The *Encyclopedia of Medical Anthropology* was prepared under the auspices and with the support of the Human Relations Area Files, Inc. (HRAF) at Yale University. The foremost international research organization in the field of cultural anthropology, HRAF is a not-for-profit consortium of 19 Sponsoring Member institutions and more than 400 active and inactive Associate Member institutions in nearly 40 countries. The mission of HRAF is to provide information that facilitates the worldwide comparative study of human behavior, society, and culture. The HRAF Collection of Ethnography, which has been building since 1949, contains nearly one million pages of information, organized by culture and indexed according to more than 700 subject categories, on the cultures of the world. An increasing portion of the Collection of Ethnography, which now covers more than 380 cultures, is accessible via the World Wide Web to member institutions. The HRAF Collection of Archaeology, the first installment of which appeared in 1999, is also accessible on the Web to member institutions. HRAF also prepares multivolume reference works with the help of nearly 2,000 scholars around the world, and sponsors *Cross-Cultural Research: The Journal of Comparative Social Science*.

Preface

Illness and death are significant events for people everywhere. No one is spared. But medical beliefs and practices are not the same everywhere. How people understand the causes of illness and death and how they cope with these events vary from culture to culture. It is not surprising therefore that medical practitioners and others are becoming increasingly aware of the need to understand the influence of society and culture on medical belief and practice. Culture—the customary ways of thinking and acting in a society—often affects the outcome of illness, and even which illnesses occur. So those who are actively engaged in studying health and illness are coming to realize that biological *and* cultural factors need to be considered if we are to reduce human suffering.

The professional medicine of Western cultures has been called “biomedicine,” because it mostly deals with the biology of the human body. But biomedicine, like the medicine of other cultures, is also influenced by conditions and beliefs in the culture, and therefore reflects the value and norms of its creators. So, if biomedicine is socially constructed and not just based on science, its beliefs and practices may partly derive from assumptions and biases in the culture. For example, it used to be thought that some people refrained from drinking milk because they were ignorant. Now, biomedicine realizes that the avoidance of milk is a rational response to the likelihood that drinking milk results in diarrhea and other discomforts in people who lack an enzyme (lactase) that allows easy digestion of the sugar in milk (lactose). Anthropologists were the first to realize that drinking milk would cause serious problems for many people. The anthropologists’ fieldwork in other cultures around the world revealed that people in many places that have milking animals must sour the milk before they can drink it, to reduce or eliminate the sugar in it that would otherwise make them sick.

Severe diarrhea may also be an effect of the culture’s system of social stratification. The direct causes of the diarrhea may be biological, in the sense that the deaths are caused by bacterial or other infection. But why are so many infants exposed to those infectious agents? Usually, the main reason is social or cultural. The affected infants may mostly be poor. Because they are poor, they are likely to live with infected drinking water. Similarly, malnutrition may be the biological result of a diet poor in protein. But such a diet is usually also a cultural phenomenon, reflecting a society that has different classes of people, with very unequal access to the necessities of life, and unequal access to decent medical care. For this and other reasons, medical anthropology is developing what has been called a “biocultural synthesis” in its studies of health and illness.

Medical anthropology may even be in the forefront of the movement that is returning the entire field of anthropology to its biocultural roots. In any case, the growth of jobs in medical anthropology is one of the more striking developments in contemporary anthropology. Medical anthropology has developed into a very popular specialty, and the Society for Medical Anthropology is now the second largest unit in the American Anthropological Association.

ORGANIZATION OF THIS ENCYCLOPEDIA

A total of 53 thematic and comparative essays begin these volumes. These essays are grouped into five sections: general concepts and perspectives; medical systems; political, economic, and social issues; sexuality, reproduction, and the life cycle; and health conditions and diseases. Then there are 52 cultural portraits of health and illness, articles that describe the state of health and illness in 52 particular cultures around the world. Every cultural region of the world is represented, as are cultures at all levels of social complexity. The *Encyclopedia of Medical Anthropology* is unique. In addition to providing a large range of thematic essays, representing the various perspectives in medical anthropology, these volumes are unique in focusing on so many particular cultures. No other single reference work comes close to matching the depth and breadth of information on the varying cultural background of health and illness around the world. We are able to provide the information contained here through the efforts of more than 100 contributors—generally

anthropologists but also other social scientists—who usually have firsthand experience with how medical cultures vary around the world. Focusing on comparative topics and how health and illness are viewed and treated in the world's cultures is consistent with HRAF's mission to encourage and facilitate comparative worldwide studies of human society, culture, and behavior. Our aim is to leave the reader with a real sense of how different cultures deal with health and illness, and what anthropology has contributed to understanding health and illness.

ORGANIZATION OF THE ARTICLES

The thematic and comparative essays vary in how they are organized, not just in their topics. The authors were encouraged by the editors to structure their discussions as they saw fit. On the other hand, the articles on health and illness in particular cultures generally follow the same format to provide maximum comparability. That is, most of the culture articles cover the same topics, the list of which we developed with the help of our Advisory Board (see the headings in boldface below). If there is substantial variation within the culture (e.g., by class or gender), the author was instructed to note it where appropriate, either in a particular section or at the end. A heading may be omitted if information on it is lacking or not applicable. The headings that follow are found in the vast majority of the articles to facilitate search and retrieval of information. Thus, the reader may easily compare how the cultures of the world differ and are similar in the ways they deal with health and illness.

The outline for the culture articles includes the following topics.

Alternative Names of the Culture

Other names or ethnonyms used in the literature.

Location and Linguistic Affiliation

Where the described culture is located (region of the world, country and location within the country, where appropriate). The language spoken by the people described, and the larger language family it belongs to.

Overview of the Culture

A summary of the culture to orient the reader, including information on demography, history, economy and occupations, social and political conditions, family and kinship, religion, etc.

The Context of Health: Environmental, Economic, Social, and Political Factors

This section first provides an overview of the health situation, with epidemiological statistics if available, or with observer assessments if statistics are not available. Then there is a discussion of the global and local factors enhancing or detracting from health, including social factors (historical and colonial, if appropriate), the impact of diet and nutrition (positive and negative), and the health infrastructure.

Medical Practitioners

Types of full-time and part-time practitioners in the society, and descriptions of their roles and the people they serve.

Classification of Illness, Theories of Illness, and Treatment of Illness

Discussion of the cultural understanding of illness (biomedical, other). Even where the biomedical paradigm is accepted, there may be alternative viewpoints, which will be described. Mental illness will also be described in this

section. Discussions of age-related conditions (e.g., cardiovascular disease) will be reserved for the section on Health Through the Life Cycle (see below).

Sexuality and Reproduction

Discussion of sexual attitudes and practices, and their impacts on health and fecundity and fertility, and other factors affecting fecundity and fertility. Ideas about conception, ideal family size, and population controls and their consequences (e.g., the effect of infertility on a woman's status).

Health Through the Life Cycle

Pregnancy and Birth. Beliefs, attitudes, and practices relating to pregnancy, abortion, miscarriage, and birth.

Infancy. Postpartum practices, including breast-feeding. Reaction to multiple births, birth defects, treatment of the healthy and unhealthy infant, and number and types of caretakers. Definitions of and duration of infancy. Special risks for one gender as compared with another. Special protections against or treatments of illness in infancy.

Childhood. Care of children, ideas about discipline and length of childhood, if known, parental acceptance and rejection, and cultural variation in concepts of child abuse. Special medical or health issues during this period.

Adolescence. If there is no apparent difference in treatment of adolescents as compared with children, this is noted. Genital operations if any. Special medical or health issues during this period.

Adulthood. Special health or medical issues that come up in adulthood or that are related to marriage (e.g., domestic abuse, unequal access by gender to medical care). Attitudes and practices regarding middle age (e.g., menopause) are addressed here.

The Aged. Status and treatment of the aged. Discussion of the major medical problems of this age group.

Dying and Death. Treatment of the dying, concepts about death, reactions to it, and treatment of the body. Risks to surviving spouses, if related to cultural practice (e.g., required suicide).

Changing Health Patterns (optional)

If changes over time have not been described in previous sections, this is where they will be described.

References

References to sources in the text are included to allow the reader to explore topics and cultures further.

USING THE *ENCYCLOPEDIA OF MEDICAL ANTHROPOLOGY*

This reference work can be used by a variety of people for a variety of purposes. It can be used both to gain a general understanding of medical anthropology and to find out about particular cultures and topics. A bibliography is provided at the end of each entry to facilitate further investigation.

Beyond serving as a basic reference resource, the *Encyclopedia of Medical Anthropology* also serves readers with more focused needs. For researchers interested in comparing cultures, this work provides information that can guide the selection of particular cultures for further study. For those interested in international studies, the bibliographies in each entry can lead one quickly to the relevant social science literature as well as provide a state-of-the-art assessment of knowledge about medical cultures around the world. For curriculum developers and teachers seeking to internationalize the curriculum, this work is a basic reference and educational resource as well as a directory to other materials. For government officials, it is a repository of information not likely to be available in any other single publication; in many cases, the information provided here is not available at all elsewhere. For students, from high school through graduate school, it provides background and bibliographic information for term papers and class projects. And for travelers, it provides an introduction to the medical cultures of places they may be visiting.

ACKNOWLEDGMENTS

There are many people to thank for their contributions. Eliot Werner, formerly at Plenum, played an important role in the planning of the project. The Advisory Board made valuable suggestions about the outline for the culture entries and possible topics to be covered in the thematic essays, and suggested potential authors. The editors were responsible for the final selections of authors and for reviewing the manuscripts. For managing the project at HRAF, we are indebted to Jo-Ann Teadtke. We thank Teresa Krauss for overseeing the production process at Kluwer/Plenum and Tracy van Staaldin for her efficient handling of the production of this Encyclopedia. Finally, and most of all, we thank the contributors for their entries. Without their knowledge and commitment, this work would not have been possible.

Glossary

- abortifacient.** Any drug or compound that induces the expulsion of an embryo or fetus.
- abortion.** A spontaneous (usually called miscarriage) or induced expulsion of an embryo or fetus.
- acculturation.** The process of extensive borrowing of aspects of culture in the context of superordinate-subordinate relations between societies; usually occurs as the result of external pressure.
- acupuncture.** A Chinese medical technique that consists of the insertion of one or several small metal needles into the skin and underlying tissues at precise points on the body.
- adaptation.** Refers to genetic changes that allow an organism to survive and reproduce in a specific environment.
- adaptive.** A trait that enhances survival and reproductive success in a particular environment. Usually applied to biological evolution, the term is also often used by cultural anthropologists to refer to cultural traits that enhance reproductive success.
- affinal kin.** One's relatives by marriage.
- agency.** Having the capacity or authority to act; also can refer to an establishment or organization that can act for another or can carry out a function.
- agricultural societies.** Societies that depend primarily on domesticated plants for subsistence; see Horticulture and Intensive Agriculture for the major type of agriculture.
- agropastoralism.** A type of subsistence economy based largely on agriculture with the raising of domesticated animals playing an important part.
- AIDS (Acquired Immune Deficiency Syndrome).** A recent fatal disease caused by the HIV virus. A positive HIV (see HIV) test result does not mean that a person has AIDS. A diagnosis of AIDS is made using certain clinical criteria (e.g., AIDS indicator illnesses such as *Pneumocystis carinii* pneumonia, malignancies such as Kaposi's sarcoma and lymphoma).
- albinism.** A hereditary condition where melanin and other pigments are absent; such pigments normally provide protection against ultraviolet radiation from the sun.
- alcoholism.** A disorder characterized by an individual's excessive consumption of alcoholic beverages that is causing harm to the individual and/or to others.
- alimentary.** Having to do with nutrition; in humans, the beginning of the digestive process begins in the mouth and proceeds through the alimentary canal or tract through connected organs (esophagus, stomach, small and large intestines; waste products are excreted through the end of the canal at the anus).
- allele.** One member of a pair of genes.
- allopathic medicine.** An alternative word for biomedicine. The term "allopathic" designates the biomedical tradition of working "against pathology," wherein the treatment is meant to oppose or attack the disease as directly as possible. Contrast with **homeopathic medicine**.
- altered states of consciousness (trance).** A range of states that generally share properties of inducing a slow wave pattern (alpha and theta) in the brain. This slow wave pattern reflects enhanced activation of lower brain structures, particularly the paleomammalian (or limbic) brain. ASC are found universally and are institutionalized in most societies in religion and healing rituals. ASC are induced through many ritual activities, such as drumming, dancing, fasting, arduous activities, and drugs. ASC provide access to basic structures of consciousness and unconscious complexes or structures that are generally interpreted as spiritual entities.
- Alzheimer's disease.** A disability characterized by memory loss that affects the middle-aged and elderly. Manifests in the fifth or later decades of life. Only 5–10% of Alzheimer's cases are inherited. Brain tissue contains unusual amounts of two gummy proteins, the beta- and tau-amyloids.
- ambilineal Descent.** The rule of descent that affiliates an individual with groups of kin related to him or her through men or women.

- amniocentesis.** A surgical procedure inserting a hollow needle through the abdominal wall to extract a sample of amniotic fluid from the amniotic sac of the uterus of a pregnant woman for the purpose of diagnosing genetic defects in the fetus.
- amok.** see **amuk.**
- amuk (amuck).** A temporary state of physically aggressive insanity relatively common in Malay populations. In a suicidal attack, the amuk person attempts to maim or kill virtually everyone present. Often thought of as a culture-bound syndrome.
- amulet.** A charm (often an ornament) believed to have powers to help the possessor or ward off evil.
- ancestor spirits.** Supernatural beings who are the ghosts of dead relatives.
- androgynous.** Refers to having both male and female characteristics or suitable for either sex, or having traditional female and male roles eliminated or reversed.
- ancestor worship.** Veneration or reverence of ancestor spirits; ancestor spirits may be called upon for help or may be given sacrifices to have them refrain from harming the living.
- Angelman syndrome.** Uncommon condition characterized by seizures, mental impairment and growth retardation, protruding tongue, floppy muscle tone, large jaw, an inability to talk, and excessive and inappropriate laughter. AS is caused by a small deletion in chromosome 15, inherited maternally.
- anemia.** A condition of too few red blood cells in the bloodstream which results in not enough oxygen to the tissues and organs of the body.
- animism.** A term used by Edward Tylor to describe a belief in a dual existence for all things—a physical, visible body and a psychic, invisible soul.
- anthropology.** A discipline that studies humans, focusing on the study of differences and similarities, both biological and cultural, in human populations. Anthropology is concerned with typical biological and cultural characteristics of human populations in all periods and in all parts of the world.
- anthropology of food.** Focuses on the cultural and social significance of food and eating. Food is studied as a way of understanding social and cultural processes and to reveal symbolic structures.
- anthropometrics.** The systematic collection and correlation of measurements relating to the human body.
- antimicrobial.** A drug for killing or suppressing the growth or proliferation of microorganisms.
- anticipation.** A phenomenon whereby a genetic disorder becomes increasingly severe from one generation to the next (the age of onset usually gets lower, as well).
- antiseptics.** Processes, procedures, or treatments for killing microorganisms.
- applied anthropology.** The branch of anthropology that concerns itself with applying anthropological knowledge to achieve practical goals, usually in the service of an agency outside the traditional academic setting. Also called **practicing anthropology.**
- association.** An organized group not based exclusively on kinship or territory.
- atherosclerosis.** Progressive narrowing and hardening of the blood vessels over time.
- asthma.** Disorder of airways and lungs characterized by reversible inflammatory obstruction, breathing difficulties, wheezing, and hypersensitivity.
- autosomal recessive inheritance.** The key feature of the recessive mode is that a new mutation does not result in a new phenotype, so that only two phenotypes exist, one containing at least one dominant allele, and the other containing two copies of the recessive allele. An autosomal chromosome is a non-sex chromosome.
- avunculocal residence.** A pattern of residence in which a married couple settles with or near the husband's mother's brother.
- Ayurveda.** A medical system whose practice (in North India, Pakistan, Bangladesh, Sri Lanka, and the Arab world) dates back thousands of years; Ayurveda emphasizes the concept of balance. There are three important biological modes and people are believed to differ in their natures as to the importance of various modes in their systems. Professionally trained Ayurvedic practitioners assess a patient's nature and try to correct imbalances primarily through diet. Different treatments are given to different patients depending upon their natures.
- balanced reciprocity.** Giving with the expectation of a straightforward immediate or limited-time trade.
- band.** A fairly small, usually nomadic local group that is politically autonomous.

- barrio.** A neighborhood in a city; used in Spanish-speaking countries.
- behavioral ecology.** The study of how all kinds of behavior may be related to the environment. The theoretical orientation involves the application of biological evolutionary principles to the behavior (including social behavior) of animals, including humans. Also called sociobiology, particularly when applied to social organization and social behavior.
- berdache.** A male transvestite in some Native American societies.
- beriberi.** A nutritional disorder due to a deficiency of vitamin B1 (thiamin) which impairs the nerves and the heart.
- bilateral kinship.** The type of kinship system in which individuals affiliate more or less equally with their mother's and father's relatives; descent groups are absent.
- bilingual.** Using or knowing two languages.
- bilocal residence.** A pattern of residence in which a married couple lives with or near either the husband's parents or the wife's parents.
- biocultural anthropology.** A field whose central interest is the evolution of successful reproductive traits and strategies in humans and nonhuman primates in the context of their physical and social environments. Considers the importance of both biological and cultural factors.
- bioethics.** Pertains to the ethical dilemmas and moral norms of health professionals (primarily physicians) emerging within contemporary biomedicine.
- biological (physical) anthropology.** The study of humans as biological organisms, dealing with the emergence and evolution of humans and with contemporary biological variations among human populations.
- biomedicine.** The dominant medical paradigm in Western countries today with the *bio* part emphasizing the biological emphasis of this professional medical system, particularly the focus on specific diseases and cures for those diseases. Diseases are considered as having natural causes (e.g., germs) and there is relatively little emphasis placed on the person in the larger social and cultural system.
- biopower.** The insight that control over health can be achieved by getting populations and individuals to internalize certain disciplinary procedures, which then do not have to be imposed from without.
- brachycephaly.** A disproportionate shortness of the head.
- brain death.** Irreversible and permanent cessation of function of the entire brain.
- brain stem.** Older, more "primitive" part of the lower central mammalian brain responsible for organizing fundamental emotions related to fear, hunger, sex, protective devices and temperature control, emotionality, arousal, sleep, heart and breathing rates, water retention, pressure and volume as well as possibly the ratio of carbon dioxide to oxygen.
- bride price.** A substantial gift of goods or money given to the bride's kin by the groom or his kin at or before the marriage. Also called **bride wealth**.
- bridewealth (or bride wealth).** See **bride price**.
- cancer.** Group of more than 100 diseases that are characterized by the uncontrolled abnormal growth of cells.
- cardiovascular diseases.** Any of the diseases of the heart and blood vessels.
- cargo cult.** Religious movement in which there is preparation for an expectation of a future state of happiness brought about by the arrival of large amounts of material goods (cargo).
- carrying capacity.** The maximum population size that can be supported in a particular environment; to calculate the carrying capacity assumptions have to be made about the subsistence patterns and technology of a group of people.
- cash crops.** Crops grown primarily for sale.
- caste.** A ranked group, often associated with a certain occupation, in which membership is determined at birth and marriage is restricted to members of one's own caste.
- catharsis.** Gaining relief from emotional tension by venting feelings.
- cathartic method.** In psychoanalysis, refers to Freud's method of treatment in which patients were relieved from the tension of their emotional conflicts by recalling, putting into words and reexperiencing the affect associated with early traumatic memories.
- cerebral palsy.** Refers to a number of neurological disorders caused by damage to the brain early in life that affect motor control (symptoms are paralysis and spasms).

- cerebrovascular disease.** Narrowing or hardening of the blood vessels of the brain.
- Chagas' disease.** Causes damage to the heart and other organs, and often goes undetected until midlife, when damage to the heart and colon can cause fatal complications. The infection from the protozoan *Trypanosoma cruzi* is transmitted to humans by bloodsucking *reduviid*.
- chief.** A person who exercises authority, usually on behalf of a multicomunity political unit. This role is generally found in rank societies and is usually permanent and often hereditary.
- chiefdom.** A political unit, with a chief at its head, integrating more than one community but not necessarily the whole society or language group.
- Chinese medical system (or Han medicine).** A professional medical system originating thousands of years ago that emphasizes harmony and balance between humans and nature and between the systems of the body. Disease is defined in terms of imbalance which must be restored. The medical system is holistic in that in diagnosis and treatment everything about the patient must be considered; treatments are individualized.
- chiropractic.** A healing system based on the theory that diseases often result from a lack of normal nerve function. Chiropractic treatments include manipulation and specific adjustment of body structures, such as the spine, as well as physical therapy.
- cholera.** An acute intestinal infection with a short incubation period that produces an enterotoxin causing copious amounts of watery diarrhea. It is caused by the practically invisible bacterium *Vibrio cholerae*. Cholera can quickly result in severe dehydration and death if left untreated.
- chromosomes.** Paired rod-shaped structures within a cell nucleus containing the genes that transmit traits from one generation to the next.
- chronic obstructive pulmonary disease.** A progressive disease commonly resulting from smoking; characterized by breathing difficulty, wheezing, and chronic cough.
- circumcision.** Male circumcision refers to a genital operation in which the fold of the skin covering the top of the penis is removed; in female circumcision the fold covering the clitoris, or all or part of the clitoris, or parts of the labia may be removed.
- cirrhosis.** A result of chronic liver disease in which scar tissue replaces normal, healthy tissue, thus blocking the flow of blood through the organ and preventing it from working as it should.
- clan.** A set of kin whose members believe themselves to be descended from a common ancestor or ancestress but cannot specify the links back to that founder; often designated by a totem. Also called a **sib**.
- clan exogamy.** A rule specifying that a person must marry outside his/her clan.
- class.** A category of persons who have about the same opportunity to obtain economic resources, power, and prestige.
- classificatory terms.** Kinship terms that merge or equate relatives who are genealogically distinct from one another; the same term is used for a number of different kin.
- class society.** A society containing social groups that have unequal access to economic resources, power, and prestige.
- cline.** The gradually increasing or decreasing frequency of a gene from one end of a region to another.
- clinical depression.** A more intense and long-lasting depression (e.g., for more than two weeks). There are usually a number of physical symptoms, which can include problems in sleeping, a loss of or great increase in appetite, and frequent fatigue or lack of energy.
- clitoridectomy.** See circumcision.
- chlamydia.** A sexually transmitted bacterial infection caused by *Chlamydia trachomatis*.
- cluster analysis.** Groups items together at increasing degrees of similarity in responses.
- complete dominance.** The key feature of the dominant mode is that a new mutation results immediately in a new phenotype in the heterozygote. In many cases, the subsequent homozygote is inviable.
- colonialism.** The control by one nation of a territory or people; the controlled territory may be referred to as a colony.
- colostrum.** A substance secreted from the breasts of human females for the first two or three days following birth. Although colostrum is not nutrient dense, it provides antibodies and other properties that enhance infant health during a particularly vulnerable period after birth.

co-parent. See **compadrazgo**.

co-sleeping. Refers to a diverse class of human-wide sleeping arrangements (e.g., mother-infant, husband-wife-children) wherein at least two or more persons sleep within proximity to permit each to detect, monitor, and exchange sensory stimuli.

commercialization. The increasing dependence on buying and selling, with money usually as the medium of exchange.

commodification. Turning something into a commodity that can be bought or sold.

compadrazgo. A fictive kinship relationship established primarily through baptism in which a child's sponsor becomes a "co-parent" and establishes a relationship with the child's parents as well as with the child.

concubinage. The custom of a socially recognized nonmarital sexual relationship between a man and a woman (concubine) who has lower status than the wife.

congenital. Referring to conditions that are present at birth (and that usually existed before birth).

consanguineal kin. One's biological relatives; relatives by birth.

contraceptives. Any of a class of methods or substances used to prevent conception.

cosmopolitan medicine. See **biomedicine**.

couvade. The classic couvade is when a man appears to experience labor during his wife's pregnancy; in milder forms a man may avoid certain types of work or rest during the pregnancy or labor.

Creole language. A language that develops under conditions where there are many different linguistic speakers needing to communicate. The most common cases are where colonial powers established commercial enterprises that relied on imported, often slave, labor. First a pidgin develops, which is usually a simplified version of the master's language, lacking many important elements of language. Creoles develop out of pidgins and are complex languages with distinct grammars different from the original languages.

crime. Violence not considered legitimate that occurs within a political unit.

cross-cousins. Children of siblings of the opposite sex. One's cross-cousins are father's sisters' children and mother's brothers' children.

critical medical anthropology. The perspective that emphasizes that social and political factors (e.g., poverty, social inequality, discrimination, structural violence, toxic work environments) are important elements in understanding and treating health and disease.

cross-sex identification. The psychological identification with the opposite sex (e.g., a boy who wishes to be like his mother).

cultural anthropology. The study of cultural variation and universals.

cultural competency. The expectation that medical professionals and bioethicists will understand and consider the cultural values and beliefs of all involved parties.

cultural ecology. The analysis of the relationship between a culture and its environment.

cultural relativism. The attitude that a society's customs and ideas should be viewed within the context of that society's problems and opportunities.

culture. The set of learned behaviors, beliefs, attitudes, values, and ideals that are characteristic of a particular society or population.

culture bound syndrome. A phrase used to describe behavioral syndromes unknown to mainstream psychiatry and denominated only by terms in local languages. There is considerable debate about whether such syndromes (e.g., *amuk* or *amok*, *latah*, "nerves") are that culture bound, suggesting that they may be somewhat different manifestations of more known illnesses.

cultural consensus analysis. Refers to both a theory and a mathematical model for estimating how much of a given domain of culture each individual informant 'knows' as well as estimating the 'correct' cultural response to each question that can be asked about the particular domain of culture under consideration.

cupping. A procedure that draws blood to the surface of the body by using a glass vessel evacuated by heat.

Darwinian medicine. The search for evolutionary explanations of vulnerabilities to disease. Also called **evolutionary medicine**.

- death.** Concepts vary across cultures and relate to how a culture defines the end of an individual's personhood; such concepts have varied over time and may even vary within cultures. (In the U.S. laws regarding definitions of death are established by individual states which define death as an event marked by the cessation of either respiratory, cardiac, or brain functioning.)
- demographic transition.** See **epidemiological transition.**
- demography.** The study of human populations, mostly using methods of quantitative analysis. Demographers may study such characteristics as the age-composition of populations, fertility, fecundity, and mortality.
- dengue fever.** Like malaria, dengue causes fever, headache and chills, as well as body pain and skin rash. Unlike malaria it is not recurrent, although persons who have had dengue are at elevated risk for the more serious forms of dengue hemorrhagic fever and dengue toxic shock syndrome.
- dependency theory.** Views "underdeveloped" or "developing" nations which have not yet had substantial economic growth as being the integral result of the processes by which other nations became "developed;" in other words, relations of dependency arose because of colonial, usually Western, powers.
- depression.** A mood state including feelings of sadness, hopelessness, and other negative feelings. Short-lived depression is normal. See **clinical depression.**
- descriptive term.** Kinship term used to refer to a genealogically distinct relative; a different term is used for each relative.
- descent rules.** See **rules of descent.**
- diabetes mellitus.** A group of metabolic diseases characterized by high blood sugar or hyperglycemia. A form of diabetes with onset in childhood is often called Type 1 diabetes; genetic factors play a major role and insulin deficiency is almost total. Type 2 or adult-onset diabetes is related to obesity.
- dialect.** A variety of a language spoken in a particular area or by a particular social group.
- diarrheal.** Disease characterized by a high number and frequent bowel movements with watery stool.
- disability.** From a relativist perspective, impairment-disability is a mapping of what a particular culture or subculture perceives as anomalous physical or behavioral differences. A more "etic" definition from the World Health Organization defines disabilities as "any restriction or lack resulting from an impairment of ability to perform an activity in the manner or within the range considered normal for a human being."
- disease.** A biomedically measurable lesion or anatomical or physiological irregularity. Compare with **illness.**
- divination.** Getting the supernatural to provide guidance, usually through the use of magic.
- diviners.** Practitioners of divination.
- division of labor.** Rules and customary patterns specifying which kinds of work different kinds of people (e.g., by age, gender, caste) perform.
- DNA.** Deoxyribonucleic acid; a long two-stranded molecule in the genes that directs the makeup of an organism according to the instructions in its genetic code.
- dolichocephaly.** Having a disproportionately long head.
- domestic violence.** Physical aggression, often repetitive, by one or more members of the household against another member or members.
- dominant.** The allele of a gene pair that is always phenotypically expressed in the heterozygous form.
- Down's syndrome.** A congenital disorder caused by an extra chromosome on the chromosome 21 pair. Often associated with congenital heart defects, mental retardation; individuals usually have a broad, short skull, broad fingers with short digits and up-slanted eyes.
- double descent.** A system that affiliates an individual with a group of matrilineal kin for some purposes and with a group of patrilineal kin for other purposes. Also called **double unilineal descent.**
- dowry.** A substantial transfer of goods or money from the bride's family to the bride.
- drug.** Generally is a substance that affects the functioning of living things; with regard to medicine it refers to any substance used as a medicine; in lay parlance drugs are often thought of as substances (sometimes illegal) that

lead to addiction or altered states of consciousness. Although drugs are usually thought of as not foods, certain foods (drug foods) can have pharmacological properties.

dysentery. Any of a number of disorders that involves inflammation of the intestines, often accompanied by pain in the abdomen and frequent bowel movements.

ecology. The field of study concerned with the inter-relationships between organisms and their environments which together constitute the ecosystem.

ecosystems. All the interrelationships between the organisms and the physical environment in a particular geographical space.

egalitarian society. A society in which all persons of a given age-sex category have equal access to economic resources, power, and prestige.

ego. In the reckoning of kinship, the reference point or focal person.

emetic. A substance that causes vomiting.

emic. From the perspective of the insider; often referring to the point of view of the society studied; contrast with **etic**.

enculturation. See **socialization**.

endemic disease. A disease that has been prevalent in an area over long periods of time.

endogamy. The rule specifying marriage to a person within one's own group (kin, caste, community).

enteric. Relates to the intestines.

endocannibalism. Cannibalism practiced with deceased members of one's own group.

epidemic disease. A disease that currently has very high prevalence. (Implies large fluctuation over time.) Compare with **endemic disease**.

epidemiological transition. Can refer to a number of demographic transitions (such as when humans became food producers) but usually refers to the more recent transition which includes lowering of infant mortality, longer birth spacing, and the lengthening of life expectancy in recent times. Also called **demographic transition**.

epidemiology. Involves the use of population-based statistical methods of data collection and analysis to elucidate and predict the patterns of development and distribution (including associated causal factors) and potential control of disease across and within populations.

epilepsy. A chronic neurological disorder that is characterized by sudden and recurrent seizures and convulsions due to disturbance of the electrical activity in the brain.

episiotomy. A surgical incision of the vagina to widen the birth outlet.

ethnicity. The process of defining ethnicity usually involves a group of people emphasizing common origins and language, shared history, and selected aspects of cultural difference such as a difference in religion. Since different groups are doing the perceiving, ethnic identities often vary with whether one is inside or outside the group.

ethnic group. A social group perceived by insiders or outsiders to share a culture or a group that emphasizes its cultural or social separateness.

ethnocentric. Refers to judgment of other cultures solely in terms of one's own culture.

ethnocentrism. The attitude that other societies' customs and ideas can be judged in the context of one's own culture.

ethnographer. A person who spends some time living with, interviewing, and observing a group of people so that he or she can describe their customs.

ethnography. A description of a society's customary behaviors, beliefs, and attitudes.

ethnology. The study of how and why recent cultures differ and are similar.

ethnomedicine. The health-related beliefs, knowledge, and practices of a cultural group.

evil eye. The belief prevalent in many cultures that a person can cause harm to another by a look. To ward off the evil eye, many people try not to make the person suspected of having the evil eye jealous.

ethnonym. An alternative name for a culture or ethnic group.

ethnopharmacology. The system of knowledge of medicines (their preparation, uses, and therapeutic effects) in a cultural system.

- ethnopharmacopoeia.** The medicines (often plant-based) and their known effects (therapeutic effects, appropriate situations for use, etc.) of a culture.
- ethnophysiology.** The systems of knowledge in a culture relating to how organisms function.
- ethos.** The dominant assumptions or sentiments of a culture.
- etic.** From the perspective of the outsider; often refers to the way a researcher will classify something in the culture studied based on her or his own scholarly perspective; allows comparison since etic categories are presumably applicable to all cultures.
- etiology.** The causes of a disease or illness.
- eugenics.** The belief or practice that seeks to improve a human population by discouraging or forcing those with perceived undesirable heritable traits to reproduce less or not at all (negative eugenics) and/or by encouraging or forcing those with perceived desirable heritable traits to reproduce more (positive eugenics).
- evolutionary medicine.** See **Darwinian medicine.**
- exogamy.** The rule specifying marriage to a person from outside one's own group (kin or community).
- exorcist.** A person who expels spirits (usually demons) from possessed people.
- explanation.** An answer to a why question. In science, there are two kinds of explanation that researchers try to achieve: associations and theories.
- extended family.** A family consisting of two or more single-parent, monogamous, polygynous, or polyandrous families linked by a blood tie.
- extensive cultivation.** A type of horticulture in which the land is worked for short periods and then left to regenerate for some years before being used again. Also called **shifting cultivation.**
- family.** A social and economic unit consisting minimally of a parent and a child.
- fecundity.** The biological capacity to have offspring; fecundity varies by individual and also by population. May be affected by breastfeeding, caloric intake, strenuous exercise, among other factors.
- filariasis.** A disease caused by a parasitic nematode worm that blocks the lymphatic system resulting in the swelling and thickening of the skin and tissues below the skin, particularly the leg, arm, or genitals.
- female genital cutting (female genital mutilation).** Usually refers to a societally mandated genital operation that removes some part of the female genitalia or alters the genitalia. See **circumcision** and **infibulation.**
- fertility rate.** Provides an indication, usually for comparative purposes, of the number of live births per standard unit of population; the total fertility rate is the average total number of live births a woman in a particular population is expected to have within her reproductive years.
- feuding.** A state of recurring hostility between families or groups of kin, usually motivated by a desire to avenge an offense against a member of the group.
- fieldwork.** Firsthand experience with the people being studied and the usual means by which anthropological information is obtained. Regardless of other methods (e.g., censuses, surveys) that anthropologists may use, fieldwork usually involves participant-observation for an extended period of time, often a year or more. See **participant-observation.**
- folklore.** Includes all the myths, legends, folktales, ballads, riddles, proverbs, and superstitions of a cultural group. Generally, folklore is transmitted orally, but it may also be written.
- food collection.** All forms of subsistence technology in which food-getting is dependent on naturally occurring resources—wild plants and animals.
- food production.** The form of subsistence technology in which food-getting is dependent on the cultivation and domestication of plants and animals.
- foragers.** People who subsist on the collection of naturally occurring plants and animals. Also referred to as **hunter-gatherers.**
- forensic anthropology.** The use of anthropology to help solve crimes.
- fossils.** The hardened remains or impressions of plants and animals that lived in the past.
- founder effect.** A variety of genetic drift that occurs when a small group migrates to a relatively isolated location. A gene that is either present or absent in that small group by chance is likely to become characteristic of the future population.

- fraternal polyandry.** The marriage of a woman to two or more brothers at the same time.
- G6PD deficiency.** A red blood cell deficiency that can result in acute hemolytic crisis, often provoked by eating fava beans.
- gastrointestinal diseases.** Any disease involving the stomach and/or intestines.
- gender.** Two or more classes of persons who are believed to be different from each other; society has different roles and expectations for different genders (most societies have two genders—male and female—but others have more than two).
- gender differences.** Differences between females and males that reflect cultural expectations and experiences.
- gender division of labor.** Rules and customary patterns specifying which kinds of work the respective genders perform.
- gender roles.** Roles that are culturally assigned to genders.
- gender status.** The importance, rights, power, and authority of a particular gender.
- gender stratification.** The degree of unequal access by the different genders to prestige, authority, power, rights, and economic resources.
- gene.** Chemical unit of heredity.
- genetic disease.** Any condition caused or influenced by a malfunctioning gene or cytogenetic (chromosome) error that affects an organism's capacity for adaptation. Excepting lethal defects and sterility, genetic diseases display certain familial modes of inheritance and exhibit morbidity and mortality patterns that may compromise direct fitness.
- genetic isolate.** A population that hardly ever interbreeds with others; usually has distinctive genetic features.
- genetics.** The study of heredity and genes.
- genitor.** The biological father.
- genome.** The total set of genes carried by an individual or cell.
- genomic imprinting.** Also known as parental imprinting in which the expression of genes depends on whether the chromosome of concern is maternal or paternal in origin.
- genotype.** The total complement of inherited traits or genes of an organism.
- gestational diabetes.** A form of diabetes that occurs in pregnancy and is usually temporary.
- geophagy.** The practice of eating earth (e.g., clay).
- ghosts.** Supernatural beings who were once human; the souls of dead people.
- globalization.** The massive flow of goods, people, information and capital across huge areas of the earth's surface.
- gods.** Supernatural beings of nonhuman origin who are named personalities; often anthropomorphic.
- goiter.** Enlargement of the thyroid gland.
- gonorrhea.** A mostly sexually transmitted disease caused by the bacterium *Neisseria gonorrhoeae*; it is marked by pain in the male urethra.
- Greek medical system.** A professional medical system that originated in Greece and spread throughout Europe and to parts of the Islamic world. Stemmed from Hippocrates and assumed that there were four "humors" (blood, yellow and black bile, and phlegm) that must be kept in balance. These humors have hot and cold and wet and dry properties.
- group marriage.** Marriage in which more than one man is married to more than one woman at the same time; not customary in any known human society.
- group selection.** Natural selection of group characteristics.
- guardian spirit.** A supernatural spirit that guides a person in important activities or decisions; the spirit may come to a person in a dream or the person may undertake a vision quest to find his or her guardian spirit.
- hallucination.** A perception of objects or events that does not come from an external source.
- headman.** A person who holds a powerless but symbolically unifying position in a community within an egalitarian society; may exercise influence but has no power to impose sanctions.
- healing.** A complex process that starts with a patient's experience of something being wrong and proceeds to some form of diagnosis and then possibly treatment. Cultural ideas and practices are fundamental in the healing process and societies vary enormously in the ways that the healing process proceeds.

- health.** A broad construct, consisting of physical, psychological, and social well being, including role functionality.
- hegemony.** The political and economic dominance one entity or group (e.g., state, nation, ruling class) has over others.
- hemoglobin.** A complex oxygen-carrying protein in red blood cells.
- hepatitis.** Inflammation of the liver. An infectious or viral form of hepatitis can be spread through contact. Symptoms are similar to influenza.
- herbalist.** A specialist skilled in the knowledge of medicinal plants.
- hermeneutics.** In contemporary anthropology involves the study of symbol systems to try to understand how people construct and interpret reality; emphasizes the subjective nature of the ethnographic enterprise.
- hernia.** The protrusion of tissue or organ through an abnormal opening.
- heterozygous.** If the two genes, or alleles, for a trait differ, the organism is heterozygous for that trait.
- historical archaeology.** A specialty within archaeology that studies the material remains of recent peoples who left written records.
- HIV.** Human immunodeficiency virus believed to cause AIDS. HIV destroys or impairs cells of the immune system, notably CD4+ T cells. HIV infection is usually acquired through sexual contact with an infected partner and also by contaminated injection equipment. Persons with HIV may not show any clinical symptoms for a long time and may not know they are infected. See **AIDS**.
- homeopathic medicine.** “Homeopathic” derives from the Greek *homoios*—“similar or like treatment” and *pathos* (suffering, disease). In this model, medicines produce symptoms similar to the illnesses that they are intended to treat.
- Homo sapiens.*** All living people belong to one biological species, *Homo sapiens*, which means that all human populations on earth can successfully interbreed. The first *Homo sapiens* may have emerged 100,000 years ago.
- homosexuality.** Defined broadly as sexual relationships between people of the same sex; however, cultures differ widely in the ways they define and treat these relationships and the people who engage in them.
- homozygous.** If two genes or alleles for a trait are the same, the organism is homozygous for that trait.
- hookworm.** An intestinal infection commonly caused by the parasite *Necator americanus*; can cause diarrhea, anemia and anorexia.
- horticulture.** Plant cultivation carried out with relatively simple tools and methods; nature is allowed to replace nutrients in the soil, in the absence of permanently cultivated fields.
- hot/cold health systems.** See **humoral medicine**.
- human paleontology.** See **paleoanthropology**.
- human genome project.** A worldwide project to determine the DNA sequences in all human DNA.
- human variation.** The study of how and why contemporary human populations vary biologically.
- humoral medicine.** A variety of medical systems based on the belief that a balanced state assures health, while an excess or deficiency yields illness. The balance needs to be maintained between various humors (see **humors**) and/or between elements such as “heat” and “cold.” Deducing the etiology of an illness points the way to appropriate therapy through the application of the “principle of opposites:” for example, illness caused by cold is treated with hot therapies, and vice versa.
- humors (humours).** One of a number of vital elements in the body (usually fluids). The various humoral medical systems had different numbers of basic humors.
- hunter-gatherers.** People who collect food from naturally occurring resources, that is, wild plants, animals, and fish. The phrase “hunter-gatherers” minimizes sometimes heavy dependence on fishing. Also referred to as **foragers**.
- hydropathy.** The treatment of diseases with the copious and frequent use of pure water.
- hypotheses.** Predictions, which may be derived from theories, about how variables are related.
- hypercholesterolemia.** One of the genetic forms of coronary heart disease that manifests in the 4th or 5th decade of life. Genetically deficient low-density lipoprotein (LDL) protein receptors (LDLRs) in the liver cause LDL cholesterol to accumulate in the blood, resulting in high blood cholesterol, atherosclerosis and heart disease.
- hyperglycemia.** Too high a level of glucose in the blood.
- hypoglycemia.** An abnormally diminished concentration of glucose in the blood.

- hypertension.** Persistent high blood pressure (the force that the blood moving through the arteries exerts on the arterial walls).
- hypertriglyceridemia.** Elevation of triglycerides in the bloodstream.
- hypoxia.** A condition of oxygen deficiency that often occurs at high altitudes.
- hysteria.** A condition (often considered a neurosis) marked by excitability and other emotional outbursts with disturbances of sensory and motor functions.
- iatrogenic.** Introduced inadvertently by medical treatment or medical procedures.
- illness.** The culturally structured, personal experience of being unwell which entails the experience of suffering. "Illness" can refer to a variety of conditions cross-culturally. In some cultures, it is limited to somatic experiences; in others it includes mental dysfunction; in others it includes suffering due to misfortune, too.
- immunization.** The process by which disease resistance is acquired. It may occur in an organism naturally when the organism produces its own antibodies in response to a pathogen or it may occur artificially with a vaccine.
- incest taboo.** Prohibition of sexual intercourse or marriage between mother and son, father and daughter, and brother and sister. May be extended to other relatives.
- incidence.** Most commonly a ratio of new cases of a disease or condition for a standard population size (e.g., per 100,000 in a given year) in a particular population. Compare with Prevalence.
- incomplete dominance ("co-dominance").** The key features of this dominant mode are that a new mutation results in a new phenotype in the heterozygote, and its phenotype is intermediate between the two homozygotes. A familiar human example is the wavy-haired heterozygous offspring of straight- and curly-haired homozygous parents. The A and B alleles in the ABO blood groups interact in a codominant fashion.
- individual selection.** Natural selection of individual characteristics.
- infant mortality.** See **mortality**.
- infanticide.** The practice of killing newborn babies; in many cultures it is not considered a crime and is generally practiced when the parents say that they do not have the resources to rear the baby.
- infectious disease.** Any of a number of diseases that results from a microorganism.
- infibulation.** Female genital surgery that involves stitching together the vulva leaving only a small opening for the passage of urine and menstrual blood. Usually done following circumcision. See **circumcision**.
- influenza (flu).** An acute viral infection involving the respiratory tract. It is also characterized by headache, aches, and fever.
- initiation ceremony (or rite).** A ceremony which marks the passage of an individual from one status to another. Male initiation ceremonies are often required of all boys in a society and mark the transition from boyhood to manhood. In societies with age-sets, initiation ceremonies may mark a series of transitions to different stages of life. Male initiation ceremonies often involve trauma such as hazing, genital operations, or tests of manliness. Female initiation ceremonies, which commonly occur after the onset of menstruation, are usually for one individual at a time.
- intensive agriculture.** Food production characterized by the permanent cultivation of fields and made possible by the use of the plow, draft animals or machines, fertilizers, irrigation, water-storage techniques, and other complex agricultural techniques.
- in vitro fertilization.** Fertilization that occurs in a laboratory.
- IQ.** An abbreviation for intelligence quotient. An intelligence quotient is a numerical measure based on a standardized test designed to measure intelligence. Among the many criticisms of IQ tests are that they are generally culture bound and therefore not good measures of intelligence for people of cultures and subcultures other than for which the test was designed.
- IUD.** Abbreviation for intra-uterine device. A contraceptive that is placed within the uterus for the purpose of preventing conception.
- jaundice.** Yellowing of the skin and eyes by bilirubin, a bile pigment, often because of a liver problem. Neonatal jaundice sometimes occurs in newborns.
- joint family.** A type of extended family with at least two married siblings in the same generation; can also contain parents.

- karma.** The doctrine that life is but one in a chain of lives and that it is determined by actions in a previous life. Past acts in previous lives can influence not only the future life but also the time in between lives.
- kindred.** A bilateral set of close relatives.
- kula ring.** A ceremonial exchange of valued shell ornaments in the Trobriand Islands, in which white shell arm-bands are traded around the islands in a counterclockwise direction and red shell necklaces are traded clockwise.
- kuru.** A chronic, progressive, uniformly fatal transmissible neurodegenerative disease now known to be caused by a prion. It is named from the Fore word meaning to shiver, shake, or tremble.
- kwashiorkor.** An extreme form of protein-energy malnutrition.
- language family.** A group of related languages that are presumed to descend from the same ancestral language.
- latah.** An emotional disorder fairly common, especially among low ranking women, in Malay populations. The affected person seems to satirize traditional manners and to mimic the words and gestures of others with whom they are interacting.
- leprosy.** A disease caused by the *Mycobacterium leprae*; it is characterized by lesions of the skin and superficial nerves. The extremities may become deformed and eroded.
- levirate.** A custom whereby a man is obliged to marry his brother's widow.
- libidinal.** Erotic in the broad sense defined by Freud, including pleasure.
- life expectancy.** The average number of years people might be expected to live in a particular population. It is based on the ages of death over a period of time. Populations with high infant mortality may have low life expectancies because of a large number of deaths at young ages; such populations might still have many people living to older ages.
- liminality.** Can refer to any transitional or in-between state, but usually refers to the transitional state in a rite of passage where an individual lacks status and prescribed codes of conduct.
- lineage.** A set of kin whose members trace descent from a common ancestor through known links.
- longhouse.** A multifamily dwelling with a rectilinear floorplan.
- maidenhood.** Refers to the customary period of time from the onset of puberty to marriage.
- mal de ojo.** See **evil eye**.
- magic.** The performance of certain rituals that are believed to compel the supernatural powers to act in particular ways.
- maladaptive customs.** Customs that diminish the chances of survival and reproduction in a particular environment. Usually applied to biological evolution, the term is often used by cultural anthropologists to refer to behavioral or cultural traits that are likely to disappear because they diminish reproductive success.
- malaria.** A set of diseases caused by various species of *Plasmodium* protozoans that are transmitted to humans from the bite of the *Anopheles* mosquito.
- malnutrition.** Deficient levels of intakes of specific nutrients.
- mana.** A supernatural, impersonal force that inhabits certain objects or people and is believed to confer success and/or strength.
- manumission.** The granting of freedom to a slave.
- market or commercial exchange.** Transactions in which the "prices" are subject to supply and demand, whether or not the transactions occur in a marketplace.
- marriage.** A socially approved sexual and economic union usually between a man and a woman that is presumed by both the couple and others to be more or less permanent, and that subsumes reciprocal rights and obligations between the two spouses and between spouses and their future children.
- matriarchy.** An old general term for the disproportionate holding of power or authority by females; since there are many domains of authority and power, anthropologists now generally identify more specific institutions or customs such as the presence of matrilineal descent, matrilineal residence, the proportion of leaders or heads of household that are female, inheritance by females, etc.
- matriclan.** A clan tracing descent through the female line.
- matrilateral.** Pertaining to the mother's side of the family, as in matrilateral cross-cousins or matrilateral parallel cousins.

