled seven-transmembrane receptors that are positively coupled to adenylate cyclase. The two receptors, which share approximately 70% homology, are products of two distinct genes. CRH-R1 exists generally as a single functional form (CRH-R1α) and CRH-R2 is expressed as three distinct functional subtypes (CRH-R2α, CRH-R2β, and CRH-R2γ).

B. Expression

There is little overlap in tissue distribution of the two major CRH receptors (Table 2). In general, CRH-R1 is highly expressed in neocortical, cerebellar, and sensory relay structures, whereas CRH-R2 is mainly limited to subcortical structures. CRH-R1 is also expressed highly in the hippocampus, the hypothalamus, the ACTH-secreting cells in the pituitary, and the brain stem. The CRH-R2 isoforms have distinct patterns of expression, with little overlap among themselves. The greatest distinction is seen between the α- and β-subtypes. CRH-R2α is expressed primarily in the brain whereas CRH-R2β has significant peripheral expression. Within the central nervous system (CNS), both receptors localize to

TABLE 2 CRH Receptors: Pharmacological Profile and Anatomic Regions of Predominant Expression

Parameter	CRH-R1	CRH-R2α	CRH-R2β	CRH-R2γ
Relative potency	CRH ≥ Ucn >>> Ucn II ≥ Ucn III	Ucn ≈ Ucn II ≈ Ucn III >>> CRH	Ucn ≈ Ucn II ≈ Ucn III >>> CRH	Ucn >> CRH
Localization	Central nervous system—pituitary corticotropes, cerebellum, amygdala, hippocampus, brain stem	Central nervous system—hypothalamus, lateral septum, olfactory bulb, cortex	Central nervous system—choroid plexus, cerebral arterioles; periphery—cardiac atria and ventricles (myocardium, epicardium, and arterioles), skeletal muscle, arterioles, lungs, intestine	Central nervous system—lateral septum, hippocampus, amygdala, nucleus accumbens, midbrain, frontal cortex

subcortical structures; CRH-R2α serves as the neuronal receptor and CRH-R2β is expressed in nonneuronal structures of the choroid plexus and cerebral arterioles. In addition, CRH-R2β has been established as the peripheral CRH receptor, with high levels of expression in the heart and skeletal muscle and lower levels in lung and intestine. CRH-R2γ is unique in that it has been found only in humans thus far. It is expressed only in the CNS, with highest concentrations in the septum and hippocampus.

C. Structure

CRH-R1, which was the first receptor identified, consists of 415 amino acids and is 98% homologous across species. Characteristic of the G-protein family, CRH-R1 has five putative N-linked glycosylation sites in the N-terminal extracellular domain as well as several potential targets for protein kinase C phosphorylation in the first and second intracellular loops. As previously mentioned, CRH-R1 exists as one functional isoform, although a truncated variant and forms with insertions within the first intracellular loop have been cloned.

In contrast, CRH-R2 exists in three distinct functional isoforms, varying slightly in residue length and differing in their N-termini due to alternative splicing. The α-, β-, and γ-subtypes are 411, 431, and 397 amino acids in length, respectively, each with five predicted N-glycosylation sites, analogous to CRH-R1. The regions of highest identity with CRH-R1 are seen within the fifth and sixth transmembrane domain, the primary site of G-protein coupling (Fig. 3).

D. Binding Affinity

CRH-R1 and CRH-R2 differ considerably in their pharmacological profiles (Table 2). CRH-R1 demonstrates reversible, high-affinity binding to CRH as well as to urocortin (Ucn), a recently identified CRH-related peptide (discussed later). CRH-R1 exhibits greater affinity for CRH than does CRH-R2. Compared to CRH-R2α, CRH-R1 shows ~13-fold greater affinity for CRH in rats and a >50-fold greater affinity in humans. Comparison to CRH-2β yields a similar range, 4-fold greater affinity in mice and >50-fold in rats and human. Data from humans reveals a 25-fold greater affinity compared with CRH-R2γ.

CRH-R1 as well as all CRH-R2 subtypes bind Ucn with uniform high affinity. Whereas CRH-R1 binds both CRH and Ucn with similar affinity across species, the CRH-R2 receptors consistently favor Ucn. This peptide as well as the recently identified Ucn II and Ucn III are discussed in Section V.

E. Determinants of Affinity

The N-terminal extracellular domain is the primary determinant of ligand selectivity in CRH-R1. The ligand selectivity of CRH-R1 resides in five N-terminal amino acids, Gly-76, Gly-81, Val-83, His-89, and Leu-90. In particular, at least two of these residues, Gly-76 and Gly-81, are instrumental in the formation of the binding pocket of CRH-R1. Mutation in either one or both of these amino acids abolishes the affinity of the receptor for CRH. In addition, two regions within the second extracellular domain, amino acids 175–178 and His-189, have been found important for CRH binding (Fig. 3).

In contrast, the N-terminal domain plays little if any role in determining affinity in CRH-R2. Instead, the major determinants of ligand selectivity in CRH-R2 have been localized to the border region between the third extracellular domain and the fifth transmembrane domain. Substitution of Val-266, Tyr-267 reduces the affinity for CRH 10-fold without affecting affinity for Ucn.

IV. CRH-BINDING PROTEIN

A. Discovery

The existence of CRH-binding protein (CRH-BP) was first postulated shortly after the placenta was identified as a major source of CRH production. The observations were made that the normally negligible circulating levels of CRH dramatically increased during the third trimester of pregnancy to levels comparable to that of the hypophyseal portal circulation. Despite these extraordinary levels of CRH in the systemic circulation, no appreciable increase in ACTH secretion could be demonstrated. These observations have since led to the cloning and sequencing of the CRH-binding protein.

B. Localization

The tissue distribution of CRH-BP is distinct among species. In humans, it is expressed in the brain, liver, and the placenta, whereas in rats and mice it has been identified only in the brain and pituitary. Additionally, CRH-BP has been demonstrated in human plasma in both males and nonpregnant females. In the brain, CRH-BP is distributed diffusely throughout the cerebral cortex, as well as in a number of subcortical structures. The protein is notably absent in the paraventricular nucleus of the hypothalamus, the acknowledged primary source of CRH in the hypophyseal portal circulation. Meanwhile, CRH-BP shows widespread and preferential expression in pituitary corticotrophs, the major target cell for CRH. The physiologic role of this protein has yet to be elucidated. Given its inhibitory action on both CRH and Ucn and its tissue distribution, CRH-BP most likely functions to maintain homeostasis during the central and peripheral stress response as well as during pregnancy.

C. Genetics

The gene encoding CRH-BP is located on chromosome 13 in mice and on the long arm of chromosome 5 (locus 5q) in humans. The gene is an 18-kb structure composed of seven exons and six introns. The nucleotide sequences of the protein-encoding exons are highly homologous in the human and rat, with all exon/intron boundaries conserved. In addition, transcriptional elements have been conserved: there is $>85\%$ homology of the first 215 bp of the $5'$ flanking DNA between rat and human genes. However, because there are multiple initiation sites in the rat brain but only one site in the human liver, transcription initiation may be species or tissue specific.

D. Processing

The initial protein undergoes several posttranslational modifications to yield the active peptide, including glycosylation, phosphorylation, and cleavage. N-Glycosylation occurs at amino acid site 203 and is preserved across species. Experimental evidence suggests that the protein then undergoes autocatalytic cleavage between Ser-234 and Ala-235, though neither the precise site of cleavage in the native peptide nor the functional significance of this modification has been elucidated.

E. Structure

The active CRH-BP consists of 322 amino acids, including a 24-residue leader sequence and 10 conserved cysteine groups, creating five sequential disulfide bridges. Additionally, there is one putative N-glycosylation site, as mentioned previously. The sequence and structure of CRH-BP is well preserved across species. There is 84% sequence homology between rat and human proteins, with all cysteine residues and the putative N-glycosylation site preserved. The absence of any extended hydrophobic regions supports the conclusion that this peptide is not a transmembrane receptor for CRH.

F. Binding Affinity

Though it binds more slowly, CRH-BP binds CRH with comparable if not greater affinity, compared to CRH-R1, as determined by dissociation constants ($K_i = 0.17$ vs 3.2 nM, respectively). Likewise, CRH-BP binds Ucn with equally high affinity ($K_i = 0.1$ nM). However, preferential binding across species first differentiated CRH-BP from the CRH receptor. Recombinant rat and human CRH-BP bind rat and human CRH with equal affinity but bind ovine CRH, which differs by seven amino acids, at a 10^3-fold lower affinity. CRH-R1 makes no such distinction, suggesting quite different structural requirements for binding.

G. Determinants of Affinity

CRH residues 9–28 are essential for ligand binding. More specifically, residues 22–25, located within the central domain, are of critical importance. Within this short span, ovine CRH differs from human CRH at residues 22, 23, and 25, accounting for the diminished binding affinity of ovine CRH. Structurally, disruption of the disulfide bridges extinguishes CRH binding, indicating that the bridges are also essential for activity.

V. UROCORTIN, UROCORTIN II, AND UROCORTIN III

The recent identification of a family of structurally related peptides has uncovered a broad CRH network that includes a specific peripheral regulatory system. Ucn, the first of these peptides identified in 1995, is a 40-amino-acid peptide that shares 45% homology with CRH (Fig. 1).

A. Localization

Although Ucn has a more limited distribution in the CNS as compared with CRH, expression occurs principally in the CNS, with lower levels of expression in the periphery (Table 1). The dominant regions of Ucn expression are the Edinger–Westphal nucleus and lateral superior olivary nucleus. Ucn immunoreactivity is relatively weak in the paraventricular nucleus, where CRH is highly expressed. Instead, Ucn is expressed in projections that descend from the Edinger–Westphal nucleus and terminate in CRH receptor-rich regions such as the nucleus of the solitary tract (NTS), which in turn innervates autonomic nuclei in the brain stem and spinal cord. Ucn is also present in several autonomic and motor nuclei of the brain stem. This pattern of expression suggests that the primary function of Ucn is related to autonomic control rather than to serve as a mediator of the HPA axis. Ucn expression in the periphery varies across species. Ucn is expressed in a wide variety of both rat and human peripheral tissues; however, in the mouse, it has been demonstrated only in the brain.

B. Genetics and Structure

The genetic organization and the posttranslational modifications of Ucn are similar to those of CRH. The mouse gene is located on chromosome 5, whereas in humans it resides on chromosome 2p23–p21. Like CRH, the gene is composed of two exons separated by a single intron, with the entire coding region residing on the second exon. In addition, the Ucn and CRH genes share in common several transcription factor binding sites within their promoter regions. The full-length translated prohormone is 122 amino acids, with little sequence similarity to pro-CRH. However, both prohormones are subject to the same posttranslational modifications. Cleavage occurs at a dibasic site preceding the active peptide sequence-in the case of Ucn this is at Arg^{79}-Arg^{80}. The Ucn C-terminus is also composed of Gly-Lys, residues that are targets of cleavage and subsequent amidation to yield the mature, active peptide. The greatest homology between CRH and Ucn is in the region between amino acids 4 and 16 (Fig. 1). Additionally, in the C-terminal portion, Ala-31 and Asn-34 are strictly conserved between Ucn and all currently identified CRH-related peptides in vertebrates.

C. Binding Affinity

The importance of the N-terminal region for receptor activation is reiterated in Ucn, because deletion of the first seven amino acids converts the peptide into a potent CRH receptor antagonist. Like CRH, stabilization of the Ucn α-helical conformation is crucial to binding. As discussed previously, Ucn and CRH display similar binding affinity (K_i) and receptor activation to CRH-R1 (Table 3). In contrast, binding affinity of Ucn to CRH-R2 is 40-fold greater than that of CRH. Ucn also shows approximately 10-fold greater potency than CRH in inducing intracellular cAMP in CRH-R2-bearing cells. In relation to the CRH-R2 splice variants, Ucn reveals only a slightly higher affinity for CRH-R2β than for the α- and γ-subtypes.

D. Urocortins II and III

Two additional members of the CRH peptide family—Ucn II and Ucn III-have recently been identified in mice; their respective human prohormone orthologues, stresscopin-related peptide and stresscopin, have also been identified. Both mature peptides consist of 38 amino acids and are more closely related to Ucn (42%) and to each other (40%) than to CRH (Ucn II, 34%; Ucn III, 26%).

TABLE 3 Relative Ligand–Binding Affinity[a]

Peptide	CRH-R1	CRH-R2α	CRH-R2β	CRH-R2γ
CRH	+++ (0.95–4.5)	+/++ (13–57)	+/++ (17–65)	++ (25)
Ucn	+++ (0.12–0.4)	+++ (0.58–8.9)	+++ (0.4–8.8)	+++ (1.4)
Ucn II	− (>100)	+++ (1.7–2.1)	+++ (0.5–0.66)	NT
Ucn III	− (>100)	+++ (1.8–13.5)	NT	NT

[a]Numbers in parentheses reflect the range of K_i (n*M*) across species. NT, Affinities not tested.

However, like Ucn, Ucn II and Ucn III bind CRH-R2 with high affinity and exhibit similar potencies in receptor activation (Table 3). The key feature distinguishing Ucn II and Ucn III from Ucn is their high degree of selectivity for the CRH-R2 receptor. Ucn II and Ucn III show no appreciable binding affinity for CRH-R1 ($K_i > 100$ nM) nor do they exhibit significant potency in activating CRH-R1 as measured by intracellular cAMP accumulation, thus supporting their candidacy as endogenous ligands for CRH-R2. Although there remains some overlap, the tissue distribution of these two peptides is quite distinct from that of Ucn (Table 1). In the mouse, distribution of both Ucn II and Ucn III within the CNS is found to be predominantly subcortical.

In the mouse periphery, Ucn II has been identified in the heart and posterior pituitary and Ucn III has been localized to the skin and small intestine. In humans, detailed CNS localization has yet to be accomplished. However, the human orthologue of Ucn II, stresscopin-related peptide, is widely expressed in the periphery, with highest expression levels found in the heart, adrenals, and peripheral blood. Likewise, the Ucn III orthologue, stresscopin, has been detected in most peripheral tissues, with highest concentrations found in the digestive tract, skeletal muscle, thyroid, adrenal, and pancreas. Either one or both of these novel peptides may be the endogenous ligand for the activation of this peripheral CRH receptor system.

VI. CONCLUSION

The CRH family of peptides and receptors represents a complex, far-reaching regulatory network spanning the CNS and the periphery. Each distinct peptide and receptor subtype has a unique tissue distribution and a selective pharmacology, and all act in concert to provide a system for neurohormonal and autonomic responses to central and peripheral stressors. Although the functional significance of each component interaction as well as the broader physiological and clinical significance of this regulatory system are not completely understood, the recent identification and pharmacological characterization of additional members of the CRH family have expanded our understanding of a broad and encompassing system.

Glossary

adrenocorticotropic hormone Adrenocorticotropic hormone (ACTH) is produced in the pituitary gland and is released following hypothalamic stimulation. ACTH acts directly on the adrenal glands to stimulate glucocorticoid production.

G-protein-coupled receptor A family of seven transmembrane-spanning receptors characterized by their activation of intracellular signaling pathways via a GTP-binding protein.

hypothalamic–pituitary–adrenal axis Represents the hierarchical organization of the physiologic response to stress by the neuroendocrine system. Activation of the pituitary gland by the hypothalamus leads to subsequent stimulation of the adrenal glands to produce systemic glucocorticoids.

Corticotropin-Releasing Hormone Receptor Signaling

BHAWANJIT BRAR, MARILYN H. PERRIN, AND WYLIE W. VALE

Salk Institute, La Jolla

The primary response to a stressful event is activation of the hypothalamic–pituitary–adrenal axis. The stress response results in the synthesis and release of corticotropin-releasing hormone (CRH) from the hypothalamus, followed by an increased release of proopiomelanocortin peptides (adrenocorticotropic hormone, melanocyte-stimulating hormones, and endorphins) from the pituitary. Adrenocorticotropic hormone (ACTH) acts on the adrenal gland to cause release of glucocorticoids. The initial isolation of CRH, a 41-amino acid peptide, was based on its function as the major secretagogue of ACTH. Three more mammalian CRH-related ligands, urocortin, urocortin II, and urocortin III, have now been cloned. The importance of the CRH system as a major integrator of behavioral, autonomic, and endocrine responses to stress is underscored by its effects on learning and memory and appetite and weight control and its possible role in affective disorders such as melancholic depression.

I. INTRODUCTION

A cascade of responses to the CRH family of peptides is initiated at the cellular level by binding of CRH ligands to integral membrane protein receptors. The complexity of the signaling pathways activated by CRH ligands has become increasingly obvious as an increasing number of CRH receptor (CRH-R) subtypes and CRH-related peptide ligands have been identified and shown to exhibit diverse tissue- and cell-type-specific distributions. The activation of specific CRH-Rs in distinct cell types by receptor-selective CRH peptides may activate selective signaling pathways. Cross talk between signaling pathways may in turn affect cell function and may activate physiological processes that are essential for the maintenance of homeostasis and survival during stress.

Early studies of anterior pituitary cells demonstrated that CRH stimulates cyclic adenosine monophosphate (cAMP) and activates protein kinase A. Subsequent studies of CRH signaling have focused predominantly on CRH in brain, heart, myometrial tissue, skin, circulatory system, and gut cells. CRH-R activation by CRH peptides results in coupling to G-proteins such as $G_{\alpha\sigma}$, $G_{\alpha i}$, $G_{\alpha o}$, $G_{\alpha q}$, and $G_{\alpha z}$. Signaling pathways stimulated by G-proteins include adenylyl cyclase (AC)/cAMP, protein kinases A, B, and C (PKA, PKB, PKC), intracellular calcium ($[Ca^{2+}]_i$), cyclic guanosine monophosphate (cGMP), and mitogen-activated protein kinase (MAPK) pathways. The cAMP/PKA pathway has been extensively studied with respect to CRH-R activation. Factors affecting CRH-R signaling, such as receptor and ligand expression, as well as cross talk with other neuromodulatory factors, are discussed in the following sections.

Corticotropin-Releasing Hormone Receptor Signaling

BHAWANJIT BRAR, MARILYN H. PERRIN, AND WYLIE W. VALE

Salk Institute, La Jolla

The primary response to a stressful event is activation of the hypothalamic–pituitary–adrenal axis. The stress response results in the synthesis and release of corticotropin-releasing hormone (CRH) from the hypothalamus, followed by an increased release of proopiomelanocortin peptides (adrenocorticotropic hormone, melanocyte-stimulating hormones, and endorphins) from the pituitary. Adrenocorticotropic hormone (ACTH) acts on the adrenal gland to cause release of glucocorticoids. The initial isolation of CRH, a 41-amino acid peptide, was based on its function as the major secretagogue of ACTH. Three more mammalian CRH-related ligands, urocortin, urocortin II, and urocortin III, have now been cloned. The importance of the CRH system as a major integrator of behavioral, autonomic, and endocrine responses to stress is underscored by its effects on learning and memory and appetite and weight control and its possible role in affective disorders such as melancholic depression.

I. INTRODUCTION

A cascade of responses to the CRH family of peptides is initiated at the cellular level by binding of CRH ligands to integral membrane protein receptors. The complexity of the signaling pathways activated by CRH ligands has become increasingly obvious as an increasing number of CRH receptor (CRH-R) subtypes and CRH-related peptide ligands have been identified and shown to exhibit diverse tissue- and cell-type-specific distributions. The activation of specific CRH-Rs in distinct cell types by receptor-selective CRH peptides may activate selective signaling pathways. Cross talk between signaling pathways may in turn affect cell function and may activate physiological processes that are essential for the maintenance of homeostasis and survival during stress.

Early studies of anterior pituitary cells demonstrated that CRH stimulates cyclic adenosine monophosphate (cAMP) and activates protein kinase A. Subsequent studies of CRH signaling have focused predominantly on CRH in brain, heart, myometrial tissue, skin, circulatory system, and gut cells. CRH-R activation by CRH peptides results in coupling to G-proteins such as $G_{\alpha\sigma}$, $G_{\alpha i}$, $G_{\alpha o}$, $G_{\alpha q}$, and $G_{\alpha z}$. Signaling pathways stimulated by G-proteins include adenylyl cyclase (AC)/cAMP, protein kinases A, B, and C (PKA, PKB, PKC), intracellular calcium ($[Ca^{2+}]_i$), cyclic guanosine monophosphate (cGMP), and mitogen-activated protein kinase (MAPK) pathways. The cAMP/PKA pathway has been extensively studied with respect to CRH-R activation. Factors affecting CRH-R signaling, such as receptor and ligand expression, as well as cross talk with other neuromodulatory factors, are discussed in the following sections.

II. CRH RECEPTORS

The type 1 CRH receptor from mammals, birds, fish, and *Xenopus* has been cloned. The gene for the type 1 human CRH receptor encodes four receptor subtypes, CRH-R1α, CRH-R1β, CRH-R1c, and CRH-R1d. The type 2 CRH receptor from mammals, fish, and *Xenopus* has been cloned and a homologous partial sequence has been reported in a study using chicken cells. The gene for the type 2 human CRH receptor encodes four alternatively spliced receptors: CRH-R2α, CRH-R2α-tr, CRH-R2β, and CRH-R2γ; to date, there are two rodent variants, CRH-R2α and CRH-R2β. The catfish is the only source of a third distinct CRH receptor that has been cloned. The CRH-R1 and CRH-R2 splice variant forms are differentially expressed in the brain and periphery. The receptors belong to the class B G-protein-coupled receptor family that includes receptors for parathyroid hormone, vasoactive intestinal peptide, secretin, growth hormone-releasing factor, calcitonin, glucagon, and insect diuretic hormone.

Receptors for the CRH family of ligands are thought to exert their cellular effects via functional linkage to heterotrimeric G-proteins (Fig. 1), which activate signaling pathways through their α and/or βγ subunits. CRH-Rs couple to $G_{\alpha s}$, $G_{\alpha i}$, $G_{\alpha o}$, $G_{\alpha q}$, and $G_{\alpha z}$, and activation of these specific G-proteins leads to the stimulation of selective intracellular signaling pathways. The functional linkage of G-proteins to the CRH-R is dependent on the cell type and ligand.

Activation of $G_{\alpha s}$ by the CRH-R stimulates AC, which in turn increases cAMP production and activates PKAs. CRH elicits the release and intracellular accumulation of cAMP from cells of various parts of the brain, from pituitary cells, and in a number of cell lines. For example, rat retinal membranes express two populations of CRH binding sites, and incubation of these membranes with an antibody that recognizes the carboxyl terminus of the α subunit of $G_{\alpha s}$ prevents

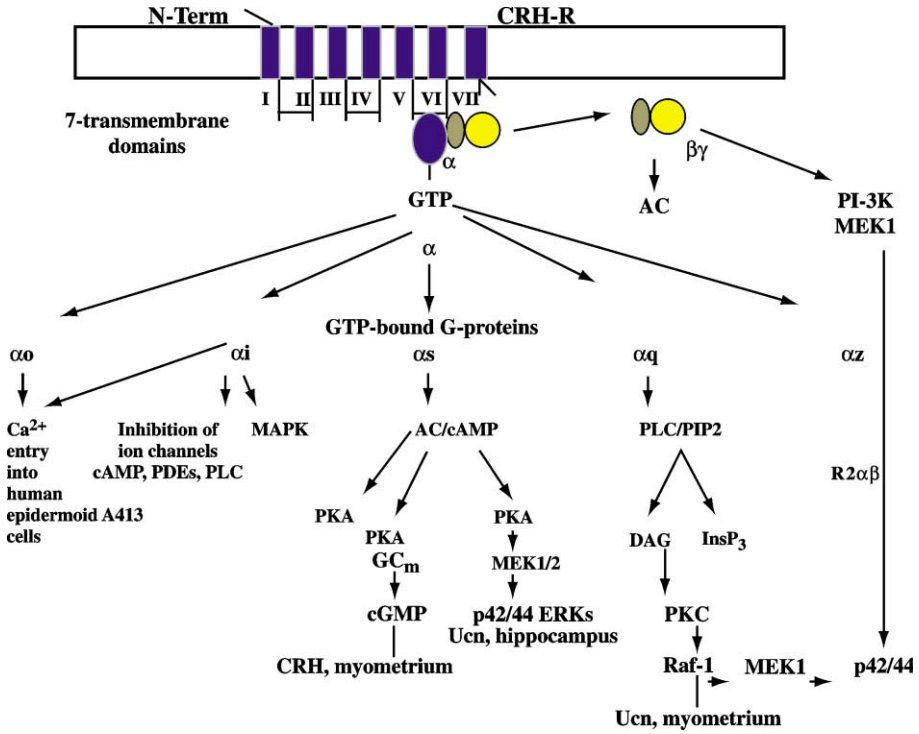

FIGURE 1 Corticotropin-releasing hormone receptor (CRH-R) activation can result in signaling through a number of different signaling pathways: the choice of pathway appears depend on preferential coupling of the G-protein to the receptor in the specific cell type. CRH-Rs are coupled to five classes of G-proteins, αo, αi, αs, αq, and αz. AC, adenylyl cyclase; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; CHO-R, Chinese hamster ovary stable cell line expressing CRH receptors; DAG, diacylglycerol; ERK, extracellular signal-related kinase; GC_m, guanylyl cyclase (membrane bound); GTP, guanosine triphosphate; $InsP_3$, inositol 1,4,5-trisphosphate; MAPK, mitogen-activated protein kinase; MEK1/2 (MEK1), MAPK kinase; PDE, phosphodiesterase; PI-3K, phosphatidylinositol 3-OH kinase; PIP_2, phosphatidylinositol 4,5-bisphosphate; PKA, PKC, protein kinases A and C; PLC, phospholipase C; Ucn, urocortin.

TABLE 1 Activation of AC and cAMP by CRH, Ucn I, Ucn II, and Ucn III in CHO-R Cells[a]

Peptide	Binding, hCRH-R1 (K_i, n*M*) membranes	Binding, rCRH-R2α (K_i, n*M*) membranes	Binding, mCRH-R2β (K_i, n*M*) membranes
h_rCRH	0.95 (0.47–2.0)	13 (7.2–22)*	17 (10–29)
rUcn	0.32 (0.14–0.77)	2.2 (0.91–5.4)	0.62 (0.14–2.8)
hUcnII	>100	1.7 (0.73–4.1)	0.50 (0.22–0.16)
mUcnII	>100	2.1 (0.78–5.4)	0.66 (0.13–3.3)
hUcnIII	>100	21.7 (8.2–57)	13.5 (9.2–9.7)
mUcnIII	>100	5.0 (4.0–6.3)	1.8 (0.77–4.1)

[a]The values were determined from three to six independent experiments using stably transfected CHO cells or their membranes. The EC_{50} and K_i values were determined using prism software. h, human; m, mouse; r, rat. Ucn II and Ucn III are more selective for CRH-R2 than for CRH-R1.

†, SEM; *, 95%, confidence limit.

CRH stimulation of AC. In hippocampal neurons, urocortin (Ucn) activates $G_{\alpha s}$ and $G_{\alpha o}$ and subsequently the AC/cAMP pathway and PKA.

CRH-Rs in myometrial cells are coupled to $G_{\alpha s}$, $G_{\alpha o}$, $G_{\alpha i}$, and $G_{\alpha q}$; selective activation of $G_{\alpha q}$ by Ucn results in MAPK activation. Ucn preferentially activates $G_{\alpha q}$ with 10-fold greater potency compared to CRH and induces inositol 1,4,5-trisphosphate ($InsP_3$) production. Both CRH and Ucn stimulate cAMP production in myometrial cells, suggesting that both activate receptor coupling to $G_{\alpha s}$. Furthermore, CRH stimulates vasodilation in the human myometrium via a nitric oxide (NO)/cGMP-dependent pathway mediated by CRH-R1, with a rank order for activation of G proteins as follows: $G_{\alpha s} > G_{\alpha o} > G_{\alpha q} > G_{\alpha i} > G_{\alpha z}$. The differential activation of G-proteins by CRH and Ucn in human myometrial cells suggests that the peptides have distinct biological roles in these cells via activation of specific CRH-Rs and signaling cascades.

CRH-R1 is highly expressed within the rat cerebral cortex and is coupled to AC. This receptor is capable of activating $G_{\alpha s}$, $G_{\alpha i}$, $G_{\alpha q}$, $G_{\alpha o}$, and $G_{\alpha z}$, with subsequent stimulation of two intracellular signaling cascades: (1) CRH predominantly activates $G_{\alpha s}$, resulting in an increase in cAMP, and (2) $G_{\alpha q}$ activation by CRH stimulates PLC, which increases $InsP_3$ and Ca^{2+}. The hydrolysis of InsPs can lead to the formation of several distinct messengers, such as diacylglycerol (DAG), raising the possibility of simultaneous CRH-mediated activation of multiple signaling pathways.

In the rat cerebral cortex, Ucn stimulates all but one of the G-proteins with a potency similar to that of CRH; the exception is $G_{\alpha q}$, for which Ucn is more potent than CRH. Incorporation of $GT^{32}P$-labeled amino acids in $G_{\alpha s}$ occurs at a 10-fold lower concentration of CRH than is required to stimulate AC, and may imply that a threshold number of $G_{\alpha s}$ molecules is required to induce activation of AC or that not all of CRH-R is coupled to AC. The $G_{\alpha z}$ and $G_{\alpha i}$ proteins are weakly coupled to the CRH-R in the cerebral cortex. It has been shown in other receptor systems that $G_{\alpha i}$, $G_{\alpha o}$, and $G_{\alpha q}$ can stimulate PLC and increase $InsP_3$s. CRH activation of $G_{\alpha i}$ may also lead to liberation of the βγ subunits and to activation of selective ACs. This may explain how pertussis toxin (PTX), an inhibitor of $G_{\alpha i}$ and $G_{\alpha o}$, can abolish the basal and CRH-stimulated AC activity in cerebral cortical membranes. The CRH-R can also activate $G_{\alpha o}$ and $G_{\alpha i}$, and these G-proteins have been implicated in the inhibition of AC and in the modulation of cation channels in human epidermoid A413 cells.

Therefore, preferential activation of specific G-proteins coupled to the CRH-Rs regulates the downstream intracellular signaling pathways that are activated by CRH or Ucn. The effects of Ucn II and Ucn III on CRH-R G-protein activation have not been extensively studied.

III. ADENYLYL CYCLASE, CAMP, AND PROTEIN KINASES

All CRH peptides increase intracellular cAMP concentrations following activation of $G_{\alpha s}$, which activates AC. An increase in intracellular cAMP can lead to activation of PKA and in some cases PKC, which in turn stimulate the activation of other signaling components within a cell. Activated PKA and PKC can feedback to regulate cAMP production by regulating AC.

The $G_{\alpha s}$/AC/cAMP pathway is the most extensively studied signaling cascade activated by the CRH-R subtypes and has been used to discriminate

subtype agonist selectivity. The relative potencies of the CRH peptides in binding to and activating CRH-Rs in Chinese hamster ovary (CHO) cells expressing CRH-R1 and CRH-R2 subtypes is summarized in Table 1. The universal activation of AC following stimulation of the CRH-Rs is observed in a diverse range of cell types. In most cell systems studied, CRH-R stimulation of AC is coupled through $G_{\alpha s}$, but CRH-R1 expressed in neutrophils of the spleen does not seem to function through $G_{\alpha s}$, as indicated by the inability of CRH to stimulate cAMP production. Also, CRH action in Leydig cells is exerted through direct or indirect activation of PKC at the level of the catalytic subunit of AC, and this effect has not been shown in any other cell type. The CRH-R in Leydig cells does not couple to $G_{\alpha s}$. In Y-79 human retinoblastoma cells, CRH-stimulated AC is amplified by Mg^{2+} and is inhibited by submicromolar [Ca^{2+}]. Therefore, in these cells specific CRH-Rs stimulate cAMP formation by interacting with $G_{\alpha s}$ and by affecting a Ca^{2+}-inhibitable form of AC.

CRH stimulates accumulation of cAMP and release of ACTH from primary cultures of anterior pituitary (AP) cells and the mouse corticotroph cell line, AtT-20. Corticosteroids depress the CRH-mediated increase in cAMP by down-regulating CRH-R expression and, hence, inhibit secretion of ACTH from these cells. Therefore, the glucocorticoid inhibition of CRH-mediated ACTH secretion from the AP may be regulated by depletion of cAMP levels.

PKC has been shown to regulate AC activity in AP cells with both inhibitory and stimulatory actions. An increase in PKC activity by phorbol ester potentiates CRH stimulation of ACTH secretion and cAMP production in AP cells. This effect was not seen in intermediate pituitary (IP) or in AtT-20 cells treated with CRH. However, long-term treatment of cultures with phorbol ester, which depletes cell stores of PKC, causes a dramatic attenuation of ACTH release by CRH, but has no significant effect on cAMP production.

Both human (h) and rat (r) Ucn peptides promote secretion of ACTH from rat AP. Intravenous (iv) administration of Ucn causes an increase in ACTH and corticosterone secretion *in vivo* and an increase in proopiomelanocortin (POMC) and CRH-R1 expression in the AP. Ucn has a more potent and longer term effect than CRH. In AP cultures, Ucn stimulation of ACTH release is seven times greater than that of CRH and the effect is enhanced by phorbol esters that activate PKC, but is reduced by PKA inhibitors. Hence activation of PKC has a synergistic effect on Ucn-induced ACTH release, similar to the synergism between CRH and PKC.

CRH-Rs are found in heart, skin, and myometrial (during pregnancy) cells and in lymphocytes. The rat heart expresses CRH-R2β. CRH peptides stimulate cAMP levels in isolated rat neonatal cardiac myocytes. In human myometrial cells CRH-Rs are functionally coupled to AC and increase intracellular cAMP levels; cAMP is a well-known myometrial relaxant. The positive inotropic effect of CRH in these cells is due to activation of cAMP and prostaglandin (PG) pathways, whereas, chronotropic action is solely due to cAMP signaling. In skin cells, CRH-R1 is more efficient than CRH-R2 at transducing the CRH signal, with greater accumulation of cAMP. In human immortalized HaCaT keratinocytes, the relative potencies for activating AC through CRH-R1 are CRH = Ucn > sauvagine > urotensin I. It is likely that CRH and Ucn bind to distinct domains within the receptors, leading to conformational changes that facilitate coupling to G-proteins and activation of intracellular signaling molecules.

In human peripheral blood mononuclear cells (hPBMCs), CRH significantly increases cAMP in human monocytes, but not in lymphocytes. A CRH-R antagonist, α-helical CRH(9-41), inhibits this effect. Moreover, the CRH-stimulated cAMP levels are reduced to baseline by the intracellular Ca^{2+} antagonist HA1004. This indicates cross talk

between Ca^{2+} and cAMP signaling in these cells. Hence, cAMP and/or Ca^{2+} play a role in the CRH transduction pathway in human lymphocytes.

CRH-R stimulation activates PKA, PKB, and PKC. The activation, regulation, and physiological response of these protein kinases is dependent on cell type, ligand, and receptor (Fig. 2).

A. PKA

CRH-R1 and CRH-R2 are positively coupled to increases in cAMP, which activates PKA by triggering the dissociation of the catalytic and regulatory subunits of the holoenzyme. The catalytic subunit of PKA directly phosphorylates and activates target proteins; phosphorylation of transcription factors such as Ca^{2+}/cAMP response element binding protein (CREB) at Ser-133 yields phospho-CREB (P-CREB), which regulates transcription of genes containing the Ca^{2+}/cAMP response element (CRE). PKA is involved in mediating the CRH/Ucn-stimulated increase in ACTH secretion and POMC and CRH-R1 expression in the AP.

PKA can directly regulate other intracellular signaling components, such as AC, MAPK, Ca^{2+}, PKC, and cGMP. For example, the CRH-mediated cAMP increase in hPBMCs is attenuated by a PKA inhibitor. Regulation of MAPK by PKA is seen in hippocampal neurons that express CRH-R1. Hippocampal neurons are protected from oxidative and excitotoxic cell death by Ucn and CRH, which has a 10-fold lower potency than Ucn, but not by Ucn II. Inhibition of PKA, MAPK kinase (MEK1), and PKC abrogates the Ucn-mediated protective effect. PKA regulates CRH-R-mediated phosphorylation of MAPK in normal ovine AP corticotrophs and the CRH-mediated inhibition of MAPK activity in AtT-20 cells. Also, the cell-differentiating action of CRH in immortalized noradrenergic neuronal CATH.a cells is mediated by PKA.

PKA can also influence CRH-R-stimulated Ca^{2+} currents. For example, the large CRH-induced oscillatory increase in cytosolic [Ca^{2+}] in corticotrophs is largely dependent on cAMP activation of PKA. PKA regulates the increase in cytosolic [Ca^{2+}] by phosphorylation and activation of voltage-sensitive

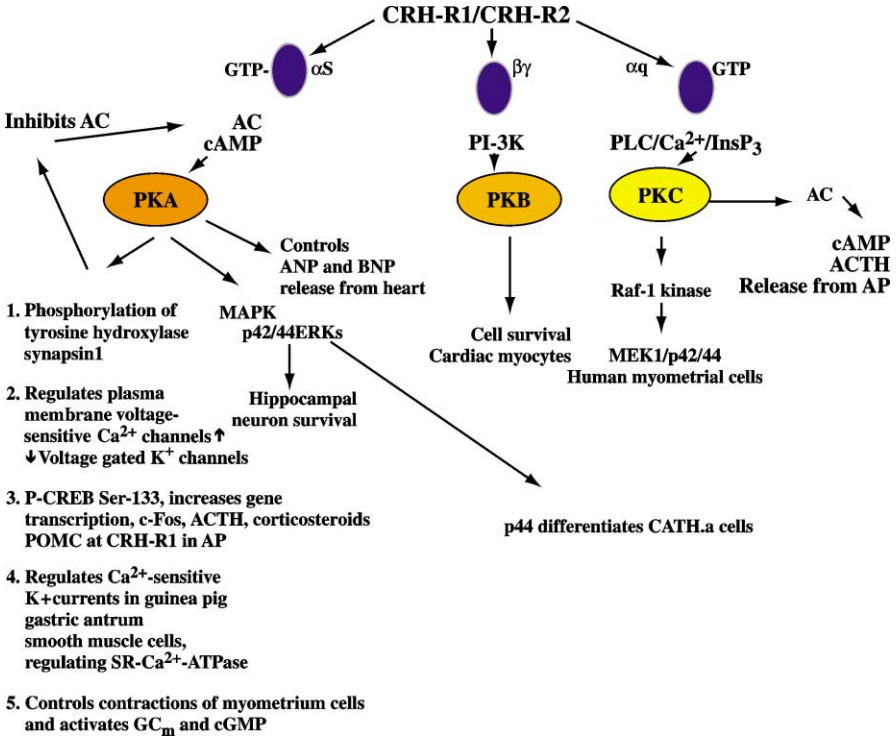

FIGURE 2 Corticotropin-releasing hormone receptor (CRH-R) stimulation can activate all three protein kinases, PKA, PKB, and PKC. Upstream activation of these kinases varies, depending on the G-protein and the cell type. Downstream signaling from the protein kinases leads to different physiological processes in different cell types. ACTH, adrenocorticotropic hormone; ANP, BNP, atrial and brain natriuretic peptides; SR, sarcoplasmic reticulum (other abbreviations as in Fig. 1).

Ca^{2+} channels, thus regulating $[Ca^{2+}]_i$ directly. Therefore, CRH-R activation results in an increase in PKA activation, change in electrical excitability, and $[Ca^{2+}]$ mobilization, which, in turn, result in ACTH secretion from corticotrophs.

In guinea pig gastric antrum smooth muscle cells, Ucn increases Ca^{2+}-sensitive K^+ currents and does not affect the kinetics and voltage dependence of inward Ca^{2+} current. The Ucn-mediated increase of Ca^{2+}-sensitive K^+ currents is regulated by PKA. The PKA-dependent increase of Ca^{2+} concentration near the plasma membrane is due to enhanced release of Ca^{2+} from intracellular Ca^{2+} stores. In rat tail arteries, Ucn is a potent endothelium-independent dilator, and Ucn-mediated CRH-R activation of PKA causes a reduction in the sensitivity of the contractile apparatus for Ca^{2+}.

PKA can also modulate receptor-mediated Ca^{2+} responses. In CATH.a cells, submaximal concentrations of pituitary AC-activating polypeptide (PACAP), vasoactive intestinal peptide (VIP, and carbachol produce transient increases in $[Ca^{2+}]_i$. This effect is abolished by prior treatment of the cells with $1\mu M$ CRH. The activation of PKA similarly abolishes the increase in $[Ca^{2+}]_i$ by these peptides. This study demonstrates that CRH inhibits receptor-mediated $[Ca^{2+}]_i$ responses in a locus coeruleus cell line, possibly by activation of PKA. This modulation could be important in controlling neuronal function *in vivo* in stressful situations in which the levels of CRH are increased in the locus coeruleus. Therefore, the physiological role for the inhibition of Ca^{2+} mobilization by CRH might be to modulate neuronal function by alteration of Ca^{2+}-dependent processes such as gene transcription, which would otherwise be stimulated by PACAP, VIP, or carbachol.

CRH increases the amplitude of and decreases the frequency of contractions in preparations of myometrium from pregnant rats, and this effect is mediated by PKA. In human myometrial cells, acute CRH administration activates CRH-R1 and stimulates the membrane-bound guanylate cyclase (GC_m), which in turn increases cGMP and contractility. PKA inhibition reduces CRH-stimulated cGMP production. Therefore, CRH-stimulated GC_m activity is partially dependent on the PKA that may phosphorylate the kinase homology domain essential for GC_m activity. Ucn stimulates the release of atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) from neonatal rat cardiac myocytes, and this process is abrogated by inhibiting PKA. Ucn stimulates cAMP and [^{3}H]leucine uptake and enhances endothelin-1-induced increase of [^{3}H]leucine uptake. Hence CRH-R2 activation by Ucn induces ANP and BNP secretions from cardiac myocytes, at least in part via a PKA pathway during cardiac hypertrophy.

B. PKC

PKA, Ca^{2+}, cAMP, and PI (DAG and $InsP_3$s) activate PKC. Prolonged activation of PKC can down-regulate CRH-R expression and reduce signaling in human myometrial cells; also in these cells, Ucn activates PKC and Raf-1 kinase and, subsequently, MAPK.

PKC has been shown to activate MAPK in hippocampal neurons. In human myometrial cells, in contrast to PKA, PKC inhibits CRH-induced GC_m activity. PKC has been shown to down-regulate the expression of CRH-Rs and PKC may target multiple components of the intracellular signaling pathway to reduce the CRH-induced cGMP response in these cells.

C. PKB/Akt

PKB/Akt functions to promote cell survival by inhibiting apoptosis. Ucn is expressed in the heart and binds with high affinity to CRH-R2β. Ucn promotes cardiac myocyte survival against hypoxia reoxygenation (HR) injury, and this survival involves activation of the MAPK pathway (MEK1/2 p42/44 MAPK). Also, Ucn stimulates the phosphorylation of PKB/Akt via phosphatidylinositol 3-OH kinase (PI-3K) in cardiac myocytes. Inhibiting MEK1, PI-3K, or PKB/Akt with genetic and chemical inhibitors inhibits the Ucn-cardioprotective effect in HR.

Additionally, exogenous CRH provokes changes in the cellular shape of invertebrate immunocytes from the mollusk *Mytilus galloprovincialis*. These changes in cell shape are mediated by PI-3K, PKB/Akt, PKC, and PKA, indicating cross talk between these pathways.

IV. CALCIUM SIGNALING

CRH also signals through the second messenger Ca^{2+}, and a majority of these effects are regulated by PKA. CRH-R-mediated Ca^{2+} signaling has been demonstrated in human and rat pituitary corticotrophs, arterial cells, smooth muscle cells, skin cells, and neuronal cell lines.