- matrilineage.** A kin group whose members trace descent through known links in the female line from a common female ancestor.
- matrilineal descent.** The rule of descent that affiliates an individual with kin of both sexes related to him or her through women only.
- matrilocal residence.** A pattern of residence in which a married couple lives with or near the wife's parents. Often referred to as uxorilocal residence in the absence of matrilineal descent.
- measles.** An acute viral infection caused by a Morbillivirus in the paramyxovirus family. Later symptoms involve a red rash that spreads from the face.
- mediation.** The process by which a third party tries to bring about a settlement in the absence of formal authority to force a settlement.
- medical anthropology.** A branch of anthropology that studies all aspects of health-related phenomena (health, illness, and health care); considers cultural systems as well as the effects of local and worldwide social and political environments.
- medical ecology.** Studies health and disease in environmental context. Central to the model is the concept of ecosystem. See **ecosystem**.
- medical hegemony.** The process by which the assumptions, concepts, and values of ruling classes or powers come to permeate medical diagnosis and treatment.
- medicalization.** The process of making something "medical." In other words, the extension of biomedicine into non-biomedical realms (e.g., pregnancy, birth, menopause, exercising).
- medical pluralism.** In contrast to indigenous societies, which tend to exhibit a more-or-less coherent medical system, state or complex societies have an array of medical systems—a phenomenon generally referred to by medical anthropologists, as well as medical sociologists and medical geographers, as medical pluralism.
- medium.** Part-time religious practitioner who is asked to heal and divine while in a trance.
- meiosis.** The process by which reproductive cells are formed. In this process of division, the number of chromosomes in the newly formed cells is reduced by half, so that when fertilization occurs the resulting organism has the normal number of chromosomes appropriate to its species.
- menarche.** The onset of menstruation.
- menstrual seclusion.** A mandated time that women must avoid all or some others (e.g., men) during their menstruation. Seclusion is often in a special menstrual hut or house.
- menstrual taboos.** Proscriptions about what women may or may not do during menstruation (e.g., must stay in a menstrual hut or avoid cooking for others); rules may also apply to men (e.g., they may not have sex with their wives during menstruation).
- mental disorder.** The Diagnostic and Statistical Manual of Mental Disorders definition is a "clinically significant ... syndrome or pattern" in which an individual exhibits behavioral or psychological patterns that are associated with "distress, disability, or increased risk of pain or death;" anthropologists have pointed out a number of problems applying this definition cross-culturally. For example, many cultures do not clearly distinguish between mental and physical disorders.
- mental illness.** See **mental disorder**.
- mental retardation.** Definitions of mental retardation need to consider the context of the individual's culture and their peers in that culture. In the United States, mental retardation is often defined as a disability characterized by significant limitations both in intellectual functioning and in adaptive behavior.
- mesaticephalic.** Having a medium-length head.
- mestizo.** A person of mixed European and Native American heritage; this term is usually used in Latin America.
- microevolution.** Small scale evolutionary change within populations or species.
- midwife.** A specialist to assist at birth.
- mitochondrial DNA.** See **mtDNA**.
- mitochondrial inheritance.** The inheritance of a trait encoded in the mtDNA.
- mitosis.** Cellular reproduction or growth involving the duplication of chromosomal pairs.

- moiety.** A unilineal descent group in a society that is divided into two such maximal groups; there may be smaller unilineal descent groups as well.
- monogamy.** Marriage between only one man and only one woman at a time.
- monogenic.** Controlled by only one gene.
- monolingual.** Using or knowing only one language.
- monotheistic.** Believing that there is only one high god and that all other supernatural beings are subordinate to, or are alternative manifestations of, this supreme being.
- morbidity.** The proportion of sickness or a specific disease in a population.
- mortality rate.** Provides an indication, usually for comparative purposes, of the death rate in a population; may be expressed as the number of deaths per 100,000 population in a given year; may be more specifically addressed to specific age ranges such as the infant mortality rate (e.g., number of infant deaths/1000 live births).
- moxibustion.** A medical practice that originated in China. Traditionally, small cones of dried leaves are burned on certain designated points of the body, generally the same points as those used in acupuncture. The term comes from the name of the wormwood plant most frequently used, *Artemisia moxa*. It is believed that burning or heating certain points on the body increased circulation “full-bloodedness” and relieved pain. Nowadays the heated material tends to be held above, not on, the body.
- mtDNA (mitochondrial DNA).** Extranuclear DNA found in the mitochondria. Mitochondria are responsible for certain oxidative metabolic functions that store and release energy. Children (both males and females) inherit **mtDNA** from their mothers only.
- mumps.** An acute infectious virus affecting the parotid glands, salivary glands in front and below the ear.
- multidimensional scaling.** Provides a visual representation in which items responded to in similar ways are placed closer together in the scaling plot.
- mutation.** A change in the DNA sequence, producing an altered gene.
- natal home.** Where a person was born and (usually) grew up.
- nationalism.** A sense of consciousness that exalts one nation-state and seeks to promote that nation’s values, culture, and interests above those of others.
- natural fertility.** Populations whose fertility patterns are not influenced to any great extent by deliberate limitation of family size are referred to as natural fertility populations; their family size and spacing is a function of the biological capacities of individuals to reproduce (fecundity).
- natural selection.** The outcome of processes that affect the frequencies of traits in a particular environment. Traits that enhance survival and reproductive success increase in frequency over time.
- naturalistic medical systems.** Sickness is explained by impersonal forces or conditions, including cold, heat, and other forces that upset the body’s balance.
- naturopathy.** A treatment system that avoids drugs and surgery and emphasizes natural means (e.g., air, sunshine, water) and physical manipulation and exercise to invigorate the body and improve health.
- negotiation.** The process by which the parties to a dispute try to resolve it themselves.
- neolocal residence.** A pattern of residence whereby a married couple lives separately, and usually at some distance, from the kin of both spouses.
- nephritis.** Inflammation of the kidneys.
- “nerves” (*nervios, nervos, nevra, worriation*).** A widespread label for similar experiences in various cultures in which patients complain of headache, dizziness, fatigue, weakness, and abdominal pain and attribute their symptoms to sadness, anger, fear, or worry.
- nervios.** The Spanish for “nerves.” See “**nerves**.”
- neurasthenia.** A disorder that is characterized by fatigue, lack of motivation, feelings of inadequacy, and psychosomatic symptoms.
- neurofibromatosis.** Genetic disorders of two types: the first is characterized by pale brown spots on the skin and soft benign, but sometimes disfiguring, tumors usually at nerve endings in the skin; the second is marked by tumors of the central nervous system and the acoustic nerve which can result in deafness.

- neurological disease.** A disease pertaining to the nerve tissue in the body (including the brain, brain stem, spinal cord, and ganglia).
- neurosis.** A form of mental distress which causes moderate to severe perturbation to relationships and ability to adapt, but not to the extent of being subject to delusions. Compare with **psychosis**.
- New World syndrome.** A collection of metabolic disorders characterized by diabetes, obesity, high blood lipids, gallstones and gallbladder cancer, resulted from a combination of founder effect and selective pressures encountered in harsh arctic environments by the first New World immigrant populations.
- norms.** Standards or rules about acceptable behavior in a society. The importance of a norm usually can be judged by how members of a society respond when the norm is violated.
- nuclear family.** A family consisting of a married couple and their young children.
- nosology.** The knowledge of and the classification of diseases.
- nutritional anthropology.** A subfield of medical anthropology in which nutritional implications of food intake, food as carrier of nutrients, nutritional status, human growth and health are the focus. Studies in nutritional anthropology draw on theories and methods from both biological and social sciences.
- oath.** The act of calling upon a deity to bear witness to the truth of what one says.
- obesity.** A state of excess accumulation of fat on the body. Cultures differ in the degree to which fat is valued; most biomedical practitioners have standardized measures for assessing degree of fat.
- obsessive-compulsive disorder (OCD).** A neurotic disorder in which a person becomes trapped in a pattern of repetitive thoughts and behaviors that are senseless and distressing but extremely difficult for the person to ignore. Usually accompanied by compulsions to repeat repetitive acts (e.g., washing hands). May if untreated interfere seriously with daily functioning.
- oedipal period.** The time, according to Freudian theory, when a child develops an Oedipal complex, which refers to sexual attraction to the opposite sex parent and feelings of rivalry with the parent of the same sex. Such feelings are normally repressed when the child fears the anger of the opposite sex parent. May commonly occur between 3 to 6 years of age.
- onchocerciasis.** Although the common name for onchocerciasis is river blindness, this form of the disease is less common than onchocercal skin disease, a disorder characterized by lesions and depigmentation.
- ontology.** The study of being or existence.
- opportunistic infections.** Infection with HIV is an example of an opportunistic infection because it weakens the immune system to the point that it has difficulty fighting off certain infections. These types of infections are called "opportunistic" infections because they take the opportunity a weakened immune system gives to cause illness.
- ordeal.** A means of determining guilt or innocence by submitting the accused to dangerous or painful tests believed to be under supernatural control.
- paleoanthropology.** The study of the emergence of humans and their later physical evolution. Also called **human paleontology**.
- osteopathy.** A profession that emphasizes the relationship between the muscle/skeletal structure of the body and organ function. Osteopathic physicians are skilled in recognizing and correcting structural problems through manipulation and other treatments.
- pandemics.** Epidemics that occur over a wide geographic area.
- paradigm.** A general concept or model accepted by an intellectual community as a effective way of explaining phenomena.
- participant-observation.** Living among the people being studied—observing, questioning, and (when possible) taking part in the important events of the group. Writing or otherwise recording notes on observations, questions asked and answered, and things to check out later are parts of participant-observation.
- pastoralism.** A form of subsistence technology in which food-getting is based directly or indirectly on the maintenance of domesticated animals.
- pater.** The socially defined father. Compare with **genitor**.
- pathogen.** Any disease-producing agent.

- pathogenic.** Causing or capable of causing disease.
- pathogenicity.** The ability of a parasite to inflict damage on the host.
- pathophysiology.** Referring to the unfolding and sometimes complex process by which an otherwise healthy biological system, partially or wholly, either slowly or instantaneously, breaks down or somehow fails to serve its intended function, potentially harming or killing the organism.
- patriarchy.** An old general term for the disproportionate holding of power or authority by males; since there are many domains of authority and power, anthropologists now generally identify more specific institutions or customs such as the presence of patrilineal descent, patrilocal residence, the proportion of leaders who are male, inheritance by males, etc.
- patriclan.** A clan tracing descent through the male line.
- patrilineage.** A kin group whose members trace descent through known links in the male line from a common male ancestor.
- patrilineal descent.** The rule of descent that affiliates an individual with kin of both sexes related to him or her through men only.
- patrilocal residence.** A pattern of residence in which a married couple lives with or near the husband's parents. Often referred to as virilocal residence in the absence of patrilineal descent.
- peasants.** Rural people who produce food for their own subsistence but who must also contribute or sell their surpluses to others (in towns and cities) who do not produce their own food.
- penetrance.** The frequency of expression of a certain phenotype; some alleles, even when present, are expressed less than 100% of the time, and thus are said to have a lowered penetrance.
- personalistic medical system.** Disease and misfortune are viewed as being caused by super-sensory or supernatural agents (usually anthropomorphic) intentionally directed toward afflicted individuals in acts initiated by humans (e.g., using sorcery) or by the super-sensory agents directly. Accident and chance are not involved. Compare with **naturalistic medical systems**.
- personality.** The distinctive way an individual thinks, feels, and behaves.
- pharmacogenetics.** The convergence of pharmacology and genetics that deals with genetically determined reactions to drugs.
- pharmacology.** The study of drugs (their preparation, uses, and therapeutic effects). The term is usually used to refer to the scientific study of drugs associated with Biomedicine. Compare with **ethnopharmacology**.
- phenocopy.** An environmentally produced phenotype that simulates the effect of a particular genotype.
- phenomenology.** The investigation, as free as possible from preconceptions, of phenomena as experienced by people. With reference to health and illness, phenomenology may, for example, examine people's experiences and feelings about their own bodies, healing, and dying.
- phenotype.** The observable physical appearance of an organism, which may or may not reflect its genotype or total genetic constitution.
- phratry.** A unilineal descent group composed of a number of supposedly related clans (sibs).
- physical (biological) anthropology.** See **biological (physical) anthropology**.
- pidgin.** See **Creole language** for explanation.
- plague.** In the broadest sense can be any epidemic disease that causes high mortality.
- pneumonia.** Inflammation of the lungs with congestion.
- political ecology.** An ecological approach that considers economic, social and political factors.
- political economy.** The study of how external forces, particularly powerful state societies, explain the way a society changes and adapts.
- pollution.** A set of beliefs and ideas that suggest that a category of persons (e.g., women; a certain caste) may be dangerous to one's health. Often pollution ideas are associated with particular states, such as menstruating women.
- polyandry.** The marriage of one woman to more than one man at a time.
- polydactyly.** Having more than the usual number of digits (fingers and toes).

- polygamy.** Plural marriage; marriage to more than one spouse simultaneously.
- polygenic.** Disorders caused by the combined action of alleles from more than one gene.
- polygyny.** The marriage of one man to more than one woman at a time.
- polymorphism.** In genetics the regular occurrence in a breeding population of two or more forms of an allele of a gene; the frequency of the rarer allele cannot be explained by mutation alone and may be explained by greater adaptive fitness of the heterozygote condition (as in balanced polymorphism).
- polytheistic.** Recognizing many gods, none of whom is believed to be superordinate.
- possession.** A state where one's normal personality is replaced or controlled by another, usually by a spirit or other supernatural being.
- possession trance.** Alterations or discontinuity in consciousness, awareness or personality or other aspects of psychological functioning which are accounted for by the belief that the person is changed through the presence in him or her by a spirit entity or power.
- postpartum.** After birth.
- postpartum abstinence or postpartum sex taboo.** Prohibition of sexual intercourse between a couple for a period of time after the birth of their child.
- postpartum amenorrhea.** The suppression of ovulation (and menses) after the birth of a baby.
- potlatch.** A feast among Pacific Northwest Native Americans at which great quantities of food and goods are given to the guests in order to gain prestige for the host(s).
- practicing anthropology.** See **applied anthropology**.
- prader-Willi syndrome.** Neurogenetic condition characterized by mental impairment, obesity, small hands and feet, and lack of sexual maturity. Exhibits evidence for genomic imprinting; PWS is caused by a small deletion on chromosome 15, and is transmitted paternally.
- prehistory.** The time before written records.
- prestation.** Any thing (material things, services, entertainment) given freely or in obligation as a gift or in exchange; more broadly refers to the total context of the exchange.
- prevalence.** The percentage of a population that is afflicted with a particular disease or rate (number per standard unit of measure). If a disease lasts 10 years on average the prevalence will be 10 times higher than the incidence. Compare with **incidence**.
- priest.** Generally a full-time specialist, with very high status, who is thought to be able to relate to superior or high gods beyond the ordinary person's access or control. A woman priest may be referred to as a priestess.
- primary health care.** Focuses on providing information and facilities to aid in preventative health care; medical anthropologists often try to encourage grassroots health care programs that integrate traditional medicine with biomedicine.
- primate.** A member of the mammalian order primates, divided into the two suborders of prosimians and anthropoids.
- primatologists.** Persons who study primates.
- primogeniture.** The rule or custom by which the first-born inherits all or most of the property or titles.
- prion.** A protein particle lacking nucleic acid that is thought to be the cause of various infectious diseases of the nervous system.
- prone.** Lying face downward.
- proteomics.** The study of gene expression and how proteins are assembled and modified by both RNAs and other proteins (including prions).
- psychiatry.** A medical specialization dealing with mental illness, nowadays generally emphasizing drug treatment, but in the past more concerned with classification and psychotherapeutic methods.
- psychoanalysis.** A type of treatment for mental disorders developed by Freud which emphasizes listening to and understanding the patient's communications, especially dreams, and helping the patient to interpret them. Traditionally used mainly to treat neurosis, it is now used effectively for psychosis as well.
- psychotherapy.** Treatment of mental disorder (neurosis or psychosis) using talking in a personal relationship. It may include psychoanalytic treatment or it may use more directive methods such as steering the patient's attention toward certain problems.

- psychosis.** A distressed state in which a person is subject to delusions and often hears voices; in crisis it incapacitates a person from usual activities and disrupts relationships.
- psychosomatic.** Referring to a physical disorder or symptom that is influenced by the mind or emotional factors.
- pulmonary fibrosis.** Chronic inflammation with progressive formation of fibrous tissue in the alveolar walls of the lung; results in progressively increasing shortness of breath.
- pardah.** (Lit. veil or curtain), the practice, including the seclusion of women from public observation, of wearing concealing clothing, and use of screens or curtains to hide women.
- race.** In biology, race refers to a subpopulation or variety of a species that differs somewhat in gene frequencies from other varieties of the species. All members of a species can interbreed and produce viable offspring. Many anthropologists do not think that the concept of “race” is usefully applied to humans because humans do not fall into geographic populations that can be easily distinguished in terms of different sets of biological or physical traits. Thus, “race” in humans is largely a culturally assigned category.
- racism.** The belief that some “races” are inferior to others.
- raiding.** A short-term use of force, generally planned and organized, to realize a limited objective.
- random sample.** A sample in which all cases selected have had an equal chance to be included.
- rank society.** A society that does not have any unequal access to economic resources or power, but with social groups that have unequal access to status positions and prestige.
- recessive.** An allele phenotypically suppressed in the heterozygous form and expressed only in the homozygous form.
- reciprocity.** Giving and taking (not politically arranged) without the use of money.
- recombinant DNA.** Formed by the splicing of DNA from more than one source.
- rectal prolapse.** Protrusion of the rectal mucous membrane through the anus.
- redistribution.** The accumulation of goods (or labor) by a particular person or in a particular place and their subsequent distribution.
- reflexology.** Uses massage and pressure techniques to relax and loosen muscles in the feet and hands. The feet and hands are viewed as maps of the body; putting pressure on and massaging specific points on the feet or hands is said to have an effect on the corresponding area of the body.
- religion.** Any set of attitudes, beliefs, and practices pertaining to supernatural power, whether that power rests in forces, gods, spirits, ghosts, or demons.
- renal.** Pertaining to the kidney.
- reproductive ecology.** The study of how human reproduction is affected by ecological factors such as seasonal variability in food, environmental carrying capacity, and the production roles and spatial distribution in work.
- respiratory disease.** A disease that affects the organs involved in breathing (nose, throat, larynx, trachea, bronchi, and lungs).
- revitalization movement.** A religious movement intended to save a culture by infusing it with a new purpose and life.
- rheumatoid arthritis.** A chronic inflammatory disease that destroys joints. May be an auto-immune disorder.
- rickets.** A condition caused by deficiency of vitamin D which disturbs normal hardening of the bones.
- rite.** A ceremonial act or series of actions.
- rite of passage.** A ritual associated with a change of status; see **initiation rite**.
- ritual.** A ceremony, usually formal, with a prescribed or customary form.
- Sahel.** The transitional semi-arid zone in Africa between the arid Sahara to the north and the humid savannas to the south. It stretches from Senegal to the Sudan. It has become increasingly desertified.
- scabies.** A contagious inflammation of the skin caused by the itch mite.
- scarification.** The practice of producing raised scars on the body, usually for marking status (e.g., a tribal marking, achievement of manhood) or for decorative purposes.
- scarpie.** A neurological degenerative disease of sheep and goats that may be a prion disease.
- section.** A group of kin related to one another by both matrilineal and patrilineal principles; excluded are those related by only one principle as well as those not related by either principle. Associated with moieties and moiety exogamy.

- schizophrenia.** A severe mental disorder that most frequently begins in late adolescence or early adulthood and is characterized by delusions (fixed, false ideas), hallucinations (either auditory or visual), and behavior that is deemed socially inappropriate (e.g., going without clothes, lack of attention to personal hygiene).
- scientific medicine.** See **biomedicine**.
- sedentarization.** The process of become sedentary or settling into permanent communities.
- segmentary lineage system.** A hierarchy of more and more inclusive lineages; usually functions only in conflict situations.
- senescence.** The state or process of becoming old.
- septicemia.** Blood poisoning by microorganisms or their toxins.
- SES.** Socioeconomic status.
- sex differences.** The typical differences between females and males that are most likely due to biological differences.
- sexual division of labor.** See **gender division of labor**.
- sexually dimorphic.** Refers to a species in which males differ markedly from females in size and appearance.
- shaman.** A religious intermediary, usually part time, whose primary function is to cure people through sacred songs, pantomime, and other means; sometimes called witch doctor by Westerners.
- shamanism.** A religion characterized by the importance of the shaman as the intermediary between people and their gods and spirits.
- shifting cultivation.** See extensive cultivation.
- sib.** See **clan**.
- siblings.** A person's brothers and sisters.
- sickle cell anemia (sicklemia).** A condition in which red blood cells assume a crescent (sickle) shape when deprived of oxygen, instead of the normal (disk) shape. The sickle-shaped red blood cells do not move through the body as readily as normal cells, and thus cause damage to the heart, lungs, brain, and other vital organs.
- sickness.** For some, sickness is defined primarily as a social category describing the sick role in society and the way a person who is ill is expected to behave; sickness may also be used to describe illness and/or disease when the distinction is not important. See **illness** and **disease**.
- SIDS.** See **sudden infant death syndrome**.
- slash-and-burn.** A form of shifting cultivation in which the natural vegetation is cut down and burned off. The cleared ground is used for a short time and then left to regenerate.
- slaves.** A class of persons who do not own their own labor or the products thereof.
- sleep architecture.** Refers to the time, duration and order by which sleep stages or awakenings and arousals are expressed throughout an organism's sleep behavior.
- sleeping sickness.** See **trypanosomiasis**.
- smallpox.** An acute viral disease characterized by a widespread rash with pustules. Considered to be eradicated but previously caused high mortality.
- socialization.** A term used to describe the development, through the direct and indirect influence of parents and others, of children's patterns of behavior (and attitudes and values) that conform to cultural expectations.
- social stratification.** The presence of unequal access to important advantages depending on the social group one belongs to. See **class** and **caste**.
- society.** A group of people who occupy a particular territory and speak a common language not generally understood by neighboring peoples. By this definition, societies do not necessarily correspond to nations.
- sociobiology.** See **behavioral ecology**.
- sociology.** A discipline that focuses on understanding social relations, social groups, and social institutions. Usually focuses on complex societies.
- sorcery.** The use of certain materials to invoke supernatural powers to harm people.
- sororal polygyny.** The marriage of a man to two or more sisters at the same time.
- sororate.** A custom whereby a woman is obliged to marry her deceased sister's husband.

- soul flight (or soul journey).** A trance state in which some aspect of the experient (soul, spirit, an animal familiar) interacts with spirits in a non-ordinary reality. The soul journey or flight is a universal feature of shamanism.
- soul loss.** An injury to the core or essence of one's being or personal identity. The loss may be characterized by despair, disharmony, and feelings of loss of meaning in life and connection with others. "Soul" constitutes a vital essence of self-emotions. Soul loss occurs from trauma that causes an aspect of one's self to dissociate. Reintegration of these dissociated aspects of self is central to healing. Soul recovery usually involves the help of a shaman.
- species.** A population that consists of organisms able to interbreed and produce viable and fertile offspring.
- spirits.** Unnamed supernatural beings of nonhuman origin who are beneath the gods in prestige and often closer to the people; may be helpful, mischievous, or evil.
- state.** A political unit with centralized decision making affecting a large population. Most states have cities with public buildings; full-time craft and religious specialists; an "official" art style; a hierarchical social structure topped by an elite class; and a governmental monopoly on the legitimate use of force to implement policies.
- statistical association.** A relationship or correlation between two or more variables that is unlikely to be due to chance.
- statistically significant.** Refers to a result that would occur very rarely by chance. The result (and stronger ones) would occur fewer than 5 times out of 100 by chance.
- stereotype.** A mental picture or attitude that is an oversimplified opinion or a prejudiced attitude.
- STDs.** Sexually transmitted diseases.
- structural violence.** The set of large-scale social forces, such as racism, sexism, political violence, poverty and other social inequalities, which are rooted in historical and economic process.
- stunting.** Process which substantially reduces size or vigor. With reference to child growth often assumed to occur if a child is more than 2 or 3 standard deviations below normal height and weight for its age. (The term wasting may be used to refer to weight and the term stunting with regard to height.)
- subculture.** The shared customs of a subgroup within a society.
- subsistence patterns.** The methods humans use to procure food.
- sudden infant death syndrome (SIDS, cot or crib death).** The sudden death of a young infant or child which is unexpected by history and in which a thorough post-mortem examination fails to demonstrate an adequate cause of death.
- supernatural.** Believed to be not human or not subject to the laws of nature.
- supine.** Lying with back downward.
- susto.** The Spanish word "susto" means "fright" or "fear." The basic idea in *susto* is that either a sudden shock as in being startled, or an emotional shock, or a series of traumatic events, or a frightening encounter with a ghost have damaged a person, often by startling their soul out of their body. Susto patients are described as restless during sleep, listless, depressed, debilitated and indifferent to food and hygiene.
- swidden.** The name used for a plot under extensive cultivation; see **extensive cultivation**.
- syphilis.** A sexually transmitted disease caused by the spirochete *Treponema pallidum*.
- syncretism.** The combination of different forms of belief or practice; usually refers to the blending of elements from different religions as a result of contact.
- syndemics.** Refers to two or more epidemics (i.e., notable increases in the rate of specific diseases in a population), interacting synergistically with each other inside human bodies and contributing, as a result of their interaction, to excess burden of disease in a population; in other words health-related problems cluster by person, place or time. Also refers to the health consequences of the biological interactions among co-present diseases. Also points to the determinant importance of social conditions in disease interactions and consequences.
- systemic lupus erythematosus.** An autoimmune disorder that causes chronic inflammation of different organs of the body.
- taboo (tabu, tapu, kapu).** A prohibition or restriction that, if violated, is often believed to bring supernatural punishment.
- tapu.** See **taboo**.

- taxonomy.** An orderly classification.
- technology.** In the broadest sense is the application of knowledge for the purpose of changing, manipulating, or controlling the natural and human worlds. Technology includes tools, artifacts, constructions, machines, prostheses, and skills.
- tetanus.** An acute infectious and often fatal disease caused by an anaerobic bacterium (*Clostridium tetani*) that often enters the body through wounds in the skin.
- thalassemia.** A serious disease characterized by severe anemia starting at a few months of age, distinctive deformities of the facial bones and enlarged spleens.
- theories.** Explanations of associations or laws.
- thrifty genotype.** A genotype that presumably makes a person's metabolism very efficient enabling one to get by on fewer food resources; such a genotype is theorized to have evolved with frequent famine or food stress. In the presence of "nutrition-rich" environments may be prone to diseases such as diabetes.
- time allocation study.** A study that systematically measures the time that people spend in various activities.
- totem.** A plant or animal associated with a clan (sib) as a means of group identification; may have other special significance for the group.
- totipotent.** Cells that retain the potential to form any specialized cell type in the body.
- trachoma.** A chronic infectious disease of the eye (in the conjunctiva and the cornea) that often results in blindness.
- trance.** See **altered state of consciousness**. Trances believed to be the result of spirit possession are called possession trances. See **possession trance**.
- transhumant.** Seasonal movement of livestock to different pastures.
- transnationalism.** A broad term referring to the extension of activities beyond national boundaries. Economic and political relationships today are often transnational. With respect to migration, there is today an enormous movement of people back and forth between national boundaries who often maintain ties with both their host and homeland communities and with others in a global community.
- tribal organization.** The kind of political organization in which local communities mostly act autonomously but there are kin groups (such as clans) or associations (such as age-sets) that can temporarily integrate a number of local groups into a larger unit.
- tribe.** A territorial population in which there are kin or nonkin groups with representatives in a number of local groups.
- trypanosomiasis (sleeping sickness).** An endemic disease among people and animals in Africa. It is caused by various kinds of trypanosome protozoa. It is transmitted by the tsetse fly. Involvement of the central nervous system produces profound lethargy.
- tuberculosis.** An infection caused by a *Mycobacterium* species (*tubercle bacillus*) that may affect almost any tissue, but especially the lungs.
- typhoid.** An infectious disease with fever that is caused by the bacterium *Salmonella typhi* usually spread in contaminated food or water.
- Unani (Unnani) medical system.** The professional medicine of the Middle East which derived originally from Greek Classical medicine and later added elements from Islamic physicians. Has a strong focus on energy or the life force and four vital humors. It is a holistic medical system with a strong emphasis on balance.
- unilineal descent.** Affiliation with a group of kin through descent links of one sex only.
- unilocal residence.** A pattern of residence (patrilocal, matrilocal, or avunculocal) that specifies just one set of relatives that the married couple lives with or near.
- unisex association.** An association that restricts its membership to one sex, usually male.
- urbanization.** The process of becoming urbanized.
- uxorilocal residence.** See **matrilocal residence**.
- variable.** A thing or quantity that varies.
- vector.** A carrier of disease (e.g., an insect).
- venereal disease.** Now usually called sexually transmitted diseases. Any of a class of diseases that is usually or often transmitted by direct sexual contact (e.g., syphilis, AIDS).

vodou. See **voodoo**.

vodoun. See **voodoo**.

voodoo. A religion that focuses on contacting and appeasing spirits to help and protect people; voodoo attributes illness to angry ancestors. Many ceremonies focus on divination to find the cause of illness, rites of healing, propitiation of spirits in which offerings are given, and sacrifices to prevent future trouble. Voodoo is the major religion of Haiti. Also spelled **vodou** or **vodoun**.

warfare. Violence between political entities such as communities, districts, or nations.

western medicine. See **biomedicine**.

witchcraft. The practice of attempting to harm people by supernatural means, but through emotions and thought alone, not through the use of tangible objects.

woman-woman marriage. A type of marriage in which a woman takes on the legal and social roles of a father and husband. The marriage partner, a younger woman, has children with a male chosen by the female husband. The female husband is considered the father.

X-linked inheritance. The key feature of the X-linked mode is that males and females are affected disproportionately. X-linked genes are transmitted in either a monogenic dominant or recessive mode of inheritance. Females can be either homozygous or heterozygous for X-linked traits, whereas normal males are always hemizygous (having only one of a pair of genes) for loci located on the X chromosome.

yaws. An infectious contagious tropical disease caused by a spirochete (*Treponema pertenue*); it is characterized by ulcerating lesions which later affect bone—also called *frambesia*.

y-linked inheritance. The key feature of the Y-linked mode is that only males carry the gene. Y-linked inheritance is displayed by genes located on the nonrecombinant region of the Y chromosome. Normal females never possess a Y chromosome, and normal males are always hemizygous (have one of a pair of genes) for the Y chromosome.

zoonotic diseases. Diseases that come from animal reservoirs.

Volume I: Topics

General Concepts and Perspectives

Theoretical and Applied Issues in Cross-Cultural Health Research

Key Concepts and Controversies

Elisa J. Sobó

INTRODUCTION

From its earliest days, anthropology has included research regarding health. However, it is only within the past quarter-century that inquiry in this area has been systematized and synthesized into the area of specialization known (but not unequivocally so) as “medical anthropology”. After discussing the concept “health,” we review the history of medical anthropology’s emergence. The historical divide between “applied” and “theoretical” medical anthropology is discussed. Our focus then turns specifically to cross-cultural or ethnological health research. Key conceptual models for understanding health-seeking and health systems cross-culturally will be described. We then contrast the explicitly comparative cross-cultural perspective with contemporary ethnography, where single cultures are generally the focus of inquiry, and we discuss the related debate over comparative research. Finally, popular research topic areas are reviewed.

What Exactly is Health?

Anthropologists generally see “health” as a broad construct, consisting of physical, psychological, and social well-being, including role functionality. Such a definition works much better cross-culturally than one that links health only to “disease,” which, technically, means simply a biomedically measurable lesion or anatomical or physiological irregularity. Disease is something that is either cured, or not. But disease itself does not spur people to seek medical treatment; illness does. “Illness” is the culturally structured, personal experience of being unwell and it entails the experience of suffering. The main goal of most people seeking medical treatment is to have their suffering removed. Illness thus underwrites

the entire medical enterprise (Hahn, 1984, p. 17; also see Mechanic, 1962).

“Illness” can refer to a variety of conditions cross-culturally. In some cultures, it is limited to somatic experiences; in others it includes mental dysfunction; in others it includes suffering due to misfortune, too. That is, some medical systems deal with human struggles related to love, work, finances, etc. Social, somatic, emotional, and cognitive troubles often are not separated at all but quite intertwined and even fused together.

This underscores a major criticism of the disease–illness dichotomy: that it recapitulates the mind–body dichotomy that biomedicine has been criticized for trafficking in. “Disease,” as the dichotomy defines it, is anchored in the body; conversely, “illness” may be seen as anchored in the mind. Disease is thus attributed a real, concrete, scientific factuality or objectivity that illness, as a subjective category, may be denied (Hahn, 1984).

A second criticism of the dichotomy hinges on the fact that both disease and illness are located in the individual or experienced at an individual level. The term “illness” does refer to an individual’s social relations, but generally it does so only insofar as these were the cause of the illness (e.g., when an offended party places a hex) or as the illness leaves the individual unable to fulfill social or role obligations. However, some scholars would link suffering more palpably to the social order by examining how macro-social forces, processes, and events (such as capitalist trade arrangements) can culminate in public health problems (such as HIV/AIDS, tuberculosis, alcoholism, pesticide-induced anomalous pregnancy outcomes) and poorly functioning health systems (see Baer, Singer, & Johnson, 1986; Waitzkin, 2000).

Taking their cue from this movement, most social-cultural anthropologists have heeded the call to link individual illness experience with social context, at least minimally. Further, while it is the case that illness

may be defined in opposition to disease, at least in more recent anthropological work (especially that which considers the concepts of embodiment or lived experience), this has generally not been the case; illness is conceived as affecting the whole person, body included. The disease–illness distinction therefore retains contemporary currency, although the term “sickness” may be used when the distinction is not important (e.g., Young, 1982) or when larger social processes are being highlighted (e.g., Frankenberg & Leeson, 1976).

A BRIEF HISTORY OF ANTHROPOLOGICAL HEALTH RESEARCH

While paradigms from all four fields of anthropology inform the work of medical anthropologists today, the roots of “medical anthropology” (a term that we later discuss) extend back in basically two directions, reflecting two kinds of anthropological orientations. If we looked back about 100 years, which is about as long as anthropology has existed in an organized fashion within the United States, then we would see a group of biological or physical anthropologists studying human growth and development, evolution and adaptation, and forensic issues. Secondly, we would see a group of social or cultural anthropologists interested in traditional or local healing practices (often linked with religion and magic). If we looked back about 70 years, the social-cultural group would also contain anthropologists interested in psychological issues related to cultural norms (this school of inquiry is often referred to as the “culture and personality” school).

With the end of World War II, medical anthropology (still at that time an unnamed specialization) received impetus and support from foundation- and government-funded applied work in the arena of international public health. The data collected by anthropologists in earlier times for non-medical purposes proved invaluable; anthropologists helped ensure that social and cultural aspects of health and healing were taken into account in ways that promoted international health program success (Foster & Anderson, 1978, pp. 7–8).

Application and Theory

The incorporation of anthropology into international public health efforts called for a distinctly applied orientation,

and medical anthropology was greatly influenced by this. Good (1994) refers to medical anthropology in the 1960s as a “practice discipline,” dedicated to the service of improving the public health of societies in economically poor nations. Indeed, initial efforts at organizing a medical anthropology interest group occurred in the late 1960s under the auspices of the Society for Applied Anthropology (Todd & Ruffini, 1979).

The interest group settled in 1971 on an affiliation with the more generalist American Anthropological Association (AAA), and is now known as the “Society for Medical Anthropology” (SMA). Although this move firmly anchored the group within anthropology, the influence of applied perspectives remained strong. From the viewpoint of those seeking practical solutions to specific health problems, theory seemed abstract, obstructive, and sometimes even irrelevant. The authority of biomedical clinical culture, where curative work and saving lives takes precedence, was manifest (Singer, 1992).

The practical bent of much of the work of early SMA members was intensified by the fact that those anthropologists *not* interested in direct involvement in the application of their work tended purposefully *not* to identify with what was now referred to as “medical anthropology” (cf. Good, 1994, p. 4). Therefore, their health-related research, in which theory was more central, failed to provide much organizing force to the growing specialization in its early days.

As the century came to a close, medical anthropology grew dramatically, partly due to increased opportunities for applied medical anthropologists. But perhaps more importantly, non-applied anthropologists interested in health saw that they too had something to gain by identifying as “medical” anthropologists. For some, including those interested in cross-cultural health research, in which comparison and contrast is central, a key benefit was access to a community of scholars with a common interest in health issues—as well as health-related data from diverse cultures that might be shared. For others, the benefits included increased credibility in biomedicine and easier access to biomedical consumers, workers, and organizations. This facilitated anthropological investigations into the cultural construction of biomedicine, which have grown increasingly popular in the past 25 years. Investigations into the medicalization of pregnancy and birth were central to the growth of this area of research (Leslie, 2001, p. 431; Rapp, 2001). (“Medicalization”

generally refers to the extension of biomedicine's authority into non-biomedical realms and the resulting regulation of everyday life.)

Once committed to the medical anthropology specialization, academically oriented scholars pushed theory into a more central role. They called their colleagues to task for forgetting that there can be neither data nor facts without theories as to what constitutes each. They promoted the notion that theory must be used or applied: through use, it is tested, revised, and strengthened (Singer, 1992). Thereby, the somewhat spurious distinction between applied and theoretical (or "basic") research has become less salient.

What's in a Name?

There are still those anthropologists who prefer to self-identify as "cultural" or "social" anthropologists interested in health, rather than as "medical" anthropologists. In some cases they cling to the old-fashioned academic belief that applied work is *infra dig*.¹ In other cases, their concern relates to their narrow definition of the term "medical."

Technically speaking, the term "medical" refers only to those curative practices engaged in by Western-trained, allopathic, biomedical physicians (and when hairs are split, surgeons are not included here). As effective as this type of curing may be, it is asocial and highly technologized, bureaucratized, and industrialized. It deals with body parts and systems rather than individuals. It values quantitative over qualitative data.

Naming the anthropological health specialty "medical anthropology" thus may be seen to suggest that the standard against which all other healing or curing practices should be measured is the "medical" model (as defined above). Such labeling may be understood to imply that an anthropology concerned with non-"medical" healing or based on the interpretive ethnographic method is unimportant or tangential.

On the other hand, many medical anthropologists' work has nothing to do with "medicine" as it is technically defined (i.e., as biomedicine; see above). For them, and even for many anthropologists working in biomedical settings, the term "medical" is used in a more generic, universalistic sense. It is understood to refer to *any* system of curing or healing—no matter what specific techniques are involved. The label "medical anthropology" is thus not problematic for them.

The Bigger Picture

Semantic debates notwithstanding, over time, what has become known, for better or worse, as "medical anthropology" has become more influential in anthropology as a whole. Theoretical and methodological advances have informed and inspired the larger discipline, and larger disciplinary debates concerning culture, power, representation, social structure, and other issues increasingly reflect advances stemming from medical anthropology research and practice. This reverse in the flow of ideas marks medical anthropology's move from the margin into the mainstream of the field (Johnson & Sargent, 1990; see also Singer, 1992).

Medical anthropology has grown respectable. It is among the most popular areas of anthropological specialization today. Indeed, SMA's membership places it fourth among the 35 special interest sections of the AAA (and it is bested only by generalist sections).²

Medical anthropology also has grown more diverse as new areas of inquiry have developed. However, it is safe to say, as George Foster and Barbara Anderson did about 25 years ago, that most medical anthropologists take somewhat of a systems approach, considering health and health care within the context of cultural and social systems (Foster & Anderson, 1978). Among biological physical medical anthropologists today, major areas of study include bio-cultural phenomena such as diet, nutrition, health disparities, and evolutionary adaptation. Epidemiology is increasingly influential. In the social-cultural arena, there has been a longstanding ethnographic interest in both psychological aspects of health, and the cultural context of medical practices, knowledge, and beliefs. And it is not only anthropologists who are interested in medical anthropology: largely due to policy relating to diversity and health disparities, medical anthropology has slowly been making its way into medical and nursing school curricula and conferences as a specific topic of interest.

HEALTH-SEEKING AND PATTERNS OF RESORT

Much medical anthropology focuses on what people do when they fall ill. In all cultures the household is the key unit in therapy-seeking; members influence each others' care either directly through resource allocation and care

provision, or indirectly through examples set and modalities recommended. Individual problems are linked (in various ways in various cultures) to the well-being of the group and the group may therefore actually organize individual care. The less individualistic a culture is and the more it promotes a socially linked self, the more whole groups may be seen as being in need of therapy. In some cultures, an entire group (e.g., the extended family) may be seen as the patient and healing intra-group conflicts may be part of the treatment regime (Janzen, 1978).

Although for some conditions only one treatment modality will be necessary, this is not always the case. There exists a “hierarchy of resort” (Romanucci-Ross, 1969/1977) in which people first try one thing and then try another until their condition is fixed to their satisfaction. While the concept, as first used, related patterns of resort to acculturation issues, the phrase is often used today to mean that people try the most familiar or simplest and cheapest treatments first and seek more expensive, complex, or unfamiliar treatments later, if necessary.

Treatment choice can follow a hierarchical sequence, but patterns of resort often involve many treatment modalities at once. Further, people do not necessarily adhere to all the official rules related to each type of treatment. People often combine recommendations creatively, creating a regimen that they feel is right for them. Health seeking is a dynamic process; people constantly re-evaluate their symptoms and revise their healthcare plans (Chrisman, 1978).

The recognition of symptoms is generally the first step in what Noel Chrisman (1978) long ago termed “the health-seeking process.” Symptom recognition depends on cultural definitions of normal well-being, and understandings about the causes and contexts of sickness. Owing to cross-cultural differences, symptoms are not always grouped together in the same way cross-culturally. However they may be grouped, some of the important factors that people in all cultures consider when evaluating symptoms include how dangerous to life they are suspected to be, and the degree to which they interfere with lifestyle or function. Also considered is the visibility and frequency of the symptoms in others, and the way this compares with their visibility and frequency in the ill individual.

Another important aspect of health-seeking is preventive behavior, and much thinking in relation to this has come from anthropologists engaged in public and international health efforts. Again, symptom recognition is

important, as is recognition that a given condition’s long-term health costs outweigh the immediate social, cultural, economic, and other benefits of non-preventive behavior (e.g., Sobo, 1995). Research also has shown the importance of understanding popular interpretations of how new medical technology or pharmacology works, and of incorporating indigenous methods for knowledge transfer into health education efforts (e.g., Nichter & Nichter, 1996). Importantly, medical anthropology projects carried out in the context of international and public health research have been key proving grounds for many now-popular applied research methods (e.g., those used in focused ethnographic study or rapid ethnographic assessment; see Pelto & Pelto, 1997).

MEDICAL SYSTEMS CROSS-CULTURALLY

What people do for health depends to a large degree on how they understand the causes of an illness. Etiological concerns have, for a long time, underpinned cross-cultural health research because etiological notions provide an excellent focus for contrasts and comparisons. Much work has focused on categorizing so-called systems of healing and curing (herein, “medical systems”).

One simple model casts illness as either “internalizing” or “externalizing.” Internalizing systems focus on proximate physiological mechanisms. They give primacy to biological or physical signs that can mark a disease’s progression (Young, 1976/1986). Illness is an individual problem, not a social problem. In contrast, externalizing systems ascribe importance to events outside of the ill individual’s body. Such systems view pathogens as purposive; often they are human or anthropomorphized. Diagnostic activity focuses on discovering what brought the (now ill) individual to the pathogenic agent’s attention, provoking the attack. Externalizing systems focus on ultimate causes, not proximate ones.

Using the externalizing–internalizing model, Young (1976/1986) offers some interesting suggestions regarding the evolution of health systems. He holds that internalizing systems evolve from externalizing systems when societies grow complex.

Externalizing systems focus on social and cosmological relations. They are interlinked with other cultural domains, such as religion, and have little conceptual autonomy (Young, 1976/1986). Many have noted that, in small-scale societies, beliefs about illness etiology often

connect with beliefs about all kinds of misfortune, including interpersonal conflicts and geological disasters. But internalizing systems are highly autonomous. So, for example, health is treated as separate from legal or religious issues. Young explains this in relation to the division of labor seen in complex societies.

In small-scale societies, specialization is uncommon and the division of labor is low. Young (1976/1986) argues that this explains the overlap between healing and other cultural domains. Large-scale societies have complex labor division patterns that include specialization and engender distinctions between cultural domains. The conceptual autonomy of internalizing systems is linked to this. The fragmentation of cultural realms in large-scale societies supports internalizing systems, which focus on the body, paying little heed to legal, religious, and other dimensions of life.

The contrast between “naturalistic” and “personalistic” medicine focuses directly on social relations (Foster, 1976). Naturalistic models explain sickness as due to impersonal forces or conditions, including cold, heat, and other forces that upset the body’s balance. Personalistic approaches, however, ascribe illness to active external agents. The agent involved in a given case may be human (such as a sorcerer), or non-human (such as an evil force or ancestral ghost). Accident or chance have no role in illness here as they do in naturalistic explanations; in personalistic systems, illness is the direct result of an agent’s purposive act. Therefore, people need to be certain that their social relations, with the living and the dead, and with deities and other agentic forces, are well maintained. If not, others may be provoked to take actions leading to one’s ill health.

While etiological questions do have importance, categorization can also rest on the organizational characteristics of the systems in question. For example, medical systems can be categorized as either “accumulating” or “diffusing” according to whether they entail accumulated, formalized teachings or, rather, encourage the fragmentation of medical knowledge (Young, 1983). Practitioners in diffusing systems generally do not communicate with one another; their knowledge is often secretly held. Accumulating systems, on the other hand, amass knowledge, generally in written form. Knowledge is shared at conferences and through professional associations and formal training institutions. Biomedicine, Chinese medicine, and Ayurveda are examples of accumulating systems.

Oversimplification and Other Dangers

Some controversy surrounds the fact that all the categorization schemes discussed above entail central contrasts. Many would argue that it is a mistake to cast medical systems as simply one or the other of a given contrasting pair. Rather, the contrasts may be thought of as occupying a continuum, with each system containing some of each emphasis. When determining a classification, the researcher must ask not which ideal type a given system represents but which of a given contrasting emphasis is most salient or primary in that system. So, for example, while biomedicine in practice may entail some personalistic touches (e.g., when a physician refers to an outcome as being in the hands of god), the overarching emphasis is naturalistic and for that reason it is classified as such.

On the other hand, not all systems will be easily classifiable because some systems explicitly accept both aspects of a contrast and focus on either one depending on the illness or condition in question. Take, for example, the old intrusion versus extrusion contrast (Clements, 1932). This model contrasts the bodily “intrusion” of substances or essences to the “extrusion” of such as the cause of illness. Extrusion would include, for example, soul loss, or the loss of blood, or even the non-absorption or leaching of nutrients, as with diarrhea. In intrusion-caused illnesses, on the other hand, noxious substances (e.g., poisons, germs, evil spirits) pierce or infiltrate the body’s barriers. Illness due to bleeding and illness due to soul loss are classified together in this model as extrusion-caused; germs and evil spirits are both categorized as intrusive. However, treatments for germ-caused or spirit-caused illness can differ. In any case, one medical system can allow for both intrusion and extrusion illnesses. So in some cases the question is not which of a given contrast dominates, but how the two are linked and under what conditions one or the other predominates.

Here, it is worth noting that not all medical systems are all that systematized; sometimes, what is actually referred to as a system is only loosely aggregated. Care must be taken to avoid reifying the terminology used to talk about diverse ways of dealing with health and illness, thus creating the impression that a culture’s loosely aggregated set of beliefs and practices is actually a highly systematized structure.

Further, systems (whether loosely or tightly systematized) typically entail sub-systems. For instance, the formal U.S. healthcare system includes not only medicine

as it is technically defined, but also nursing, the child-life specialty, social work, occupational therapy, etc. Medical systems generally include a diverse array of practitioners, such as herbalists, chemists, surgeons, bone setters or body workers, midwives, sorcerers, priests, and shamans (Loustaunau & Sobo, 1997). Within any given cultural group's medical system, diverse practitioners' work—and their understandings of how health is produced, maintained, and compromised—may or may not overlap.

When does a culture's loosely coupled system stop counting as one loosely coupled system and start counting as several distinct systems? This question has not been sufficiently considered as yet, but the answer may lie in the degree to which the various components compete with each other for clients. That is, in a loosely coupled system, the sub-systems each serve distinct, diverse needs. But in a pluralist system (comprised of two or more distinct medical systems) components may be in competition, each claiming to be able to meet the same needs, albeit in a different fashion. Again, the distinction is not an all-or-nothing one; there may be a continuum and some systems (using that term in its broadest sense) may be more or less pluralistic than others.

In addition to maintaining caution regarding all-or-nothing contrasts, medical anthropologists must be aware that classifying a system is not the ultimate goal of our discipline. Classifications are helpful only as they propel us forward in theoretical contributions to the field, or make helpful action possible.

Within-System Distinctions

One common typology describing complex medical systems is the tripartite scheme of popular, folk, and professional medicine (Kleinman, 1978). The key variables are: who provides care and in what context. In the "popular" sector, non-specialists, such as one's self, mother, friends, or other kin and relations, provide treatment. Treatment is based on shared cultural understandings, and generally occurs in a family or household context. Folk sector healers are specialists; their practice is based on cultural traditions and philosophies. Legally sanctioned official systems make up the "professional" sector.

This three-part scheme is an advance on simple public-private dichotomizing, in which private or household care is separated from care provided within the formal health care system, and discounted. But the typology does have an unanticipated shortcoming in relation to

its potential for cross-cultural application: although it specifically allows that some non-biomedical practices, such as Ayurvedic or traditional Chinese medicine, should be classed as professional medicine due to their routinized, formalized, professionalized nature, this is easily forgotten by those who would view those therapeutic modalities as so-called folk practices.

Bonnie O'Connor's model (1995) has only two parts: conventional medicine, and vernacular medicine. "Vernacular" medicine subsumes Kleinman's (1978) folk and popular sectors; "conventional" medicine consists only of the official, authorized, authoritative, dominative health care industry or system—whatever that may be in a given cultural context. The contrast is simple but important, because it explicitly highlights the dominative position held by conventional medicine. Anthropologists can apply this lesson cross-culturally because the power dynamics and medical status hierarchy that O'Connor's model reflects are, to at least some extent, universal (all systems have conventional medicine of some kind).

CROSS-CULTURAL (ETHNOLOGICAL) VERSUS MONO-CULTURAL (ETHNOGRAPHIC) RESEARCH

In the preceding sections we reviewed some of the key concepts and models used in medical anthropology. In doing so we concentrated on cross-cultural research, in which numerous groups are compared in order to generate insights that will apply across all cultures. However, not all anthropologists work with multiple cultures concurrently. Some choose to scrutinize one group intensively, either staying with that group for the duration of their career, or moving slowly and serially between groups. The choice between cross-cultural ("ethnological") and mono-cultural ("ethnographic") research depends on many things, including where one stands on the controversial question of epistemology—what kind of knowledge is possible.

Cross-cultural research assumes that comparison is possible. Those who conduct cross-cultural research believe that fruitful comparisons can be made because the culturally constructed, health-related categories that they would study are universally, or at least regionally, meaningful (e.g., flow and blockage; see Sobo, 2003); or because historical connections justify comparisons

(e.g., between humoral systems; see Foster, 1994); because human physiological processes are similar around the world (Browner, Ortiz de Montellano, & Rubel, 1988); etc.

In contrast, ethnographers—especially those concerned with the particulars of meaning and symbolism within given cultures—may hold that comparative, cross-cultural approaches are invalid. They may argue that the act of comparison involves forcing complex, context-specific ethnographic data into simplistic categories that are themselves culture-bound. They may argue that there is in fact no objective, universally applicable perspective.

However, many believe that all ethnography is comparative: ethnographers—explicitly or implicitly, self-consciously or not—compare and contrast the culture under study with the culture that they or their audiences are most familiar with (generally, their own). The question then is not whether comparison is possible, but how much of it is reasonable to expect if a valid, in-depth, meaning-centered analysis is intended. Related to this is the question of how to maintain as much objectivity as possible, both for mono- and cross-cultural studies.

Some ethnographers do deal with more than two cultures or make within-society comparisons (e.g., Jordan, 1993; Rubel & Moore, 2001). But, because careful ethnography takes so much time, full-scale, cross-cultural studies—those dealing with more than a handful of cultures—are generally undertaken with the use of more than one scholar's data. Scholars engaged in full-scale, cross-cultural research may work collaboratively with others, or they may use others' published data or ethnographic accounts to make their comparisons. For example, they may use the Human Relations Area Files (HRAF), a collection of over 7,000 ethnographic accounts concerning over 380 cultures from around the world. The accounts have all been coded and indexed so that researchers may examine how given cultural traits are expressed in various types of groups, or how various physiological processes are dealt with by different cultures.

Ethnographers, as opposed to cross-culturalists, are generally concerned more with local details than with global cultural patterns. They prefer describing a specific culture's health-related logic or sensibility or ethos and its impact on lived experience. Or they are fueled by the previously noted macro-social orientation that links specific, local health-related phenomena with the larger political and economic world. Scholars adopting this approach use in-depth ethnography to demonstrate how

social processes and forces become embodied, literally, in human suffering (e.g., Farmer, 1999). (Cross-culturally oriented anthropologists would seem well positioned to work from a political-economic viewpoint but in fact, with few exceptions, scholars doing full-scale, cross-cultural research rarely situate cultures in a total world context. They generally compare and contrast according to variables such as geographic or ecological region, or subsistence type, rather than global political-economic ties.)

RESEARCH INTERESTS

Applied or theoretical, comparativist or not, today's medical anthropologists remain very interested in issues relating to health education and promotion. Medical and popular social representations of the body and of disease—for example, the differing ways in which medical and scientific rhetoric has, across time, anchored popular theories of gender in the body (e.g., Lacquer, 1990; Martin, 1987)—have also received a good deal of attention. The ways in which people come to experience their bodies, according to how they are brought up to believe that their bodies work and should feel or function, has been another very productive topic for exploration, and has generated theories of embodiment and lived experience which sometimes even posit the body and its physiological and anatomical reality as a crucial foundation for the creation of culture itself (e.g., Csordas, 1990; Lakoff, 1987; Sobo, 1996).

Issues related to the therapeutic alliance between patient and practitioner have been perennially popular topics of inquiry for ethnographers, who have long been interested in the psychological aspects of health and in the social and cultural context of medical knowledge and practice. More and more recent works have examined how professionally dominated knowledge and practice patterns are socially established, maintained, expressed, or negotiated—or subverted—during patient-practitioner interaction (e.g., Lindenbaum & Lock, 1993). Other aspects of the therapeutic alliance that have garnered attention include the role of narrative employment and interlocutory storytelling in healing (e.g., Delvecchio Good & Good, 2000; Mattingly & Garro, 1994), the impact of illness on identity (e.g., Green & Sobo, 2000), and the moral and ethical dimensions of the alliance, especially in relation to new biomedical technology (e.g., Brodwin, 2000; Lock, Young, & Cambrosio, 2000).

Medicalization also has continued appeal as a framework for anthropological health studies.

The pluralistic approach that many patients take to their own health and the impact of the latter on biomedicine, which generally assumes that it is the only medical system being consulted, is also an increasingly important area of inquiry. [For example, self-care in relation to biomedicine, either as a supplement or adjunct to biomedical care or as an alternative when biomedicine fails to meet people's needs or in the case of uninsurance, has received increasing scrutiny (e.g., Vuckovic, 2000).] The impact and approaches of pharmaceutical advertising on self-care patterns are bound to garner increased attention as such advertising becomes routine practice in the United States. The organizational aspects of the failure of systems to meet people's needs, also already an area of concern within international health circles (Justice, 1989), promises to become a more popular area for inquiry as medical anthropology's alliance with health services research at home begins to burgeon.

CONCLUSION

Anthropologists have always been interested in health. This interest has recently been systematized and synthesized into the area of specialization called "medical anthropology," and key concepts have been developed. Controversies in this growing specialization have concerned, among other things, the label "medical," cross-cultural versus ethnographic orientations, and applied versus theoretical approaches.

Much of the cross-cultural research in this field has concentrated on categorizing medical systems, understanding patterns of health-seeking, and, more recently, comparing cultural responses to universal physiological processes as well as comparing variations on universal (or at least regionally or historically common) cultural constructions related to health. Much of the in-depth ethnographic research on health has focused on questions relating to suffering, and its link to the relationship between individual and society, as mediated by culture. Patient-practitioner communication and relations as well as the role of the body have also been salient concerns of late.

After several decades of marginalization on the basis of its practical (i.e., applied) orientation, medical anthropologists have begun to move toward the center of the

larger anthropological discipline. This move was underwritten by an overt acceptance of the importance of not only pragmatic action but also the theory that inevitably drives it, and a growing agreement that the relationship between theory and action is neither oppositional nor simply complementary; it is circular, dialogical, and coherent. Just as mind and body only exist as a duality theoretically, so too are theory and action only hypothetically divided. Experientially, and in good anthropology, they are a unity. Advances made within the field of medical anthropology once the false dichotomy was exposed have helped to ensure its continued growth and development as well as its value to those outside of the academic arena.

Cognitive Medical Anthropology

Linda C. Garro

INTRODUCTION

The term cognitive medical anthropology does not refer to a recognized and clearly demarcated field of study but rather to a body of work that addresses topics of relevance to medical anthropologists while also reflecting cognitive anthropological interest in “the relation between human society and human thought” (D’Andrade, 1995, p. 1, italics removed).

Initially labeled as the “new ethnography,” “ethnoscience,” “ethnosemantics,” or “ethnographic semantics” (Casson, 1994), the emergence of cognitive anthropology dates to the beginning of what has been called the “cognitive revolution” in the late 1950s (D’Andrade, 1995). After a “long cold winter of objectivism” and the domination of behavioristic theories, the cognitive revolution “was intended to bring ‘mind’ back into the human sciences” (Bruner, 1990, p. 1). A recurring commitment expressed in much of the cognitive anthropological literature is to describe and represent cultural knowledge in a manner compatible with what is known about human cognition. For many, another longstanding orientation is to

the insider’s view: the society member’s perspective on what things mean and what is going on in his or her social world. The principal aim of cognitive anthropology is to understand and describe people in other societies in their own terms, as they conceive and experience it. A further aim is to avoid the biases induced by ethnocentrism, distortions that result when an investigator imposes an outsider’s view on life in another society and describes it from this external perspective. (Casson, 1994, p. 61)

An early and influential conceptualization of culture formulated by Ward Goodenough motivated much subsequent work within cognitive anthropology. Goodenough (1957, p. 167) defined culture as “whatever it is one must know or believe in order to operate in a manner acceptable to its members, and do so in any role that they accept for any one of themselves. Culture . . . must consist of the end product of learning: knowledge, in a most general, if relative, sense of the term.” While a focus on describing shared and internalized cultural content (e.g., shared understandings about illness or widely known cultural

models) has been and continues to be a productive venue of inquiry, some cognitively oriented work within medical anthropology points to the limitations of focusing on the “end product” without also attending to process. Such work has underscored the socially situated nature of cognition, embedded in and unfolding in interactions and activities to meet the needs of everyday life.

Although the specific studies examined here concern topics of interest to medical anthropologists, not all the literature reviewed here is authored by individuals who self-identify as medical anthropologists. Links to broader trends and themes in cognitive anthropology are provided to situate the research discussed. The first section introduces some methodologies proposed for discovering the underlying conceptual organization of the illness domain. Other topics explored here include: measuring variability in cultural knowledge and the development of cultural consensus theory; comparing cultural knowledge across cultural settings; cognitive–ethnographic studies of illness treatment decisions; and cultural models of illness and illness narratives.

METHODS AND THE CONCEPTUAL ORGANIZATION OF THE ILLNESS DOMAIN

Under Goodenough’s broad mandate, considerable attention became directed to developing “a kind of ethnography in which the methods of description are public and replicable” (Tyler, 1969, p. 20) as integral to the process of discovering “how cultural knowledge is organized in the mind” (D’Andrade, 1995, p. 248). In this section, three such methodologically oriented approaches used in studying the conceptual organization of the illness domain are described.

An early article by Frake entitled “The Diagnosis of Disease Among the Subanun of Mindanao” showcases elicitation and analytic methods applicable to “a more rigorous search for meanings” (Frake, 1961, p. 113) as

a step “toward the formulation of an operationally-explicit methodology for discerning how people construe their world of experience from the way they talk about it” (Frake, 1969, pp. 28–29). During his fieldwork, Frake found that: “Their continual exposure to discussions of sickness facilitates the learning of disease concepts by all Subanun.” Characterizing the meaning of a disease concept as the “information necessary to arrive at a specific answer” or diagnosis (Frake, 1961, p. 114), Frake limited the terms elicited to the perceptual realm of skin diseases and the culturally specific (emic) diagnostic criteria which serve to define and differentiate them. Noting the “conceptual exhaustiveness of Subanun classification of natural phenomena” (Frake, 1961, p. 131), Frake portrayed the underlying conceptual organization as taking taxonomic form with different diagnostic criteria operative at different levels of contrast and with increasing specificity at lower levels of the hierarchy. While “informants rarely disagree in their verbal descriptions of what makes one disease different from another,” the “‘real world’ of disease presents a continuum of symptomatic variation which does not fit neatly into conceptual pigeonholes” (Frake, 1961, p. 130). As a “social activity” that involves negotiating the relevance of culturally shared categories to specific instances, the diagnosis of a particular disease may “evoke considerable debate” (Frake, 1961, pp. 129 & 130–131). Thus, while the “analysis of a culture’s terminological systems will not, of course, exhaustively reveal the cognitive world of its members . . . it will certainly tap a central portion of it” (Frake, 1969, p. 30).

Aiming for a more comprehensive understanding of the conceptual domain of illness, subsequent researchers (D’Andrade, Quinn, Nerlove, & Romney, 1972; Young, 1978; Young & Garro, 1994) report unsatisfactory results from efforts to elicit taxonomies or “to carry out standard feature analysis” (D’Andrade, 1995, p. 70). Researchers turned to methods, such as the term–frame substitution task, which allowed for directly comparable responses across informants. Constructing a term–frame interview requires a list of illness terms as well as a set of statements about illness. Each illness term is systematically inserted into each question frame and informants are asked whether the resulting sentence is correct or not (see Weller & Romney, 1988, for further details on this and other systematic data collection techniques). From “Categories of Disease in American-English and Mexican-Spanish” (D’Andrade et al., 1972), an

American-English question frame is “You can catch _____ from other people.” The number of responses analyzed for each individual can be quite large as this is determined by the product of the number of terms and the number of frames. Analytic techniques for such similarity judgments used in a number of studies include multi-dimensional scaling (MDS) and cluster analysis (see also D’Andrade, 1976; Garro, 1983). MDS provides a visual representation in which items responded to in similar ways are placed closer together in the scaling plot. Cluster analysis groups items together at increasing degrees of similarity in responses.

In work carried out by Young and Garro in Pichátaro, a Tarascan town in the Mexican state of Michoacán, the set of 34 illness terms and 43 frames used in a term–frame interview came primarily from wide-ranging informal interviews about different kinds of illnesses and specific illness episodes, with selected statements recast as yes/no questions (Garro, 1983; Young, 1978; Young & Garro, 1994). Although not intended to be exhaustive, representativeness was a goal, both with regard to the range of illnesses covered and in terms of what matters to community members when they talk about and deal with illness. Rather than being a “short-cut,” considerable ethnographic grounding is required to construct a suitable term–frame interview. While the responses can be analyzed in a number of ways, including MDS, that converge on similar patterning (see Garro, 1983), organizing the relatively large number of terms and frames according to the results of a hierarchical cluster analyses facilitated the discovery of similarities and contrasts across this rather large number of terms and frames (Young, 1978; Young & Garro, 1994). Further, a formal analysis of the distribution of frames relative to illness clusters served to differentiate the characteristics linked with particular clusters from those that are more general. Through this procedure the findings are tied to patterns in the data and thus are less dependent on what the researcher sees than when the MDS plot is interpreted. At the broadest level, which clustered illnesses into two main groups, there was an overall distinction between external versus internal locus of cause—illnesses resulting from contact with hazardous environmental agents versus those resulting from internally initiated conditions (related to diet and emotion). Other key distinctions were made on the basis of illness gravity and the life stage of the characteristic victim. All the aforementioned were also among the most important con-

siderations involved in actions aimed at preventing and alleviating illness. Conspicuously absent from this discussion, however, is the “hot–cold” etiological distinction, even though this was the subject of a number of the question frames. This distinction does not play an important role in the conceptual structuring of the illness categories present in the cluster analysis (see also Weller, 1984b). This was perhaps because, in Pichávaro, distinctions based primarily on these etiological principles did not necessarily reflect the types of knowledge most significant for purposive action in relation to illness. In contrast with Frake’s efforts to discover the defining features relevant to diagnosis (the distinctive features that define illness terms), the use of the term–frame substitution task in Pichávaro as well as in D’Andrade et al. (1972) was oriented around discovering the underlying conceptual distinctions that matter most to people in avoiding and dealing with illness in the context of everyday life.

Using different methods, Weller (1984a) tested the cultural salience of concepts reported in the D’Andrade et al. (1972) study with “samples of urban literate women with children living in the United States and Guatemala.” In the earlier research, the concepts of degree of contagion and severity were highlighted for English speakers. For Spanish speakers, important concepts included the relative frequency of occurrence in children versus adults and the appropriateness of hot or cold remedies. Weller (1984a, p. 341) measured “agreement among informants to assess the relative cultural salience” of these illness concepts, starting from the assumption that concepts with the “highest agreement are culturally more salient than those with lower agreement.” An initial pile-sort task with well-known illnesses provided similarity judgments used to construct a “‘conceptual model’ of disease” using MDS. A comparison between the Americans and the Guatemalans carried out by restricting the analysis to the subset of illness terms common to both groups found a high degree of correspondence between the two conceptual models. The data used to assess the saliency of the four concepts mentioned above were separate ranking orderings of the illness on each concept obtained from each of the participants (the Americans did not rank illness on hot–cold). Both agreement among individuals and the fit between the conceptual model and the individual rank-order data for each concept were assessed. For the Americans, the results indicated that all three ranked concepts were important in the cognitive organization of illness. For the Guatemalans, the “conceptual

structure” is “best characterized by the concepts of contagion and severity.” More variation among informants and a poorer fit between the rankings and the model were reported for the age-related and hot–cold concepts. Indeed, the “variation on the hot–cold dimension is so extreme that it seems to indicate that there may not be a culturally shared definition of that concept” (Weller, 1984a, p. 345; see also Weller, 1983).

MEASURING VARIABILITY IN A CULTURAL SETTING AND CULTURAL CONSENSUS THEORY

Variability in cultural knowledge about illness within an identified setting was first systematically addressed by Fabrega in the Mayan community of Zinacantan, Mexico (Fabrega, 1970; Fabrega & Silver, chapter 7, 1973). A form of term–frame interview was used where a set of 18 illness terms were paired with 24 possible bodily disturbances (symptoms). Two groups—one composed of 30 practicing *h’iloletik* (shamans) and the other 30 laymen—were compared. A chi-square analysis found no significant differences between the groups (see Garro, 1986, p. 352).

As noted above, Weller (1983, 1984a) relied upon the extent of intracultural variability as a way for assessing what is culturally shared. Along with Boster’s (1980) finding that consensus indicates shared knowledge, Weller’s work exploring the implications of intraindividual and interindividual agreement for identifying individuals with cultural expertise foreshadows the formal development of cultural consensus theory (Weller, 1984b). Cultural consensus (Romney, Weller, & Batchelder, 1986) refers to both a theory and a mathematical model for “estimating how much of a given domain of culture each individual informant ‘knows’ (called cultural competence in the theory) as well as estimating the ‘correct’ cultural response to each question that can be asked about the particular domain of culture under consideration” (Romney, 1994, pp. 268–269). Prompted by the “need to find more objective ways to investigate culture” (Romney et al., 1986, p. 314) and given the existence of intracultural variability, cultural consensus theory “helps describe and measure the extent to which cultural beliefs are shared. . . If the beliefs represented by the data are not shared, the analysis will show

this” (Romney, 1999, p. S103). A reanalysis of the contagion and hot–cold rankings from the urban Guatemalan women (Weller, 1984a) was presented in the article introducing the cultural consensus model (Romney et al., 1986, pp. 327–329) and reinforced the earlier findings—cultural consensus characterized the contagion rankings but not the hot–cold rankings—leading the authors to conclude that “informants do not share a coherent set of cultural beliefs concerning what diseases require hot or cold medicines” (Romney et al., 1986, p. 328).

Another study exploring variation in cultural knowledge about illness and its treatment compared curers and non-curers (all women) in Pichátaro using responses from a term–frame interview (Garro, 1986). The Quadratic Assignment Program (Hubert & Schultz, 1976) was used to test three alternative hypotheses of interinformant agreement. Although not originally analyzed using the cultural consensus approach, a reanalysis illustrated both sharing and variability within cultural consensus theory (Garro, 2000a, pp. 281–283). The cultural consensus findings were consistent with a high level of sharing in cultural knowledge across both the curers and non-curers. Yet, there was variability in the extent to which individuals could be said to represent this shared knowledge. A specific prediction was that curers, by virtue of their greater experience in dealing with illness and differential opportunities to learn about it, would better represent shared cultural knowledge as evidenced by higher overall levels of agreement (consensus) within this group. This hypothesis was supported but it was also discovered that there was a confounding with age such that older individuals, irrespective of curer status (and curers tended to be older), also agreed more among each other. Like curers, older individuals were socially positioned to have learned more, and hence share more knowledge about illness. Both of these findings were consistent with cultural consensus theory’s conceptualization of variation across informants as indicating measurable differences in the amount of knowledge about a cultural domain, with some knowing more than others.

COMPARING CULTURAL KNOWLEDGE ACROSS DIFFERENT SETTINGS

In addition to the general comparisons across cultural settings discussed above, a number of studies have taken

a closer look at what can be learned through a comparative approach. Three different approaches are examined here. The most ambitious of these is a “collaborative, multisite study using a shared methodology” to study “intra- and inter-cultural variation in beliefs” (Weller, Pachter, Trotter, & Baer, 1993, p. 109) for four geographically separated and distinctive Latin American samples. The illnesses are considered to be either biomedical or folk conditions. Weller and Baer (2001) present findings for five of the eight illnesses studied (AIDS, diabetes, the common cold, empacho, and mal de ojo; with asthma, nervios, and susto also included in the larger design) and some detailed studies, comparing beliefs for individual illness conditions have been published (Weller et al., 1993, 1999). Noting that it “is usually impossible to know if reported differences between cultures are due to cultural differences or due to a difference in methods used to study the cultures,” the researchers constructed a series of 100–150 yes/no questions for each of the illnesses which allowed them to collect comparable data at each site. The questions asked about “potential causes, susceptibility, signs and symptoms, treatments, healers, and sequelae” and were constructed on the basis of informal interviews at each of four sites and some additional sources (Weller & Baer, 2001). With cultural consensus analysis supporting high agreement within samples (Weller et al., 1993), the results of a binomial test indicating a “strong majority response (>66%) in each sample for each illness was used to estimate group beliefs about the presence/absence of features that best described each illness” (Weller & Baer, 2001, p. 201). Features determined to be of high concordance within each setting were then directly compared as a way of assessing what was distinctive or unique across the four groups. The finding of a high degree of sharing with little unique variation across the groups led Weller and Baer (2001, p. 222) to reflect on the underlying cognitive representation and suggest that “the illnesses and features that define them may compose a systemic culture pattern or high concordance code in the sense that they may form a structured set of related items with high agreement and stability across culture members.” These comments about “feature sets” brought to mind D’Andrade’s (1976) somewhat different assessment, based on work involving the term–frame substitution interview, that it was cognitively plausible to expect that knowledge about illness or any other cultural domain is stored in terms of propositions, or in other ways of representing conceptual relationships,

which have the generative or productive capacity to answer novel questions and make inferences.

Garro (1996) explored the generalizability of causal accounts of diabetes through an analysis of 88 dual-format interviews carried out across three Canadian Anishinaabe (Ojibway) communities. In all three communities type-II diabetes was viewed as a relatively “new” illness, with the first cases diagnosed within living memory, but also as a disease which affected so many people that it was seen to be a major health problem. The three communities were chosen to vary in significant ways from each other, including the relative degree of geographic isolation and language use. The first interview format was an open-ended and wide-ranging discussion where individuals talked about their experiences with diabetes. The second was a structured interview consisting of a series of yes/no questions about diabetes based on comments and reflections made by community members in earlier informal interviews about diabetes and other illnesses. Agreement and variation in the structured interview responses were analyzed through a variety of means (including cultural consensus analysis, the binomial test, and the Quadratic Assignment Program). While the direct comparisons using the yes/no responses converged upon a set of explanations which could be found in all three communities, comments made in the open-ended interviews allowed for an exploration of differences in how explanations were framed and emphasized across the three communities. Particularly in areas where agreement was less strong, the dual interview format allowed for a deeper and more finely nuanced representation of understandings about the causes of diabetes across the three communities.

Based on her work in Pichátaro and a Canadian Anishinaabe community, Garro (2000b, 2002) explored potential connections between a cognitive anthropological focus on illness understandings and efforts concerned with cross-cultural comparisons at the level of meaning across culturally divergent sites. Mindful of Hallowell’s admonition (1955, p. 88) that the categories used for making comparisons need to be grounded in an examination of how experience is endowed with meaning within the context of culturally constituted behavioral environments, Garro drew on information from multiple sources using diverse methods to explore the range of explanatory frameworks that were culturally available for conferring meaning on illness at both of her research sites. With reference to existing comparative frameworks, Garro

discussed the challenges in working toward the construction of a comparative framework that captures the range of known variability across cultural settings while still remaining open to ethnographic possibilities.

COGNITIVE–ETHNOGRAPHIC STUDIES OF ILLNESS TREATMENT DECISIONS

Studies of decision-making in real-world settings provide an arena for addressing the question: Why do people do what they do? For cognitively oriented ethnographic studies, a frequent starting assumption is that in recurring decision situations where alternative courses of possible action exist, members of a group come to have shared understandings, a common set of standards concerning how such choices are made (Goodenough, 1963, pp. 265–270; Quinn, 1978; Young & Garro, 1994). Cognitive–ethnographic studies of medical decision-making seek to understand what people do when faced with illness and typically attempt to account for actions taken to deal with illness. To gain insight into the relationship between cultural knowledge and specific treatment actions, careful consideration is given to how people talk about treatment decisions. Such studies are concerned with the nature of cultural knowledge brought to the occurrence of illness, how this knowledge is applied in evaluating illness, and the process whereby decisions about treatment are made. Some, although by no means all decision-making studies are overtly concerned with developing and testing decision models. When attempted, a common strategy is to build a decision model using interview data and other information obtained primarily from one sample, and then to validate the model using decisions made by a second, independent sample. Here, reference to a decision-making approach or perspective serves an inclusive higher-level category, with a “decision model”—the more formal representation of the decision-making process that can be evaluated using actual choices—as a subcategory. Garro (1998a) presented a review and counter-perspective to several broadly based critiques leveled at anthropological studies of care-seeking and decision-making.

Rather than attempt a comprehensive discussion of similarities and differences among relevant studies (e.g., Bauer & Wright, 1996; Hill, 1998; Kayser-Jones, 1995; Mathews, 1982; Mathews & Hill, 1990; Nardi, 1983;

Ryan & Martinez, 1996; Sargent, 1982, 1989; Stoner, 1985; Weller, Ruebush, & Klein, 1997), discussion is limited to two studies—one carried out in the Mexican town of Pichátaro (Garro, 1998a, Young & Garro, 1994) and the other in an Anishinaabe (Ojibway) community in Manitoba, Canada (Garro, 1998b). While the two settings differed radically in terms of the political–economic context of health care, both studies were concerned with how families make treatment decisions among different alternatives.

In both studies an objective was to discover if there were generally shared considerations and cultural understandings that helped to explain variability in each community. At each site there was variability in patterns of resort to different treatment alternatives at different times, both within and between households. The comparability of the two studies was facilitated by adopting the same overall research design in both, despite the methodological challenges and substantive issues involved in adapting the general data-collection strategy to such quite different research settings. In addition to participant observation, informal talks, and interviews, there were two main phases. First, a group of individuals within each community participated in a series of structured interviews organized to learn about local medical understandings and how medical treatment decisions were made when a family member was ill. These interviews served to elucidate the shared understandings and constraints on preferred actions relevant to treatment decisions. The term–frame interview in Pichátaro discussed in the preceding section was part of this process. In Pichátaro, interviews designed to learn about patterns of care-seeking included systematic contrastive questioning about the use of treatment alternatives, presenting hypothetical illness situations designed around contrasts mentioned in earlier interviews and asking individuals what should be done, and recording family-based histories of past illness. In addition, ranking tasks were used to explore assessments of “faith” in different treatment alternatives for a set of illnesses. Pile sorts and ranking tasks obtained judgments of severity for separate sets of illnesses and symptoms. This phase of the research design took a somewhat different form in the two settings, to be expected as the format and content of structured interview methods depend upon prior ethnographic research. In the Anishinaabe community, for example, considerably more attention was given to etiological concerns. However, some approaches, such as the term–frame

interview that worked well in Pichátaro, did not transfer to the Anishinaabe community (see Garro, 2000b, for details).

For both communities, Garro (1998a) maintained that a decision-making perspective was compatible with how individuals talked about actions taken in response to illness and proved to be a useful means for learning about the process of seeking care. Still, as commented on again below, Garro concluded that the stages of developing and testing a formal decision model were better suited to the Pichátaro context than to the Anishinaabe community. For Pichátaro, two basic strategies or general principles underpinned the decision model which specified how assessments of a given illness and judgments about appropriate sources of treatment resulted in expected patterns of treatment choice. But the model also detailed the constraints, such as lack of money or transportation, that at times led to less preferred treatment alternatives being selected.

The second major phase involved collecting actual illness case histories and treatment decisions from a separate, randomly selected group of families in each community through regular household visits over an approximately half-year period. These case studies provided a basis for assessing the relationship between what people say they do and what they actually do. For both sites, the case studies provide independent confirmation for the depiction of the decision-making process from the first phase of the project. This correspondence can be more clearly seen in the Pichátaro study where the decision model successfully predicted a high proportion of both initial and subsequent treatment choices, approximately 90% of all treatment actions (80% if initial home treatments, which can be seen as a “largely routine initial response,” are excluded from the calculations). Further, what the data indicated was that it was not the case that community members generally felt that biomedical treatment was incompatible with their own understandings about illness—such instances do exist but they are relatively uncommon—nor did they believe (for the vast majority of cases) that biomedical treatment was less likely to result in a cure than the other alternatives. Instead, the observed patterning in treatment actions can be accounted for by the relative inaccessibility of physician services, including the high costs of obtaining such care and transportation difficulties. A subsequent comparative study examining use of physician services in Pichátaro as well as another nearby, culturally similar

community with much better access to physician services tested the prediction that better access would result in much higher rates of physician utilization (Young & Garro, 1982). And this is what was found. The study was also designed to examine a plausible alternative explanation for the observed differences in patterns of resort, namely that the second village had a much stronger biomedical orientation with regard to illness understandings. Support for this hypothesis was not found, however, as no significant differences in illness understandings for the two communities were discovered through an analysis comparing responses to two different structured interview methods (a term–frame interview and a triads comparison task). It was not a difference in cultural knowledge, including the adoption of biomedical understandings, that accounted for the increased rates of physician utilization in the second community, but rather a reduction in the financial and structural constraints impeding care-seeking from physicians.

Still, even for studies like the one in Pichátaro where a decision model is seen to provide a reasonably good guide to an understanding of treatment actions and the culturally based rationality that underlies them, insufficient consideration has been given to the jointly cultural, social, and cognitive constructive processes through which meaning is conferred upon perceived afflictions (Garro, 1998a). To move in this direction would involve attending to how signs of trouble come to be “framed” in the context of everyday life—by individuals and in social interactions—as certain types of illness amenable to certain kinds of treatment. This framing of a problem is integral to the decision-making process but is often treated as given in decision modeling studies (cf. Mathews, 1987). Multiple possibilities may be entertained as the framing process unfolds in time, drawing upon cultural and personal knowledge, while often taking shape within social interactions and in relation to ongoing “social activity” (cf. Frake, 1961).

The import of this framing process in studies of illness treatment decision-making relates to the claim that developing and testing a decision model is better suited to accounting for treatment actions taken in the Mexican community than in the Anishinaabe community (Garro, 1998b). It is the framed situation, not the process of speculating or converging on a particular framing, that decision models are set up to handle. This precondition of a framed illness was met in the Pichátaro study, where diagnoses and other efforts characterizing illness provide

a guide to the presumed cause and suitable forms of care for an illness at a given point in time. In contrast, a greater degree of interpretive openness and ambiguity often accompany illness in the Anishinaabe community. There was an openness to framing the “same” condition in quite variable ways—an individual may juggle alternative possible framings with divergent implications for care-seeking, and family members may have different interpretations of what is going on. In addition, there was a variable potentiality for illness and its treatment to be understood within a cultural framework of Anishinaabe sickness a framework in which the underlying assumptions are distinctive from those implicit in studies of decision modeling (but which do not extend to studies of decision-making more generally). Decision models entail tacit assumptions: the problem prompting care-seeking is localized to an individual; illness episodes are discrete and bounded in time; there is a decision-making entity (person or group of persons) whose decisions are to be modeled. But these tacit cultural assumptions underlying the decision modeling approach cannot accommodate all aspects of the version of reality that often guides decisions in the Anishinaabe community. These tacit assumptions will be met in many settings; the Pichátaro study is one example. In the Anishinaabe community, however, these assumptions did not apply to an appreciable proportion of cases involving consultations with Anishinaabe healers. While research in both sites affirmed the broad applicability of a cognitive–ethnographic decision-making perspective to the understanding of actions taken in response to illness, the possibility remains that a decision-making approach may not be as productive in other cultural settings or that it may not even be applicable.

CULTURAL MODELS AND ILLNESS NARRATIVES

In the 1980s, considerable attention within cognitive anthropology became directed to cultural models: “pre-supposed, taken-for-granted models of the world that are widely shared . . . by members of a society and that play an enormous role in their understanding of that world and their behavior in it” (Quinn & Holland, 1987, p. 4). Good (1994, p. 50) points to transitional writings in medical anthropology (e.g., Clement, 1982; White, 1982a) in

which “anthropologists sought ways to represent the ‘ethnotheories’ that organize cultural worlds rather than lexical items that demarcate objects in that world.” Although not reviewed here, the increased interest in ethnopsychological approaches (e.g., Lutz, 1985; White, 1982b; White & Kirkpatrick, 1985) for exploring talk about persons, feelings, motivations, and related matters, is relevant to considerable work in medical anthropology.

Garro (1988) suggested that complementing a cultural model type approach with a cultural consensus approach could help illuminate underlying culturally shared understandings, in this instance cultural knowledge relating to high blood pressure, while providing the basis for exploring variability within a cultural setting, in this case an Anishinaabe community in Manitoba, Canada. The research design included both open-ended interviews and a series of yes/no questions about the illness asked of individuals previously diagnosed with high blood pressure. Responses to the yes/no questions were analyzed using cultural consensus analysis (with the actual questions used based on informants’ statements from an earlier series of wide-ranging informal interviews about illness and high blood pressure). The cultural consensus analysis supported the assumption of shared cultural knowledge about high blood pressure and statements with higher levels of agreement across informants were seen as more culturally salient. Responses across both sets of interviews were used to infer a prototypical cultural model for “blood that rises.” This interactive analytic process drew on the patterning among informants across both types of interview formats. The four key propositions of the prototypical model proposed revolved around the episodic and embodied nature of high blood pressure and were seen to provide a framework for interpreting and making causal attributions for perceived symptoms (the model is prototypical in terms of serving as the “best example” of cultural understandings about high blood pressure across informants). While some of the observed variation in both sets of interviews was considered to be outside the cultural model, much of the variation expressed by informants was shown to be neither idiosyncratic nor systematically patterned, but as originating in and accommodated by the key concepts of the prototypical model. Thus, personal experiences with high blood pressure and causal attributions were typically cast within the bounds of the cultural model.

Within medical anthropology, though not within cognitive anthropology more generally, a considerable

body of work pertaining to cultural models also involves narratives relating to illness. While the literature on illness narratives is wide ranging (Garro & Mattingly, 2000), here the focus is on writings that open onto viewing narrative as a mode of thinking “for ordering experience, of constructing reality” (Bruner, 1986, p. 11). Narrative is an active and constructive form of cognitive engagement that reflects participation in specific social and moral worlds and depends upon personal experience and cultural resources, including culturally available models. Along with studies of decision-making, narrative provides a way of linking together cognitive anthropology’s focus on shared cultural content with greater attention to process. Some of the ways that this has been explored are sketched out in the closing paragraphs.

Motivated by what narrators judge to be worth talking about, illness stories often convey the emotional, the moral, and the social, providing a “powerful means of socializing values and world views to children and other intimates” (Capps & Ochs, 1995, p. 13). Through both what was said and what was left unsaid, the illness stories recorded by Price (1987) in urban Ecuador contained implicit moral and affect-laden messages drawing on “situation knowledge about social roles in illness” (p. 334). Caretakers, such as the mothers of ill children, often implicitly but emphatically disclosed “I did the right thing.” Narrative recountings where individuals act counter to cultural expectations are often elaborated, judged morally commendable or reprehensible, and so emotionally charged “that it can be said that if cultural models of social roles drive the narratives, emotional propositions are the fuel that empower them” (p. 319). As Price (pp. 328–329) points out, the “situated social purposes” of narrative tellings likely opens onto different forms of cultural knowledge than what may be obtained through formal elicitation procedures.

At a pragmatic level, hearing narrative accounts is a principal means through which cultural understandings about illness—including possible causes, appropriate social responses, healing strategies, and characteristics of therapeutic alternatives—are acquired, confirmed, refined, or modified. Hearing a story augments the listener’s “fund of cultural knowledge” with which to meet the future (Price, 1987, p. 315). Studies depict how personal narratives of illness experience are shaped by social context and informed by cultural models. Cain (1991), for example, examines how the well-established model associated with Alcoholics Anonymous (AA) guides

individuals in reframing their lives as expressed in personal stories. She provides insight into the learning process and its consequences through an analysis of individual narratives at different points in this process. Through participation in AA meetings and hearing the conventionalized stories of established AA members, a culturally specific narrative form or genre is learned, a form that provides the schematic basis for the reflexive construction and communication of an individual's past: "the AA member learns the AA story model, and learns to place the events and experiences of his own life into the model, he learns to tell and to understand his own life as an AA life, and himself as an AA alcoholic" (Cain, 1991, p. 215). Through this process, an individual's life story comes to more closely resemble the prototypic AA story. The stories of those who fit the AA model of what it means to be an alcoholic come to be resources which may help guide how others come to reconstruct their past.

Even when no well-established story model exists, as in the case of a chronic and often difficult to treat illness attributed to the temporomandibular joint (TMJ), autobiographical accounts told by members of a TMJ support group living in the United States drew on broadly shared models of illness, mind, and body (Garro, 1994) that underlie and give coherence to the diversity of individual accounts. Narrative provided a vehicle for confronting contradictions between the individual's experience and expectations based on shared cultural models relating to illness and its care, divergences between what was expected and what transpired. In addition, individual narratives were structured in line with a broad model for TMJ that was shared by members of the group. This model reflected interactions with others, including treatment providers and other support group members. Past events were often reinterpreted or reconstructed as supporting the TMJ model.

In a processual ethnography that traced the emergence of a cultural model for AIDS in a village in rural Haiti, Farmer maintains that stories told about known individuals with the then unfamiliar illness, "provide the matrix within which nascent representations were anchored" (Farmer, 1994, p. 801). Consensus in cultural models associated with AIDS emerged and became established through the generation and discussion of illness stories. The model encompassed two disparate explanatory frameworks, either "naturally" (e.g., sexual contact with someone who "carries the germ") or "unnaturally"

(with AIDS being willfully and maliciously "sent" by another person).

The process of relating culturally available knowledge to a particular life context does not happen in a straightforward, deterministic manner (cf. Price, 1987). In addition to Farmer's work, other studies point to multiple, even conflicting cultural models that can potentially be applied to individual illness cases. With regard to diverse explanatory frameworks for diabetes in a Canadian Anishinaabe community, Garro (2000c) examined "how cultural knowledge serves as a resource in guiding remembering about the past." Case examples are presented to illustrate how individuals variably draw upon culturally shared knowledge in constructing a narrative account: "Through remembering, culturally available knowledge becomes situated knowledge, connected to a particular person, context and illness history." These reconstructions of past personal and collective experience played a powerful role in guiding action, influencing and justifying decisions about how to combat the illness (including decisions to reject the doctor's advice), and shaping expectations about what the future would hold. The constructive nature of remembering complicates any neat division between cognitive content and cognitive process while also providing an avenue for exploring the interdependency of social, cultural, and cognitive processes (see Garro, 2001). In a separate analysis (Garro, 2000a), a close look at the responses given in the open-ended interviews as well as the yes-no questions showed that variation in reliance on different cultural models for diabetes was also patterned along social lines that reflected different life experiences. Rather than characterizing the observed variation in a manner consistent with cultural consensus theory where differences are explained by some people knowing more and others knowing less about diabetes, the differences appeared to be more a matter of knowing differently; reflecting historically divergent experiences for which age is a convenient marker associated with differential reliance on culturally available models. Rather than focusing on depicting shared cultural content, the focus is on knowing as situated in individual life experiences, but life experiences that are socially situated and historically grounded, resulting in patterned variability with regard to what is shared.

In an article by Mathews, Lannin, and Mitchell (1994), the narrative accounts told by southern African American women with advanced breast cancer draw on

multiple sources of knowledge in “coming to terms” with a diagnosis of breast cancer and making some sense, at least provisionally, of what is happening. The multiple sources included an “indigenous model of health emphasizing balance in the blood,” popular American notions about cancer, and biomedical understandings. How women understood their own experiences with reference to these conflicting models was highly variable. Looking at instances where women worked out some form of accommodation, Mathews et al. related these narratives to ways in which different interpretive schemas can be learned and mentally stored. They maintain that narrative provides a window on the processes involved in aligning an individual’s experiences with one or more of these pre-existing cultural models and how these alignments change in light of continuing experiences and new information.

A closer look at how social processes impact on illness understandings is provided by Mathews’ (2000) work on the negotiation of cultural agreement in a spontaneously organized breast cancer self-help group in North Carolina. Having attended the group meetings since its inception, Mathews’ analysis “of a group information helps to illuminate ways in which participants actively negotiate a new set of cultural meanings, which they then use to make sense of their own personal experiences of breast cancer” (Mathews, 2000, p. 400). The shared model that emerged through ongoing discussion and negotiation was a synthesis based on the three different knowledge sources mentioned above as well as a view that God was the ultimate source of healing, but also contained a critique of certain aspects of the biomedical view of cancer and its treatment. Over time, the “initial stories of all four original members were modified, some more dramatically than others, to fit the contours of the agreed-upon model” (Mathews, 2000, p. 407).

Many of the studies reviewed in this final section open onto an understanding of how culturally based knowledge and the social world form and inform each other. With reference to narrative accounts of troubling experiences that come to be understood as illness, Garro (2003) presents a process-oriented perspective for constructing illness through available cultural resources. Rather than regarding culture as content, a process-oriented perspective draws attention to how culturally available interpretive frameworks—some widely shared and others not—serve as resources which may be variably drawn upon to navigate the ambiguity surrounding

illness; resources which both enable and constrain interpretive possibilities. In the narrative accounts examined, social interactions guide the interpretation of experience with regard to pre-existing shared models but the diversity of cultural resources for making narrative sense of troubling experience leaves open alternate framings with divergent implications. Garro’s formulation of a process-oriented perspective revolves around the interplay between the range of historically contingent cultural resources available for endowing experience with meaning and the socially and structurally grounded processes through which individuals learn about, orient toward, and traffic in interpretive plausibilities.

Critical Medical Anthropology

Merrill Singer

BACKGROUND

Since its inception, medical anthropology has had an applied orientation; much of the work done by medical anthropologists is concerned with understanding and responding to pressing health issues and problems around the world as they are influenced and shaped by human social organization, culture, and context. Despite its strong emphasis on addressing practical health issues, initiatives within the discipline have tended to be guided by one or another of several alternative theoretical perspectives. While the boundaries between these frameworks for explaining health in a socio-cultural context have not been always sharply defined, and, although there have been disagreements about which are the leading theoretical approaches at any point in time, most medical anthropologists are influenced in their work by the dominant theories within the field.

Several efforts have been made to describe and contrast the most influential theories within medical anthropology. In his book *Sickness and healing: An anthropological perspective*, Robert Hahn (1995) identified three dominant theoretical frameworks within medical anthropology, including environmental/evolutionary theories, cultural theories, and political/economic theories. In his book, *Medicine, rationality, and experience: An anthropological perspective*, Byron J. Good (1994) identified four theoretical orientations found in medical anthropology: the empiricist paradigm, the cognitive paradigm, the meaning-centered paradigm, and the critical paradigm. Finally, in *Medical anthropology in ecological perspective*, Ann McElroy and Patricia Townsend (1996) also discussed four approaches, namely medical ecological theories, interpretive theories, political economy or critical theories, and political ecological theories. Despite these varying ways of grouping and ordering conceptual

and explanatory models in medical anthropology, it is evident that there is general agreement that there are a small number of identifiable clusters of theory guiding the work that is done within the field. Prominent among these is the perspective that has been labeled either critical medical anthropology (CMA) or, less frequently, political economic medical anthropology (PEMA) (Baer, Singer, & Susser, 2002; Morsy, 1996).

THE CRITICAL PERSPECTIVE IN THE HEALTH SOCIAL SCIENCES

During its formative phase, explanations within medical anthropology tended to be narrowly focused on the micro level and involved explaining health-related beliefs and behaviors at the local level in terms of specific ecological conditions, cultural configurations, or psychological factors. From the perspective of CMA, these traditional approaches, while providing insight into the nature and function of folk medical models, tended to ignore the wider causes and determinants of human decision-making and action. From the critical vantage, explanations that are limited to accounting for health-related issues in terms of the influence of human personalities, culturally constituted motivations and understandings, or even local ecological relationships are inadequate because this distorts and hides the structures of social relationship that unite (in some, often unequal fashion) and influence far-flung individuals, communities, and even nations. A critical understanding, by contrast, involves paying close attention to what Mullings (1987) has called the “vertical links” that connect the social group under study to the larger regional, national, and global human society and to the configuration of social relationships that contribute to the patterning of human behavior, belief, attitude, and emotion. For the last 150 years, this broader, encompassing perspective has been known as political economy, although, as Morsy (1996) emphasizes, its deeper roots can be traced to the thinking of Abdul Rahman Muhammad Ibn Khaldun, a 14th century North African scholar.

Despite the frequency with which the term “political economy” is used in the social science literature, it is not certain that a clear understanding of the term exists. In part, this confusion may be rooted in the fact that the most common meanings attached to the term have changed over time. Eric Wolf, in his seminal political economic study entitled *Europe and the People Without History*,

examined the nature of this socio-linguistic change and its underlying causes. As Wolf (1992, pp. 7–8) emphasizes, the field of political economy predates and was parent to contemporary social sciences such as sociology, anthropology, economics, and political science. Until the middle of the 19th century, political economy referred to study of “the wealth of nations,” which included the production and distribution of wealth within and between political bodies and the social classes that composed them. But events at mid-century led the global field of political economy to fragment, and research into the nature and varieties of human society split into separate (and unequal) specialties and disciplines (Wolf, 1992).

The key events in question, namely the rise to dominance of the capitalist mode of production and of a set of opposed social classes brought into existence by it, disrupted the unity not only of social inquiry but, ultimately, the pre-existent frameworks of cohesiveness and health configurations of all societies around the globe as well. By mid-century, the specter of revolution hung in the air in Europe and eventually found expression in the armed clashes of a looming class war. In the midst of mounting turmoil, the question of the nature of social solidarity and social order was raised as a burning issue of structurally determined scholarly interest, suggesting the usually unspoken social function of much academic inquiry. The field of sociology branched off from political economy with the expressed mission of delving into the structure of social relations and social institutions. The new disciple came to define the core challenge as understanding the character of the bonds and associated cohesion-generating beliefs and customs that tie individuals together to form families, small groups, institutions, and whole societies. Quickly the early sociologists came to view ties among individuals and the development of community as the casual engine driving the functioning and unity of society. In this way, the issues of concern to political economy, including how ties among individuals are shaped by the relations among classes in the production of national and international wealth, were submerged.

While sociology focused its attention on the grand industrial societies brought into existence by the rise of capitalism, anthropology, its exotic sister discipline, developed as the study of the small-scale, non-Western societies situated in the interstitial spaces between and within industrial centers. Under the methodological banner of direct observation in natural settings, anthropologists came to

concentrate their investigative lens on the subtle details and unique social and cultural configurations of individual cultural cases, while, as noted, ignoring, for the most part, the sweeping processes and broader social relations that transcend micro populations historically tying them to each other and to developments within capitalist mode of production (e.g., the emergence of the national corporation and later the multinational corporation and subsequent rise of globalism). Wolf (1992) argues that all the contemporary social sciences, each of which now has developed its own approach to (and subdiscipline concerned with) health issues, owe their existence to a shared rebellion against political economy, which had been their parent discipline.

In the aftermath of this transition, and with the rise of a new set of conventional perspectives within the social sciences, those individuals who still attempted to promote a critical political economic orientation tended to be marginalized within their respective disciplines. As Navarro (1986) argues, even the terms of political economic discourse have been tainted. In mainstream scholarship, concepts and terms such as class struggle, capitalism, and imperialism are frequently treated as rhetorical and are dismissed by the dominant schools. Further, such terms often are written between quotation marks, presumably to alert the reader that they are under suspicion. Marxists who submit papers to social science journals commonly are instructed to rewrite their papers using “fewer value-laden terms” that are more attune to prevalent sociological thought.

Despite discrimination, an academic tradition of political economy of health survived and the literature associated with this perspective began to grow during the 1970s, becoming considerable during the 1980s and 1990s. Adherents, individuals who embrace the notion that social inequality and inequality of power in society are primary determinants of health, health-related behavior, and health care, see the critical approach as offering a much needed corrective for the disciplinary fragmentation of social science that hides the relationship among economic systems, political power, and social ideologies (Wolf, 1992).