In pituitary corticotrophs, a change in the cytosolic free $[Ca^{2+}]_i$ is important in controlling ACTH secretion. CRH-R stimulation by CRH results in an increase in the cell firing frequency of corticotroph action potentials and induces an oscillatory increase in cytosolic $[Ca^{2+}]_i$. CRH also increases membrane

depolarization, which is associated with the generation of action potentials in quiescent corticotrophs and an increase in action potential frequency in spontaneously active corticotrophs. The increase in $[Ca^{2+}]_i$ is due to an increase in frequency and amplitude of cytosolic Ca^{2+} transients into the cell; the Ca^{2+} transients are completely dependent on voltage-sensitive L-type Ca^{2+} channels and are regulated by P-type Ca^{2+} channels that are activated by CRH-induced membrane depolarization. The voltage-dependent Na^+ channel depolarizes the membrane, thereby activating the voltage-gated Ca^{2+} channels, and is therefore involved in the rapid initial component of the CRH-induced action potential. Inhibition of PKA does not inhibit CRH-induced membrane depolarization, but attenuates the CRH-induced increase in action potential frequency and $[Ca^{2+}]_i$ transients. The phosphorylation targets for PKA have not been identified; however, PKA is known to phosphorylate L-type voltage-sensitive Ca^{2+} channels. Also, CRH induces inhibition of K^+ currents that maintain a negative resting membrane potential, which is believed to contribute to the membrane depolarization and increased membrane excitability. In rat corticotrophs, a CRH-induced inhibition of an identified Ba^{2+}-sensitive inwardly rectifying K^+ channel is believed to contribute to the membrane depolarization and to increases in firing frequency. The effects of CRH on dorsal raphe neurons revealed that, in the presence of Ca^{2+}, CRH rapidly and reversibly increases firing rates of serotonergic neurons located in the ventral portion of the dorsal raphe nucleus. Similar to its effect on the AP, CRH at physiological concentrations increases $[Ca^{2+}]_i$ in isolated single beta cells of rat islets via the L-type Ca^{2+} channel by activating the cAMP/PKA pathway.

CRH and Ucn are endogenous vasodilators in rat mesenteric, cerebral, and femoral arteries as well as in rat aorta and in rat basilar and uterine arteries. The CRH-R2-mediated vasodilatory effect in rat aorta and in fetal–placental circulation is endothelium dependent and most likely is mediated by NO release and cGMP. In the rat basilar artery, Ucn antagonizes vascular contraction mainly via AC stimulation and subsequent activation of Ca^{2+}-dependent K^+ channels. Ucn is also a potent endothelium-independent dilator of rat tail arteries, an effect likely to be mediated by PKA, causing a reduction in the sensitivity of the contractile apparatus for Ca^{2+}.

Alterations of $[Ca^{2+}]_i$ are responsible for the vasodilatory effect of Ucn in guinea pig gastric antrum smooth muscle cells. In these smooth muscle cells Ucn causes a concentration-dependent increase of Ca^{2+}-sensitive K^+ currents and does not affect the kinetics and voltage dependence of inward Ca^{2+} currents. This results in an increase in $[Ca^{2+}]$ at the plasma membrane. Emptying of intracellular Ca^{2+} stores, as well as activity of blockers of AC and PKA, antagonize the effect. Therefore, Ucn binds at physiological concentrations to the CRH-R and activates AC/cAMP/PKA. The final target for these biochemical events is most probably the sarcoplasmic reticulum (SR) Ca^{2+}-ATPase or another integral SR membrane protein that is functionally involved in the regulation of the SR Ca^{2+} pump.

In contrast to smooth muscle cells, the vasodilatory effect of CRH and Ucn on the isolated rat heart appears not to be mediated by Ca^{2+}, but by prostaglandins (PGs). Finally, Ucn stimulation of ANP and BNP from neonatal rat cardiac myocytes is mediated by PKA and a voltage-dependent Ca^{2+} channel.

In a number of skin cell types, CRH-R-mediated stimulation of $[Ca^{2+}]_i$ is largely due to an influx of Ca^{2+} through the extracellular membrane. High $[Ca^{2+}]_i$ in malignant melanocytes is due to CRH-R activation. CRH-R-mediated changes in $[Ca^{2+}]_i$ have antiproliferative effects on Cloudman melanoma cells, on B16 melanoma growth *in vivo*, on human immortalized keratinocytes (HaCaT), and on hamster melanomas (SK-MEL188, AbCl). In A431 cells, CRH increases $[Ca^{2+}]_i$ by stimulating Ca^{2+} influx through channels coupled to $G_{\alpha i}$ and $G_{\alpha o}$ and by mobilization through production of $InsP_3$'s. Treatment of CHO cells stably expressing CRH-R1α and CRH-R2β with sauvagine results in an increase of intracellular Ca^{2+}, both by mobilization of Ca^{2+} from intracellular stores and by influx across the plasma membrane.

V. MITOGEN-ACTIVATED PROTEIN KINASES

The activity of three main families of MAPKs can be regulated by several G-proteins, including $G_{\alpha s}$, $G_{\alpha q}$, and $G_{\beta\gamma}$. CRH peptides activate the MEK1/ERK1/2/p42/44 pathway and differentially activate p42/44 MAPKs in a number of cell lines and tissues (Fig. 3).

MAPK is activated by sauvagine in CHO cells stably expressing rat CRH-R1, CRH-R2α, and CRH-R2β. Sauvagine activation of p42/44 MAPK results in phosphorylation of Elk1, which can bind to the serum response element (SRE). Phosphorylated Elk1, together with a serum response factor protein, can increase transcription of immediate early genes containing the SRE, such as the gene for c-Fos. The p42/44 MAPKs are partially regulated through PI-3K

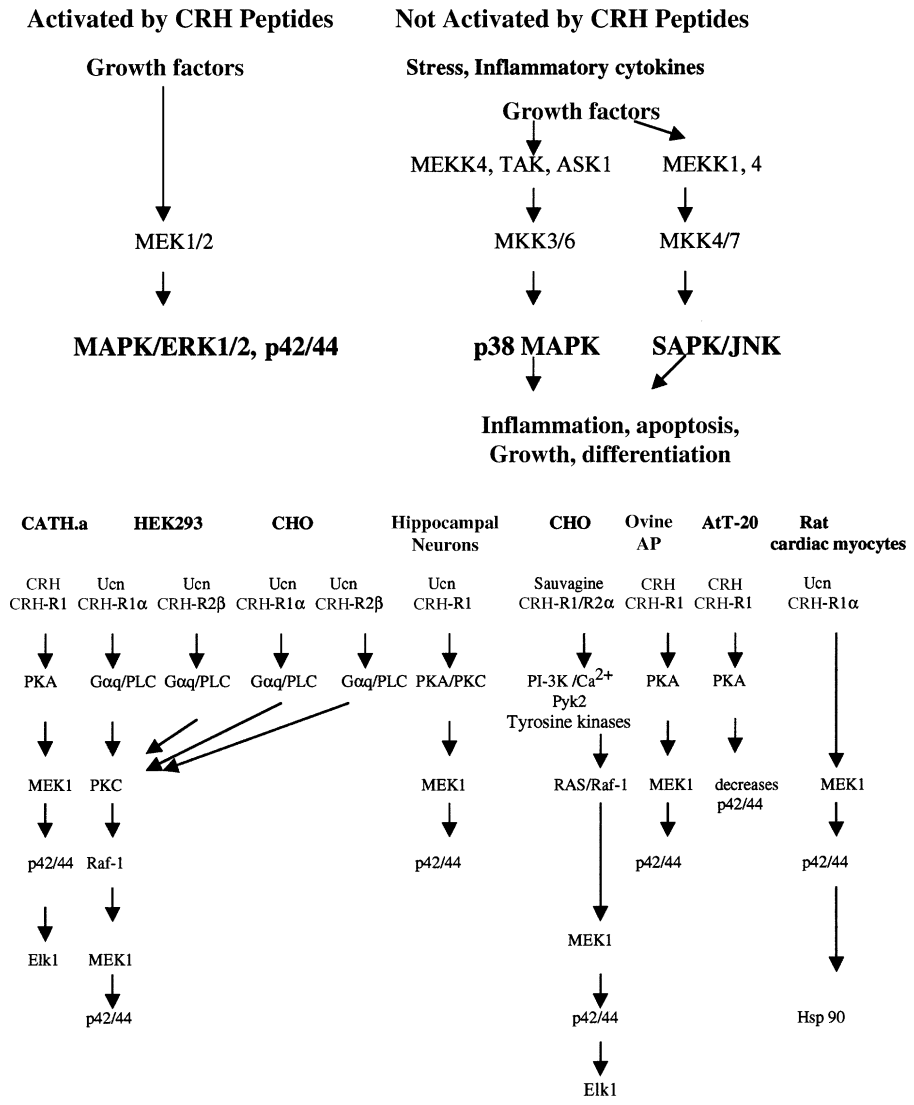

FIGURE 3 Multiple pathways of activation in a number of cell systems, mediated by corticotropin-releasing hormone receptor (CRH-R) stimulation. CRH-R stimulation can result in activation of the MEK1/2, MAPK/ERK1/2, p42/44 pathway; activation depends on the CRH-R subtype stimulated, the ligand, and the cell type. ASK1, apoptosis signal-regulating kinase; JNK, JUN N-terminal kinase; SAPK, stress-activated protein kinase; TAK, transforming growth factor-B-activated kinase (other abbreviations as in Fig. 1).

and through PI-specific phospholipase C (PLC) of the Ca^{2+}-sensitive proline-rich tyrosine kinase (Pyk2). Pyk2 can then activate tyrosine kinases and MAPKs. Activation of MAPK by sauvagine is independent of PKA and of cAMP, but is dependent on Ca^{2+} in the CHO CRH-R1α and CRH-R2α cell lines.

As is observed in the transfected CHO cell lines, activation of MEK1 by Ucn in primary cultures of rat cardiac myocytes results in the phosphorylation of p42/44 MAPKs. In the heart, the MEK1 pathway is involved in the cardioprotective effect of Ucn against HR injury by reducing apoptosis and necrotic cell death. Ucn causes an increase in expression of the cytoprotective heat-shock protein 90 (Hsp 90) via MEK1 activation. Ucn, but not Ucn II, promotes survival of hippocampal neurons via CRH-R1 activation. Inhibition of PKA, MEK1, and PKC inhibits the Ucn-mediated protective effect. MEK1 is also a substrate for PKC and PKA, suggesting that crosstalk between signaling pathways is required for the protective effect of Ucn in these hippocampal cells.

CRH acts as a differentiation factor in CATH.a cells, and blocking either the ERK pathway or PKA inhibits neurite outgrowth. The transcription factors

activated by PKA and p42/44 MAPK were investigated and it was shown that PKA inhibition inhibits CRH-mediated phosphorylation of the p44 isoform in CATH.a cells. CREB is phosphorylated and activated by PKA and Elk is phosphorylated by p42/44 MAPK. ERG-1 is involved in neuronal differentiation and CRH activates the ERG-1 promoter, possibly via activation of MEK1 and PKA.

CRH differentially regulates MAPK activity in normal ovine anterior pituitary cells, as compared to regulation in AtT-20 cells. Incubation of ovine interior pituitary cells with CRH increases MAPK activity mediated by PKA. In contrast, incubation of AtT-20 cells with CRH inhibits MAPK activity mediated by PKA. Interestingly, ANP reverses the effects of MAPK activity in both cell types, suggesting that ANP is involved in MAPK regulation in the AP.

In myometrial cells from pregnant humans, Ucn, but not CRH, activates the MEK1 p42/44 MAPK pathway. These cells express CRH-R2β, CRH-R1α, CRH-R1β, CRH-R1c, and CRH-R1d, with CRH-R1 being the prominent receptor subtype. In HEK293 and CHO cells stably expressing these receptors CRH fails to activate p42/44 MAPK. Ucn activates both CRH-R1α and CRH-R2β, and not the other receptor subtypes, resulting in MAPK activation by stimulating $G_{\alpha q}$/PLC/$InsP_3$, DAG/PKC/Raf-1 kinase/MEK1/p42/44. In comparison to the MAPK pathway, CRH and Ucn activate cAMP at all receptor types. This study suggests that Ucn and CRH have distinct biological roles in the myometrium. CRH-R1α, which binds Ucn and CRH with equal affinity, can differentially activate MAPK. CRH receptors selectively activate MAPK, but all of the receptors activate AC.

VI. CGMP

cGMP is another molecule implicated in CRH receptor signaling. In response to G-protein-coupled receptor (GPCR) activation, cGMP is synthesized by membrane-bound guanylate cyclase (GC_m) and soluble guanylate cyclase (GC_s). In cultured rat AP cells and immortalized GH3 cells, CRH-R activation by CRH increases cAMP and cGMP. Inhibition of PKA inhibits CRH-R-mediated activation of GC_s in pituitary cells. CRH-R activation by CRH modulates GC_s signaling though $G_{\alpha s}$, AC, and cAMP.

$$\text{CRF} + \text{CRF-R} \rightarrow G_{\alpha s} \rightarrow \text{AC} \rightarrow \text{cAMP} \rightarrow \text{PKA} \rightarrow \text{GCs} \rightarrow \text{GMP}$$

In myometrial cells from pregnant humans, CRH stimulates vasodilation through an NO/cGMP-dependent pathway by activating CRH-R1. The actions of NO in the myometrium are mediated, at least partly, via activation of GC_s and increased production of cGMP, which reduces myosin light chain phosphorylation. CRH, but not Ucn II or Ucn III, has a dual effect on the myometrial nitric oxide synthase (NOS)/GC pathway, with a short-term effect mediated by PKA (acute) and a long-term effect mediated by increased NOS expression. Acute stimulation of these cells with CRH results in the activation of the cGMP pathway by enhancing GC_m and to a lesser extent GC_s. This effect is independent of NOS but is partially dependent on PKA. PKC inhibits the CRH-induced GC_m activity, possibly by down-regulating the expression of CRH-Rs. Long-term treatment with CRH up-regulates endothelial NOS (eNOS) and brain NOS (bNOS) mRNA. The increase in eNOS and bNOS expression results in an increase in activity of GC_s and cGMP.

VII. EXTRACELLULAR FACTORS THAT REGULATE CRH RECEPTOR SIGNALING

CRH-R and CRH-R ligand expression levels, CRH-binding protein (CRH-BP), and other neuromodulators can all regulate CRH-R signaling. In the heart, CRH-R2β mRNA decreases in response to Ucn. Lipopolysaccharide (LPS) increases plasma ACTH levels, which in turn decreases heart CRH-R2β mRNA. Corticosterone, dexamethasone, and physical restraint-induced stress decrease CRH-R2β mRNA in the heart and aorta. Tumor necrosis factor α (TNFα), interleukin-6 (IL-6), and IL-1α decrease CRH-R2β in A7R5 aortic smooth muscle cells. Systemic IL-1α and TNF administration significantly down-regulate CRH-R2 mRNA in mouse heart. *In vivo*, inflammatory mediators such as LPS and/or cytokines increase Ucn, which in turn down-regulates CRH-R mRNA levels. Because CRH and Ucn increase cardiac contractility and coronary blood flow, impaired CRH-R2 function during systemic inflammation may ultimately diminish the adaptive cardiac response to adverse conditions. Within the human heart, CRH-R signaling may be modulated in different pathological conditions, such as left ventricular hypertrophy, in which Ucn levels increase and CRH-R2β mRNA levels decrease. Both CRH-R1 and CRH-R2 are expressed in different regions within the human heart, but CRH-R1 has not been reported in mouse or rat heart. With the discovery of new CRH-R-selective peptides and differential heart receptor

TABLE 2 Summary of Signaling Components Activated by CRF Ligands at CRF-Rs in Specific Tissues and Cell Types

Tissue/cell[a]	CRF[b]	Ucn[b]	Ucn II[b]	Ucn III[b]	Sauvagine[b]
Anterior pituitary corticotrophs (r/h)	PKC, PKA, AC/cAMP, MAPK, Ca^{2+}, K^+, cGMP	PKC, PKA, AC/cAMP	cAMP	No response	cAMP
AtT-20 cells (m)	cAMP, PKA/MAPK	cAMP	cAMP response at high doses	No response	cAMP
Hippocampal neurons(r)	cAMP, PKA	$G_{\alpha s}$,$G_{\alpha o}$/AC/cAMP/PKA, MEK1, MAPK, PKC	No cAMP response	—[c]	—[c]
Cerebral cortex (r)	$G_{\alpha s}$/AC/cAMP, $G_{\alpha q}$/11/PLC/$InsP_3$/DAG/Ca^{2+}	$G_{\alpha s}$/AC/cAMP, $G_{\alpha q}$/11/PLC/$InsP_3$/DAG/Ca^{2+}	—[c]	—[c]	—[c]
Heart cells (r/m)	cAMP	MAPK, cAMP, PGs, ANP/BNP, release, PKA, PI-3K, PKB/Akt, voltage-dependent Ca^{2+} channel	—[c]	—[c]	—[c]
Skin cell types	AC/cAMP, Ca^{2+} influx via $G_{\alpha i}$, $G_{\alpha o}$, $InsP_3$s	AC/cAMP	—[c]	—[c]	AC/cAMP
Guinea pig gastric smooth antrum muscle	AC/cAMP	Ca^{2+}-sensitive K^+ currents, AC/cAMP, PKA/SR-Ca^{2+}-ATPase	—[c]	—[c]	—[c]
Retina(r)	$G_{\alpha s}$/cAMP	—[c]	—[c]	—[c]	—[c]
Myometrium (h)	$InsP_3$,AC/cAMP, PG_s, GC_m-PKA, cGMP, PKC, eNOS/bNOS, NO/GC_s cGMP	Gαq/PKC, PLC/$InsP_3$, PKC, Raf-1 kinase, MAPK, AC/cAMP	—[c]	—[c]	—[c]
Tail artery(r)	PKA, Ca^{2+}	PKA, Ca^{2+}	—[c]	—[c]	—[c]
Basilary artery (r)	AC/cAMP, PKA Ca^{2+}	AC/cAMP, PKA Ca^{2+}	—[c]	—[c]	—[c]
CATH.a cells	PKA, MAPK Ca^{2+}	—[c]	—[c]	—[c]	—[c]
CHO-R1α	cAMP	cAMP	cAMP response at high doses	No response	cAMP, MAPK, Ca^{2+}
CHO-R2β/α	cAMP	cAMP	cAMP	cAMP	cAMP, MAPK, Ca^{2+}
Blood cells	cAMP/Ca^{2+} PKA	—[c]	—[c]	—[c]	—[c]

[a] Tissues and cells were from rats (r), humans (h), or mice (m).
[b] All MAPK was P42/44 MAPK.
[c] Data not available.

expression, Ucn may exhibit differential signaling pathways in different areas of the heart.

In vivo, during sustained stress, elevated CRH levels result in a reduction of cAMP and ACTH release by rat corticotroph cells, due to down-regulation in expression of CRH-R1. A similar desensitization effect has been seen in other cell lines. The G-protein receptor kinases (GRK2/3) are involved in homologous desensitization of this receptor in a number of cell lines. An increase in PKC also decreases CRH-R expression and sensitivity to ligand in pituitary and myometrial cells. In human myometrial cells, oxytocin reduces CRH binding to CRH-Rs and AC activity (at term, during pregnancy, but not preterm) via PKC activation. PKC directly phosphorylates and desensitizes the CRH-R in human myometrial cells. In CATH.a cells, in addition to PLC and PKC, cAMP down-regulates CRH-R1 mRNA.

CRH-BP may selectively inhibit CRH and Ucn actions by inhibiting access of these ligands to their receptors. CRH-BP maintains appropriate levels of these peptides in the central nervous system and therefore controls their signaling.

CRH and Ucn interact with other signaling pathways. CRH and Ucn inhibit feeding by acting downstream of the leptin signaling pathway, and CRH modulates the immune system by regulating the secretion of cytokines and neuropeptides of purified macrophage and lymphocytes. Ucn inhibits LPS-induced increases in TNF and IL-1α *in vivo* and TNF release from Kupffer cell cultures. This supports the function of Ucn as an anti-inflammatory agent. CRH and Ucn are vasodilatory and have inotropic effects on the rat heart. Inhibiting cyclooxygenase inhibits the vasodilatory effect of Ucn, suggesting that Ucn regulates PG production in the rat heart and providing evidence that there is cross talk between pathways.

In the human myometrium, CRH controls symmetrical contractility, whereas IL-1α and oxytocin stimulate production of PGs. CRH partially inhibits IL-1α- and oxytocin-stimulated prostaglandin E2 (PGE2) production. This effect is dependent on the CRH-R and not on cyclooxygenases involved in PG synthesis. At term in pregnancy, there is a reduction in the functional ability of CRH to stimulate cAMP due to a reduction of the number of $G_{\alpha s}$ subunits and an inhibitory action of oxytocin, which activates PKC, leading to phosphorylation and desensitization of the CRH-R. In the human myometrium, a dose-dependent increase of trophoblast ACTH or PGE2 secretion is induced by Ucn and is inhibited by astressin (a CRH-R peptide antagonist). Ucn increases PGE2-induced myometrial contractility.

VIII. SUMMARY

CRH ligands activate specific intracellular signaling pathways in different cell types (see Table 2 for summary). A great deal of cross talk exists between the different CRH-R-mediated signaling pathways, in particular with regard to the cAMP/PKA pathway. The intricacies of CRH signaling probably reflect the presence of more than one receptor subtype and ligand in cells involved in orchestrating the endocrine and paracrine stress response. In addition, the coupling of these receptors to specific G-proteins provides a diversity of multiple signaling pathways that may be activated following CRH-R stimulation.

Glossary

adenylyl cyclase Enzyme that catalyzes conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). There are 10 known isoforms of the enzyme; 9 are membrane bound and 1 is soluble. The various forms of adenylyl cyclase (AC) are differentially regulated; however, all membrane-bound forms are stimulated by the stimulatory GTP-binding protein of AC, $G_{\alpha s}$. All but one membrane-bound AC isoform are stimulated by forskolin.

corticotropin-releasing hormone family of peptides Isolated in 1981, corticotropin-releasing hormone (CRH) was characterized as the major factor that orchestrates the endocrine stress response in mammals. Urocortin (Ucn) is a mammalian CRH-related peptide; two new members of the CRH peptide family, stresscopin-related peptide/urocortin II (Ucn II) and stresscopin/urocortin III (Ucn III), have recently been identified in humans, mice, and fish.

corticotropin-releasing hormone receptors Bind to two types of 7-transmembrane domain (TMD) G-protein-coupled receptors, CRH-R1 (type 1) and CRH-R2 (type 2).

extracellular signal-related kinases Belong to one subfamily of mitogen-activated protein kinases (MAPKs) composed of 42- and 44-kDa kinases, known as p42-ERK and p44-ERK, respectively. Phosphorylation and activation of p42-ERK and p44-ERK are mediated by MAPK kinase MEK1/2, commonly referred to as MEK1.

G-proteins Composed of three subunits, α, β, and γ. Activation of receptors that couple to G-proteins results in GTP exchanging for GDP on the α subunit, a process that can further activate a number of signaling pathways. The βγ subunit can itself activate a number of effectors.

mitogen-activated protein kinases Constitute a widely conserved family of serine/threonine protein kinases involved in many cellular programs, including proliferation, differentiation, movement, and death. MAPKs are phosphorylated and activated by MAPK kinases (MAPKKs) such as MEK1. Stress-activated protein kinase (SAPK)/JUN N-terminal kinase (JNK) and p38 are phosphorylated and activated by MAPK kinases, which in turn are phosphorylated and activated by MAPKK kinases (MAPKKKs). The MAPKKKs are activated by a family of small GTPases and/or protein kinases connecting the MAPK module to the cell surface receptor or to external stimuli.

protein kinase A Tetrameric holoenzyme that is activated when cAMP binds to its two regulatory subunits, resulting in release of active catalytic subunits. Three catalytic subunits have been identified, designated Cα, Cβ, and Cγ.

protein kinase B and phosphatidylinositol 3-OH kinase Phosphatidylinositol 3-OH kinase (PI-3K) consists of an 85-kDa regulatory (p85) and a 110-kDa catalytic (p110) subunit. It catalyzes the phosphorylation of PI to phosphatidylinositol 3-phosphate, PI-4-phosphate to PI-3,4-bisphosphate, and PI-4,5-bisphosphate to PI-3,4,5-trisphosphate. The products of PI-3K act on multiple downstream effectors, including the serine/threonine kinase, PKB/Akt. The activation of PKB/Akt requires phosphorylation on both Thr-308 and Ser-473 and the direct interaction of PI-3K lipid products with a pleckstrin homology domain at its N-terminus. The phosphorylation of Thr-308 is catalyzed by 3-phosphoinositide-dependent kinase-1 and may contribute to the phosphorylation of Ser-473.

protein kinase C Family of serine/threonine protein kinases that are activated by Ca^{2+} and/or phospholipids in response to extracellular signals. The isoforms of PKC have been classified into three groups: (1) classical PKCs are Ca^{2+} dependent and are activated by phosphatidylserine, diacyglycerol (DAG), and phorbol esters (such as phorbol myristic acid); (2) "novel" PKCs are Ca^{2+} independent; and (3) atypical PKCs do not require DAG and Ca^{2+} for their activation.

Corticotropin-Releasing Hormone, Stress, and the Immune System

SUSAN E. MURRAY AND MARY P. STENZEL-POORE
Oregon Health and Science University, Portland

The neuroendocrine and immune systems are activated during times of threat to survival. The former is activated during psychological or physical stress, and both are activated during infection, or immunological stress. Thus, stress-activated pathways and immune responses are coregulated and intimately affect one another. Corticotropin-releasing hormone is a principal regulator of the stress response through activation of the hypothalamic–pituitary–adrenal axis as well as through stress-responsive pathways in the central nervous system.

I. INTRODUCTION

This article focuses primarily on the effects that stress and corticotropin-releasing hormone (CRH)-activated pathways have on immunity. Anecdotal and clinical evidence suggest that major life stress may dispose individuals to increased risk for illness, including infectious disease. This has led to the idea that compromised immunity may play a role in stress-related diseases. In fact, various measures of immune function have been shown to be altered during chronic stress, such as during long-term care giving or following the death of a family member. For instance, antibody responses to vaccination and several measures of cellular immunity are correlated negatively with life stress. However, the relationship between altered immune parameters and increased susceptibility to infectious disease in humans is difficult to define. Although gross immunosuppression (such as during human immunodeficiency virus infection) clearly increases susceptibility, it is unknown if smaller alterations in individual immune parameters bear significant consequence for infectious disease in otherwise healthy adults. Furthermore, a limited number of immune functions can be measured in humans. Such difficulties have driven the development of animal models to address these questions. Thus, much of the following discussion is derived from studies of animal models of stress.

II. STRESS-ACTIVATED PATHWAYS

Corticotropin-Releasing Hormone, Stress, and the Immune System

SUSAN E. MURRAY AND MARY P. STENZEL-POORE
Oregon Health and Science University, Portland

The neuroendocrine and immune systems are activated during times of threat to survival. The former is activated during psychological or physical stress, and both are activated during infection, or immunological stress. Thus, stress-activated pathways and immune responses are coregulated and intimately affect one another. Corticotropin-releasing hormone is a principal regulator of the stress response through activation of the hypothalamic–pituitary–adrenal axis as well as through stress-responsive pathways in the central nervous system.

I. INTRODUCTION

This article focuses primarily on the effects that stress and corticotropin-releasing hormone (CRH)-activated pathways have on immunity. Anecdotal and clinical evidence suggest that major life stress may dispose individuals to increased risk for illness, including infectious disease. This has led to the idea that compromised immunity may play a role in stress-related diseases. In fact, various measures of immune function have been shown to be altered during chronic stress, such as during long-term care giving or following the death of a family member. For instance, antibody responses to vaccination and several measures of cellular immunity are correlated negatively with life stress. However, the relationship between altered immune parameters and increased susceptibility to infectious disease in humans is difficult to define. Although gross immunosuppression (such as during human immunodeficiency virus infection) clearly increases susceptibility, it is unknown if smaller alterations in individual immune parameters bear significant consequence for infectious disease in otherwise healthy adults. Furthermore, a limited number of immune functions can be measured in humans. Such difficulties have driven the development of animal models to address these questions. Thus, much of the following discussion is derived from studies of animal models of stress.

II. STRESS-ACTIVATED PATHWAYS

Stress-activated systems originate in the brain. To regulate the immune system, signals generated in the central nervous system (CNS) must be translated to the periphery. This is accomplished through two

primary systems—the hypothalamic–pituitary–adrenal (HPA) axis and the sympathetic nervous system (SNS). The central components of these systems are located in the paraventricular nucleus (PVN) of the hypothalamus, which produces CRH, and the locus coeruleus (LC) in the brain stem, a site of catecholamine production (Fig. 1).

CRH is a 41-amino-acid neuropeptide that is produced in numerous brain regions, although the name CRH reflects stimulatory actions on adrenocorticotropic hormone (ACTH). CRH produced by neurons of the PVN travels the hypophyseal portal system and binds CRH type 1 receptors on pituitary corticotrophs, which causes secretion of ACTH into the bloodstream. ACTH, in turn, drives release of glucocorticoids (cortisol in humans, corticosterone in rodents) from the adrenal cortex (Fig. 1). Peripheral SNS effects are mediated primarily by catecholamine release from peripheral nerves, although some fibers release neuropeptides. Postganglionic SNS fibers that originate in the brain stem innervate peripheral organs and, for the most part, release norepinephrine. Additionally, preganglionic fibers innervate the adrenals and cause the release of epinephrine and, to a lesser extent, norepinephrine (Fig. 1).

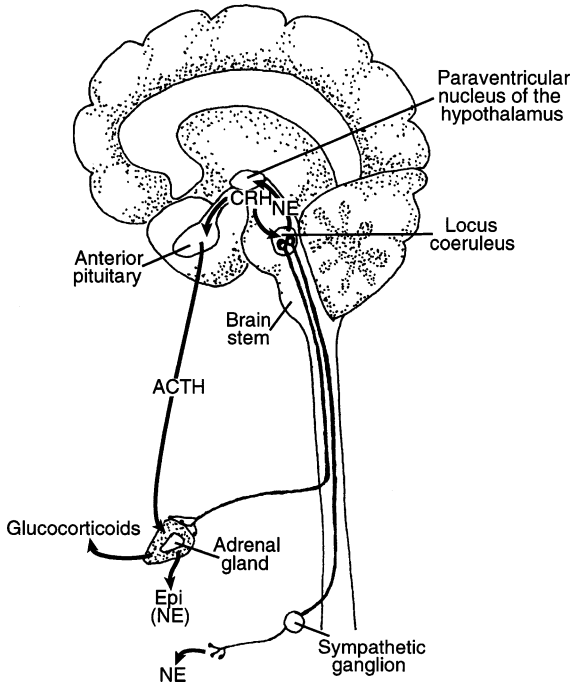

FIGURE 1 Components of the stress system. Two major stress-responsive systems are shown, the hypothalamic–pituitary–adrenal axis and the sympathetic nervous system. Corticotropin-releasing hormone (CRH)-producing neurons of the paraventricular nucleus of the hypothalamus and norepinephrine (NE)-producing neurons of the locus coeruleus positively regulate one another. CRH from the paraventricular nucleus causes adrenocorticotropic hormone (ACTH) release from the anterior pituitary, which then induces glucocorticoid release from the adrenal cortex. Sympathetic nerves innervate the adrenal directly or synapse at a sympathetic ganglion, causing peripheral release of epinephrine (Epi) and norepinephrine (NE).

The CRH and LC-norepinephrine systems are enjoined in a mutual positive regulation. Thus, hypothalamic CRH activates not only the HPA axis, but also the SNS through release of CRH from projections to the brain stem. Conversely, catecholaminergic (primarily norepinephrine) fibers that project from the LC to the hypothalamus activate CRH (Fig. 1).

III. IMMUNE SYSTEM

The immune system defends the body against invading bacterial, viral, and parasitic pathogens as well as malignancies. For simplicity, the immune system can be divided broadly into two arms, the innate and the adaptive. The innate immune system is a rapid, nonspecific first line of defense against infection. Innate effector cells include phagocytes such as macrophages, monocytes, dendritic cells, and neutrophils, which bind and ingest pathogens nonspecifically and in some cases release microbicidal molecules. Additionally, granular lymphocytes known as natural killer (NK) cells contribute to innate immunity by recognizing surface changes on virus-infected and malignant cells and targeting them for destruction. The innate immune response also causes release of acute-phase proteins, which aid directly in pathogen clearance and may promote host survival by inducing fever and adaptive behavior, i.e., sickness behavior (malaise, appetite suppression).

In contrast, the adaptive immune system is slower to respond but is more specific and allows for the development of immunologic memory. Lymphocytes, which express unique antigen receptors, must bind the infectious agent and undergo multiple rounds of proliferation. A portion of the expanded population persists as memory cells, which respond more quickly and robustly if the same pathogen is encountered again. T lymphocytes, responsible for "cellular" immunity, recognize small peptides from pathogenic proteins that are presented on the surface of cells harboring a pathogen. When stimulated, T lymphocytes produce cytokines to aid macrophages or B lymphocytes, or directly kill the antigen-presenting cell. B lymphocytes are responsible for "humoral" immunity. Stimulation through the B-cell antigen

receptor induces secretion of pathogen-specific antibodies that cause uptake, destruction, or neutralization of a pathogen.

The innate and adaptive arms of the immune system do not operate in isolation, but regulate one another. Importantly, the innate immune system produces cytokines, which help recruit lymphocytes to the site of injury and alert the adaptive immune system of danger. Cytokines fall generally into two "helper" categories, T_H1 and T_H2. T_H1 cytokines are proinflammatory and preferentially activate cellular immunity. T_H2 cytokines, in contrast, are anti-inflammatory and preferentially activate humoral immunity.

IV. HPA ACTIVATION AND IMMUNE EFFECTS

Glucocorticoids, a downstream product of HPA activation, exert a wide array of immunomodulatory effects. A vast literature documents effects of glucocorticoids on various immune parameters; however, much of this research has been done *in vitro* or *in vivo* using synthetic glucocorticoids (i.e., dexamethasone, prednisolone) at supraphysiologic concentrations. Thus, the discussion here focuses on immune alterations observed with endogenous glucocorticoids produced in response to stress or CRH activation.

A. Inflammation

A major role of glucocorticoids is to limit inflammation during an immune response. The proinflammatory cytokines interleukin-1β (IL-β), IL-6, and tumor necrosis factor α (TNFα) are released very early during an immune response. These cytokines act as signals of immunologic stress, activating the HPA axis at the level of the pituitary and hypothalamus. Glucocorticoids produced in response to hypothalamic–pituitary activation then inhibit cytokine production from leukocytes (Table 1). This negative regulatory loop is crucial during intense inflammatory processes, such as sepsis; without this feedback, elevated cytokine levels cause fever, vascular leakage, and subsequent organ failure, leading to death. Thus, linking the HPA axis with immune activation is an adaptive response, designed to control excess inflammation during immune responses. Clinicians take advantage of this property of glucocorticoids to treat chronic inflammatory diseases such as asthma and rheumatoid arthritis. However, a certain degree of inflammation is necessary for immune activation to signal the host of an invading pathogen. Thus, overactivity of the HPA axis during a non-immune-type stress (e.g., starvation, predator attack, social stress) may alter how the immune system responds to a subsequent pathogenic insult.

TABLE 1 Effects of Glucocorticoids on the Immune System

Target	Effect
Precursor lymphocytes	Apoptosis
Pro-inflammatory cytokines	Decreased
Th 1/Th 2 balance	Shift toward Th 2
Cytotoxic T lymphocytes	Decreased cytotoxicity
DTH response/leukocyte traffic to skin	Augmented (acute); inhibited (chronic)
Neutrophils	Increased numbers
B lymphocytes	Decreased IgG/memory responses

B. Leukocyte Populations

One well-studied immunomodulatory effect of HPA activation is lymphocyte death. B and T lymphocytes alike are sensitive to glucocorticoid-induced apoptosis, with immature lymphocytes being most sensitive (Table 1). Extended periods of HPA activation cause a striking decrease in thymus cellularity as well as more modest changes in spleen and lymph node size—the largest decrement occurring in lymphocyte populations.

However, it is important to appreciate that the effects of glucocorticoids are dependent on cell type and duration of exposure. For instance, glucocorticoids increase neutrophil numbers by increasing their release from the bone marrow and lengthening their half-life. In addition, short periods of stress affect lymphocyte populations through trafficking rather than cell death (Table 1). Glucocorticoids released during acute stress decrease most populations of circulating leukocytes, but these cells are redistributed to the skin and lymphoid organs (spleen and lymph nodes). This redistribution is thought to be adaptive because injury and/or infection are likely to accompany acute stress; thus, mobilization of immune cells to the site of pathogen entry (the skin) and to the sites of lymphocyte activation (peripheral lymphoid organs) prepares the host for possible infection.

C. Leukocyte Function

Glucocorticoids can also affect immune function, both directly and through leukocyte trafficking as mentioned previously. For instance, the leukocyte redistribution during acute stress correlates with enhanced T-cell-mediated immune responses in the skin [delayed-type hypersensitivity (DTH) reaction].

This again demonstrates the idea that acute and chronic stress will often exert distinct immunomodulatory effects, because the same stressor (restraint in this case) applied chronically induces the opposite effect—the DTH response is decreased significantly (Table 1). This effect of chronic stress is due primarily to glucocorticoids, which may also inhibit cellular immunity by shifting the balance of cytokine response from a T_H1 to a T_H2 type. Additionally, glucocorticoids produced during chronic stress diminish the cytolytic function of cytotoxic T lymphocytes (Table 1). This impairment likely bears relevance to disease progression because it correlates with herpes virus reactivation during chronic social stress.

The effects of glucocorticoids on B lymphocyte function are less clear. Stress has been shown to decrease antibody responses to pathogens or protein antigens in both human and animal studies. Generally, immunoglobulin G (IgG) and secondary (memory) responses are more severely diminished, whereas IgM and primary responses are minimally affected. Some evidence indicates that the impairment may stem from lack of adequate T-cell help, rather than direct effects on B lymphocytes. However, few studies that examined the effect of stress on antibody production have determined the mediators of this suppression. In one case, SNS activation appears important, but in transgenic mice overexpressing CRH, elevated levels of glucocorticoids are likely involved.

V. HPA-INDEPENDENT EFFECTS ON IMMUNITY

A. Effects of SNS Activation

Activation of the SNS is also involved in immunomodulation. Effects can be mediated by circulating catecholamines released from the adrenals or by catecholamines released from nerve fibers that innervate lymphoid organs (Fig. 1). SNS activation accounts, in large measure, for stress- and CRH-mediated suppression of NK activity as well as some degree of T lymphocyte cytotoxicity (Table 2). In addition, catecholamines favor development of T_H2-type cytokines by the immune response (Table 2). It should be noted that distinct immune compartments may respond differently to these stress mediators; for example, splenic T-cell responses are suppressed by catecholamines whereas blood T-cell responses are unaffected. Also, in many circumstances immune effects of stress or CRH result from a combination of HPA and SNS activation, with partial effects seen when one pathway is blocked.

TABLE 2 Non-HPA Effects of Stress on the Immune System

Catecholamines	Peripheral CRH/Ucn I, II, III
Shift toward Th 2 cytokines	Augment inflammation
Decrease cytotoxic responses	Increase pro-inflammatory cytokines
Decrease Ig responses	Augment mast cell degranulation

B. Direct Effects of CRH

CRH expression is most robust in the CNS and rarely detected in the circulation. However, CRH is also found peripherally, where it is produced locally in peripheral tissues or released from peripheral nerves. In addition, the discovery of several neuropeptides related to CRH adds to the family of ligands that can bind CRH receptors. The first of these, urocortin I (Ucn I), was originally identified in mammals by homology with the fish peptide, urotensin, which is involved in osmotic regulation. Subsequently, Ucn II and Ucn III (in humans also referred to as stresscopin-related peptide and stresscopin, respectively) were discovered based on sequence similarity with Ucn I. All three urocortins are expressed in the CNS as well as in the periphery, including immune compartments. Ucn II and Ucn III are selective agonists for the CRH type 2 receptor, and, unlike the CRH type 1 receptor, CRH type 2 receptor is highly expressed outside of the CNS. Therefore, immune actions previously attributed to CRH may, in fact, be mediated by a related peptide. Several types of leukocytes (e.g., T lymphocytes, neutrophils, and monocytes) express CRH receptors and, in the case of neutrophils, CRH receptor expression increases on immunologic or psychological stress. Most studies on direct effects of CRH in the immune system have been performed *in vitro* and demonstrate that CRH stimulates various leukocyte populations to increase proliferation or cytokine production. Studies that have shown a physiologic effect of endogenously produced CRH have primarily examined inflammatory processes.

In contrast to its action via glucocorticoids, peripheral CRH appears to be proinflammatory, increasing exudate in models of aseptic inflammation and enhancing proinflammatory cytokine production (Table 2). This effect may be due in part to vasodilation and increased vascular permeability, but leukocyte populations are probably direct targets as well. In addition, CRH induces mast cell degranulation via direct actions on CRH receptors expressed by these cells (Table 2). Histamine released from mast cell

degranulation mediates acute inflammation and allergic responses. The precise source of CRH during these inflammatory processes is not certain, but inflamed tissue can show immunoreactivity for CRH, as can infiltrating leukocytes. Furthermore, peptidergic nerve fibers are associated closely with mast cells in perivascular spaces and lymphoid tissues.

VI. CONCLUSIONS AND PERSPECTIVES

Stress clearly exerts profound influence over immunity through activation of CRH-responsive pathways. We are beginning to define these pathways and their immune targets, but a major challenge remains in determining the consequences of stress-induced immunomodulation on human health. It is simplistic, perhaps, to view stress as immunosuppressive. Activation of stress pathways results in an array of specific immune alterations; some cell populations or functions are augmented while others are inhibited. In acute stress, many of these changes are likely adaptive, regulating the immune response to avoid overactivation or directing effector cells to susceptible sites. Chronic activation of these pathways, however, threatens immune function and leads to serious impairments in health and survival against pathogens.

Glossary

catecholamines A class of neurotransmitters, including epinephrine and norepinephrine, involved in autonomic nervous system actions.

cytokines Leukocyte-secreted proteins that affect the behavior of other cells.

glucocorticoids A class of adrenal-gland-secreted steroid hormones involved in regulating metabolism and immune activation.

immunoglobulins Also known as antibodies; a secreted form of B lymphocyte antigen receptors that bind to pathogens.

leukocytes Cells of hematopoietic origin; i.e., white blood cells.

lymphocytes Leukocytes that express antigen receptors encoded by rearranged gene segments.

sympathetic nervous system A division of the autonomic nervous system that mediates responses to stress, e.g., increased heart rate, blood pressure, and energy mobilization.

Cripto

CATERINA BIANCO*, NICOLA NORMANNO†, DAVID S. SALOMON‡, AND FORTUNATO CIARDIELLO*

*Università di Napoli "Federico II" • †Istituto Nazionale Tumori Napoli • ‡National Cancer Institute, Maryland

Cripto is a glycoprotein member of the epidermal growth factor (EGF) related family of growth factors and has a length of 188 amino acids. Cripto protein is produced in large amounts by human undifferentiated teratocarcinoma cells and the murine P9 teratocarcinoma cell line. Cripto transcripts are detected only in undifferentiated cells and disappear from the cell after its differentiation induced by treatment with retinoic acid and hexamethylenbisacetamide. Cripto can function as a dominantly acting oncogene because its over expression in mammary epithelial cells can lead to transformation *in vitro*.

I. INTRODUCTION

The EGF (epidermal growth factor)–CFC (cysteine-rich domain) family consists of extracellular, cell-associated proteins that have been identified in several vertebrate species. Members of this family of genes include human Cripto-1 (CR-1) (also known as teratocarcinoma derived growth factor-1/TDGF-1) and criptin, mouse cripto-1 (Cr-1) and *cryptic*, chicken Cripto, *Xenopus laevis* FRL-1, and zebrafish *one-eyed pinhead* (*oep*).