THE ORIGIN OF CRITICAL MEDICAL ANTHROPOLOGY

Medical anthropology as a distinct, named subdiscipline of anthropology can be traced to the 1950s. Otto von

Mering (1970, p. 272), however, contends that the formal relationship between anthropology and medicine is much older and began when Rudolf Virchow, a renowned pathologist interested in social medicine, helped to establish the first anthropological society in Berlin. Indeed, Virchow influenced Franz Boas, the father of American anthropology, while he was affiliated with the Berlin Ethnological Museum during 1883–1886 (Trostle, 1986, p. 45). Nevertheless, the keen political economic perspective that Virchow fostered did not really have its impact on medical anthropology until the 1970s.

The initial effort to develop a distinct critical orientation within medical anthropology can be traced to the symposium “Topias and Utopias in Health” at the 1973 Ninth International Congress for Anthropological and Ethnological Sciences, which ultimately developed into a volume with the same title (Ingman & Thomas, 1975). Six years later, a consciously critical perspective within medical anthropology was launched by Soheir Morsy’s (1979) review essay entitled “The Missing Link in Medical Anthropology: The Political Economy of Health.” Morsy’s article, as well as exposure to the political economy of health literature, particularly the work of Vicente Navarro, a progressive physician with extensive training in the social sciences, prompted Hans Baer (1982) to write a short review of this corpus of literature and its relevance for medical anthropologists. Beginning in 1983, Baer and others began organizing scholarly sessions at anthropological meetings and editing and writing articles, special issues of journals, and books on critical medical anthropology (Baer, 1996; Baer, Singer, & Johnson, 1986; Crandon-Malamud, 1991; Farmer, 1999; Frankenberg, 1980, 1981; Morsy, 1993; Scheper-Hughes, 1990; Singer, 1986, 1989; Singer & Baer, 1995; Singer, Baer, & Lazarus, 1990). Central to this effort has been the “making social of disease” (Frankenberg, 1980, p. 199).

The emergence of CMA reflects both the turn toward political-economic approaches in anthropology in general and an effort to engage and extend the broader political economy of health tradition by marrying it to the micro-level understandings of on-the-ground behavior in local settings and socio-cultural insights of medical anthropology. As Morsy (1996) notes, the critical approach to health in medical anthropology is distinctive not simply because of its scope and concern with the macro level, but more importantly by its commitment to embedding culture in historically delineated political-economic contexts. The goal is not to dismiss the contributions of microanalyses

of illness and healing but rather to extend the realization of the relevance of culture to issues of power, control, resistance, and defiance associated with health, illness, and healing (Morsy, 1996).

KEY CONCEPTS IN CRITICAL MEDICAL ANTHROPOLOGY

Health

Conventionally, within the dominant perspective of biomedicine, health has tended to be thought of as the absence of disease. The World Health Organization (WHO), recognizing the shortcomings of this biomedical model of health, sees health as the possession of complete physical, mental, and social well-being (WHO, 1978). What are the barriers to achieving well-being of this sort? From the critical perspective, in the contemporary world, such barriers include social inequality, class, gender, racial, and other discrimination, poverty, structural violence, social trauma, relative deprivation, being forced to live or work in a toxic physical environment, and related factors. Consequently, within CMA health is defined as access to and control over the basic material and non-material resources that sustain and promote life at a high level of satisfaction. Health is not some absolute state of being but an elastic concept that must be evaluated in a larger socio-cultural context.

Disease

Even under the best of circumstances, human beings inevitably find themselves confronted with disease or illness. As it is for biomedicine, a central question for medical anthropology must be: What is disease? It is clear why this question is important to biomedicine. Medical anthropologists, however, have tended to avoid the question altogether by defining "disease" (i.e., clinical manifestations of ill health) as the domain of medicine and "illness" (i.e., the sufferer's experience of those manifestations) as the appropriate arena of anthropological investigation. From the perspective of CMA, however, defining disease as beyond the concern or expertise of anthropologists is a retreat from ground that is as much social as it is biological in nature. Disease varies from society to society in significant ways because of organic, climatic, or geographical conditions, but also because of

the ways productive activities, resources, and reproduction are organized and carried out, and because of the living and working conditions that flow from the social distribution of resources. From the CMA perspective, discussion of specific health problems, apart from their social contexts, only serves to downplay social relationships underlying environmental, occupational, nutritional, residential, and experiential conditions. Disease is not just the straightforward result of a pathogen or physiological disturbance. Instead, a variety of social problems such as malnutrition, economic insecurity, occupational risks, industrial pollution, substandard housing, and political powerlessness contribute to susceptibility to disease (Baer, Singer, & Johnson, 1986). In short, disease is as much social as it is biological. In this light, the tendency, be it in medicine or in medical anthropology, to treat disease as a given, as part of an immutable physical reality, contributes to the tendency to neglect its social origins. CMA strives, in McNeil's (1976) terms, to understand the nature of the relationship between microparasitism (the "tiny organisms," malfunctions, and individual behaviors that are the proximate causes of much sickness) and macroparasitism (the social relations of exploitation that are the ultimate causes of much disease). For example, an insulin reaction in a diabetic postal worker might be seen in a very reductionist mode as an excessive dose of insulin that causes an outpouring of adrenaline, a failure of the pancreas to respond with appropriate glucagon secretion, etc. However, a critical perspective would tend to lead a researcher to investigate whether the postal work skipped breakfast because of being late for work, the psychobiological effects of the derisive demands of a supervisor, or the inability to break for a snack because of pressure from above to increase productivity, or, more broadly, the health consequences of the structure of class forces in U.S. society that ensures capitalist domination of production and the moment working lives of working people like postal employees (Woolhandler & Himmelstein, 1989).

Syndemics

As part of its effort to identify and understand health within the intersecting frameworks of political economy and bio-social causality, the CMA approach to the study of disease is characterized by the investigation of a set of factors including biology, epidemiology, sufferer and community understandings of the disease(s) of concern,

and the social, political, and economic conditions that may have contributed to the development of ill health. To help frame this “big picture” approach to the conception of diseases, critical medical anthropologists introduced the concept of “syndemic” in the mid-1990s (Singer, 1994, 1996). While biomedical understanding and practice, traditionally, have been characterized by the tendency to isolate, study, and treat diseases as if they were distinct entities that existed separate from other diseases and independent of the social contexts in which they are found, CMA, by contrast, focuses on trying to understand social and biological interconnections as they are shaped and influenced by inequalities within society. At its simplest level, and as now used by some researchers at the Centers for Disease Control and Prevention (CDC), the term syndemic refers to two or more epidemics (i.e., notable increases in the rate of specific diseases in a population), interacting synergistically with each other inside human bodies and contributing, as a result of their interaction, to excess burden of disease in a population. As Millstein (2001), the organizer of the Syndemics Prevention Network at the CDC, notes, syndemics occur when health-related problems cluster by person, place, or time. Importantly, the term syndemic refers not only to the temporal or locational co-occurrence of two or more diseases or health problems, but also to the health consequences of the biological interactions among co-present diseases. For example, researchers have found that co-infection with HIV and *Mycobacterium tuberculosis* (MTb) augments the immunopathology of HIV and accelerates the damaging progression of HIV disease (Ho, 1996). At the same time, studies have shown that because HIV damages human immune systems, individuals with HIV disease who are exposed to TB are more likely to develop active and rapidly progressing tuberculosis compared with those who are HIV negative. The important feature of syndemics is not just co-infection but enhanced infection due to multiple disease interactions. Importantly, beyond the notion of disease clustering in a social location or population and the biological processes of disease interaction, the term syndemic also points to the determinant importance of social conditions in disease interactions and consequences. For example, as Paul Farmer (1999, p. 13) argues, if we look at the persistence of TB in poor countries and its resurgence among the poor in industrialized countries, we find that it is impossible to understand its marked patterned occurrence—in the United States, for example, disproportionately

striking those in homeless shelters and in prisons—without assessing how social forces, such as political violence and racism, come to be embodied and expressed as individual pathology (Farmer, 1999). Living in poverty increases the likelihood of exposure to the bacteria that causes TB because of overcrowding in poorly ventilated dwellings. Research in homeless shelters has shown that they are a focal point of TB transmission among the poor. Once infected, the poor are more likely to develop active TB, both because they are more likely to have multiple exposures to the TB bacteria (which may push dormant bacteria into an active state) and because they are more likely to have pre-existent immune system damage from other infections and malnutrition. Also, poverty and discrimination place the poor at a disadvantage in terms of access to diagnosis and treatment for TB, effectiveness of available treatments because of weakened immune systems, and ability to adhere to TB treatment plans because of structurally imposed residential instability and the frequency of disruptive economic and social crises in poor families. As the case of TB suggests, diseases do not exist in a social vacuum nor solely within the bodies of those they inflict, and thus their transmission and impact is never merely a biological process. Ultimately, social factors such as poverty, racism, sexism, ostracism, and structural violence may be of far greater importance than the nature of pathogens or the bodily systems they infect. A shift in focus from individual diseases to syndemics and even individual diseases in social contexts allows a more encompassing understanding of disease as far more than a clinical challenge.

Sufferer Experience

Medical social scientists have become increasingly concerned about sufferer experience—the manner in which an ill person manifests his or her disease or distress. Writing from a critical perspective, Margaret Lock and Nancy Scheper-Hughes have criticized the Cartesian duality of body and mind that pervades biomedical theory (Lock & Scheper-Hughes, 1996). In this effort, they have made a significant contribution to an understanding of sufferer experience by developing the concept of the “mindful body” (Scheper-Hughes & Lock, 1987). Lock and Scheper-Hughes delineate three relevant “bodies” in health: the individual body, the social body, and the body politic. An individual’s image of his/her body, whether in a state of health and well-being or in a state of distress or

disease, is mediated by particular meanings of being human as defined by the local cultural system. The body also serves individuals in society as a cognitive map of their conceptions of natural, supernatural, socio-cultural, and spatial relations. Further, individual and social bodies express power relations in both a specific society or in the world system.

Sufferer experience can be understood, therefore, as a social product, one that is constructed and reconstructed in the action arena between socially constituted categories of meaning and the political-economic forces that shape daily life. Although individuals often react to these forces passively, they may also respond to economic exploitation and political oppression in very active ways. In her highly acclaimed and controversial book *Death without weeping: The violence of everyday life in Brazil*, Scheper-Hughes (1992), for example, presents a vivid and moving account of human suffering in Bom Jesus, an abjectly impoverished *favela* or shantytown in northeastern Brazil. She contends that the desperate and constant struggle for basic necessities in this community induces in many mothers an indifference to the weakest of their offspring. Scheper-Hughes argues that ultimately the suffering of the mothers, their children, and others in Bom Jesus is intricately related to the collapse of the local sugar plantation industry, which has left numerous people in the region without even a subsistence income. Most of the residents of Bom Jesus have not benefited from the development of agribusiness and industrialization sponsored by both transnational corporations and the Brazilian state. Their suffering, in short, is far from a local phenomenon, and certainly not a narrowly individual experience, but rather it is intimately connected to global changes in the capitalist world economic system as these are played out on the local stage of Bom Jesus.

Medicalization

This process entails the absorption of ever-widening social arenas and behaviors into the jurisdiction of biomedical treatment through a constant extension of pathological terminology to cover new conditions and behaviors. Health clinics, health maintenance organizations, and other medical provider organizations now offer classes on managing stress, controlling obesity, overcoming sexual impotence, alcoholism, and drug addiction, and promoting smoking cessation. Even the birth experience, not just in the United States but also in many

countries that pride themselves on undergoing modernization, has been distorted into a pathological event rather than a natural physiological one for childbearing women and their families. Aspects of the medicalization of birthing, for example, include (1) the withholding of information on the disadvantages of obstetric medication, (2) the expectation that women give birth in a hospital, (3) the elective induction of labor, (4) the separation of the mother from familial support during labor and birth, (5) the confinement of the laboring woman to bed, (6) professional dependence on technology and pharmacological methods of pain relief, (7) routine electronic fetal monitoring, (8) the chemical stimulation of labor, (9) the delay of birth until the physician's arrival, (10) the requirement that the mother assume a prone position rather than a squatting one, (11) the routine use of regional or general anesthesia for delivery, and (12) routine episiotomy (Haire, 1978, pp. 188–194). Beginning in the 1970s, the feminist health movement, an expression of resistance and advocacy in the health arena, has prompted many women and men to challenge many of these practices and has contributed to a heavier reliance on home births conducted by a now significant cadre of lay midwives in industrialized societies. One factor driving medicalization is the profit to be made from “discovering” new diseases in need of treatment. Medicalization also contributes to increasing social control on the part of physicians and health institutions over behavior. It serves to mystify and depoliticize the social origins of personal distress. Medicalization transforms problems at the level of social structure—such as stressful work demands, unsafe working conditions, and poverty—into individual-level problems subject to medical control (Waitzkin, 1983).

Medical Hegemony

Underlying the medicalization of contemporary life is the broader phenomenon of medical hegemony, the process by which capitalist assumptions, concepts, and values come to permeate medical diagnosis and treatment. Antonio Gramsci, an Italian political activist who fought against fascism under Mussolini, developed this concept as an elaboration upon Marx and Engels' observation that the ideas of the ruling class are, in every age, the ruling ideas in society. Whereas the ruling class exerts direct domination through the coercive vehicles of the state apparatus (e.g., the government, courts, military, police,

prisons), hegemony, as Femia (1975) observes, is exercised through the institutions of civil society such as the educational system, religious institutions, and the mass media. Hegemony refers to the process by which one class exerts control of the cognitive and intellectual life of society by structural means as opposed to coercive ones. Hegemony is achieved through the diffusion and constant reinforcement throughout the key institutions of society of certain values, attitudes, beliefs, social norms, and legal precepts. Doctor–patient interactions also constitute an arena of hegemonic interaction. Studies of these interactions show that they commonly reinforce non-egalitarian hierarchical structures in the larger society by (1) stressing the need for the patient to comply with a social superior’s or expert’s judgment, and (2) directing patient attention to the immediate causes of illness (e.g., pathogens, diet, exercise, smoking) and away from structural factors (over which physicians feel they have little control). For example, although a patient may be experiencing job-related stress caused by an onerous work environment, the physician may prescribe a sedative to calm the patient rather than challenging the power of an employer or supervisor over employees. In the contemporary world, globalization is a primary engine of medical hegemony. As Whiteford and Manderson (2000) stress, the forces shaping the contemporary health scene, for example health care and health practices around the world, including those promoted by the main international lending institutions upon which many countries are fiscally dependent, derive from Western domination and reflect Western values of rationality, competition, and progress, in all of which contexts there is an implicit assumption that with modernization local “traditional” institutions and structures in and out of health care will be replaced by Western alternatives.

Medical Pluralism

Regardless of their degree of complexity, all health care systems are based upon a dyadic core consisting of a healer and a patient in interaction. The healer role may be occupied by a generalist, such as the shaman in preindustrial societies or the family physician in modern societies. It may also be occupied by a complex array of specialists from herbalists to oncologists even within a single society. Rather than a single medical system, contemporary societies can sport a pluralistic set of healing traditions, some of indigenous origin within particular

subgroups in society and others imported from other societies. Medical pluralism, which flourishes in all class-divided societies, tends to mirror the wider sphere of unequal social relationships, with the patterns of hierarchy among co-present medical systems being based upon the reigning structure of class, caste, racial, ethnic, regional, religious, or gender distinctions. It is perhaps more accurate to say that national medical systems in the modern or postmodern world tend to be “plural,” rather than “pluralistic,” in that biomedicine enjoys a dominant status over all heterodox and ethnomedical practices. In reality, plural medical systems may be described as “dominative” in that one medical system generally enjoys a pre-eminent status vis-à-vis other medical systems (Baer, 1989). While within the context of a dominative medical system one healing tradition attempts to exert, with the support of elites of society, dominance over other medical traditions, people are quite capable of the simultaneous use of quite distinct medical systems.

THE IMPACT OF CRITICAL MEDICAL ANTHROPOLOGY STUDIES

As Morsy (1996) observes, a review of the CMA literature shows that this genre of medical anthropology spans a range of both substantive and analytical concerns. Critical medical anthropologists have worked on a growing number of health-related issues and health conditions, including mental health, illicit substance abuse, smoking, AIDS, homelessness, reproduction, folk healing, infant care and mortality, diabetes, medical pluralism, immunology, nutrition, health policy, health care disparities, the pharmaceutical industry, rural health services, doctor–patient relationships, the role of the state in primary health care, and medical hegemony. As this (quite partial) list suggests, CMA theory has fostered numerous research and explanatory efforts and proven to be particularly fertile ground for the development of new explanatory concepts and new research questions. Consequently, the CMA perspective has not only strongly influenced the work of many medical anthropologists who define themselves as working in a critical vein, but its emphasis on the fundamental importance of considering political economic factors in health has influenced the work of many medical anthropologists identified with an alternative explanatory framework. In fostering debate among the various perspectives in medical anthropology,

CMA also has contributed to a greater focus on theory in what, as noted, has tended to be a highly applied subdiscipline.

Evolutionary and Ecological Perspectives

Ann McElroy

A NEW SYNTHESIS: THE EVOLUTION AND ECOLOGY OF DISEASE

Evolutionary and ecological perspectives have transformed medical anthropology from a traditional focus on cultural aspects of health and healing and comparative study of medical systems to a broader perspective on human health in an environmental context. This transformation has been truly interdisciplinary. Medical ecologists, human biologists, and health practitioners have joined forces with epidemiologists, medical geographers, and medical historians to generate a new synthesis in the anthropological study of health. The scope of this review ranges from classic studies in medical ecology to current trends in Darwinian medicine, with focus on the history, methods, controversies, and debates associated with ecological and evolutionary perspectives in medical anthropology.

History

Field research in the mid-20th century on disease distribution and human adaptation in various habitats formed a solid foundation for foraging theoretical links among medicine, ecology, and evolution. In *The Ecology of Human Disease* (May, 1958), physician and geographer Jacques May applied spatial analysis to regional and cultural differences in malaria prevalence in Vietnam. Livingstone (1958) correlated hemoglobin frequencies with the histories of migration and ecological change in West Africa. Research on the microevolution of indigenous South American populations (Neel, 1971) generated profiles of genetic differences and disease resistance in relatively isolated foragers and cultivators. Research among high-altitude peoples by Baker and Little (1976) and colleagues revealed the physiological plasticity of humans and the limits to adaptability in rigorous environments. Field studies in subarctic regions (Steggmann, 1983) and in the Arctic (Laughlin, 1964) explored the

subtle interplay of adaptive genetic, physiological, and behavioral responses to cold environments.

An early formulation of the connections between health practices and evolutionary theory was Alland's *Adaptation in cultural evolution: An approach to medical anthropology* (1970). This pioneering work helped to crystallize the emerging field of medical anthropology and provided models for studying the health repercussions of ethnomedical practices. In applying game theory and risk-benefit analyses to agricultural and dietary practices, Alland suggested that cultural evolution involved trial-and-error adaptive strategies.

The classification of medical ecology as a distinct subfield of medical anthropology was formulated in Fabrega's volume, *Disease and Social Behavior* (1974). Landy (1977, p. 12) noted that the ecological approach directly linked to evolutionary theory and held "great promise for anthropology." Anthropologists refined the concepts of ecosystem and evolutionary ecology throughout the 1980s, building on earlier formulations by Geertz (1963), Rappaport (1968), Steward (1955), and many others, and developing a new methodology for studying environmental variables in relation to subsistence, population size, and health (Moran, 1984). Regional field studies (cf. Schull & Rothhammer, 1990) and reviews of urban ecology and health in developing countries (cf. Schell, Smith, & Bilsborough, 1993) demonstrated the strengths of ecological models in research. With ecology and environment the central focus of several teaching texts (Moore et al., 1980; McElroy & Townsend, 2003; Townsend, 2000), the medical ecology paradigm has become well established.

Methods

Medical ecology is a theoretical orientation rather than a formal theory (Wellin, 1977), encompassing a broad systems approach in research. Hence the choice of research methods is eclectic, ranging from clinical measures (anthropometrics, fecal analysis for parasites, blood

pressure readings) to standard ethnographic techniques (census and mapping, nutrition studies, genealogies) to geographic information systems (GSI) analysis. Medical ecology is explicitly a field science, whether in rural or urban settings, with small-scale foraging societies or with migrants and squatter residents in large cities, and often involves multidisciplinary teams collaborating in data collection. Although traditionally the preferred field site has been one or a few isolated, indigenous communities, increasingly studies of human adaptation have shifted to regional analysis, systematic sampling, and incorporation of historical and economic variables (Moran, 2000, pp. xix–xx). The gold standard for studies of health in an environmental context included the collection of field data from a wide sample of households and communities, archival research on historic change, and ethnographic interviews to assess health behaviors and beliefs.

Evolutionary studies may involve the collection of samples in the field for later analysis, but research is also likely to take place in laboratories, using diagnostic equipment and computer analysis of genetic, demographic, and epidemiological data. Scholars of evolutionary medicine are often trained in physical anthropology and human biology, and some have medical degrees as well. Thus all the research methodologies of forensic anthropology, paleoanthropology, comparative anatomy, and clinical medicine can be put to use in testing hypotheses regarding the evolution of adaptive and maladaptive traits in various human populations.

ECOLOGY AND DISEASE

Medical ecology studies health and disease in an environmental context. Central to the model is the concept of ecosystem: a set of relationships among organisms within a given environment that provides both opportunities and constraints (Moran, 2000). The environment has three major components: biotic elements (sources of food, building materials, predators and vectors), abiotic (climate, solar energy, inorganic materials), and cultural elements (human systems). Each of these components play a central role in human well-being and survival.

Equilibrium and Change

Just as genetic variation and natural selection are key components of evolutionary medicine, models of

equilibrium and change are central to medical ecology. Fluctuations among, or disruption of biotic, abiotic, and cultural subsystems are part of normal cycles and can be accommodated to a certain extent through a variety of adaptive mechanisms, both at the individual level and the population level. But when too severe an imbalance occurs, repercussions may include environmental degradation, loss of resources, population decline, changes in trophic (feeding) relations, and disease. This model suggests that the health of a population is a function of its ecosystem and of the adaptive mechanisms used by the population to maintain its place in the ecosystem (Moran, 2000). Yet adaptation does not always lead to optimal health; examples abound throughout history and prehistory of populations threatened by the long-term repercussions of their own subsistence, as well as of societal segments that do not benefit or flourish within the midst of profitable and productive economies.

When human activities (e.g., farming or building roads) disrupt the ecological niches of other fauna, subsistence changes may bring increased food security but also increased disease prevalence. On the one hand, the massive development projects of the last century have contributed to sharp increases in the incidence of previously endemic diseases. On the other hand, public health promotion of childhood immunization, nutritional supplements, improved water systems, and disease prevention have led slowly to the “epidemiological transition” of the 20th century, with lowered infant mortality and longer average life expectancy.

Infectious disease patterns vary by subsistence type and by region, but no society is free from disease. Medical ecologists are particularly concerned with “emerging” (and re-emerging) infectious diseases: HIV/AIDS, dengue fever, West Nile virus, antibiotic-resistant strains of tuberculosis, trypanosomiasis, schistosomiasis, Chagas’ disease, and others. Malaria is among the most significant of the resurgent diseases. Once relatively contained by DDT, the anopheline vectors are now resistant to insecticides, and the parasites causing malaria have mutated into resistant strains. The current crisis in preventing malaria is due not only to biological change in disease agents, but also to poverty, malnutrition, and inadequate healthcare in the regions most sharply affected. This case demonstrates political ecology, an approach which includes economic and social factors in conceptual models (Brown, Inhorn, & Smith, 1996).

Reproductive Ecology

Human reproduction is affected by ecological factors such as seasonal variability in food, environmental carrying capacity, the production roles and spatial distribution in work of men and women, and diseases causing infertility or subfecundity (Townsend & McElroy, 1992). Studies of reproductive ecology have been carried out in isolated populations by Konner and Worthman (1980), Ellison (1990), and Binford and Chasko (1976). MacCormack (1994) was among the first anthropologists to focus on women as energy producers, with trade-offs between subsistence and reproductive roles. The idea of trade-offs, or reproductive compromises, is also fundamental in the work of Trevathan (1987), not only in a socio-cultural sense, but also in terms of the evolution of human fetal development and gestational parameters.

Controversies in Medical Ecology

Medical ecology has been criticized by cultural anthropologists and by critical medical anthropologists, who argue that adaptation theory, or “adaptationism,” is politically conservative. Believing that adaptation theory explains poor health as evidence of “inferior genes,” some equate medical ecology to Social Darwinism. One positive outcome of this dialogue has been steps toward merging medical ecology and the political economy of health into a “political ecology of health.” This developing subfield holds promise for future research.

A second area of controversy is whether ecological models and methods, derived from studies of animal populations, can be applied accurately to human populations, given the far-reaching influence of culture. The concept of carrying capacity is particularly problematic, in the sense that it has been difficult to demonstrate that human regulation of family size or of sex ratios in offspring is directly related to environmental resources (Smith & Smith, 1994).

Despite these criticisms, medical ecology remains promising in the study of health in rigorous environments in which the limits of human plasticity and cultural ingenuity are tested. Traditionally these environments were those of climatic and barometric extremes. In recent years, extreme outposts such as Antarctic research facilities, submarines, and space stations have posed new challenges of crowding, isolation, and boredom. The application of medical ecology in these settings may prove productive in future research.

EVOLUTIONARY PERSPECTIVES ON DISEASE

Evolutionary perspectives encompass two dimensions: the evolution of disease organisms affecting human populations, and the impact of human biological and cultural evolution on the behaviors of these organisms, including interactions between vectors and hosts. Medical anthropologists also study evolutionary models of sickness behavior.

Evolution and Disease

Evolutionary medicine, also called Darwinian medicine, derives its intellectual and theoretical base from the theory of natural selection. Differences in mortality and reproductive success linked to genetic traits lead to the differential intergenerational transmission of those traits. Traits that emerge from random mutations and that prove beneficial in given environments are differentially transmitted and retained under selective mortality over many generations. Selective forces include climate, altitude, food availability, environmental hazards, and disease.

Hypothetically, genetic variation providing resistance to infection, accommodation to nutritional deficiency, or acclimation to environmental constraints such as hypoxia are retained at varying rates in diverse populations due to differential survival and differential reproduction. That is to say, variants are correlated with increased Darwinian fitness. Stressors affecting the survival of children and the fecundity of young adults are most pertinent. While discrete genetic markers such as hemoglobin variants are easiest to correlate with morbidity, mortality, and fertility rates, behavioral traits may clearly correlate with fitness. Pregnancy management techniques, dietary patterns, birth systems, and infant care are non-genetic variables with immense importance in maternal and child survival rates in rigorous or pathogenic environments.

Differential fitness involves more than disease resistance, of course. The evolution of successful reproductive traits and strategies is a central interest in biocultural anthropology (Trevathan, 1987) and underlies much of “life history” theory (Hill & Hurtado, 1996). Parental care (especially maternal stimulation and bonding) has been studied in relation to normal and abnormal infant and child development in various environments,

including historical conditions of extreme poverty in which child abandonment and infanticide were common (Hrdy, 1999).

The Evolution of Disease

In tracing the etiology of a disease or symptoms, evolutionary medicine distinguishes proximate and ultimate causation, following Mayr's 1961 dichotomy (Durham, 1991). The proximate cause of type II (non-insulin dependent) diabetes mellitus is the inefficient use of insulin by the body. Genetic predisposition to this type of diabetes, typically seen in older adults, appears maladaptive. However, the ultimate causation in an evolutionary sense can be discovered in the pressures of prehistoric times. Given the unreliability and fluctuation in food supplies for foragers and cultivators, genes that increased the efficiency of energy extraction from food sources and increased storage of dietary energy would prove particularly critical for survival in times of food shortages or famine. However, contemporary populations who have inherited the trait, called a "thrifty genotype" (Neel, 1962), may find that this genetic pattern is no longer adaptive in situations of ample or excessive food supplies, especially carbohydrates.

Paradoxically, the concept of "adaptive trait" comes from analysis of homozygous inheritance of alleles leading to clinical problems such as sickle cell anemia, thalassemia, and G6PD deficiency (Greene & Danubio, 1997). In heterozygous inheritance, a modified genotype may change host characteristics so that a parasite cannot function normally, in many cases providing disease resistance or immunity. In homozygous form, the genotype may be deleterious to the host.

Evolutionary medicine provides clues for understanding chronic degenerative diseases (CDD) that affect elders in contemporary populations. The human species evolved over several million years in ecosystems unlike from the modified environments and subsistence patterns of the last 10,000 years. The human genome derived from a highly active, mobile lifestyle, an omnivorous, high-protein diet, a relatively short average life expectancy, and endemic parasitic infections. As Gerber and Crews (1999, p. 447) note, "alleles that have been retained in the gene pool are those associated with enhanced early survival, growth, development, and maturation to reproductive age, regardless of any late-acting detrimental effects they may have." Alleles that

predispose individuals to physiological degeneration in mid-life, for example, through type II diabetes, gall bladder disease, autoimmune diseases, and hypertension, are examples of antagonistic *pleiotropy*, that is having opposite effects on fitness at different ages (Gerber & Crews, 1999, p. 446).

In addition to recasting the ailments of old age as evolutionary byproducts, Darwinian medicine also interprets health problems of youth, for example, neonatal jaundice, through an adaptive framework. Neonatal jaundice involves excessive bilirubin levels in the blood, indicating inadequate clearance of red blood cells and other proteins and slowed elimination of waste products through the intestinal tract. Elevated bilirubin can be toxic in the brain, leading to disability, hearing loss, or death (Brett & Niermeyer, 1999, p. 8).

Since more than half of all newborns, especially breast-fed infants, develop jaundice in the first week of life without experiencing neurological complications, evolutionary medicine asks the logical question: Is this condition a disease? In the majority of infants, does it serve an adaptive function? Or was it adaptive in our evolutionary past? Brett and Niermeyer (1999, pp. 9, 14–15) suggest that bilirubin serves as an antioxidant in a stressful, relatively oxygen-rich environment. The infant's antioxidant enzyme defenses are immature in a situation of exposure to high levels of oxygen free-radicals in the lungs. Thus elevated levels of bilirubin may provide a selective advantage.

Similar analyses have been applied to infant colic, a mysterious condition of prolonged crying that seems to peak at two months and then gradually dissipates. In an evolutionary sense, crying represents an infant's communication to elicit feeding and care. Because care-givers and infants are often spatially separated in contemporary households, infant crying may be prolonged and fretful because of the difficulty of securing feeding and comfort. Rather than treating the infant, the implications of this perspective is that parental care-giving patterns could be modified (Barr, 1999).

The Evolution of Healing Behaviors

Current interpretations of the origins of health-maintaining behaviors and of medical systems posit the evolution of "healmemes" in higher primates and in humans (Fabrega, 1997, p. 184; the term *meme* comes from Dawkins, 1982). A *healmeme* is a unit of information or

instruction learned by an individual in dealing with pain, injury, or illness. This unit is stored in the brain and later communicated and transmitted to others. It is not a genetic trait, but if it has beneficial effects at the individual or group level, it will be retained. If not, it will be deselected.

More firmly rooted in genetic evolution, according to Fabrega (1997, p. 31), is the biological adaptation for sickness and healing, termed the SH adaptation. Elements of this adaptation include seeking relief for pain, communicating pain and distress through gestures and vocalization, and seeking or giving help to conspecifics. Nurturing and carrying helpless members of the group, sharing food and water, and direct healing actions (e.g., licking wounds, pressure to stop bleeding, resting to conserve energy) are other examples. Specific SH behaviors are not necessarily instinctive, especially in social animals. What is genetically programmed or “wired in” (Fabrega, 1997, p. 34) is the propensity to seek help and to give help when injury or illness occurs, or when problems arise such as parasite infestation (hence, grooming behaviors). Other aspects of the adaptation include “curiosity about sickness, some fascination with its manifestations, a compassionate appreciation of its burdens, and attempts to reverse its morbid effects” (Fabrega, 1997, p. 38). These components form the basis for the evolution of medical systems in human groups.

Applications of Evolutionary Theory to Cultural Variation

In recent decades, medical anthropologists have been searching for evidence of feedback loops between cultural variation, population dynamics, health, and genetics in the controversial field of Darwinian medicine. The theory of evolution itself, and the role of cultural factors in adaptive change, is being re-examined. For example, co-evolution, “a theory of evolution by *cultural* selection” (Durham, 1991, p. 38), is believed to parallel organic, molecular evolution.

An example illustrating links between cultural variation and evolution is the unusual degree of diversity in Tibetan marriage systems, including polygyny, polyandry, polygynandry, and monogamy. This variation, in Durham’s view (1991, pp. 59–70), is a solution to female and male infertility. It allows an infertile couple to bring an additional wife, husband, or *p’horjag* (“extra man”) to the household so that heirs could be produced.

It also allows considerable economic flexibility, a benefit in a high altitude ecosystem with low and seasonal productivity of scarce arable lands (Durham, 1991, p. 71). Parenthetically, similar flexibility in household structures and marriage forms were found traditionally in Arctic peoples for many of the same reasons.

Co-evolution theory does not imply that variation in marriage forms is genetically programmed. Rather, behavioral diversity parallels genetic diversity, and both lead to optimal flexibility in environmental uncertainty. The enhanced fertility of households contributes to reproductive success, while the marriage systems themselves are preserved due to their “replicative success” in achieving benefits to the household and the community (Durham, 1991, p. 78).

Controversies in Disease Evolution Studies

Physical and biocultural anthropologists have long argued over the issue of indigenous responses to viral and bacterial pathogens of historical import, for example, measles, smallpox, and malaria. Most indigenous populations experience high morbidity and mortality from diseases introduced by explorers and settlers during early contact. The reasons suggested for heightened susceptibility of native peoples range from inability to form antibodies (Black, 1975) to the synergism of malnutrition, stress, and disease exposure in conditions of contact (Cook, 1976). Other researchers have attributed high mortality during epidemics to the collapse of social structure, community provisioning, and care systems (Neel, 1970). Psychological reactions involving apathy and hopelessness contribute to dehydration, malnutrition, and increasingly lowered resistance to secondary infection.

Evolutionary medicine has proposed explanations for an array of modern ailments ranging from obesity to lower back pain, asthma, otitis media, depression, and addictions. Allergies, for example, are thought to be related to originally adaptive responses to parasitic infections (Nesse & Williams, 1994). Even more problematic are evolutionary explanations for current behavioral aberrations, such as homicidal assault, sexual abuse and incest, depression, and infanticide. Intellectually it may be satisfying to link contemporary ills to past conditions, but the extent of genetic determinism is problematic.

SUMMARY

Medical anthropologists trained in many specialties are developing models of evolution and ecology to explain and predict factors affecting the well-being of individual organisms, growth or decline of various populations, and the survival of the human species. As the human genome is mapped and analyzed by biologists and biocultural anthropologists, evidence of the connections between environmental adaptation and genetic change will become increasingly clear.

At present we have relatively few strong cases linking evolutionary change to historically documented ecological change. A classic case involves cultural shifts to agriculture in West Africa some 4,000 years ago, leading to increased prevalence of particularly lethal forms of malaria. In this case, natural selection for alleles providing resistance to malaria (e.g., hemoglobin variants such as S, C, and E and enzyme deficiencies such as G6PD) provides a clear example of genetic adaptation to environmental perturbations (Greene & Danubio, 1997). Medical geographers and physical anthropologists continue to look for equally strong evidence for population resistance to plague, tuberculosis, smallpox, syphilis, and other diseases that have changed the course of human history. With suitable models of disease ecology and evolutionary mechanisms, medical anthropologists may contribute to future understanding and prevention of disease, disability, and environmental disequilibrium.

Forensic Anthropology

Douglas H. Ubelaker

DEFINITIONS

Forensic anthropology represents the application of our knowledge and techniques of physical anthropology to medico-legal problems. Historically, such applications have focused on skeletal remains, although issues involving soft tissue are at times included. With skeletal remains forensic anthropologists are asked to offer opinions if the evidence represents human, non-human animals, or other materials. If the remains are thought to be human, then analysis is directed toward such problems as determining the age at death, sex, ancestry, living stature, postmortem interval (time since death), anatomical parts represented, the presence of disease or injury and if so, any treatment of the conditions, any unusual features that might facilitate identification, any evidence of injury that might have contributed to death and postmortem change (İşcan & Kennedy, 1989; Krogman & İşcan, 1986; Maples and Browning, 1994; Rathbun & Buikstra, 1984; Reichs, 1998; Rhine, 1998; Stewart, 1970, 1979; Ubelaker, 1999a; Ubelaker & Scammell, 1992). Evidence of post-mortem change is important because it can (1) contribute

to the estimation of the time since death, (2) provide important environmental information to help determine the postmortem history of the remains, and (3) assist with perimortem (at or about the time of death) trauma interpretation (Haglund & Sorg, 2002).

Forensic anthropologists usually work closely with forensic pathologists and other specialists in forensic science in a team approach. Forensic anthropologists become involved in such work because of their unique experience and training in human skeletal biology, human variation, growth and development, and other anthropological areas of speciality. Although they usually work with human remains that have been altered through advanced decomposition or other factors, at times they also assist medical specialists in the autopsy of relatively complete remains in cases when anthropological expertise is needed.

HISTORY

The roots of forensic anthropology extend back to 19th-century interests in the biological basis of abnormal

behavior (Lombroso, 1887), Bertillonage (human identification using anthropometric measurements), and early anatomists and physicians called upon to examine human remains. Stewart (1979) has suggested that Thomas Dwight (1843–1911) deserves the title of “Father of Forensic Anthropology in the United States” for his 1878 essay on medical–legal identification of the human skeleton and other works (Dwight, 1878). Other notable early contributors were Jeffries Wyman (1814–1874), George Dorsey (1869–1931) and Harris Hawthorne Wilder (1864–1928) (Stewart, 1979; Ubelaker, 1999b).

Although the early pioneers of physical anthropology Aleš Hrdlička (1869–1943) and Earnest A. Hooton (1887–1954) were involved in casework (Stewart, 1979; Ubelaker, 1999c), publication and professionalization of the field came later, largely through the work of Wilton M. Krogman (1903–1988) and T. Dale Stewart (1901–1997) (Ubelaker, 2000a, 2000b). Key factors in the development of forensic anthropology were the growth of skeletal collections supporting forensic research, routine consultation of Smithsonian anthropologists with the FBI, anthropological involvement with the military to assist in identification issues, formation of the Physical Anthropology Section of the American Academy of Forensic Sciences in 1972, and the formation of the American Board of Forensic Anthropology in 1977 (Snow, 1982; Ubelaker, 1997). By the year 2001, membership had grown to 252 in the Physical Anthropology Section and to 50 Diplomates recognized by the ABFA.

TRAINING

Certification in the ABFA requires a Doctoral degree in Anthropology with an emphasis on Physical Anthropology and evidence of advanced study of human osteology, human anatomy, and dental anthropology. Such a requirement strongly suggests that forensic anthropologists receive their formal training in a PhD granting Department of Anthropology with an emphasis on the specialized areas mentioned. Training is also useful in archeological recovery techniques, appropriate legal issues, related areas of forensic science, and evidence handling. Experience with actual forensic cases is extremely important and usually is obtained by working with a practicing forensic anthropologist. Courses, workshops, fellowships, and internships are also available to

supplement formal programs and to provide exposure and experience in casework.

PRIMARY GOALS

Usually, analysis in forensic anthropology is oriented toward two major goals: (1) establishing a profile of the individual represented that will assist in positive identification, and (2) the recognition and interpretation of evidence of foul play.

As mentioned above, the “identification profile” can involve determining that the remains are of human origin, estimation of age at death, sex, ancestry, living stature, general robusticity, the presence and treatment of medical conditions, and noting any unusual biological features that might be known about the once-living individual. The accumulation of such information helps narrow the search for the missing person and excludes individuals who do not fit the profile.

In cases of recent origin in which identification has remained elusive, a facial reproduction may be called for (Taylor, 2001; Ubelaker, 2000c). This involves generating an image of the head of the individual to be presented to the public through the media. Such a technique is used to reach out to the public for information about possible missing persons. Different techniques can be employed to generate such an image but most begin with markers placed on the skull to document the depth of the soft tissue at various places (Manhein et al., 2000). The anthropologist and/or artist then produces either a two-dimensional or three-dimensional image of the person using various combinations of sculpture and/or computer techniques.

If a photograph of a suspected missing person is available, then it can be compared directly with a recovered skull through a process usually referred to as “photographic superimposition.” Using video and computer equipment, specialists can directly compare the images and assess the extent to which they are consistent (Ubelaker, 2000d). This technique is used primarily for exclusion (to indicate that the skull and photograph represent different individuals), but its use has diminished (Ubelaker, 2000e) as more powerful molecular techniques for identification have become available.

Positive identification results when unique features are found on recovered remains that are known to have existed in a missing person. To establish positive

identification, the investigator must find the shared unique features and be able to explain any differences that occur. Although such identifications usually are made currently by experts working with DNA, dental restorations, or fingerprints, they also can stem from forensic anthropology. In particular, radiographs of the living person retrieved from medical records may reveal unique anatomical details that can be compared with recovered remains (Ubelaker, 1990) or other evidence (Fenger, Ubelaker, & Rubinstein, 1996).

Medical specialists are responsible for the determination of cause and manner of death. Forensic anthropologists can also be helpful in this effort through the recognition and interpretation of key evidence. Such evidence can take the form of blunt force trauma (Galloway, 1999), patterned trauma, sharp force trauma, or gunshot injury. The type of injury likely associated with cause and manner of death is termed *perimortem*, or occurring at or about the time of death. Such alterations have to be distinguished from those sustained *antemortem* (during the life of the individual) and *postmortem* (after death) (Ubelaker, 1991; Ubelaker & Adams, 1995). Such alterations also have to be distinguished from naturally occurring anatomical variants which are developmental in origin.

The postmortem alterations may not be related to cause and manner of death but they can reveal a great deal of information about time since death and the postmortem history of the remains. Such observations may provide environmental clues indicating where the remains were located between death and discovery and aspects of what happened to them.

METHODOLOGY

Like other experts in forensic science, forensic anthropologists need to present objective, factual, and interpretative opinions on the evidence presented to them. Although a case may be brought to the anthropologist by a particular law enforcement group or others, it is important to retain objectivity and focus on the scientific issues concerning the evidence presented.

The forensic anthropologist also must be flexible and thoughtful in the selection of procedures and methodology. Many techniques are available to assist analysis, but proper selection of those employed must be dictated by the particular problem presented and the individual

circumstances. Reports must be accurate and carefully worded since they become legal documents examined by many individuals involved with the case. Fundamental rules of documentation and chain of evidence must be followed.

NEW TECHNIQUES

Recent years have witnessed accelerated research in forensic anthropology resulting in many new techniques to support all areas of analysis. These are too numerous and complex to be discussed in detail here, but the following represent a few highlights.

Recovery efforts continue to rely primarily on careful archeological-type techniques with extensive documentation. These efforts are supported by the use of aerial photography, surface topography study, ground penetrating radar, cadaver dogs (dogs trained to detect the odor of decomposing human tissue), and other technological advances.

The differentiation of human tissue from other materials continues to rely extensively upon macroscopic morphological indicators, but in fragmentary and other difficult cases these techniques can be supplemented with microscopic histological examination and/or elemental analysis using a scanning electron microscope (SEM) with associated energy dispersive spectrometer (EDS). SEM/EDS analysis allows bones and teeth to be distinguished from most other materials. Microscopic analysis of histological structure (Mulhern & Ubelaker, 2001) allows human bone to be distinguished from some other animals.

New techniques in the estimation of age at death, sex, and stature have become available for more parts of the skeleton and with a greater appreciation for the population variation involved.

In 1984, the physical anthropology section of the American Academy of Forensic Sciences initiated a data bank managed at the University of Tennessee, Knoxville. This data bank maintains measurements and observations on identified forensic cases and documented museum collections which has been used to generate new methodology for analysis. Since these data were largely derived from forensic cases, they are of obvious utility in developing new methods to use in individual cases. New methodology stemming from this effort includes the computer program FORDISC 2.0 (Ousley & Jantz,

1996), a flexible interactive system which enables available measurements from a forensic case to be used to generate estimates of sex, ancestry, and stature.

Interpretations of time since death, trauma, and post-mortem indicators (usually referred to as taphonomy in the forensic literature) have been augmented by several recent volumes on these subjects which document the complexity of the issues involved.

APPLICATIONS

Most forensic anthropologists routinely work on individual cases presented to them by law enforcement, forensic pathologists, or other parties. The military employs a group of anthropologists to assist with the recovery and identification effort of decedents associated with military operations, especially those in southeast Asia. Anthropologists also have become increasingly involved in the investigations of mass disasters and suspected international human rights violations.

In 1996 Diplomates of the American Board of Forensic Anthropology reported that they had worked on 1,439 individual cases that year. Of these, 81% had been presented to them by such agencies as local law enforcement, state police, military, coroners, medical examiners, or sheriffs' departments. The remaining 19% represented civil cases; the majority of these were requested by the plaintiff. Of the agency submissions, most originated from medical examiners' or coroners' offices with the military representing an additional major contributor. Also in that year, Diplomates most commonly reported on skeletons, but also on decomposed and relatively fresh remains (Ubelaker, 2000f).

INTERFACE WITH RELATED DISCIPLINES

Forensic anthropologists work closely with law enforcement, legal specialists, and a variety of scientific disciplines. Within forensic science the interface is strongest with forensic pathology and forensic odontology. Forensic pathologists conduct autopsies on relatively complete remains and usually are responsible for the overall interpretation relative to cause and manner and death. Forensic anthropologists contribute to that effort and frequently directly interact with the pathologists and related specialists at autopsy or other examination.

Information provided by the forensic anthropologist can be integrated into the overall report issued by the forensic pathologist.

Forensic anthropologists also have expert knowledge about the anatomy, development, and variation of teeth and thus interface with forensic odontologists. Although there is some overlap of interest in regard to dental anatomical issues, forensic anthropologists usually defer to odontologists on issues of treatment of disease, especially restorations and related therapeutic efforts.

Particular issues in individual cases can lead anthropologists to interact with radiologists, surgeons, entomologists, botanists, geologists, zoologists, and many other experts. The nature of this interaction is dictated by the problem under investigation and the experience of those involved.

The following fictitious example illustrates applications of forensic anthropology.

Carl and Myrtle Brown were resting on the front porch of their rural home when they noticed their family hound coming into the yard with something in his mouth. They were used to this, since Fido usually came home with a bone or something similar to gnaw on beneath the porch. However, this was different, the bone looked like part of a human skull. After taking the bone inside and examining it, they decided to call the sheriff's office. A sheriff's deputy responded, took custody of the bone, and called the local medical examiner's office.

When the report came in that a suspected human bone had been found, officials at the medical examiners' office called their consulting forensic anthropologist, a professor certified by the American Board of Forensic Anthropology who taught at a nearby university. Examination by the forensic anthropologist revealed that it was in fact of human origin, of adult age, and likely of relatively recent origin since some odor and traces of soft tissue were still present.

Armed with this information, the anthropologist and the other investigators returned to the scene to try to find additional remains. The owners had no idea where the dog had been that day and a preliminary search of the premises was unsuccessful. A decision was then made to bring in a "cadaver dog," a dog specially trained to detect the odor of decomposing human tissue. After making several circles around the house, the dog indicated to his trainer that he detected the appropriate odor in some brush 200 yards from the house. Investigation revealed that most of the remainder of the skeleton was there on

the ground surface, along with some clothing. Careful recovery documented the location of the remains and all seemingly important factors.

Back in the laboratory, the authorities carefully separated the remains from the clothing and other materials. The anthropologists cleaned the remains and began the analysis. A careful inventory revealed that most of the bones were present, except for a few small bones that likely had been carried away by the dog to another location. Some additional bones were found that did not appear to the anthropologist to be human. Consultation with a zooarcheologist at the university suggested they represented small rodent and were not related directly to the human remains.

Examination of the pelvis revealed a wide sciatic notch, broad sub-pubic angle, and many other features suggesting female sex. The bones also were small and gracile as occurs in many females.

The bones were of adult size, all long bone epiphyses were united, and all teeth fully formed, suggesting the remains were older than the teenage years. Examination of the vertebrae revealed extensive arthritic change, also apparent on some of the long bone joints. Examination of the extent of cranial suture closure, dental changes, appearance of the pubic symphysis area of the pelvis, and sternal ends of the ribs also suggested advanced age. All the age indicators collectively suggested an advanced age likely between 65 and 85 years.

Features of the face, especially its relatively pointed nature, receding cheekbones, prominent chin, narrow nasal aperture, narrow interorbital distance, and the sharply defined border of the inferior nasal margin suggested a likely European ancestry. As a second approach to this problem, the anthropologists decided to take cranial measurements and analyze them using FORDISC 2.0. This test also strongly suggested a likely European ancestry.

To calculate the stature of the individual, the anthropologist measured the maximum length of the femur and then selected the appropriate published regression equation. The stature was estimated to be about 5 ft. 4 in. tall, plus or minus about 3.7 cm.

There were many suspicious alterations on the remains. Careful examination using a dissecting microscope revealed that some of these alterations were developmental anomalies that had been with her throughout her life. Others originated from trauma in the nasal area sustained by her many years before death. Additional

alterations were postmortem in origin, changes caused by sun exposure and the chewing by rodents and the dog.