Multiple copies of cripto-related sequences are present in the human and mouse genomes. At least five other human Cripto-1 (CR-1)-related pseudogenes and two mouse cripto-1 (Cr-1) pseudogenes have been identified. The EGF (epidermal growth factor)–CFC (cysteine-rich domain) family of proteins has a general profile consisting of a potential amino-terminal signal peptide, a variant EGF-like motif, a conserved CFC region, and a short hydrophobic carboxy-terminus that is essential for membrane anchorage by a glycosylphosphatidylinositol moiety. The overall sequence identity between these proteins is only 22–32%, whereas in the EGF-like domain the sequence similarity is nearly 60–70% and in the CFC domain is 35–48%. The variant EGF-like domain is a region of approximately 40 amino acids containing six cysteine residues that can form three intramolecular disulfide bonds. Although in the canonical EGF-like domain three loops (A, B, and C) can be recognized, the variant EGF-like domain in the EGF–CFC proteins lacks the A loop, possesses a truncated B loop, and has a complete C loop. This differentiates the EGF–CFC proteins from other members of the EGF family of growth factors such as EGF, transforming growth factor-α (TGF-α), amphiregulin (AR), and heregulins. Since members of the EGF–CFC family lack the A loop, this suggests that these proteins do not directly bind to any of the *erb* B type I tyrosine kinase receptors, including the epidermal growth factor receptor (EGFR), *erb* B-2, *erb* B-3, and *erb* B-4. EGF–CFC proteins range from 171 to 230 amino acids with a core protein of 15–21 kDa. Native mouse and human cripto proteins range in size from 24 to 36 kDa but additional proteins ranging in size from 14 to 60 kDa have been identified by gel electrophoresis. This variation in size could be due to the removal of the hydrophobic signal peptide and to posttranslational modifications of the core protein. In fact, all the members of the EGF–CFC family, except for *oep*, are glycoproteins that contain a single N-glycosylation site and potential O-glycosylation sites. Recently, a single O-linked fucosylation site has been found between the second and the third cysteines in the EGF-like domain of all the EGF–CFC proteins. This rare modification is also present in the EGF domain of secreted proteins involved in blood coagulation or clot dissolution such as blood coagulation factor VII and urokinase plasminogen activator and in *Drosophila melanogaster* and mammalian Notch1, and it is critical for cell signaling and receptor binding. EGF–CFC proteins also contain several potential myristylation sites and consensus sequence for potential phosphorylation on serine and threonine by protein kinase C, cyclic AMP-dependent protein kinase A (PKA), and casein kinase II.

II. THE EGF–CFC FAMILY IN EMBRYONIC DEVELOPMENT

During early mouse embryogenesis, low levels of Cr-1 mRNA expression can first be detected by reverse transcription–polymerase chain reaction in the inner cell mass of the postimplantation mouse blastocyst at day 4 of development. By *in situ* hybridization, Cr-1 mRNA expression is restricted to the epiblast cells of the primitive streak, to the developing mesoderm during gastrulation, and later to the myocardium of the truncus arterious of the developing heart. After day 8, very little expression of Cr-1 can be detected in the embryo, with the exception of the developing heart. Cr-1 protein expression has also been detected in the developing embryo by Western blot analysis. In concordance with Cr-1 mRNA expression, Cr-1 protein is found in the developing mesoderm at day 6.5 and in the myocardium of the developing heart at later fetal stages. The presence of Cr-1 in the developing cardiac outflow suggests that it may play an essential role during embryonic cardiac development and differentiation. In this respect, Cr-1-deficient pluripotential embryonic stem cells lose their ability to differentiate *in vitro* in cardiomyocytes, whereas they maintain the ability to differentiate in other cell types. Germ-line knockout of mouse Cr-1 is embryonically lethal, with homozygous embryos lacking a primitive streak and embryonic mesoderm. In particular, homozygous embryos are composed mostly of anterior neuroectoderm with a severe loss of mesoderm and endoderm. Furthermore, mouse Cr-1 is necessary for the correct orientation of the anterior–posterior (A–P) axis, since in homozygous embryos markers of the head organizer are localized in the distal visceral endoderm and markers of the primitive streak are located in the proximal epiblast. In contrast, heterozygous embryos are normal, suggesting that Cr-1 produced by the wild-type host is able to rescue the mutant phenotype. Genetic studies have also demonstrated that zebrafish *oep* and mouse cryptic are involved in the establishment of the left–right (L–R) embryonic axis. In this regard, mutation of *oep* in zebrafish and targeted disruption of cryptic in the mouse result in several L–R laterality defects including randomization of cardiac looping and atrial–ventricular septal defects, right pulmonary isomerization, inverted situs of the spleen, pancreas, and stomach, hyposplenia, and heterotaxia. Moreover, embryos that lack both maternal and zygotic activity of *oep* display a severe phenotype characterized by cyclopia, lack of head, trunk, mesoderm, and endoderm, and altered orientation of the A–P axis. Recent data have demonstrated that zebrafish *oep* is an essential component of the signaling pathway of the zebrafish Nodal-related genes *cyclops* and *squint* and can function as a possible co-receptor or competence factor for Nodal-related proteins. Nodal-related proteins and *oep* subsequently signal through the downstream activin type IIB and type I (ALK4) receptors that induce Smad-2 and Smad-4 activation. In fact, mutations in *oep*, *cyclops*, and *squint* display a similar phenotype, suggesting that they act in the same pathway. The *oep* mutant phenotype can be rescued by expression of a full-length or secreted carboxy-terminal truncated *oep* protein, overexpression of activin, or activation of downstream components in the activin signaling pathway, such as ALK4 or Smad-2. Recently, mouse Cr-1 has been shown to bind to the ALK4/ActRIIB receptor complex and to induce Smad-2 phosphorylation in a Nodal-dependent fashion when ectopically expressed in *Xenopus* oocytes.

III. BIOLOGICAL EFFECTS OF EGF–CFC PROTEINS IN MAMMALIAN CELLS

The first evidence of the biological activity associated with cripto-1 in mammalian cells was provided by studies that demonstrated the ability of human CR-1 to transform mouse NIH 3T3 fibroblasts, mouse NOG-8 mammary epithelial cells, and mouse CID-9 mammary epithelial cells *in vitro*. However, NOG-8- and CID-9-transformed cells are unable to form tumors in nude mice, suggesting that additional genetic alterations are necessary to complete the tumorigenic phenotype *in vivo*. In rat CREF embryo fibroblasts or rat FRLT-5 thyroid epithelial cells that have been transformed by either c-Ha-*ras* or c-Ki-*ras* proto-oncogenes, respectively, expression of rat Cr-1 is up-regulated. Reversion of the transformed phenotype by overexpression of a *ras* suppressor gene, K*rev*-1, results in a loss of expression of rat Cr-1, suggesting that Cr-1 might significantly contribute to cellular transformation induced by p21 *ras*. Overexpression of mouse Cr-1 in primary mouse mammary epithelial cells induces lateral ductal branching and clonal expansion of ductal hyperplasias when these cells are reintroduced into the cleared mammary fat pad of syngeneic, ovariectomized virgin mice. However, mammary carcinomas have not been observed in these hyperplastic outgrowths even after several *in vivo* transplantations. When inserted into the fourth inguinal mammary gland of ovariectomized mice, slow-release Elvax pellets containing a peptide corresponding to the EGF-like domain of

CR-1 produce a 20-fold increase in DNA synthesis in the adjacent epithelial cells and a 3-fold increase in lateral ductal branching in the areas surrounding CR-1 pellets. A comparable *in vitro* effect has also been observed with recombinant human CR-1 protein or with different mouse mammary epithelial cells overexpressing mouse Cr-1. In fact, NMuMG, TAC-1, and EpH4 mouse mammary epithelial cells overexpressing Cr-1 when cultured in a three-dimensional type 1 collagen gel matrix are able to form branching tubules. Furthermore, all the Cr-1-transfected mouse mammary epithelial cells and human Caski cervical carcinoma cells overexpressing CR-1 exhibit an increase in migratory potential in Boyden chamber studies and in wound healing assays. Exogenous, recombinant CR-1 protein is also able to stimulate chemotaxis of wild-type EpH4 cells and can induce scattering of NOG-8 mammary epithelial cells grown at low density as colonies on plastic. The ability of Cr-1 to stimulate both scattering and branching morphogenesis in collagen gels is similar to the effects induced by hepatocyte growth factor or transforming growth factor-β1 (TGF-β1) in mammary epithelial cells. The scattering effect is characterized by a change in the morphology of the epithelial cells to a more fibroblastic-like phenotype and is characterized by a decrease in cell–cell adhesion. In this respect, loss of expression in β-catenin or an increase in tyrosine phosphorylation of β-catenin can inhibit its association with E-cadherin, facilitating cell scattering and migration. In fact, Cr-1-overexpressing mouse mammary epithelial cells exhibit an enhanced basal level of tyrosine phosphorylation of β-catenin, resulting in a decreased association with E-cadherin.

Another property associated with CR-1 is the ability to modulate milk protein expression in HC-11 mouse mammary epithelial cells. HC-11 mouse mammary epithelial cells express the milk protein β-casein at confluency after exposure to the lactogenic hormones dexamethasone, insulin, and prolactin (DIP). Similar to other EGF-related peptides, pretreatment of HC-11 cells with CR-1 during logarithmic growth induces a competency response to DIP with respect to the induction of the milk protein β-casein. In contrast, simultaneous treatment of HC-11 cells with CR-1 in the presence of DIP inhibits β-casein expression. This inhibitory effect of CR-1 on β-casein expression in response to DIP is not unique to this mouse mammary epithelial cell line, since β-casein expression is also inhibited by CR-1 in primary mouse mammary explant cultures established from midpregnant mice. The ability of CR-1 to block lactogenic hormone-induced expression of β-casein is mediated through a $p21^{ras}$-dependent, phosphatidylinositol 3-kinase (PI3K) pathway. CR-1 can also induce apoptosis in HC-11 mouse mammary epithelial cells when they are grown under serum-restricted and survival factor-deprived conditions. Apoptosis is mediated through the induction of a caspase-3-like protease and down-regulation of the expression of the anti-apoptotic protein Bcl-X_L. However, the effects of CR-1 on apoptosis in some tumor cell lines are completely different. In this respect, CR-1 can function as a survival factor protecting human cervical carcinoma cells from apoptosis through a PI3K/AKT-dependent signaling pathway.

IV. CR-1 RECEPTOR AND DOWNSTREAM SIGNALING PATHWAYS

Human CR-1 is not able to directly bind to the EGFR or to *erb* B-2, *erb* B-3, or *erb* B-4 type I receptor tyrosine kinases when they are ectopically expressed either alone or in various pairwise combinations in Ba/F3 mouse pro-B lymphocytes or mouse 32D myeloid cells. Rather, CR-1 binds to a specific high-affinity saturable receptor that does not interact with other EGF-related peptides. Interestingly, CR-1 can indirectly enhance the specific tyrosine phosphorylation of *erb* B-4 in several different mouse and human mammary epithelial cells either by facilitating heterodimerization of *erb* B-4 with a novel CR-1 receptor or by indirectly stimulating *erb* B-4 tyrosine phosphorylation through a soluble *src*-like tyrosine kinase. Finally, chemical cross-linking of ^{131}I-CR-1 to mouse and human mammary epithelial cells identifies two bands of 60 and 120 kDa, suggesting the presence of a novel multicomponent receptor complex for CR-1. Recently, using an immunoglobulin CR-1 fusion protein, specific binding and localization of CR-1 receptor were detected in mouse mammary epithelial cells and in the developing mouse mammary gland. Interestingly, the immunoglobulin–CR-1-binding pattern in the mouse mammary gland significantly correlates with the expression of the mouse Cr-1 protein, suggesting that Cr-1 may function in an autocrine pathway with its putative receptor during development of the mammary gland.

CR-1, on binding to its unknown receptor, can activate the *ras*/*raf*/mitogen-activated protein kinase (MAPK) pathway in several types of nontransformed and malignant human mammary epithelial cells. In particular, CR-1 full-length protein or a p47 refolded peptide corresponding to the EGF-like domain can induce a rapid and transient increase in the tyrosine

phosphorylation of p66, p52, and p46 isoforms of the adapter protein Shc (Src homology and collagen), facilitating its association with growth factor receptor-binding protein 2 and leading to the subsequent downstream activation of p42 and p44 isoforms of MAPK. Furthermore, CR-1 is able to stimulate the tyrosine phosphorylation of the p85 regulatory subunit of PI3K and induce the phosphorylation of AKT and glycogen synthase kinase 3β in HC-11 mouse mammary epithelial cells and in SiHa human cervical carcinoma cells. Although CR-1 is involved in a Nodal signaling pathway during embryonic development, activation of an activin/TGF-β signaling pathway in mammalian cells by CR-1 has not been demonstrated yet.

V. EXPRESSION OF CR-1 IN HUMAN CARCINOMAS AND PREMALIGNANT LESIONS

CR-1 is overexpressed, relative to noninvolved adjacent tissue, in approximately 50–90% of carcinomas that arise in the colon, breast, stomach, pancreas, gallbladder, ovary, endometrium, and cervix. Additionally, enhanced expression of CR-1 has also been detected in premalignant lesions in the breast, colon, stomach, and gallbladder, suggesting that CR-1 overexpression might be an index of precancerous changes in some of these tissues. For example, the frequency and the level of CR-1 expression in colon adenomas or intestinal metaplasia in the stomach are directly correlated with the size, histological subtype, and degree of dysplasia in these lesions. The gradual increase in CR-1 expression that is observed in the multistage process that evolves from colon adenoma to carcinoma suggests that CR-1 might be an early marker for malignant transformation in the colon. In this context, immunoreactive CR-1 has been detected in approximately 60% of colon mucosa specimens from individuals with a high risk of colorectal carcinoma, but in only 20% of colon mucosa from low-risk individuals. A statistically significant correlation has also been found between a high proliferation rate and increased expression of CR-1 in the mucosa specimens from high-risk individuals. Finally, expression of CR-1 in the adjacent noninvolved colon epithelium surrounding colon tumors is significantly correlated with increased lymph node involvement and with a higher rate of recurrence of colorectal cancer.

Since CR-1 is expressed at high levels in several different types of human malignancies, different approaches have been successfully used to impair CR-1 expression in several human carcinoma cells. In fact, the *in vitro* growth of human colon, breast, ovarian, and teratocarcinoma cell lines is significantly inhibited following treatment with specific anti-CR-1 antisense oligonucleotides or transfection with antisense expression vectors directed against CR-1. Furthermore, inhibition of CR-1 expression in GEO colon cancer cells significantly reduces their tumorigenicity *in vivo* in nude mice. Data from several studies suggest that CR-1 cooperates with other EGF-related peptides in sustaining the proliferation of human cancer cells through autocrine pathways. Therefore, a combination of different antisense oligonucleotides directed against various EGF-related growth factors has been used in human cancer cells. In fact, treatment of human colon, breast, and ovarian carcinoma cells with a combination of antisense oligonucleotides directed against AR, TGF-α, and CR-1 results in a more efficient growth inhibition *in vitro* when compared with treatment with a single oligonucleotide. In addition, a combination of the three antisense oligonucleotides directed against AR, TGF-α, and CR-1 is able to induce programmed cell death in human breast cancer cells, whereas treatment with a single oligonucleotide does not increase apoptosis, suggesting that EGF-related growth factors cooperate in the regulation of cell survival. Finally, a combination of AR, TGF-α, and CR-1 antisense oligonucleotides significantly inhibits the growth of human colon xenografts *in vivo* in nude mice. A significant reduction in microvessel count can also be observed in mice treated with a combination of the three antisense oligonucleotides. Furthermore, interesting results have been obtained using combinations of CR-1 antisense oligonucleotide with conventional chemotherapeutic drugs in colon cancer cells. In a clonogenic assay, an additive *in vitro* growth inhibitory effect has been observed when GEO cells are pretreated with different concentrations of 5-fluorouracil, adriamycin, *cis*-platinum, or mitomycin followed by treatment with a CR-1 antisense oligonucleotide. Recently, promising results have been obtained using a combination of a novel mixed-backbone CR-1 antisense oligonucleotide with agents that block intracellular signal transduction pathways, such as humanized anti-EGFR monoclonal antibody (MAb C225) and 8-Cl-cAMP, an inhibitor of type I PKA. Low doses of each agent produce only a 15–35% growth inhibition in GEO colon cancer cells *in vitro*. In contrast, a combination of CR-1 antisense oligonucleotide with either MAb C225 or 8-Cl-cAMP induces a synergistic

anti-proliferative effect *in vitro* in GEO cells. Furthermore, when the three agents are combined, a nearly complete inhibition of GEO growth *in vitro* is observed. Combination of the three agents also induces apoptosis, whereas a single treatment or combination of two agents does not have any apoptotic effect.

Glossary

cripto Cripto is a novel growth factor that is normally expressed during embryonic development in a select group of fetal tissues. Cripto is also expressed at high levels in several types of human cancers.

embryogenesis The development of an individual from a fertilized ovum; the process of embryo formation.

nucleotide The hydrolysis product of a nucleic acid, consisting of a purine or pyrimidine base combined with a ribose or deoxyribose sugar and a phosphate group; a phosphate ester of a nucleoside.

Crosstalk of Nuclear Hormone Receptors with STAT Factors

CARRIE S. SHEMANKO* AND BERND GRONER†

**University of Calgary • †Institute for Biomedical Research, Frankfurt*

Nuclear hormone receptors interact with signal transduction and transcription (Stat) molecules to regulate genes. Crosstalk, the convergence of different signaling pathways, occurs between the receptors and the Stat family of proteins

during gene transcription and provides an additional level of regulation. The molecular mechanisms by which crosstalk is accomplished depend on the nuclear hormone receptor, the Stat protein, and the promoter sequence.

I. INTRODUCTION

A. Transcriptional Regulation by Nuclear Receptors as Ligand-Dependent Transcription Factors and as Cofactors

The classic model of transcriptional regulation by nuclear hormone receptors involves binding of monomers, homodimers, or retinoid X receptor (RXR) heterodimers to DNA regulatory sequences in the promoters of target genes. The DNA response element for monomers is a single hexameric site. Homodimers or heterodimers bind to two hexameric motifs arranged as palindromes, inverted palindromes, or direct repeats. The arrangement and spacing of the DNA response element help to determine binding specificity. Some hexameric response elements can mediate the transcriptional response from more than one ligand–receptor complex, resulting in transcriptional control of target genes from overlapping signals (e.g., thyroid hormones and retinoic acid).

Dimerization is mediated by the multifunctional ligand-binding domain (LBD) as well as the DNA-binding domain (DBD) of the nuclear hormone receptors (NHRs). The DBD zinc fingers mediate specific and high-affinity DNA binding as well as DNA-based receptor dimerization. There are three types of heterodimeric complexes: unoccupied (unliganded) heterodimers, nonpermissive heterodimers, and permissive heterodimers. Permissive heterodimers, such as peroxisome proliferator-activated receptor/RXR (PPAR/RXR), can be activated by ligands of either RXR or its partner and are synergistically activated in the presence of both ligands. In nonpermissive heterodimers, RXR often acts as a silent partner. Dimers can also bind negative response elements and cause gene repression. These sites have been found for the glucocorticoid receptor (GR) and thyroid hormone receptor (TR). Negative or positive regulation of gene transcription usually results from the interaction of NHRs with corepressors or co-activators.

A second, nonclassic mode of nuclear hormone receptor function has been recently discovered. This mechanism of transcriptional regulation is based on specific protein–protein interactions and allows the integration of seemingly unrelated signaling pathways. Crosstalk was initially suspected when the simultaneous activation of two transcription factors resulted in a different qualitative or quantitative regulation of genes compared to a situation in which only one of the factors was activated. The effect could be observed even in the regulation of genes that contained a DNA response element in their promoter region for only one of the two transcription factors. The crosstalk of different families of transcription factors with NHRs has been investigated in detail. Examples of this regulatory principle include the functional interaction between the GR and activator protein 1 (AP-1) and also the between the GR and signal transducers and activators of transcription (Stats). Other transcription factor families, such as nuclear factor κB (NF-κB)/Rel, Oct, and CCAAT/enhancer-binding protein (C/EBP), have also been shown to participate in crosstalk with members of the NHR family. The comprehensive molecular mechanisms for the negative or positive crosstalk that can ensue have not been fully elucidated, though many important aspects have been described. Here the focus is on data concerned with crosstalk between the NHR and the Stat family of transcription factors.

Transcriptional crosstalk can be the consequence of different molecular interactions (Fig. 1). First, it has been shown that two transcription factors with specific DNA-binding potential interact, but that only one of them is bound to DNA via its DNA-binding domain—the second factor is recruited to the promoter through protein–protein interactions. Second, each transcription factor can recognize different elements in the same promoter of the target gene. Third, transcription factor binding sites are arranged so that they are neighboring or overlapping each other, and that proximity influences the activity or binding of the other protein. It enables direct protein–protein interactions, but can also cause competition for DNA binding sites or limiting amounts of cofactors. The effect of this third mode of crosstalk is often manifested in gene repression. Elucidation of the different modes of receptor action, classic and transcriptional crosstalk mediated, have been aided by the utilization of various ligands or gene mutations.

II. STAT SIGNALING PATHWAY

In mammalian cells, seven genes encode seven Stat family transcription factors: Stat1, Stat2, Stat3, Stat4, Stat5a, Stat5b, and Stat6. Diversity of function is further enhanced by the production

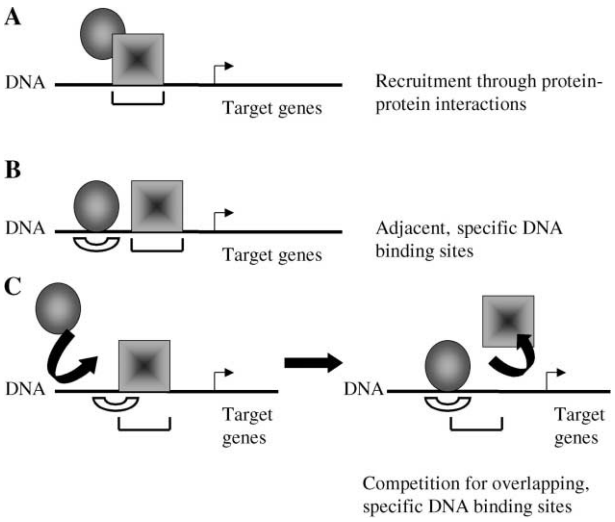

FIGURE 1 Transcriptional crosstalk. (A) Protein–protein interactions result in the recruitment of two transcription factors to the promoter sequence, only one of which is bound to a specific DNA sequence. (B) Each transcription factor recognizes its own element in the gene promoter, with the possibility of direct or indirect contact. (C) Specific DNA binding sites can involve overlapping sequences. The binding of factors is determined by relative affinity and can result in mutual interference. An example of this (not shown) is the binding of YY1 and Stat5 to the β-casein promoter, where, as long as YY1 is bound, the promoter is repressed. On Stat5 activation, YY1 is replaced by Stat5.

of alternatively spliced variants and proteolytic posttranslational processing. Stat1, Stat3, and Stat4 mRNAs have been found to be alternatively spliced and Stat5 can be proteolytically processed to yield alpha (long) and beta (short) forms. The short forms lack transcription-activating domains and may act as naturally occurring dominant negative proteins. Cytokines and/or growth factors can specifically activate Stat molecules. Specific ligand binding initially causes receptor activation and tyrosine phosphorylation by the associated Janus kinase (JAK) (Fig. 2). Stat molecules, present in a latent state in the cytoplasm, interact with the phosphotyrosyl sites in the intracellular domain of the receptor through their SH2 domains and are in turn tyrosine phosphorylated by JAK. These activated molecules now dimerize and translocate to the nucleus, where they regulate the transcription of target genes. The target genes are involved in a wide range of cellular processes, including growth, differentiation, and apoptosis. The diversity of the signals that mediate their effects through Stat factors and the various functions affected by Stat factors in different cell types make it reasonable to assume that combinatorial mechanisms are at work to mediate the cellular responses.

III. ESTROGEN RECEPTOR PLUS STAT5B

Estrogen receptor-α (ER-α) and ER-β bind the steroid hormone estrogen and xenoestrogens, and are also activated by peptide growth factor signals to mediate effects on growth and development in a wide range of tissues. ERs can crosstalk with other DNA-bound transcription factors in order to regulate gene expression. This can cause up-regulation of genes with promoter binding sites for Sp-1 and AP-1 (differential effects with the two ERs) and can negatively affect genes with regulatory sites for NF-κB, GATA-1, and C/EBP. The receptors bind additional cofactors in order to integrate multiple signals.

Crosstalk can also be observed between the ER and Stat5. This crosstalk results in an estrogen-dependent inhibition of Stat5-mediated transcriptional induction and is accompanied by decreased Stat5 DNA binding and tyrosine phosphorylation. The latter two events also occur independently of ER ligand. These observations, however, have not been consistently made in all cell types (Fig. 3A). Synergism between ER-α or ER-β and Stat5b was also reported. Transcription induced by prolactin-activated Stat5b was enhanced by the expression of either ER, though with a larger quantitative effect through ER-β, in a mammary epithelial cell line. The synergism required activation of Stat5b, but not ligand activation of the ERs. The DNA-binding domain and the hinge of the ERs were essential for the functional interaction with Stat5b, though it was not determined if the effect was mediated by a direct physical interaction. Recruitment of additional cofactors or binding to the promoter might be required.

It has also been determined that other members of the steroid hormone receptor family crosstalk with Stat5. Mineralocorticoid, progesterone, and glucocorticoid receptors synergize with Stat5 in the induction of transcription from a Stat-responsive promoter. Conversely, Stat5 negatively interferes with transcription from promoters carrying DNA response elements for those receptors. The androgen receptor does not appear to interact with Stat5.

IV. PEROXISOME PROLIFERATOR-ACTIVATED RECEPTORS PLUS STAT5B

The NHR subfamily of PPARs consists of three receptor types, PPAR-α, PPAR-δ, and PPAR-γ, each

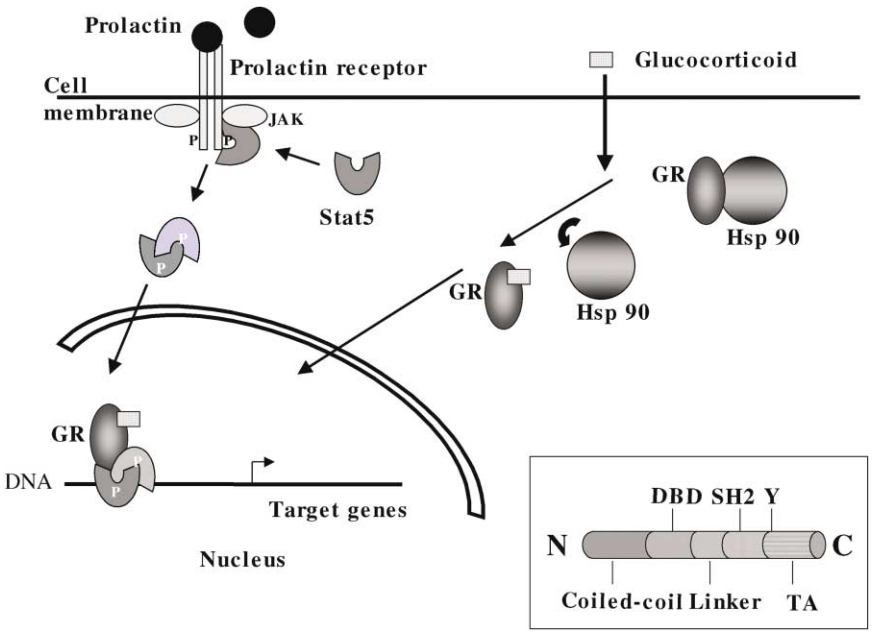

FIGURE 2 The prolactin–JAK–Stat pathway. Left-hand pathway: Prolactin or another cytokine binds to its receptor and induces receptor and Janus kinase (JAK) activation. This creates a docking site for latent Stat5 or for the Stat appropriate to the signal. Stat is in turn phosphorylated and activated, whereupon it heterodimerizes or homodimerizes and translocates to the nucleus to regulate gene transcription. Right-hand pathway: Glucocorticoid activates the glucocorticoid receptor (GR), which is held in a responsive state by heat-shock protein 90 (Hsp 90), and the ligand/GR unit translocates to the nucleus to bind to promoters carrying a glucocorticoid response element, or to promoters dependent on Stat5 for transcription. Inset: Functional domains of the Stat proteins, showing the coiled-coil domain, which is important for protein–protein interactions; the DNA-binding domain (DBD); the flexible linker region; the SH2 domain; the transactivation domain (TA); and the tyrosine residue (Y), which, when phosphorylated, represents Stat activation.

of which is developmentally and tissue-specifically expressed. They are ligand-activated transcription factors that recognize PPAR response elements (PPRE) when heterodimerized with RXR. PPARs can repress gene transcription by negatively interfering with NF-κB, and AP-1.

PPAR-α mediates hepatic peroxisome proliferation after induction by nongenotoxic carcinogens. This response is inhibited by growth hormone (GH), a peptide hormone that stimulates the activation of Stat1, Stat3, Stat5a, and Stat5b. It was experimentally shown that the GH inhibition of PPAR-α reporter gene transcription was mediated specifically by Stat5b. Stat5b tyrosine phosphorylation, its DBD, and its transcription activation domain plus the amino-terminal activation function-1 (AF-1) transactivation domain of PPAR-α were essential to mediate the inhibition. Direct protein–protein interactions were not detected (Fig. 3B). It is possible that Stat5b competes with PPAR-α for an essential co-activator, though p300 and steroid receptor co-activator-1 (SRC-1) were shown not to be involved in this case. This negative crosstalk is most likely the molecular basis for the regulation of PPAR-α-dependent responses by GH. This could be important in the modulation of inflammatory responses by leukocytes, which have an intact GH-JAK-Stat pathway, or by inflammatory cells, which have the capacity to synthesize and secrete GH. GH may also inhibit tumor development by suppressing the PPAR-α response to peroxisome proliferators that have been linked to carcinogenesis. GH-activated Stat5b also inhibited the transcriptional activity of PPAR-γ, PPAR-δ, and thyroid hormone receptor.

V. GLUCOCORTICOID RECEPTOR PLUS STAT1 AND PU.1

Inflammatory and immune responses are signaled through interferon γ (IFNγ) and Stat1 as well as corticosteroids, which activate the GR. These signals converge on the Fcγ receptor I (FcγRI) gene promoter region through crosstalk between Stat1 and the GR. Monocyte-specific transcription of this gene is

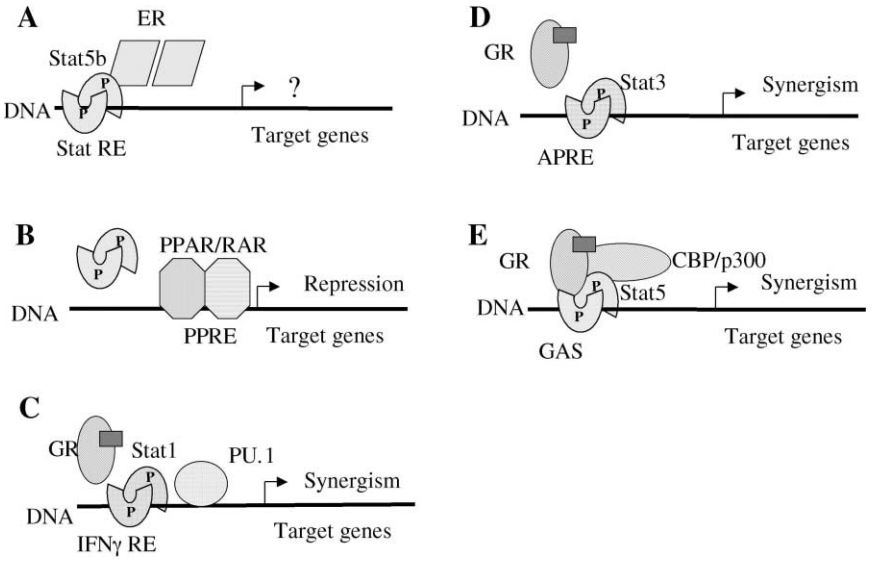

FIGURE 3 Various mechanisms of transcriptional crosstalk between NHRs and Stats. (A) Stat5b is able to affect gene regulation by its interaction with the estrogen receptor (ER) (Stat RE, Stat response element). (B) Stat5b, in the absence of direct contact with a peroxisome proliferator-activated receptor (PPAR-α, -γ, or -δ), causes inhibition of transcription on a promoter with a PPAR response element (PPRE). (C) The glucocorticoid receptor (GR) does not interact with Stat1 but promotes transcription, with PU.1 providing cell type specificity (IFNγ RE, interferon γ response element). (D) The GR acts indirectly with Stat3 to enhance transcriptional response on the interleukin-6 response element of the rat α_2-macroglobulin promoter response element (APRE). (E) The GR and Stat5 interact to promote transcription on a promoter with Stat binding sites (CBP, Ca^{2+}/cAMP response element-binding protein; GAS, interferon γ-activated sequence).

mediated by a second response element that binds PU.1, an Ets family transcription factor, and activation of this gene is dependent on both Stat1 and PU.1. Action of the GR results in an enhancement of Stat1-dependent gene activation. Crosstalk between Stat1 and the GR does not appear to involve direct physical interaction between the two proteins (Fig. 3C). The use of GR variants showed that the functional crosstalk does not depend on the interaction of the GR with this promoter, although its DNA-binding domain was important, as was its hormone-dependent transactivation function. The DNA-binding function of active Stat1 was essential. It was shown that although the GR activated transcription on the Stat1-responsive promoter, Stat1 did not affect GR-dependent transcription. The requirement of protein synthesis in the process indicates that the GR may enhance transcription by inducing synthesis of transcriptional coregulators. Recruitment of cofactors could not be ruled out, although CREB-binding protein (CBP), an important co-activator for both GR and Stat5, was not a rate-limiting component. Up-regulation of the-high affinity Fcγ receptor I in monocytes is important for endocytosis of immune complexes and in antibody-mediated cytotoxic reactions. The GR integrates its signal differently with Stat1 and Stat5 in order to regulate gene expression that results in coordinated cytokine and glucocorticoid signaling.

VI. GLUCOCORTICOID RECEPTOR PLUS STAT3

Synergism of the GR with Stat3 has been documented on the Stat3-responsive promoter, α_2-macroglobulin. The synergism is dependent on the binding of interleukin-6 (IL-6)/JAK-activated Stat3 to the DNA response element, α_2-macroglobulin promoter response element (APRE). Testing two other Stat3-responsive promoters containing a dual Stat3 response element plus a cAMP-responsive element did not result in synergism with the GR, indicating specificity for the APRE. There was no detectable physical interaction between the GR and Stat3 (Fig. 3D), although the synergism appears to involve an undefined co-activator process, and not secondary gene expression. IL-6 activation of acute-phase proteins such as α_2-macroglobulin is important in host defense mechanisms and relies on glucocorticoid for maximal expression.

VII. GLUCOCORTICOID RECEPTOR PLUS STAT5

The most extensively characterized crosstalk between a NHR and a Stat factor is that between the GR and Stat5 (Fig. 2). An inverse regulatory mechanism has been described through which the two transcription factors modulate each other's function. The GR can participate in the induction of Stat5-responsive promoters and enhance the extent of Stat5 induction (Fig. 3E). Stat5 can inhibit GR-mediated transcription from a GR-responsive promoter. It was shown that this interaction depends on the specific DNA binding of Stat5, whereas the GR DNA-binding domain does not seem to be important. Activation of Stat5 is essential, with the stimulus provided by prolactin or IL-2 on respective responsive promoters. Ligand binding of the GR was nonessential, but its AF-1 transactivation domain was critical. Both Stat5a and Stat5b were shown to interact with GR *in vivo*, independent of lactogenic hormone signaling in mammary epithelial cells and at all stages of mammary gland development. After lactogenic hormone induction, the GR was identified as part of the Stat5/DNA-bound complex, indicating a functional coupling between Stat and NHR pathways. The GR appears to promote the active conformation of C/EBPβ as well as prolong the activated state of Stat. p300/CBP is an important co-activator for Stat5 and the GR, but was not rate limiting in the repression mediated by Stat5 on a GR-responsive promoter. The *in vivo* interaction between the GR and Stat5 was also detected in liver extracts and in NIH 3T3 cells. Mice in which the GR has been inactivated through homologous recombination die shortly after birth. Mice homozygous for a GR mutation that disrupts dimerization and DNA binding are viable, indicating that the mutant GR still functions in the mice. One possible explanation is that crosstalk with Stat5, and possibly other transcription factors, is responsible for the survival of the mice.

Stat5 and the GR also synergize in the regulation of the whey acidic protein gene promoter, another milk protein gene. It is possible that a different mechanism is involved, because this regulation depends on the presence of the nuclear factor I (NF-I) response element, the Stat5 site, and clustered GR half-sites. NF-IB2 was found to participate in full synergism with Stat5 and GR. NF-IA4, NF-IB2, and NF-IX1 are developmentally regulated in the mammary gland but interact with the DNA response element on this promoter with differential specificity. A common GR-based mechanism conveys crosstalk with Stats and cytokine signaling in coordination with cell type-specific gene expression. GR crosstalks with Stat1, Stat3, Stat5a, Stat5b, and Stat6 in order to add additional levels of regulation to cytokine/growth factor/peptide hormone signaling.

VIII. CONCLUSIONS

The interaction of nuclear hormone receptors with Stat molecules is a common mechanism for specific gene regulation that is shared among many different family members, such as estrogen, glucocorticoid, mineralocorticoid, progesterone, and thyroid hormone receptors and PPAR-α, PPAR-γ, and PPAR-δ. It is likely that other members of the NHR family will be found to interact with one of the Stat family members in order to achieve transcription crosstalk. Although the crosstalk of NHRs with Stats to regulate gene transcription is a common theme, the molecular mechanisms appear to depend on the Stat, the NHR, and the promoter sequences involved. Physical interaction of the NHR with the Stat is not always detectable (in Fig. 3, compare B–D to 3A and 3E, showing interaction), nor is DNA binding of both partners commonly found (Fig. 3). Another important question to be answered concerns the qualitative and quantitative effects of crosstalk. Two transcription factors that act positively in gene induction on their own can result in gene repression on simultaneous activation and complex formation.

NHRs mediate their transcriptional regulatory function through at least two qualitatively different classes of cofactors—co-activator and corepressor molecules and their associated chromatin remodeling components. The recruitment of these cofactors is tightly regulated, ordered, and necessary for transcription initiation and attenuation of hormone-regulated genes. How multiple cofactors are recruited into large transcription complexes and what determines the balance between positively and negatively acting factors are the focus of current research. The potential of Stats to recruit co-activators and co-repressors with their associated chromatin remodeling functions makes them formally quite similar to TRs and RARs, members of the NHR family. Through direct physical interactions or through adjacent DNA binding sites Stats might be able to influence the timing of NHR binding to the DNA, the recruitment of chromatin remodeling complexes, assembly of the transcription preinitiation complex, and recruitment of cofactors, and thus modify the cellular response to nuclear hormones.

Glossary

co-activator Protein or protein complex that can act as a bridging factor to recruit other cofactors to the DNA-bound transcription factor, can act to bridge DNA-bound factors to the basal transcription machinery, or can acetylate nucleosomal histones or transcription factors.

corepressor Can bind transcription activators and inhibit formation of active complexes, or can recruit histone deacetylases, causing transcriptional repression.

crosstalk The point at which two signaling pathways converge to provide an additional level of regulation.

DNA response element The DNA nucleotide sequence of a gene promoter that confers specific interaction with a signal-activated DNA-bound transcription factor.

transcriptional crosstalk The crosstalk of two signaling pathways converging on a gene promoter.

Crustacean Endocrine Systems

DAVE BORST

Illinois State University

Crustaceans produce a number of endocrine compounds, including neuropeptides, steroids, and terpenoids. Some of these compounds are

secreted by glandular tissues such as the Y-organ, the mandibular organ, and the androgenic gland. Others are secreted by neurosecretory centers, such as the sinus gland-X-organ complex and the pericardial organs, or by cells in the gut and brain. These compounds regulate a wide range of essential physiological processes in this large and diverse group of anthropods.

I. INTRODUCTION

Crustaceans form a diverse, monophyletic group of over 50,000 known species. Although most crustaceans live in marine environments, many species live in freshwater and terrestrial habitats. Currently, this group is divided into 11 classes, 6 of which contain only a few (<100) species. The 5 largest crustacean classes are the *Brachiopoda*, which includes fairy shrimp, brine shrimp (*Artemia*), and water fleas (*Daphnia*); the *Ostracoda*, which includes seed shrimp; the *Copepoda*, which includes both parasitic and free-living species, some of the latter being major contributors to marine plankton; the *Cirripedia*, which includes the barnacles and several crustacean parasites (*Sacculina*); and the *Malacostraca*, which contains over half of the known crustaceans. This last class has several important orders, including the *Isopoda* (woodlice and pillbugs), *Amphipoda* (sand fleas and whale lice), and *Decapoda* (lobsters, crabs, and shrimp). Because of their large size, commercial importance, and relative ease in handling, the endocrine systems of decapods have been most thoroughly studied.

Crustaceans use a variety of endocrine compounds, including neuropeptides, steroids, and terpenoids. Some of these compounds are produced by endocrine systems that show complex (second and third order) levels of regulation. As shown in Fig. 1, the major crustacean endocrine tissues include the following:

1. The sinus gland–X-organ complex of the eyestalk (the source of several neuroendocrine peptides);
2. the Y-organ (the source of ecdysteroids);
3. the mandibular organ (the source of methyl farnesoate);
4. the pericardial organs (the source of peptides that regulate cardiac function); and
5. the androgenic gland (the source of androgenic hormone).

However, other tissues (e.g., the gonads, gut, brain, and thoracic ganglia) also produce hormones. Together, these endocrine compounds regulate a wide range of important physiological processes, including molting, metamorphosis, reproduction, osmoregulation, metabolism, coloration, and behavior.

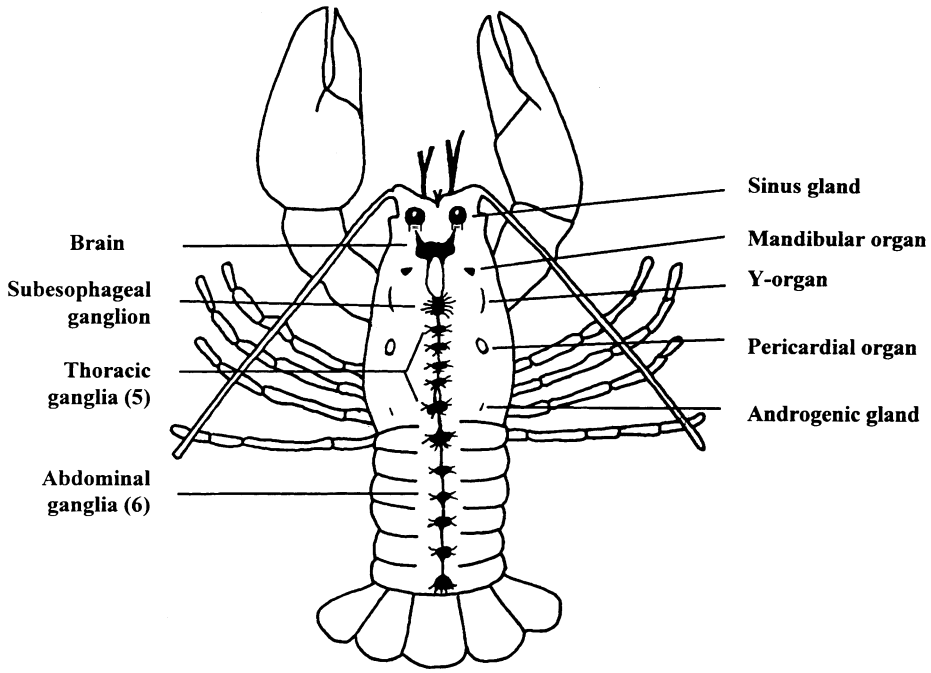

FIGURE 1 The location of the major endocrine and neuroendocrine tissues in crustaceans.

II. ECDYSTEROIDS AND THE CONTROL OF CRUSTACEAN MOLTING

A. The Molt Cycle

Arthropods are covered by an exoskeleton that provides a framework for physical support, muscle attachment, and protection from trauma and pathogens. The benefits of the exoskeleton are offset by the limitations it places on somatic growth, requiring the periodic molting of the old exoskeleton and its replacement with a larger one. Thus, crustaceans and other arthropods show an incremental rather than a continuous increase in body size, although the growth of internal tissues to fill the new exoskeleton continues throughout the molt cycle. In some crustaceans (e.g., lobsters and crayfish), growth is indeterminate, and molting continues throughout the life of the animal, albeit at a slower pace as an individual grows larger. In other species (e.g., many crabs), growth is determinate, and molting ends when an individual reaches sexual maturity. The elaboration of a new exoskeleton is metabolically expensive, so the processes involved in the molt cycle tend to dominate the activities of crustaceans. In addition, the soft shell of a freshly molted animal limits its movement and makes it more vulnerable to predation.

The structure of the exoskeleton during intermolt (stage C4) is shown in Fig. 2a. The exoskeleton is produced by a single layer of epidermal cells (the hypodermis) lying directly below it. The exoskeleton has four major layers: the outermost epicuticle, the exocuticle, the endocuticle, and the inner membranous layer. These layers are composed of various combinations of lipids, chitin (a carbohydrate polymer), protein, and calcium salts. Some parts of the exoskeleton (e.g., the arthrodial membranes that join leg and body segments) are not calcified to maintain their flexibility. The hypodermis secretes the layers of the exoskeleton sequentially during different stages of the molt cycle, allowing the stages to be identified by the morphological characteristics of the exoskeleton. The stages of the molt cycle are typically divided into postmolt (metecdysis, stages A, B, and C_{1-3}), intermolt (anecdysis, stage C_4), premolt (proecdysis, stage D_{0-3}), and molting (ecdysis, stage E).

B. The Ecdysteroids

Among the more important hormones regulating molting are the ecdysteroids. Several ecdysteroids

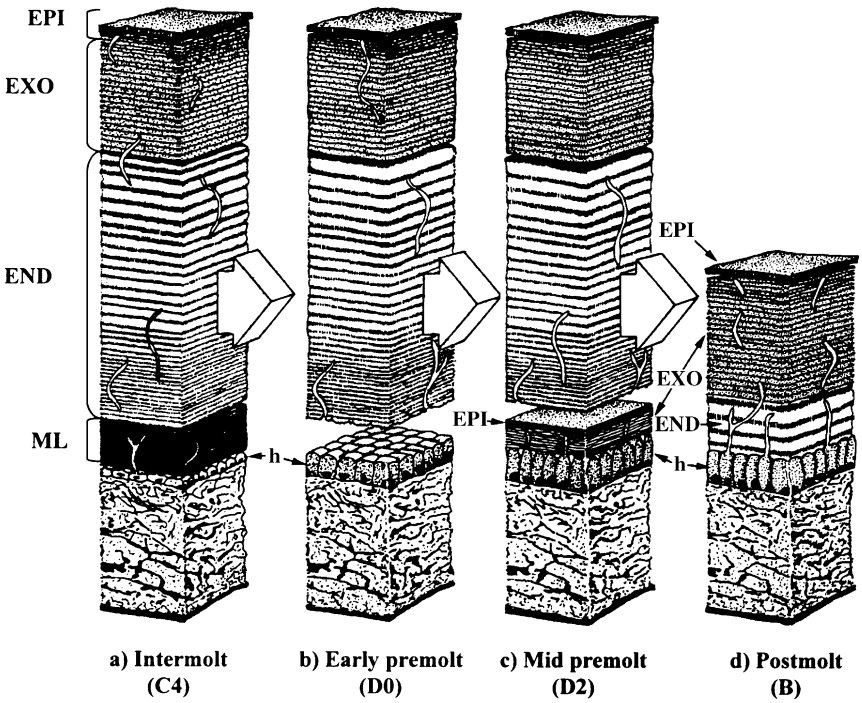

FIGURE 2 Changes in the crustacean exoskeleton during the molt cycle: EPI, epicuticle; EXO, exocuticle; END, endocuticle; ML, membranous layer. The epithelial cells in the hypodermis (h) hypertrophy when the exoskeleton is being synthesized. Reprinted with permission from Aiken, D. E., and Waddy, S. L. (1992). The growth process in crayfish. *Rev. Aquat. Sci.* **6**, 335–381. Copyright CRC Press, Boca Raton, Florida.

have been detected in crustaceans, including ecdysterone and ponasterone A (see Fig. 3). The most common form appears to be ecdysterone (20-hydroxyecdysone; β-ecdysone, crustecdysone), the same compound that regulates molting in insects. The rise in ecdysteroid levels from the low or undetectable levels of the intermolt stage heralds the onset of premolt. During premolt, ecdysteroid levels rise, stimulating the hypodermis to secrete hydrolytic enzymes that dissolve the membranous layer, separating the hypodermis from the exoskeleton (apolysis, stage D0; see Fig. 2b). As premolt continues, these hydrolytic enzymes digest the inner layers of the exoskeleton, allowing the recovery of its components (e.g., sugars and amino acids) and causing it to become thinner and weaker. During premolt (stages D1–D3), the hypodermis also produces and secretes the materials that form the epicuticle and exocuticle layers of the new exoskeleton, which remains soft and pliable inside the old exoskeleton (Fig. 2c).

Immediately prior to molting, ecdysteroid levels fall to very low levels. During this period, water is absorbed, increasing the hydrostatic pressure within the old exoskeleton. This pressure ruptures the thoracicoabdominal membrane, allowing the individual to withdraw from the old exoskeleton (ecdysis, stage E). Molting is rapid and typically requires only a few minutes. The newly molted animal absorbs more water, which expands the new exoskeleton to a volume approximately 50% greater than before molting. The exoskeleton is then hardened by tanning and calcification (stage A). During the postmolt period (stages B–C_2), ecdysteroid levels remain low or undetectable, and their hypodermis secretes the endocuticle (Fig. 2d). At the end of the postmolt period (stage C_3), the hypodermis secretes the membranous layer, completing the exoskeleton. The intermolt period (stage C_4) is typically the longest phase of the molt cycle and is used to accumulate metabolic reserves. However, in rapidly molting individuals, it may be curtailed or absent.

In adults, the intermolt period is often used for reproduction. Indeed, the metabolic demands of reproduction and molting in females usually make these processes mutually exclusive. In species with indeterminate growth (e.g., the American lobster), females often have a 2-year cycle, molting 1 year and reproducing the next. In contrast to reproduction, mating in many decapods is synchronized with molting. Sexually mature individuals have complex courting behaviors that begin a few days prior to the female molt, and most matings occur within 24 h after the female molts. The male's spermatophore is carried by the female until spawning occurs.

In addition to the hypodermis, other tissues are affected by the molt cycle. For example, there are extensive changes in the muscle tissue of crustaceans during the molt cycle. This is quite obvious in the American lobster, in which the muscle of the large claws (first pereiopods) is much larger in diameter than the proximal segments of the appendage. Up to 60% of the claw mass may be lost during premolt, facilitating its withdrawal during the molt. Molting also provides a time for the regeneration of lost limbs. Limb loss usually occurs along a predesignated breaking point (the autotomy plane), followed by the rapid formation

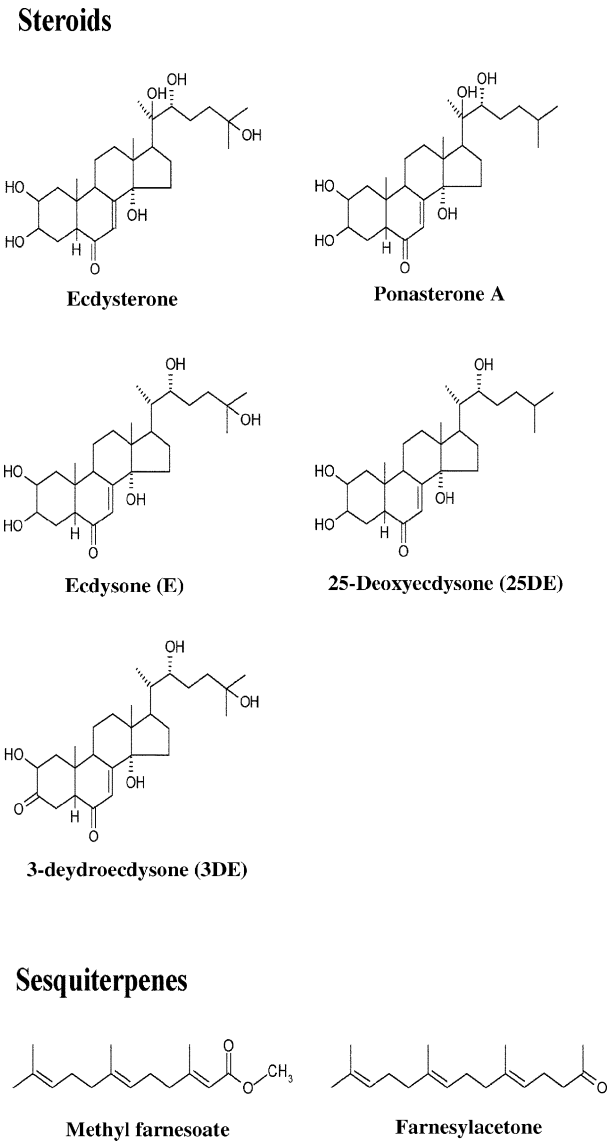

FIGURE 3 Structures of some crustacean steroid hormones and sesquiterpene hormones.

of the autotomy membrane and a scab. Within a few days, a blastema forms on the stump of the appendage. During premolt, this differentiates into a limb bud, and at molting, the limb bud will expand to form a replacement limb or claw.

C. The Y-Organ and Its Regulation

In decapods, ecdysteroids are produced by the Y-organs, which are located in the anterior region of the cephalothorax. Ecdysteroids are synthesized from dietary cholesterol, which circulates in the hemolymph bound to high-density lipoprotein (HDL). The cholesterol–HDL complex binds to HDL receptors on the Y-organ and enters the cells by endocytosis. The Y-organs convert the cholesterol to ecdysteroid precursors that are further converted to the active steroids by peripheral tissues. The identities of these precursors vary somewhat by taxonomic group. In the crab *Cancer antennarius*, the Y-organs secrete ecdysone (E) and 3-dehydroecdysone (3DE) (or 3-oxo-ecdysone). These are converted in peripheral tissues by 3-reductase (which converts 3DE to E) and ecdysone 20-monooxygenase (which converts E to ecdysterone). In contrast, Y-organs from the green crab *Carcinus maenas* secrete E and 25-deoxyecdysone, which are converted peripherally to ecdysterone and ponasterone A, respectively, by ecdysone 20-monooxygenase (see Fig. 3).

The production of ecdysteroids by the Y-organ is regulated in part by molt-inhibiting hormone (MIH), a peptide hormone produced by the sinus gland–X-organ complex of the eyestalk (see below). MIH inhibits the production of ecdysteroids by the Y-organ, so eyestalk ablation often (but not always) causes an animal to precociously molt. MIH binds to high-affinity binding sites on Y-organ membranes, increasing cytosolic levels of cyclic nucleotides [either cyclic AMP (cAMP) or cyclic GMP (cGMP), depending on the species]. For example, treatment of Y-organs from *Car. maenas* with MIH causes cGMP levels to rise 60-fold. Elevated levels of cyclic nucleotides cause a decrease in both HDL uptake and the conversion of cholesterol to ecdysteroids. Ecdysteroid production is stimulated by extracellular calcium, in part by increasing the activity of cyclic nucleotide phosphodiesterase, thereby lowering levels of cAMP or cGMP. In some species, calcium has also been reported to stimulate the activity of protein kinase C, which then increases the production of ecdysteroids.

In addition to MIH, there appear to be other compounds that regulate Y-organ activity. One source of these compounds is the regenerating limb bud, which appears to contain compounds that accelerate and delay molting. For example, removal of multiple limbs from the land crab *Gecarcinus lateralis* during intermolt can stimulate the precocious entry of an individual into premolt, allowing the lost limbs to be more rapidly regenerated. This appears to be due to a stimulatory compound produced by the limb bud. In contrast, removal of limbs during early premolt before a critical period delays molting until the limb buds are sufficiently developed to allow their regeneration. This appears to be due to an inhibitory compound released by the regenerating limb.

D. Ecdysteroid Receptors

Ecdysteroids affect target tissues by binding to nuclear receptor proteins that act as transcription factors. The ecdysteroid receptors (EcRs) belong to a large superfamily of related proteins that includes receptors for vertebrate steroid hormones, vitamin D, retinoic acids, thyroid hormones, and ecdysteroids. The amino acid sequences of these proteins are highly conserved in regions that are critical for receptor function. Thus, the amino acid sequences of the DNA-binding domain and the ligand-binding domain of the EcR in the fiddler crab *Uca pugilator* and the fruit fly *Drosophila melanogaster* are 89 and 59% identical, respectively. In addition, insect EcR forms a heterodimer with ultraspiracle (USP), a homologue of the vertebrate retinoid-X receptor (RXR). Crustacean tissues also contain a RXR receptor protein that has a high degree of similarity to the USP protein.

III. METHYL FARNESOATE, A CRUSTACEAN JUVENILE HORMONE

Juvenile hormone (JH) is a family of sesquiterpene compounds found in insects. JH regulates a number of processes, most notably metamorphosis, reproduction, and caste formation in social insects. Methyl farnesoate (MF) is the only member of this family that has been detected in crustaceans, and it appears to have analogous functions in these species (see Fig. 3). Administration of MF to larvae of the lobster *Homarus americanus* and the prawn *Macrobrachium rosenbergii* has been shown to retard their growth and development. Likewise, hemolymph levels of MF in the spider crab *Libinia emarginata* are elevated in males that are reproductively mature, suggesting a role in male reproduction and morphogenesis. MF levels have been correlated with ovarian development in several species, and treatment of *Procambarus clarkii* with MF stimulates ovarian maturation.

MF has also been shown to stimulate ecdysteroid synthesis by Y-organs *in vitro*, suggesting a role in the molt cycle. Finally, MF levels in the green crab *Car. maenas* have been shown to rise chronically in response to osmotic stress, suggesting a possible role in osmoregulation.

In decapods, MF is synthesized in the mandibular organ. The final step in the MF pathway is the activity of the enzyme farnesoic acid *O*-methyl transferase, which has been characterized and cloned. The activity of this enzyme and the overall production of MF by the mandibular organ are regulated in part by a neuroendocrine peptide(s) from the sinus gland–X-organ complex that inhibits the activity of the mandibular organ [mandibular organ-inhibiting hormone (MO-IH); see below]. Evidence for this peptide came from observations that eyestalk ablation caused the hypertrophy of the mandibular organ and increased production of methyl farnesoate. MO-IH appears to inhibit MF synthesis by increasing intracellular levels of cyclic nucleotides (cAMP or cGMP, depending on the species).

MF is hydrophobic, causing it to bind to hemolymph proteins. In some species, there appear to be preferred proteins for this binding, and these may be analogous to the JH-binding proteins found in insect hemolymph. Unlike insects, many of which have JH-specific esterase in their hemolymph, crustaceans do not have hemolymph esterases that degrade MF. Even so, the half-life of MF in hemolymph appears to be quite short (ca. 45 min), probably a consequence of its adsorption by cellular membranes.

IV. NEUROENDOCRINE COMPOUNDS

Neuroendocrine cells have been identified in the eyestalk, the brain, the subesophageal ganglion, the thoracic ganglia, and other parts of the central nervous system. Some of these cells release their products in neurohemal organs, collections of enlarged nerve terminals that store and release neuroendocrine peptides. In decapod crustaceans, there are several neurohemal organs, the best studied being the pericardial organs and the eyestalk sinus glands.

A. Pericardial Organs

The pericardial organs (POs) are found in the pericardial cavity near the heart and are formed by axons projecting from the thoracic ganglia. As implied by their location, the POs control cardiac function by releasing peptides (see Fig. 4a) and biogenic amines (e.g., serotonin, octopamine, and dopamine). The neuropeptides released by the POs include crustacean cardioactive peptide (CCAP, a nonapeptide, variants of which are found in several invertebrate phylla) and proctolin (a pentapeptide, first isolated as a factor that stimulates hindgut contractions in the cockroach). These affect the rate and amplitude of heart muscle contractions, respectively. In some species, CCAP may also stimulate respiratory rhythm. Proctolin-like immunoactivity has been found widely throughout the nervous system, suggesting that it may have additional functions.

B. The Sinus Gland

The sinus glands (SGs) are formed from axons projecting from the X-organ, a cluster of neurosecretory neurons located in the most proximal (the medulla terminalis) of the three neural ganglia in the eyestalk. These axons project distally to the juncture of the medulla interna and the medulla externa, where they form the sinus gland (see Fig. 5). This structure stores and releases two major classes of neuroendocrine peptides: pigment-effector hormones, which regulate the movement of pigment granules in chromatophores and retinal cells, and the crustacean hyperglycemic hormone (CHH) family of peptides, which regulate a wide variety of physiological processes including glucose levels, osmoregulation, reproduction, and molting. Some of these SG neuropeptides are also found in other tissues, where they may be systemically released to act as hormones or locally released to act as neuromodulators.

C. Pigment-Effector Hormones

These neuropeptides control pigment granule movement in chromatophores and retinal pigment cells. Chromatophores are integumental cells with cytoplasmic extensions that contain pigment granules (the most common colors are red, white, yellow, and black). Most chromatophores are monochromatic and appear colored when the granules are dispersed and are largely colorless when the granules are condensed. These cells are responsible for the rapid and reversible changes in the color of crustaceans. Retinal pigment cells control the amount of light that illuminates the eye. These cells include the distal pigment cells, which lie along the length of each ommatidium (the functional subunit of the crustacean compound eye). In light-adapted eyes, hormones disperse the pigment granules in these cells,

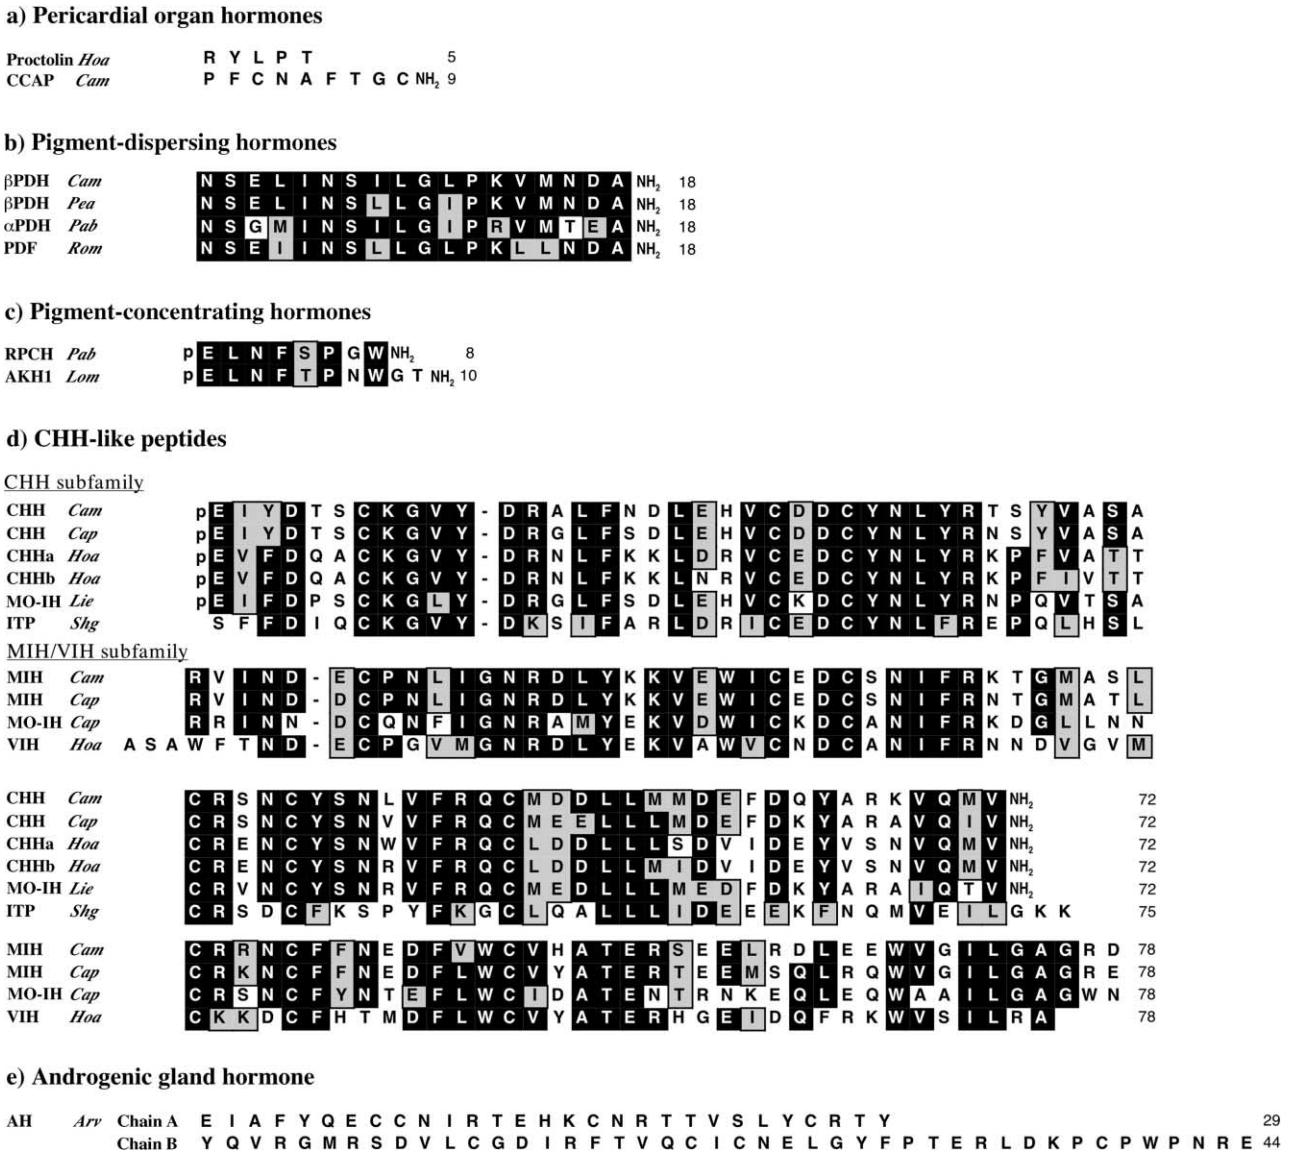

FIGURE 4 Structures of crustacean peptide hormones. The amino acid sequences of several crustacean endocrine peptides and related insect peptides. Most of these peptides have been sequenced in several species but space permits the display of only a few examples. Residues on a black background are identical; those on a gray background have similar chemical properties. Some peptides contain a modified N-terminal amino acid (pE, pyroglutamate) and/or C-terminal amide (NH_2). (a) Peptides present in the pericardial organs. Both peptides are also found in insects. (b) Pigment-dispersing hormones (α and β) and the related insect peptide PDF. (c) Pigment-concentrating hormone and the related insect peptide AKH. (d) CHH-like peptides, including the related insect peptide ITP. The CHH-like peptides are grouped into two subfamilies, the CHH subfamily (which includes lobster CHHa, the lobster MIH) and the MIH/VIH subfamily. The sequences of subfamily members are compared in this figure. (e) Androgenic gland hormone, which contains two peptides (the A chain and the B chain) connected by disulfide bonds (not shown). AH, androgenic gland hormone; AKH1, adipokinetic hormone; CCAP, crustacean cardioactive peptide; CHH, crustacean hyperglycemic hormone; ITP, ion transport peptide; MIH, molt-inhibiting hormone; MOIH, mandibular organ-inhibiting hormone; PDF, pigment-dispersing factor; PDH, pigment-dispersing hormone; RPCH, red pigment-concentrating hormone; VIH, vitellogenin (gonad)-inhibiting hormone. *Arv*, *Armadillidium vulgare*; *Cam*, *Carcinus maenas*; *Cap*, *Cancer pagurus*; *Hoa*, *Homarus americanus*; *Lie*, *Libinia emarginata*; *Lom*, *Locusta migratoria*; *Pab*, *Pandalus borealis*; *Pea*, *Penaeus aztecus*; *Rom*, *Romalea microptera*; *Shg*, *Shistocerca gregaria*.

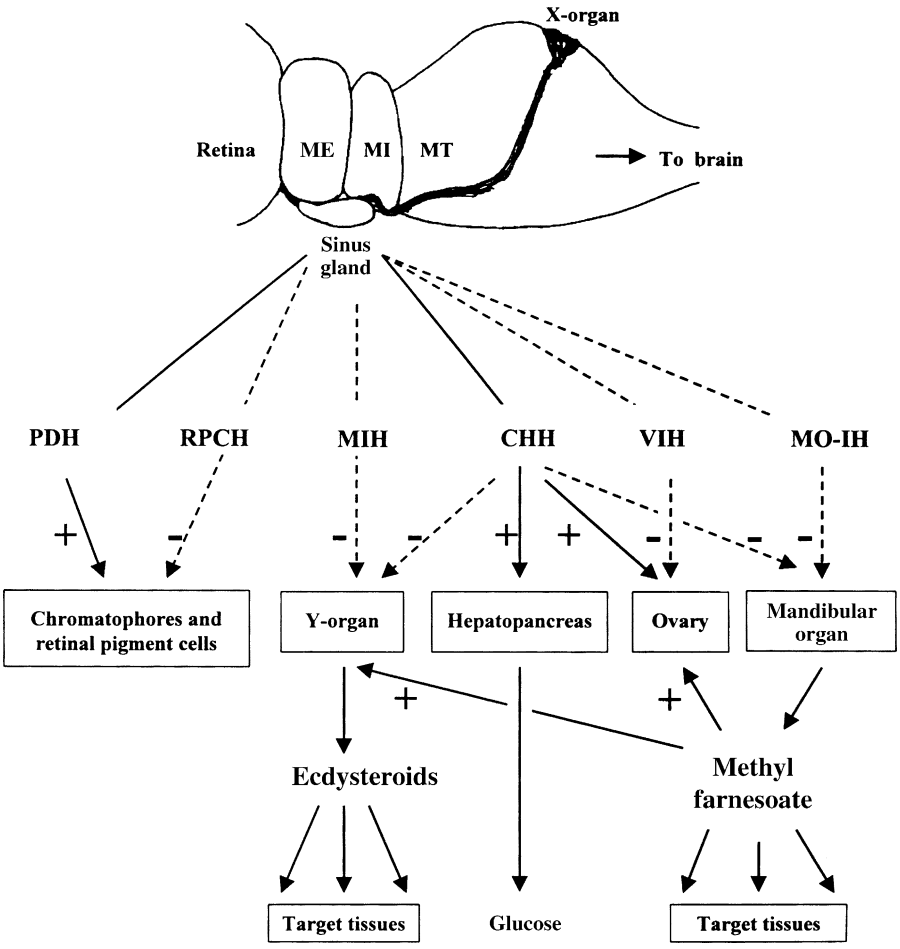

FIGURE 5 Neuroendocrine compounds released by the eyestalk sinus gland. Hormones with a stimulatory effect (including pigment granule dispersion) have solid arrows and a plus sign, hormones with an inhibitory effect (including pigment granule concentration) have dashed arrows and a minus sign. ME, medulla externa; MI, medulla interna, MT, medulla terminalis; PDH, pigment-dispersing hormone; RPCH, red pigment-concentrating hormone; MIH, molt-inhibiting hormone; CHH, crustacean hyperglycemic hormone; VIH, vitellogenesis (or gonad)-inhibiting hormone; MO-IH, mandibular organ-inhibiting hormone.

screening the photoreceptor of the ommatidium from light entering through neighboring ommatidia. In dark-adapted eyes, the pigment granules are concentrated, allowing more light to reach the photoreceptor.

Although the sinus gland is one of the richest sources of pigment-effector hormones, these hormones have a widespread distribution in the crustacean nervous system, where they act as neuromodulators. These peptides have been isolated from many crustaceans, and their eyestalks usually contain two types of mutually antagonistic factors. Peptides related to pigment-dispersing hormone (PDH) cause pigment dispersion in chromatophores and light adaptation pigment movements in retinal pigment cells. In contrast, hormones such as red pigment-concentrating hormone (RPCH) cause pigment concentration in chromatophores and dark adaptation in retinal pigment cells.

1. PDH

The chromatographic separation of eyestalk extracts usually reveals multiple peaks of PDH activity. These peptides form a family with two related branches (α-PDH and β-PDH), and each branch contains multiple variants (see Fig. 4b). The β-PDH variants appear to be more widely distributed. PDH peptides show substantial sequence similarity, including the same length (18 residues), conserved residues at seven positions, and conservative amino acid substitutions at other positions. The precursors for β-PDH have been identified by cDNA sequencing and have similar

structures, including a signal peptide of 20–23 residues and a precursor-related peptide with 33 or 34 residues. PDH is closely related to a family of insect peptides known as PDFs (pigment-dispersing factors), named initially for their effects on crustacean chromatophores (see Fig. 4b). PDFs are involved in insect biological rhythms and PDF immunoreactivity co-localizes with PER (the clock gene) immunoreactivity in *D. melanogaster.*

2. RPCH

Chromatographic analysis of eyestalk extracts indicates that at least two pigment-concentrating hormones are present in eyestalk extracts. Only RPCH has been isolated and sequenced (see Fig. 4c). This octapeptide has a pyroglutamate at the N-terminal end and an amide at the C-terminal end. The identical peptide appears to be present in over 15 species, indicating that it is highly conserved among crustaceans. RPCH is closely related to adipokinetic hormone (AKH), an insect family of decapeptides (see Fig. 4c). RPCH is found in other tissues, including the lobster stomatogastric ganglion, where it acts as a neuromodulator. Cloning studies show that the precursor of RPCH in the green crab *Car. maenas* contains a signal peptide of 25 amino acids and a precursor-related peptide of 74 amino acids.

D. The CHH Family of Neuroendocrine Peptides

The sinus gland contains a number of neuropeptides with 70–80 residues that regulate a wide variety of physiological functions. These peptides are related to CHH, and some (but not all) of these peptides have hyperglycemic activity. In addition to their similarity in size, they share similarities in their amino acid sequences, including the conserved locations of 6 cysteine residues that form three disulfide bridges. In addition to CHH, they include MIH, MO-IH, and vitellogenesis-inhibiting hormone [(VIH) also known as gonad-inhibiting hormone (GIH)].

1. CHH

CHH is the best-studied member of this family. CHHs have 72 or 73 residues, a pyroglutamate at the N-terminus, and an amide at the C-terminus (see Fig. 4d). CHH is synthesized as a preprohormone of several peptides arranged from the N-terminal end in the following order: a 26-amino-acid signal peptide, a precursor-related peptide of variable length (33–38 amino acids), an N-terminal dipeptide fragment, CHH, and a C-terminal fragment with 2–4 residues. Many species contain multiple CHH peptides that have closely related amino acid sequences. In addition, some species have stereoisomers of the same peptide that differ in the D- or L-configuration of the third amino acid (phenylalanine). These stereoisomers are due to the posttranslational modification of the protein. Both types of variants can have different activities and functions. The amino acid sequences of CHHs from different species are highly conserved and show greater than 55% identity. CHH is also related (40% identity) to the ion transport peptide, which stimulates chloride transport in the hindgut of the desert locust, *Shistocerca gregaria* (see Fig. 4d).

CHH regulates many physiological functions, including hemolymph levels of both glucose and lipids, digestive enzyme secretion by the hepatopancreas, osmoregulation by the gills, and ovarian development during reproduction. These pleiotropic effects of CHH may reflect the activity of different isoforms. Its hyperglycemic effects have received the most attention. Hemolymph levels of glucose are normally quite low, but treatment with CHH will cause a transient rise in glucose levels. This effect is due to the binding of CHH to membrane receptors on the hepatopancreas and abdominal muscle cells, which increases their levels of cAMP and cGMP. These cyclic nucleotides bind to protein kinases that activate phosphorylase and inhibit glycogen synthase. Recent studies have shown that stress (e.g., hypoxia and parasitic infection) causes a rise in the hemolymph levels of CHH and glucose. CHH also appears to have a role in osmoregulation, and perfusion of gills with this peptide causes a rapid and reversible increase in the transepithelial potential and the Na^+ influx by gill tissue. CHH also appears to have a stimulatory effect on oocyte growth (see discussion of VIH below). In addition to the sinus gland, CHH is present in the second roots of the thoracic ganglia. It is also found in the paraneurons of the foregut and hindgut immediately prior to molting. These cells release large amounts of CHH that increase water uptake during the molting process.

2. MIH

MIH regulates molting by inhibiting the production of ecdysteroids by the Y-organ (see above). The MIH peptides in crabs, such as *Car. maenas* and *Cancer pagurus*, form a separate subgroup of the CHH family, the MIH/VIH subfamily (see Fig. 4d). These peptides have 78 amino acids and unblocked N- and C-termini and are synthesized as a 113-amino-acid prohormone with a 35-amino-acid signal peptide. The amino acid sequences of crab MIHs are highly conserved. In *Car. maenas* and *Can. pagurus*, these

peptides show approximately 80% identity. In contrast, MIH peptides from these species show far less similarity (approximately 30% amino acid identity) to their own CHH peptides. In other species, isoforms of CHH have MIH activity. MIH in *H. americanus* appears to be a CHH isoform (CHH-A) and has both hyperglycemic and MIH activity. CHH has MIH activity in other species, including *Car. maenas* and *P. clarkii*, even when a separate MIH peptide is also present. In *Car. maenas*, CHH and MIH can act synergistically to inhibit Y-organ production of ecdysteroids.

3. MO-IH

MO-IH inhibits the production of MF by the mandibular organ (see above). In *Can. pagurus*, MO-IH has 78 amino acids and unblocked N- and C-termini and is a member of the MIH/VIH subfamily of CHH-like peptides (see Fig. 4d). It is synthesized as a prohormone with a 34-amino-acid signal peptide. The MO-IH of *Can. pagurus* is closely related to MIH (approximately 60% amino acid identity) and less related to its own CHH (approximately 20% identity). In other crustaceans, it appears that CHH is the MO-IH (see Fig. 4d). In *L. emarginata*, the MO-IH has 72 amino acids and has hyperglycemic activity. Its sequence is closely related to that of CHH (approximately 80% identity to CHH in *Can. pagurus*) and is less closely related to that of MO-IH in *Can. pagurus* (approximately 20% identity).

4. VIH

VIH (or GIH) inhibits gonadal development. Eyestalk ablation of females in the right physiological status accelerates gonadal maturation rather than molting, suggesting the presence of an eyestalk peptide that inhibits gonadal growth. In females, VIH inhibits oocyte growth, by interfering with the uptake of vitellogenin (the major yolk protein found in oocytes) or by inhibiting the synthesis of this protein. This peptide is also found in males, but its function is unclear. VIH in *H. americanus* has 77 amino acids, has unblocked N- and C-termini (see Fig. 4d), and is related to the MIH/VIH subfamily of CHH-like peptides. It is synthesized as a prohormone with a 34-amino-acid signal sequence. Lobster VIH shows approximately 50% sequence identity to MIH from crabs and approximately 42% sequence identity to MO-IH from *Can. pagurus* (see Fig. 4d). Of particular interest is the observation that VIH is synthesized in the same neuroendocrine cells that produce CHH, suggesting that they may both be involved in oogenesis. Measurement of the hemolymph levels of these two peptides appears to confirm this idea. Hemolymph levels of VIH are high during immature and previtellogenic stages of ovarian growth and levels of CHH are high during stages of oocyte maturation. This finding and other evidence suggest that CHH may be a gonad-stimulating hormone, acting in opposition to VIH.

V. ANDROGENIC GLAND HORMONE

The androgenic glands have been identified in most orders of the Malacostraca, but many recent studies have used amphipods and isopods. The androgenic gland is associated with the terminal region of the sperm duct and in many species can be easily removed. This tissue produces androgenic gland hormone, which can masculinize individuals. However, the response to this hormone varies with the species and the specific tissue. Ablation of the gland in the isopod *Armadillidium vulgare* causes feminization of young males, resulting in the development of oocytes, an oviduct, and female external morphology. Implantation of androgenic glands into young genetic females of this species will masculinize both their primary and secondary sexual characteristics, including behavior, creating functional males that can produce progeny. These data suggest that the undifferentiated crustacean gonad will autodifferentiate into ovarian tissue unless the androgenic gland hormone induces male morphogenesis.

The androgenic glands contain several compounds that affect gonadal function. In *Car. maenas*, this tissue produces C_{18} isoprenoid ketones, such as farnesylacetone, that inhibit ovarian protein synthesis (see Fig. 3). However, these compounds do not appear to be responsible for the effect of this gland on sexual differentiation. A second product of this tissue is a peptide hormone, androgenic gland hormone (see Fig. 4e). In *A. vulgare*, this hormone is an 11 kDa glycopeptide with two subunits (A and B with 29 and 44 amino acids, respectively) that are stabilized by both intra- and interchain disulfide bridges. In a manner analogous to the synthesis of insulin, the androgenic hormone is produced as a preprohormone from which a 21-residue signal peptide and a 46-residue C peptide (located between the N-terminal B subunit and the C-terminal A subunit) are removed to yield the mature hormone.

The androgenic glands appear to be regulated by neurohormones from the eyestalk. Eyestalk ablation in immature crabs causes hypertrophy of the androgenic gland and precocious spermatogenesis.

Ablation of the protocerebrum in isopods has the same effect. Preliminary evidence suggests that this inhibitory compound may be CHH. There is also evidence for the presence of a stimulatory factor in the ventral ganglion, but this compound(s) has not been characterized.

VI. SUMMARY

Although the past decade has brought considerable progress in identifying the endocrine compounds in crustaceans, the endocrine systems of these species are still poorly characterized. More information would be welcome, since it would allow us to compare crustacean endocrine systems to those of other arthropods. In addition, such information may have direct application in the cultivation of species that are important as food (lobsters, shrimp, and crabs) or in suppressing the growth of species that have destructive effects (barnacles). Finally, crustacean endocrine systems may be useful for monitoring and predicting the effects of chemical pollutants that could disrupt the physiology of other crustaceans (and thus the life-webs in which they play a role) and possibly humans and other vertebrates.

Glossary

androgenic gland Strands of cells associated with the male gametic duct. These cells produce androgenic gland hormone, which induces primary and secondary male sexual characteristics.

ecdysteroids (molting hormone) A family of steroid hormones regulating molting in arthropods. The most common form is ecdysterone (20-hydroxyecdysone, β-ecdysone).

mandibular organ The site of methyl farnesoate synthesis. In decapod crustaceans, this compact gland is located in the thoracic region attached to the mandible adductor tendon.

methyl farnesoate (MF) A sesquiterpenoid compound that is a member of the insect family of juvenile hormones (JH). MF has been detected in crustaceans and may function as their JH.

molting (ecdysis) The shedding of the old exoskeleton and its replacement by a new exoskeleton. This periodic process has specific stages leading up to and following the molt that make up the molt cycle.

sinus gland/X-organ complex A neurosecretory complex in the eyestalk of decapod crustaceans. Several important peptide hormones are produced and released by this complex.

Y-organ Paired glands of ectodermally derived cells that produce ecdysteroids.

CXC Chemokines

PHILIP M. MURPHY

National Institute of Allergy and Infectious Diseases, National Institutes of Health, Maryland

The CXC chemokines constitute a functionally diverse division of the chemokine superfamily defined by the presence of the eponymous CXC motif (Cys–any amino acid–Cys) near the N-terminus of the protein sequence. Three other principal chemokine divisions have been defined, based on other arrangements of conserved cysteines in this location. They are named accordingly C, CC, and CX3C. At the functional level, chemokines are signaling molecules that act primarily at seven-transmembrane domain G-protein-coupled receptors. Their main targets are hematopoietic cells, and their main biologic functions are immunoregulation, host defense, and inflammation, although additional roles in cancer, human immunodeficiency virus infection, wound healing, and other settings have been described. Apart from the CXC motif, there is no property common to all CXC chemokines that distinguishes them from all other types of chemokines. Still, this system of organization is useful since all the chemokines that attract neutrophils and/or regulate angiogenesis have the CXC motif. During the immune response, CXC chemokine functions are coordinated with those of the other chemokine families.

I. INTRODUCTION

Half of the known human CXC chemokines, CXCL1–3 and CXCL5–8, are important neutrophil chemoattractants and pro-angiogenic factors and act in the setting of innate immunity, sometimes redundantly. Members of a smaller functionally related cluster, CXCL9–11, regulate Th1 immune effector function and are angiostatic. The other six family members have more unique and nonoverlapping functions. CXCL12 is critical for hematopoiesis and embryogenesis and its receptor, CXCR4, is used by human immunodeficiency virus (HIV) to enter target cells. CXCL13 regulates B-cell and T-cell migration to B-cell zones of secondary lymphoid tissue. CXCL14–16 have only recently been identified and their properties are not yet well understood. CXCL4 is the least "chemokine-like" since it is not chemotactic; instead, it has strong prothrombotic and angiostatic activity. In addition to these human chemokines, some herpesviruses encode CXC chemokines and chemokine receptors, and one of these, viral G-protein-coupled receptor (vGPCR) of human herpesvirus 8, appears to play an important role in the pathogenesis of Kaposi's sarcoma (KS). The CXC chemokine receptors CXCR2 and CXCR3 have emerged as attractive targets in immunologically mediated inflammatory diseases and CXCR4 may be an important target in HIV/acquired immune deficiency syndrome (AIDS). CXC chemokines themselves have potential applications in wound healing, cancer, HIV/AIDS, and inflammation and as vaccine adjuvants.

II. CLASSIFICATION

CXC chemokines can be divided by structure into two main subgroups according to the presence or absence of the tripeptide sequence ELR (glutamic acid–leucine–arginine) N-terminal to the first cysteine (Table 1). The seven human ELR CXC chemokines target a common neutrophil receptor and are angiogenic. Non-ELR CXC chemokines differentially regulate T and B lymphocytes, pre-B cells, monocytes, and dendritic cells (DCs) through a separate set of differentially expressed GPCRs, and several of them

CXC Chemokines

PHILIP M. MURPHY

National Institute of Allergy and Infectious Diseases, National Institutes of Health, Maryland

The CXC chemokines constitute a functionally diverse division of the chemokine superfamily defined by the presence of the eponymous CXC motif (Cys–any amino acid–Cys) near the N-terminus of the protein sequence. Three other principal chemokine divisions have been defined, based on other arrangements of conserved cysteines in this location. They are named accordingly C, CC, and CX3C. At the functional level, chemokines are signaling molecules that act primarily at seven-transmembrane domain G-protein-coupled receptors. Their main targets are hematopoietic cells, and their main biologic functions are immunoregulation, host defense, and inflammation, although additional roles in cancer, human immunodeficiency virus infection, wound healing, and other settings have been described. Apart from the CXC motif, there is no property common to all CXC chemokines that distinguishes them from all other types of chemokines. Still, this system of organization is useful since all the chemokines that attract neutrophils and/or regulate angiogenesis have the CXC motif. During the immune response, CXC chemokine functions are coordinated with those of the other chemokine families.