Still other alterations in the skull represented perimortem trauma, sustained at or about the time of death. A roughly circular perforation was present on the left parietal with internal beveling suggesting it represented an entrance gunshot injury. A similar but larger perforation with external beveling was present on the right parietal suggesting it represented an exit gunshot injury.

All available missing persons reports for the area were examined using the profile of an elderly woman of European ancestry approximately 5 ft 4 in. tall, but no one matched the profile. Accordingly, authorities requested a facial reproduction be prepared. The anthropologist and an artist worked closely together to choose the appropriate soft tissue depth markers, place them appropriately on the cranium, and rebuild the features of the face. The resulting estimate of what the woman looked like was released to the media for publication. Subsequently a reader of the newspaper in a nearby city thought that the image was similar to an elderly woman he knew whom he had not seen in over six months and he reported this information to the police. Their investigation led to the woman's family and DNA samples that were used to make a positive identification. She was 72 years old, 5 ft 4½ in. tall, of European ancestry, and had suffered a broken nose five years before she disappeared.

SUMMARY

Forensic anthropology has evolved into an important sub-field of physical anthropology and forensic science (Ubelaker, 1996). Forensic anthropologists routinely contribute to casework involving human remains and through research and experience have increased their collective ability to learn a great deal about an individual from their remains.

Illness Narratives

Ron Loewe

THE ILLNESS AUTOBIOGRAPHY

Over the last quarter century the illness biography or “pathography,” as some prefer to call it, has emerged as a

popular literary form as well as a primary data source for medical anthropologists. Through vivid, personal stories seriously ill patients have attempted to educate medical professionals and the general public about the impact of

disease on work, family life, identity, and self-image as well as to recount their experiences with impersonal, bureaucratic, medical institutions. While such narratives have been written by people from various walks of life, and deal with a variety of different medical conditions, the stories share many common narrative elements: mystery (disease is unexpected or difficult to diagnose), betrayal by one's *own* body, conflict with medical professionals or medical bureaucracies, the failure of medical science to heal, the need for self-reliance, and, generally, but not always, a return to good health. An early and successful prototype of the new genre was Norman Cousins' *Anatomy of an Illness* (1979), a poignant account of the author's struggle with a painful collagen disorder which sat atop the *New York Times* best seller list for more than 40 weeks. In *Anatomy*, the former editor of the *Saturday Review*, not only questions the value of high-tech medicine by describing how he substituted "laughter" (by watching Alan Funt films) for the toxic anesthetics he was given in the hospital, but celebrates the power of human creativity and emotion by describing how the great Pablo Casals would daily relieve his swollen, arthritic fingers in an early morning rendition of Bach's *Wohltemperierte Klavier* or a Brahms' concerto. "... [H]is fingers now agile and powerful, raced across the keyboard with dazzling speed. His entire body seemed fused with the music; it was no longer stiff and shrunken, but supple and graceful and completely freed of its arthritic coils" (Cousins, 1979, p. 73). While Cousins' narrative was clearly less critical of medicine than many subsequent illness narratives—praising physicians at the same time that he excoriated hospitals and other medical behemoths—*Anatomy* can be seen as an early attempt to show how the Cartesian mind/body dualism on which medical science depends is an obstacle to good health. At the same time, by selecting Rene Dubos to write the introduction, and citing numerous works by Dubos and other anthropologists in the bibliography (Comaroff, 1976; Fabrega, 1976), Cousins revealed a debt to cultural anthropology.

In the wake of *Anatomy* have come many more illness autobiographies including; Arthur Frank's, *At the Will of the Body* (1995), A. Manette Ansay's *Limbo: A Memoir* (2001), Lisa Roney's *Sweet Invisible Body: Reflections on Life with Diabetes* (1999), Norman Cousins', *The Healing Heart* (1983), a sequel of sorts to *Anatomy*; anthropologist, Michael Dorris's *The Broken Cord* (1990), *The Body Silent* (1987) by Robert Murphy, another cultural anthropologist who worked in central

Brazil, and Stephan Jay Gould's "The Median is Not the Message (1998)." In the latter, the eminent Harvard paleontologist not only recounts the circumstances surrounding his diagnosis with an abdominal mesothelioma, a rare and deadly cancer associated with asbestos exposure, but breaks the mold by showing how one can fashion a hopeful narrative from the raw materials of science itself. Gould's doctor is reluctant to direct him to the relevant medical literature, because as the paleontologist soon discovers, the median mortality for his disease is eight months. However, after recovering from his initial shock, Gould uses his knowledge of statistics and human variation to create a more comforting scenario. He discovers that he possesses the characteristics which place him on the right half of the curve (e.g., good overall health, youth, health insurance) and that the curve has a long tail, suggesting that he may actually have many years of good health in front of him. Unlike many other mesothelioma sufferers, he is also aware that the clinical trial he is participating in may ultimately shift the whole distribution to the right, increasing the median mortality. In short, while medicine and epidemiology, and the institutions they serve, can lose sight of individuals, illness biographies, if nothing else, are about individuals and about hope.

Even physicians have contributed to this literature (Broyard, 1993; Jamison, 1995; Morrison, 1991; Sacks, 1984). In *A Leg to Stand On*, for example, the neurologist Oliver Sacks recounts a catastrophic injury he suffered while hiking through the Alps. As a result of an unusual fall, Sacks severs the ligaments in his right leg and must drag himself in excruciating pain to a small village to obtain help. The greater catastrophe, however, occurs in the London-based hospital where he attempts to convince his surgeon and the other medical staff that he is something more than the sum of his rather tenuously connected body parts. As a result of his traumatic injury Sacks loses his sense of proprioception, his ability to think of his leg as part of a larger, integrated body that he himself controls. In fact, in his tragi-comic style, Sacks describes his inability to "find" his leg even after the operation is complete and his surgeon, a self-described "carpenter," has successfully reattached all the ligaments. However, the more Sacks tries to explain the nature of his problem—and his inability to walk—the more he is viewed as a quirky, non-compliant patient. Indeed, Sacks' status as an eminent physician does little to mitigate his new status as a patient. As Sacks concludes, the first thing one learns as a patient is "to be patient."

ILLNESS NARRATIVES IN ANTHROPOLOGY AND BEYOND

The use of narrative to describe *other* people's experiences of acute or chronic illness is also something of a growth industry. In the last few years, analyses of patient narratives have been used to explore everything from autism (Gray, 2001) to temporomandibular joint syndrome (Garro, 1994). In between one finds studies of breast cancer (Langellier & Sullivan, 1998), depression (Kangas, 2001), diabetes (Hunt, Valenzuela, & Pugh, 1998; Loewe & Freeman, 2000), HIV (Bloom, 2001; Ezzy, 2000), mental illness (Goodman, 2001), and schizophrenia (Lovell, 1997), to mention just a few of the more recent ones. Ironically, though, as Byron Good notes, there are relatively few studies that take an explicitly cross-cultural perspective (Good, 1994), or venture beyond the borders of the author's native land. Some that do, include: Evelyn Early's study of the informal stories Baladi (Egyptian) women tell to clarify illness episodes and garner emotional support (Early, 1985), Laurie Price's use of illness narratives to understand gender relations surrounding care-giving in Ecuador (Price, 1987); Sam Miglione's study of "nerves" among Sicilians living in Canada (Miglione, 2001), Byron Good and Mary Del Vecchio Good's study of epilepsy, and the possibility of healing through narrative, in Turkey (Good & Del Vecchio Good, 1994); and Paul Farmer's discussion of how a model of AIDs was gradually developed through stories about afflicted individuals in rural Haiti (Farmer, 1994).

In the latter, *AIDS—Talk and the Constitution of Cultural Models*, Farmer is in the unique position of studying a disease which is in the process of emerging, and is able to follow the evolution of thinking about AIDs from the early 1980s, when many Haitians had not heard of the disease, and there was nothing that could reasonably be called a "story," through 1989 when local conceptions of the disease began to stabilize. In particular, Farmer is able to trace changing concepts of AIDs from a variant of tuberculosis in 1983–84, to an ill-defined blood disease in 1986, to a Duvalier conspiracy in 1987, and, finally, to a type of "sent disease" (e.g., voodoo). As a type of disease that can be "sent" through microbes, AIDs was new wine in old bottles; however, according to Farmer, it was not simply the insertion of a new disease into an old paradigm which lent stability to the public's

conception of disease, it was the narratization that occurred when villagers began to witness and discuss the suffering and eventual death of individuals they knew, like Manno, the Do Kay school teacher. "Manno's sickness," writes Farmer, "offered a 'plot' for stories of great immediacy to those living in a small village" (Farmer, 1994, p. 807).

The second irony is that many of these studies, including those authored by cultural anthropologists, presuppose a Western or biomedical nosology. Despite frequent references to the "social construction of disease," and various attempts to highlight differences in the way particular cultural groups respond to pathogens or chronic conditions, work in this area reveals a disease focus in the sense that the topics selected (e.g., diabetes, AIDS, hypertension) could be drawn from *The Physician's Desk Reference*. In this way, authors inadvertently undercut the argumentation contained *within* otherwise quite persuasive articles.

Although it can be dangerous to attempt to identify a single source for a pervasive trend, it seems safe to say that the emphasis on illness narratives, and the hermeneutic tradition within medical anthropology more generally, can be traced back to the work of Arthur Kleinman. By arguing that disease was an "explanatory model," and, thus, part of culture rather than nature—or at least the result of a complex interaction between the two—Kleinman helped open a discursive space in which alternative explanations of the etiology, course, and treatment of disease were worth exploring through patient accounts. And in his more recent work, *The Illness Narratives: Suffering, Healing and the Human Condition* (1988), Kleinman continues his effort to persuade physicians to listen closely to what their patients say.¹ However, as noted in the first section of this study, the illness narrative was a cultural phenomenon before it was cultural anthropology. As always, social theory follows social life.

A discussion of narrative should also make reference to Levi-Strauss's *The Effectiveness of Symbols* (1963a), although this anthropological classic might be more appropriately termed a "therapeutic narrative" than an illness narrative. Here, as some readers will recall, Levi-Strauss examines a Cuna shaman's use of narrative and vivid visual imagery in order to help a pregnant woman through a particularly difficult delivery. The delivery is complicated because Muu has "exceeded her functions" (p. 187) and has absconded with the *niga purbelele*, the soul or vital essence of the afflicted women. To resolve

the “impassé,” the shaman narrates a heroic journey through the depths of “Muu’s way” (the uterus or vagina) where he and the *nuchu* (tutelary spirits) “wage victorious combat” in order to retrieve the *niga pubelele* and open a path for the fetus. As Levi-Strauss notes, the treatment was purely “psychological” because the shaman neither administers a remedy nor touches the woman. Instead, he provides the afflicted woman with a “*language* by means of which the unexpressed psychic states ... can be immediately expressed ... [and] which induces the release of the physiological process ...” (p. 198, emphasis in the original). Through this essay, and *The Sorcerer and His Magic* (1963b), Levi-Strauss not only reveals the power of the story, but attempts a rapprochement between indigenous healing and Western medicine, particularly psychotherapy. Other, more recent studies that examine the power of words to heal include Csordas (1983, 1988), Finkler (1983), Kapferer (1983), and Laderman (1991).

ILLNESS NARRATIVES IN CLINICAL MEDICINE

Because symptoms are by definition the patient’s interpretation of a malady, illness narratives have always been considered a part of clinical medicine. As Greenhalgh and Hurwitz note in *Narrative Based Medicine: Dialogue and Discourse in Clinical Practice* (1998), even in the most autocratic, doctor-centered redoubts of clinical medicine the patient retains a special status as an information bearer, and the most effete professors will exhort their students to “listen to the patient; she’s telling you the diagnosis” (p. 6). What role the patient narrative plays in medicine, of course, varies greatly from subspecialty to subspecialty as well as across space and time. While the practice of medicine by epistle in the 18th century obviously required a detailed written narrative (and a well-educated patient), the development of new technologies, such as MRI and CAT scans, which allow physicians to visualize the deepest recesses of the human body, and the emphasis on medical testing, make patient narratives seem almost dispensable. Ironically, as Kay and Purvis note (1998), the development of electronic medical records may contribute to a similar decline in *doctor* narratives, depending on whether, or to what extent, they allow physicians to enter unstructured comments or free text (pp. 192–193).

The ambivalence toward patient narratives in modern medicine is also symbolized by the structure of the medical record, the so-called SOAP note, which divides the clinical encounter into four distinct moments: “subjective,” “objective,” “assessment,” and “plan.” While the “subjective” heading (the patient’s account) seems to guarantee a place for illness narratives of *some sort*, the juxtaposition of the patient’s subjective account with the doctor’s purportedly objective account clearly minimizes the importance of the former.

However, notwithstanding the rapid growth of medical technology and evidence-based medicine, or, perhaps, as a response to these trends, there seems to be a growing interest in narrative as a part of the therapeutic process, as well as an aid to diagnosing disease and to educating medical students.

The idea of narrating one’s way to better health is certainly nothing new. Freud’s patient recognized this when she uttered the immortal phrase “talking cure.” However, the way in which narratives are viewed, and the relationship between doctor talk and patient talk does appear to be different in the postmodern era. Instead of treating patient narratives as a treasure trove, a mysterious place where therapists can discover secrets buried in the patient’s subconscious, the emphasis is now on jointly creating appropriate new stories (Launer, 1998). In this process, form is emphasized over content; as long as the story coheres and makes sense to the patient, there is little concern over his or her difficult past. For example, in discussing recent research on adult attachment disorder, Holmes (1998) describes a system for classifying patient narratives into four domains—secure-autonomous, insecure-dismissive, insecure-enmeshed and disorganized—and notes that admission to the first category requires the ability to speak “logically and concisely about the past” (p. 180). Not surprisingly, as Holmes implies further on, the therapist functions primarily as a competent editor, providing “shaping remarks” (p. 182) for an enmeshed patient (e.g., we’ll come back to that in a minute), and author queries for the dismissive patient (e.g., when did you begin to feel miserable?).

In addition to diagnosis and therapy, illness narratives, especially those found in contemporary fiction, are increasingly being used in medical education to overcome the gap between knowledge of a disease and the patient’s experience of it. In *Teaching Humanities in the Undergraduate Medical Curriculum*, for example, Squier (1998) discusses how Ethan Canin’s *We Are Nighttime*

Travelers helped a group of second-year medical students look beyond the outcomes described in three clinically oriented articles on hip replacement surgery. Initially, as Squier notes, the students had difficulty thinking of the social or familial consequences of such surgery—the articles looked “pretty complete”—however, after reading the tale of the elderly couple, their health problems, and the husband’s valiant attempts to rekindle their marriage by sending poetry to his wife, the students begin to ask a new set of questions. What would happen if the diabetic husband should need surgery? What if the wife, the strong partner, were to break a hip? While the emphasis among medical educators is to use narrative as a way of teaching empathy or “moral imagination” (Scott, 1998), an understanding of narrative may also serve as a way of better understanding medical decision-making (Hunter, 1991).

NARRATIVE AND THE NARRATOLOGIST

While the word narrative now appears with notable regularity in the titles of anthropological studies of illness or disease, there are relatively few studies that explore the philosophical or ontological basis of narrative, or that avail themselves of the large body of writing on narrative in literary criticism, philosophy, or linguistics. Indeed, like the social science “interview” analyzed by Briggs in *Learning How to Ask* (1986), “narrative” is often conceived of as a more or less transparent medium for obtaining or revealing information about disease X from the perspective of ethnic group Y or interest group Z. In other words, what linguistic anthropologists like Briggs describe as the referential function of language (e.g., the world of objects) is privileged over the pragmatic or metacommunicative functions of language. Nevertheless, as Good notes in *Medicine Rationality and Experience* (1994), anthropologists, and social scientists more generally, are becoming increasingly concerned with questions like: “To what extent do the stories report or depict events or experiences as they occurred? ... Does a good history mirror events and experience, or does it select events and organize them culturally? To what extent is social life itself organized in narrative terms?” (p. 139).

Using the work of William Labov as a baseline, it is also possible to detect a shift in the way these questions are answered, although there is clearly no consensus, and, undoubtedly, never will be, about what a narrative is.

As several authors have noted (Langellier, 1989; Mishler, 1995; Reissman, 1993), the prototype for examining orally produced texts is found in an article by Labov and Waletzky, “Narrative Analysis: Oral Versions and Personal Experience,” published in 1967. In this early work, which focused on stories African-American teenagers tell to members of their peer group (and, of course, Labov & Waletzky), narrative is a very restricted speech category. Minimally, to be considered a narrative, a speech act must describe an *actual* event that occurred sometime in the *past*, and is remarkable or *extraordinary* in some way. A *fully* formed narrative, in turn, contained six additional attributes: (1) an *abstract* or summary of the story that followed, (2) an *orientation* which set the story in time and place, (3) a *complicating action* or plot (e.g., a sequence), (4) an *evaluation* or interpretation of the events by the narrator, (5) a *resolution*, an account of how things turned out, and, finally, (6) a *coda*, a summation which brings the audience back to the present.

Moreover, according to Labov and Waletzky, narrative was representational rather than constitutive of reality. The storyline is not only chronological, it reflects the order of events in the narrated world. As the two authors note, events move in a linear way through time and the “order can not be changed without changing the inferred sequence of events in the original semantic interpretation” (p. 21).

If the early work of Labov and Waletzky provides a convenient starting point for discussing narrative analysis in the social sciences, it is clear that anthropologists have not been constrained by the definitions proposed in this piece. Indeed, “Narrative Analysis” serves more as a monument to change than a guide for analysis, since virtually all the assumptions about narrative in the article have been challenged.

For one thing, the separation between narrative description and the narrated world is considered highly problematic in the post-modernist context. In *Healing Dramas and Clinical Plots*, for example, Mattingly (1998) argues that narratives are so compelling because life itself is structured narratively; “patients have a need for narrative” and experience contains “the seeds of narrative.” By positing a homology between experience and narrative description, or better, by suggesting that the experience we are concerned with is the “experience and action created by *telling* the story” (p. 43), not the experience described *in* the story, narratologists, like Mattingly, avoid some of the methodological

conundrums that surfaced in correspondence theories or mimetic theories like Labov's. After all, since we learn about events *through* stories, how could we ever determine whether the story matches the *actual* event, except through another narrative? And, then, how does one adjudicate between different narratives? Since illness narratives are by many accounts "polyphonic" this is, indeed, a difficult nut to crack.

By intentionally focusing on ordinary therapy sessions (p. 86) and routine activities (e.g., checkers games), Mattingly also raises the question: What is it, or who is it, that makes narratives extraordinary? While nothing, it seems, is *inherently* interesting, or eventful; any event—a walk down a corridor, combing one's hair—can become so, if the therapist figures out "what story [she's] in" (p. 72), and how a sequence of activities connects to the patient's new life story. Indeed, Mattingly departs from other contemporary writers, such as Becker, Gay (1994), by arguing that narrative has more to do with locating *desire* or overcoming a gap than with attempting to maintain or restore a semblance of unity to a badly disordered body (p. 107). In short, what makes narrative extraordinary is not a unique sequence of events, but the many small acts of *interpretation* through which the therapist/narrator uniquely connects an activity or event with an individual patient.

The idea that narrative is singularly concerned with *past* events is also viewed as overly restrictive (Langellier, 1989). For example, in describing illness narratives in Turkey, Good (1994) notes that stories not only tell of past events, but project them forward in time, "organizing our desires and strategies teleologically, directing them toward imagined ends or forms of experience which our lives . . . are intended to fulfill" (p. 139). And in *Doctor Talk and Diabetes* (1998), Loewe, Freeman, Schwartzman, Quinn, and Zukerman argue that physician narratives are even more future-oriented. While patients are often uncertain about what the future will bring, or are simply caught up in the act of daily life, physician time, rooted in epidemiological models, can be thought of as "organic time in the sense that it is marked by the progressive and relatively predictable breakdown of specific organ systems" (p. 1271).

In recent years, narratologists have also moved away from the assumption that narratives of any type are the product of an individual author (Jefferson, 1978; Langellier, 1989; Mishler, 1995; or that stories are passively consumed by a listening audience. Whether

narratives emerge out of a medical consultation (Mishler, 1995), an occupational therapy session (Mattingly, 1998), a family squabble (Stein, 1985), or an interview, they are increasingly seen as joint productions. Similarly, Good, following Ricoeur, Iser, and the reader response theorists, asserts that the plot of the story is not simply there for the taking, but is composed moment by moment by the reader/listener as he or she proceeds through the text.

Finally, as Good (1994) suggests, illness stories may not provide very much resolution (Labov's fifth criteria), since the narrators are "still engaged in the striving, in the quest for a cure" (p. 146), and may be considering several alternative outcomes at a given time. Indeed, as Price (1987) notes in her study of illness narratives in Ecuador (p. 328)—or for that matter as Garcia-Marquez and Rabasa (1996) suggest in *Chronicles of a Death Foretold*—there can be six different ways to account for an illness and there are many ways to interpret a death.

Paleopathology and the Study of Ancient Remains

Michael R. Zimmerman

INTRODUCTION

Paleopathology, the study of disease in ancient remains, is aimed at improving our understanding of the evolution of diseases and their interaction with human biologic and social history (Aufderheide & Rodriguez-Martin, 1998; Brothwell & Sandison, 1967; Ortner & Aufderheide, 1991). Pathogenic organisms, environmental factors, and patterns of disease evolve just as do larger organisms, including hosts and vectors of disease. There is evidence, however, for considerable stability in some host–parasite relationships. Similar parasitic worms have been found in Egyptian mummies and modern Egyptians. Such historical perspectives are necessary to prepare us for changes in disease incidence and for new diseases, such as Legionnaire’s disease and AIDS (Zimmerman, 2001).

Evidence of ancient disease is obtained from historic records, works of art such as paintings, pottery effigies, and figurines, religious statuary, figures and faces on coins, skeletons, and mummies. Many diseases leave little or no direct mark on the bones and pseudopathologic changes can be produced by erosive forces or animals chewing on bones. Although lesions in archeological specimens represent only a small proportion of the total morbidity, the incidence of disease of a population, there are valid reasons for such studies. Certain characteristics or anomalies are useful as genetic markers. Evidence of traumatic injuries can give information on the occupational or military orientation of the group under study. Infectious diseases provide inferences on the general health status of the population.

A major consideration in dealing with ancient material is that modern patients with skeletal pathology present one with symptoms and signs, whereas archeological material presents one with a bone that has either a hole or a bump. The diagnosis of skeletal lesions is properly based on history, radiological findings, and pathology, but we rarely have adequate history in dealing with ancient skeletal material, and pathology is generally confined to the gross appearance, as microscopy is highly technical (Schultz, 2001). One other caution is the paradox that skeletons showing pathology are usually those of relatively healthy individuals. Unhealthy individuals die very quickly, before they have time to develop skeletal lesions.

Mummies are bodies preserved either artificially or naturally. The Egyptian practice of artificial mummification developed from the natural preservation of bodies buried in the desert in pre-Dynastic times, which may have had a role in the development of the belief in life after death. When it became customary to provide the deceased with food and funerary furniture, larger graves and above-ground tombs allowed decomposition, necessitating the development of artificial techniques of mummification. All deceased Egyptians were mummified until the Christian era, *ca.* 200–400 AD, with a gradual refinement of technique over the millennia, although in all periods the poor were less carefully mummified (Zimmerman & Angel, 1986). Artificially preserved mummies are found in many other areas of the world as well.

Natural mummies, due to freezing or drying, have been found in bogs and in arctic and arid areas.

These bodies, both human and animal, often show excellent preservation (Spindler, Wilfing, Rastbichler, et al., 1996).

The rehydrated tissues of mummies subjected to autopsy examination result in the diagnosis of many conditions with a considerable degree of confidence and accuracy (Cockburn & Cockburn, 1998). Mummified tissues and bones are studied by light and electron microscopy, chemical analyses, and paleoserology. Microbiological studies have not been useful, as viable pathogens have not been cultured from paleopathologic material, although organisms can be identified histologically, including viruses, using electron microscopy.

THE HISTORY OF PALEOPATHOLOGY

After an early 19th-century period focusing on the examination of native American skulls, interest shifted to evidence of disease, dominated by activities at the Smithsonian Institution, the Army Medical Museum, and the Peabody Museum at Harvard. In Europe a controversy arose when Rudolf Virchow, the German pathologist, anthropologist, and politician questioned the authenticity of the Neander Valley specimen, suggesting that the Neanderthal remains were those of an abnormal modern man suffering from rickets or syphilis.

The next period, from 1900 to 1970, began with the Smithsonian appointment of Ales Hrdlicka. Describing lesions that he called "symmetrical osteoporosis," he noted that they were probably representative of a systemic disorder. He built one of the world's great collections and contributed to the training of many anthropologists. Flinders Petrie examined prehistoric Egyptian bones by X-ray in 1897, but the technique was little used until the work of Roy Moodie in the 1930s, and is only now beginning to be fully utilized.

The first of the truly modern paleopathologists was Sir Marc Armand Ruffer. Ruffer was an English experimental pathologist and bacteriologist of some note when an illness forced him to Egypt for recuperation. He developed the rehydration technique that is still in use for preparing microscopic sections of mummies and made a number of important diagnostic contributions before being lost at sea in World War I (Ruffer, 1921).

The first full-length book on paleopathology was written by Roy L. Moodie (1923), an American

anatomist. His book covers humans, lower vertebrates, plants, etc. and contains many errors, mostly related to the theories of the early 20th century. Moodie also edited Ruffer's collected papers and published other books and papers in the field.

Paleopathology was revitalized in the 1970s by the activities of three groups. The Paleopathology Association was founded in Detroit by Aidan and Eve Cockburn and 12 charter members. The association publishes a quarterly newsletter and has studied a number of mummies. These studies have gone far toward improving the difficulties that were experienced in interpreting lesions in the past, and a wide variety of new techniques have come into play. These include more sophisticated radiographic studies such as computed tomographic scanning, electron and scanning electron microscopy, fluorescent antibody and other serologic techniques, neutron activation analysis, and other chemical and microbiological techniques.

A second group, headed by Marvin Allison and Enrique Gerszten at the Medical College of Virginia, Richmond, has conducted an extensive survey of Peruvian and Chilean mummies.

A seminar in paleopathology was held at the Smithsonian Institution from 1971 to 1974. This full-length course provided a continuing major impetus in paleopathology. As world-wide interest in the field increases, with much research being conducted in Europe, South America, and Australia, the number of journals accepting paleopathology articles also is increasing, as summarized by the Bibliography of Paleopathology published by the San Diego Museum of Man (Tyson, 1997).

TECHNICAL CONSIDERATIONS

The preservation of buried bone varies with soil type. Bones from acidic soil areas, such as Mesoamerica, will be softened and often in poor condition. Careful excavation of skeletons, with complete clearing of the soil, is essential. Most bones can be cleaned with warm water. Skulls should be examined first for remnants of brain tissue and for ear ossicles.

Hot paraffin wax, formerly used for conservation of bone, can be damaging. Shellac preserves the surface but tends to peel off in a few years, taking bone with it. Soluble plastics are the best preservatives. Plaster of Paris

is good for support but difficult to remove from bones (Brothwell, 1972).

Examination of mummified remains depends on rehydration of the tissues. Ruffer's rehydrating solution, still in use today, is 50 parts water, 30 parts absolute alcohol, and 20 parts 5% sodium carbonate solution, most easily prepared by dissolving 0.6 gm of sodium carbonate in 42 ml of water and adding 18 ml of absolute (100%) alcohol. Allison simplified Ruffer's technique by immersing the tissue in Ruffer's solution until fully rehydrated to visual inspection (usually 24–48 hr). The tissue is then fixed in alcohol and processed. If the tissues dissolve in the solution it is because they are completely contaminated by bacteria. The solution always develops a dark brown turbidity (Zimmerman & Kelley, 1982).

A variety of special stains can be used to demonstrate specific features of the tissues. In general, connective tissues and any foreign elements, such as pigments, bacteria, or parasites are best preserved, while epithelial tissues fare less well. Thus the connective tissues stains are those used most. The standard hematoxylin and eosin is useful only in a very general sense. Other techniques that have been applied to rehydrated tissue include plastic embedding of bone specimens and scanning and transmission electron microscopy.

Dating of biological materials, human or non-human, is often of importance in dating an archeological site, either independently or in correlation with conventional archeological techniques such as the evaluation of pottery, hieroglyphic texts or other artifacts, or historical records. In paleopathology, dating is essential in providing an historical context for the evaluation of disease processes detected. Radiocarbon dating is the "gold standard," but a variety of other techniques are applicable. These include amino acid racemization, which is temperature dependent, electron spin resonance, and ancillary techniques such as dendrochronology, mummification styles, and tattoos (Zimmerman & Angel, 1986).

Age determination is another important facet of the study of human remains, allowing the construction of population profiles and the development of a paleoepidemiologic approach. At the individual level, many diseases occur in specific age ranges and age determination can be a critical factor in differential diagnosis, particularly with regard to bone diseases. In contrast to dating, no single aging technique is best. Techniques used include gross evaluation of the skeleton and viscera, hand–wrist radiographs, bone histology, dental changes,

and, in special cases, amino acid racemization (Zimmerman & Angel, 1986).

THE CLASSIFICATION OF DISEASE

Cells continuously adapt to internal and environmental stimuli and stresses. If the cell is no longer able to adapt, then cell injury results, either reversible or leading to cell death, necrosis.

Injury that cannot be limited at the cellular level calls forth an inflammatory response. If the stimulus is terminated, then the acute reaction subsides and there is usually healing and regeneration of the tissue, although specialized tissue such as the brain is replaced by scar tissue. If stimulus and inflammation continue, then a chronic phase follows. Regeneration and repair are attempted, with scarring the almost inevitable result.

Special types of inflammation include allergic inflammation, granulomatous inflammation (tuberculosis or foreign body reactions), ulceration (the loss of the lining or surface of an organ), and abscess formation (accumulation of pus in solid tissues).

These cellular and tissue reactions to stresses and stimuli result in a wide variety of disease states, falling into the following broad categories: congenital defects, trauma, infectious disease, metabolic and nutritional disease, degenerative disease, immunologic disease, circulatory disorders, and neoplastic disease.

PALEOPATHOLOGIC FINDINGS

Congenital Defects

These defects, which are present at birth, may be hereditary or acquired before birth. Many are minimal and do not cause any functional disability. There can be abnormal fusions of bones, or failure of bone components to fuse. Skull sutures may vary in their relationship. Statistical analysis of skeletal variations can reveal significant associations and inferences as to the biological affinities of the individuals under study. Examples of acquired congenital disorders are infections such as German measles and syphilis, and chemically induced abnormalities such as the thalidomide babies born in the 1950s.

Congenital dwarfism is a generalized condition that is easily recognized. Achondroplasia, the most common form, is due to a hereditary defect in the formation of

enchondral bone, that is bone formed first as cartilage. There is shortening of the bones of the extremities and the mandible and forehead appear prominent. The long bones are relatively thick and the head is larger than normal, with a prominent frontal region, small face, and depression of the bridge of the nose. The legs and spine are curved as well.

This condition is of great antiquity and wide geographic distribution, with skeletal remains from the pre-Columbian New World and documentation in ancient Egypt from pre-Dynastic times up to the 30th Dynasty by skeletons, wall paintings in tombs, figurines, and statues. The ancient word for an achondroplastic dwarf was *nemew* and they held various offices, as these dwarves are generally of high intelligence. Very accurate depictions show them in charge of jewelry or pets or in personal attendance on their masters, often acting as jesters. Several of these dwarves must have been persons of considerable wealth and importance, being found in elaborate and costly tombs. There was also a magical significance, accounting for the figurines and amulets, associated with spells to facilitate birth.

Other examples of congenital disease include: hydrocephaly from Roman Britain, Egypt, and Neolithic Germany; a case of Down's Syndrome in a 15th century AD Inuit child mummy from Greenland (Hart Hansen, 1998); alpha-1-antitrypsin (AIAT) deficiency and emphysema in another Inuit child, from 10th century AD Alaska (Zimmerman, Jensen, & Sheehan, 2000); and spina bifida, a failure of closure of the sacrum, in Egyptian mummies.

Traumatic Injury

Fracture constitutes the most common bone pathology in both ancient and modern material (excluding arthritis). If there is adequate immobilization of the bone, then healing can be almost perfect, while poor immobilization can lead to imperfect healing or nonunion. However, many wild animals have well healed fractures. Medical intervention may not be as necessary as we think; a well healed fracture in an archeological specimen need not imply the presence of an ancient orthopedic surgeon.

The recognition of traumatic injury in ancient material can be difficult. Fractures or wounds, such as sword cuts, if incurred shortly before death, will show no evidence of healing and may be impossible to differentiate from postmortem injury. If there has been time for healing, then rounding of the edges of wounds or callus

in a fracture site will be seen. Although sprains and dislocations probably cannot be recognized in skeletons, both are mentioned extensively in the Egyptian medical papyri.

Fractures have been noted in Peruvian, Alaskan, and Egyptian mummies. Some of the fractures are either postmortem or "embalmer fractures," but there is radiological evidence of healing in some cases.

Trauma appears to have been common throughout human evolution, and before humans as well, with fractures being seen in dinosaur skeletons. The history of human violence is certainly a long one and different weapons produce different types of injury. These have been divided into four classes: (1) large stones or clubs produce gross crushing, with a primary depressed area and radiating cracks; (2) smaller clubs, maces, and missiles produce less extensive fractures, often of the nose or long bones, which are likely to show signs of healing; (3) spears, arrows, and daggers produce well-defined piercing wounds and the weapon occasionally remains in the body; and (4) sword cuts produce long deep gashes.

Examples of trauma and violence are seen in Neanderthal skeletons from Shanidar Cave in Iraq, dated to 47,000–60,000 years BP. Four of six adult skeletons exhibit some form of trauma-related abnormality and at least two of the individuals appear to have been severely debilitated by their injuries.

Shanidar 1, the most severely debilitated, had suffered multiple fractures. A crushing fracture in the area of the left eye probably caused blindness. His right arm had suffered multiple fractures of the distal humerus, with amputation above the elbow, osteomyelitis of the clavicle, and a marked decrease in size of the remaining humerus, clavicle, and scapula.

All of the fractures and injuries occurred years before his death, as indicated by extensive healing and resorption of callus. The most likely explanation is that he sustained a massive crushing injury to the right side of the body, perhaps in a rock fall in a cave, with loss of the distal right arm. The small size of the arm bones could be the result of hypoplasia if the injury occurred in childhood or atrophy due to associated nerve injury and disuse if the damage had been done in adulthood. Either interpretation is consistent with a prolonged period of survival.

The right foot shows a well healed fracture, with osteoarthritis of the ankle and knee. Since the left foot, ankle, and knee appear normal, such asymmetry suggests disruption of normal function and abnormal locomotion.

Shanidar 3 shows a penetrating wound involving the 8th and 9th left ribs, with survival for several weeks. The angle and position of the wound are what one would expect if a right-handed individual had stabbed Shanidar 3 in a face-to-face confrontation. If this interpretation is correct, then this is the oldest case of human interpersonal violence, although it could have been accidental. Whatever the circumstances, Shanidar 3 was clearly nursed for at least several weeks and intentionally buried. He also had severe osteoarthritis in his right ankle. This asymmetrical arthritis was probably related to a fracture or severe sprain. Shanidar 3 therefore suffered a locomotor disability and died a violent, although perhaps accidental, death.

Every currently known and reasonably complete Neanderthal skeleton shows evidence of trauma, suggesting that life in this group was indeed harsh and dangerous. Evidence of healing and long life span implies that the Neanderthals had achieved a societal level in which disabled individuals were well cared for by other members of the group. Elderly Neanderthals such as Shanidar 1 and 3 must have contributed in an intellectual manner to the group well-being and it is not surprising that many of these individuals were intentionally buried (Trinkaus, 1983).

Trauma was common in ancient Egypt. Parry fractures of the left ulna (due to raising the left arm to ward off a blow) are often seen in Egyptian skeletons. The Edwin Smith medical papyrus is primarily a surgical treatise with much emphasis on physical injuries. Fractures were treated by reduction and splinting and many well healed fractures have been seen, as well as examples of malunion and nonunion.

Death due to aspiration of foreign material has been seen in two mummies. A Peruvian mummy of 950 AD was found to have aspirated a molar tooth, with pneumonia distal to the obstruction (Allison, Pezzia, Gerszten, Giffler, & Mendoza, 1974). An Inuit woman died 1,600 years ago of asphyxiation secondary to aspiration of moss when she was trapped in her house during an earthquake or landslide and buried under the moss roof (Zimmerman & Smith, 1975).

Another example of trauma is the finding of a family in Barrow, Alaska, dated to *ca.* 1500 AD, all killed by an incursion of ice crushing their winter home. The bodies showed fractured ribs and fatal hemorrhage into the chest cavities; one of the bodies was found with a roof beam across her chest (Zimmerman & Aufderheide, 1984).

Trephination (a type of surgical trauma), the removal of a piece of the skull without damaging the underlying vessels, meninges, or brain, is a well-known and widespread phenomenon. The practice was world wide, beginning in Europe 10,000 years ago and in Egypt, where there are only a few examples, about 1200 BC. In South America the practice dates to about the 5th century BC. It may have been done for fracture or headache, or to let out "evil spirits." In 20th-century Kenya it was most often done for headache. When done postmortem, the piece of bone from the skull is used as a good luck charm. The procedure generally involved alcohol as an anesthetic and a variety of instruments to remove the pieces of bone, by drilling, scraping, or cutting. The majority of patients appear to have survived the procedure. The technique, still practiced in Africa until recently, is performed by some in the United States even today. One caution is that spontaneous diseases can cause similar appearing holes in the skull.

Infectious Disease

These disorders are caused by microorganisms, including bacteria, viruses, rickettsia, fungi, and single-celled protozoan parasites. Invasion by macroorganisms, those visible to the eye, such as worms and insects, constitutes infestation. Modern treatment has altered many diseases and comparison between ancient and modern diseases must keep this fact in mind.

Most infections do not affect the skeleton directly, but the skeleton can be involved indirectly. Childhood infections can result in the production of growth arrest lines or Harris lines in the long bones, resulting in a very rough index of morbidity. Infections that result in anemia cause a secondary hyperplasia of the bone marrow, particularly in the skulls of children. X-rays show a characteristic hair-on-end appearance and the external surface of the bone shows osteoporotic pitting, called porotic hyperostosis. The geographic distribution of this lesion has been shown to overlap that of malaria and these conditions have been linked to sickle cell anemia and thalassemia.

Bone infections, osteomyelitis, mostly bacterial infections, reach the bone by a penetrating injury such as a laceration or open fracture, by the bloodstream from a distant site, or by direct extension from an infection such as a soft tissue or dental abscess or a sinus infection. Mastoiditis has been found in Neanderthal, Nubian,

Egyptian, and American Indian skulls, secondary to middle ear infection. The infected bone becomes necrotic and is surrounded by pus, which may drain to the surface through sinus tracts. Such infections can still be very difficult to treat and may persist for years. Pyogenic osteomyelitis is an ancient disease, having been described in dinosaur skeletons.

An infection with extensive historical documentation is bubonic plague, caused by *Yersinia pestis*. The black death killed more than a quarter of the population of Europe in the 14th century. Infection is transmitted to humans by the bite of an infected rat flea. The lymph nodes become greatly swollen (bubos), or, under conditions of crowding, transmission is by inhalation, causing a rapidly fatal pneumonia. Sporadic infections still occur, traceable to wild rodents.

A spirochetal disease of significance in human history is syphilis. Advanced acquired disease results in damage to many organs, including the cardiovascular system, skeleton, skin, and upper respiratory tract. Congenital syphilis is passed across the placenta and is characterized by deformities of the teeth, legs, and face. The periostitis of syphilis is quite distinctive, but in archeological material can be impossible to distinguish from yaws.

The origin of syphilis, New World or Old, has long been a point of controversy. One school holds that the varying spirochetal diseases are different manifestations of the same disease in different populations. Some feel that yaws originated in the Pacific, spread to the New World and manifested itself as syphilis when contracted by adult European explorers, while others believe that syphilis was present in the pre-Columbian Old World.

Tuberculosis, caused by an acid-fast bacillus, affects the bone in a certain percentage of cases with destruction of joints as well as bone. Involvement of the vertebral bodies causes collapse and hunchback (kyphosis or Pott's disease). There are good examples from Dynastic Egypt, but not pre-Dynastic, suggesting a possible evolution from the bovine form of the disease, cattle having been domesticated at the beginning of the Dynastic period. Tuberculosis has been found in Europe at about 2000 BC and in a mummy from pre-Columbian America, where pottery figurines with kyphosis are also found.

Leprosy, caused by another acid-fast bacillus, is a disease of considerable historical interest, because of Biblical references and the fact that the characteristic bone changes in the disease were first delineated in

a study of medieval skeletons. The primary infection is through the nose, with atrophy of the maxilla in the region of the incisors, with or without loss of teeth, inflammation of the hard palate, and atrophy of the nasal spine, these lesions having been identified by Moller-Christiansen in medieval lepers. While leprosy is mentioned in the Old Testament, the earliest skeletal evidence dates only to early Christian era Europe. The disease was certainly common in Europe by medieval times, but most of the lepers were killed off by the bubonic plague.

Although viruses are responsible for a long list of human diseases, there is little evidence of these intracellular parasites in paleopathology. A rare example is the mummy of the Pharaoh Siptah, of the 19th Dynasty, which shows a leg deformity characteristic of polio. Smallpox has been diagnosed in the mummy of Ramses V and a mummy of the 20th Dynasty. The effects of viruses on nonimmune populations have been demonstrated repeatedly. Measles, smallpox, and yellow fever have been largely responsible for the decimation of aboriginal populations in America, Australia, New Zealand, and among the Inuit.

Fungi are plants that produce chronic infections in humans. These organisms are often seen in paleopathology but are invariably postmortem contaminants.

Protozoa are single-celled animals responsible for many infections, primarily in tropical and underdeveloped countries. Evidence of the malaria has been found in Egyptian mummies.

Diseases caused by helminths (worms) are relatively uncommon in temperate climates but have a major impact on tropical and subtropical areas. Worms are classified morphologically as roundworms (nematodes), flatworms, or "tapeworms" (cestodes) and flukes (trematodes). Most helminths have elaborate life cycles often requiring intermediate hosts and almost always involving the ingestion of infective forms, ova or larvae, by the definitive host. The effect on the host is variable. Some parasites cause profound debilitation while others have a more benign course. The latter probably are better adapted to their host, as it is to the advantage of the parasite for the host to be in relatively good health, death of the host meaning at the least a search for a new host, if not death for the parasite as well. The effects of the parasite on the host may bear a roughly inverse relationship to the time that the two genera have been associated.

Parasitic worms and their ova remain well preserved for millennia, and the characteristic ova of a roundworm,

Ascaris lumbricoides, tapeworm, *Taenia solium*, and blood fluke, *Schistosoma hematobium*, have been reported in Egyptian mummies, including one case of death due to cirrhosis. Parasitic worms and ova have been seen in European bog bodies and in the New World. Adult hookworms, *Ancylostoma duodenale*, have been seen in the small intestine of a 1,000-year-old Peruvian mummy.

Metabolic and Nutritional Disorders

Metabolic diseases may affect the skeleton. A condition of too little bone, osteoporosis, has three major causes: (1) disuse atrophy; (2) a decrease in anabolic hormones, especially in postmenopausal women, and (3) an increase in catabolic hormones, such as androgens or corticosteroids. Affecting the weight-bearing vertebrae predominantly, the bones are thin, light, and weak, and pathologic fractures can occur, causing kyphosis (hunchback), or scoliosis (lateral curvature of the spine), and loss of stature.

Excessive production of growth hormone in the adult results in acromegaly, which has been diagnosed in ancient skulls and on some depictions on coins. It has been suggested that the skull of the Pharaoh Akhenaten showed acromegalic changes, perhaps as a manifestation of a multiple endocrine adenopathy syndrome.

A chemical abnormality of bone is the deposition of abnormal elements, such as lead, which concentrates in the brain and kidneys as well. Chronic lead poisoning has been postulated as a factor in the fall of ancient Rome and in the high incidence of gout in Victorian England (lead damage to the kidneys causing decreased uric acid excretion and elevated serum uric acid levels).

Calcium can be deposited in tissues under conditions of high blood levels and may occasionally progress to the formation of bone in abnormal areas—ectopic bone formation. An example is the ossification of the thyroid cartilage seen frequently in ancient skeletal remains.

The metabolic disease seen most frequently in paleopathology is porotic hyperostosis, noted above in relation to malaria and other infections. In the prehistoric New World, the disorder has been linked to the transition from hunting and gathering to maize- and grain-based agriculture (El-Najjar, Ryan, Turner, & Lozoff, 1976). Maize, which is very low in usable iron, contains phytic acid, a compound that binds iron in other foodstuffs and reduces its absorption in the intestine. Children require a specific minimum iron intake during the first three years

of life and display porotic hyperostosis more frequently than adults. Hyperplasia of the bone marrow, particularly evident in the skull, results in a coral-like external appearance and X-rays show a characteristic hair-on-end change. The lesions seen in ancient specimens closely resemble those seen in contemporary iron deficiency anemia, which is the most common cause of porotic hyperostosis worldwide.

Vitamin abnormalities affect the skeleton. Scurvy (vitamin C deficiency) produces subperiosteal hemorrhage and new bone formation. Rickets (vitamin D deficiency) causes osteomalacia, softening and decalcification of the bone, with fractures, bowing deformities, and scoliosis. There is some scattered evidence for rickets, ranging from the possibility of the disease in *Homo erectus* and (more likely) in Neanderthals to Cro-Magnon and medieval Europe. Some cases have been suggested in Egyptian remains, perhaps related to *purdah*.

An example of hypervitaminosis A has been diagnosed in a 1.5 million-year-old *Homo erectus* skeleton found in Kenya, probably due to eating raw liver (the ingestion of 400 g a day would be enough to cause the disease). The long bones show a diffuse diaphyseal periosteal bone deposition, consisting of cancellous type bone sharply demarcated from the overlying cortex, with a striking enlargement of the osteocytic lacunae. This was a time before the use of fire, so the liver may well have been a preferential food, as it is easily chewed when raw—an illustration of the risks of changes in food sources.

Endogenous or exogenous pigments are extraordinarily persistent in ancient remains and thus of great interest in paleopathology. The endogenous pigments are melanin and pigments derived from hemoglobin. An abnormal breakdown product of hemoglobin, hemein, is deposited in the liver and spleen in malaria and has been seen in one Egyptian mummy.

Pneumoconiosis is the deposition of exogenous pigments in the lungs, including coal dust or carbon pigment (anthracosis), silicon dioxide (silicosis), iron dust (siderosis), and asbestos fibers (asbestosis). Anthracosis and silicosis have been documented in virtually all civilizations, past and present. Anthracosis usually is due to the inhalation of smoke from open cooking or heating fires, in the home or in industrial settings, while silicosis is due to sandstorms or mining activities. Carbon pigment appears to be relatively inert, but the other pneumoconioses lead to inflammation and fibrosis and predispose to other diseases, such as tuberculosis and cancer.

Immunologic Diseases

Although these are serious problems in the modern world (AIDS, lupus erythematosus, etc.), these diseases have not been identified in the paleopathologic record.

Degenerative Disease

Osteoarthritis (OA) is probably the best documented disease in paleopathology. It has been described in Neanderthals and in Cro-Magnon and Paleolithic humans. Many Egyptian skeletons show characteristic lesions, indicating that this is truly a “wear and tear” disorder, rather than being due, as was once thought, to cold damp climates. The disease has also been described in more recent skeletons from Britain and Europe. OA is seen in joints that are used excessively. Examples of this are OA of the temporomandibular joint in populations that employ vigorous mastication of a rough diet, and *atlantl* elbow seen in native American populations using a throwing stick.

Rheumatoid arthritis is a disease of the smaller bones of the hands and feet and the changes are sometimes only radiological, so the diagnosis is difficult in the usual archeological material. An Egyptian mummy has been diagnosed as having gout, with uric acid deposits in the joints.

Circulatory Abnormalities

Changes in the delivery to the tissues of a normal amount of blood containing the proper amount of electrolytes, nutrients, and oxygen at the proper pressure can result in damage. Infarction is necrosis of tissue due to interruption of the blood supply, usually due to atherosclerosis. Myocardial (heart) and pulmonary (lung) infarcts are often immediately fatal, but they may heal, often with scarring and impaired function. There is considerable paleopathologic evidence of atherosclerosis and Egyptian tomb paintings give evidence of acute myocardial infarction, but experimental studies show that the necrosis of an acute infarct is indistinguishable from postmortem autolysis and thus probably undiagnosable.

Cancer

This class of diseases is among the most important in industrialized societies. Benign tumors grow slowly,

remain localized, and cause only cosmetic or, occasionally, pressure effects. Malignant tumors, or cancers, grow rapidly and have the ability to invade locally and to spread throughout the body, metastasize, causing the death of the individual. The progression of such tumors can be erratic, but, if unchecked by medical or surgical intervention, cancers will metastasize to vital organs via lymphatics or blood vessels, destroying the function of organs such as the liver, lung, or brain and causing death.