I. INTRODUCTION

Half of the known human CXC chemokines, CXCL1–3 and CXCL5–8, are important neutrophil chemoattractants and pro-angiogenic factors and act in the setting of innate immunity, sometimes redundantly. Members of a smaller functionally related cluster, CXCL9–11, regulate Th1 immune effector function and are angiostatic. The other six family members have more unique and nonoverlapping functions. CXCL12 is critical for hematopoiesis and embryogenesis and its receptor, CXCR4, is used by human immunodeficiency virus (HIV) to enter target cells. CXCL13 regulates B-cell and T-cell migration to B-cell zones of secondary lymphoid tissue. CXCL14–16 have only recently been identified and their properties are not yet well understood. CXCL4 is the least "chemokine-like" since it is not chemotactic; instead, it has strong prothrombotic and angiostatic activity. In addition to these human chemokines, some herpesviruses encode CXC chemokines and chemokine receptors, and one of these, viral G-protein-coupled receptor (vGPCR) of human herpesvirus 8, appears to play an important role in the pathogenesis of Kaposi's sarcoma (KS). The CXC chemokine receptors CXCR2 and CXCR3 have emerged as attractive targets in immunologically mediated inflammatory diseases and CXCR4 may be an important target in HIV/acquired immune deficiency syndrome (AIDS). CXC chemokines themselves have potential applications in wound healing, cancer, HIV/AIDS, and inflammation and as vaccine adjuvants.

II. CLASSIFICATION

CXC chemokines can be divided by structure into two main subgroups according to the presence or absence of the tripeptide sequence ELR (glutamic acid–leucine–arginine) N-terminal to the first cysteine (Table 1). The seven human ELR CXC chemokines target a common neutrophil receptor and are angiogenic. Non-ELR CXC chemokines differentially regulate T and B lymphocytes, pre-B cells, monocytes, and dendritic cells (DCs) through a separate set of differentially expressed GPCRs, and several of them

TABLE 1 The CXC Chemokine Family: Nomenclature and Organization

Systematic name	Common names		Human chromosome	Structural subgroup	Receptors	General phenotypes	
	Human	Mouse				Immune	Vascular
CXCL1	Groα/MGSA	MIP-2, KC	4q21.1	ELR	CXCR2	Inflammatory	Angiogenic
CXCL2	Groβ	MIP-2, KC	4q21.1	ELR	CXCR2	Inflammatory	Angiogenic
CXCL3	Groγ	MIP-2, KC	4q21.1	ELR	CXCR2	Inflammatory	Angiogenic
CXCL4	PF-4	PF-4	4q21.1	Non-ELR	ND	ND	Angiostatic
CXCL5	ENA-78	GCP-2, LIX	4q21.1	ELR	CXCR2	Inflammatory	Angiogenic
CXCL6	GCP-2	GCP-2, LIX	4q21.1	ELR	CXCR1 & 2	Inflammatory	Angiogenic
CXCL7	NAP-2	NAP-2	4q21.1	ELR	CXCR2	Inflammatory	Angiogenic
CXCL8	IL-8	Unknown	4q21.1	ELR	CXCR1 & 2	Inflammatory	Angiogenic
CXCL9	Mig	Mig	4q21.1	Non-ELR	CXCR3	Inflammatory	Angiostatic
CXCL10	IP-10	IP-10/CRG-2	4q21.1	Non-ELR	CXCR3	Inflammatory	Angiostatic
CXCL11	I-TAC	I-TAC	4q21.1	Non-ELR	CXCR3	Inflammatory	Angiostatic
CXCL12	SDF-1 α/β	SDF-1/PBSF	10q11.21	Non-ELR	CXCR4	Homeostatic	Angiogenic
CXCL13	BCA-1	BLC	4q21.1	Non-ELR	CXCR5	Homeostatic	ND
CXCL14	BRAK	BRAK	5q31.1	Non-ELR	ND	ND	ND
(CXCL15)	Unknown	Lungkine		Non-ELR	ND	ND	ND
CXCL16			17p13	Non-ELR, Multimodular	CXCR6	Homeostatic	ND

Note. ND, not determined.

are angiostatic. CXC chemokines can also be divided into two main immunoregulatory subgroups designated "homeostatic" and "inflammatory", depending on whether they regulate leukocyte migration mainly during development and surveillance or during the effector phase of the immune response.

CXCL16 deserves special mention because it is a non-ELR CXC chemokine with a complex multimodular structure shared not with other CXC chemokines but with CX3CL1, the sole CX3C family member. Both molecules have transmembrane domains, which tether them to the plasma membranes of the producing cells, mucin-like stalks, which extend the chemokine domains from the plasma membrane, and cytoplasmic domains of unknown function. Since CX3CL1 is a direct cell–cell adhesin, it is expected that CXCL16 will also have this activity.

Several unconventional CXC elements have also been identified, including the nonsignaling CXC chemokine-binding protein Duffy on red blood cells, which may function as a chemokine scavenger, and virus-encoded CXC chemokines, chemokine mimics, chemokine receptors, and chemokine scavengers.

III. STRUCTURAL BIOLOGY

Chemokines range from ~7 to 16 kDa in molecular mass and appear to fold in the same general manner. Three anti-parallel β-sheets are arranged in the shape of a Greek key and are connected by loops and stabilized by disulfide bonds between the first and third and between the second and fourth conserved cysteines. The domain N-terminal to the first cysteine is unordered, and the C-terminal domain forms an α-helix draped over the Greek key domain.

Seven-transmembrane domain (7TM) receptors have an extracellular N-terminus and an intracellular C-terminus, which together with the transmembrane domains define three extracellular loops (ECLs) and three intracellular loops (ICLs). The protein sequences of CXC chemokine receptors are co-linear and ~340–360 amino acids in length, and their amino acid identity ranges from 25 to 80%. The least conserved amino acids cluster on the extracellular face of the receptor. Other common features include an acidic and relatively short N-terminal segment, the sequence DRYLAIVHA or a variation of it in ICL2, a short basic ICL3, and a cysteine in each of the four extracellular domains.

The three-dimensional structure of chemokine receptors is unknown; however, a reasonable model can be constructed based on analogy with the crystal structure of rhodopsin. The model contains two disulfide bonds, one linking the N-terminus with ECL3 and the other linking ECL1 and ECL2, which constrain the transmembrane domains (TMDs) like staves in a barrel arranged in a counterclockwise orientation relative to the cell interior. The ICLs form a large docking surface for heterotrimeric G-proteins and potentially other independent downstream effectors.

Most CXC chemokines can bind to glycosaminoglycans (GAGs) *in vitro* and therefore *in vivo* may be tethered by GAGs on endothelial cells and in the extracellular matrix during presentation to leukocyte receptors. The receptor appears to have two functionally distinct ligand-binding subsites. The first provides a docking site for the folded domain of the chemokine monomer, whereas the second, formed by the TMDs, accepts the chemokine's N-terminus when the first subsite is occupied and is used for triggering. Subsite 1 accounts for high-affinity binding, which is the sum of multiple low-affinity interactions involving multiple extracellular determinants on the receptor. The exact location of the binding determinants may differ for different chemokines and receptors. Unlike many cytokine receptors, chemokine receptors are composed of a single polypeptide chain. Some GPCRs form dimers as part of the signaling mechanism, but whether this is required for chemokine signaling is controversial.

IV. SIGNALING PATHWAYS

CXC chemokines activate G-protein-dependent and G-protein-independent pathways involving diverse intracellular effectors including phospholipases (PL) A2, C, and D and phosphatidylinositol-3 kinase γ (PI-3Kγ). They may also activate effectors for classic growth factor pathways, including protein tyrosine kinases and phosphatases, low-molecular-weight GTPases, and mitogen-activated protein (MAP) kinases, even in nondividing cells such as neutrophils. The phospholipases and lipid kinases induce extensive remodeling of plasma membrane phospholipid and generate lipid second messengers. Different chemokines and the different cellular responses induced by chemokines—migration, cytotoxicity (degranulation and oxidant production), and proliferation—involve both common and distinct signaling pathways. Moreover, different chemokines may activate different signaling pathways via the same receptor in the same cell. Most of the information about CXC chemokine signaling is based on studies of neutrophil activation by CXCL8 and T-cell activation by CXCL12 (also known as stromal cell-derived factor-1 or SDF-1).

Pertussis toxin-sensitive G_i-proteins are the main G-protein subtypes coupled to all CXC chemokine receptors in all types of leukocytes. The precise α-, β-, and γ-subunit subtypes have not been unequivocally delineated. Studies in phagocytes suggest that the main signaling subunit for the chemotactic pathway is βγ, not α, and that βγ must come specifically from G_i. This indicates that βγ is necessary but not sufficient to support chemokine functional responses.

Beyond G_i, CXC chemokine signaling pathways become much more diverse and complex. The best-characterized immediate downstream effectors activated by βγ in leukocytes are phospholipase C (PLC) subtypes β2 and β3, and PI-3Kγ, all of which catalyze the formation of distinct plasma membrane-associated lipid second messengers from phosphorylated phosphatidylinositol (PI) substrates. PLC generates diacylglycerol and an intracellular calcium flux, which are important for CXCL8 induction of superoxide production in neutrophils but not for chemotaxis. PI-3Kγ generates phosphatidylinositol-3,4,5-trisphosphate, which is thought to act by recruiting proteins containing pleckstrin homology (PH) or Phox domains to the plasma membrane. Four PH domain-containing targets—Akt/PKB and the guanine nucleotide exchange factors for the Rho family members Rac 2, Rho, and cdc42—have been shown to modulate distinct phases of cell movement in various model systems. Analysis of PI-3Kγ knockout mice has indicated that this enzyme plays a differential role in the chemotactic responses of different leukocyte subpopulations to chemoattractants. However, CXCL8 is the only chemokine among the chemoattractants evaluated thus far using cells from these mice. Neutrophils from Rac2 knockout mice are defective in CXCL8-induced chemotaxis and actin polymerization.

G_i-independent signaling mechanisms may include the Ras–Raf MAP kinase pathway and various nonreceptor tyrosine kinases such as the focal adhesion-associated protein Pyk2. However, the importance of these pathways may differ for different chemokines and leukocytes. For example, pharmacologic blockade of the MAP kinase pathway has been reported to disrupt CXCL12 activation of T-cell chemotaxis but not CXCL8 activation of neutrophil chemotaxis. CXC chemokines have been reported to cross talk with other signaling systems, including priming of CXCL8 by hematopoietic growth factors and inhibiting CXCL12 by signaling through B-cell antigen receptors, ephrin-B, and the neuronal guidance factor Slit through its neutrophil receptor, Robo.

V. INFLAMMATORY CXC CHEMOKINES

A. CXCL8 and Related ELR CXC Chemokines in Innate Immunity

CXCL8 is the prototypical inflammatory chemokine and the first chemokine shown to have leukocyte

chemotactic activity. The CXCL8 gene is normally silent in most cells, but can be rapidly induced in most if not all cell types by diverse stimuli, including pro-inflammatory cytokines [e.g., interleukin-1 (IL-1) and tumor necrosis factor (TNF)], oxidant stress, viruses, and bacterial products such as lipopolysaccharide (LPS). In contrast, glucocorticoids and immunoregulatory cytokines (e.g., IL-10 and both type 1 and type 2 interferons) suppress CXCL8 production. Key nuclear factors that mediate CXCL8 gene expression include nuclear factor κB (NF-κB), CCAAT/enhancer-binding protein β (C/EBP), activator protein-1 (AP-1), and NF–IL-6. In a blister model of acute inflammation in human, endogenous CXCL8 peaks at nanomolar concentrations at ~24 h, whereas C5a and leukotriene B4, which unlike CXCL8 do not require new gene expression but instead are formed enzymatically from precursor substrates, appear earlier. This suggests that orderly sequential expression of chemoattractants may control the evolution of the inflammatory response.

The neutrophil appears to be the major chemotactic target of CXCL8 *in vitro* and *in vivo*. Intradermal injection of CXCL8 in human causes rapid (< 30 min) and selective accumulation of large numbers of neutrophils in perivascular regions of the skin, and many neutrophil-mediated human diseases have been associated with the presence of CXCL8, including psoriasis, gout, acute glomerulonephritis, acute respiratory distress syndrome (ARDS), rheumatoid arthritis, reperfusion injury, and urinary tract infection. Systemic administration of neutralizing anti-CXCL8 antibodies is protective in diverse models of neutrophil-mediated acute inflammation in the rabbit (skin, airway, pleura, glomeruli), providing proof of concept that CXCL8 is a nonredundant mediator of innate immunity and acute pathologic inflammation in these settings (see Table 2). *In vitro*, neutrophils can also produce CXCL8, suggesting that it may work in an autocrine and paracrine manner to amplify neutrophil accumulation at inflamed sites.

There is therefore great interest in developing drugs that block CXCL8 action. However, selecting a target is complicated by the fact that CXCL8 binds to two high-affinity, structurally related [78% amino acid (aa) identity] chemotactic receptor subtypes, CXCR1 and CXCR2, which are both constitutively co-expressed at high levels on human neutrophils (see Table 3). Moreover, all six other human ELR CXC chemokines bind CXCR2 with high affinity and CXCR1 with substantially lower affinity and could function redundantly with CXCL8. Studies using selective blocking agents have disagreed on the relative importance of CXCR1 and CXCR2 in CXCL8-induced chemotaxis of primary human neutrophils. Unfortunately, rodents cannot be used to settle the issue genetically because mice lack counterparts of both CXCL8, and rat CXCR1 is expressed in macrophages, not neutrophils. Recently, SB-265610, a nonpeptide small-molecule antagonist with exquisite selectivity for CXCR2, has been shown to completely block CXCL8-induced chemotaxis of human neutrophils *in vitro* and to prevent neutrophil accumulation in the lungs of hyperoxia-exposed newborn rats. Still, other data suggest that CXCR1 cannot be ignored. For example, a patient study found that CXCR1 expression levels on neutrophils, possibly modulated by genetic polymorphism in the CXCR1 coding region, may be an important risk factor in bacterial pyelonephritis.

CXCR2 appears to play key roles in neutrophil-mediated acute inflammation and anti-microbial host defense in the mouse. CXCR2 knockout mice are less susceptible to acute urate crystal-induced gouty synovitis and are more susceptible to *Escherichia coli* pyelonephritis, *Onchocerca volvulus* keratitis, *Aspergillus fumigatus* and *Nocardia asteroides* pneumonia, gram-negative bacterial brain abscess, and *Toxoplasma gondii* encephalitis.

CXCL8 and its receptors may also have functions that extend beyond neutrophil migration and innate immunity. CXCL8 receptors are also expressed on T cells, monocytes, natural killer (NK) cells, immature dendritic cells, and basophils, as well as on nonhematopoietic cell types, including endothelial cells, neurons, and keratinocytes. Interestingly, CXCL8 can induce monocyte adhesion to endothelial cells but not monocyte chemotaxis. The biological significance of this is borne out by the ability of adoptively transferred $CXCR2^{-/-}$ bone marrow to protect mice in a model of atherosclerosis. In addition, CXCL8 has been found in human atheroma and may also promote lesions through effects on angiogenesis.

An unsuspected role for CXCL8 in adaptive immunity was suggested by the ability of neutralizing anti-CXCL8 antibody administration to block delayed-type hypersensitivity reaction to tuberculin in rabbit skin. A role in hematopoiesis *in vivo* was revealed in CXCR2 knockout mice, which have massive expansion of neutrophils and B cells throughout the hematopoietic system. This occurs only when the mice are derived in pathogen-free, not germ-free, environments, which suggests that normal hematopoiesis is regulated by a balance of CXCR2

TABLE 2 Some Biological Roles Found for CXC Chemokines and CXC Chemokine Receptors in Patient Studies or in Animal Models by Molecular Targeting (Gene Knockout, Chemokine Neutralization, or Receptor)

Chemokine	Biological roles	Species
CXCL1	• Melanoma and other cancers	Human
KC, MIP-2	• Bleomycin-induced pulmonary fibrosis	Mouse
	• Acute neutrophil-mediated inflammation (many models)	
	• Antimicrobial host defense (many models)	
CXCL4	• Autoimmune heparin-induced thrombocytopenia	Human
CXCL8	• Acute neutrophil-mediated inflammation (many models)	Rabbit
	• Cancer-associated angiogenesis	Human
CXCR2	• Wound healing	Mouse
	• Antimicrobial host defense (many models)	
CXCL9/(CXCR3)	• Resistance to mouse CMV infection	Mouse
CXCL10/CXCR3	• Cardiac allograft rejection	Mouse
CXCL12/CXCR4	• HIV infection	Human
	• Bone marrow myelopoiesis	Mouse
	• B-cell lymphopoiesis	
	• Cardiovascular development	
	• Cerebellar development	
	• Breast cancer metastasis	
CXCL13/CXCR5	• B-T positioning in secondary lymphoid tissue	Mouse
CXCL15	• Resistance to *Klebsiella pneumoniae*	Mouse

inhibitory signals and undefined enhancers induced by environmental factors. The mechanism may involve in part direct inhibition of mouse hematopoietic progenitor cell proliferation by signaling through CXCR2. CXCR2 knockout mice also revealed a role for this receptor in wound healing.

The expression of other ELR CXC chemokines has both features that it shares with the expression of CXCL8 and features that are unique, and together these chemokines may act redundantly in some contexts but not in others. For example, in most cell types, CXCL1–3 (also known as Groα, Groβ, and Groγ, respectively), CXCL5 (also known as epithelial cell-derived neutrophil activator-78 or ENA-78) and CXCL6 (also known as granulocyte chemotactic protein-2 or GCP-2) are all regulated at

TABLE 3 Differential Expression of CXC Chemokine Receptors on Leukocyte Subpopulations

	Receptor

the level of transcription and subsequent protein production after induction with most of the same inflammatory stimuli that turn on CXCL8 production. Yet neutrophils stimulated with fibrinogen and formylmethionyl-leucyl-phenylalanine (fMLF) express massive amounts of only CXCL8; melanoma cells selectively express CXCL1, which has been implicated as an important growth and angiogenic factor for this and other tumors; and CXCL5 is selectively expressed in unstimulated colonic epithelial cells. In mouse, TNF-induced neutrophil extravasation requires neutralization of both MIP-2 and KC, the CXCL1–3 homologues of mice, indicating redundant function in this setting. In contrast, MIP-2 is the major chemokine that attracts neutrophils into herpes simplex virus 1 (HSV-1)-infected mouse cornea, perhaps due to the fact that resident corneal cells and inflammatory cells contribute to MIP-2 synthesis, whereas KC production is restricted to corneal cells.

ELR CXC chemokines have been evaluated as therapeutic agents in diverse disease settings. For example, they can accelerate hepatic regeneration when administered systemically in an acetaminophen-induced hepatotoxicity mouse model. CXCL10 has similar activity but acts by inducing CXCR2 on hepatocytes. They have also been tested as DNA vaccines. In mouse, a MIP-2-encoding plasmid given mucosally with a plasmid encoding gB of HSV induces a Th1 immune response and renders recipients more resistant to HSV vaginal infection.

CXCL1, CXCL7 (also known as neutrophil-activating peptide 2 or NAP-2), and CXCL8 also bind to Duffy. The concentration of Duffy in blood is far higher than the concentration of CXCR1 or CXCR2, so that it may serve as an effective scavenger to maintain effective gradients from tissue to blood. This could also explain in part why systemic administration of these chemokines is well tolerated.

B. Platelet-Specific Chemokines CXCL4 and CXCL7

CXCL4 (also known as platelet factor-4 or PF-4) and CXCL7 are considered together because of their shared structure and their unusual distribution and regulation. They are 50% identical at the amino acid level, less homologous to all other chemokines, and restricted primarily to platelets, where unlike CXCL8 and other inflammatory chemokines, they are regulated posttranslationally. Paradoxically, despite high amino acid sequence identity, these chemokines are members of different CXC subclasses, which has important implications for their function. CXCL4, the first chemokine ever discovered, lacks the ELR motif and may be the only chemokine that is not a leukocyte chemoattractant or a ligand for a GPCR. In contrast, CXCL7 is a typical ELR CXC chemokine, able to induce neutrophil chemotaxis by activating CXCR2. Yet both chemokines are stored in platelet α granules and are released at extremely high concentrations (micromolar) upon platelet activation.

Upon release, CXCL4 aggregates to form tetramers that are critical for binding to chondroitinsulfate proteoglycans, their major known binding sites. In contrast, CXCL7 is activated by sequential proteolysis of its N-terminus. The prepropeptide form, platelet basic protein (92 aa), is trimmed during platelet maturation to produce the 85-amino-acid major stored form, connective tissue activating peptide-III (CTAP-III), which is inactive on neutrophils. CTAP-III is further processed during platelet release to 81-amino-acid β-thromboglobulin, which is also inactive. This is then cleaved by a cell surface-bound, cathepsin G-like enzyme on neutrophils to form 70-amino-acid CXCL7. CXCL7 may function as an immediate-early mediator of neutrophil recruitment released from platelets at sites of inflammation. An alternative possibility is that the massive release of CXCL7 from platelets may provide a mechanism for immobilizing neutrophils at the vessel wall under conditions of high shear through down-regulation of CXCR2. Compared to ELR CXC chemokines, CXCL4 does not induce chemotaxis or degranulation of lysosomal enzymes. It does, however, induce secondary granule exocytosis and release of matrix-degrading enzymes, which may facilitate neutrophil penetration of inflamed tissues. Moreover, it mediates strong adhesion of neutrophils to endothelial cells by functional activation of lymphocyte function-associated antigen-1 (LFA-1), unlike the ELR CXC chemokines, which induce adhesion by up-regulating the adhesion molecule Mac-1.

A common function reported for CXCL4, CXCL7, and CXCL8 is to increase the survival of normal hematopoietic precursors and to protect them from the toxicity of chemotherapeutic agents. A more unique function for CXCL4 is its strong prothrombotic activity, due to its ability to bind heparin. Unfortunately, this sometimes results in the clinical condition heparin-induced thrombocytopenia, which is characterized by formation of antibodies to a

complex of CXCL4 and heparin. This is a well-recognized risk factor for thromboembolic complications that occurs in approximately 1–5% of patients treated with heparin.

C. CXCL15 and Innate Immunity

CXCL15 (lungkine) is a non-ELR mouse chemokine that lacks a defined human counterpart. The selective and constitutive expression of CXCL15 mRNA in fetal and adult mouse lung, particularly in epithelial cells, is distinct from that of all other known chemokines, which suggested at first that it may have a developmental or homeostatic function. However, the CXCL15 knockout mouse has normal lung development. Instead, it has increased susceptibility to *Klebsiella pneumoniae*, indicating that CXCL15 functions in innate immunity. Consistent with this finding, CXCL15 is secreted into the air spaces, induces *in vitro* and *in vivo* migration of neutrophils, and is up-regulated in lung inflammation models.

D. CXCL9, CXCL10, and CXCL11: Non-ELR Inflammatory CXC Chemokines in Adaptive Immunity

CXCL9, CXCL10, and CXCL11 (also known as Mig, IP-10, and I-TAC, respectively) form a structurally and functionally related subgroup of non-ELR CXC chemokines that regulate the migration of Th1-polarized effector T cells to inflamed sites during the adaptive immune response. Two key properties common to all three of these chemokines account for their involvement in Th1 responses. First, all three are induced at the transcriptional level in diverse cell types by the Th1 immunoregulatory cytokine interferon-γ (IFN-γ), but not by the Th2 cytokine IL-4. Second, all three signal via the same receptor, CXCR3, which is invariant among chemokine receptor combinations that mark activated Th1-polarized $CD4^+$ T cells. Thus, in Th1 immunity, there is a positive feedback loop in which IFN-γ induces the production of these chemokines, which then recruit T cells that produce IFN-γ.

Other factors may differentially regulate CXCL9, CXCL10, and CXCL11 expression, which may account for their specialized biological roles. CXCL9 is the most strongly dependent on IFN-γ for expression. Nevertheless, it can also be induced by TNF-dependent factors in high endothelial venules, which results in monocyte migration to lymph nodes draining inflamed tissues. CXCL10 is constitutively expressed in stromal cells of lymphoid organs (spleen, thymus, and lymph nodes), suggesting a potential role in T-cell development and effector function. Detailed study of CXCL9 and CXCL10 during viral and protozoan infections of mice has revealed overlapping but distinct patterns of expression. CXCL11 is the most potent CXCR3 agonist in chemotaxis assays and preferentially induces transepithelial migration of T cells and down-regulation of the receptor.

CXCL10 appears to be the most powerful chemokine mediator of acute cardiac allograft rejection. In human, this chemokine and leukocytes expressing CXCR3 are detected in rejecting human cardiac allografts, and in a mouse model, rejection does not occur if the recipient mouse, treated with a brief, subtherapeutic course of cyclosporin A, comes from a CXCR3 knockout background or if the donor heart is from a CXCL10 knockout background. Moreover, wild-type mice treated with an anti-CXCR3 monoclonal antibody show prolonged allograft survival. Apparently, CXCL9 and CXCL11 do not compensate for the absence of CXCL10 because they are expressed later and at lower levels. CXCL10 neutralization is also protective in experimental autoimmune encephalomyelitis.

Likewise, in mouse cytomegalovirus infection, which causes hepatitis, a chemokine-to-cytokine-to-chemokine cascade selectively involving CXCL9 is required for antiviral host defense. In particular, hepatic CCL3 (MIP-1α) production is required for recruitment of NK cells to the liver. NK cells are the major source of IFN-γ in this model, and IFN-γ induces CXCL9, which is required for protection.

Consistent with these observations, CXCL9 and CXCL10 have been associated mainly with Th1-polarized human diseases such as psoriasis, tuberculoid leprosy, and sarcoidosis. In addition, virtually all T cells in rheumatoid arthritis synovial fluid and in various inflamed tissues, such as in ulcerative colitis, chronic vaginitis, and sarcoidosis, express CXCR3, particularly in perivascular regions. CXCR3 is also consistently detected on transformed B cells from chronic lymphocytic leukemia (CLL) patients. Thus, CXCR3 and its ligands are attractive clinical targets in Th1-polarized immunologically mediated diseases and possibly cancer. CXCL9 and CXCL10 have also shown efficacy as anti-tumor agents in mouse models, delivered directly as protein or by genetic vectors. Moreover, CXCL10 has been used therapeutically in a Th2-polarized mouse model of airway inflammation, resulting in

conversion to a Th1 immune response and reduced disease progression.

VI. HOMEOSTATIC CXC CHEMOKINES

A. CXCL12

CXCL12, the only chemokine essential for life, is constitutively expressed in most tissues and is a major regulator of hematopoiesis and embryonic development. The gene is alternately spliced to encode two functionally indistinguishable variants, CXCL12α and CXCL12β, which differ by a 4-amino-acid extension at the C-terminus. Originally isolated from bone marrow stromal cells, CXCL12 is the only known endogenous ligand for CXCR4, the most broadly expressed and highly conserved of all chemokine receptors. In addition to cells in many tissues, CXCR4 is found on all types of leukocytes and unlike many other chemokine receptors it does not require cell activation for expression on freshly isolated T cells from peripheral blood. Accordingly, CXCL12 is a powerful pan-leukocyte chemoattractant *in vitro*, although specific roles in the inflammatory response, lymphocyte homing, and recirculation have not yet been delineated.

Genetic disruption of CXCL12 and CXCR4 in the mouse gives the same phenotype, suggesting that they make up a monogamous signaling unit *in vivo*. The animals die of unclear causes in the perinatal period, with abnormal bone marrow myelopoiesis and defective B-cell, but normal T-cell, lymphopoiesis. Together with the fact that CXCL12 is the most highly expressed chemokine in bone marrow, these data suggest that CXCL12 may promote hematopoiesis in part by regulating the trafficking and positioning of hematopoietic precursor cells in this organ. Consistent with this finding, human stem cell engraftment has been reported to be regulated by CXCR4 in non-obese diabetic/severe combined immunodeficiency disease (NOD/SCID) mice. CXCL12 may also be important in thrombopoiesis and platelet activation. It induces megakaryocyte migration and is the only known chemokine that induces platelet aggregation, mediated through CXCR4. Since CXCL12 is expressed by smooth muscle cells, endothelial cells, and macrophages in human atherosclerotic plaques but not in normal vessels, it may play a role in the pathogenesis of atherosclerosis and thrombo-occlusive diseases. CXCL12 and CXCR4 knockout mice also have ventricular septal defects, defective gastric vasculogenesis, and defective cerebellar granule cell positioning, indicating a broad role in development of multiple nonhematopoietic cell lineages.

The CXCL12/CXCR4 axis may also be important in cancer through diverse mechanisms, including promotion of angiogenesis, recruitment of cancer-associated leukocytes, and direct guidance of cancer cells to metastatic sites. In this regard, human breast cancer cells but not normal breast epithelium express CXCR4, and preferred target organs for breast cancer metastasis (bone marrow, lymph node, liver, and lung) are rich in CXCL12. In a mouse model, the blockade of CXCR4 prevented metastasis of breast cancer to liver and lymph node. Roles in melanoma and ovarian cancer have also been suggested. Furthermore, high CXCR4 levels on cancer cells have been associated with extramedullary organ infiltration in childhood acute lymphoblastic leukemia.

Along with CCR5, CXCR4 is a major HIV co-receptor that facilitates the infection of $CD4^+$ target cells. HIV strains that use CXCR4 selectively, known as X4 strains, typically do not transmit disease but emerge in a subset of patients late in the course of infection. CXCL12 can specifically inhibit X4 HIV replication by steric blockade as well as by inducing internalization of CXCR4. X4 HIV gp120 has additional diverse CXCR4-dependent effects on cells that have interesting implications for mechanisms of HIV pathogenesis. It is able to induce monocyte migration, which may be important for recruitment of additional target cells. It can induce apoptosis of human neurons, which may be relevant to the pathogenesis of HIV encephalitis and AIDS dementia. In addition, it can stimulate macrophages to induce apoptosis of $CD8(^+)$ T cells, suggesting a co-receptor mechanism of cytotoxic T-lymphocyte suppression of viral replication.

Several small molecules and peptides, including some originally identified in HIV drug discovery programs, have been shown to selectively block chemokine receptor and/or HIV co-receptor activities of CXCR4. They include CXCL12-derived peptides, the polyarginine ALX40-4C, and the bicyclam AMD3100. The last substance is currently in clinical trials for HIV/AIDS. CXCR4 has also been blocked with intrakines, which are modified forms of CXCL12 delivered by gene therapy that remain in the endoplasmic reticulum and block the surface expression of newly synthesized CXCR4. Clinical development of CXCR4-blocking agents in HIV infection will have to confront safety questions as to whether the virus will evolve to use other co-receptors

and whether one or more of the phenotypes seen in CXCR4 knockout mice will occur.

B. CXCL13

CXCL13 [also known as B-cell-attracting chemokine 1 (BCA1)] and CXCR5 comprise a monogamous ligand–receptor pair critical for the homeostatic organization of B-cell zones of secondary lymphoid tissue. CXCR5 has been detected on all peripheral blood and tonsillar B cells, but on only a fraction of cord blood and bone marrow B cells. A third subset of $CD4^+$ memory cells, designated follicular helper T cells (T_{FH}), is defined by CXCR5 expression and the absence of CCR7. These cells do not produce Th1 or Th2 cytokines upon activation but are able to provide help for B-cell maturation and antibody production. Consistent with this finding, they constitute the majority of $CD4^+$ memory cells in follicular zones of inflamed tonsils. Like other chemokine receptors, CXCR5 is dynamically regulated on T cells. Following TCR stimulation, CXCR5 is up-regulated on memory/effector T cells, whereas IL-2 causes down-regulation.

CXCL13, the major chemokine active on mature B cells, is constitutively expressed in secondary lymphoid organs on follicular high endothelial venule (HEV) and therefore is properly positioned to focus $CXCR5^+$ B and T cells from the blood into follicles. Consistent with this finding, CXCR5 knockout mice have a severe defect in normal B-cell migration and localization and have aberrant lymphoid development, including absent inguinal lymph nodes, absent or phenotypically abnormal Peyer's patches, and ectopic development of germinal centers in T-cell zones of the spleen. CXCL13 is also required for B1-cell homing, natural antibody production, and body cavity immunity. CCL19/CCL21–CCR7 play an analogous role for T-cell–dendritic cell positioning in T-cell zones.

C. CXCL14

CXCL14, also known as BRAK (breast and kidney chemokine), is a recently identified non-ELR CXC chemokine with three unusual properties. First, it is constitutively expressed in diverse human tissues (heart, brain, placenta, lung, intestine, liver, skeletal muscle, and pancreas) and cell types (squamous epithelium, keratinocytes, dermal fibroblasts, and lamina propria cells of the intestine). Second, like CXCL12 and unlike all other chemokines, it is highly conserved among species (two amino acid differences between human and mouse). Third, it is the only chemokine that chemoattracts only monocytes. *In vivo*, macrophages were reported to colocalize with CXCL14-producing fibroblasts, suggesting that it may regulate the homeostatic recruitment and development of tissue macrophages. Resting leukocytes do not express CXCL14; however, tumor-infiltrating leukocytes and LPS-stimulated B cells and monocytes are strongly positive, suggesting additional potential roles in host–tumor interactions and inflammation. In striking contrast to normal tissue, most cancers do not express CXCL14.

D. CXCL16

CXCL16 is distantly related to other CXC chemokines. Its unique hybrid structure is described in Section I. CXCL16 is expressed on the surface of antigen-presenting cells (B cells, macrophages, and dendritic cells in lymphoid organ T-cell zones) and by cells in the splenic red pulp. Functional CXCL16 is also shed from macrophages. The CXCL16 receptor CXCR6 is expressed preferentially on memory T cells and on activated Th1 and Tc1 effector T-cell subsets. The exact biological role of the CXCL16/CXCR6 axis is unknown; however, reasonable hypotheses include attraction of activated T-lymphocyte subsets during inflammation, facilitation of immune responses via cell–cell contact, and guidance of T-cell trafficking in the splenic red pulp. CXCL16 is also expressed in the thymic medulla and in some nonlymphoid tissues, suggesting roles in thymocyte development. Like CXCR4, CXCR6 functions as an HIV co-receptor and is able to support cell entry by simian immunodeficiency virus and both X4 and R5 strains of HIV. Its precise role in HIV pathogenesis has not been defined.

VII. CXC CHEMOKINES AND ANGIOGENESIS

There is growing evidence that angiogenesis is regulated in part by the balance of angiogenic and angiostatic chemokines in tissue microenvironments. CXCL12 and all ELR CXC chemokines are angiogenic in rat corneal micropocket and related assays, whereas CXCL4 and the CXCR3 ligands CXCL9–11 are angiostatic. CXCR2 is expressed on endothelial cells and appears to mediate angiogenic signals, whereas angiostatic chemokines appear to work not by GPCRs but by binding to glycosaminoglycans on endothelial cells, which prevents docking of pro-angiogenic growth factors such as basic fibroblast growth factor (bFGF). A functional CXCL10-specific

receptor expressed by epithelial and endothelial cells that is neither CXCR3 nor glycosaminoglycan must also be considered.

The balance of angiogenic and angiostatic CXC chemokine expression has been proposed to regulate wound healing, fibrotic diseases, and cancer growth and spread. More generally, the overall balance of these chemokines may regulate the extent of injury and the rate of repair in disease. In addition to direct effects on endothelial cells, a countercurrent principle of chemokine action has been proposed in which paraneoplastic expression of ELR CXC chemokines promotes tumorigenesis by favoring a pro-angiogenic environment in part by inducing the release of pro-angiogenic factors such as gelatinase B from recruited neutrophils. This indicates that blocking pro-angiogenic chemokines or administering angiostatic chemokines may be beneficial in appropriately selected cancers. This has been borne out in several instances, including human non-small-cell lung carcinoma (NSCLC), in which the ratio of ELR to non-ELR CXC chemokine expression has been reported to be high, and in a SCID mouse model in which either administration of exogenous CXCL9 or neutralization of endogenous tumor-derived CXCL8 could inhibit tumor growth and metastasis via a decrease in tumor-derived vessel density. Importantly, CXCL8 did not act as an autocrine growth factor for NSCLC proliferation, and in general, for reasons that are unclear, tumors appear to have surprisingly small numbers of leukocytes given the amount of chemokines that they make. Thus, their major effects on tumorigenesis may be at the level of angiogenesis.

Chemokines may also have immunologically mediated effects on cancer. In this regard, induction of tumor-protective $CD8^+$ cellular immunity by IL-12 in a murine neuroblastoma model has been reported to depend entirely on endogenous CXCL10, and exogenous CXCL10 has been reported to block establishment of tumor in a thymus-dependent manner. CXCL9 and CXCL10 have also been reported to enhance the anti-tumor effects of IL-2 and IL-12 in mouse models. Genetic fusion of CXCL10 to a self tumor antigen induces protective, T-cell-dependent anti-tumor immunity; however, the mechanism appears to involve recruitment of antigen-presenting cells. With regard to fibrotic disorders, neutralization of endogenous MIP-2 has been shown to be protective in bleomycin-induced pulmonary fibrosis in mice.

Taken together, CXC chemokines deserve attention as potential therapeutic agents in cancer. This concept has been tested clinically in the case of CXCL4, which produces striking anti-tumor effects in animal models; however, responses have thus far been disappointing in humans.

VIII. VIRAL CXC CHEMOKINES

HIV and many herpesviruses and poxviruses deploy chemokine mimics, which are used for diverse purposes including immune evasion and cell entry. Among the herpesviruses, these mimics are typically acquired by copying host chemokine and chemokine receptor genes. Three herpesvirus CXC chemokines and two CXC chemokine receptors have been identified to date. Human cytomegalovirus (HCMV) has two adjacent open reading frames (ORFs) that encode CXC chemokines vCXC-1 (ORF UL146) and vCXC-2 (ORF UL147). The function of vCXC-2 has not been reported; however, vCXC-1 is a potent neutrophil chemoattractant acting specifically at CXCR2. This may account for the presence of neutrophils at sites of HCMV infection and could function to recruit more target cells for viral dissemination. Of note, MCK-2, a CC chemokine encoded by mouse CMV, appears to work in this manner. Specifically, it induces inflammation early at the site of infection and later promotes dissemination of the virus to the salivary gland.

Marek's disease virus (MDV), an α herpesvirus of chickens that infects the feather follicle epithelium and causes a variety of syndromes, including generalized immunosuppression, acute neuronal symptoms, paralysis, T-cell lymphomas, and, rarely, atherosclerosis, encodes a CXC chemokine designated vIL-8. Like host chemokine genes, and unlike other known viral chemokine genes, vIL-8 is encoded by multiple exons, suggesting that it was captured from genomic DNA or nuclear mRNA. It is expressed with late (γ2) kinetics. Baculovirus-expressed vIL-8 is secreted and directly chemoattracts chicken peripheral blood mononuclear cells but not heterophils. Direct effects of this chemokine on inflammation *in vivo* have not been defined. Instead, through undefined mechanisms, recombinant MDV lacking vIL-8 has been reported to support a decreased level of lytic infection and is less oncogenic.

Herpesvirus saimiri is also an oncogenic herpesvirus, but from the γ herpesviridae. It does not encode chemokines but instead encodes a receptor, ECRF3, encoded by ORF 74, which can be activated by human CXCL1, CXCL7, and CXCL8. This gene

does not appear to be required for transformation and its actual biological role is undefined. ECRF3 is syntenic with ORF 74 of the related γ herpesvirus HHV8, which encodes vGPCR. HHV8 is thought to be necessary although not sufficient for development of Kaposi's sarcoma and is thus also known as the Kaposi's sarcoma-associated herpesvirus. Transgenic mice expressing vGPCR under the control of the CD2 promoter develop multicentric, angioproliferative Kaposi's sarcoma-like lesions, although the receptor is actually expressed in a minority of proliferating cells. At the biochemical level, vGPCR constitutively induces NIH 3T3 cell transformation and angiogenesis *in vivo*, as well as pro-inflammatory cytokine, chemokine, and growth factor gene expression *in vitro*, and the activity can be modulated by chemokine agonists such as CXCL1 and by inverse agonists such as CXCL10 and CXCL12. The ability to respond to agonists appears to be important *in vivo* since KS-like tumors in mice do not occur when agonist recognition is abolished by receptor mutagenesis. The basic role of this receptor in the normal life cycle of HHV8 is not known.

IX. SUMMARY

The CXC chemokines, initially studied for their potent effects on neutrophils, are now generally recognized to have diverse pleiotropic activities, covering hematopoiesis, immunoregulation, and both innate and adaptive immune effector function and extending to hemostasis, organ development, angiogenesis, cancer, HIV pathogenesis, and herpesvirus infection. Emerging evidence suggests that cancers may grow and spread in part according to the balance of endogenous pro-tumorigenic and anti-tumorigenic CXC chemokines, which may have direct effects on cell proliferation and migration as well as modulate angiogenesis. These biological connections have come from systematic programs of chemokine and chemokine receptor discovery and expression. In contrast, the connection of CXC chemokines to HIV/AIDS and facilitation of other infectious diseases was completely unpredicted. CXCR2, CXCR3, and CXCR4 are now attractive therapeutic targets in inflammation, cancer, and HIV/AIDS, and selected chemokine ligands have potential applications as anti-tumor agents and as adjuvants in DNA vaccines. The stage is now set to discover whether the basic science reviewed here can be translated into clinical benefits.

Glossary

angiogenesis Blood vessel formation.

chemokine The term is derived from "chemotactic cytokine", which was coined to identify members of a family of structurally defined proteins, most of which directly chemoattract leukocytes. Collectively, chemokines and chemokine receptors coordinate specific leukocyte trafficking and are therefore critical to the development and function of the immune system.

chemotaxis Migration of a biological entity toward the source of a chemical stimulus. In the case of leukocytes, migration requires adhesion to a substrate, polarization of the cell's sensing surface, and cytoskeletal remodeling, which leads to protrusion of a leading edge and retraction of a trailing edge.

G-protein A guanine nucleotide-binding protein involved in intracellular signaling.

immune system The physiologic system consisting mainly of white blood cells that specializes in protecting the organism from infection and clearing debris after tissue injury.

leukocyte Any kind of white blood cell, divided into two main subgroups: phagocytes and lymphocytes. Phagocytes, which include neutrophils, monocytes, eosinophils, and dendritic cells, directly engulf microbes and other particulate matter. Lymphocytes, which include T cells and B cells, attack targets either directly, in the case of cytotoxic T cells, or indirectly, in the case of plasma cells, a terminally differentiated B cell specialized to produce antibodies.

receptor A cell-associated molecule able to activate the cell upon interaction with an extracellular stimulus. Chemokine receptors are all members of the G-protein-coupled receptor superfamily, which have seven conserved plasma membrane-spanning domains.

Cytokines and Anterior Pituitary Function

ADRIAN J. DUNN AND DAVID E. SCARBOROUGH
Louisiana State University Health Sciences Center

Cytokines are proteins or glycoproteins that are secreted by cells of the immune system. They play numerous important roles in coordinating immune system function and are the major messengers between immune cells. In this role, they are the hormones of the immune system. However, it has long been recognized that cytokines may also be synthesized and secreted by nonimmune cells and that they exert important effects on nonimmune cells.

I. INTRODUCTION

Cytokines comprise families of proteins formerly known as lymphokines (from lymphocytes), monokines (from monocytes), and the interleukins. The cytokine family includes 18 interleukins (ILs), numbered accordingly (IL-1 through IL-18), the interferons, and other molecules named for the function for which they were first discovered, such as tumor necrosis factor α (TNFα), transforming growth factor (TGF-α and TGF-β), leukemia inhibitory factor (LIF), macrophage-migrating inhibitory factor (MIF), and granulocyte/macrophage colony-stimulating factor (GM-CSF). A summary of the nature and activities of the principal cytokines follows.

A. Interleukin-1

IL-1 exists in two forms, IL-1α and IL-1β. The two forms are closely related but differ significantly in their amino acid sequences within species, and substantial differences exist in the amino acid sequences between species. There are two receptors for IL-1, type I and type II, but only the type I receptor is thought to be involved in physiological responses. The type II receptor does not contain an internal signaling sequence and has been postulated to function as a "decoy" receptor. Physiologically this may be equivalent to the presence of binding proteins or soluble receptors that buffer the free concentrations of important messengers. Both IL-1α and IL-1β bind on type I (and type II) receptors, and although IL-1α is somewhat less potent than IL-1β, both induce similar responses. There is an endogenously produced antagonist for the receptor to IL-1 (the IL-1 receptor antagonist, IL-1ra). IL-1 is

Cytokines and Anterior Pituitary Function

ADRIAN J. DUNN AND DAVID E. SCARBOROUGH
Louisiana State University Health Sciences Center

Cytokines are proteins or glycoproteins that are secreted by cells of the immune system. They play numerous important roles in coordinating immune system function and are the major messengers between immune cells. In this role, they are the hormones of the immune system. However, it has long been recognized that cytokines may also be synthesized and secreted by nonimmune cells and that they exert important effects on nonimmune cells.

I. INTRODUCTION

Cytokines comprise families of proteins formerly known as lymphokines (from lymphocytes), monokines (from monocytes), and the interleukins. The cytokine family includes 18 interleukins (ILs), numbered accordingly (IL-1 through IL-18), the interferons, and other molecules named for the function for which they were first discovered, such as tumor necrosis factor α (TNFα), transforming growth factor (TGF-α and TGF-β), leukemia inhibitory factor (LIF), macrophage-migrating inhibitory factor (MIF), and granulocyte/macrophage colony-stimulating factor (GM-CSF). A summary of the nature and activities of the principal cytokines follows.

A. Interleukin-1

IL-1 exists in two forms, IL-1α and IL-1β. The two forms are closely related but differ significantly in their amino acid sequences within species, and substantial differences exist in the amino acid sequences between species. There are two receptors for IL-1, type I and type II, but only the type I receptor is thought to be involved in physiological responses. The type II receptor does not contain an internal signaling sequence and has been postulated to function as a "decoy" receptor. Physiologically this may be equivalent to the presence of binding proteins or soluble receptors that buffer the free concentrations of important messengers. Both IL-1α and IL-1β bind on type I (and type II) receptors, and although IL-1α is somewhat less potent than IL-1β, both induce similar responses. There is an endogenously produced antagonist for the receptor to IL-1 (the IL-1 receptor antagonist, IL-1ra). IL-1 is

produced mainly by activated monocytes but may be produced in many kinds of cells (e.g., epidermal cells).

IL-1 was initially characterized as an endogenous pyrogen, i.e., a substance that induces fever. However, it was soon discovered that purified recombinant IL-1β administered to rats potently activated the hypothalamic–pituitary–adrenocortical (HPA) axis. This activity was confirmed in other species and is not confined to the HPA axis. It is now known that IL-1 has a plethora of diverse effects on different cells in the body. It is recognized as a major proinflammatory cytokine—it is produced rapidly after damage to many different cell types and it signals other cells to initiate inflammatory responses.

B. Interleukin-2

IL-2 is produced by T helper (T_H1) lymphocytes and is a growth-promoting factor that is critical for the clonal proliferation of T cells.

C. Interleukin-6

IL-6 is a glycoprotein and a proinflammatory cytokine produced in large quantities by monocytes early in immune responses. It is considered to be responsible for the acute-phase response, a critical step in immune activation. The acute-phase response involves induction of fever, activation of the HPA axis, and production of a number of circulating proteins (α1-acid glycoprotein, α_2-macroglobulin, β-fibrinogen, C-reactive protein, serum amyloid A protein, and transferrin); the acute-phase response also results in an increase in the number of peripheral leukocytes, especially neutrophils. It is important in B-cell proliferation. Many of the functions of IL-6 overlap with those of IL-1. Plasma concentrations of IL-6 are elevated dramatically and rapidly after infections and following many other kinds of biological stress.

D. Transforming Growth Factor-β

TGF-β exists in five isoforms (TGF-β1–TGF-β5). The functions of these isoforms overlap. TGF-β is produced in large quantities by platelets and certain other tissues and is a potent growth inhibitory factor for many kinds of cells, but especially for T lymphocytes.

E. Tumor Necrosis Factor α

As its name implies, TNFα has the ability to kill cells by inducing cytotoxicity. It is considered to be the third major proinflammatory cytokine. It is thought to be responsible for apoptosis and cachexia, the life-threatening state associated with severe infections.

F. Interferons

The interferons (IFNα, IFNβ, and IFNγ) are regarded as antiviral agents. IFNγ is produced by T_H1 cells and enhances natural killer (NK) cell activity.

G. Cytokines and the Pituitary Gland

The presence of certain cytokine receptor messenger RNAs (mRNAs) and, in some cases, of the cytokine receptors (especially receptors for IL-1, IL-2, and IL-6) has been demonstrated in various preparations of anterior pituitary cells. Cytokine mRNAs and cytokines have also been found (IL-1, IL-1ra, IL-2, and IL-6). Unfortunately, although the presence of mRNA is suggestive, it should not be assumed that gene products are properly formed and are functional. Generally, an abundance of cytokines and their receptors has been found only in abnormal preparations, in cell lines derived from the anterior pituitary, or in *ex vivo* preparations. Nevertheless, limited amounts of these cytokines and their receptors may exist under normal physiological conditions, and they certainly appear to be induced during sepsis and other pathological conditions. There has been much speculation that cytokines can directly affect the release of anterior pituitary hormones, but there are few if any convincing data indicating a physiological role. An important exception is IL-6, which may act directly on the pituitary to elicit HPA activation (see later).

The following discussions review and summarize the known actions of cytokines impacting the secretion of hormones of the anterior pituitary. Table 1 provides a summary of the known actions of cytokines on anterior pituitary hormones.

II. EFFECTS OF CYTOKINES ON THE HPA AXIS

A. The HPA Axis

The HPA axis is a hierarchy in which activation of neurons in the paraventricular nucleus (PVN) of the hypothalamus, which contains corticotropin-releasing hormone (CRH), results in the secretion of CRH in the median eminence region of the hypothalamus. CRH is secreted into the portal blood supply and is carried to the anterior pituitary; there it acts on specific receptors on corticotrophs, resulting in the

TABLE 1 Summary of Cytokine Actions on Anterior Pituitary Hormone Secretion

secretion of adrenocorticotropic hormone (ACTH) into the general circulation. ACTH is transported throughout the body, but as it passes through the adrenal cortex it binds to specific receptors that stimulate the synthesis and subsequent secretion of adrenal glucocorticoids (corticosterone in rodents, cortisol in humans and many other species). Circulating glucocorticoids are ultimately responsible for a host of metabolic and regulatory responses. Compared to intact animals, glucocorticoid-deficient animals and humans are profoundly more likely to succumb to a wide variety of illnesses and stresses, especially infections and trauma. Routinely, glucocorticoid concentrations are markedly elevated in severe infections and injuries. Thus, the mechanism for inducing a glucocorticoid response to infection and injury is of major physiological importance.

1. IL-1-Induced Activation of the HPA Axis

A particularly critical observation is that intraperitoneal (ip) administration of purified recombinant human IL-1β to rats potently activates the HPA axis. This phenomenon has been confirmed by a number of researchers and in other species, including humans. The activity is not confined to IL-1 or to the HPA axis, although IL-1 is the most potent stimulator of this axis. The mechanism of this effect is still somewhat controversial, and multiple mechanisms exist. Apparently, IL-1 can act at multiple levels of the HPA axis, i.e., the brain, the hypothalamus, the anterior pituitary, and the adrenal cortex. It may well be that the most important mechanism varies with the physiological state of the animal. However, the weight of the evidence suggests that under normal physiological circumstances the primary mechanism involves hypothalamic CRH.

B. IL-1 Action on the Adrenal Cortex

IL-1 has been shown to stimulate the secretion of corticosterone from the adrenal cortex *in vitro* in some studies, but not in others. A direct effect on the adrenal cortex is unlikely to explain the normal *in vivo* elevation of plasma concentrations of corticosterone because IL-1 administration also elevates plasma ACTH in both rats and mice. Also, IL-1 fails to induce increases in plasma corticosterone in hypophysectomized rats and mice (one rat study, however, did show some increase). Moreover, the corticosterone response to IL-1 in rats and mice is largely prevented by pretreatment with an antibody to CRH.

C. IL-1 Action on the Anterior Pituitary

An early report indicated that IL-1 induces ACTH secretion from AtT-20 cells, but studies of abnormal cells may not be relevant in intact animals. Several reports have indicated that IL-1 stimulates ACTH release from the anterior pituitary *in vitro*, but many other investigators have failed to find effects of IL-1 on the *in vitro* pituitary secretion of ACTH. It is important to note that *in vitro* studies cannot answer questions concerning *in vivo* mechanisms. Interestingly, the conflicting results might be explained by the observation that prolonged incubation appears to increase the sensitivity of pituitary ACTH secretion to IL-1, while decreasing the response to CRH. A direct pituitary effect appears to be excluded as the normal physiological mechanism because lesions of the hypothalamic PVN and pretreatment with CRH antibodies prevent the ACTH and glucocorticoid responses to IL-1.

D. IL-1 Action via the Hypothalamus

A hypothalamic site of action of peripherally administered IL-1 is suggested because lesions of the PVN prevent increases in plasma ACTH and corticosterone. Also, IL-1 increases the electrophysiological activity of CRH neurons *in vivo*. In support of a hypothalamic involvement, IL-1 stimulates CRH release from hypothalamic slabs *in vitro*,

although such *in vitro* studies cannot provide definitive conclusions. CRH is implicated by the observation that peripherally administered IL-1 elevates concentrations of CRH in portal blood and depletes CRH from the median eminence, both actions presumably reflecting increased release of CRH. Also, *in vivo* immunoneutralization of CRH prevents increases in plasma ACTH and corticosterone in response to IL-1 in rats and mice. Moreover, CRH knockout mice (mice lacking the gene for CRH and thus unable to produce it) show only a very small increase in plasma corticosterone after IL-1 administration.

The evidence for direct actions on the pituitary and adrenal glands derives largely from *in vitro* experiments and is therefore susceptible to artifact. The *in vivo* evidence strongly favors a role for hypothalamic CRH as the major mechanism in normal healthy animals. However, in studies of mice treated with antibody to CRH, there were small increases in plasma corticosterone following intraperitoneal IL-1, and similar small increases were also observed in CRH knockout mice. This suggests that when the HPA axis is impaired, the pituitary or adrenal cortex may gain the ability to mount a modest glucocorticoid response. This may have pathological significance in that a glucocorticoid response may be conserved when the pituitary or hypothalamus fails to respond. It is to be noted that an IL-1- and lipopolysaccharide (LPS)-induced secretion of ACTH and corticosterone can be observed in young rats at a time when HPA responses to stressors are minimal or absent.

It should not be assumed that the action of IL-1 is exerted directly on the hypothalamus, even though intrahypothalamic injections of IL-1 can activate the HPA axis. There is some evidence that IL-1 may act on the median eminence, on the organum vasculosum laminae terminalis (OVLT), and/or on the area postrema. All three structures are circumventricular organs that lack a blood–brain barrier, thus the entry of IL-1 would not be hindered. There is also substantial evidence for the involvement of brain noradrenergic systems. Peripheral administration of IL-1β activates brain noradrenergic neurons, especially in the hypothalamus. These neurons may be activated in the nucleus tractus solitarius of the brain stem, the site of origin of ascending noradrenergic neurons that innervate the hypothalamus, including the PVN. The activation may be local via the area postrema or indirectly via vagal afferents from the periphery. In rats, lesions of this ascending noradrenergic projection impair the HPA response. A subdiaphragmatic vagotomy, which lesions the vagal afferents that project to the nucleus tractus solitarius, also inhibits the noradrenergic response and the increase in plasma ACTH. However, the increase in plasma corticosterone is significantly less affected.

It is entirely possible that more than one mechanism is involved in the IL-1-induced activation of the HPA axis and that the precise mechanism may depend on the site in which IL-1 is produced or the route of its injection. The HPA response to intravenous (iv) IL-1 occurs very rapidly after injection, dissipates rapidly, and is quite sensitive to cyclooxygenase (COX) inhibitors. By contrast, the response to ip IL-1 is sensitive to COX inhibitors only in the early phase of the response (which is much more prolonged than the response to iv IL-1). The latter may be more dependent on the noradrenergic system, which responds in a manner that closely parallels the increases in plasma corticosterone.

The elevation of glucocorticoids by IL-1 (and IL-6 and TNFα) has been speculated to provide feedback, limiting immune responses during inflammatory responses. Perhaps more importantly, it may serve to limit inflammatory responses by confining them to the damaged or infected sites in the body.

E. Other Cytokines

1. Interleukin-2

Although a few reports suggest that IL-2 can activate the HPA axis, most indicate very little effect, unless IL-2 is infused chronically.

2. Interleukin-6

IL-6 administration has HPA-activating activity, increasing plasma concentrations of ACTH and corticosterone in rats, mice, and humans. The HPA response to ip IL-6 is fast and short-lived compared to the response to IL-1. IL-6 is significantly less potent in elevating plasma ACTH and corticosterone compared to IL-1, requiring doses an order of magnitude higher. Moreover, the maximum response is well below that elicited by IL-1, and even microgram doses fail to induce maximal plasma concentrations of corticosterone in mice. However, in humans, plasma cortisol is readily elevated by relatively small doses of IL-6.

The HPA-activating effect of IL-6 in rats has been reported to be sensitive to an antibody to CRH. However, IL-6 induces relatively normal ACTH responses in CRH knockout mice. IL-6 is known to have a direct stimulatory effect on ACTH secretion

from the pituitary and, unlike IL-1, stimulates Fos expression in the pituitary gland, but not in the PVN. These latter results suggest a pituitary site of action for IL-6 in elevating plasma ACTH and corticosterone, consistent with the rapid time course. IL-6 may be important in mediating ACTH responses in the absence of CRH. The HPA response to IL-6 is not sensitive to COX inhibitors.

3. Tumor Necrosis Factor α

Administration of TNFα to rats at doses that fail to affect blood pressure, food consumption, or plasma prolactin concentrations causes significant elevations of plasma ACTH within 20 min. Most reports have found TNFα like IL-6, to be significantly less potent than IL-1 in rats and mice, although perhaps with a more prolonged effect. However, one group found human TNFα to be almost equipotent with human IL-1β in rats. Activation of the HPA axis by TNFα is abolished by lesions of the PVN and appears to be mediated at least partially by CRH. Treatment with a CRH antibody completely blocks the ACTH response, whereas the corticosterone response is only partially inhibited. Indomethacin blocks the ACTH response to TNFα in rats in a dose-dependent manner.

4. Interferons

Intraperitoneal administration of human or mouse IFNα to mice fails to alter plasma ACTH or corticosterone. Administration of IFNα to humans, however, elevates plasma cortisol. Most studies have shown that IFNγ has little effect on the HPA axis.

5. Leukemia Inhibitory Factor

LIF appears to play a role in HPA activation. LIF knockout mice show impaired HPA responses to stress and immune stimuli, and this deficit is reversed by LIF administration.

III. GROWTH HORMONE AND INSULIN-LIKE GROWTH FACTOR-I

Growth hormone (GH) plays a major role in assuring the proper growth of long bones during maturation; it also modulates carbohydrate and fat metabolism at all ages and provides an ongoing stimulus to a wide variety of tissues in adulthood. GH-deficient adults suffer loss of bone mineral density, loss of muscle mass, and decreased ability to maintain blood glucose levels. GH also appears to have a variety of effects on immune cells. Most of these are supportive or stimulatory. Because systemic cytokine concentrations are elevated in response to major tissue trauma and serious infection, cytokine modulation of GH secretion may be useful in coordinating a metabolic response to the starvation that accompanies major illness or injury and in supporting the immune and inflammatory aspects of the host response. Many actions of GH are believed to be mediated by its secondary hormone insulin-like growth factor-I (IGF-I). In the circulation IGF-I is associated with a number of binding proteins that may modulate its activity. Thus, assessing the full physiological action of GH is quite complex and simple measurements of GH levels may be misleading.

Acute LPS administration stimulates GH secretion in humans and in sheep but suppresses it in rats, chickens, and cattle. In humans, many stressors induce increases in GH secretion, including exogenous pyrogen and bacterial sepsis. These increases are associated with declines in the levels of IGF-I, suggesting resistance to the usual GH stimulation of IGF-I. GH has some direct actions, especially the mobilization of fatty acids from fat stores, which likely circumvent the resistance phenomenon. In chronic critical illness, GH secretion declines to below normal levels over the initial 2 weeks and stays low until recovery occurs. Recent studies of exogenous GH treatment in prolonged critical illness have shown some improvement in nitrogen balance, but have not shown improved patient survival. Administration of growth hormone-releasing hormone (GHRH) in such patients improves GH secretion, suggesting that suppression of GH secretion is at the hypothalamic level.

The precise role of cytokines in these changes in GH secretion and action is still unclear. Hypothalamic regulators of pituitary GH secretion include stimulation by GHRH and inhibition by somatostatin. IL-1β, TNFα, and IL-6 have been shown to stimulate somatostatin release from rat hypothalamic cells *in vitro*. IL-1 also stimulates GHRH release. In some studies, IL-1 administered into the third ventricle of male rats increased GH secretion, but other investigators have found the opposite effect. IL-6 given iv to rats did not alter GH secretion. *In vitro*, IL-1 stimulates GH release from rat hemipituitary and dispersed pituitary cell cultures. TNFα inhibits basal release and GHRH-stimulated GH secretion from dispersed rat anterior pituitary cell cultures. Thus, in rat cells *in vitro* there are opposing effects of different cytokines on GH secretion. The inhibitory effect of TNFα on GH release and the stimulatory effects of IL-1, IL-6, and TNFα on somatostatin would be

consistent with the tendency of LPS to suppress GH in the rat. The stimulatory effects of IL-1 on GH in the rat model *in vitro* and *in vivo* run counter to the *in vivo* effect of LPS. In sheep, LPS stimulates GH secretion *in vivo*. *In vitro* in dispersed sheep pituitary cells, IL-1 stimulates basal GH secretion, but not GHRH-stimulated GH secretion. TNFα inhibits GHRH-stimulated GH secretion, but not basal GH release. IL-2 and IFNγ are without effect.

In sum, there are major species differences in the response of GH to inflammatory mediators. It is unclear whether the down-regulation of GH observed in prolonged human critical illness is harmful or helpful, and whether any cytokine effects at the level of the hypothalamus or pituitary are key elements of that down-regulation. Cytokine stimulation of hypothalamic somatostatin and TNFα inhibition of pituitary GH release are consistent with the dominant GH changes seen in humans.

IV. THYROID-STIMULATING HORMONE

In humans with severe illnesses, there are multiple abnormalities in thyroid hormone economy, including low plasma triiodothyronine and normal or low plasma thyroxine. Collectively, these changes are called the euthyroid sick syndrome, meaning that the patient has no intrinsic disease of the thyroid and that the changes seen are temporary and entirely secondary to the nonthyroidal illness. Clinically, these patients lack signs and symptoms of hypothyroidism. Even so, these changes could have survival value in that the catabolic state that usually accompanies severe illness may be moderated by the reduction in thyroid hormone activity and gluconeogenesis may be facilitated. Treatment to increase the abnormally low thyroid levels has not proved beneficial. Ordinarily, low levels of triiodothyronine (T3) and tetraiodothyronine (T4, or thyroxine) result in stimulation of pituitary thyroid-stimulating hormone (TSH) secretion. However, TSH levels in inflammation and sepsis are more commonly low or normal, suggesting that TSH secretion is inhibited. Pituitary TSH secretion is stimulated by hypothalamic thyrotropin-releasing hormone (TRH) and inhibited by hypothalamic somatostatin. Because stalk section results in loss of TSH secretion, TRH is believed to be the more important regulator.

Pharmacologic doses of glucocorticoids are known to suppress TSH secretion. Because cytokines are strong stimulators of ACTH and glucocorticoid secretion, one possibility is that the suppression of TSH seen with cytokine stimulation is secondary to elevation of glucocorticoids. Against this, at least one study comparing heart attack patients with septic patients found suppression of TSH only in the sepsis group, despite both groups having equivalent elevations of ACTH and cortisol.

Bacterial endotoxin given to hypothyroid subjects with basally elevated TSH levels produces a rapid decline in TSH levels. In both rats and humans the major inflammatory cytokines (IL-1, TNFα, and IL-6) suppress TSH secretion *in vivo*. In general, cytokines appear to mediate most of the effects of endotoxin on neuroendocrine systems. Although this is likely to be true for endotoxin effects on TSH, neutralization of TNFα with a fusion protein and blockade of IL-1 with the IL-1 receptor antagonist did not block the suppression of TSH produced by endotoxin given to human volunteers. IL-1β inhibits hypothalamic TRH gene expression in the rat hypothalamus and in rat hypothalamic cell cultures. TNFα treatment reduces hypothalamic TRH content in rats. IL-1β, TNFα, and IL-6 also stimulate somatostatin secretion by hypothalamic cell cultures. IL-1β stimulates somatostatin release from hypothalamic slices. Either inhibition of TRH or stimulation of somatostatin would tend to suppress pituitary TSH secretion. Most *in vitro* studies of cytokine actions on cultured pituitary cells have not found significant changes in either basal or TRH-stimulated TSH secretion.

In sum, infection and inflammation affect thyroid hormone metabolism at multiple levels. The major neuroendocrine change is suppression of TSH secretion, which seems likely to be mediated by cytokine inhibition of hypothalamic TRH or stimulation of hypothalamic somatostatin.

V. LUTEINIZING HORMONE AND FOLLICLE-STIMULATING HORMONE

Gonadal function is regulated in an unusually complex manner. Multiple gonadal hormones interact with the pulsatile release of hypothalamic gonadotropin-releasing hormone (GnRH) to control secretion of the pituitary gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH secretion is specifically controlled by modulation of the pulsatile release of the hypothalamic peptide GnRH, interacting with the feedback effects of gonadal hormone levels. [GnRH is also called luteinizing hormone-releasing hormone

(LHRH). Some investigators prefer the latter term on the grounds that there may be separate specific hypothalamic regulators of FSH secretion.] FSH regulation is further complicated in that members of a family of peptide hormones, the activins and inhibins, are secreted by the gonads and interact with gonadal hormone levels and GnRH activity in the control of pituitary FSH secretion. Severe illness and stress generally inhibit gonadal function. As with the thyroid axis, cytokines and severe illness produce direct effects, lower circulating concentrations of the end-organ hormones without the expected increase in pituitary tropic hormone secretion. Cytokines can regulate some steroidogenic enzymes, and the direct effects of cytokines on both male and female gonads have been the subject of numerous studies. Early in critical illness in males, LH and FSH rise as testosterone falls, suggesting primary failure of the testis. Soon LH and FSH decline to a healthy, normal range. Analogous to the euthyroid sick syndrome, normal levels of gonadotropin in the face of low testosterone levels suggest inhibition of gonadotropin secretion. From a teleological perspective, how low testosterone would benefit the organism in conditions of stress or tissue injury is not readily apparent. In chronic stress, the anabolic effects of androgen on muscle mass would seem to be preferred to unopposed catabolism. Androgens have been used therapeutically in the cachexia associated with advanced AIDS, but otherwise there are very few data concerning their utility in illnesses associated with elevated cytokine concentrations.

A brief period of lower testosterone with elevated LH is observed in human males following acute administration of IL-6, paralleling the early response to endotoxin administration. In human males with prolonged critical illness and elevated plasma IL-6 and TNFα, pulsatile LH secretion and mean LH concentrations are suppressed when testosterone and estradiol levels are low. Administration of pulsatile GnRH substantially enhances pulsatile LH secretion, but this effect wanes over a 5-day period and is accompanied by only a partial, transient rise in testosterone levels. This suggests that the gonadal axis suppression associated with this kind of chronic critical illness operates at hypothalamic, pituitary, and gonadal levels.

Additional evidence that major illness operates at the hypothalamic and pituitary levels comes from studies of LH and FSH in severely ill, postmenopausal human females. LH and FSH rise markedly after the menopause, following the cessation of ovarian function. In hospitalized, ill postmenopausal women, LH and FSH levels are often inappropriately in the premenopausal normal range, or even frankly low. In females, inhibition of ovulation during infection or chronic illness, or inhibition of the gonadal hormone needed to continue a pregnancy during infection, makes more intuitive sense than does inhibition of testosterone in males. Here again, however, there are few or no direct data to support this intuitive notion. Estrogen administration to stressed, ill, hypogonadal females has not been actively studied.

Again, analogous to the situation with the thyroid axis, high glucocorticoid concentrations might be a primary mechanism for suppression of the reproductive axis. A number of observations argue against this. In castrated male rats, destruction of the PVN does not prevent the suppression of LH secretion observed following footshock. Peripheral administration of IL-1β provokes marked activation of the HPA axis, but does not suppress LH secretion. For example, 1 μg of IL-1β ip does not significantly alter LH over 4 h in male rats, a dose that markedly stimulates corticosterone secretion. HPA activation and LH suppression are thus dissociable, suggesting that LH suppression does not depend on elevation of glucocorticoids.

In contrast to the lack of effect of peripheral administration, intracerebroventricular (icv) administration of IL-1 into the third ventricle inhibits pulsatile secretion of GnRH and suppresses LH secretion. CRH appears to mediate the effect of many stressors on LH secretion, and IL-1 certainly activates central CRH, but CRH probably does not mediate the effect of cytokines on gonadotropin secretion. CRH antagonists in rat models can block most of the effects of stress and some effects of cytokines, such as the pyrogenic effect of IL-1β. However, even when administered into the third ventricle, these antagonists appear unable to block IL-1-induced suppression of GnRH neuron activity or suppression of LH secretion. An exception to this was observed in a study of rhesus monkeys, suggesting that there may be species differences in this mechanism.

Central IL-1 decreases GnRH mRNA in the cell bodies of GnRH neurons, as well as c-fos expression, suggesting that these GnRH cell bodies are a key target of IL-1 activity. The effects of central IL-1 on GnRH and LH secretion are blocked by naloxone, suggesting a role for opioid agonists in this effect. The central IL-1 effect is most pronounced with IL-1β, IL-1α being less effective. Some effect is also seen with TNFα but IL-6 is relatively ineffective.

Because systemic cytokine administration appears to have minimal effects on LH secretion *in vivo*, and because systemic cytokines probably have ready access to both the median eminence and the pituitary gland, it seems unlikely that direct cytokine effects on the pituitary gland are major regulators of LH secretion. *In vitro* studies of cytokine effects on pituitary LH release have yielded variable results. IL-6 stimulates LH from dispersed pituitary cell cultures and perifused pituitaries. TNFα inhibits GnRH-stimulated LH secretion from 3-day-old dispersed rat anterior pituitary cell cultures, but not basal LH release.

In sum, severe illness and stress generally suppress the reproductive axis in both males and females. While stress of many kinds may involve activation of the inflammatory cytokines, experimental work suggests that circulating cytokines are not key to the suppression of the gonadal axis. Rather, central cytokines acting via the suppression of GnRH neuron cell bodies seem to be the major pathway. Whether this suppression has survival value remains to be investigated.

VI. PROLACTIN

Prolactin (PRL) serves to prepare the breast for lactation late in pregnancy and has some effects on fuel metabolism and immune function. These latter effects appear to be relatively minor in most circumstances. PRL is unique among the anterior pituitary hormones in that stalk section increases its secretion. Thus, the dominant regulatory effect from the hypothalamus is inhibitory. Hypothalamic dopamine is inhibitory to PRL secretion and TRH is stimulatory. Blocking TRH often has little effect on plasma PRL, tending to confirm the dominance of dopamine in prolactin regulation. Other hypothalamic factors, such as vasoactive intestinal polypeptide (VIP), have been implicated in PRL regulation, but their importance *in vivo* is unclear.

PRL is regarded as a stress hormone in that blood concentrations are increased in response to numerous stressors. The value of this response is not clear. Prolactin resembles GH in both structure and activity; PRL- and GH-secreting cells derive from the same lineage in pituitary development. Combined PRL/GH tumors are the most common type of multi-hormone-secreting pituitary adenoma. The effects of PRL on immune functions resemble those of GH, being supportive or stimulatory to immune activity in most experimental settings. PRL is elevated in some patients with lupus and Reiter's syndrome, raising the possibility that excessive immune activation and hyperprolactinemia might be causally related. There is thus some circumstantial evidence to suggest that PRL stimulation by cytokines could be biologically useful.

Administration of IL-1, TNFα, and IFNγ iv and icv usually have little effect on PRL secretion *in vivo*, although stimulation is sometimes observed. Similarly, 1 μg of IL-1 ip did not significantly alter PRL over 4 h in male rats, despite a marked increase in corticosteroid secretion. In dispersed pituitary cell cultures *in vitro*, various results have been reported: IL-6 stimulates PRL secretion, IL-1 has no effect or is inhibitory, IL-2 is stimulatory, TNFα has no effect or is stimulatory, and IFNγ both stimulates and inhibits. Overall, current evidence does not support any consistent effect of cytokines on PRL secretion, or that any such effect is of major physiological importance.

VII. SUMMARY

Certain cytokines can alter the secretion of hormones of the anterior pituitary. The literature suggests that such activities are most commonly observed with the proinflammatory cytokines, IL-1, IL-6, and TNFα. However, this conclusion may be attributed to the fact that these have been the most well studied cytokines. Whether cytokines exert direct effects on the anterior pituitary is still controversial. Although cytokines and their receptors have been reported to be present in the anterior pituitary, most of the physiological evidence indicates that the hypothalamus is critically involved in the secretory process, using the normal releasing and release-inhibiting factors. An important exception may be IL-6, which may act directly on the pituitary to stimulate ACTH secretion. With the important exception of IL-1, the physiological significance of these effects of cytokines is unresolved. The IL-1-induced activation of the HPA axis is considered an important mechanism for triggering the stress response to cell damage. It appears to be a universal response and functions in ontogeny before the HPA axis responds normally to other stressors. The subsequent glucocorticoid suppression of immunity is speculated to suppress widespread inflammatory responses in favor of local processes that can deal with the damage or infection. Suppression of some aspects of thyroid axis function is common in inflammatory states and cytokines appear to play a role in this, particularly at the level of hypothalamic regulation of the pituitary secretion. Suppression of

reproductive function is also common in inflammatory states, with the best current evidence implicating cytokine effects at the hypothalamus in this modulation of pituitary function. The biological value of these changes in thyroid and gonadal function is unclear. Given the lack of good physiological evidence for most of the known cytokines, our understanding of the involvement of cytokines in the orchestration of neuroendocrine responses to infection and inflammation is very incomplete and is likely to be subject to revision as new data accumulate.

Glossary

corticotropin Synonymous with adrenocorticotropic hormone.

cytokine A protein or glycoprotein synthesized and secreted by immune cells; plays roles in communication within the immune system.

gonadotropin-releasing hormone The hypothalamic decapeptide that stimulates the pituitary to secrete LH and FSH; usually used as a synonym for luteinizing hormone-releasing hormone.

gonadotropins A generic term for the pituitary hormones that regulate or stimulate the gonads, i.e., luteinizing hormone and follicle-stimulating hormone.

growth hormone-releasing hormone The hypothalamic peptide, found in several molecular forms, that stimulates the pituitary to secrete growth hormone.

hypothalamic-pituitary-adrenal axis Cells and pathways that form the communications between the hypothalamus, the pituitary, and the adrenal gland. The major hypothalamic factors are corticotropin-releasing hormone and vasopressin, both of which stimulate the release of pituitary adrenocorticoticopic hormone, which in turn stimulates the release of glucocorticosteroids from the adrenal cortex (principally corticosterone and cortisol).

lipopolysaccharide A group of related compounds released when the cell walls of gram-negative bacteria are degraded. Also known as endotoxin, lipopolysaccharide is a potent stimulator of the immune system and the vasculature, acting on the specific receptors (toll-like receptor 4) on B cells, macrophages, and endothelial cells.

negative feedback In the context of pituitary function, the extremely common phenomenon by which hormones modulate the activity of their own regulatory apparatus (e.g., insulin-like growth factor-I, which is induced by growth hormone, is able to act on the hypothalamus and the pituitary to reduce growth hormone secretion).

somatostatin A 14- or 28-amino-acid peptide, found in the hypothalamus and elsewhere, that inhibits pituitary secretion of growth hormone and, to a lesser degree, other pituitary hormones, such as thyroid-stimulating hormone.

thyrotropin (thyroid-stimulating hormone) The pituitary hormone that stimulates the thyroid gland to produce thyroxine and triiodothyronine.

thyrotropin-releasing hormone The hypothalamic tripeptide that stimulates the pituitary to secrete thyroid-stimulating hormone and, to a lesser degree, prolactin.

Cytokinins

FABIEN NOGUÉ, MARTINE GONNEAU, AND JEAN-DENIS FAURE

Institut National de la Recherche Agronomique, Versailles

Cytokinins were first described as molecules promoting cell division and differentiation in plants. It was later discovered that cytokinins regulate a wide range of responses involved in plant development, including shoot meristem maintenance, leaf formation, root growth, chloroplast biogenesis, and senescence.

I. INTRODUCTION

Miller and co-workers discovered the first cytokinin, kinetin, in 1955. Kinetin, purified from autoclaved herring sperm, was a compound that restored normal division of tobacco stem pith tissue cells cultured in the presence of auxin. Kinetin does not occur naturally in plants but results from rearrangement of heated DNA. A large group of molecules structurally related to kinetin have now been identified in plants as endogenous active cytokinins (CKs).

II. STRUCTURE OF NATURAL AND SYNTHETIC CYTOKININS

CKs that occur naturally in plants are adenine derivatives (Fig. 1). The most common is zeatin, which was the first natural cytokinin to be identified.

II. STRUCTURE OF NATURAL AND SYNTHETIC CYTOKININS

CKs that occur naturally in plants are adenine derivatives (Fig. 1). The most common is zeatin, which was the first natural cytokinin to be identified.

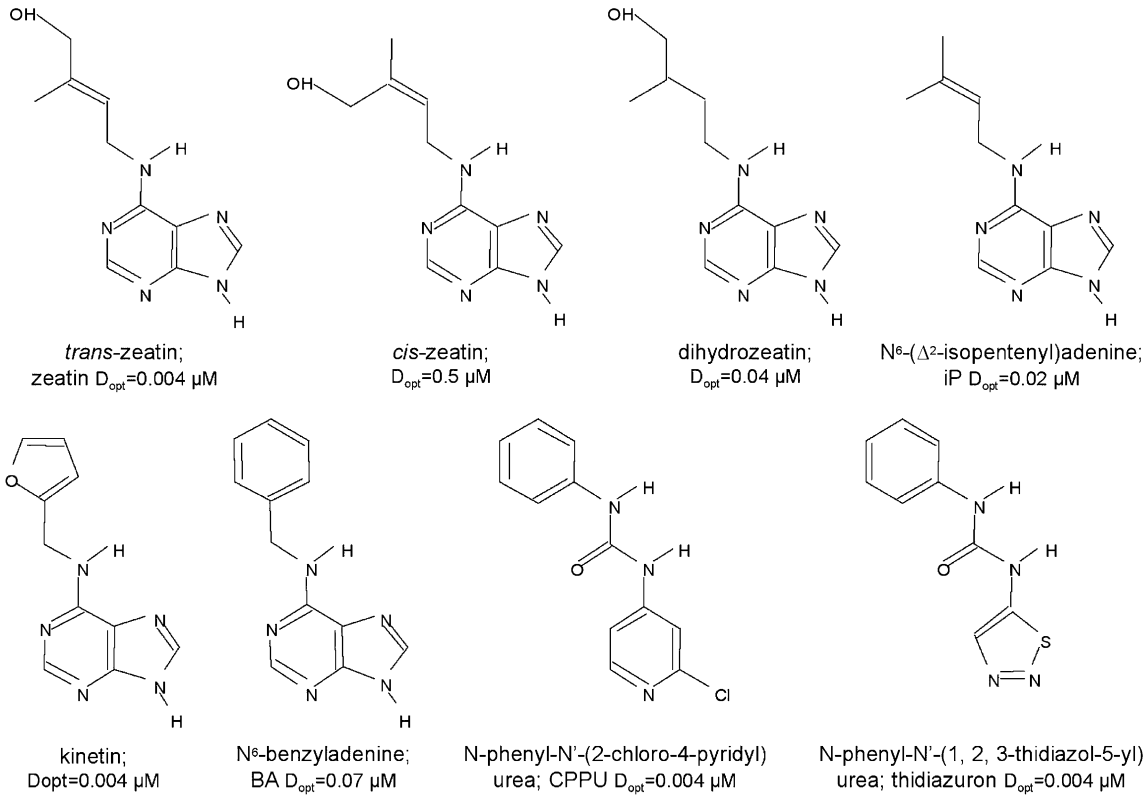

FIGURE 1 Structures of natural and synthetic adenine and synthetic phenylurea cytokinins. D_{opt}, optimum concentration for the maximal response in tobacco callus growth bioassay (Skoog test).

Dihydrozeatin, which is zeatin with a saturated side chain, has also been identified in many species, whereas *cis*-zeatin and isopentenyladenine are generally minor components. These molecules can also exist as ribosides, which have also been shown to be active in plants.

Synthetic analogues of adenine that have cytokinin activity have been generated. These include kinetin and benzyladenine, which have been commonly used for *in vitro* tissue culture work. Synthetic urea derivatives can also act as CKs. Diphenylurea (DPU) was the first urea thought to possess cytokinin activity, which was discovered in coconut milk and was at one time used as a growth substance for tissue culture work. In fact, DPU probably did not contribute significantly to the CK activity because zeatin is the active native cytokinin molecule in the milk. Nevertheless, urea-type molecules do show potential as synthetic CKs (Fig. 1). A level of cytokinin activity similar to that of zeatin has been described for *N*-phenyl-*N*′-(2-chloro-4-pyridyl)-urea (CPPU). Thidiazuron, a urea-type molecule used as a cotton defoliant, also acts as an effective cytokinin. In contrast to zeatin, these active phenylureas are highly stable.

There is no evidence that phenylurea-type CKs occur naturally in plant tissues. Since of this, only the adenine-type cytokinin metabolism is described here. Cytokinin metabolism has been largely elucidated and genes have been identified for some enzymes involved. Regulation of active cytokinin levels in plants may occur by control of synthesis, reversible conjugation, or irreversible inactivation.

III. CYTOKININ BIOSYNTHESIS AND METABOLISM

CKs are present in most plant tissues, but synthesis is believed to be localized to root tips, shoot meristems, and immature seeds. Since several CKs are found as components of transfer RNA (tRNA), a central element of protein biosynthesis, it had been speculated for many years that tRNA was the primary source of CKs. However, because the major cytokinin found in tRNA is the less active *cis*-zeatin, this pathway is not considered to be the main route of biosynthesis. A second pathway is the adenosine monophosphate (AMP) pathway (Fig. 2). In this pathway an isopentenyl group is transferred from dimethylallyl diphosphate (DMAPP) to the N^6 of AMP, resulting in the

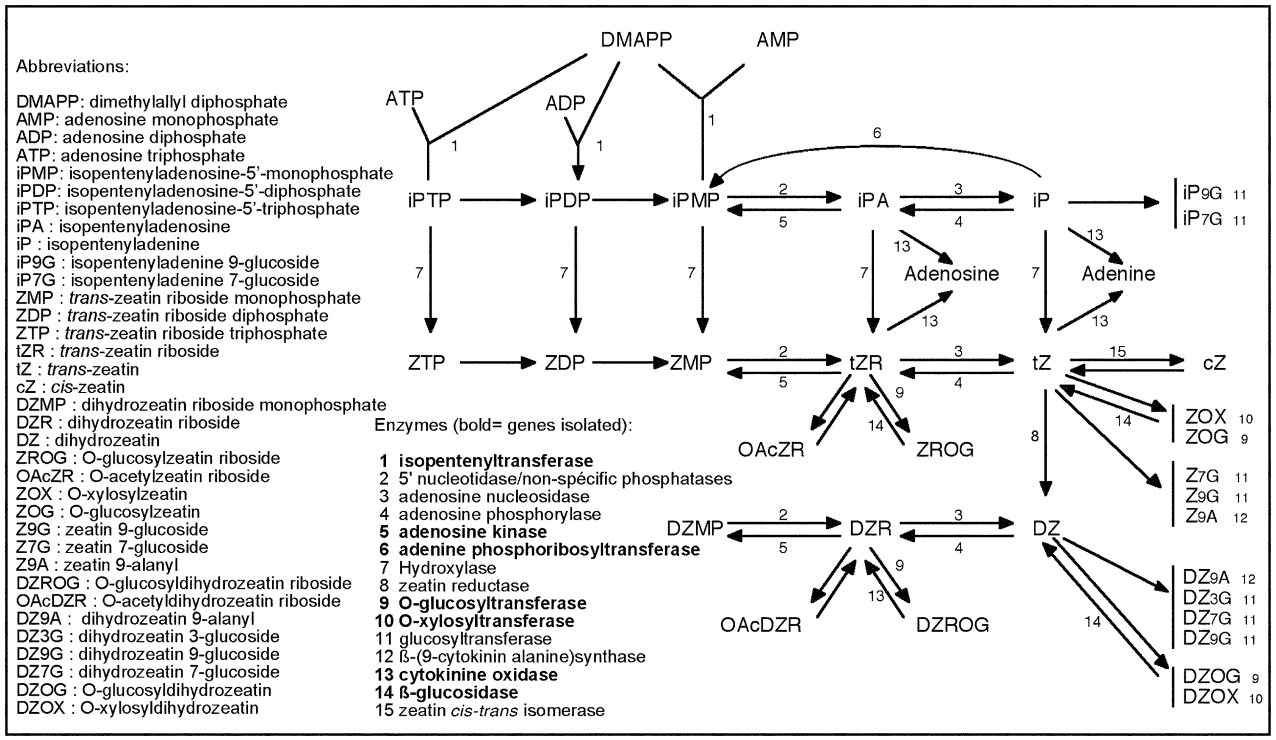

FIGURE 2 Cytokinin biosynthesis and metabolism. The identity of the main substrate for isopentenyltransferase (AMP, ADP, or ATP) needs to be determined.

production of isopentenyladenosine-5′-monophosphate (iPMP). This reaction is thought to be catalyzed by a DMAPP:AMP isopentenyltransferase. The most well-characterized isopentenyltransferase (IPT) is the IPT enzyme of the gall-forming bacteria *Agrobacterium tumefaciens*. Completion of the *Arabidopsis* genome has allowed for the identification of nine putative genes coding for isopentenyltransferases in the model plant. Expression of these genes in *Escherichia coli* resulted in DMAPP:AMP isopentenyltransferase activity in crude bacterial extracts. Recently, another cytokinin pathway has been demonstrated in *Arabidopsis* in which *trans*-zeatin riboside monophosphate (ZMP) is synthesized independently of iPMP (Fig. 2). Interestingly, one *Arabidopsis* IPT enzyme, AtIPT4, was shown to have DMAPP:ATP/ADP isopentenyltransferase activity, instead of either DMAPP:AMP or DMAPP:tRNA isopentenyltransferase activity. The realization that zeatin-type compounds are the predominant CK in plants has led to the hypothesis that isopentenylation of ATP and/or ADP is one of the key steps in cytokinin biosynthesis in plants.

A. Modification of the Adenine Ring

Following synthesis, CKs can be metabolized via one of three reactions: conversion to the base/nucleoside/nucleotide forms, modification of the adenine ring, or modification of the N^6-isoprenoid side chain (Fig. 2). Depending on whether these reactions are reversible, the final products are considered to be either storage or inactivated forms of CKs. Although the conversions between base/nucleoside/nucleotide seem primarily related to purine metabolism and only incidental to cytokinin metabolism, the fact that, at least in tobacco cell suspension cultures, only the base form is active confirms the importance of these conversions to the activity.

The enzymes involved in these interconversions generally display a higher affinity for adenine, adenosine, and AMP than for the corresponding CKs. This is the case for the 5′-nucleotidase that converts cytokinin nucleotides to bases, for the adenosine nucleosidase that converts cytokinin nucleosides to bases, for the adenine phosphorylase that converts cytokinin bases to nucleosides, and for the adenosine kinase that converts cytokinin nucleosides to nucleotides. Two genes encoding the adenine phosphoribosyltransferase that converts cytokinin bases to nucleotides have been isolated from *Arabidopsis*. The adenine phosphoribosyltransferase 1 (APT1) enzyme shows a much higher affinity for adenine than for benzyladenine, whereas the other enzyme, APT2, has threefold higher affinity for benzyladenine than for adenine. A gene encoding an adenosine kinase has been cloned from moss, but its substrate specificity has not yet been reported.