There have been a number of studies indicating that cancer is a relatively modern disease. Comparative evidence shows that tumors are rare in nonhuman primates. One very early tumor is most likely not a cancer but a benign proliferation of bone of the femur of *Homo erectus*, the immediate predecessor of *Homo sapiens*, discovered in Java in the early 20th century. This lesion has been diagnosed as either myositis ossificans, a reaction to trauma, or an example of fluorosis. Identical lesions have been seen in modern patients suffering from excess ingestion of fluorine and similar lesions are noted in sheep grazing in volcanic areas, such as Java. Tumors are mentioned in the Egyptian medical papyri but have been interpreted by modern readers as simply swellings or perhaps varicose veins. Cancer’s crab-like nature was noted by the Greeks about 200 AD, but the first reports in the scientific literature of a number of distinctive tumors have only been over the past 200 years. Examples include scrotal cancer in chimney sweeps in 1775, nasal cancer in snuff-users in 1761, and Hodgkin’s disease in 1832. Only one diagnosis of a soft tissue tumor has been reported in a mummy—rectal carcinoma in an Egyptian of the 3rd century AD.

Tens of thousands of skeletons have been examined and only a few tumor diagnoses made. Osteomas of the skull have been described in several different skeletal populations. Osteochondromas have been diagnosed in skeletons from Scandinavia, Egypt, and in the New World. A medieval skeleton from the Swedish island of Gotland showed multiple exostoses, some of which occluded the pelvic outlet, with death in labor. The unborn fetus showed evidence of the same disease. Tumors described by Elliot-Smith and Ruffer in Egyptian skeletons as osteosarcoma, primary malignancy of bone, are unlikely to be so, based on the gross morphology. Some more likely cases have been reported from Europe and Peru, although these could be reactive processes, secondary to infection. Osteosarcoma is not an exceptionally rare tumor now and, as it usually produces bone,

one might expect it more frequently in archeological material than we do, especially as this is a tumor of young people. Bone is notorious for trapping radioactive minerals and one can speculate on the role of radiation in our modern world in causing bone tumors.

Bone can be invaded by local tumors, and bone metastases are common in the modern world but have been diagnosed only rarely in ancient material. Metastatic carcinoma and postmortem erosion can produce similar changes, namely the formation of multiple round defects in the bone.

It has been suggested that the short life span of individuals in antiquity precluded the development of cancer. Although this statistical construct is true, many persons did live to a sufficiently advanced age to develop other degenerative diseases, such as atherosclerosis, Paget's disease of bone, and arthritis. It must also be remembered that, in modern populations, bone tumors primarily affect the young.

Another explanation for the rarity of tumors in ancient remains is that tumors might not be well preserved, but experimental studies show that mummification preserves the features of malignancy. In an ancient society lacking surgical intervention, evidence of cancer should remain in all cases. The virtual absence of malignancies must be interpreted as indicating their rarity in antiquity. The majority of human cancers are believed to be related to environmental factors, and studies indicating a rarity of cancer in antiquity suggest that such factors are limited to societies affected by modern industrialization.

Dental Paleopathology

Caries (cavities) is very much a disease of civilization but has probably always been associated with humans and is found in wild apes as well. Caries have been noted in Australopithecines, *Homo erectus*, and Neanderthals. Neolithic populations show caries in 2–10% of all teeth. For the Roman period and the middle ages the figure is slightly higher, 5–14%, but with the increase in the use of more refined sugars and flours in the diet over the past 1,000 years the incidence has risen to the modern figure of 50–90%.

Caries has an inverse relationship with dental attrition, tooth wear, which has decreased since antiquity. The diet in ancient times contained much grit, as flour or meal was made by grinding wheat or corn on stone slabs.

X-rays of ancient Egyptian bread have demonstrated significant amounts of grit. Native Americans in the southwest prepared corn meal on a stone mano/metate and it has been estimated that the average Indian ate three manos and metates in a lifetime. It is common to find ancient teeth worn down to the gumline as a result of this type of diet. As the teeth are worn down, they continue to erupt, so-called supereruption, and can eventually be lost as the roots are exposed.

Periodontal disease (pyorrhea) was also more common in antiquity. This condition is an infection involving not only the alveolar bone (the tooth socket) but also the soft tissues of the mouth. Incidence rates on skulls will be underestimates, as minor infections may not involve the bone. The effect of the disease is to cause recession of the alveolus, with loosening and eventual loss of the teeth. The gradual softening of the diet and improved oral hygiene has greatly reduced the incidence of this disease. However, evidence of periodontal disease extends back into the Pleistocene.

Enamel hypoplasia is the appearance of depressed bands across the enamel, usually of the incisors. The cause has been related to nutritional deficiency and/or childhood illness, which are in turn related to social factors.

CONCLUSION

The paleopathologic examination of ancient human remains is useful for archeologists, anthropologists, and physicians. Paleopathologic techniques can also be applied to any desiccated tissues, including recent remains, as in forensic settings.

For the archeologist there is information on living conditions and social organization. In this context infectious and traumatic conditions are probably of the most interest. Infectious diseases require a certain minimal population living in close contact for their propagation and are thus associated with at least village living, if not urbanization. Disabling diseases, such as arthritis, which take some time to develop, imply a degree of social organization adequate to assume the burden of a cripple. The congenital disorders, such as achondroplasia, have a similar implication. Traumatic injuries tell us about the military or industrial status of a population. Tumors, while of interest to the pathologist studying the evolution of disease, are sporadic and probably of little interest to

the archeologist. In general, diseases seen in bones and mummies constitute a reflection of a certain aspect of the population or society under study and can provide information in the same fashion as do pottery or monumental architecture. On the other hand, different patterns of incidence or manifestation of disease can provide information on the evolution of diseases. Paleopathology adds a critical dimension to our study of human history and evolution in relation to the environment.

Psychoanalysis and Anthropology

Waud H. Kracke

Anthropology and psychoanalysis have much in common. The ability to listen, for example, is crucial to both disciplines. The approach psychoanalysis takes to mental illness is to listen to the patient and try to understand the structure of his symptoms and the origin of these symptoms in repressed or disavowed desires. The analyst supports the patient's quest to understand the reason these desires were disavowed, in conflicts between the desires and the person's values in the context of a set of

assumptions about life that grew up as a response to childhood experiences. Anthropology is likewise based on listening—listening to a person (“informant” or “collaborator”) and trying to understand the structure of this person's system of symbols, including the value system and the root assumptions about reality. Despite obvious differences—the psychoanalyst is responding to an individual patient who came to him for alleviation of personal suffering; the anthropologist is trying to understand

the shared culture of a large number of people—there is also considerable overlap in their concerns. Edward Sapir (1938/1963b), the anthropological linguist who shaped American cultural anthropology in the 1930s, believed that anthropology and psychoanalysis should be united under a common field of “cultural psychiatry.”

From the time of W.H.R. Rivers—a British psychiatrist who treated war neuroses with psychotherapeutic methods, contributed to the interpretation of dreams (Rivers, 1917–18, 1923), did the classic ethnography of the Todas, and made significant contributions to the development of social anthropology (Slobodin, 1978)—the mutual influence and shared interests of anthropology and psychoanalysis have been great. Following Sapir’s lead in bringing the two disciplines together, the psychoanalysts Erik Erikson, George Devereux, and most recently Jacques Lacan and Willy Apollon have made culture and language central to their psychoanalytic thought.

Of special interest to medical anthropology are studies of ritual modes of curing mental illness (shamanism, possession ritual, and others), and rituals that have a prophylactic effect in helping to resolve emotional conflict in situations of vulnerability, such as mourning. One anthropologist/psychoanalyst has applied cultural understandings to effective treatment of psychosis (Apollon, 1991). Several writers have drawn comparisons between the anthropologist’s relationship with his or her native collaborators or “informants” and the kind of relationship established in the therapeutic situation. Culture shock is also a concern which was first identified in anthropology and which has important consequences for mental health—whether of the anthropologist in the field, or of the visitor or immigrant to another culture (Kracke, 1987). Also of anthropological interest is the development of psychoanalytic movements in new countries, especially those of the Third World. New cultures may face psychoanalysts with new kinds of personal problems and the culture itself may reshape the central concepts of psychoanalysis as it is practiced and thought about in each country. This may be seen in comparing psychoanalytic movements in different European cultures—the special developments of psychoanalysis in England and in France, for example; but even more, as psychoanalysis has taken root in many Third World cultures, the growth of psychoanalysis in India (Kakar, 1990), Japan (Okonogi, 1978–79), and most recently China.

PSYCHOANALYTIC UNDERSTANDING OF RITUAL CURE AND PROPHYLAXIS

Psychoanalysis, Freud tells us, is a mode of treatment of mental illness, a method on which that treatment is based, and a theory built on the results of that method. Let us begin with the mode of treatment.

If psychoanalysis can provide a treatment that cures neurosis in our own culture, then it must also be possible, using psychoanalytic theory, to understand the successes of native therapies in other cultures. To the extent that shamanic cures (Freeman, 1967; Toffelmeier & Luomala, 1936), healing by curanderos or diviners (Turner, 1961/1972, 1967, chapters 6 and 10), cures of spirit possession by trance, and cures through “sings,” or other ritual means are effective in overcoming symptoms—psychoanalysis may be able to provide some understanding of their process of cure. In a case I have discussed with David Szanton, a girl was taken to 16 different *babaylans* (a kind of curer in the Philippines) for episodes of violent symptoms. Only the seventeenth was able to relieve her, at least for a time. She did this by identifying an intense emotional issue in the family that had remained submerged: the mother had had a call to be a *babaylan* but the father would not permit her to do so (Guthrie & Szanton, 1972). Sudhir Kakar (1982, chapters 2 and 3) was able to interview patients visiting a Muslim *pir* (saint) and a healing shrine, to understand their problems and some of the ways in which the cure helped them.

Such cures need not be limited to hysterical or purely psychosomatic symptoms, or illnesses traditionally regarded as having a psychological component. It is becoming increasingly evident that the effective working of the immune system and the body’s combating of illness respond strongly to emotional states, so that the seemingly astonishing cures by faith healing or other ritual methods may be attributed, in some cases at least, to the effect of belief on the sick person’s ability to combat disease.

Although not generally considered a psychoanalytic anthropologist, Claude Lévi-Strauss has provided the best comparison I know of between healing ritual and the psychoanalytic process, and an excellent formulation of the nature of psychoanalytic treatment. His 1949 article “The Effectiveness of Symbols,” gives a brilliant demonstration of the healing effectiveness of a Cuna shamanic

ritual to deal with difficult childbirth, and a comparison with psychoanalytic cure. He shows that the Cuna ritual (in Panama) works through reproducing, in a shaman's song, a Cuna mythic landscape, creating an identification between the woman's own internal "landscape" (her birth canal), as subjectively perceived by her, and the cosmological landscape of the myth. By naming the pains to the suffering woman—"presenting them to her in a form accessible to conscious or unconscious thought"—the shaman's song "renders acceptable to the mind pains which the body refuses to tolerate" (Lévi-Strauss, 1963, p. 197). "In our view," Lévi-Strauss concludes, "the song constitutes a *psychological manipulation* of the sick organ, and it is precisely from the manipulation that a cure is expected" (p. 192; italics in original). Conversely, Lévi-Strauss suggests that psychoanalysis works by taking a "personal myth" constructed by the patient from his own past, and recreating it as a new personal myth incorporating previously repressed memories of the patient's. While some psychoanalytic anthropologists object to Lévi-Strauss's reformulation of the psychoanalytic cure (Bernard Juillerat, personal communication), I am not alone in considering it a brilliant formulation of the psychoanalytic process. The French psychoanalyst Jacques Lacan, whose theoretical formulations of psychoanalysis owe a great deal to Lévi-Strauss, borrowed the concept of "the individual myth of the neurotic" in his reformulation of psychoanalytic theory of treatment (Lacan, 1953).

A number of psychoanalytic anthropologists have looked at treatments for aberrant states of mind—mental illness—in "primitive" or nonwestern cultures. Anthony Wallace, for example, in several articles discussed traditional Iroquois dream interpretation rituals as a way of dealing with the psychic conflict expressed in dreams. The requirement that the dream be acted out, literally or symbolically, provided a kind of catharsis, he suggested, which prevented the conflicts in the dream from fulminating under repression into a full blown mental disorder. He compared this method to Freud's early "cathartic method" of hypnotic treatment that preceded the full development of psychoanalysis (Wallace, 1958, 1959). Yoram Bilu, an Israeli psychoanalytic anthropologist, has also shown parallels between the interpretations given by an early 20th-century mystic healer in Baghdad, Iraq, and some of Freud's dream interpretations (Bilu, 1979).

RITUAL AS PROPHYLAXIS: FUNERALS, MOURNING, AND THE WORK OF REMEMBERING

Not only rituals that are directed to healing illness, but other more general rituals may have a beneficial emotional or psychological effect on participants. Life crisis rituals and rites of passage deal with important crises or transitions in life which necessarily have personal meaning, and can stir up emotional conflict (Herdt, 1981, 1982). Victor Turner (1967) has written extensively on such rituals, and his formulations on ritual symbols are helpful in thinking about the personal issues dealt with in the ritual as well as the social issues of the transition. An especially helpful concept is his notion of the "bipolar symbol": that ritual symbols have both an "ideological pole," which represents important social values asserted in the ritual, and an "orectic pole," an aspect of the symbol that (often in a vivid way) calls up desires and emotions which may either reinforce the social values represented by the symbol, or be at odds with them, but which are in any case often unconscious. This concept is of great value in enabling us to understand the emotional import of a ritual, and the way it helps the celebrant deal with emotional issues stirred by a transition (cf. Ewing, 1992). It may be extended to thinking about the relationship between the explicit cultural value expressed in a myth and fantasies which may be unconsciously embedded in it (see Bettelheim, 1975); or indeed to any cultural product created by an individual or transmitted by individuals.

The way in which ritual may support emotional processes is especially evident in rituals of mourning. Several anthropologists have examined the ways in which ritual and cultural attitudes toward death support (or impede) the work of mourning (Bateson 1968; Levak, 1979; Reid, 1979). Beth Conklin discusses how the endocannibalistic funerary rites of the Wari Indians of Brazil work. She appropriately rejects the stereotyped "Freudian" explanations of some self-styled "psychoanalytic" folklorists of the old school such as: "Aggression. It's all about aggression. Every time you put something in your mouth, it's aggression" (Conklin, 2001, pp. 93–108). Then, after developing Wari ethnopsychology and their ideas about grief, ghosts, and the dangers of dwelling on memories, she gives her own interpretation

of how the mourning ritual helps the bereaved person to come to terms with the loss (pp. 228–239)—an interpretation which, despite her protests, is a very psychoanalytic one.

A concept which has been of great utility to the psychoanalytic understanding of ritual is Melford Spiro's (1961, 1965) concept of "culturally constituted defense mechanism." Certain social forms, from a custom to an entire social institution, may provide ways for individuals to deal with particular emotional conflicts: they are, as it were, social forms which are especially adapted to serve as personal defense mechanisms in the inner handling of those emotional issues. Spiro first introduced this concept in discussing Freud's (1914) suggestion that political institutions like the taboo on touching sacred chiefs, may be a way of simultaneously expressing and defending against the ambivalence all followers feel toward their leaders, or that mother-in-law avoidance may be a way of managing incestuous sexual desires in the family (Spiro, 1961). He developed the concept more fully in an article analyzing the psychological functions of Burmese monasticism (Spiro, 1965).

George Pollock (1972) drew on Melford Spiro's (1965) concept of a "culturally constituted defense" to demonstrate how orthodox Jewish mourning prescriptions segment mourning into periods that correspond to natural phases of mourning—crisis, grief, and coming to terms with loss. The directives mandate conduct in keeping with the shifting needs of the work of mourning that evolve through these periods. Emotional conflicts that are issues in mourning, such as the sense of guilt over ambivalence toward the lost person (one of the most frequent problems that disrupt mourning and lead to pathological grief), are articulated in the dominant symbols in the prayers and ritual injunctions. Thus, he suggests, mourning prescriptions help the bereaved person to deal with the needs of the work of mourning and to face the more difficult emotional issues that might otherwise lead to persisting emotional problems.

For Freud (1917/1957, pp. 244–245), the heart of mourning is the "work of remembering": the task of going through one's memories of life with the lost person and accepting that life will henceforth be without the person. Among the Sora of eastern India, Piers Vitebsky, an anthropologist trained in psychoanalysis, goes even more deeply into the sequence of states the deceased goes through, as the deceased person—or the memory of him or her—is gradually detached from the world of the

living. The different stages of this process make their "memories" into successively different kinds of presences for their surviving relatives—at first a presence whose nature depends on the way in which the person died, then a more generalized kind of presence. Vitebsky views this sequence of stages of dying not just as a "psychology of death," but as a "total interpretation of death," invoking the continued but gradually attenuated participation of the recently dead in the community (Vitebsky, 1993, p. 17); and he draws a parallel between this and the work of mourning as described by Freud.

Spiro's "culturally constituted defense," or as he later generalized it "culturally constituted compromise formation," can be used to mediate between the cultural level and the individual psychic level. It may be used, for example, to describe the way in which Parintintin Indians of Brazil use food taboos—avoidance of certain foods by both parents during a woman's pregnancy, or when one's child is sick. Dreams which the Parintintin report show that their food avoidances represent ambivalent feelings toward the coming infant or toward a sick child, feelings which they cannot acknowledge openly to themselves; the food avoidances serve simultaneously as a way of expressing the ambivalence, and of expiating it (Kracke, 1990).

PERSONAL SYMBOLS

In a study of Sri Lankan Sinhalese ascetic mystics, Gananath Obeyesekere has focused on one symbol of their ascetic condition: matted locks of hair, which are regarded as the *lingam* (phallus) of the god. In a series of in-depth interviews with several of these women, he discovers how they use this collective religious symbol to resolve personal, emotional problems in their lives (Obeyesekere, 1981). Such symbols—publicly recognized symbols which, however, retain a deep and unique personal significance—he terms "personal symbols." He develops an argument in his book, based on interviews with a number of these ascetic mystics, that such "personal symbols" may express problematic emotions, forbidden wishes, and guilt over them. The public symbols are appropriated by each individual as a kind of collectively provided personal symptom. In a subsequent book (Obeyesekere, 1990), he generalizes this line of thinking, in an analogy with the "dream work" (Freud, 1900/1955),

to “the work of culture”: the transformation of personal fantasy into collective symbols.

Obeyesekere’s term “personal symbol” has gained currency in psychoanalytic anthropology. Earlier Vincent Crapanzano had made some similar points about the female *jinn* figure, Aisha Qandisha, a Moroccan incubus demon who seduces men in their dreams and compels those who submit to her advances to marry her. A jealous bride, she permits no rivals in the waking lives of those men who have dreamed of her. While each man so trapped by her has his own dreams of her, his own personal conflicts expressed in the dream, she is nonetheless a shared cultural spirit. Crapanzano referred to such culturally provided vessels for personal fantasy as “symbolic–interpretive elements” in terms of which personal conflicts can be “symbolically articulated and resolved.”

ANTHROPOLOGICAL CONTRIBUTIONS TO THE TREATMENT OF PSYCHOSIS

The treatment of mental illness is a subject of considerable interest for psychoanalytic anthropology, in nonwestern societies and closer to home. Treatment programs of psychosis that integrate native healers into the treatment process have had striking results. A well-known example is the program started by T. Adeoye Lambo at Naro in Nigeria, in which patients were taken into families in the village of Naro and, as part of the treatment, worked and participated in village and family life. Native healers were used alongside psychiatrists as part of the treatment (Lambo, 1964).

The psychoanalytic treatment of psychosis in North America was pioneered by two psychoanalysts who are also anthropologists. Bryce Boyer, who, together with his anthropologist wife Ruth, has lived among the Apache and done extensive field work with them (to the extent of being initiated as an Apache shaman: Boyer, 1964), was one of the first analysts in the United States to undertake psychoanalytic treatment of psychotic patients. His successful practice stimulated others, and led to the formation of the Boyer Institute in San Francisco. An extraordinarily successful treatment program for psychosis has been developed and run by Willy Apollon, a psychoanalyst from Haiti with anthropological training, with his colleagues, Danielle Bergeron and Lucie Cantin. Apollon, who did anthropological study of Vaudou for

his Sorbonne degree in philosophy (Apollon, 1998), together with Bergeron and Cantin, has constructed a psychoanalytically based program for the treatment of young adult psychotics in Quebec (Apollon, Bergeron, & Cantin, 2000). The program, run by GIFRIC (“The Interdisciplinary Freudian Group for Research and Clinical Intervention”), treats psychotic patients with a combination of milieu therapy (art programs, discussion groups), close personal contacts with staff, and individual psychoanalytic treatment based on Lacanian principles. Anthropologists participate in the program, interviewing patients, studying patterns in the patients’ family backgrounds, and participating in the treatment process of each patient. The program has had impressive results, leading most of the patients eventually to the point where they have no further hospitalizations (most came into the program after repeated hospitalizations) and in many cases resume a productive life of work or study (Apollon, Bergeron, & Cantin, 1990, 2000). This program can be considered a successful integration of anthropological and psychoanalytic approaches in an effective treatment program (Apollon, 1999).

CULTURAL EXPRESSION OF NEUROSES AND PSYCHOSES

Symptoms, as Freud emphasized, do not necessarily reveal the underlying pathological process. The important thing to understand is the underlying psychic structure: a phobia or an obsession may be the expression of a hysterical or obsessive neurotic structure, or they may be the symptoms of a psychosis. If the structures of a personality or an individual neurosis may be expressed in quite different ways, then it stands to reason that neurotic and psychotic processes would express themselves in different ways in different cultures.

The prevalence and forms of mental illness in different cultures is an old concern of psychoanalytic anthropology; culturally specific behavioral manifestations of schizophrenia have been discussed for Japan (Caudill, 1959), Italy (Parsons, 1969), and many other cultures. Parsons also raised the question of how people in a community differentiate mental illness from culturally appropriate accusations of witchcraft. Melford Spiro wrote on a case of psychosis in Ifaluk (Spiro, 1950), and later considered the cultural factors that contribute to mental illness in that culture (Spiro, 1959). One of

George Devereux's better known articles deals with the cultural aspects of mental illness, arguing that psychological dysfunction can be seen as a malfunction in the individual's relationship to his culture.

The "ethnic psychoses" have been another concern (Foulks, 1972). Thomas Hay (1971) analyzed Ojibwa windigo psychosis—possession by a cannibalistic "windigo" demon—as a culturally patterned manifestation of clinical depression. The analyst Daniel K. Freeman treated an Apache man with Ghost Sickness while a resident in psychiatry in a hospital near the Apache reservation (Freeman, Foulks, & Freeman, 1976), again seeing it as an expression of disordered mourning. Yoram Bilu (1985) analyzed 17–19th-century *dybbuk* possession as a "culture-specific syndrome," and showed how the descriptions of *dybbuk* exorcism could be understood psychoanalytically. He discusses several cases of possession, comparing them with Freud's (1923/1961) analysis of a 17th-century "demonological neurosis" and arguing that they can be understood as cases of hysteria. More recently, Douglas Hollan (1994) has discussed a case of "magical poisoning" among the Toraja: a man who, after a confrontation with another man in a market over the exchange of some chickens, had "visions of chickens crawling all over his body" and other symptoms conventionally linked to magical attack. Hollan situates this event in his life history, accounting for the man's symptom as a response to his own anger. Other manifestations of anxiety (including anxiety after a death), and of neurotic symptoms, are discussed in his book of the same period (Hollan, 1994).

In Brazil, there is a lively interest in the social aspects of mental illness and its treatment, evidenced not only in publications (Cerqueira, 1982; Freire Costa, 1986, 1989, 1994) but also in the active meetings of the Brazilian Association of Ethnopsychiatry (ABE). A special cultural problem of mental health has been of considerable concern to psychoanalysts and anthropologists (Sebe Bom Meihy, 1991): the incidence of suicide in many Brazilian (and other American) indigenous cultures, nowhere higher than among the Kaiowá Guaraní. Darcy Ribeiro first called attention to the problem of suicide in Tupí groups in his moving story of an Urubú Indian man who, after the death of his son, goes on a long wandering journey culminating in his suicide by drowning himself in a river (Ribeiro, 1957/1980). More recently the problem of frequent suicide among Guaraní Indians has been discussed at anthropological conferences and

at meetings of the ABE. The psychoanalyst Sergio Levcovitz (1998) made a personal visit to the Kaiowá reservation to investigate the factors that lead to this situation. In a framework that combines Durkheim's concept of *anomie* and Lévi-Strauss's of structure (Lévi-Strauss, 1949/1963) with Freud, Levcovitz undertook a field study and an exploration of the comparative anthropological literature on other related (Tupí) groups, exploring the traditional identity of the Guaraní and the impact on it of the conditions to which they have been subjected in their reservation. This is an important study worthy of being more widely read, and (like several of the other works mentioned in this paragraph) should be translated.

ANTHROPOLOGICAL INTERVIEWING AND PSYCHOANALYTIC PROCESS: COMPARISON

Anthropologists from early on have been aware of the importance of the relationship between the ethnographer and his or her principal "informants," and the relationships he or she forms in the culture studied. Malinowski wrote a great deal about his close relationship with the chief of Kiriwina and the garden magician Bagido'u; Joseph B. Casagrande (1950) even published a collection of articles written by anthropologists about their principal informants, or those with whom they had closest relationships in the culture. Roberto DaMatta, in an article in Portuguese on "The Vocation of the Ethnographer," distinguished the "chief informant"—the person who provides the ethnographer with the most information—from the "cultural guide," those with whom one forms a personal relationship which helps one adapt to the culture (DaMatta, 1978). These relationships can be quite intense, as testified by many of the articles in Casagrande's book, both (as DaMatta suggested) on the part of the anthropologist and on the part of the people in the culture with whom the ethnographer forms relationships. Gilbert Herdt and Robert Stoller (1987, 1990) have written an article and a book comparing Stoller's psychoanalytic interviews with Herdt's anthropological ones. Katherine Ewing (1987) compares an anthropological interview with a psychoanalytic session using her own field interviews and treatment interviews as examples. Very roughly summarized: psychoanalysts put greater stock in withholding closure and "listening

between the lines,” noting discrepancies between what is said and the tone in which it is said, supporting the emerging thought rather than the finished argument; they privilege listening for the hesitant expression of personal, individual thoughts and feelings rather than the confident expression of shared values. Anthropologists focus more attention on agreement or disagreement between different people being interviewed, eliciting the shared pattern of thought or the social emotion. Yet, perhaps emphasizing the compatibility of the two points of view, a number of psychoanalytic anthropologists have taken full psychoanalytic training and are now treating patients psychoanalytically—a trend led by Melford Spiro (2003) and Robert Paul. Anthropologists have also contributed to psychoanalytic thinking. Vincent Crapanzano has stressed the linguistic basis of the concept of transference, comparing it with the linguistic concept of “pragmatics” (Crapanzano, 1981, 1994).

Comparison between anthropological interviewing and psychoanalytic sessions can clarify the understanding of what goes on between an anthropologist and his “informant” or “native associate” (if we may use this term to avoid the wartime associations of the now popular term “collaborator”), and perhaps put the analytic interview in a new light as well. The relationship that an anthropologist develops with those he works with in the field become quite close, and may have a significant impact on the life of the associate. A well-known example is that of the Hopi “Sun Chief” Don Talayesva and the anthropologist who recorded his life history, Leo Simmons. Dorothy Eggan’s (1949) article on Don Talayesva’s dreams bring out on the one hand Don’s idealization of his biographer, and on the other hand the extremely destructive effect on his life of Simmons’s insistence that he break his culture’s code of secrecy about ritual matters and disclose secret rituals in detail. This insistence was acknowledged in Simmons’s own introduction to the book, apparently without recognition of its significance. Simmons published these disclosures in his book (Talayesva/Simmons, 1900), resulting in near ostracism of Don in his own village and intense guilt, which was revealed in the dreams he recounted to Eggan. While the main point of Eggan’s article was a different one—Don’s guilt over his attraction to a forbidden woman—his complex feelings about his relationship with Otto Simpson come out clearly in the article. Eggan’s own work with him, on the other hand, was beneficial for him, helping him to resolve not only conflicts concerning a certain “Molly,” but also to rework some of the con-

flicting feelings in his relationship with Simmons, and to resolve some conflicts that were active in him since childhood (see discussion of the article in Kracke, 1991, pp. 211–217).

The relationship with an anthropologist may be psychologically harmful or helpful to the informant (or cultural associate), even therapeutic for some (for example, Victor Turner’s native assistant Muchona; Turner, 1959/1967a). I have noticed in my own field work that many of those I had interviews with made use of them to resolve personal issues; their interviews turned into brief periods of psychoanalytic therapy. One used the interviews to work through the mourning of two children who had just died (Kracke, 1980, 1981); another worked on a lifelong problem of insomnia, and gained some relief (Kracke, 1999); and a third abated his fear of illness when he recovered a childhood memory of the death of his father. Vincent Crapanzano discussed similar processes in his relationship with an old Moroccan man, Tuhami (Crapanzano, 1980). Michele Stephen takes these authors to task in her book on dreams (Stephen, 1995) for “being negotiated into the therapeutic role” (fn. 4, p. 337); but she herself, in an article on Mekeo (New Guinea) dreams, shows how empathically she was able to listen to her informant’s dreams and thus offer her informant an opportunity to work through her anger and guilt feelings. I do not recommend that anthropologists undertake psychotherapy with their informants (which would only be advisable for those trained in psychotherapy); but it is important for anthropologists to give much greater attention to the effect that their relationships with informants have on the emotional life of the informant, and be aware of issues such as the emotional process of disengagement as the time of departure nears (Kracke, 1999; see also the last paragraph of Turner, 1959/1967a).

The comparison of the anthropologist–informant relationship with psychotherapy can also be reversed. More than one ethnographer has compared the anthropologist’s position with that of the patient in analysis (DaMatta, 1978). Jean Briggs discusses the intense relationship she formed with Inuttiaq, the Utku group leader who adopted her as a “daughter” in his family. The anthropologist is placed in a situation where she or he is dealing with unfamiliar stimuli and unexpected responses, a situation in which (like a child) he does not know what to expect, does not understand what is going on. This, like the psychoanalytic situation, promotes regression, and dependence and idealization of the persons who are willing to provide succor. Since in

anthropology, as in psychoanalysis, the person of the ethnographer himself or herself is the instrument of observation (Bateson, 1968), it is important for us to understand the nature of our responses to the situation in which we find ourselves. The mental health of the anthropologist, as well as that of the native colleagues, is of concern, not only to medical anthropology, but also to the ethics of every anthropologist who works in the field with living people.

CULTURE SHOCK: A PHENOMENON FUNDAMENTAL TO ANTHROPOLOGY AND A HEALTH CONCERN

The immersion in a culture different from one's own alternates periods of excitement and exhilaration with periods of great stress and exhaustion. This is true for anthropologists visiting another culture as much as for immigrants or visitors to a new culture. The various experiences involved in encountering a new culture, only partially encompassed by Kalervo Oberg's (1950) term "culture shock," are at the heart of the anthropological experience. They have been well described by novelists: E. M. Forster's *Passage to India*, Chinua Achebe's *Things Fall Apart*, and Laura Bohannan's *Return to Laughter*, to mention just a few. This process of adaptation to another culture is also of importance to medical anthropology: culture shock may be a major precipitant of emotional and psychological breakdown. Perhaps this is one reason why many of the people writing about culture shock have been psychotherapists and psychoanalysts (Antokoletz, 1987; Desai & Coelho, 1980; Garza-Guerrero, 1974; Ticho, 1971). The Japanese psychoanalyst Takeo Doi described his own culture shock on coming to the United States (Doi, 1973, chapter 1). But it has also, particularly recently, been an issue discussed by anthropologists with an interest in psychoanalysis (Bateson, 1968; Briggs, 1970, esp. chapter 6, Kracke, 1987, 2002). William Caudill (1961) has written of the process of adapting to another culture as one of "resocialization," going through childhood socialization again in the new culture. Garza-Guerrero (1974) stressed the mourning of one's own culture and the formation of a new identity in the new one, a model which Desai and Coelho (1980) apply to their therapeutic work with Indians having difficulty in adapting to the United States. I have argued (Kracke, 1987) that the experience of encountering a new culture can be

likened to an analytic experience, with the ambiguity and uncertainty of the new environment and the relationships formed in it promoting regression and transferences to the new culture. The experience puts one at risk of emotional distress, but also offers the opportunity for deep personal change in adapting to the new culture.

PSYCHOANALYTIC MOVEMENTS IN THIRD WORLD COUNTRIES: BRAZIL, JAPAN, INDIA, CHINA AND RUSSIA

The establishment of psychoanalytic movements in many non-European countries, especially in the Second and Third Worlds, offers an opportunity for psychoanalytic anthropology to study the adaptation of psychoanalysis itself to diverse cultures (Kutter, 1995). In Russia, psychoanalysis was centrally involved in the 1917 revolution, being regarded as a liberating intellectual movement; but was suppressed when Stalin took a dislike to it. Many of the well-known Russian psychologists, such as Alexander Luria and Lev Vygotsky, were analytically trained (Etkind, 1995). It has recently been undergoing a resurgence there. I have mentioned psychoanalysis in Brazil, which began early (Mezan, 1988); the first talk by a Brazilian psychiatrist on Freud's theory of neurosis was in 1899—though interest in Freud's theories of childhood sexuality was at first directed toward stricter controls on children's expression of sexuality. Real interest in psychoanalysis began among the group of artists who were active in the "Week of Modern Art" (*Semana de arte moderna*) in 1922, and by the psychiatrist Durval Marcondes; the history of Brazilian psychoanalysis has been ably researched by anthropologist Roberto Yutaka Sagawa (1985, 1994). Brazilian psychoanalysis, like Brazilian intellectual life in general, is deeply concerned with social justice. The accessibility of psychoanalysis for all, regardless of income, has been a constant ethical issue. An event from the time of the Brazilian dictatorship, when a psychoanalytic candidate was revealed to have been participating as a doctor in a government torture team, has continued to raise ethical concerns in Brazil, with worldwide repercussions (Vianna, 1994, 1997; Villareal, 1997; Villela 1998; see also Danneberg, 1995).

The psychoanalytic movements in India and Japan were established at an early date, in the 1920s and 1930s when Freud was still alive and able to engage with

them. The Indian psychiatrist Girindrashakhar Bose (1886–1953) read Freud's work and by 1914 undertook the use of Freud's methods, and his variants on them, in his own practice. In 1929 he corresponded with Freud about the difference between the underlying fantasies of his Indian patients and European ones: the fantasy of wishing to be a woman—what Karen Horney termed “womb envy”—was much more accessible to his Indian patients (Kakar, 1990). He did not just apply Freud's ideas to his Indian patients, but also “used Indian cultural categories to domesticate psychoanalysis for Indians” (Nandy, 1995, p. 123; Ramanujam, 1992). The Indian Journal of Psychoanalysis, *Samiksa*, has become a major organ for publication of articles by Indian psychoanalysts, including some interesting case histories (e.g., Kakar, 1979, 1980). Sudhir Kakar is India's best known psychoanalyst today. A student of engineering, Kakar befriended a lonely Erik Erikson while the latter was in India researching his book on Gandhi (Erikson, 1969). Then, with Erikson's influence, Kakar undertook psychoanalytic training in Berlin. He went on to author a number of books on psychoanalysis and Indian culture (Kakar, 1978, 1982, 1989). An article of special clinical importance is his “Psychoanalysis and Nonwestern Cultures” (Kakar, 1985), discussing the differences in experiences brought about by different conditions of child-rearing in India, and the modifications that must be made in psychoanalytic method to analyze Indian patients. Complaining of ethnocentric evaluations of Indian child development in American psychoanalytic articles—assertions of “overstimulation in the oedipal period” and the “pull toward oral fixation” because of “intense libidinal gratification”—he responds that from the Indian point of view a European or American child might just as well be seen as “sensually starved or understimulated” (p. 442). He calls for a “relativising” of psychoanalysis through exploration of the range of family conditions experienced by growing children in the different cultures of the world. On the other hand, he finds the kind of introspection presupposed in psychoanalytic treatment something characteristic of European thought, derived from Greek precedents, posing difficulties for psychoanalytic treatment with traditional Indian patients. B. K. Ramanujam (1986) offers a slightly different perspective through clinical examples, presenting his successful analytic work with two traditional Indians.

Though interest in psychoanalysis began in Japan in the early part of the 20th century, 1912–1914, and a

school influenced by Adolph Meyer flourished in the 1920s, psychoanalysis in Japan began in earnest when Heisaku Kosawa (1897–1968) went to Vienna for training in 1932. While there he had training analysis with Richard Sterba and supervision from Paul Federn, and visited Freud to present Freud with his paper on the “Ajase complex.” Kosawa's analysis of the myth of Ajase, which epitomizes the intense ambivalence of the son toward the mother stemming from intense dependency feelings, was a first step toward a distinctively Japanese psychoanalytic theory (Okonogi, 1978–79). More recently, Takeo Doi (1973)—a Japanese psychoanalyst who did his psychiatric training in the United States—has developed a psychoanalytic theory in which the central part is played by the emotion designated in Japanese *amae*, referring to the dependent love an infant has for the mother—a form of love for which there is no term in English (but which is comparable to Balint's “primary object love,” or Heinz Kohut's “self-object relationship”). What is especially distinctive about Doi's psychoanalytic theory, and what makes it of special interest to psychoanalytic anthropology, is that he has elaborated the theory entirely from Japanese ethnopsychological concepts. Doi's theory, translated into English, has provoked some interest in psychoanalytic circles around the world. It has also stirred controversy at home in Japan, where some other analysts and sociologists suggest that *amae* is regarded as more problematic in Japanese culture than Doi has portrayed it (Kumagai & Kumagai, 1986).

In China, the works of Freud were translated in the 1930s by a small group of analysts, but it is only recently that Chinese psychoanalysis has taken a major leap forward. Until recently, most mental patients in China have been treated by drugs, sometimes with antipsychotic medications used to treat patients with a neurosis much more appropriately treated by psychotherapy. An “International Symposium of Psychoanalysis” was held for the first time in 2001 and repeated in 2002, the first under the auspices of the Beijing University Medical Center and its director Hu Peicheng, and the second hosted by Professor Huo Datong in Chengdu. Translation and important contributions were provided by the Taiwan-based psychoanalyst Therese Bai. A major figure in Chinese psychoanalysis today is Huo Datong, who was analyzed in Paris and trained there in Lacanian psychoanalysis. Huo Datong has established a school of psychoanalysis at Sichuan University in Chengdu, Sichuan,

where a generation of psychoanalysts is now in training. Huo Datong's thesis in Paris was on the analysis of Chinese folklore. At the two conferences, he has been developing a theory of the unconscious expressed in Chinese characters, comparing the structure of dreams with the structure of meaning in characters. This work, which promises to establish a distinctly Chinese perspective on psychoanalysis, is being translated into English and French. Professor Hao's work, and the problem of reconciling psychoanalysis with the reticence before authority figures traditional in Chinese society—still true even with the cultural changes that have gone on in mainland China—these developments promise interesting cultural developments.

The introduction of psychoanalysis to a new country, particularly one of a nonwestern cultural heritage, offers an opportunity for psychoanalytic anthropology to examine the adaptation of psychoanalysis to new cultural conditions, and the new perspectives in psychoanalysis that may result from this adaptation. It may be seen as a continuation of the mutual relationship between psychoanalysis and anthropology envisioned by Sapir.

Medical Systems

Bioethics

Contemporary Anthropological Approaches

Elisa J. Gordon

INTRODUCTION: THE IMPORTANCE OF ANTHROPOLOGY TO BIOETHICS

Anthropology offers much to the world of bioethics, including theoretical approaches, methods, and practical guidance to health care professionals. Theoretically, anthropological research challenges cultural and social norms about identity, personhood, distinctions between self and other, definitions of life and death, and what it is that makes us human. Our comparative approach enables us to reveal just how moral assumptions and norms are not universal while demonstrating at the same time the cultural basis of moral reasoning. The social sciences also contribute to a view of ethical issues as societal problems, in this way illuminating the cultural processes that constitute ethical concerns (Haimes, 2002). Methodologically, anthropology has helped to “humanize” (Kleinman, 1995a, 1995b) bioethics by using ethnographic methods that enable a thick description of cases which illuminate people’s grounded experiences of responding to ethical dilemmas and the values that enter into their moral reasoning (Hoffmaster, 1990, 1992; Marshall & Koenig, 2001). A contextualist approach to bioethics therefore prioritizes the “is” (people’s actions and the values informing those actions) over the “ought” (what people believe they ideally should do), while recognizing that moral ideals vary cross-culturally. Anthropological approaches help develop “a more empirically grounded theory of morality” (Hoffmaster, 1992) and herald new or previously unrevealed moral considerations that help refine normative analysis (Haimes, 2002; Hoffmaster, 1990). Such first-hand experiences facilitate informed health policy-making.

In the following discussion I will explore ways in which anthropologists and sociologists have worked toward “humanizing” bioethics (Kleinman, 1995a, 1995b). First, I will briefly review the development of the

field of bioethics and present some relevant concepts. I will then review anthropological research that examines bioethics as a cultural domain of inquiry and cultural process. A number of theoretical issues and topical areas will be discussed in light of cross-cultural research in the field. Second, I will cover various applied efforts of anthropologists working in bioethics. Lastly, I will explore some promising avenues for further research in bioethics. While anthropological contributions to the field of bioethics are central to our discussion, it is paramount to include some related work by those outside the discipline since: (1) anthropologists are increasingly engaged in interdisciplinary collaborations, and (2) non-anthropologists, for example sociologists and philosophers, are adopting anthropological methods and theoretical approaches to better understand bioethical issues from a cultural perspective. These trends are not surprising given that bioethics is a multidisciplinary field without its own discipline. This discussion picks up where several review articles have left off to provide a more current review of contemporary debates and issues in the anthropological inquiry into bioethics (Kleinman, 1995a; Marshall, 1992; Marshall & Koenig, 1996; Muller, 1994).

HISTORICAL DEVELOPMENT OF BIOETHICS AS A CULTURAL DOMAIN OF INQUIRY

Bioethics emerged in the 1960s in response to myriad factors including: biotechnological developments, namely hemodialysis, organ transplantation, and mechanical ventilation; the civil rights movement; the backlash against physician paternalism; and revelations about abuses in human subjects research (Beecher, 1966; Fox, 1990; Rothman, 1990). Technological developments, for instance, raised questions about allocation of scarce

resources and whether quality or quantity of life should figure in decisions about the use of life-prolonging interventions. Patients' rights efforts challenged physician authority to know what is in patients' best interests and paved the way for greater patient involvement in medical decision-making. The revelations of experimentation atrocities committed during World War II against human prisoners, against human subjects in the course of clinical practice in the 1960s, coupled with ongoing revelations of abuses such as the syphilis study in Tuskegee, GA, and human radiation experiments conducted in the 1940s–1970s, have opened the door to new protections of human subjects participating in scientific research (Advisory Committee on Human Radiation Experiments, 1996; Jones, 1993).

Though some early work appeared in the 1980s (Kunstadter, 1980), anthropological interest in bioethics began to take root in the early 1990s. Medical sociologists' earlier works inspired anthropological theories about moral worlds within biomedicine (Bosk, 1979; Fox & Swazey, 1978, 1984). Anthropological interest in bioethics grew out of the work in anthropology of biomedicine. Within the biomedical health care setting, ethical or moral dilemmas arise every day since biomedicine is fraught with uncertainty and medical decisions must be made. Medical decisions, particularly those at the end of life and beginning of life, are informed by a host of moral values about doing what is considered best for the patient, particularly preventing suffering (Kleinman, 1995a, 1995b) and ensuring an acceptable quality of life. Similar issues within the study of biomedicine also drove the study of bioethics, especially concerns about how power dynamics affect the relationship between doctors and patients. Thus, anthropologists studying bioethics examine how issues come to be defined or established as moral quandaries, people's grounded experiences of engagement with and responses to ethical dilemmas, and the cultural values, beliefs, and social structural dynamics that contribute to ethical decision-making. Additionally, just as medical anthropologists have examined the cultural values underpinning biomedical theory and practice (Gordon, 1988; Hahn & Gaines, 1985), anthropologists have similarly turned their attention toward examining the cultural assumptions of normative principles of bioethics (we will explore this theme later on). Through these efforts, anthropologists have been leaders in the development of empirical bioethics (Frank et al., 1998; Gordon, 2001a;

Levin, 1988; Marshall, Koenig, Barnes, & Davis, 1998; Siminoff & Chillag, 1999).

DISTINCTIONS: BIOETHICS AND MEDICAL ETHICS; ETHICS AND MORALITY

The terms “bioethics” and “medical ethics” are frequently used interchangeably but they are distinct (Marshall & Koenig, 1996). Bioethics pertains to the ethical dilemmas and moral norms of health professionals (primarily physicians) emerging within contemporary biomedicine. In contrast, some scholars advocate a comparative approach to the study of medical ethics or “ethnoethics” that expands its purview beyond Western biomedical systems (Fabrega, 1990; Lieban, 1990). “Ethnoethics” is concerned with cross-cultural variations in ethical issues and moral norms within any health care setting or healing environment to illuminate their cultural underpinnings (Lieban, 1990, p. 223). Most anthropological research has concentrated on bioethics perhaps due to the breadth of compelling moral quandaries generated by biotechnology. Less work has been done on ethical issues arising outside of biomedicine (see Weisz, 1990), except for issues that more traditionally fall under the rubric of human rights, such as cliterodectomy (Gordon, 1991; Lane & Rubinstein, 1996).

There are multiple philosophical definitions of “ethics” and “morality.” For instance, “ethics” refers to the theoretical, practical, and descriptive study of moral life: people's standards of good action (as in professional codes) and moral behaviors and beliefs; “morality” refers to socially shared worldviews or conventions about right and wrong human conduct (in the context of medical care) (Beauchamp & Childress, 1994, pp. 4–5). Moral values are shaped by socio-cultural values and beliefs. “Ethical dilemma” denotes a situation in which a clinical decision must be made but there are at least two valid, opposing options, which are informed by moral values. Anthropologists may find these distinctions useful so that they can determine which cultural activities to analyze: values or decisions or both. Anthropological distinctions emphasize the cultural basis of local moral worlds (Kleinman, 1995a, p. 42). Certainly, not all anthropological inquiry into bioethics focuses on decision-making; much work has sought to thickly describe cases and experiences of moral issues.

BIOETHICS AS A CULTURAL DOMAIN OF INQUIRY AND CULTURAL PROCESS

Theoretical Issues in Bioethics

An exciting area of anthropological and sociological research has focused on critiquing the field of bioethics by highlighting the social, political, and cultural dimensions of its theoretical frameworks and what bioethics construes as topics of interest and topics to silence, for example cultural relativism (Crigger, 1998; Kleinman, 1995a, 1995b; Marshall, 1992; Muller, 1994). Echoing concerns noted by Fox and Swazey (1984) of bioethics' "provincialism," Kleinman (1995a, 1995b) contends that bioethics is limited in orientation because it is ethnocentric, psychocentric, and medicocentric in its inattention to non-Western moral traditions. Much of the critique aims to uncover the Western cultural foundations of the normative philosophical principles contributing to bioethical discourse. Early bioethics philosophers contend that the principles of autonomy, beneficence, non-maleficence, and justice are universal concepts (Beauchamp & Childress, 1994). However, several U.S. studies show that, for example, expressions of "justice" in terms of allocating scarce medical resources in a rural primary care practice setting differ from practices in urban settings (Brown, 1994; Jecker & Berg, 1992). The contingencies of rural life that engender face-to-face, everyday interpersonal relations with health providers who must make allocative decisions reveal that justice is not a blinded, impersonal process, as many philosophers contend. The principle of respect for "autonomy"—self-rule or agency that is free from interference from others (Beauchamp & Childress, 1994)—has been the target of greatest criticism because it prioritizes a sense of personhood as the individual, which is clearly Western, particularly American in orientation (Fox & Swazey, 1984; Wolpe, 1998). When most cultures espouse a socio-centric conception of personhood as opposed to an ego-centric or indexical self (Gaines, 1982; Shweder & Bourne, 1982), the enduring preeminence of an individualistic approach to moral reasoning and medical decisions appears limited, since families play an important role or even greater role than the individual in care-taking and decision-making in the United States and cross-culturally (Kuczewski & Marshall, 2002). A noteworthy contribution toward this line of work examined preferences for autonomous decision-making among four different

ethnic groups in the United States (Blackhall, Murphy, Frank, Michel, & Azen, 1995; Frank et al., 1998). Other bioethical constructs and assumptions that serve to buttress ethical arguments and health policies have also been subject to cultural analysis. For instance, while bioethics scholars presume that altruism drives people's decisions to donate their loved one's cadaveric organs, anthropological research shows that altruism plays little or no role in their decisions, but rather, decisions are made out of the personal desire to witness the loved one living on in another person, thus helping to make a devastating experience meaningful (Siminoff & Chillag, 1999). Moreover, concomitant to such challenges to the four principles is a growing recognition of other cultural norms that guide how people experience and resolve moral dilemmas and ethical issues, including the value of the community, respect for the elderly, or care (Das, 1999; Fox & Swazey, 1984; Gilligan, 1982; Kohn & McKechnie, 1999).