Most adenine-type CKs can also undergo other types of conversions, restricted only by steric hindrance. For example, the adenine ring can be glucosylated at the 3, 7, or 9 position and conjugated to alanine at the 9 position. A glucosyltransferase that catalyzes the formation of 7- and 9-glucosides has been isolated from radish. Also, a transferase that converts zeatin to its 9-alanyl derivative has been purified from lupine seeds. The exact role of those conjugates is still unclear and, with the exception of the 3-glucosides, they exhibit low or no cytokinin activity in bioassays.

B. Modification of the N^6-Isoprenoid Side Chain

Modifications of the N^6-isoprenoid side chain of CKs have pronounced effects on cytokinin activity. For example, the zeatin side chain can be reduced to produce the aforementioned dihydrozeatin, conjugated to O-glycosides, converted to *cis*-zeatin, or cleaved by cytokinin oxidases (Fig. 2). The side chain on dihydrozeatin can also be conjugated to O-glycosides but it is resistant to cytokinin oxidases. A zeatin reductase that converts *trans*-zeatin to dihydrozeatin has been isolated from *Phaseolus vulgaris* seeds. Because dihydrozeatin is resistant to cytokinin oxidases, zeatin reductase may play an important role in cytokinin homeostasis.

Cytokinin *O*-glycosyltransferases are highly specific to CKs. Two *O*-glycosyltransferases have been isolated, an *O*-xylosyltransferase from *P. vulgaris* and an *O*-glucosyltransferase from *Phaseolus lunatus*. Those two enzymes are specific for zeatin and dihydrozeatin, with no activity toward *cis*-zeatin and cytokinin ribosides. Besides showing high specificity for particular CKs, these enzymes also show specificity for the sugar donor, leading to the hypothesis that O-glycosylation of CKs is tightly regulated in plants.

A gene encoding a *cis*-zeatin O-glucosyltransferase that does not recognize *trans*-zeatin or dihydrozeatin has been isolated from maize. In addition, an enzyme specific for *cis*-zeatin, called *cis–trans*-zeatin isomerase, has been partially purified from *Phaseolus*. This enzyme preferentially converts the cis isomer to the trans isomer and may play an important role in regulating cytokinin activity because it converts

the less active *cis*-zeatin to the highly active *trans*-zeatin. The existence of *cis*-zeatin O-glucosyltransferase and *cis-trans*-zeatin isomerase increases the complexity of the cytokinin metabolism scheme and emphasizes the potential role of *cis*-zeatin derivatives in cytokinin homeostasis.

A major modification of the cytokinin N^6-isoprenoid side chain is a reduction by cytokinin oxidase, which results in formation of adenine-type compounds from cytokinin bases and nucleosides, but not from nucleotides. Because of its crucial role, cytokinin oxidase has been extensively studied and purified from a variety of plants, with genes representing cytokinin oxidases from maize and *Arabidopsis* being recently cloned. These enzymes share homology with flavin adenine dinucleotide (FAD)-dependent oxidases. Kinetic analyses have shown that urea-type CKs are strong competitive inhibitors of cytokinin oxidase activity. Benzyladenine and kinetin are not substrates for this enzyme.

IV. CYTOKININ SIGNALING

The first step of cytokinin signaling is recognition and binding by specific receptors. For many years, several groups have employed biochemical strategies in order to identify cytokinin-binding proteins that may represent cytokinin receptors. Some of these proteins demonstrate the properties expected for receptors but their physiological functions have never been established. Genetic and genomic approaches have allowed for important progress in the field of plant hormone perception and signaling, including the mechanism of CK signal transduction. Although our knowledge is still limited, the transduction pathway that is initiated by cytokinin has recently begun to be elucidated.

To identify components of the CK signaling pathway, *Arabidopsis* mutants were screened for those that demonstrated altered cytokinin responses, including rapid cell proliferation and shoot formation in tissue culture. Mutants that qualified were subsequently called *CK response* and *CK independent* (*cre1*, *cki1*, and *cki2*). Wild-type hypocotyl explants, when exposed to increasing levels of active cytokinin (kinetin, benzyladenine, isopentenyladenine, and the phenylurea-type CKs), respond with rapid cell proliferation and with greening and formation of shoots. The *cki1* mutant displayed typical CK-dependent phenotypes in the absence of exogenous hormone, whereas *cre1* mutant explants were less responsive. The structures of the predicted CRE1 and CKI1 proteins are similar to those of the sensors of two-component regulators, which are important signaling systems commonly found in prokaryotes and lower eukaryotes.

A. CK Receptors Are Histidine Protein Kinase

A typical prokaryotic two-component system is composed of a sensor histidine kinase (also termed sensor) and a response regulator (Fig. 3). Sensors included a variable input domain responsible for the perception of external stimuli and a conserved histidine kinase domain (transmitter). Response regulators consist of a receiver domain and an output domain. The signal perception by the input domain results in autophosphorylation of a conserved histidine residue in the histidine kinase domain of the sensor. The phosphoryl group is then transferred to a conserved aspartate residue in the receiver domain of a cognate response regulator. In some two-component systems, a multistep phosphorelay is utilized, involving a sequential phosphorylation of intermediate histidine phosphotransmitter proteins (HPts) and, finally, transfer of the phosphoryl group to a response regulator. Typical eukaryotic two-component systems comprise a sensor histidine kinase domain fused to a receiver domain and are therefore termed hybrid two-component regulators. CRE1 is a predominantly hydrophobic two-membrane-spanning domain in the N-terminal region, with an extracellular loop that can

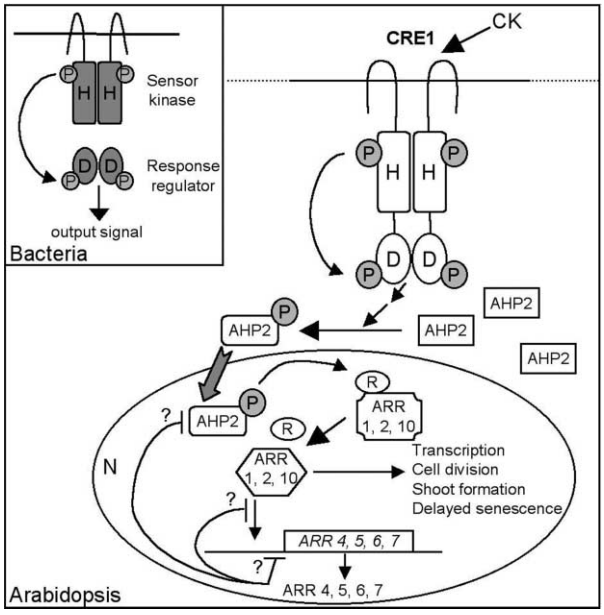

FIGURE 3 Two-component signaling in *Arabidopsis*. Model of the cytokinin signal transduction pathway. Adapted from Hwang and Sheen (2001).

bind a ligand. The C-terminal region is probably cytoplasmic and consists of a histidine kinase domain and an unusual tandem of two receiver domains. By contrast, the ethylene receptor (ETR1) family and the putative *Arabidopsis thaliana* histidine kinase (AtHK1) osmosensor have only a single receiver domain.

Elegant experimental approaches using yeast complementation have demonstrated that CRE1 functions as the cytokinin receptor. Heterologous complementation of a yeast histidine kinase sensor mutant by CRE1 successfully restores growth of the mutant but only if active CKs are present. CRE1 (AtHK4) binds a variety of natural and synthetic CKs and diphenylurea derivatives with a high affinity ($K_d = 5 \times 10^{-9}\ M$), indicating that the receptor is responsive to physiological concentrations of the hormone. This demonstrates that, in yeast, cytokinin-dependent CRE1 activation leads to SSK1-mediated mitogen-activated protein kinase (MAPK) inactivation via an existing signaling pathway. Similar approaches in *Schizosaccharomyces pombe* and *Escherichia coli* demonstrated that CRE1 (AtHK4) as well as closely related *Arabidopsis* sensor histidine kinases (AtHK2 and AtHK3) function as cytokinin-responsive sensors. In contrast, the CKI1 histidine kinase that was identified from an *Agrobacterium*-mediated activation tag mutant screen does not bind CKs and its role in CK signaling remains to be elucidated.

B. Cytokinin Signaling Involves Histidine Phosphotransfer Proteins and Response Regulators

Two-component regulator signaling requires a phosphotransfer that initiates with a histidine kinase and either terminates with a receiver domain or continues through a phosphororelay that includes an HPt protein and an *Arabidopsis* response regulator (ARR). All of the elements of two-component signaling systems are present in plants. Analysis of the *Arabidopsis* genomic system reveals at least 11 histidine kinase sensors; five ethylene receptors; three cytokinin receptors, AtHK2, AtHK3, and AtHK4 (CRE1); and one osmosensor (AtHK1). Five genes (*AHP1–AHP5*) encode typical histidine phosphotransmitters and *Arabidopsis* possesses at least 20 genes encoding proteins similar to response regulators (the ARR series). *ARR* genes have been classified into two distinct subtypes. Members of the A-type have been found to be rapidly induced by cytokinin. *ARR4* and *ARR5* transcripts accumulate within 10 min after application of either adenine or phenylurea-type cytokinin. The ARR5 protein is expressed primarily in root and shoot meristems, which is consistent with a role for CK in the regulation of cell division *in vivo*. The B-type ARRs act as transcriptional factors.

A transient expression assay based on transcriptional activation of a cytokinin primary response gene, *ARR6*, in protoplasts of *Arabidopsis* leaves has been developed to dissect the regulatory components of the cytokinin signal transduction pathway. This assay allows for analysis of the role of two-component regulators and begins to decipher their involvement in cytokinin signaling. It appears that histidine kinase activities are linked to various *Arabidopsis* histidine phosphotransmitter (AHP) proteins that serve as cytoplasmic/nuclear shuttles to distinct ARR proteins in the nucleus. The last steps are an ARR-dependent transcriptional activation of target genes and a negative feedback loop through cytokinin-inducible *ARR* genes. CRE1 transcriptionally activates *ARR6* only after application of CK, whereas CKI1 activity is CK independent, indicating that it may continuously activate the pathway. Histidine protein kinase activity is required because mutations in the critical histidine and aspartate residues of CRE1 and CKI1 have a dominant negative effect. AHP proteins are not limiting factors in the cytokinin signaling pathway and are transferred into the nucleus in a cytokinin-dependent manner. In this transient expression assay, B-type ARRs were capable of activating cytokinin responses, including A-type ARR expression. CK-induced A-type ARR proteins in turn act to repress their own expression. Ectopic expression of one cytokinin-related *ARR* (*ARR2*) results in senescence delay, a typical cytokinin response. ARR2 is thought to act downstream in the pathway because it is independent of CKI1 activity and blocks CK signaling if expressed as a mutated dominant negative allele.

From these results, a hypothetical model of the cytokinin signal transduction pathway in *Arabidopsis* can be developed (Fig. 3). In this model, the cytokinin signal is externally perceived by multiple histidine protein kinases located at the plasma membrane. On perception of a cytokinin stimulus, the histidine protein kinases initiate a phosphorelay signaling cascade that results in the nuclear translocation of phosphorylated AHP proteins from the cytosol. Activated AHP proteins can then release B-type ARR proteins from a putative repressor complex in the nucleus, the nature of which remains to be elucidated. The B-type ARR proteins (ARR1, ARR2,

and ARR10) can then act as activators of transcription of various target genes that control shoot formation and senescence. The cytokinin-inducible A-type *ARR* genes are directly up-regulated by B-type *ARR* and are involved in a negative feedback loop.

V. BIOLOGICAL ROLES

CKs are involved in many processes throughout plant growth and development (Fig. 4). However, the precise roles of CKs have been difficult to analyze, mainly because (1) many of the classic CKs responses are also controlled by other hormones (auxin, abscisic acid, or ethylene) or environmental stimuli (light or carbon/nitrogen source) and (2) development of most of the physiological responses is slow (a few hours to days). Most early work was performed with exogenously supplied CKs, which has the drawback of poor spatial and temporal control of CK levels in plants. Recent advances have allowed local and temporal endogenous CK accumulation to be controlled—for instance, by expressing the *IPT* (isopentenyltransferase) gene, which produces CK, under specific inducible promoters. An alternative is to control CK degradation as a means to decrease endogenous CK concentration.

A. Cell Division

CK was first described as a necessary factor, in conjunction with auxin, for the promotion of cell proliferation *in vitro*. CK was found to regulate the cell cycle machinery directly at the G_1–S transition

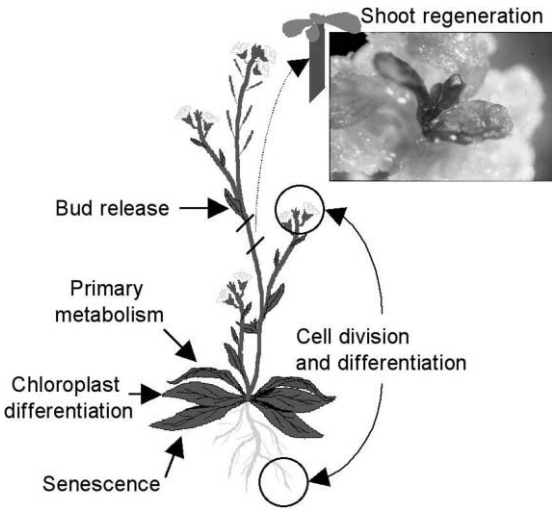

FIGURE 4 Cytokinin responses in plants.

through the specific induction of cyclin D3 (CycD3) mRNA in *Arabidopsis* cell culture. *CycD3* is expressed in *Arabidopsis* dividing tissues such as shoot meristems, young leaf primordia, axillary buds, procambium, and vascular tissues. Exogenously supplied CKs enhance *CycD3* expression in these different tissues but do not lead to ectopic expression. CK-regulated *CycD3* is a key step in cell division because constitutive expression of *CycD3* in transgenic leaf explants allows induction and maintenance of cell divisions in the absence of exogenous CKs. CKs also control cell division at the G_2–M transition: *Nicotiana plumbaginifolia* cell cultures deprived of CKs arrest in G_2 and present a highly tyrosine-phosphorylated cyclin-dependent kinase (CDK, also named p34cdc2). In yeast and mammals, CDK dephosphorylation of a specific tyrosine by the phosphatase cdc25 is required for progression through mitosis. This result suggests that CKs might stimulate a cdc25-like activity required for the G_2–M transition.

Cell division in meristems is controlled by a specific set of transcription factors, including the homeobox-related factors encoded by *KNOTTED-like1* (*KNAT1*) and *SHOOT MERISTEMLESS* (*STM*). *STM* is required for the maintenance of the meristematic stem cells and *KNAT1* induces lobed leaves with ectopic meristems when overexpressed in *Arabidopsis*. Both genes are up-regulated by CKs. Conversely, overexpression of the maize *KNOTTED1* (*KN1*) gene in tobacco and overexpression of *KNAT1* in lettuce lead to CK accumulation. Ectopic expression of maize *KN1* in cultured tobacco tissues results in growth independent of exogenously supplied cytokinin. In the case of lettuce, *KNAT1* overexpression shifts leaf determinate growth to a shootlike indeterminate growth. These data suggest the existence of a regulatory loop between this class of homeobox transcription factor genes and cytokinin accumulation.

To identify genes involved in control of cell division by cytokinin, mutants showing ectopic cell proliferation specifically enhanced by CKs were isolated in *Arabidopsis*. The apical portions of the mutant seedlings were transformed into a callus-like structure by the application of CKs. Cells of the mutant seedlings were found to dedifferentiate and lose intercellular adhesion. In weak alleles, plants could be grown to the adult stage and showed spontaneous and local cell proliferation as well as cell invasiveness leading to organ fusion. These phenotypes, reminiscent of mammalian tumor development, were linked to three genes called

PASTICCINO1, *PASTICCINO2*, and *PASTICCINO3* (*PAS1, PAS2*, and *PAS3*). *PAS1* was found to encode a protein similar to FK506-binding proteins from the immunophilin family. This family of proteins has been found to be involved in the regulation of activities of protein complexes in various signaling pathways, probably due to their foldase activity.

B. Cell Differentiation

Soon after its discovery, CK was found to be necessary and sufficient for shoot development for *in vitro* tissue regeneration of many plant species (Fig. 4). This role has been confirmed *in vivo* by numerous studies using local or systemic CK accumulation. In almost every case, the main effect of cytokinin is reduction of apical dominance by the growth of axillary buds.

Several mutant screens were performed to identify the genes involved in CK-induced shoot production. The screens allowed isolation of the two-component histidine kinase, CKI1 and CRE1/AtHK4. A loss-of-function screen was also undertaken in *Arabidopsis* to identify mutants that grow as callus on hormone-free medium and can form shoots. Six lines that were identified (called *shooty callus*) were sterile and thus could not be analyzed genetically. Nonetheless, the mutants showed an increase in *CKI1*, *KNAT1*, and *STM* expression, suggesting that cytokinin signaling was modified. Similar *Arabidopsis* mutants that respond more sensitively than the wild type to CKs were isolated and were designated *ckh1* and *ckh2*, for cytokinin-hypersensitive. The calli produced from *ckh* mutants exhibit typical cytokinin responses, including rapid proliferation and chloroplast development in response to lower levels of CKs than is seen in the wild type. The cytokinin levels in all these mutants were not increased.

To analyze the effect of decreased CK levels on plant development, the *Arabidopsis* cytokinin oxidase gene was overexpressed in transgenic tobacco. Cytokinin-deficient plants developed stunted shoots with smaller apical meristems. The time between new leaf initiation was prolonged, and leaf cell production was only 3–4% of that of wild type, indicating an absolute requirement of CKs for leaf growth. In contrast, root meristems of transgenic plants were enlarged and gave rise to faster growing and more branched roots. These results suggest that CKs are an important regulatory factor of plant meristem activity and morphogenesis, with opposing roles in shoots and roots.

Cks are also involved in other differentiation processes, such as vascular tissue development, as illustrated by the mutations in one of the cytokinin receptors (CRE1/AtHK4). The developmental ontogeny of the vascular system (consisting of xylem, phloem, and procambium) is specified early in the *Arabidopsis* root meristem. The absence of the CK receptor CRE1/AtHK4 leads to the absence of phloem and procambium, which are established through a set of asymmetric cell divisions. This demonstrates that CKs are required for phloem and procambium development in the root.

C. Senescence and Carbon/Nitrogen Metabolism

Leaf senescence is an active process involving remobilization of nutrients from senescing leaves to other parts of the plant. Whereas senescence is accompanied by a decline in leaf cytokinin content, supplemental cytokinin, such as in *IPT* or *KN1* overexpressors, delays senescence.

Although cytokinin and ethylene have opposite roles in the control of senescence, they elicit similar responses in early seedling development. Dark-grown *Arabidopsis* seedlings treated with low levels of CKs show the characteristic ethylene-mediated triple response. Cytokinin-insensitive mutants (*cin*) were isolated based on the lack of a triple response in the presence of cytokinin. The *CIN5* gene was identified as a member of the *Arabidopsis* gene family that encodes 1-amino-cyclopropane-1-carboxylate synthase. This first enzyme in the ethylene biosynthesis pathway is mainly responsible for the sustained rise in ethylene biosynthesis observed in response to low levels of cytokinin. This provides direct evidence for the existence of cross talk between CKs and ethylene.

CKs were originally thought to affect carbon/nitrogen metabolism by promoting the "sink" effect. A plant organ becomes a "sink" when import of photoassimilants exceeds export. A large number of genes involved in carbon and nitrogen metabolism have been found to be regulated by CKs at both the transcriptional and the posttranscriptional levels. Several genes encoding ribulose 1,4-bisphosphate carboxylase, chlorophyll *a* and *b* binding proteins, or phosphoenolpyruvate decarboxylase were up-regulated by CKs. CKs also control expression of the regulatory components of carbon metabolism, such as the members of the SNF1-related protein kinase family. Less is known about regulation of nitrogen metabolism by cytokinin, although the

nitrate reductase transcript level is up-regulated by CKs. CK can mimic some light-induced effects in dark-grown seedlings, including induced chloroplast differentiation and greening. Interestingly, CKs repress expression of the photoreceptor phytochrome, probably through a negative feedback regulatory loop.

VI. CONCLUSIONS

A complex biosynthetic and degradation network controls the levels of the large family of cytokinin molecules found in plants. The mode of action of each cytokinin is determined by a vast spectrum of molecules and interconnecting metabolic pathways. Cytokinins were the second plant hormone (after ethylene) for which receptors were discovered. As was the case for ethylene, the cytokinin receptors were found to be histidine kinase sensors. Interestingly, the two-component signaling system employed by cytokinins in the plant kingdom seems to be absent from the animal kingdom. The diversity of cytokinins and their biological responses, associated with a relatively simple transduction cascade, constitute a paradigm that represents the next challenge for understanding the role of this fundamental plant growth factor.

Glossary

activation tag mutant Produced by *Agrobacterium tumefaciens*-mediated transfer DNA integration, which randomly inserts into the plant genome a DNA fragment that harbors at one extremity a transcriptional enhancer element. After DNA integration, expression of neighboring genes is increased, leading in some cases to mutants with a gain-of-function dominant phenotype.

Agrobacterium tumefaciens Plant pathogen causing crown gall tumors on susceptible plants. Tumor induction results from the transfer of a small piece of DNA, called transfer DNA, from the bacterium to the plant cell during infection. The transfer DNA becomes integrated into plant cell nuclear DNA and expression of genes on this segment causes the plant cell to differentiate into a tumor cell.

differentiation Acquisition by an unspecialized plant cell (meristematic cell) of a specialized function.

meristem A group of undifferentiated and proliferating cells that continuously give rise to all plant organs and tissues throughout the plant life cycle.

two-component system A signal perception and transduction system constituted by a sensor histidine kinase and a response regulator. Sensors include a variable-input domain, which is responsible for perception of external stimuli, and a conserved histidine kinase domain. Response regulators consist of a receiver domain and an output domain. This signaling system is found in prokaryotes, lower eukaryotes, and plants.

Decidualization

THOMAS G. KENNEDY
University of Western Ontario, Canada

In mammalian species with invasive implantation, the endometrium undergoes substantial morphological and functional changes that are collectively referred to as decidualization; the endometrial stromal cells proliferate and differentiate into decidual cells, which ultimately form the maternal component of the placenta.

I. INTRODUCTION

The process of blastocyst implantation in mammals is remarkably variable, especially in the extent of trophoblast invasion of the endometrium. In species with invasive implantation, the endometrium undergoes substantial morphological and functional changes, referred to as decidual transformation of the endometrium. In most species, the transformation primarily involves the endometrial stroma; the fibroblastic stromal cells proliferate and differentiate into decidual cells that ultimately give rise to the maternal component of the placenta. Decidualization during pregnancy in most species is localized to sites of blastocyst implantation. An increase in endometrial vascular permeability, also localized to sites of blastocyst implantation, precedes the proliferation and differentiation of stromal cells into decidual cells and is thought to be an essential prerequisite for the transformation.

In many species, a nonspecific stimulus can result in an increase in endometrial vascular permeability and subsequent decidual transformation of the endometrium, provided that the stimulus is applied at the appropriate time. This artificially induced decidualization has been a useful experimental tool that allows the investigation of decidualization without the complications arising from the presence of the conceptus.

Decidualization in the human differs from that in other species in at least two respects. First, a conceptus does not have to be present to initiate the process; it begins "spontaneously" in the late luteal phase of the menstrual cycle with the differentiation of "predecidual cells." Exposure of the endometrium to progesterone beyond the length of the normal nonpregnant luteal phase results in decidual transformation of the endometrium. Second, decidualization in the human endometrium is generalized, rather than being localized to the site of blastocyst implantation. Presumably, this is a consequence of the fact that a signal from the conceptus is not required for the initiation of this process in the human.

II. MORPHOLOGICAL CHANGES

The changes in morphology associated with decidualization have been studied in detail in laboratory rodents but are thought to be basically similar in most species. The earliest macroscopically identifiable event is an increase in endometrial vascular permeability that results in the development of stromal edema. It is localized to implantation sites but is generalized if an artificial deciduogenic stimulus is applied along the full length of the uterus. The permeability response is followed by an increase in alkaline phosphatase activity. The differentiating stromal cells become enlarged with rounded nuclei. Subsequently, the cells become rounded and typically have two or more polyploid nuclei. Ultrastructurally, the differentiation of decidual cells is characterized by the accumulation of glycogen and lipid droplets and increased amounts of filament proteins. The content of polyribosomes and rough endoplasmic reticulum also increases.

In laboratory rodents, in response to either an implanting blastocyst or an artificial stimulus, decidualization begins in the anti-mesometrial pole of the endometrium and, over time, spreads to involve the mesometrial stromal cells. Why this is the case is poorly understood. It is possible that the lumenal epithelial cells that have an essential transductive role in the initiation of decidualization differ depending on their location in the endometrium. Alternatively, the anti-mesometrial and mesometrial stromal cells may differ. During pregnancy, the definitive placenta is formed at the mesometrial pole and the anti-mesometrial decidual cells undergo apoptosis to

form the decidua capsilaris. The anti-mesometrial and mesometrial decidual cells are morphologically and functionally distinct. For example, rat anti-mesometrial decidual cells produce and/or express insulin-like growth factor-binding protein-1, follistatin, prolactin, and interleukin-11 (IL-11), whereas mesometrial decidual cells produce and/or express prolactin receptors, α_2-macroglobulin, and basic fibroblast growth factor.

III. FUNCTIONS OF THE DECIDUA

Several functions have been ascribed to the decidual cells. These include a nutritional role for the conceptus until formation of the definitive placenta, a role in limiting trophoblast invasion, an immunoprotective role, and an endocrine role.

The putative nutritional function follows from the observations of accumulation of glycogen granules and lipid droplets in the cytoplasm of decidual cells. Proteins are also secreted into the implantation chamber and may be utilized by the conceptus.

The decidua may protect the uterus from the actively invading trophoblastic cells. At extrauterine sites, trophoblastic cells are similar to malignant cells in their invasive properties. In the uterus in the absence of decidualization, trophoblastic cells can perforate the uterus. Decidual cells may limit invasion by establishing a structural barrier and/or by producing factors that act locally to restrict invasion. The extensive remodeling of the extracellular matrix that occurs during decidualization may protect the endometrium against trophoblast invasion. In addition, decidual cells express proteins, such as tissue inhibitor of matrix metalloproteinase, cystatin C, and plasminogen activator inhibitors, that are able to inhibit the activity of proteinases produced by trophoblastic cells, thereby restricting invasion.

The decidual tissue may provide immunological protection for the conceptus by suppressing the maternal immune response, thereby allowing successful completion of pregnancy. The mechanism by which this is accomplished is unknown.

The fact that decidual cells produce prolactin and/or prolactin family members suggests that the decidual tissue has an endocrine function. The physiological roles of these decidual products are unknown but it seems likely that they may be involved in the regulation of maternal adaptations to pregnancy. There is evidence of a paracrine, rather than endocrine, role for decidual prolactin in the rat. Prolactin produced by anti-mesometrial decidual cells acts on mesometrial stromal/decidual cells to regulate their function.

IV. ENDOMETRIAL RECEPTIVITY AND SENSITIZATION

Implantation and subsequent decidualization can be initiated by a blastocyst only during a limited time when the endometrium is said to be receptive. In laboratory animals that respond to stimulation of the endometrium, there is likewise a transient period when decidualization is obtained, provided that the stimulus is relatively nontraumatic. During the responsive period, the endometrium is said to be sensitized for the decidual cell reaction. Endometrial receptivity and sensitization are thought to refer to identical states, and the terms will be used interchangeably in this article. The timing and endocrine control of receptivity and sensitization are similar and absolutely dependent on progesterone. The requirement for estrogen along with progesterone varies with species. In some animals (e.g., mouse and rat), estrogen is essential, but in others (e.g., hamster and rabbit), it is not. In addition, the amount of estrogen that the uterus is exposed to prior to the onset of receptivity and sensitization is crucial. In ovariectomized rats, for example, estrogen at low doses acts synergistically with progesterone to induce endometrial sensitization; estrogen at high doses is inhibitory.

At the molecular level, the mechanisms by which the steroid hormones bring about endometrial receptivity and sensitization are unknown, but presumably involve changes in gene expression. Studies in this area are complicated by the fact that the endometrium is a heterogeneous tissue consisting of numerous cell types including lumenal epithelium, glandular epithelium, stromal cells, endothelial cells, and bone marrow-derived cells. Decidualization almost certainly involves interactions between cell types. For example, the importance of the lumenal epithelium has been established by experiments demonstrating that if the lumenal epithelium is destroyed or removed, decidualization cannot be obtained in response to stimuli that otherwise would be deciduogenic. The results are consistent with the hypothesis that the lumenal epithelium responds to natural and artificial deciduogenic stimuli with the production of a compound that then acts on the stromal cells to trigger decidualization. Thus, at least in theory, the changes in gene expression regulating receptivity and sensitization could be

limited to the lumenal epithelium and related to its ability to produce the triggering compound. This seems unlikely, however, because endometrial stromal cells from nonsensitized uteri undergo decidualization to a lesser extent *in vitro* than cells from sensitized uteri. This difference presumably indicates that gene expression in stromal cells from sensitized and nonsensitized uteri differs.

In general, two approaches have been taken to investigate the mechanisms underlying receptivity and sensitization. The first involved the study of putative mediators of the process of decidualization on the premise that the receptive/sensitized state may be explainable in terms of the synthesis and/or action of the mediators. This approach will be reviewed in a later section. The second and more recent approach has been the use of gene expression screening techniques, such as mRNA differential display or gene array chips, to detect changes in gene expression in the peri-implantation period. Many of the data obtained in these studies have been correlative in nature. In addition, some of the studies have compared implantation sites with interimplantation sites, and the altered gene expression so identified may be the consequence of the initiation of blastocyst implantation and the associated decidualization, rather than being related to receptivity and sensitization. Finally, some of the identified differentially expressed genes encode cell surface or cell adhesion molecules in the lumenal epithelium. Although these molecules may be very important for blastocyst implantation by facilitating the attachment of the blastocyst to the epithelium, they are considered to be outside the scope of this article.

A. Leukemia Inhibitory Factor

Although uterine expression of leukemia inhibitory factor (LIF) was not discovered by a screening process, it is now well known to have an essential role in uterine receptivity, at least in the mouse. LIF is a secreted glycoprotein that has multiple activities in various *in vitro* culture systems. In the mouse, LIF expression is markedly up-regulated in the endometrial glands just prior to the onset of implantation and then declines to low levels for the remainder of pregnancy. In LIF-deficient mice, implantation does not occur and the uterus does not respond to the intrauterine injection of oil with decidualization. The administration of LIF can override the inhibition of implantation and artificially induced decidualization. Thus, LIF is essential in the mouse for the onset of uterine receptivity and sensitization. It acts predominantly on the lumenal epithelium of the endometrium by a signal transduction pathway involving phosphorylation and nuclear transfer of signal transducer and activator of transcription 3 (Stat3). Interestingly, the lumenal epithelial cells are only transiently responsive to LIF despite the presence of constant levels of LIF receptor throughout the peri-implantation period. Consequently, uterine receptivity appears to be regulated by both the onset of LIF expression in the endometrial glands and its ability to activate Stat3.

The essential role of LIF in regulating endometrial receptivity may not be limited to mice. Uterine LIF expression has been investigated in a number of species and the findings have consistently suggested that LIF may be involved in preparing the endometrium for implantation.

B. Calcitonin

By using a gene expression screening technique, calcitonin was found to be transiently expressed in rat endometrial glandular epithelial cells in the peri-implantation period, reaching a peak on day 4 of pregnancy, the day before the initiation of implantation, and declining thereafter. Subsequent studies demonstrated that the down-regulation of calcitonin expression by the administration of antisense oligonucleotides targeted against calcitonin mRNA substantially reduced the implantation rate. At present, it is not known whether calcitonin acts on the embryos or the endometrium; there is evidence from *in vitro* studies that calcitonin can accelerate blastocyst differentiation. The effects of calcitonin on endometrial receptivity and sensitization have not yet been reported.

Calcitonin is also expressed in human endometrium during the midsecretory phase of the menstrual cycle that corresponds with the putative timing of endometrial receptivity.

C. HOX Genes

Homeobox (HOX) genes, which encode highly conserved, developmentally regulated transcription factors used to establish body plans, are usually thought to be expressed only during embryonic development. However, HOX gene expression has been observed in the reproductive tracts of adult mice and humans. The importance of this expression has been demonstrated by targeted disruption of the genes; there is implantation failure as well as resorption of embryos in mice deficient in either

Hoxa10 or Hoxa11. In addition, the intrauterine administration of antisense oligonucleotides targeted against Hoxa10 mRNA decreases the implantation rate. Investigation of the mechanisms underlying the uterine deficits in Hoxa10 mice has found inappropriate regulation of prostaglandin E_2 receptor subtypes EP_3 and EP_4. Down-regulation of endometrial Hoxa10 expression by an antisense strategy has been shown to decrease lumenal epithelial pinopod formation. Since pinopods develop transiently on the lumenal epithelial cells at the time of uterine receptivity, this suggests that Hoxa10 expression is required for the acquisition of receptivity.

D. Other Genes

The expression of several additional genes has been reported to change in association with the onset of uterine receptivity and sensitization. These include interleukin-15 in human endometrium, glucose-regulated protein 78, and a novel previously uncharacterized gene designated uterine sensitization-associated gene-1 in rats. However, the functional role, if any, of the products of these genes remains to be established.

V. LOCAL MEDIATORS OF DECIDUALIZATION

This article will restrict itself to consideration of potential mediators of decidualization that are produced and act within the endometrium. Although it is possible that the blastocyst produces a chemical signal that modifies endometrial function, there is relatively little evidence for this. The fact that a variety of nontraumatic stimuli, such as the intrauterine injection of oil, are very effective at inducing decidualization suggests that the endometrium is able to produce the mediators required for the process. However, it is always possible that the mediators of decidualization during blastocyst implantation differ from those mediating artificially induced decidualization. Because of the evidence for an essential role of the lumenal epithelium in implantation and decidualization, it seems likely that the epithelial cells are a source of essential components of the cascade.

The list of potential mediators of decidualization has increased in length in recent years. Historically, the list of potential mediators has included histamine, blastocyst-produced estrogen, leukotrienes, platelet-activating factor, angiotensin II, and neutrophil-derived factors. The evidence for and against these compounds can be found elsewhere.

A. Prostaglandins

There is considerable evidence that prostaglandins (PGs) have an obligatory role in implantation and decidualization. Numerous studies have shown that inhibitors of PG synthesis and PG antagonists inhibit or delay the initiation of implantation. Exogenous PGs can reverse, at least partially, the effects of inhibitors of PG synthesis on implantation. During pregnancy, the concentrations of PGs are elevated at implantation sites.

During artificially induced decidualization, uterine concentrations of PGs increase in a temporal pattern consistent with PGs being a cause, rather than a consequence, of increased endometrial vascular permeability. Inhibitors of PG synthesis substantially attenuate the increase in endometrial vascular permeability, attenuate alkaline phosphatase activity, and attenuate the subsequent decidualization that normally occurs in response to an artificial deciduogenic stimulus. These responses can be restored by the intrauterine administration of PGs with a time course not different from that occurring in the absence of the inhibitor. It should be noted that, at least for rats, full restoration of decidualization was obtained only if the PGs were infused into the uterine lumen; the intauterine injection of PGs, although effective at restoring the vascular permeability response, did not bring about full decidualization. These and other observations have been interpreted as indicating that PG levels must be elevated within the uterus throughout decidualization.

The sites of synthesis, types, and sites of action of the PGs within the endometrium remain unknown. PGs are produced from arachidonic acid by cyclooxygenase (COX); this enzyme has two isoforms, COX-1 and COX-2, the products of two different genes. Both isoforms are expressed in the endometrium in the peri-implantation period. In the mouse uterus, COX-1 is expressed in the lumenal epithelium of the endometrium until blastocyst attachment late on day 4 of pregnancy (the day when the vaginal plug first appears is considered day 1) when expression is down-regulated before reappearing some 48 h later in the secondary decidual zone. By contrast, COX-2 is expressed in the lumenal epithelium and subepithelial stromal cells at the anti-mesometrial pole only at the sites of blastocyst attachment for a limited time on days 4 and 5, after which expression is localized to the mesometrial pole. More recently, the essential role of COX-2, and by inference of PGs, in implantation and decidualization has been demonstrated by

the findings that these processes are dramatically affected in COX-2 null mice; by contrast, COX-1 null mice are fertile.

Which PG is involved in implantation and decidualization is at present controversial. A number of approaches have been taken to identify the PGs involved. Measurements of PGs have not been informative because all that have been measured are elevated at implantation sites and following the application of an artificial deciduogenic stimulus. Binding sites, presumably representing receptors for prostaglandin E_2 (PGE_2) but not for prostaglandin $F_2\alpha$ ($PGF_{2\alpha}$), are present in the endometrium. PGE-binding sites were detected in the endometrial stroma but not in the lumenal epithelium of rats, whereas in the human, binding has been localized by autoradiography to stromal cells, glandular epithelium, arterioles, and erythrocytes. More recently, *in situ* hybridization has been used to localize transcripts in the mouse and rat uterus. At least four PGE receptor subtypes (EP_{1-4}) exist, whereas only one receptor for each of $PGF_{2\alpha}$ and prostaglandin I_2 (PGI_2) (receptors FP and IP, respectively) has been identified. In agreement with the binding studies in rats, *in situ* hybridization in mice did not detect FP transcripts in the endometrium on day 4. IP mRNA levels were found to be very low or undetectable in the endometrium of mice in the peri-implantation period, as were EP_1 transcripts in mice and rats. By contrast, mRNA expression of EP_2, EP_3, and EP_4 was cell specific and correlated with endometrial preparation for implantation and decidualization. For both mice and rats, EP_2 transcripts were localized in the lumenal epithelium, whereas EP_4 transcripts were localized in both the lumenal epithelium and the stroma of mice but were restricted to the subepithelial stroma in rats. EP_3 transcripts were localized to the glandular epithelium and subepithelial stroma of rats and to stromal cells at the mesometrial pole in mice. The failure to detect PGE-binding sites in membrane preparations from rat endometrial epithelial cells contrasts with the detection of EP_2 transcripts in these cells. This apparent discrepancy is almost certainly a consequence of the fact that the binding studies were performed on lumenal epithelium from ovariectomized rats treated with progesterone. EP_2 transcripts were detected in lumenal epithelium only after the administration of estradiol to progesterone-treated rats.

It is intriguing that in the rat the transcripts for EP_2 and EP_4 were concentrated in the anti-mesometrial pole of the uterus. COX-2 expression has not been reported for the rat endometrium, but in the mouse at the equivalent stage, its expression is also at the anti-mesometrial pole. The apparent co-localization of the enzyme that is essential for implantation and decidualization and the two E-prostanoid receptors could facilitate the initiation of decidualization in the anti-mesometrial region. However, it should be noted that blastocyst implantation is not affected in EP_2 null mice, suggesting that this receptor is not essential for implantation and decidualization. There does not appear to be information on whether the EP_4 receptor is essential for implantation and decidualization. Depending on the genetic background, all or the majority of EP_4 null mice die shortly after birth.

Based on studies in COX-2 null mice, it has recently been proposed that PGI_2, acting via peroxisome proliferator-activated receptor-δ (PPAR-δ), mediates implantation and decidualization. This proposal is based in part on observations that analogues of PGI_2 and PPAR-δ ligands were more effective than PGE_2 at inducing implantation and decidualization. Although implantation rates not different from those obtained in wild-type controls were achieved with some treatments, at best only partial restoration of decidualization was reported. This may be a consequence of the mode of administration of the compounds: intrauterine injection in oil or intraperitoneal injection. As mentioned previously, full restoration of decidualization in indomethacin-treated rats requires intauterine infusion of PGs, presumably because the concentrations of PGs need to be elevated within the endometrium throughout the response. Recently, the abilities of PGE_2 and some analogues of PGI_2 to induce decidualization when infused from Alzet osmotic minipumps into the uterine lumen of indomethacin-treated rats have been compared. PGE_2 was more effective than the analogues of PGI_2 at increasing endometrial vascular permeability and inducing decidualization.

It seems unlikely that the early events during decidualization could be mediated by PPAR-δ. Based on *in situ* hybridization studies, *PPAR*-δ transcripts are detected in the endometrium of mice 24 h, but not 8 h, after the application of a deciduogenic stimulus. The increase in endometrial vascular permeability is first detectable approximately 4 h after uterine stimulation and is therefore not likely mediated by PPAR-δ. Indeed, PPAR-δ is not essential for implantation and decidualization because *PPAR*-δ null mice are fertile.

B. Growth Factors and Cytokines

There has been considerable interest in the possibility that growth factors and cytokines may have important roles in implantation and decidualization. This is based in part on observations that these factors and their receptors are expressed within the uterus. In this article, consideration will be limited to possible endometrial roles of the factors as opposed to possible effects of the factors on the embryos.

1. Epidermal Growth Factor Receptor and Its Ligands

There are a number of ligands that bind to and activate the epidermal growth factor (EGF) receptor; these include EGF, transforming growth factor-α (TGF-α), heparin-binding epidermal growth factor (HB-EGF), amphiregulin, betacellulin, epiregulin, and heregulins/neu-differentiating factors. These are expressed in the endometrium of many species, often with temporal and spatial specificity. HB-EGF has received particular attention because its expression is induced in the lumenal epithelium at the site of blastocyst implantation. However, because EGF receptors are expressed in stromal cells but not epithelial cells during implantation, any effect that HB-EGF might have on decidualization would presumably involve actions on stromal cells.

Additional evidence for the involvement of EGF receptor ligands in implantation and decidualization has come from studies of the effects of the ligands. Under very constrained conditions, EGF is capable of substituting for estrogen in terminating delayed implantation in rats. Intrauterine injections of EGF or TGF-α increase the decidual cell reaction in rats and augment progesterone-induced decidualization of cultured human endometrial stromal cells. Beads soaked in HB-EGF and introduced into the uterus of mice induce local responses in the endometrium similar to those produced by blastocysts.

It is not currently known whether maternal EGF receptors are required for implantation and decidualization, because adult EGF receptor null mice have not yet been generated. Depending on the genetic background, EGF receptor null mouse embryos die just before implantation, at midgestation, or 2–3 weeks postnatally. However, the mutant mouse waved-2 has defective EGF receptors that bind ligand but subsequent receptor autophosphorylation is reduced by up to 10-fold. These mice are fertile, suggesting that fully functional EGF receptors are not required for implantation and decidualization. However, because there was some residual signaling via the EGF receptor, these observations do not establish that maternal EGF receptors are not absolutely required.

2. Interleukin-1 Receptor Ligands

The interleukin-1 (IL-1) receptor system is complex. There are two types of IL-1 receptors, IL-1RI and IL-1RII, with the former transducing signals in response to ligand binding and the latter acting as a "decoy" receptor, binding ligand without transducing a signal. Proteolytic cleavage of IL-1RI and IL-1RII results in the formation of soluble receptors (IL-1sRI and IL-1sRII) that bind ligand without transducing signals. The membrane-bound and soluble forms of both receptors bind all three members of the IL-1 ligand family but with differing affinities. In general, it is believed that IL-1RI is the only signal transducing receptor, whereas IL-1RII and the soluble forms of both receptors act as binding molecules that compete with IL-1RI for ligand. There are three ligands for the IL-1 receptors: IL-1, IL-1, and interleukin receptor antagonist (IL-ra). IL-1α and IL-ra preferentially bind to IL-1RI and IL-1sRI. IL-1β, on the other hand, preferentially binds to IL-1RII and IL-1sRII. IL-ra binds to all four types of IL-1 receptors and competitively inhibits IL-1α and IL-1β binding.