Topical Issues in Bioethics

Anthropological inquiry into bioethics has spanned a wide array of issues. However, many studies focus on the moral issues raised by the use of technological innovations in biomedicine because these technologies push social and cultural boundaries to new limits (e.g., Brodwin, 2000; Lock, Young, & Cambrosio, 2000). Also, much research shows high variability in decision-making processes by ethnicity, age, and cultural group. Let us consider the main topical areas by highlighting some of the relevant cross-cultural studies and current controversies.

Definitions of Death. Defining death fundamentally entails arbitrarily determining the end of an individual's personhood. The demarcation of death moves in concert with the use of mechanical ventilation and the recognized need for organ donation. Determinations of biological markers of death and of indicators of social death are largely culturally based. In Japan, for instance, death is traditionally construed as a process in which the spirit disconnects from the body in stages; thus, brain death is not recognized (Lock, 1996, 2002; Lock & Honde, 1990; Ohnuki-Tierney, 1994). In contrast, U.S. laws regarding definitions of death are established by individual states which define death as an event marked by the cessation of either respiratory, cardiac, or brain functioning to allow for cadaveric organ donation

(Lock, 2002; Lock & Honde, 1990). Importantly, Lock and Honde (1990) remind us to problematize the biomedical model of death such that we question why Americans so willingly accept new definitions of death. Definitions of death directly affect organ donation rates; living donation is more common in Japan whereas cadaveric donation is more common in the United States (Lock & Honde, 1990). Studying definitions of death reveals much about cultural politics and the cultural basis of health policies within a global context. Japanese resistance to organ donation and transplantation can also be attributed to reluctance to utilize imported transplant policies and technology because these are imbued with Western values of individualism and autonomy which run counter to traditional Japanese cultural values of family (Lock, 1995).

Organ Transplantation and Donation. Much anthropological research has concentrated on organ donation in the United States, exploring the cultural construction of gift-giving and the gift-giving bind emerging between organ donor family and recipient (Fox & Swazey, 1992; Fox, Swazey, & Cameron, 1984; Ikels, 1997; Joralemon, 1995; Sharp, 1995, 2001, 2002). Cultural beliefs and values greatly affect organ donation rates (e.g., Siminoff & Arnold, 1999). In Japan, cadaveric donation rates are low due in part to Japanese social practices dictating that taking things (organs) from others is socially unacceptable (Lock & Honde, 1990). Since gift-giving in Japan is grounded in a framework of reciprocity, organ recipients are in an awkward situation because they are obliged to repay the donor but cannot (Lock, 1995, p. 31). Given the greater need for organs than availability worldwide, some anthropologists have analyzed policies designed to increase national and international rates of organ and tissue donation, particularly financial incentives (Das, 2000; Joralemon, 2000; Marshall & Daar, 2000; Scheper-Hughes, 2000; Siminoff, Arnold, Caplan, Virnig, & Seltzer, 1995). Research examining the human experiences involved in the trade in human organs has shown that philosophical assumptions about the anonymity and freedom of exchange and improved lot in life among organ sellers and recipients do not bear out, as in the case of India (Cohen, 1999; Marshall & Daar, 2000). Other work has focused on organ procurement practices and policies in Germany (Hogle, 1999), decisions about distribution of organ transplants in the United States (Gordon, 2000), or socio-demographic

disparities in gaining access to kidney transplantation in the United States (Gordon, 2001a, 2001b).

Truth-Telling: Disclosure of Terminal Diagnosis and Prognosis.

The issue of disclosure of terminal diagnosis and prognosis (usually of cancer) has been examined in great depth cross-culturally. The comparative research has revealed much about the cultural influences on the doctor-patient relationship and the relative importance of autonomy. In Italy, China, and Japan, physicians have traditionally viewed their role as protecting patients by not disclosing to patients a diagnosis of cancer or prognosis of terminal illness, though this view is changing (Gordon, 1990, 1994; Gordon & Paci, 1997; Long, 1999, 2000b). In the United States, physicians disclose terminal diagnoses because of informed consent statutes (the Common Rule), which legally require patients' consent before physicians can administer treatment. Nevertheless, many American physicians hold a metaphysical view of hope as essential for patients in maintaining a will to survive (Christakis, 1999; DelVecchio Good, Good, Schaffer, & Lind, 1990; DelVecchio Good, Munakata, Kobayashi, Mattingly, & Good, 1994). In contrast to European Americans, diverse ethnic and religious groups in the United States, including Mexican Americans, Korean Americans, Chinese Americans, and non-protestants, report being averse to the idea of oncologists telling patients about a diagnosis of metastatic cancer and a terminal prognosis (Blackhall et al., 1999; Muller & Desmond, 1992; Orona, Koenig & Davis, 1994). Among such groups, discussions of impending death are avoided and believed to cause further suffering and believed to even be physically harmful to the dying; instead, a family-centered model of medical decision-making is preferred as a form of familial duty (Blackhall et al., 1995; Marshall et al., 1998; Muller & Desmond, 1992; Orona et al., 1994). Disclosing negative information such as a diagnosis of terminal illness is likewise avoided among Navajos because it undermines their cultural value of *hózhó*—a composite sense of beauty, goodness, order, and harmony—since language and thought have the power to affect reality (Carrese & Rhodes, 1995). Similar views about disclosure are maintained among Aboriginal patients in Canada (Kaufert, 1999). Most of these studies focus on the attitudes of patients and on the disclosure of diagnosis of cancer. Much less is known about disclosing prognosis to patients cross-culturally, though one U.S. study analyzed

the metaphors implicit in oncologists' perceptions of disclosing the prognosis of advanced cancer (Gordon & Daugherty, 2003a).

End-of-Life Care. End-of-life decision-making has been the focus of considerable anthropological attention, particularly as it relates to ethnic and cultural perspectives toward issues such as completing advance directives (do-not-resuscitate orders, living wills), withdrawal of ventilator support, artificial nutrition, and hydration, and euthanasia in the United States and Japan (Crawley, Marshall, & Koenig, 2001; Hern, Koenig, Moore, & Marshall, 1998; Koenig & Gates-Williams, 1995; Long, 2000a, 2001; Marshall et al., 1998; Slomka, 1995). Many of these studies frame the discussion in light of facilitating culturally effective care at the end of life by focusing on ethnic group values and practices. Few studies have explicitly examined the social and political processes by which patients and health care professionals come to make end-of-life decisions, as in the case of medical residents negotiating do-not-resuscitate orders for critically ill patients (Muller, 1992; Muller & Koenig, 1988; Slomka, 1992).

One of the key issues to emerge is the significant role families play in end-of-life decision-making. Often, families are more involved than the individual patient. This fact contrasts with the biomedical expectation of patients in the United States which holds that they are actively engaged in treatment decision-making, are future oriented, and are willing to participate in frank discussions about their medical conditions (Hern et al., 1998; Marshall et al., 1998; Muller & Desmond, 1992). Efforts to implement end-of-life planning, namely, the use of advance directives, are contingent upon such traditionally dominant Western values, for example as derived from Northern European protestants (Gaines, 1992). Yet most other cultural or ethnic groups do not share these values. This divergence is apparent, for example, in the ambivalence Japanese citizens feel toward using hospices, which espouses a philosophy of autonomous decision-making (Long, 2001; Long & Chihara, 2000), and research showing ethnic differences in the use of life-sustaining treatment (Blackhall et al., 1999). Still others have taken bioethical concepts and examined the impact of these on actual patient experiences, such as how the clinical ethics concept of "futility" can influence precisely when death occurs and thus affect experiences of death and dying (Joralemon, 2002).

Beginning-of-Life Decision-Making. Relatively little attention has been paid to beginning-of-life decision-making, including whether to pursue treatment or allow newborns to die based on medical and/or parental assessments that their condition is too critical and future quality of life is too grim to warrant continued intervention. Some ethnographic research in the United States has explored the organizational and intra-professional dynamics that figure in decision-making for critically ill babies in the neonatal intensive care unit (NICU) (Anspach, 1993; Guillemin & Holstrum, 1986; Heimer & Staffen, 1998; Jennings, 1990). Anthropological work has investigated the cultural factors that enter into treatment decisions highlighting how different cultures contextually create different decisions in the NICU (Levin, 1985, 1988, 1989). Decisions are couched within ever-evolving bioethical, political, and societal constructs of social worth, quality of life, rights of the handicapped, parent versus government authority, and the technological imperative (the proclivity of health care professionals to use high technology because of its availability) (Levin, 1988). Different social constituencies play important roles in neonatal decision-making cross-culturally: for instance, the best interest of the child is the core framework in the United States, while the best interests of the extended family is important in Japan, and the best interests of parents and siblings is paramount in Britain (Levin, 1990). One cross-cultural study currently underway compares how the doctor-parent relationship affects decision-making for critically ill neonates in France and the United States (Orfali, 2001, 2002, in press). Notably, mothers in both countries participated little in medical decision-making. In France, this is due to a "paternalistic" context where mothers provide consent at the beginning of the baby's hospital stay, which neonatologists believe helps prevent parents from feeling guilty; in the United States, mothers were asked for consent for most procedures to respect legal claims to parental autonomy; however, the mothers felt they provided assent instead. The difference pertains to cultural values about severe disability: while French neonatologists viewed letting babies with severe disabilities live as the worst case scenario, American neonatologists maintained the opposite view, due to the American practice of erring on the side of life, uncertainty about prognosis, proclivity toward medical interventionism, and concerns about respecting Baby Doe Regulations in light of the best interests of the baby. Others have examined how various ethnic and

cultural groups construct notions of risk and benefit (Burgess, Rodney, Coward, Ratanakul, & Suwonnakote, 1999), and identified how the professional culture of hospitals creates and maintains moral interpretations of technology used for neonates and consequently patient identity (Nelson, 2000).

Reproductive Ethics. The development of reproductive technologies has created a host of new reproductive choices and experiences. Anthropological studies explore the social processes and cultural assumptions embedded within U.S. prenatal screening practices (Browner, Preloran, & Cox, 1999; Franklin, 1998; Press, Browner, Tran, Morton, & Le Master, 1998; Rapp, 1999) and genetic counseling (Bosk, 1992), especially the value of professional neutrality. Others reveal the cultural values informing: mothers' resistance to giving birth in a hospital instead of at home (Kaufert & O'Neil, 1993), the use of reproductive technologies (Beeson & Doksum, 2001), and parents' frustrations with insufficient informed consent for what life is like with multiple gestations, often resulting from in vitro fertilization (Price, 1999). Much of this discourse centers on the cultural construct of "risk" as negotiated between parent-to-be and health practitioner.

Genetics, Identity, and "Race". At the forefront of anthropological investigation into genetics is the issue of identity deconstruction of kinship, "race," ethnicity, and religion. While anthropologists problematize the concepts of "race" and family, bioethicists generally do not, and thus use these constructs as though they were naturally occurring. One line of research critiques the genetic basis of medical conditions, for example Alzheimer Disease, by pointing out the cultural bases of "risk" and kinship systems, which are essential to understanding hereditary diseases (Gaines, 1998; Koenig & Silverberg, 1999). Anthropologists are collaborating with philosophers and bioethicists to investigate the impact of genetics on cultural understandings of individual and collective identity (Brodwin, 2002). Such research raises politically charged questions about the use and interpretation of genetics data and the authority to obtain and request DNA tests (Brodwin, 2002). Should genetic knowledge trump other claims to group identity such as oral history and cultural practices? For example, should evidence of a genetic link to Semitic peoples among the Lemba of South Africa and Zimbabwe have the authority to confirm

their already present claim to Jewish identity (Brodwin, 2002)? Claims to an identity entail certain rights and thus politically, genetic knowledge can impact one's sense of group cohesion and access to resources, and has implications for redressing human injustices (Brodwin, 2002).

Anthropologists are keen to point out that genetics knowledge and research poses the danger of essentialism (Brodwin, 2002; Gordon, 2002; Wolpe, 1996)—the assumption that people who share a culture, nationality, sex, or putative "race" will think and act in similar ways that are purportedly unique to that group (Gordon, 2002). This point is especially relevant to research examining putatively "racial" differences in health, illness, and access to care, for example the "black" sickle cell disease (Wailoo, 1997), the "Jewish" Tay-Sachs disease (Wolpe, 1996), social disparities in access to kidney transplantation (Gordon, 2002), and health disparities research (Lee, Mountain, & Koenig, 2001). Such studies are important for identifying the cultural construction of clinical realities that figure in bioethical debates and for suggesting other criteria for documenting inequities in health so as to avoid essentialism. Others have examined the cultural constructs of "whiteness" within bioethics theory, methods, and practice to challenge the dominance and normativity of white values inscribed therein (Myser, 2002).

ETHNO-ETHNIC TRADITIONS

Another body of work presents various religious, ethnic, or cultural perspectives on bioethics (e.g., Ellerby, McKenzie, McKay, Garipey, & Kaufert, 2000). This work is less empirical and more theoretical in orientation. While one may find entire books devoted to Jewish bioethics or Muslim bioethics, for instance, these do not necessarily problematize the value systems of a religion or present the religious systems within a broader cultural context. Both *A Cross-Cultural Dialogue on Health Care Ethics* (Coward & Ratanakul, 1999), and *Transcultural Dimensions in Medical Ethics* (Pellegrino, Mazzarella, & Corsi, 1992) provide excellent collections of papers comparing religious (e.g., Jewish, Islam, Buddhist) and cultural (e.g., Thai, Indian) developing world views about health care ethics and health policy issues from a cross-cultural perspective. These texts fall within a larger group of handbooks written by non-anthropologists and designed to guide health professionals in providing

culturally competent care. Anthropologists are debating the value of these books and the casual use of the word “culture” therein.

IDENTITY OF BIOETHICISTS

The field of bioethics is currently undergoing a moment of self-awareness and self-reflection as it seeks to define itself. Anthropologists and sociologists are particularly interested in examining the people who comprise the field of bioethics because their identity helps us understand the world of ethics; moreover, the field exhibits signs of undergoing the process of professionalization given various developments (Bosk & Frader, 1998; Churchill, 1999; Crigger, 1995, 1998; Haines, 2002). One indication of professionalization is the increasingly routinized role of clinical ethicists who serve as ethics consultants in hospitals to improve patient care by analyzing ethical dilemmas (Fletcher & Siegler, 1996, p. 125), which is legally mandated by the the Joint Commission on Accreditation of Healthcare Organizations (1992). To better understand who bioethicists are and what they do, anthropologists and sociologists have turned their attention to studying bioethicists in their everyday practice. Ethnographic studies examining the process of clinical ethics consultations and hospital ethics committees in the United States and Canada reveal how consultations involve negotiation of cultural values and ethical constructs depending on the agendas of the participants, and that power relations and social status within the medical hierarchy constrain who may request an ethics consultation as well as efforts to attain consensus among the medical team and patient/family (Flynn, 1992; Kelly, Marshall, Sanders, Raffin, & Koenig, 1997; Marshall, 1996; McBurney, 2001). Yet anthropologists and others should be aware that studying bioethicists may be a difficult process because there is reluctance to self-identify as a bioethicist (see DeVries & Conrad, 1998). This reluctance is due in part to the tentative relationship bioethicists have with the public and critics who view them as “moral police” in health care matters (Satel, 2000; Smith, 2000) as well as a lack of consensus on what training and background are necessary to engage in bioethics or clinical ethics consultation. Moreover, while some anthropologists now work as a hybrid anthropologist–bioethicist, by serving on institutional review boards or ethics committees, and even consulting for Presidential

Advisory Commissions, including the National Bioethics Advisory Commission (Marshall, 2001), to date there are no first-hand accounts of becoming an anthropologist–bioethicist. The confluence of a move toward professionalization and multiple identities of bioethicists make for interesting research into who bioethicists are and what they do.

APPLIED ANTHROPOLOGICAL WORK IN BIOETHICS

Bioethics lends itself well to anthropologically informed applied work. Since legal and bioethics guidelines, notably informed consent, are particularly relevant to clinical practice and research, anthropologists have much to contribute to shaping clinical practice and moral reasoning through analyzing bioethics and health policy. Consequently, research conducted in this vein tends to be oriented less toward understanding bioethics as a cultural process, and more toward using anthropological methods and theory to analyze bioethical issues and resolve moral quandaries both in theory and practice. Consider two examples of how anthropologists have been doing applied work in bioethics.

Ethics Consultation and Cultural Diversity

Anthropologists have been at the forefront in advocating for ethical clinical practice and decision-making that takes into account the cultural values and beliefs of all involved parties. Much of this work describes the kinds of cross-cultural ethics cases (predominantly end-of-life issues) that can occur and provide guidance to health care professionals and bioethicists to resolve ethical dilemmas in a culturally respectful manner (Carter & Klugman, 2001; Crawley et al., 2001; Hern et al., 1998; Jecker, Carrese, & Pearlman, 1995; Kaufert & Putsch, 1997; Koenig & Gates-Williams, 1995; Marshall, Thomasma, & Bergsma, 1994; Orr, Marshall, & Osborn, 1995). This process has come to be referred to as “cultural competency.” Such attention and guidance is essential because respecting patient and family cultural and moral values and practices can conflict with U.S. law. For example, the U.S. Patient Self-determination Act mandating that hospitals ask all admitting patients whether they have an advance directive can disrespect Navajo values of balance and beauty by

forcing them to discuss future health problems (Carrese & Rhodes, 1995). Similarly, health care professionals and bioethicists may wonder what they should tell a patient with terminal cancer when their family members request that no information be disclosed in order to respect traditional Chinese or Latino/a values of respect for the elderly and/or protection from the harm of the truth of the diagnosis and prognosis. Should health care providers disclose this information because they are bound by U.S. legal imperatives requiring informed consent so as to respect an individual's autonomous self-determination? Contributors to this discourse have suggested helpful steps to engage in cross-cultural ethical dialogue as well as a variety of techniques for enhancing cross-cultural communication, including making reference to a hypothetical third party, reframing a clinical problem in terms of benefits instead of poor outcomes, and acknowledging that individuals have the right to relegate decision-making authority to others as an expression of their own autonomy (Hern et al., 1998; Jecker et al., 1995; Orona et al., 1994).

International Human Subjects Research Ethics

Informed consent is the mechanism by which healthcare professionals and researchers protect human self-determination in the context of participation in scientific research nationally and internationally. Informed consent requires the provision of information (including procedures, risks, benefits, ability to withdraw), ensuring subject comprehension, and voluntary participation (Council for International Organizations of Medical Sciences, 1993; U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1978). Clinical research conducted internationally faces critical challenges in adhering to guidelines because of cultural factors—including the fact that codes of research ethics derive from Western cultural values of individual autonomy, the prevalence of language barriers and difficulties with using interpreters, different ethnomedical understandings of the body, and power dynamics between investigators and subjects (Barnes, Davis, Moran, Portillo, & Koenig, 1998; Kaufert & O'Neil, 1990; Kaufert & Putsch, 1997; Marshall, 2001). A compelling area of investigation determines whether research concepts translate into other languages or cultural worldviews, and if not, determining how to translate them in such a way as to ethically justify the conduct of research

in those cultures (see Marshall, 2001; Wertz, 1998). For example, comprehension of genetics research is minimized when translating the English consent form to Yoruba, as there are no words for “genotyping” or “gene” (Marshall, 2001). Implementing Western standards of research ethics is compounded when other cultures establish their own codes of research ethics shaped by local, cultural values, as in Egypt (Lane, 1994).

Conducting research in communities, nationally or internationally, raises additional questions about the application of standards set forth in Western research ethics. Traditionally, informed consent is obtained from the individual asked to participate in the research. However, decisional authority does not always rest within the individual, but among extended family, community groups, or with tribal leaders. In the United States, African Americans may be weary of participation in clinical research given a history of medical abuses (Jones, 1993; Reverby, 2000). Thus, anthropologists have illuminated the cultural processes for conducting community-based research that respect the needs of the local group through mechanisms of community involvement in the study design while simultaneously ensuring respect for individual autonomy (Marshall & Rotimi, 2001). These examples demonstrate the usefulness of employing anthropological approaches to analyze bioethical issues and develop health policy (Gordon, 2001a; Koenig et al., 1998; Siminoff et al., 1995).

FUTURE RESEARCH AREAS

Areas holding promise for future anthropological investigation in bioethics include: justice and public health ethics, and evidence-based medicine.

Justice and Public Health

The principle of “justice” has been examined in subfields of bioethics and has recently gained broader consideration (Daniels, Kennedy, & Kawachi, 1999). Within the rubric of justice and equity, the issue of socio-demographic disparities in health and access to health care warrants substantial examination. Although public health specialists and epidemiologists are already at the forefront of such investigations, anthropologists could take a stronger role by exploring how cultural competency and social structural factors contribute to disparities both nationally and

internationally (e.g., Levin & Schiller, 1998). Specifically, some have argued for extending bioethics attention beyond biomedical matters within Western borders to the global arena (Brodwin, 2001; Das, 1999; Farmer, 1999). For instance, attention to the impact of globalization on policy-making requires that we consider public health issues of managing epidemics and disease given the increased international movement of people, including refugees, immigrants, and travelers (Das, 1999). Some anthropologists and bioethicists are beginning to create a code of ethics for public health (Callahan & Jennings, 2002; Kass, 2001; Levin & Fleischman, 2002). Similarly, international bioethics requires that we consider ethical pluralism, and recognize how local contexts shape the construction of ethical dilemmas; for instance, low-income countries raise moral issues of dealing with scarcity and equity rather than individualism (Brodwin, 2001).

Evidence-Based Medicine (EBM)

Evidence-based medicine (EBM) is “the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients” (Sackett, Straus, Richardson, Rosenberg, & Haynes, 2000). Within Western countries, EBM has grown in importance in the clinical arena as a mechanism to eliminate the over- or under-use of medical services and thus to maximize efficient care (Sackett et al., 2000). Few anthropologists have begun to explore the cultural values underpinning both the reliance on randomized clinical trials to inform health policy, and health professionals’ resistance to implementing such guidelines into clinical practice (Bogdan-Lovis, 2001; Gordon, 2003b). Ethically, EBM raises questions about macro-allocation in the provision of quality care because health insurance plans increasingly depend on EBM guidelines to determine which problems receive coverage (Hope, 1995). Since EBM has become integrated into medical education, future research could investigate shifts in medical knowledge (epistemology) and concomitant changes in clinical practice by, for instance, investigating how physicians negotiate between drawing on population-based data (consistent with the goals of public health) and drawing on the knowledge and preferences of individual patients (consistent with the traditional goals of medicine and ethics) (Tonelli, 1998). Thus, research in EBM is a fertile area that entails the intersection of cultural studies of science, decision-making, and health policy.

CONCLUSION

Anthropological research in bioethics has flourished in its first decade. We can see that the relationship between anthropology and bioethics is twofold: some do research “of” bioethics as a cultural domain while others do research “in” bioethics, often collaborating with others outside the field to better address more applied concerns. The field of bioethics as well as its methods, theories, and practices are all rich areas for anthropological inquiry given the diverse range of topics and issues that call for a contextualized exploration of what it means to be a moral human being. The continued development of biotechnological advances, health care challenges, and greater concern for the moral life or suffering experienced by patients, families, and clinicians in a global world context generates new questions about the definition of life and death, self, other, personhood, power dynamics, and right and wrong in the context of illness, health, and healing. To answer these questions and to better inform health policies, anthropologists are increasingly participating in interdisciplinary collaborative bioethics research. Such participation enables anthropological concerns to be given greater voice in ensuring that taken-for-granted cultural assumptions are not accepted *prima facie* but are instead contextually considered when analyzing theory and practice within the bioethics enterprise.

Biomedical Technologies

Anthropological Approaches

Margaret Lock

INTRODUCTION

The history of technology¹ has usually been transmitted in Europe and North America as an heroic tale about the conquest of the enemy, whether this be aspects of the human or natural worlds—a narrative of progress, and of the betterment of social life in general. This has been characterized as the Standard View of technology (Pfaffenberger, 1992), one which assumes that necessity is the mother of invention, causing humans to produce tools, devices, and artifacts that permit us, we believe, increasingly rational, autonomous, and prosperous lives, liberated from the constraints imposed by individual biology, oppressive human enemies, and the environment.

It has been suggested that inherent to the Standard View are two sets of tacit meanings that at first glance appear to be contradictory. The first assumes that the relationship of humans to technology is too obvious to need examination. Organizations, industries, technicians, craftspeople, and so on simply make things that are in themselves neither good nor bad. The second approach, one of technological determinism, conceives of technology as a powerful and autonomous agent, inherent to progress, and therefore by definition an unquestionable good, but that inevitably dictates the form to be followed by human social life (see, for example, Heilbroner, 1967).

Marshall Sahlins (1976) takes a very different approach. For him neither technologies nor the human

“needs” they are devised to alleviate should be conceptualized as autonomous, but must inevitably be understood as embedded in cultures and histories. Cultural analyses of technology are concerned with the attribution of meaning to technologies and their application, and hence with “entrenched moral imperatives” (Pfaffenberger, 1992, p. 506). The politics of national, community, and individual identity making is intimately associated with the development, global transfer, and implementation of socio-technical artifacts and systems. Pfaffenberger concludes that “when we examine the ‘impact’ of technology on society, we are talking today about the impact of one kind of social behavior on another” (Pfaffenberger, 1988). For him technology is “humanized nature,” and inseparable from both political relationships and the culturally informed meanings associated with it.

It has been shown repeatedly that artifacts, including biomedical technologies, can be introduced successfully to new cultural settings without a simultaneous adoption of the logical use originally associated with them (Lock & Kaufert, 1998; Van Der Geest & Reynolds Whyte, 1988). New meanings and social relations coalesce around transported artifacts, whatever the direction of their travel.² This is not an argument for the autonomy of artifacts (or for that matter for the autonomy of culture), but rather for their inherent heterogeneity as social objects. Alternatively, some artifacts and technologies, notably when they threaten entrenched values, are

actively rejected, or after attempted adoption fail to take root or their use is severely restricted.

Disputes among politicians, scientists, clinicians, and activists within any given location often take place over access to and distribution of technologies. Breast cancer activists have, for example, lobbied hard for increased research and technological developments in connection with this disease, forcing the hand of politicians (Kaufert, 1998). The governments of many countries with few economic resources, often to the consternation of Western trained physicians and the World Health Organization (WHO), encourage pharmacologists, traditional practitioners, or even itinerant vendors of medicine, to diagnose diseases and prescribe medicine, thereby economizing dramatically on health care expenditure (Van Der Geest & Reynolds Whyte, 1988). Several of the best documented examples of cultural dissonance in connection with biotechnology transfer have to do with contraceptive and reproductive technologies, and with AIDS prevention (Epstein, 1996; Ginsberg & Rapp, 1995; Lock & Kaufert, 1998). For example, the technology that identifies the sex of a fetus has been applied in some locations to systematically practice selective abortion of female fetuses.

For anthropologists, it is technologies in practice—their differential development, transfer, and application, relationship to politics and economics, national interests, and dominant values, and their impact on individuals, communities, and societies at large—that is of over-riding concern. Also of considerable interest is the relationship of the technologies of biomedicine to indigenous technologies. Inevitably the ethnographic approach is central to such research; further more, the culture concept is almost without exception drawn on either explicitly, or else is implicitly assumed to be an influential force in individual and community responses to technologies, both indigenous and those that are imported. This entry will be confined largely to such research.

It is not possible to make a comprehensive coverage of the anthropology of biomedical technologies, as even a cursory glance at journals such as *Medical Anthropological Quarterly* will show. Notably absent is recent research into new techno/visual representations of the body, including the emerging field of telemedicine (Csordas, 2000; Sinha, 2000; Taylor, 2000). Nor does space permit an evaluation of how politics and values are implicated in the development and application of specific biomedical technologies while others are never supported.

Coverage of the rich literature produced by sociologists of science that has direct relevance to the conceptualization and development of technologies and their implementation is also absent (see, for example, Berg, 1997; Berg & Mol, 1998; Cambrosio & Keating, 1995; Latour, 1999; Timmermans, 1999).

BIOGRAPHIES OF PHARMACEUTICALS AND CONTRACEPTIVES

Numerous scholars, among whom Charles Leslie was perhaps the first, have shown how medical pluralism is the rule in virtually all societies today, so that competition among medical sectors is common (Leslie, 1980), often with major repercussions on the health of populations. This tendency is well illustrated by examining the availability and use of medicinal technologies. Beginning in the 1950s anthropologists showed concern about the effects of imported pharmaceuticals, notably antibiotics, on the health of people in developing countries, when it became clear that these powerful medications were being misapplied. Anthropologists also were interested in the impact of the availability of pharmaceuticals on the use of indigenous medicines.

It was quickly recognized that politics are inevitably implicated in the global transfer of drugs, but in addition that pharmaceuticals have not only biochemical properties but are also associated with culturally defined meanings. “We can speak of the biography of a drug: its production, distribution, marketing, interpretation and use,” argue Van Der Geest and Reynolds Whyte (1988). Etkin (1988), in a similar vein, discusses the cultural construction of efficacy with respect to pharmaceuticals and suggests that healing should be understood as processual in order to grasp the way in which a series of outcomes are usually considered important to efficacy, not all of them physical.

It has been shown repeatedly that the introduction of pharmaceuticals has had major impacts, many of them negative, in societies without a health sector that has a well-functioning and well-funded infrastructure. In El Salvador, for example, when the use of locally produced indigenous medicinals was largely replaced, due to the introduction of a commercial pharmaceutical sector, community breakdown was evident as well as individual dependence on brand name prescription medications (Ferguson, 1981). Van Der Geest and

Reynolds Whyte (1988) describe the formation of an informal sector for the purchase of pharmaceuticals, one that included smuggled medicines in the Cameroon. They argue that self-medication with products bought in the informal sector can be detrimental to health (not only to individuals but to populations as antibiotic-resistant bacteria multiply); that money is often wasted on useless medication but that, for certain medical problems, the availability of pharmaceuticals sold across the counter is better than nothing. In such instances a form of autonomy can be achieved by patients that would otherwise not be possible. Nichter (1989) shows how in South India over the past two decades use of herbal remedies has rapidly been overtaken by sales of commercial medications. He argues that biomedicine is equated with modernity and progress, and pharmaceuticals have in effect become fetishes imbued with power, as is the case elsewhere. Family members share medications with each other. But Nichter detects ambivalence at work as well, because danger and impurity are also associated with these new, foreign drugs.

Oral rehydration salts (ORS) have been widely promoted by WHO and other organizations to combat infant diarrhea, the major cause of infant mortality in areas where poverty is widespread. MacCormack and Draper (1988) write about how mothers in Jamaica were taught to use ORS imported from Switzerland in place of very effective mint teas or coconut water prepared at home. They note the irony of importing ORS at great expense when one of the two ingredients in the packages is sugar—the bedrock of the Jamaican economy. These authors go on to show how aid agencies actively promote the use of ORS as a medicine—as a quality-controlled chemical formula—when in fact all that the packages contain are sugar and salt. Mothers must walk for hours with their sick children to clinics to obtain this “medicine” rather than caring for the children at home. Nichter argues that in Sri Lanka, ORS have been introduced to that country as a “technical fix.” He shows how purveyors of this technology draw on local beliefs about health and “strength” to assist in their marketing strategies (Nichter, 1989). Increased infant mortality has been documented in connection with the promotion of bottle-feeding in regions where poverty and unhygienic conditions are present (Van Esterik, 1989). Numerous anthropologists writing on the subject of the introduction of pharmaceuticals, bottle-feeding, and ORS to the “developing” world have pointed out that, increasingly,

governments adopt a reductionistic approach to the health of populations—a medicalized technical fix—at the expense of dealing with public health and environmental issues. Global and capitalist interests are rarely concerned with preventive medicine, and local elites, including many members of the medical profession trained overseas, give priority to high-tech medicine over primary care.

When biomedical technologies are adopted in countries supposedly dedicated to the idea of development, the response from some sectors is often one of nationalism. The result is that even as new biomedical technologies are incorporated, usually unevenly across society, there is a renewal of interest in indigenous techniques and therapies, although efforts are very often made to have them rationalized and scientized. Public interest in indigenous technologies is usually fired up through appeals to nationalism and often also to naturalism (Adams, 2002; Farquhar, 1995; Leslie, 1989; Nichter, 1989).

The globalized distribution of pharmaceuticals has another dark side that anthropologists have recently begun to research. The experimental trials of contraceptives in Egypt prior to their approval by the Food and Drug Administration (FDA) in the United States (Morsy, 1998) is one telling example of the use that the bodies of peoples in Africa, the Caribbean, the Middle East, and South East Asia have been put to as experimental subjects in the interests of drug companies. The cost of drugs proven to be effective against HIV/AIDS and of crucial medications for other diseases including malaria and multi-drug resistant TB, and the impact of these marketing strategies on the everyday lives of people has also been documented by anthropologists (Farmer, 1999; Nguyen, 2001).

CONTRACEPTIVES AND ABORTION

Indigenous contraceptive knowledge and practices are widely dispersed, and the systematic importation of new contraceptive technologies does not take place in a vacuum. As with pharmaceuticals, it is largely through the mediation of government that contraceptives such as the contraceptive pill (the Pill) and intra-uterine devices (IUDs) are made available to populations and this is carried out, almost without exception, in association with national policies of “family planning.” The large ethnographic literature on contraception produced by

anthropologists reveals several dominant themes, among which is a prominent concern by informants about unwanted side-effects associated with pharmaceutical contraceptives, and with the insertion of objects into the body for contraceptive purposes. Nichter (1989) writes about a “rhetoric of rumor and side effects” in Sri Lanka and describes how local accounts about the way in which the Pill works are absorbed into ethnophysiological knowledge. Fear about negative effects of the Pill on the normal functioning of the body make its use unacceptable to many women. Good (1980) notes that Iranian women fear that the Pill will render them sterile because it “dries out the uterus.” Similar concerns about the drying properties of the Pill have been reported worldwide. In Japan the Pill was not made legally available as a contraceptive until 2000 due in part to a powerful opposition lobby by Japanese companies that make condoms and to a concern among men about female promiscuity associated with the Pill (noted in many other parts of the world). But a fear among women about unwanted side-effects was also implicated (Lock, 1993). The result has been that abortion, relatively easily available in Japan, has been made of regular use for family planning (Coleman, 1983).

Lopez (1998), whose research deals with sterilization, the preferred method of population control in Puerto Rico, argues that a focus on individual women is inappropriate in this type of research. Lopez insists that the reproductive decisions made by Puerto Rican women, and by implication women virtually everywhere, can only be understood within a larger historical and social framework as well as through an ethnographic lens. Contradictions in connection with the application of technologies of contraception are then made apparent. She wants more attention given to community rights in connection with such technologies, and less on individual rights and interests, as is the case for the bulk of research carried out in North America and Europe.

Family planning in most countries is implemented by governments on the assumption that economic development can be brought about by reducing family size. China is the best known example of this approach, where a rhetoric of an overly populous nation prevails, and the enforced one-child policy is implemented with a concurrent discourse of neo-eugenics about “raising the quality of people” (Anagnost, 1995). Ong (1995) shows how the ideology of family planning in Malaysia increases tensions between many husbands and wives. The Pill was introduced in Malaysia together with a

rhetoric that implied that the life of couples would improve with its use by reducing the burden placed on women. Moslem men actively resisted the planning of their families, and although birth rates among the Chinese and Hindu populations fell in Malaysia, among the Moslem population it rose, something that Ong attributes to the negative reaction of men. Moslem men argued that the Pill was making their wives sick, and even very poor men with large families resisted its use.

In Egypt, the state, collaborating with donor agencies, explicitly uses a family-planning program as a tool to modernize its population, to improve its overall health, and to remove “weakness.” The concepts of “progress” and of “material wealth” are made use of in association with efforts to normalize nuclear families and to promote ideas about individuality and privacy in the hope of reducing family size. Ali (1996) shows how Islamic principles have been interpreted by the State so as to support family planning, but he also demonstrates the mixed reception this policy has had, particularly among Islamic parties who object vehemently to the secularization of the moral and family life of Egyptians. Similarly to the responses of nationalist and religious groups in India, Indonesia, Nepal, North America, and elsewhere, Islamists in Egypt actively seek to defend the domestic sphere from what they perceive to be moral breakdown. Clearly, accounts about increasing individual autonomy for women, so often associated with the introduction of birth control, must be situated in context and suitably tempered. It may well be that at times the reverse is actually the case.

In recent years condom use has been widely promoted because of its value in preventing the transmission of HIV, and several anthropologists have documented the social, cultural, and political issues at stake here (see Grundfest-Schoepf, 1993, for example). (Pigg, 2002) has analyzed the fraught relationship among participants in a public debate about sexuality, national identity, and the introduction of HIV/AIDS prevention strategies in Nepal.

NEW REPRODUCTIVE TECHNOLOGIES AND NEW FORMS OF KINSHIP

A large literature exists on the anthropology of birth and the technologies associated with birth practices (see the entry Medicalization and the Naturalization of Social Control for a review of some of this research). Research has also demonstrated the lengths to which women are

driven to try to overcome infertility (Inhorn, 1994; Kielmann, 1998). Much of this research, like many of the materials cited above, highlight the global, local, political, and economic strategies associated with the introduction of technological interventions, while at the same time documenting local responses to and experiences with both indigenous and newly imported technologies.

In recent years the systematic development and implementation of assisted conception and the new reproductive technologies has generated a rather different body of research that focuses on the technologies themselves as objects of knowledge and on what they make possible. The effects of these technologies on the lives of women who use them, on their partners, and on the new forms of kin relations they permit, are integral to these analyses. But so too is a reflective examination of contemporary society and the impact of science on society—such research comes under the umbrella of “science as culture, cultures of science” (in Franklin’s 1995, idiom). This approach is concerned less explicitly with political economies, and focuses instead on the scientific enterprise itself, on its impact on human relationships in late modernity, and at times on policy-making. Politics, power relations, and the reproduction of hegemonies are part of this research, but so too is the way in which biomedical technologies, despite objectification of the body and body parts, can enable individual agency (Cussins, 1996; Lock, 1998). Overt national interests are less evident in this research, as is the way in which the adoption of technologies is a sign of modernization and rationalization. But inevitably, given the globalized economy and the protean spread of values associated with the idea of modernity as it took shape originally in Europe, there are links between research into the new high-tech biomedical technologies and studies based in locations other than where these technologies are developed.

Marilyn Strathern was perhaps the first to use the discourse associated with the new reproductive technologies to reflect critically on the classical categories of anthropology. She noted early in the 1990s the power of these technologies to challenge received wisdom in the social sciences about an inherent dichotomy between nature and culture, and between biological and social reproduction. Taking the concept of culture to be “the way people imagine things are,” Strathern analyses official debates in the United Kingdom about assisted conception focusing on how the representation of persons and individuality that are used in these debates displaces

other ways of representing human communities. She uses her years of experience as an anthropologist in Papua New Guinea to create a critical argument. Strathern’s thesis is that when humans reproduce themselves, no matter in what way this is achieved, they inevitably do so with already existing and specific forms of themselves and of genealogy making in mind (Strathern, 1992, p. 10). She highlights how in Euro-America ideas about particular social arrangements, notably the nuclear family, in theory inform the way in which reproductive technologies will be put into practice. This is so because the nuclear family and inter-generational ties of blood are understood as “natural” and indisputable, and technology may, therefore, be used to bring about the “natural” family when Nature itself fails to do so. But, as Strathern points out, new reproductive technologies also permit us to challenge what is assumed to be “natural,” in particular, who can be counted as “natural” mothers and fathers.

Overcoming infertility, whether male or female, is set up as a matter of individual choice in contemporary society. Individuals become consumers of the new products of human gametes and fertilized embryos, a market enhanced through technological manipulation, advertising, and promotions. These medicalized objects become absorbed into the enterprise culture in which we moderns participate. Strathern argues that above all the new technologies “enable” rather than simply producing products *per se*; they carry the connotations of service. Moreover, these technologies broach a distinction between body and machine believed to be unassailable—they permit the creation of hybrids of nature and culture (p. 47). We are now able to artificially intervene into what have been represented as supremely natural processes—whether it be in order to create embryos *in vitro* and then re-implant them into either the woman who donated the egg or into another woman for gestation; to genetically modify fetuses created *in vitro* before re-implantation; or to manipulate the process of dying.

Sarah Franklin, like Marilyn Strathern, uses a cultural account of assisted conception and the uncertainties associated with these new technologies to reflect on anthropological theory about kinship and reproduction. Reciprocally, she uses anthropological insights to produce a critical account of assisted conception (Franklin, 1997). See also Edwards, Franklin, Hirsch, Price, and Strathern, (1993) and Franklin and Ragone, (1998). Franklin shows how media and popular representations about reproductive technologies inform subjective knowledge

and experience. She argues that in vitro fertilization (IVF) is portrayed as a “hope technology,” and notes that both failure (which is very high in IVF clinics) and success is continually subject to re-definition. Failures can be a “relative success” under certain circumstances. And retaining hope and “hope management” are key to the practice of this technology (Franklin, 1997, p. 158).

Handwerker reports how, in China, despite the existence of the one-child policy, to have no children is regarded with disfavor. She documents resort to IVF clinics by women whose infertility means that they are stigmatized. But Handwerker also makes it clear that some Chinese women deliberately choose to remain single or not to have children. This research is one of an increasing number of recent publications that highlight the contradictions and ambiguities associated with the new reproductive technologies. Prominent is the way in which some women respond by embracing the possibilities that the technology offers, while others resist or are indifferent to technological intervention (Handwerker, 1998; see also Cussins, 1996). Lock tracks the history in Japan of several hundred years of a “planned family” and how the implementation of reproductive technologies carried out under government and medical guidelines show continuities with the past so that only the reproduction of the “natural” family is permitted. Use of sperm donors and surrogate mothers are prohibited except under very exceptional circumstances when close “biological relatives” are made use of as substitutes (Lock, 1998).

Becker (2000) has analyzed an increasing politicization of infertility together with a consolidation of the industry of reproductive technology in the United States. She shows how the staggering array of medical options now available to women and men have profound financial and emotional impacts on consumers of these technologies. Her interviews with hundreds of infertile people make clear that the majority question the claims made for the technologies and how they are put into practice—patients become vigilantes as they act out their ideals of informed choice and autonomy. However, even in the world of high-tech medicine men are often protected from the “stigma” of infertility, and the assumption all too often remains that the “problem” lies with the woman. Becker concludes that despite experimentation with reproductive technologies people strive to achieve continuity and normalcy and the idea that the family is biologically based is upheld as is the ideal of a two-parent family as the reproductive unit. Lewin (1998) has

shown how lesbian couples to some extent emulate these ideals when they make use of reproductive technologies.

Becker argues that when people believe themselves to be infertile, they embody the idea that they have a disability and resort to technology to overcome the problem. At the same time, they resist the way in which the medical world transforms their whole life into an infertility problem. Becker concludes, as do other researchers, that “technology as a template of culture is one arena in which normalcy is both resisted and reaffirmed and through which the enactment and transformation of cultural practice occurs” (Becker, 2000, p. 250). One other feature of Becker’s research is that she has been involved personally with the technology about which she writes, as has Layne (1996), whose research comprises a biographical and autobiographical account of her experiences with a neonatal intensive care unit.

BOUNDARY CROSSINGS: ORGAN TRANSPLANTS AND THE MIXING OF SELF AND OTHER

Research into organ transplants carried out by medical anthropologists deals, as does inquiry into assisted conception, with boundary demarcations and crossings, the commodification of bodies and body parts, and with the way in which technologies such as these impact on subjectivity, individual identity, and what counts as kin relations.

Sharp (1995) argues that receiving an organ transplant is a personally transformative experience that may impact on how recipients assess their own social worth. She shows how this transformation takes place at two levels—first, subjectively so that a recipient’s sense of self may be extended to include qualities attributed to the donor and, second, through interactions with family, communities, and the medical profession. Sharp notes, as does Hogle (1995, 1999) how the language used in connection with organ procurement depersonalizes bodies and body parts, but that many recipients re-personalize organs through the creation of narratives about their re-birth. Subjectivity is “intensely corporeal” but contradictions are rife. Transplant specialists insist that organs should be objectified and reified, especially when communicating with recipients, but when talking with potential donor families they make free use of

a metaphor of the “gift of life,” and insist that the donor will “live on” in another’s body. The organ, as do pharmaceuticals and even contraceptives, takes on a biography of its own, independent of the persons in whom it resides (see also Crowley, 2001; Lock, 2001).

Hogle (1999) shows how disputes in Germany about the commodification of human body parts and their use as therapeutic tools are powerfully influenced by the history of National Socialism in that country and its practices of eugenics. In particular, revulsion about the history of Nazi experimentation makes many people reluctant to cooperate. Much earlier beliefs about the diffusion of the essence of life throughout the entire human body are also influential in culturally informed responses to the transformation of body parts into technological artifacts. The ideas of “solidarity” (a powerful metaphor from the former East Germany) and Christian “charity” are both made use of to encourage organ donation, but Hogle argues that in multicultural Germany making organ donation into a social good in which everyone can participate is fraught with difficulties (p. 192).

The problem of body commodification and biomedical technologies becomes overtly political in countries where an enormous disparity exists between rich and poor. Das (2000) and Scheper-Hughes (1998) have both shown how the poor are particularly vulnerable to exploitation. By tracing the complex networks of activities between organ procurement and their transplantation, sometimes involving criminal activity and the unwilling participation of living kidney donors, these researchers show how societal inequities are reproduced and even magnified through the practices of transplant technology. Moreover, organ tourism permits citizens from wealthy countries to obtain organs from vulnerable people living in poverty. Das’s research in India enables her to critique both contract law and the bioethics usually associated with organ transplants in North America, grounded in the language of rights. She argues that such language masks the politics of violence and the suffering involved in organ procurement where gross inequalities are present in social life, and where bribery and corruption are not uncommon. On the other hand, using extensive ethnographic research, Crowley (2001) is able to show that in Mexico poor people quite often become organ recipients, and that at times economic assistance and organs donated from Mexicans living in America permit their relatives in Mexico to obtain organ transplants. She argues for recognition of greater complexity.

Joralemon (1995) notes a “cultural rejection” of the transplant enterprise in the United States, in that at least half the population remains unwilling to donate organs. He documents the creation of a rhetoric across several domains to the effect that donating organs is a public good. Mixed usage of a contradictory language of property rights on the one hand, and of gift-giving and altruism in connection with organ donation on the other, is used liberally in the United States in an attempt to overcome cultural resistance. This rhetoric must suppress strongly held beliefs about bodily integrity if it is to be increasingly successful, something about which Joralemon remains skeptical. Once again, ambiguities and contradictions are made evident through ethnographic research. Organ transplants, like other biomedical technologies, function to fulfill what society, and in particular the State, recognizes as genuine needs or even as a right. However, the impact of these technologies on the everyday lives of those people directly involved in their use is context dependent, complex, and cannot be measured directly. Above all, these technologies set up a challenge to what is taken to be the natural order of things; as such they bring with them a moral dimension which can act as a touchstone for larger debates about nationalism, modernization, progress, equity, whose lives are valuable and whose are not, and what parts of the human body can be commodified and under what circumstances.

MAKING UP THE GOOD-AS-DEAD

The majority of organ transplants make use of organs procured from donors diagnosed as brain-dead. Creation of the concept of brain-death in the late 1960s, immediately following the world’s first heart transplant, could not have happened without the prior invention of the artificial ventilator. This machine enables the heart and lungs of a patient whose brain is irreversibly damaged to continue functioning. Brain-dead entities are hybrids, both alive and dead, and their existence challenges, as do so many new biomedical technologies, the fundamental assumptions made until recently in the social sciences and in society at large about clear dichotomies between nature and culture, life and death, mind and body (Lock, 1997, 2000, 2001). Lock has shown how the ambiguous condition of the brain-dead has been largely repressed in the public domain in most of Europe and North America

(but see Hogle, 1999, in connection with Germany). The power of the metaphor of the “gift of life” passed along through organ donation has usurped uncertainties in connection with this new entity about where exactly organs come from. On the other hand, in clinical settings where medical practitioners and families must confront the ambiguities associated with the brain-dead at first hand, there is considerable evidence that these patients are not regarded as fully dead. However, in intensive care units (ICUs) in the United States and Canada sending the brain-dead for procurement of their organs is justified in people’s minds, whether they be family or health care practitioners, on the assumption that the “person” is dead (Lock, 2000, 2002). In Japan, on the other hand, brain-dead patients have not been regarded as medically or legally dead until very recently, and then only if there is evidence of a clear indication on the part of the patient and their family that donation is acceptable. Lack of trust in the medical profession, a massive public debate about brain-death, and differing ideas about personhood are just three of the reasons that account for the Japanese situation.

Simple technologies such as tube-feeding in ICUs mean that patients who are permanently unconscious but whose lower brain continues to function (and therefore are not brain-dead) can be kept alive for years on end. Kaufman (2000) has shown that this condition too challenges our conventional ideas about identity, personhood, and agency. Increasingly there is pressure, primarily economic, to count such patients as good-as-dead (Lock, 2002) so that “death” becomes an ever-more problematic category, as is the case for “life” in the world of reproductive technologies. As Kaufman (2000) notes, the very existence of technologically produced hybrid forms of human existence “subvert the meaning of nature” and of the “natural” (p. 79).