IL-1RI, IL-1α, and IL-1β are expressed in human and mouse endometrium. In mice, the mRNA levels of both IL-1α and IL-1β increase dramatically in response to a deciduogenic stimulus. The function of the IL-1 receptor–ligand signaling system in implantation is controversial. It has been reported that implantation in mice could be prevented by the intraperitoneal administration of IL-1ra. However, it was subsequently found that IL-1RI null mice were fertile. Although there was a 20% decrease in litter size, this was not a consequence of decreased implantation rates. By contrast, the IL-1 receptor–ligand signaling system may have an inhibitory role in decidualization in the human. IL-1β inhibits *in vitro* decidualization of human endometrial stromal cells, whereas IL-1α inhibits stromal cell proliferation.

3. Interleukin-11

IL-11 signals by binding to a complex of IL-11 receptor-α (IL-11Rα) and gp130. The key role of IL-11 signaling in implantation and decidualization was revealed by the discovery that IL-11Rα null female mice were infertile because decidualization was defective, resulting in the death of embryos at approximately day 8 of pregnancy. The initial stages of decidualization were unaffected, but the subsequent progression of decidualization to involve

the mesometrial region did not occur. IL-11 expression is up-regulated at the time of blastocyst implantation, especially in the primary decidual zone, in both mice and rats. By contrast, IL-11Rα expression in the uterus remains unchanged during early pregnancy. IL-11 may also have a role in decidualization of human endometrium. IL-11 mRNA and protein have been detected in human endometrium, with maximum concentrations of immunoreactive IL-11 being found in decidual cells.

VI. SUMMARY

In response to an implanting blastocyst or an artificial stimulus, endometrial stromal cells proliferate and differentiate into decidual cells that are morphologically and functionally distinct. There is a restricted time in pregnancy or pseudo-pregnancy when this transformation can be initiated, and it is under hormonal control. Cell–cell interactions are very important in the process, and the autocrine/paracrine factors mediating the proliferation and differentiation are now being established. Key mediators are PGs and IL-11.

Glossary

decidualization The collective morphological and functional changes that the endometrium undergoes, in mammalian species with invasive implantation. The endometrial stromal cells proliferate and differentiate into decidual cells that ultimately form the maternal component of the placenta.

endometrial receptivity The endometrium will allow a blastocyst to initiate successful implantation for only a limited period of time; during this time, the endometrium is said to be receptive.

endometrial sensitization In many species, there is a transient period when decidualization is obtained in response to the application of relatively nontraumatic stimuli; during this responsive period, the endometrium is said to be sensitized.

Defensins

DE YANG AND JOOST J. OPPENHEIM

National Cancer Institute, National Institutes of Health, Maryland

Defensins are widely distributed, small, cationic antimicrobial peptides containing three to four pairs of intramolecular disulfide bonds.

They are synthesized predominantly in epithelial and/or phagocytic cells either constitutively or upon induction by proinflammatory agents as prepro forms and are processed into mature forms. Structurally common to all defensins is the spatial separation of their positively charged regions and hydrophobic regions, a characteristic allowing them to interact with the microbial membrane, which contains negatively charged phospholipids. The primary activity of defensins is antimicrobial. Defensins in mammals also participate in augmenting *in vivo* host innate and adaptive immune responses through a receptor-mediated mechanism(s) as well as inhibiting the production of immunosuppressive glucocorticoids.

I. INTRODUCTION

Macroorganisms including plants, invertebrates, and vertebrates live in an environment laden with microorganisms that are potentially hazardous to life. To survive, macroorganisms have developed various host defense strategies to protect against microbial invasion and to fight and eliminate microbial invaders. One of the strategies of the macroorganisms is the generation of a number of antimicrobial mediators including microbicidal peptides and proteins.

Defensins consist of a family of host gene-encoded antimicrobial peptides widely distributed in plants, insects, birds, and mammals. They are small, cationic, and characterized by six to eight well-conserved cysteine residues that form three to four pairs of intramolecular disulfide bonds. Approximately 150 defensin molecules have been identified in various species. Defensins are classified into several groups of widely divergent peptides whose evolutionary relationships are uncertain (Table 1). Defensins are produced predominantly by epithelial cells separating the host from the environment and by phagocytes. Defensins are synthesized as precursor forms and processed posttranslationally into mature forms. Some defensins are constitutively expressed, and others are induced by proinflammatory signals. Defensins share some common structural features and their primary activity is antimicrobial action against bacteria and fungi. In addition to directing antimicrobial activity, some mammalian defensins regulate a variety of the host innate defense and adaptive immune responses and thus have intracellular as well as extracellular functions. Low levels of human defensins ($\approx$40 ng/ml) are detected in normal plasma, which can increase to 1000 ng/ml with infection. Consequently, although defensins are not secreted by discrete glands, they can act as intracellular mediators that behave like cytokines and have the potential to act as endocrine hormones.

II. CLASSIFICATION AND STRUCTURE

Based on their sources, defensins are conventionally grouped into three families: plant, insect, and vertebrate defensins (Table 1). Plant defensins, although varying in size (45 to 54 amino acids), share 8 conserved cysteine residues that form four pairs of intramolecular disulfide bridges (C1–C8, C2–C5, C3–C6, and C4–C7). The three-dimensional structures of several plant defensins have been determined by nuclear magnetic resonance (NMR) spectroscopy. The common structure adopted by plant defensins is a βαββ scaffold, consisting of a triple-stranded, antiparallel β-sheet and a single α-helix lying parallel to the β-sheet (Table 1 and Fig. 1). Two disulfide bridges (C3–C6 and C4–C7) connect the CXXXC segment of the α-helix to the CXC segment in the third β-sheet, forming a structural motif known as a cysteine-stabilized α-helix. The disulfide bond C1–C8 connects the amino-terminal short strand of the β-sheet to the carboxyl-terminal cysteine residues, and the disulfide bond C2–C5 connects the second β-sheet to the second cysteine residue.

Insect defensins are usually 36 to 46 amino acids long with the exception of the 51-residue bee and bumblebee defensins that possess a 12-amino-acid carboxyl-terminal extension. All insect defensins have 6 conserved cysteine residues that are disulfide-bonded C1–C4, C2–C5, and C3–C6. Insect defensins adopt an αββ scaffold comprising a central α-helix and a double-stranded carboxyl-terminal β-sheet. Similar to plant defensins, the CXXXC segment of the α-helix is connected by two disulfide bridges (C2–C5 and C3–C6) to the CXC segment of the second β-sheet, thus also forming a cysteine-stabilized α-helix. The amino-terminal is brought close to the first β-sheet by the disulfide bond C1–C4 to form an amino-terminal loop.

Vertebrate defensins have been identified in mammals and birds. Similar to insect defensins, vertebrate defensins also have 6 well-conserved cysteine residues. Based on the spacing and disulfide bonding of their six cysteine residues, vertebrate defensins are further classified into α-, β-, and θ-subfamilies (Table 1). The three disulfide bonds of α-defensins are paired C1 to C6, C2 to C4, and C3 to

TABLE 1 Classification, Source, and Structure of Defensins

Classification		Source	Structure[a]	
Family	Subfamily	(producing cells)	Size (aa)	Consensus, disulfide bond, and conformation
Plant defensins	–	Seeds, cell wall, epidermis	45–54	
Insect defensins	–	Epithelial cells of fat body & trachea, thrombocytoids	36–46	
Vertebrate defensins	α	Mammalian phagocytes, Paneth cells	29–35	
	β	Mammalian & avian epithelial cells, keratinocytes, phagocytes	38–42	
	θ	Primate phagocytes	18	

[a]The consensus of each defensin group is illustrated by conserved cysteines (C) linked by a dashed line (one dash represents one residue). Disulfide bonds are illustrated by solid lines. Amino acid residues that form β-strands and α-helices are highlighted by rectangular and oval shadows, respectively. The size is the number of amino acid residues (aa) in defensins.

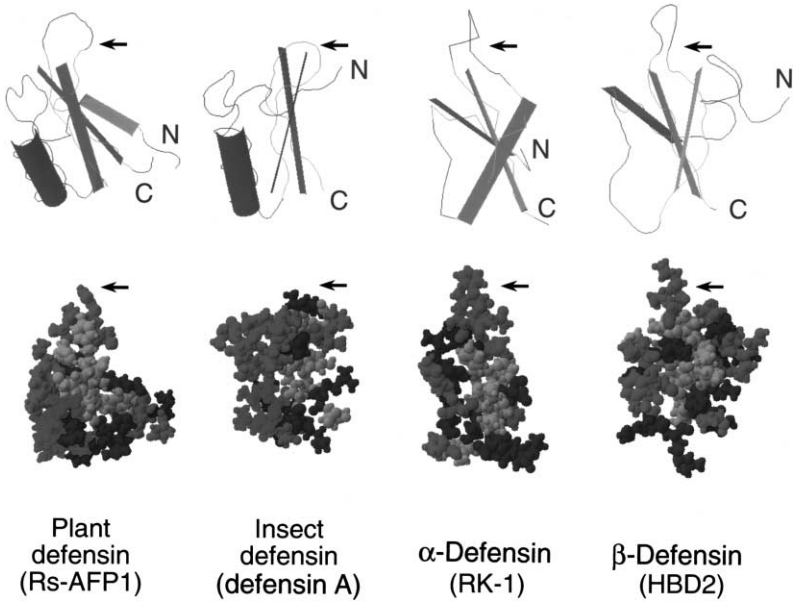

FIGURE 1 The three-dimensional structures of selected defensins shown as ribbon-like (top) or space-filling (bottom) models. Shown are the α-helix, the β-strand, and the other structural features including loops, turns, and coils. Arrowheads mark the β-hairpin. N and C indicate the amino- and carboxyl-termini, respectively. In the bottom panel, charged residues are highlighted in black. Rs-AFP, antifungal peptide of *Raphanus sativus* (radish). RK-1, an α-defensin from rabbit kidney. HBD2, human β-defensin 2. [All structures were adapted from the Molecular Modeling Database (MMDB) of the National Center for Biotechnology Information. The MMDB identification numbers for Rs-AFP1, defensin A, RK-1, and HBD2 are 7107, 3486, 16138, and 16324, respectively].

C5, and those of β-defensins are paired C1 to C5, C2 to C4, and C3 to C6. The θ-defensins are cyclic peptides of 18 amino acid residues, with 6 cysteine residues disulfide-bonded C1 to C6, C2 to C5, and C3 to C4. The structures of two human α-defensins (HNP-1 and HNP-3), two rabbit α-defensins (NP-2 and RK-1), one human β-defensin (HBD-2), and one bovine β-defensin (bBD12) have been determined by NMR and/or X-ray crystallography. The backbones of both α- and β-defensins adopt a βββ scaffold, an anti-parallel β-sheet consisting of three β-strands held together by the disulfide bonds (Table 1 and Fig. 1). There is no cysteine-stabilized α-helix in vertebrate defensins. In contrast to α-defensins, β-defensins have a relatively long amino-terminal segment prior to the first β-sheet, within which a short α-helical segment is formed in some β-defensins.

Apart from the evolutionarily conserved cysteine residues, there is no apparent homology among plant, insect, α-, β-, and θ-defensins at the amino acid sequence level. The marked divergence of defensins is probably due to the huge evolutionary pressure exerted by the wide variety of microbial flora that defensins confront. However, the overall structures of defensins have two characteristics in common (Fig. 1). One is that all defensins have a similar structural element, a β-hairpin. In insect defensins, the β-hairpin consists of two β-strands and the interconnecting turn. In plant and vertebrate defensins, the β-hairpin is made of the second and third β-strands as well as the interconnecting turns. The other shared characteristic is that the charged residues (mostly cationic) tend to cluster, allowing the spatial separation of hydrophilic and hydrophobic regions.

III. CELL SOURCES AND DISTRIBUTION

Defensins are produced primarily by two cell types: epithelial cells separating the host from the external environment and phagocytic cells (Table 1). In plants, defensins accumulate in seeds, in the outer cell wall lining the epidermis of cotyledons, hypocotyls, and endosperm, as well as in the epidermis of seedling and leaf primordia. In insects, defensins are generated by epithelial cells of the fat body and the trachea as well as by thrombocytoids, one type of insect blood cell. Insect defensins can be detected in the hemolymph.

In vertebrates, defensins are produced by epithelial cells of the gastrointestinal, respiratory, urinary, and reproductive systems, Paneth cells, skin keratinocytes, neutrophils, and monocytes/macrophages. Although multiple tissues can express one given defensin, the highest level of gene expression is usually found in one tissue type. In humans, six α-defensins and at least three β-defensins have been identified and cloned (Table 2). HNP1–4 are synthesized by promyelocytic precursors and stored in the granules of phagocytes. HNP1–4 are released upon neutrophil degranulation and can therefore be distributed systemically in the blood. The concentration of HNP1–4 in the plasma of

TABLE 2 The Number, Distribution, Gene Location, Inducibility, and Activities of Human Defensins[a]

Subfamily	Conventional nomenclature	Expressing cells	Chromosome location	Regulatory element	Inducibility	Activity
α	HNP1	Neutrophils, monocytes, macrophages	8p21–p23	C/EBPα	Constitutive	Antimicrobial, chemotactic, immunomodulatory, antagonistic for ACTH
	HNP2					
	HNP3					
	HNP4					
	HD5	Paneth cells, epithelial cells of the reproductive system	8p21–p23	NF–IL-6	Constitutive	Antimicrobial
	HD6					
β	HBD1	Epithelial cells, keratinocytes	8p21–p23	NF–IL-6	Constitutive	Antimicrobial, chemotactic
	HBD2			NF-κB	Inducible	
	HBD3			NF–IL-6, AP-1, GAS		

[a]HNP, human neutrophil-derived peptide; HD, human defensin; HBD, human β-defensin; C/EBPα, CCAAT/enhancer-binding protein α; NF, nuclear factor; IL-6, interleukin-6; AP-1, activation protein-1; GAS, IFN-γ activated site; ACTH, adrenocorticotropic hormone.

normal individuals is ~40 ng/ml, but can rise to >1000 ng/ml during severe infection. Human defensin 5 (HD5) and HD6 are produced by Paneth cells. HBD1–3 are predominantly generated by skin keratinocytes and epithelial cells.

The number of defensins varies greatly from one species to another. In contrast to human neutrophils, bovine neutrophils have no α-defensin, but instead store as many as 12 β-defensins. Three additional β-defensins, including tracheal antimicrobial peptide, lingual antimicrobial peptides, and an enteric β-defensin, are generated by bovine tracheal, lingual, and enteric epithelial cells, respectively. Although mouse neutrophils contain neither α- nor β-defensins, mice have at least 6 α-defensins called cryptdins and 6 β-defensins produced by Paneth cells and various epithelial cells, respectively. Rabbits and rats have 6 α-defensins stored in the granules of phagocytes and several β-defensins generated by epithelial cells and keratinocytes.

IV. GENES AND THEIR EXPRESSION, POSTTRANSLATIONAL PROCESSING, AND REGULATION

The genes of human α- and β-defensins have been relatively well investigated. The genes encoding human α- and β-defensins are localized to a single chromosome region, 8p21–p23 (Fig. 2). The genes encoding HNPs are composed of three exons, with the first exon encoding the 5′-untranslated region (5′-UTR) and the second exon encoding the signal peptide. The genes for HD5, HD6, and HBD1–3 have two exons, with the first exon encoding the 5′-UTR and the signal peptide. In both cases, the last exon encodes the propiece, the mature peptide, and the 3′-UTR. Translation of the defensin mRNA gives rise to preprodefensin, which consists of a signal peptide, a propiece, and the mature defensin. Mature defensin is generated by posttranslational processing or proteolytic removal of the signal peptide and propiece. For HNPs, the processing occurs during transport from the Golgi body to the azurophilic granules, but for the remaining α- and β-defensins, it happens after the extracellular secretion of preprodefensins. The enzymes responsible for the processing of mammalian defensins are not completely understood.

Although HD5–6 and HBD1–3 have their own genes, four HNPs are actually encoded by two genes (Fig. 2). HNP1 and HNP4 are encoded by genes designated *HDEFA1* and *HDEFA4*, respectively. HNP3 arises from a single nucleotide substitution in one of several *HDEFA1* copies, *HDEFA1A*. HNP2 results from the posttranslational removal of the amino-terminal residue from HNP1 and/or HNP3.

The promoter region of human α- and β-defensin genes contains various regulatory elements including CCAAT/enhancer-binding protein α (C/EBPα), nuclear factor–interleukin-6 (NF–IL-6), NF-κB, activation protein-1 (AP-1), and interferon-γ (IFN-γ)-activated site (GAS) (Table 2). The expression of HNP1, HNP3, HNP4, HD5, HD6, and HBD1 is constitutive, whereas that of HBD2 and HBD3

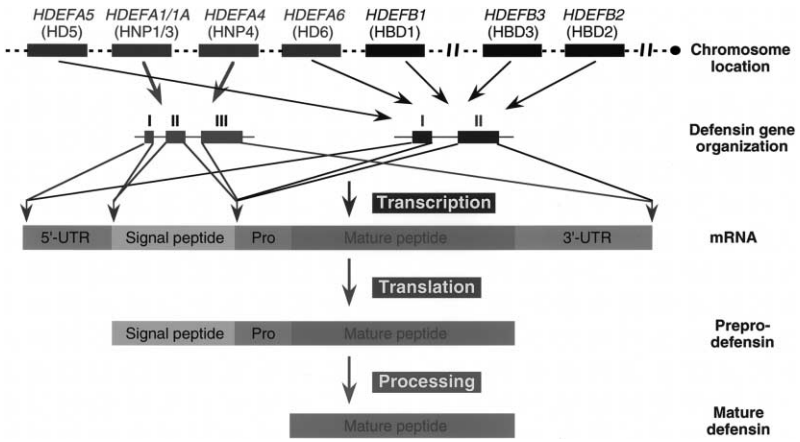

FIGURE 2 Schematic illustration of the gene location and organization, transcription, translation, and posttranslational processing of human α- and β-defensins. The short arm of human chromosome 8 is shown at the top. The intervening sequences between defensin genes are not drawn to scale. The closed, black circle indicates the centromere. *HDEFA/B*, human α/β-defensin gene. UTR, untranslated region.

is inducible by proinflammatory cytokines (e.g., tumor necrosis factor α, IL-1β, IFN-γ), bacterial products such as lipopolysaccharide, and microorganisms. The inducibility of HBD2 and HBD3 is due to the existence of sites for NF-κB and GAS, respectively, in their promoter regions. C/EBPα, NF–IL-6, and AP-1 sites presumably participate in maintaining the constitutive or basal expression of defensins.

Reports on the gene structure and regulation of expression of defensins distributed in plants, insects, and vertebrates other than humans are still fragmentary; however, the expression patterns fall into three categories: constitutive, inducible, or both. Plant defensins are expressed either in a constitutive, organ-specific manner or in a pathogen-modulated manner. Insect defensins are mostly inducible. For vertebrate defensins, those generated by leukocytes and Paneth cells are, in general, constitutively expressed. Those generated by epithelial cells are mostly inducible with the exception of β-defensin 1 from many species.

V. ACTIVITIES AND MODE OF ACTION

A. Antimicrobial Activity

Plant, insect, and vertebrate defensins exhibit antimicrobial activities generally at concentrations higher than 1 μg/ml (Tables 2 and 3). Plant defensins are predominantly antifungal, whereas insect defensins are cytotoxic only to bacteria, especially gram-positive bacteria (Table 3). In contrast, vertebrate α-, β-, and θ-defensins have potent microbicidal activity against fungi and gram-positive and gram-negative bacteria. In addition, some α-defensins are active against enveloped viruses. The antimicrobial activity of defensins is usually measured *in vitro* in low-ionic-strength (10 mM) sodium phosphate buffer, pH 7.4. With the exception of θ-defensins, which are insensitive to high concentrations of salt, the antimicrobial activity of most plant and insect α- and β-defensins is ablated in the presence of high-ionic-strength salt (e.g., 150 mM NaCl). Furthermore, the antimicrobial activity of defensins is also sensitive to divalent cations, especially Ca^{2+}, and impaired in the presence of serum. Thus, defensins are more efficient in phagocytic vacuoles and on the surfaces of epithelium and skin than in blood and extracellular fluids.

The antimicrobial spectrum and sensitivity to ionic strength of defensins vary considerably among individual defensin members. For example, both HBD2 and HBD3 are produced by human skin keratinocytes, but their antimicrobial spectra are different. HBD2 is restricted to gram-negative bacteria such as *Escherichia coli* and in particular *Pseudomonas aeruginosa*, as well as yeast such as *Candida albicans*. In contrast, HBD3 is also active against gram-positive bacteria such as *Staphylococcus aureus* and *Streptococcus pyogenes*.

The mechanism(s) by which microorganisms are killed by defensins is not completely understood; however, it is generally believed that the killing is a consequence of disruption of the microbial membrane. The polar topology of defensins with spatially separated charged and hydrophobic regions allows them to insert themselves into the phospholipid membranes so that their hydrophobic regions are buried within the lipid membrane interior and their charged (mostly cationic) regions interact with anionic phospholipid head groups and water. Subsequently, some defensins may aggregate to form "channel-like" pores; others may bind to and cover the microbial membrane in a "carpet-like" manner.

TABLE 3 The Antimicrobial Spectrum of Defensins

Defensin		Antimicrobial spectrum			
			Bacteria		
Family	Subfamily	Viruses	Gram-positive	Gram-negative	Fungi
Plant defensin		−	+	−	+++
Insect defensin		−	+++	+	−
Vertebrate defensin	α	(+)[a]	+++	+++	+++
	β	−	+++	+++	+++
	θ	NT	+++	+++	+++

Note. NT, not tested yet.
[a]Active only on some enveloped viruses.

The net outcome is the disruption of membrane integrity and function, which ultimately leads to the lysis of microorganisms. Defensin's cytotoxic effects on microorganisms are relatively selective because the membrane of microorganisms, in contrast to that of host cells, is relatively rich in negatively charged phospholipids.

B. Chemotactic Activity

Defensins of mammalian species exhibit functional diversification. In addition to their antimicrobial activity, some mammalian defensins promote various host immune responses against microorganisms by having chemotactic activity for host immune cells including dendritic antigen-presenting cells and T lymphocytes, by inducing the production of cytokines such as interleukin-8 by epithelial cells, by degranulating mast cells, and by enhancing *in vivo* immunological reactions.

Human neutrophil-derived α-defensins are chemotactic for human immature dendritic cells (DCs) and peripheral blood naive T lymphocytes. Human β-defensins and mouse β-defensins are chemotactic for human and mouse immature DCs, respectively, as well as human resting memory T cells. The capacity of defensins to induce the chemotaxis of immune cells is optimal at nanomolar concentrations and, unlike their microbicidal activity, is not ablated by the presence of physiologic concentrations of salt (150 mM NaCl) and serum. Defensins are rich at sites of microbial entry as a result of degranulation of recruited neutrophils and/or induced production by local epithelial cells or keratinocytes. Since DCs are the most potent antigen-presenting cells, defensin-mediated recruitment of immature DCs to sites of microbial entry facilitates the uptake, processing, and presentation of microbial antigen and subsequently enhances the initiation of antigen-specific immune responses by DCs that mature and migrate to draining lymph nodes. Indeed, defensins markedly enhance antigen-specific immune responses when administered simultaneously with antigens or as DNA vaccines in which defensin and antigen are linked as a fusion construct.

The effects of defensins on host cells are based on a receptor-mediated mechanism(s). The chemotactic activity of defensins is mediated by a G-protein-coupled seven-transmembrane domain chemotactic receptor(s). One of the receptors that human β-defensins utilize to induce chemotaxis is human CCR6, a CC chemokine receptor that also interacts with human CC chemokine CCL20/LARC/MIP-3α.

The dual (antimicrobial and chemotactic) activities of defensins are not unique since a number of other endogenous antimicrobial peptides such as cathelicidins and azurocidin are also chemotactic for various leukocyte subpopulations. Furthermore, human interferon-γ-inducible chemokines, including MIG, IP-10, and I-TAC, in addition to mobilizing and activating immune cells, also exhibit antimicrobial activities.

C. Antagonistic Activity for Adrenocorticotropic Hormone

Some mammalian neutrophil-derived α-defensins have the capacity to inhibit the production of immunosuppressive adrenal steroid hormones and thus are also known as "corticostatins." This inhibitory activity is effective at nanomolar concentrations and is achieved by blocking the interaction between adrenocorticotropic hormone and its receptor. During systemic infections, α-defensin levels in plasma can reach up to 100 μg/ml, a concentration sufficient to interfere with the production of adrenal glucocorticoids. Inhibition by α-defensins of immunosuppressive glucocorticoid production facilitates the global immune responses during the early phase of infection.

The importance of defensins in host defense against microbial invasion is supported by many studies. In particular, genetic knockout of the mouse gene encoding matrilysin, which participates in the processing of murine α-defensins, prevents the production of mature murine α-defensins and reduces the resistance of mice to bacterial challenge. Conversely, transgenic overexpression by potatoes of alfAFP, a plant defensin isolated from alfalfa, confers protection against pathogenic fungi to such transgenic potatoes.

Glossary

chemotaxis Directional migration of cells toward a gradient of mediators called chemotactic factors.

dendritic cells A type of mammalian leukocyte with dendritic processes and the most potent capacity to take up, process, and present antigens to T lymphocytes.

keratinocytes A specialized type of epithelial cell that covers the body surfaces of mammals.

Paneth cells A specialized type of secretory cell located at the bottom of small intestine crypts of Lieberkühn.

regulatory element A stretch of DNA sequence in the promoter region of genes that when bound by a specific

transcription factor results in the regulation of gene transcription.

Deiodinases

JUAN BERNAL

Instituto de Investigaciones Biomedicas Alberto Sols, Madrid

Deiodination, the most important metabolic pathway of thyroid hormones, is catalyzed by deiodinases, which contain the amino acid selenocysteine in their active center. Three types of deiodinase have been identified in vertebrate tissues: D1, D2, and D3. Deiodinase activity is regulated during development and by physiological factors including the thyroid hormones. D1 and D2 are expressed postnatally and in the adult; D3 is expressed at high levels in placenta, pregnant uterus, and fetal tissues. Deiodinases appear to play a role in regulating intracellular T3 levels in a tissue-specific manner and in coordinating vertebrate growth and development.

I. INTRODUCTION

The thyroid gland synthesizes and secretes two hormones that are iodinated amino acids known as iodothyronines: 3,5,3′5′-triiodo-L-thyronine (thyroxine or T4) and 3,5,3′-triiodo-L-thyronine (T3). Under normal conditions, the major circulating form of thyroid hormone is T4. T4 functions primarily as a pro-hormone and can be converted in the tissues to T3, the hormone that is responsible for the majority of thyroid hormone action. Thyroid hormone action is mediated primarily by the interaction of T3 with nuclear receptors, which are ligand-modulated transcription factors that regulate the expression of many genes. Conversion of T4 to T3 in extrathyroidal tissues is a physiologically important, tightly

transcription factor results in the regulation of gene transcription.

JUAN BERNAL

Instituto de Investigaciones Biomedicas Alberto Sols, Madrid

Deiodination, the most important metabolic pathway of thyroid hormones, is catalyzed by deiodinases, which contain the amino acid selenocysteine in their active center. Three types of deiodinase have been identified in vertebrate tissues: D1, D2, and D3. Deiodinase activity is regulated during development and by physiological factors including the thyroid hormones. D1 and D2 are expressed postnatally and in the adult; D3 is expressed at high levels in placenta, pregnant uterus, and fetal tissues. Deiodinases appear to play a role in regulating intracellular T3 levels in a tissue-specific manner and in coordinating vertebrate growth and development.

I. INTRODUCTION

The thyroid gland synthesizes and secretes two hormones that are iodinated amino acids known as iodothyronines: 3,5,3′5′-triiodo-L-thyronine (thyroxine or T4) and 3,5,3′-triiodo-L-thyronine (T3). Under normal conditions, the major circulating form of thyroid hormone is T4. T4 functions primarily as a pro-hormone and can be converted in the tissues to T3, the hormone that is responsible for the majority of thyroid hormone action. Thyroid hormone action is mediated primarily by the interaction of T3 with nuclear receptors, which are ligand-modulated transcription factors that regulate the expression of many genes. Conversion of T4 to T3 in extrathyroidal tissues is a physiologically important, tightly

regulated reaction, which is catalyzed by specific enzymes known as deiodinases.

Deiodination is also an important metabolic pathway for the inactivation of thyroid hormones. Other pathways in the metabolism of thyroid hormones include modifications of the alanine side chain, conjugation of the phenolic group, and oxidative cleavage of the diphenyl-ether bridge (Fig. 1). These reactions also produce some potentially important metabolites, such as the acetic acid analogues of T3 and T4, 3,5,3′-triidothyroacetic acid (TRIAC) and 3,5,3′,5′-tetraiodothyroacetic acid (TETRAC), and conjugates of T4 and T3 with sulfate and glucuronic acid. TRIAC has an affinity for the nuclear receptors that is one order of magnitude higher than that of T3, but has only a short residence time and its contribution *in vivo* to thyroid hormone action is unknown. The conjugated forms of T4 and T3 with sulfate are present in cord serum, amniotic fluid, and fetal tissues and may constitute hormone reservoirs in tissues with high sulfatase activity, such as fetal liver and brain.

There are two types of iodothyronine deiodination, 5′ deiodination (5′D) and 5 deiodination. 5′D results in the removal of an iodine atom from the 5 (or chemically equivalent 3) position of the outer or phenolic ring of an iodothyronine. Because 5′D of T4 results in the formation of T3, it can be considered an activating system. 5D results in the removal of iodine from the 3 or 5 position of the inner or tyrosyl ring of iodothyronines, and this process inactivates both T4 and T3. Three types of deiodinase have been identified in vertebrate tissues and the general properties of each are listed in Table 1. The interplay among the different deiodinases on the different substrates and intermediates results in a deiodination cascade, illustrated in Fig. 2. The genes encoding the three deiodinases have been identified and their respective cDNAs have been cloned. All three deiodinases contain the rare amino acid selenocysteine (Se-Cys) at their active sites, and selenium is needed for enzyme activity. Se-Cys is encoded by an AUG codon, which, in the presence of a specific element known as a selenocysteine insertion sequence (SECIS), does not function as a terminator of translation but recognizes a specific Se-Cys tRNA. SECIS elements are RNA sequences present in the 3′-untrans-untranslated region (3′-UTR) of mRNAs that code for selenoproteins.

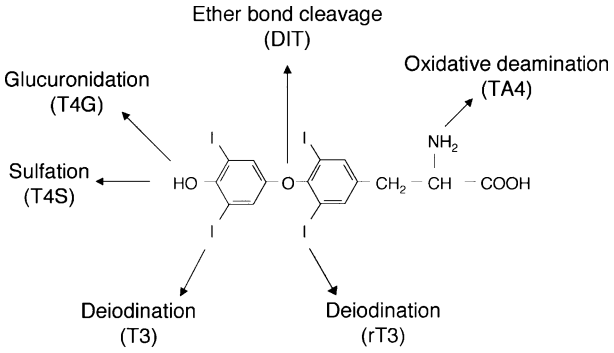

FIGURE 1 Pathways of thyroid hormone metabolism. Thyroid hormone may be subjected to the following modifications: (1) Oxidative deamination, with the production of tetrac (TA4) from T4 or triac (TA3) from T3. (2) Ether bond cleavage, with the production of diiodotyrosine (DIT). (3) Conjugation of the phenolic group by glucoronic acid (T4G or T3G) or sulfate (T4S or T3S). (4) Deiodination, the loss of iodine atoms that proceeds sequentially as shown in Fig. 2. Modified from T. J. Visser in Thyroid Hormone Metabolism in http://www.thyroidmanager.org, with permission of the authors and Endocrine Education, Inc.

II. TYPE I DEIODINASE

Type I deiodinase (D1) has both 5′D and 5D activities. T4 and rT3 are the preferred substrates for the 5′D activity while the sulfate conjugates of T4 and T3 are the preferred substrates for the 5D activity. The half-life of the enzyme *in vivo* is about 20–30 h and its activity is inhibited both *in vivo* and *in vitro* by propylthiouracil (PTU) and by aurothioglucose.

In vitro D1 needs free sulfhydryl groups for enzymatic activity. It has been proposed that *in vitro*, D1 reacts by a two-substrate mechanism following so-called "ping-pong" kinetics. By virtue of this mechanism, and after interaction with the substrate and deiodination, the enzyme is regenerated by reaction with a thiol co-factor. *In vitro*, dithiothreitol is very effective as a free sulfhydryl compound, but the physiological co-factor has not been identified. *In vivo*, the deiodination reaction might be link to a NADPH-regenerating co-factor system possibly coupled to the pentose phosphate cycle. One candidate for the physiological co-substrate is glutathione, although *in vitro* it is a weak inducer of the enzyme. The possibility remains, however, that the enzymatic reaction *in vivo* proceeds without a thiol co-substrate and that the enzyme is not regenerated after each deiodination cycle, in a sort of suicide reaction.

A. The D1 Gene

The human gene (*hdio*1) is located at chromosome 1p32–p33, spans 17.5 kb, and contains four exons.

TABLE 1 Properties of Deiodinases

Property	Type I	Type II	Type III
Activity	5′D and 5D (outer and inner rings)	5′D (outer ring)	5D (inner ring)
Deiodination site	Selenocysteine	Selenocysteine	Selenocysteine
K_m	10^{-7} M (rT3) 10^{-6} M (T4)	10^{-9} M (T4) 10^{-8} M (rT3)	10^{-9} M (T3) 10^{-8} M (T4)
Substrate preference	rT3 > >T4 > T3	T4 > T3	T3 > T4
Inhibition by PTU and ATG	Sensitive	Resistant	Resistant
Tissue distribution	Liver, kidney, thyroid, brain, pituitary	Rat: brain, puitary, BAT, placenta Human: brain, pituitary, BAT, placenta, thyroid gland, heart, muscle	Placenta, skin, brain, uterus, fetal tissues
Physiological role	Provide T3 to plasma; inactivate T3 and T4; degrade T4 and T3 sulfates; degrade rT3	Provide intracellular T3; Provide plasma T3 in humans	Inactivate T4 and T3
Hyperthyroidism	Increased	Decreased	Increased
Hypothyroidism	Decreased	Increased	Decreased

The UGA codon is present in the second exon. The gene is transcribed from two start sites and produces a 2.2 kb mRNA. Expression of the gene correlates with the presence of a 27 kDa protein (p27) and with D1 activity. The *dio*1 promoter does not contain TATA- or CAAT-boxes, but does contain GC-boxes, which are binding sites for the transcription factor Sp1. In the upstream region of the gene, there are two thyroid hormone-response elements and one retinoic acid-response element. Depending on the presence of these regulatory sites, D1 is stimulated by retinoic acid in undifferentiated cells

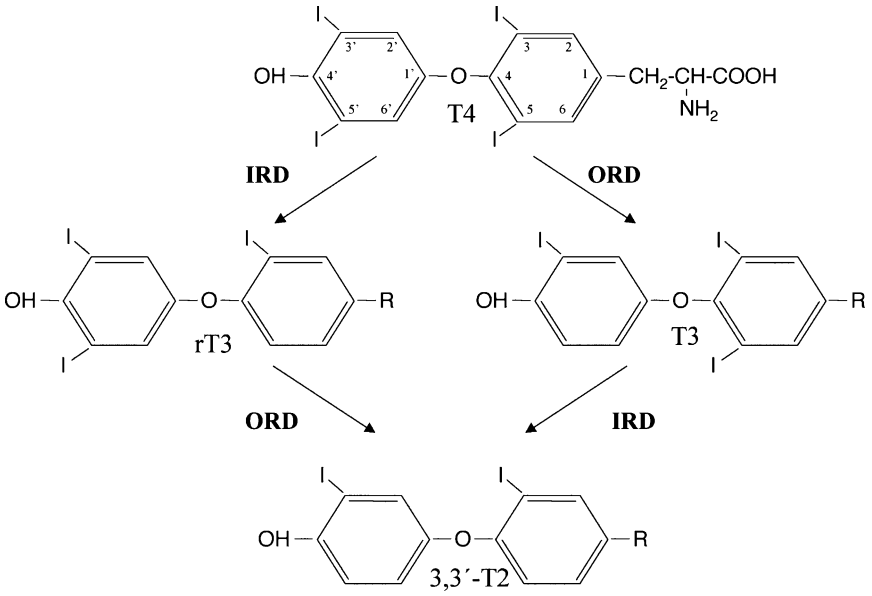

FIGURE 2 The deiodination cascade. T4 may be deiodinated by D1 or D2, with the generation of the active hormone, T3, or by D3 with generation of the inactive compound rT3. T3 and rT3 can be further metabolized to T2, as shown. ORD, outer ring deiodination; IRD, inner ring deiodination. and by T3 in differentiated cells. The mouse gene is on chromosome 4. A mouse strain with decreased D1 expression due to an altered promoter is available.

B. D1 Expression and Physiological Role

D1 is a cell membrane protein expressed in liver, kidney, thyroid, and pituitary. In the kidney, it is expressed in the S3 segment of the proximal tubule. In the pituitary gland, D1 is expressed in thyrotrophs, lactotrophs, and somatotrophs. Other tissues, such as lung, intestine, muscle, spleen, placenta, mammary gland, white adipose tissue, lymphocytes, and salivary gland, display D1 activity but at relatively low levels. In liver, D1 serves two important functions. On the one hand, it contributes to the pool of circulating T3; indeed approximately 70% of circulating T3 in the rat may be produced in the liver under euthyroid conditions. In addition to providing most of the circulating T3, D1 in the liver degrades rT3 through 5′-deiodination and catalyzes the 5 deiodination of the sulfate derivatives of T4 and T3.

C. Regulation of D1 Activity

D1 activity is induced by thyroid hormones, by retinoic acid in thyroid and liver carcinoma cells, and by TSH, via cAMP, in thyrocytes. Basal expression and induction by thyroid hormones require the presence of the β1 isoform of thyroid hormone receptor, which is the main T3 receptor present in liver. Induction by thyroid hormones means that D1 activity is increased in hyperthyroidism and decreased in hypothyroidism.

Expression in liver, pituitary, and thyroid is critical for the compensatory mechanisms afforded by D1 in situations of deficiency or excess of thyroid hormone. In liver, these situations will result in a decreased or an increased degradation of thyroid hormone, respectively. In the pituitary, it is likely that the increased activity of pituitary D1 in hyperthyroidism would increase local conversion of T4 to T3, thereby increasing receptor occupancy and reducing TSH secretion. In the thyroid gland, there is some evidence that D1 is induced in situations of low T4, such as in iodine deficiency, through TSH-induced stimulation of the cAMP pathways. The increased D1 activity would likely result in an increased proportion of hormone secreted as T3 due to increased intrathyroidal conversion of T4 to T3.

The following pathological states are associated with a reduction in D1 activity: starvation, severe illness, bacterial sepsis, surgical interventions, and severe trauma. These conditions are associated with reduced levels of circulating T3, normal T4, and normal or low TSH. The situation is known as "euthyroid sick syndrome," "nonthyroidal illness," or "low T3 syndrome." The mechanism for D1 reduction in these states is not fully understood, but interleukin-1β and TNFα are known to inhibit D1 activity, and the presence of inhibitory cytokine-responsive elements in the human *dio*1 promoter might play a mechanistic role in the pathogenesis of the syndrome.

III. TYPE II DEIODINASE

Type II deiodinase (D2) has only 5′D activity. The K_m of this enzyme for T4 and rT3 is three orders of magnitude lower than that of D1, approximately 1 nM for T4 and 10 nM for rT3. One important property that was instrumental in its identification as a second enzyme with 5′D activity, is that its activity is insensitive to PTU or aurothioglucose, despite the presence of selenocysteine in the active center of the enzyme. *In vitro*, D2 needs high concentrations of free SH groups. The enzymatic reaction follows a "sequential reaction kinetics" typical of multisubstrate reactions, in which both the substrate and the co-factor combine with the enzyme. D2 is inhibited by its substrates, T4 and rT3. Thus, when the concentration of T4 decreases, as in hypothyroidism, the level of D2 activity is increased.

A. The D2 Gene

The human D2 gene (*hdio*2) is present on chromosome 14q24.3. It contains two exons, separated by a single 7.4 kb intron located at codon 75. The promoter region of the gene contains a strong cAMP-responsive element. The gene is transcribed from two alternative, tissue-specific start sites, giving 6.8 to 7.5 kb mRNAs. Human, rat, mouse, chicken, and frog D2 mRNAs contain an in-frame UGA codon in the deduced amino acid sequence of the active center (position 133 in hD2) and therefore are all considered to be selenoenzymes. Conceptual translation of the human D2 cDNA results in a 31 kDa protein with a high level of similarity to D1 and D3 in the selenocysteine-containing active center of the putative enzyme. A SECIS element has been identified in the extreme 3′-UTR of the mouse, human, and highly homologous chicken Dio2 genes. D2 is an integral membrane protein located in the endoplasmic reticulum.

B. D2 Expression and Physiological Role

D2 is expressed in the pituitary gland, central nervous system (CNS), brown adipose tissue (BAT), uterus, and placenta of rats and humans. The highest levels of expression in brain are found in a specialized type of glial cell called tanycytes, which line the walls of the third ventricle and extend processes to the hypothalamus and median eminence. Astrocytes also contain D2 mRNA but at lower concentrations than tanycytes. Expression of D2 in the human is less restricted than in the rat and is also present in skeletal muscle, cardiac muscle, and the thyroid gland. Due to its widespread expression in the human, some authors think that D2 contributes to circulating T3 in addition to D1. As an indication that this may indeed be the case, T3 production in the human is much less inhibited by PTU than rT3.

One important role for D2 is the generation of intracellular T3, especially in tissues such as the CNS, pituitary, and BAT. It can be speculated that these tissues may require a high degree of saturation of the nuclear T3 receptor, and the intracellular production of T3 would allow rapid transport of T3 to the nucleus, which may be facilitated by the subcellular location of D2. Liver and kidney, which express predominantly D1, derive most of the T3 from the plasma, and the physiological saturation of nuclear T3 receptors is approximately 50%. BAT and brain, in contrast, derive more than 50% of intracellular T3 from local deiodination of T4, and the occupancy of the nuclear receptor may reach 80% under physiological conditions. In the pituitary, D2 is involved in the regulation of TSH secretion as a function of serum T4 concentration. Changes in serum T4 influence TSH secretion after conversion to T3, which might be carried out by D1 or D2. The relative contribution of each enzyme might be influenced by the thyroid state. Because D2 is increased in hypothyroidism and decreased in hyperthyroidism, D2 is the predominant enzyme in the pituitary of hypothyroid animals.

D2 activity is detectable in the brain of the rat fetus and increases markedly by the end of pregnancy to reach adult levels. This increased D2 activity is apparently responsible for the 18-fold increase of brain T3 during the same period. Higher than adult levels of D2 activity are transiently achieved during the first month of life in cerebrum and cerebellum. It is believed that high-level expression of D2 may provide a high local concentration of T3 needed for some developmental processes. One of the best examples is the cochlea, in which D2 activity rises dramatically just before the onset of hearing in the neonatal rat.

C. Regulation of D2 Activity

As stated above, D2 activity is very sensitive to thyroid status and changes inversely with thyroid hormone concentration. Thyroidectomy increases, and thyroid hormone administration decreases, D2 activity in the rat cerebral cortex and other tissues. Changes in D2 activity presumably influence intracellular T3 levels and thus may protect the brain from either hypo- or hyperthyroidism. Under conditions of low iodine intake, increased D2 activity helps to maintain normal T3 concentrations in brain despite greatly reduced T4 concentrations in plasma. Regulation of D2 activity occurs at two levels. The D2 substrates T4 and rT3 rapidly inhibit D2 activity through posttranslational mechanisms involving the ubiquitin-proteasome pathway. In addition, D2 is regulated at the mRNA level.