The new genetics and the mapping of the human genome present further challenges to the nature/culture divide. We can intervene in the body in ways never before possible and claims are being made by certain scientists that we will soon be able to manipulate fetuses so that babies will be made to order. Genetic testing and screening, often leading to abortion, are already well entrenched (see the entry Medicalization and the Naturalization of Social Control), but to date the hype associated with genetic enhancement technologies far exceeds what can actually be accomplished. It is not simply the implementation of those technologies that already exist to which we must pay attention, but also to the claims made about the

imagined futures that technologies in the making may bring about. Anthropology has already given us plenty of evidence as to the way in which biomedical technologies, as they spread globally, are at once agents of hope and transformation and at the same time foster alienation and destruction. It is not to simply argue for technology as progress.

NOTES

1. By technology I mean tools, machines, artifacts, prostheses, and other devices that have been created through human effort for the purpose of changing, manipulating, or controlling the natural and human worlds. Included are the technologies of the survey as discussed by Foucault (1979).
2. This is as equally true for acupuncture and herbal medicines being imported and adopted for use in Europe and North America, as it is, for example, for vaccinations being administered throughout Africa.

Biomedicine

Atwood D. Gaines and Robbie Davis-Floyd

NAMING THE SUBJECT

The designation “Biomedicine” as the name of the professional medicine of the West emphasizes the fact that this is a preeminently biological medicine. As such, it can be distinguished from the professional medicines of other cultures and, like them, its designation can be considered a proper noun and capitalized. The label Biomedicine was for these reasons conferred by Gaines and Hahn (1982, 1985) (after Engel, 1977) on what had variously been labeled “scientific medicine,” “cosmopolitan medicine,” “Western medicine,” “allopathic medicine,” and simply, “medicine” (Engel, 1980; Kleinman, 1980; Leslie, 1976; Mishler, 1981). “Medicine” as a label was particularly problematic: it effectively devalued the health care systems of other cultures as “non-medical,” “ethnomedical,” or merely “folk”—and thus inefficacious—systems based on “belief” rather than presumably certain medical “knowledge” (Good, 1994). The term “allopathic” is still often employed as it designates the biomedical tradition of

working “against pathology,” wherein the treatment is meant to oppose or attack the disease as directly as possible. In contrast, “homeopathic” derives from the Greek *homoios*—“similar or like treatment”—and *pathos* (suffering, disease). In this model, medicines produce symptoms similar to the illnesses that they are intended to treat. Today, the designation Biomedicine is employed as a useful shorthand more or less ubiquitously in medical anthropology and other fields (though often it is not capitalized) for this preeminently biological medicine.

EARLY STUDIES OF BIOMEDICINE

Early studies of what we now call Biomedicine were primarily conducted by sociologists during the 1950s and 1960s (e.g., Goffman, 1961; Merton et al., 1957; Strauss, Schatzman, Bucher, Ehrlich, & Sabzhin, 1964). Sociologists did not question the (cultural) nature of biomedical knowledge nor assess the cultural bases of

medical social structures. Both were assumed to be scientific and beyond culture and locality. Rather, their central concerns were the sociological aspects of the profession such as social roles, socialization into the profession, and the impact of institutional ideology. With few exceptions (see Fox, 1979), a lack of a comparative basis inhibited sociology from recognizing the cultural principles that form the basis for biomedical theory, research, and clinical practice.

Biomedicine first came into the anthropological gaze as a product of studies that sought to consider professional medicines of other “Great Traditions” rather than the folk or “ethnomedicines” of traditional, small-scale cultures. Indian Ayurvedic (Leslie, 1976), Japanese Kanpo (Lock, 1980; Ohnuki-Tierney, 1984), and Traditional Chinese Medicine (Kleinman, 1980; Kleinman, Kunstadter, Alexander, & Gale, 1975) were objects of study in comparative frameworks that included Biomedicine. In these contexts, Biomedicine began to receive some scrutiny suggestive of its cultural construction, but this was not yet the primary focus of research.

ANTHROPOLOGY AND BIOMEDICINE

Early on, Biomedicine was *the* reality in terms of which other medical systems, professional or popular, were implicitly compared and evaluated. Like science, Western medicine was assumed to be acultural—beyond the influence of culture—while all other medical systems were assumed to be so culturally biased that they had little or no scientific relevance (e.g., Foster & Anderson, 1978; Hughes, 1968; Prince, 1964; Simons & Hughes, 1985). Not only did this ideological hegemony devalue local systems, it also stripped the illness experience of its local semantic content and context (Early, 1982; Good, 1977; Kleinman, 1980, 1988a). This stripping served to obscure the “thick” polysemous realities that became obvious in ethnographic and historical inquiries, challenging the “thin” biomedical interpretations of disorder (Early, 1982; Good, 1977; Ohnuki-Tierney, 1984).

An appreciation of the diverse cultures of illness and of professional and folk medicines arose as Biomedicine itself came under a comparative scrutiny through the incorporation of symbolic and interpretive anthropology into medical anthropology. Interpretive perspectives were being applied in the fields of the anthropology of religion and psychological anthropology by people specializing in

one (e.g., Margaret Lock, Nancy Sheper-Hughes) or both (e.g., Thomas Csordas, Atwood Gaines, Byron Good, Robert Hahn, Arthur Kleinman, & Allan Young) (Gaines, n.d., a). During the 1980s, these two fields were enfolded within the expanding domain of medical anthropology because of their foci on (religious and ritual) healing and (ethno-)psychiatric and medical knowledge systems (Gaines, n.d., a) (e.g., Deveraux, 1953, 1963, Good, 1977; Early, 1982; Edgerton, 1966; Evans-Pritchard, 1937; Jordan, 1993; Levi-Strauss, 1963a, 1963b; Middleton, 1967; Prince, 1964; Vogt, 1976).

Anthropologists initially exploring Biomedicine met resistance both from fellow anthropologists, even medical anthropologists, and from their biomedical host-subjects. This resistance may have had a common source—“a blindness to a domain of one’s own culture whose powers and prestige make it invisible to member participant observers” (Gaines & Hahn, 1985). A major turning point in medical anthropology’s consideration of Biomedicine was the publication of two largely interpretive works edited by Gaines and Hahn (Gaines & Hahn, 1982; Hahn & Gaines, 1985). These works “marked a new beginning in medical anthropology” (Good & DeVecchio Good, 2000, p. 380). They featured empirical studies of a variety of medical specialties, including psychiatry, internal medicine, family medicine, and surgery, as well as considerations of the conceptual models in medicine that guide and made sense of clinical practices. These works “legitimized anthropological work on North American and European biomedicine and launched wide-ranging studies of biomedicine by these authors and their students” (Good & DeVecchio Good, 2000, p. 380). They pointed to variations within biomedical praxis as well as to its ideological commonalities.

In these seminal works, Gaines and Hahn defined Biomedicine as a “sociocultural system,” a complex cultural historical construction with a consistent set of internal beliefs, rules, and practices. Analyzing Biomedicine in this way enabled medical anthropologists to fruitfully cast their gaze on it from a relativistic perspective, (re)conceiving Biomedicine as “just another ethnomedical system,” one that, like all others, reflects the values and norms of its creators (Hahn & Gaines, 1982).

This perspective has greatly facilitated the comparative study of Biomedicine vis-à-vis other medical systems because it challenges Biomedicine’s claims to the singular authority of truth and fact. Gaines and Hahn identified three features of Biomedicine as a sociocultural system: it

is a domain of knowledge and practice; it evidences a division of labor and rules of and for action; and it has means by which it is both produced and altered (Gaines & Hahn, 1985, pp. 5–6). These features are elaborated and extended here.

First, Biomedicine is a distinctive domain within a culture that features both specialized knowledge and distinct practices based on that knowledge (Gaines, 1979, 1982a, 1982b; Lindenbaum & Lock, 1993). In any medical system, a key factor is the relationship of medical knowledge to medical action (e.g., Gaines, 1992d; Hahn & Gaines, 1982, 1985; Kleinman, 1980; Kuriyama, 1992; Leslie & Young, 1992; Lock, 1980, 1993; Unschuld, 1985). Action is made reasonable and is justified by belief in the form of medical “knowledge”; in Biomedicine’s biologically defined universe, only somatic interventions make sense (Good, 1994).

Second, Biomedicine exhibits a hierarchical division of labor as well as guides or rules for action in its social and clinical encounters. The hierarchies of medicine are complicated and multiple. Some are based upon the nature of intervention: intensive somatic intervention is more highly prized, hence surgeons have more prestige and higher compensation than family doctors or psychiatrists (Johnson, 1985). The treatment of women, children, and older people all carry less prestige in Biomedicine, as well as usually lower compensation (Gaines, 1992d; Hinze, 1999). While such social structures are specific to Biomedicine’s domain, its fundamental principles, generative rules, and social identities mirror the discriminatory categories of the wider society in terms of gender and sexual identity (Hinze, 1999; Ginsburg & Rapp, 1995; Martin, 1994) and ethnicity, social status, and age (Baer, 1989, 2001; Gaines, 1982a, 1986, 1992d, 1995; Good, 1993; Hahn, 1992; Nuckolls, 1998). For specific examples, we note that nurses, traditionally subordinate to physicians, have traditionally been women, and both women and members of ethnic minorities have had to struggle for access to biomedical treatment and education.

The focal subject of Biomedicine is the human body. The body so treated is a construct of biomedical culture (Foucault, 1975; Gaines, 1992c), exhibiting the scars of specialty conflict as well as marks of the often invidious and discriminatory distinctions made in the wider society (Gaines & Hahn, 1985; DelVecchio Good, Helman, & Johnson, in Hahn & Gaines, 1985). Through its discursive practices (Gaines, 1992b), Biomedicine creates

bodies as figures of speech in culturally specific ways. These form part of what Gaines (1992c, n.d., b) calls “Local Biology.”

Third, as an internally cohesive system, Biomedicine reproduces itself through studies that confirm its already-established practices and, most salient, through apprenticeship learning—mentors tend to pass on to students what they are sure they already know. This self-reproduction is encapsulated in a term physicians themselves often use to refer to their knowledge system: “traditional medicine.” Yet all biomedical practitioners are taught, and tend to believe, that Biomedicine is science-based. In part, it is. As a consequence, the field also contains means by which it alters itself (e.g., medical research and its “advances,” practice and its presentation in medical journals and conferences, and concomitant alterations in what mentors “know”). Social scientists have shown that science itself is culturally constructed (Kuhn, 1962; Rubinstein, Laughlin, & McManus, 1984). Scientific traditions can be extremely resistant to change, yet the culture of science in general has shown itself to adapt more quickly to new information than the culture of Biomedicine. Issues of “competence” (DelVecchio Good, 1985, 1995) arise here because the scientific “standard of practice” can change abruptly with the reporting of new research findings, as in the cases of X-ray, thalidomide, cholesterol, and, most recently, hormone replacement therapy. Often scientific evidence that challenges traditional medical practice takes decades to be incorporated (a phenomenon known as the “evidence–practice gap”), whereas evidence that supports traditional assumptions is more likely to be quickly taken into account.

BIOMEDICAL KNOWLEDGE, PRACTICE, AND WORLDVIEW

Gaines (1992b) refers to two discursive modes by which Biomedicine is learned, shared, and transmitted: “embodied” and “disembodied” discourses. Through embodied person-to-person communication and through disembodied texts and images of various kinds, biomedical realities are (re)created over time. Both means have served to (re)produce popular as well as scientific knowledge. But it is noteworthy that science can and does recreate popular knowledge as scientific knowledge. For example, U.S. Biomedicine continues to consider “race” to be a biological reality (Gaines, 1995). This Local Biology,

reflected in scientific medical research and practice, has been augmented over the last several decades by the misinterpretation of genetic research results—an unfortunate situation that has reinforced unfounded racial ideologies (Barkan, 1992) and their eugenic overtones (Duster, 1990).

The relatively recent emphasis on “evidence-based medicine” expresses many physicians’ dawning realizations that much of their practice, in fact, has not been based on scientific evidence but on medical habits and tendencies, ingrained popular beliefs, and mentor-to-student traditions (e.g., radical mastectomies, low cholesterol diets, circumcision). Medical socialization explicitly and implicitly teaches professional assumptions about biological verities (Good, 1994; Good & DelVecchio Good, 1993) heavily influenced by a variety of sociocultural distinctions (Hinze, 1999). These powerful formative processes of socialization (Good, 1994) and those of medical practice employ an “empiricist theory of language” (Good & DelVecchio Good, 1981) wherein what is named is believed to exist independently in the natural world. Nature, too, is believed to exist “out there,” independent of the mind of the knower (Gordon, 1988; Keller, 1992).

Through naming and consequent diagnosis, medical language affects and effects transformations of culturally perceived reality. As Gaines and Hahn (1985, p. 6) noted:

That the system of Biomedicine is a sociocultural system implies that Biomedicine is a collective representation of reality. To claim that Biomedicine is a representation is not to deny reality which is represented, which affects and is affected by what it represents. It is rather to emphasize a cultural distance, a transformation of reality; an ultimate reality cannot be known except by means of cultural symbol systems. Such systems are both models *of* and *for* reality and action [Geertz, 1973]. Our representations of reality are taken to be reality though they are but transformations, refracted images of it.

Biomedical representations of reality have been based from its inception on what Davis-Floyd and St John (1998) call the “principle of separation”: the notion that things are better understood in categories outside their context, divorced from related objects or persons. Biomedical thinking is generally ratiocinative, that is, it progresses logically from phenomenon to phenomenon, presupposing their separateness. Biomedicine separates mind from body, the individual from component parts, the disease into constituent elements, the treatment into measurable segments, the practice of medicine into multiple specialties, and patients from their social relationships and culture. This drive toward separation

and classification can obscure the many meanings in the non-linear, non-logical relationships between and among entities.

Nevertheless, Biomedicine’s atomistic trend continues to escalate. A few years ago, biomedical researchers were talking excitedly about a “paradigm shift” away from disease-causing organisms to genes. From an anthropological viewpoint, of course, this did not constitute a full ideological paradigm shift but rather an intensification of Biomedicine’s separatist approach. Then, in 2001, the Human Genome Project demonstrated that the human genome consists of only 30,000 genes. As a result, the once apparently vast field of genetic explanations of disease suddenly collapsed, and researchers have shifted their focus to proteins in the emerging field of “proteomics.”

Biomedicine’s separatist tendency results in part from its coming of age during the period of intense industrialization in the West, which led it to adopt the machine as its core metaphor for the human body. This metaphor underlies the biomedical view of body parts as distinct and replaceable, and encouraged the treatment of the patient as an object, the alienation of practitioner from patient, and the discursive labeling of patients as “the gallbladder in 112” or “the C-sec in 214.” Patients were not expected to be active agents in their care (Alexander, 1981, 1982); the physician was the technical expert in possession of the uniquely valued “authoritative knowledge” (Jordan, 1993, 1997)—the knowledge that counts.

In the past few decades the Western world has exported much of its industrial production to the Third World, where the process of industrialization continues apace. The West itself has transformed into a technocracy—a society organized around an ideology of technological progress (Davis-Floyd, 1992). Thus, Davis-Floyd and St John (1998) describe Biomedicine’s dominant paradigm as “the technocratic model of medicine”—a label meant to highlight its precise reflections of technocratic core values on generating cultural “progress” through the development of ever-more-sophisticated technologies and the global flow of information through cybernetic systems. Such developments have generated a new form of medical discourse in which patients themselves are often now expected to be conversant because of the wide availability on the Internet—the ultimate agent in the global flow of information—of even abstruse biomedical information.

Mary Jo DelVecchio Good (1995) has noted the dual emphasis on “competence and caring” that characterizes contemporary biomedical education in some locations. This emphasis reflects the growing valuation within Biomedicine of what Davis-Floyd and St John (1998) have termed “the humanistic model of medicine”—a paradigm of care that stresses the importance of the practitioner–patient relationship as an essential ingredient of successful health care. This paradigm (previously also known as the “bio-psycho-social approach” (Engel, 1980)) replaces the metaphor of the body-as-machine and the patient-as-object with a focus on “mind–body connection” and the patient as a relational subject. The “gallbadder in 112” becomes Mrs Smith, mother of four, suffering from the stress of an unhappy marriage and the looming poverty that will result from her divorce. Kleinman’s *Illness Narratives* (1988a) has made many physicians more aware of the importance of listening to their patients and including their personal and sociocultural realities in diagnosis and treatment. This “conversation-based” approach is augmented by the “relationship-centered care” stressed by the Pew Health Foundation Commission Report (Tresolini et al., 1994) and a new emphasis on “cultural competence” in biomedical training, to which many anthropologists have contributed (see Lostaunau & Sobo, 1997).

Humanism was the central feature of the family practitioner until its near-obliteration by the splintering of Biomedicine into specialized fields that involved minimal practitioner–patient contact, which gained impetus during the 1960s and 1970s. Humanism’s renaissance among contemporary physicians has led to the development of more patient-centered approaches to medical education such as the case-study method, in which students are taught through a focus on specific patients instead of a detached focus on disease categories.

Biomedical humanism reflects the technocracy’s growing supervaluation of the individual (the “consumer” whose individual decisions affect corporate bottom lines), in contrast to industrial society’s subsumption of the individual (the “cog-in-the-wheel”) to bureaucratic systems oblivious to individual needs and desires. Humanistic touches range from the superficial—for example the interior redecoration of many hospitals (a prettier and softer environment has been shown to positively influence patient outcomes)—to the deep, such as encouraging parents of ill newborns to hold them skin-to-skin (an effective therapeutic technique known as kangaroo care).

A third transnational paradigm, identified by Davis-Floyd and St John (1998) as the “holistic model of medicine,” recognizes mind, body, and spirit as a whole, and defines the body as an energy field in constant relation to other energy fields. Whereas humanistic reform efforts arose from within Biomedicine (at first largely driven by nurses), the holistic “revolution” has arisen since the 1970s largely from outside Biomedicine, driven by a wide variety of non-allopathic practitioners and consumer activism (Fox, 1990). It increasingly incorporates elements of traditional and indigenous healing systems.

At present, a small percentage of physicians worldwide define themselves as “holistic,” but in general, biomedical practitioners have been resistant to accepting other knowledge systems as valid, and continue to regard their own system as exclusively authoritative. Nevertheless, as the limits of Biomedicine (which cannot cure many common ailments) become increasingly evident, millions of people in the postmodern world continue to rely on, or are beginning to revalue, indigenous healing systems and to incorporate holistic or “alternative” modalities into their care.

BIOLOGY AND NATURE: CONSTRUCTING BIOMEDICINE’S ULTIMATE REALITIES

The study of the clinical practices of Biomedicine has led to major observations about the realities with which it is concerned. Such research has demonstrated that professional medical systems represent a variety of biological realities, not one. Traditional Chinese medicine is very distinct from Biomedicine (Kleinman, 1980; Unschuld, 1985); its biological focus is complemented by a strong focus on energy. The same is true of Unnani, the professional medicine of the Middle East derived from Greek Classical medicine. Unnani and its Greek predecessor are involved in the somatic domain, but may add to it energetic and cosmological elements and interpretations that make their reading of human biology unique (Good & DelVecchio Good, 1993).

A key formulation, then, is Gaines’ notion of Local Biology, which sees biology as plural, as “biologies,” all of which are products of historical moments that are culturally specific, reflecting the worldviews of their creators. Local biological constructions are ubiquitous in both folk and professional medicines of various cultures (Gaines, 1987, 1992a, 1995). The concept of Local

Biology transforms the putative acultural bedrock of Biomedicine into porous shale, reformulating the ultimate, allegedly universal reality (Gaines, n.d., b) (Mishler, 1981) into an ever-changing cultural construction. To Westerners, it has been clear that the professional and folk medicines of Japan, China, Tibet, and India encompass very different biologies (Leslie, 1976; Leslie & Young, 1992; Kuriyama, 1992; Lock, 1980, 1993; Ohnuki-Tierney, 1984; Unschuld, 1985), but perhaps less obvious that French notions of the body and illness differ from those of the United States or Germany, just as Germany's differs from those in the United States and France (Gaines, 1992c; DeVries, Benoit, van Tiejlingen, & Wrede, 2001; Payer, 1989). The term Local Biology highlights for us the fact that the professional and folk biologies of the world are specific to historical time and cultural place (e.g., Desai, 1989; Gaines, 1987, 1992c, 1995; Kuriyama, 1992; Lock, 1993; Zimmerman, 1987).

Central to the (re)conceptualizations of human biology in various societies are certain root metaphors: for "traditional" U.S. medicine, the body is like a machine; in Traditional Chinese medicine, it is like a plant; in Indian Ayurveda, the body is seen as an element in an ecological system. These analogies greatly affect medical nosologies (system or study of the classification of diseases), diagnostics, and therapeutics. A cross-cultural vantage point makes it clear that biology is relative, not constant and universal in its normal or pathological states as Biomedicine asserts. Yet the thrust of Biomedicine remains the reduction of pathology to elementary, universal biological abnormalities that are believed to reside in "Nature" and there can be "discovered" (Gordon, 1988; Keller, 1992; Mishler, 1981).

Anthropologists, historians, and philosophers of science, among others, have shown that nature too is a construction whose elements reflect our own cultural projections back to us (Davis-Floyd, 1994; Foucault, 1975, 1977; Gordon, 1988; Keller, 1992; Schiebinger, 1993). Most cultural constructions of nature reflect cosmologies, and these cosmological underpinnings ensure the uniqueness of most medical systems, from Chinese medicine to local indigenous types of shamanism or witchcraft. Such underpinnings, especially in indigenous systems, are in fact what made them early candidates for anthropological investigation, allowing, as we noted above, the field of medical anthropology to grow rapidly by incorporating studies already carried out.

As we have seen, biomedical belief and praxis are as culturally constructed as any other medical system; they profoundly reflect the belief and value system—the worldview—of the postmodern technocracy. But this reflection is not made explicit in the biomedical literature or teaching. Rather, Biomedicine purports to be belief- and value-free. Thus, it is one of the few medical systems in the world that does not ground itself in an overt cosmology connecting medical diagnosis and practice to a larger grand design. Through the anthropological lens we can see that Biomedicine does in fact arise out of a cosmology, albeit an implicit and thoroughly secularized one. Its cosmological underpinnings are encompassed in what Davis-Floyd calls "the myth of technocratic transcendence": the hope-filled notion that through technological advances we will ultimately transcend all limitations seemingly placed on us by biology and nature.

Moore and Myerhoff (1977) have pointed out that the less verbally explicit a group's cosmology, the more rituals that group will develop to enact and transmit its cosmology. Davis-Floyd (1992, p. 8) has defined rituals as "patterned, repetitive, and symbolic enactments of cultural values and beliefs." Various anthropologists have shown Biomedicine to be heavily ritualized. The rituals of surgery not only serve instrumentally to prevent infection, but also enforce and display Biomedicine's attempts at maintaining the greatest possible distance from nature and its various organisms (Katz, 1981, 1998). Rituals of childbirth, such as electronic fetal monitoring, pitocin (synthetic oxytocin) augmentation, and episiotomy deconstruct this biological process into measurable and thus apparently controllable segments, reconstructing it as a process of technological production (Davis-Floyd, 1992). The rituals of medical education construct it as an intensive rite of passage that limits critical thinking and produces practitioners heavily imbued with technocratic core values and beliefs (Davis-Floyd, 1987; Davis-Floyd & St John, 1998, pp. 49–80; Konner, 1987; Stein, 1990). Rituals of communication reinforce biomedical hierarchies and the authoritative knowledge vested in physicians (Hinze, 1999; Jordan, 1993, p. 70; Stein, 1967/1980), and maintain the discursive "realities" that Biomedicine creates (e.g., DiGiacomo, 1987; Rapp, 2001). These analyses of biomedical rituals bring us back to medical anthropology's early corpus of research—interpretive studies of the medical rituals of other cultures—revealing Biomedicine's reliance on ritual to be at least as heavy as that of traditional medicines.

BIOMEDICAL REALITIES: CONSTRUCTING DISEASES

Biomedicine's non-spiritual, non-religious biotechnical approach stems logically from its core metaphor of the body as machine, which is both grounded in and a result of Biomedicine's secular (i.e., non-divine) worldview (Keller, 1992). This focus leads biomedical practitioners to try to cure (to fix malfunctions), but not to heal (to effect long-term beneficial changes in the whole somatic–interpersonal system). Thus, not only spiritual but also psychosocial issues are still often ignored, as are the multilevel semantic dimensions of clinical practice raised by anthropologists (Gaines, 1992c; Good, 1993). The “New Ethnopsychiatry” proposes that the incorporation of a variety of extra-clinical realities into clinical diagnosis and practice would provide for increased efficacy as well as healing (as opposed to curing) (Gaines, 1992a).

George Devereux, a psychiatrically and psychoanalytically sophisticated theoretician, was a pioneer in the critical examination of Biomedicine (Devereux, 1944, 1949). Devereux (1980) was among the first to argue that a major disease category, schizophrenia, was probably a “culture-bound disorder”. He saw that the conceptualization of this illness was deeply influenced by Western local cultural beliefs and social practices that in turn shaped the forms, consequences, and significance of the disorder(s). Subsequent work confirmed the cultural creation of this and other disorders such as depression which, after schizophrenia, is the most biologized mental disorder in the West (Gaines, 1992a; Kleinman & Good, 1985; Marsella, 1980). Schizophrenia, assumed to be chronic because of its presumed biological basis, is not chronic in non-Western and underdeveloped countries and may not exist at all in some cultures (Blue & Gaines, 1992; Devereux, 1980; Kleinman, 1988b). The same problematic status of the universality and character of depression has also been demonstrated (Kleinman & Good, 1985). It was Devereux (1961) who coined the term “ethnopsychiatry,” which later was used to subsume Western professional psychiatry (Gaines, 1992a) as the accumulating evidence suggested strongly that mental disorders were indeed cultural constructions and showed wide cultural variation in categorization and social responses (Jenkins, 1988; Kleinman, 1988b; Obeyesekere, Lutz, & Schieffelin, in Kleinman & Good 1985; Nuckolls, 1999).

Sociolinguistic and narrative studies of Biomedicine take discourse as a central topic in terms of education (Good, 1994) and therapeutics (Labov & Fanshel, 1977; Mattingly, 1999). Biomedical communication patterns, physician silence, and aspects of a discourse of practitioner “error” have been investigated, as well as the discourse on medical “competence” (Bosk, 1979; DelVecchio Good, 1995; Paget, 1982), and the logic and semantic load of patients' discourse (Good, 1994; Kleinman, 1988b; Mattingly, 1999; Young, 1995). Physician discourse also serves to construct the patient not only as body part, but also in terms of social identity (e.g., implicative age, “race,” gender or gender categories). Such constructions have strong consequences for treatment (Gaines, 1992c, 1992d; Good, 1994; Gordon & Paci, 1997; Lindenbaum & Lock, 1993); for example, physicians often create probabilistic scenarios about patients that guide diagnosis and treatment (e.g., “this 50-year-old white female patient with mood problems is probably going into menopause”) (Gaines, 1992d; Good, 1993).

Increasing anthropological awareness of the cultural construction of disorders and conditions in Biomedicine has angered feminist scholars, who have justly critiqued biomedical theory and practice for its patronizing pathologization of the female. Since its inception, Biomedicine has idealized the male body as the “prototype of the properly functioning body-machine” (Davis-Floyd, 1992, p. 51), and has defined the female body as dysfunctional insofar as it deviates from the male prototype (Fausto-Sterling, 1992, 2000). Consequently, specifically female biological processes such as menstruation, pregnancy, childbirth, and menopause are pathologized and subjected to technological interventions (Ehrenreich & English, 1973; Lock, 1993; Martin, 1987, 1990; Rothman, 1982, 1989).

NEW TRENDS IN THE STUDY OF BIOMEDICINE

The anthropology of reproduction is a relatively new subfield within medical anthropology. It comparatively explores both reproductive processes and their sociomedical treatment (for overviews, see Franklin & Davis-Floyd, 2001; Ginsburg & Rapp, 1991). It includes emerging anthropologies of menstruation (Buckley & Gottlieb, 1987); childbirth (see Davis-Floyd & Sargent, 1997);

midwifery (see Davis-Floyd, Cosminsky, & Pigg, 2001); and menopause (e.g., Lock, 1993)—all of which have been intensely biomedicalized. Many of its latest works focus on Biomedicine's new reproductive technologies (NRTs), which have expanded exponentially in recent years, from the birth of the world's first test-tube baby in 1978 to current attempts at human cloning.

The NRTs include, among others: (1) birth-control technologies such as diaphragms, intra-uterine devices (IUDs), and "the pill"; (2) technologies of conception such as artificial insemination and in-vitro fertilization (IVF); (3) screening technologies such as ultrasound, amniocentesis, and blood testing; (4) reparative technologies such as fetal surgeries performed in utero; (5) labor and birth technologies such as electronic fetal monitoring, synthetic hormones for labor induction and augmentation, and multiple types of anesthesia; and (6) postnatal technologies such as infant surgeries and NICU (Neonatal Intensive Care Unit) infant care.

Like the early forceps developed by men for application to the bodies of women, which both saved babies' lives and caused major damage to their mothers, the NRTs have been fraught with contradiction and paradox, reflecting their embeddedness in the patriarchal culture that invented them. Their centrality to cultural issues surrounding women's bodies and women's rights has made them a focal point for feminist and anthropological analysis from the early 1980s on. Some of these analyses have made their way into the heart of anthropological theory just as reproduction and kinship lie at the heart of social life. Salient among these is Ginsburg and Rapp's (1995) development of Shellee Colen's (1986) notion of "stratified reproduction." The concept encapsulates the myriad discriminatory hierarchies affecting women's reproductive choices and treatments. Indeed, as we have seen, Biomedicine itself is intensely stratified, as are its relationships to all other medical systems (Baer, 1989, 2001; Hahn & Gaines, 1985; Hinze, 1999).

A focus on Biomedicine also has led to the development of the study of medical technology and its implications for society (Lock, Young, & Cambrosio, 2000; Mitchell, 2001) which now forms an important part of the developing field of Science and Technology Studies (STS), aka Cultural Studies of Science (CSS) (Gaines, 1998b). This new field unites medical anthropology with historians and philosophers of science and medicine in new spaces of intellectual inquiry. Here we see studies of the sciences that Biomedicine applies, studies of

scientific social organizations (e.g., Gaines, 1998a; Gaines & Whitehouse, 1998; Haraway, 1991, 1997; Latour & Woolgar, 1979; Lock, 2002; Rabinow, 1996; Young, 1995), and clinical studies of new biomedical technologies (e.g., Cartwright, 1998; Casper, 1998; Cussins, 1998; Mitchell, 2001). CSS theorists recognize science as cultural enterprise and focus on scientific knowledge and its production and change; the label "Science and Technology Studies" more specifically reflects an emphasis on technology and its impact on society (Gaines, 1998b). Here, Haraway's (1991) explication of the "cyborg," the ambiguous fusion of human and machine, has served as a strong focal point for analysis (e.g., Davis-Floyd & Dumit, 1998; Downey & Dumit, 1997; Dumit & Davis-Floyd, 2001; Gray, 1995).

The work of Michel Foucault (1975, 1977, 1978) has been formative for many anthropologists' understandings of Biomedicine, in particular his concept of biopower—the insight that control can be achieved by getting populations and individuals to internalize certain disciplinary procedures, which then do not have to be imposed from without. In many ways this notion is a restatement of Freud's argument of the discontents of civilization and the development of the superego, but without a theory of the unconscious.

Theorists in Critical Medical Anthropology (CMA) have extended Foucault's concepts into the realm of political economy. For example, Scheper-Hughes and Lock demonstrated the value of viewing the body not only from individual/phenomenological and social/symbolic perspectives, but also as "the body politic"—"an artifact of social and political control" (Scheper-Hughes & Lock, 1987, p. 6). Other theorists in CMA have adapted work in political economy to analyze the development of biomedical hegemony and agency in tandem with political, institutional, and financial structures of control. These studies are generally not interpretive but rather offer traditional causal realist forms of analyses (Gaines, 1991; Hacking, 1983).

Exemplary here is Singer, Valentin, Baer, and Jia's (1998) study of "Juan Garcia's drinking problem," which analyzes one man's alcoholism in light of the U.S. colonization and exploitation of Puerto Rico and the cultural discrimination against the immigrants who fled the resultant poverty to seek work in the United States. Later, the farming out of factory production to cheaper Third World locations resulted in the closing of many American factories where such workers used to find

employment. These authors show that the biomedical diagnosis and construction of Juan Garcia's "disease of alcoholism" limits cause to the individual, obscuring the effects of the sociopolitical and economic forces that curtailed his access to education and employment. This biomedicalization of alcoholism, as of many other conditions from pregnancy to malnutrition, likewise limits attempts at treatment to individual biology and tends to obscure extra-clinical factors.

In the United States, disability has also traditionally been biomedically defined. But recent research in disability studies clearly shows its relativity in time and social space (both cultural and locational within a culture) (Edgerton, 1971; Frank, 2000; Groce, 1985; Ingstad & Whyte, 1995; Langness & Levine, 1986). For example, to be deaf within a community of the deaf is not a disability (Groce, 1985). Many people defined by Biomedicine as disabled assert that they comprise a culture, not a "disability." New research continues to challenge limited biomedical definitions of dis/ability.

Bioethics constitutes an additional new area of anthropological research and practice. Since the 1970s anthropologists have been increasingly concerned with the ethics of biomedical practice, spurred by a variety of factors. These include patient activism, the declining sovereignty of Biomedicine, the resultant increase in biomedical susceptibility to lawsuits, and ethical lapses in experiments both during and after World War II (Fox, 1990). Bioethics constitutes both an area of theorizing and of practice: some anthropologists work as bioethicists or consultants who raise sociocultural issues (Carrese & Rhodes, 1995; Marshall, 1992); others study bioethics as a cultural phenomenon (Gaines & Juengst, n.d.; Gordon, 1999); and still others use ethics to critique biomedical theories (e.g., Gaines, 1995).

THE STANCE OF PRACTICE

While all Biomedicines generate clinical practices, they differ significantly in their stances vis-à-vis disease and the patient. The foundational studies of Biomedicine in the 1980s showed that it is not unitary but rather consists of "many medicines" (Gaines & Hahn, 1985). Within and across medical specialties, as well as across cultures, we find a variety of views all called Biomedicine (Hahn & Gaines, 1985; Lock & Gordon, 1988; Lührman, 2000; Wright & Treacher, 1982).

Nevertheless, as DelVecchio Good (1995) and Davis-Floyd (2001) suggest, key characteristics of Biomedicine (such as its separation of mind and body, its mechanistic metaphors, its distancing style) tend to remain constant across cultures. Equally salient among these characteristics is aggressive intervention, most particularly in the United States but also in many other countries. For example, throughout their history, U.S. biomedical practitioners have aggressively treated many disorders without a trace of scientific basis, often to the detriment of the patient. The mercury and bloodletting of earlier times nowadays are replaced by massive over-prescription of drugs (one of the leading causes of death in the contemporary United States) and the overuse of invasive tests and surgical interventions. The surgical maxim "when in doubt, cut it out" aptly expresses American Biomedicine's aggressive focus. Here gender once again becomes salient: cesarean sections, hysterectomies, and (until recently) radical mastectomies have been among the most commonly performed of unnecessary surgeries in the United States (see Katz, 1985, 1998).

In contrast, French Biomedicine has long been characterized by its non-interventive strategies; for example, it has minimized radical surgery, seeing it as too aggressive and too destructive of the body esthetic (Payer, 1989). Likewise, within American Biomedicine the "culture of medicine" (a term physicians use to refer to internal medicine), often conflicts with the "culture of surgery": internists tend to prefer a more patient, "wait and see" approach (Hahn, 1985; Helman, 1985).

Biomedicine's traditional aggressiveness has carried with it the promise of dramatic cures. This promise has become its Achilles' heel as lawsuits proliferate when this promise is not fulfilled. The baby is not perfect, the surgery results in infection, the dialysis fails—it must have been someone's fault, as Biomedicine seemed to have promised all would be well. In general, biomedical practitioners justify their frequent use of aggressive interventions in historical terms, citing the drastic reductions in mortality that have resulted from early 20th-century understandings of the etiology of infectious diseases and the discovery of antibiotic drugs. Their critics, however, can show that disease rates were already dropping in the industrialized world because of cleaner water and improvements in sewage treatment and nutrition. In the developing world, this argument continues (McKeown, 1979).

TRANSLATING BIOMEDICINE

Throughout the late 19th and 20th centuries, Biomedicine was massively exported into Third World countries. Sometimes it was borrowed and at others it was exported as a result of its colonialist imposition (Kleinman, 1980; Lock, 1993; Reynolds, 1976; Weisberg & Long, 1984). Still later, it was actively sought by developing countries as a feature of modernization. The modernizing process acts as an homogenizing funnel that channels "development" toward univariate points: in economics, capitalism; in production, industrialization; in health care, Biomedicine. The three work in tandem, as the importation of Biomedicine means the investment of huge sums of money in the construction of large hospitals (the factories of health care), the training of staff, and the incorporation of expensive medical technologies. Such modern biomedical facilities usually serve the colonizers and the middle and upper classes of colonized populations and are largely inaccessible to the majority of the population.

As in the West, major improvements in health for these biomedically underserved majorities have primarily resulted not from Biomedicine but from public health initiatives to clean water and improve waste disposal and nutrition (McKeown, 1979)—improvements that many Third World communities still sorely lack.

When Biomedicine is transplanted, it is altered in significant ways in terms of clinical practices, nosologies, medical theory, concepts of self, and therapeutics (Farmer, 1992; Feldman, 1995; Gaines & Farmer, 1986; Hershel, 1992; Kleinman, 1980; Lock, 1980; Reynolds, 1976; Weisberg & Long, 1984). For example, pharmaceutical agents only available by physician prescription in the First World often take on a life of their own in Third World countries: traditional healers and midwives incorporate allopathic injections into their pharmacological repertoires; drugs are sold in pharmacies and on the streets without prescription. In a sense, people become their own diagnosticians and self-prescribe, without the biomedical establishment but also without a systematic way of dealing with the biological implications of their use of allopathic medicines (Nichter, 1989; Van Der Geest & Whyte, 1988).

Biomedicine's inaccessibility and lack of cultural fit often ensure that practitioners in the developing world do not enjoy a monopoly on medical care; indigenous and professional healers from non-biomedical systems continue to serve large clienteles. In some areas,

postmodernization is beginning to limit Biomedicine's reach, as literate and savvy non-biomedical healers, from shamans to curanderos to naturopaths, increasingly tap into and augment scientific evidence supporting the herbal, humanistic, and spiritual elements of their practices.

In all instances of culture contact, Biomedicine generally attempts to maintain its modern scientific status by co-opting and redefining knowledge, therapies, or therapeutic agents found in other traditions, professional or popular. Medical dialogues are transformed into biomedical monologues (Gaines & Hahn, 1985). In this way, Biomedicine continually revitalizes itself and reinforces its hegemonic status by expanding to incorporate elements from other modalities.

In the cultural arena of childbirth, for example, core challenges to the intense medicalization of birth came from birth activists in the 1970s who demanded "natural childbirth" in the hospital, meaning in this case that women gave birth without drugs or technological interventions. By the 1980s, Biomedicine had humanized its approach to birth, redecorating delivery rooms, allowing the presence of family members and friends, and offering epidural analgesia so that women could be both pain-free and "awake and aware." These humanistic reforms took the steam out of the natural childbirth movement by incorporating some of its recommendations. Yet at the same time, the technologization of birth increased: for example, the use of electronic fetal monitors has risen exponentially since the 1970s, as has the cesarean rate. Thus, Biomedicine reinforced its biopower over birth while at the same time allowing women a greater sense of agency and respect.

Analogously, pharmaceutical companies now move into indigenous areas, harvest local botanical specimens (often stealing them from local healers), sell them as vitamins or herbs, or mix them with drugs to create "nutraceuticals"; they then try to control the use of the ingredients they have taken, limiting or eliminating their availability to local populations. As with childbirth, this process of co-option continually revitalizes Biomedicine without giving status or credit to other medical systems and their distinctive ideologies of illness and healing.

Yet even in the West, Biomedicine does not hold a monopoly on healing. In Europe, homeopathic and naturopathic medicines are part of institutionalized health care systems, as are forms of hydrotherapy (Maretzki, 1989; Maretzki & Seidler, 1985; Payer, 1989). In European,

Canadian, and some American pharmacies, naturopathic and homeopathic medicines are sold alongside biomedical pharmaceuticals. In the United States, Osteopathy and Chiropractic compete successfully in the professional health care arena (Coulehan, 1985; Gevitz, 1982; Oths, 1992), as does professional Chinese medicine in the Western states.

Around the world, the narrow funnel of modernization is opening to more expansive appreciations of what has been lost, what can be preserved or re-created, and what is still to be learned. It is increasingly clear that in the postmodern era, multiple medical knowledge systems can co-exist and come to complement each other. Biomedicine in all likelihood will continue to advance within its own parameters and to hold on to some status, if not its earlier hegemony, for decades to come. But, increasingly biomedical practitioners will have to respond to the existence and strengths of other ways to heal.

Medical Pluralism

Hans A. Baer

INTRODUCTION

Medical systems in all human societies, regardless of whether they are indigenous or state-based, consist of a dyadic core consisting of a healer and a patient. Healers range from generalists, such as the shaman in indigenous societies or the proverbial family physician in modern societies, to specialists, such as the herbalist, bonesetter, midwife, or medium in preindustrial societies or the urologist, internist, or psychiatrist in modern societies. In contrast to indigenous societies, which tend to exhibit a more-or-less coherent medical system, state or complex societies exhibit the conflation of an array of medical systems—a phenomenon generally referred to by medical anthropologists, as well as medical sociologists and medical geographers, as medical pluralism. The medical

system of a society consists of the totality of medical subsystems that coexist in a cooperative or competitive relationship with one another. Although much of the initial work that anthropologists conducted on medical pluralism occurred in African and Asian societies, Leslie (1976, p. 9) notes that “[e]ven in the United States, the medical system is composed of physicians, dentists, druggists, clinical psychologists, chiropractors, social workers, health food experts, masseurs, yoga teachers, spirit teachers, Chinese herbalists, and so on.”

Medical pluralism is not a recent phenomenon but has its roots in increasing patterns of ranking and social stratification in human societies. Fabrega (1997) argues that, as opposed to foraging and village-level societies, chiefdoms and early state societies exhibit the beginnings of the “institution” or “system” of medicine which

includes: (1) an elaborate corpus of medical knowledge which continues to embrace aspects of cosmology, religion, and morality; and (2) the beginnings of medical pluralism, manifested by the presence of a wide variety of healers, including general practitioners, priests, diviners, herbalists, bonesetters, and midwives who undergo systematic training or apprenticeships. He delineates two broad levels in the plural medical systems of early civilizations and empires: (1) an official, scholarly academic system oriented to the care of the elite; and (2) a wide array of less prestigious physicians and folk healers who treat subordinate segments of the society, such as craftspeople, artisans, soldiers, peasants, and slaves. The state plays an increasing role in medical care by hiring practitioners for the elites and providing free or nominal care for the poor, especially during famines and epidemics. The literate or "great" medical tradition includes the formation of a medical profession, the beginnings of clinical medicine, and the increasing commercialization of the healing endeavor.

With European expansion and colonialism, allopathic medicine, or what eventually evolved into biomedicine, came to supersede in prestige and influence even professionalized traditional medical systems. Third World societies are characterized by a broad spectrum of humoral and ritual curing systems. Some of these are associated with literate traditions, such as Hinduism, Islam, Confucianism, Buddhism, and Taoism, and have schools, professional associations, and hospitals. Even though the upper and middle classes resort to traditional medicine as a backup for the shortcomings of biomedicine and for divination, advice, and luck, it constitutes the principal form of health care for the masses. As Frankenberg (1980, p. 198) observes, "The societies in which medical pluralism flourishes are invariably class divided."

CONCEPTIONS OF MEDICAL PLURALISM

Various medical anthropologists have formulated various schemes or approaches that recognize the phenomenon of medical pluralism in complex societies. Based upon their cultural ecological settings, Dunn (1976) delineates three types of medical systems: (1) local medical systems, (2) regional medical systems, and (3) the cosmopolitan medical system. Local medical systems are folk or indigenous medical systems in foraging, horticultural or pastoral societies, or peasant communities in state

societies. Regional medical systems are systems distributed over a relatively large area, such as Ayurveda and Unani medicine in India and Sri Lanka and traditional Chinese medicine. Cosmopolitan medicine refers to the world-wide system commonly referred to as Western medicine, regular medicine, allopathic medicine, scientific medicine, or biomedicine. Complex societies generally contain all three of these systems. In modern industrial or post-industrial societies, biomedicine—the dominant system—tends to exist in a competitive relationship with other systems such as chiropractic, naturopathy, Christian Science, evangelical faith healing, and various folk medical systems. It often seeks either to annihilate these systems or to restrict their scope of practice. In some instance, biomedicine seeks to absorb or co-opt them, particularly if the latter achieve increasing legitimacy.

Chrisman and Kleinman (1983) created a widely used model that delineates three overlapping sectors in health care systems. The popular sector consists of health care performed by patients themselves, their families, social networks, and communities. It includes a wide array of therapies, such as special diets, herbs, exercise, rest, baths, and massage, and, in the case of modern societies, articles such as over-the-counter drugs, vitamin supplements, humidifiers, and hot water bottles. Based on research in Taiwan, Kleinman estimates that 70–90% of the treatment episodes on the island occur in the popular sector. The folk sector encompasses various healers who function informally and often on a quasi-legal or even illegal basis. These include shamans, mediums, magicians, herbalists, bonesetters, and midwives. The professional subsector includes the practitioners and bureaucratic structures, such as clinics, hospitals, and associations, which are associated with both biomedicine and professionalized heterodox medical systems, such as Ayurvedic and Unani medicine in South Asia, herbalism and acupuncture in the People's Republic of China, and homeopathy, osteopathy, chiropractic, and naturopathy in Britain.

In keeping with Navarro's (1986, p. 1) assertion that classes as well as races, ethnic groups, and genders within capitalist societies "have different ideologies which appear in different forms of cultures," it may be argued that these social categories also construct different medical systems to coincide with their respective views of reality. In contrast to many medical anthropologists who observe that complex societies exhibit a pattern of medical pluralism, many neo-Marxian medical social

scientists confine their attention to the dominant capital-intensive system of medicine and ignore or at best give fleeting attention to alternative medical systems. Critical medical anthropology (CMA), which builds on the work of the political economy of health, attempts to overcome these shortcomings (Singer & Baer, 1995). It asserts that patterns of medical pluralism tend to reflect hierarchical relations in the larger society. Patterns of hierarchy may be based upon class, caste, racial, ethnic, regional, religious, and gender distinctions. Medical pluralism flourishes in all socially stratified or state societies and tends to mirror the wide sphere of class and social relationships. National medical systems in the modern world tend to be “plural,” rather than “pluralistic,” in that biomedicine enjoys a dominant status over heterodox and/or folk medical practices. In reality, plural medical systems may be described as “dominative” in that one medical system generally enjoys a preeminent status vis-à-vis other medical systems. While within the context of a dominative medical system one system attempts to exert, with the support of social elites, dominance over other medical systems, people are quite capable of “dual use” of distinct medical systems (Romanucci-Ross, 1977).

Medical pluralism in the modern world is characterized by a pattern in which biomedicine exerts dominance over alternative medical systems, whether they are professionalized or not. The dominant status of biomedicine is legitimized by laws that grant it a monopoly over certain medical practices, and limit or prohibit the practice of other types of healers. Nevertheless, biomedicine’s dominance over rival medical systems has never been absolute. The state, which primarily serves the interests of the corporate class, must periodically make concessions to subordinate social groups in the interests of maintaining social order and the capitalist mode of production. As a result, certain heterodox practitioners, with the backing of clients and particularly influential patrons, have been able to obtain legitimation in the form of full practice rights (e.g., homeopathic physicians in Britain, osteopathic physicians in the United States, and Ayurvedic and Unani physicians in India) or limited practice rights (e.g., chiropractors, naturopaths, and chiropractors in North American societies, many European societies, as well as Australia and New Zealand). Lower social classes, racial and ethnic minorities, and women have utilized alternative medicine as a forum for challenging not only biomedical dominance but also, to a degree, the hegemony of the corporate class and its political allies.

CASE STUDIES OF MEDICAL PLURALISM

India

Leslie (1977) has conducted historical and ethnographic research on medical pluralism in India. He delineates five levels in the Indian dominative medical system: (1) biomedicine, which relies upon physicians with M.D. and Ph.D. degrees from prestigious institutions; (2) “indigenous” medical systems, which include practitioners who have obtained degrees from Ayurvedic, Unani, and Siddha medical colleges; (3) homeopathy, whose physicians have completed correspondence courses; (4) religious scholars or learned priests with unusual healing abilities; and (5) local folk healers, bone-setters, and midwives. In contrast to some 150,000 biomedical physicians, there were an estimated 400,000 practitioners of Ayurveda, Unani, and Siddha in the early 1970s. Ayurveda is based upon Sanskrit texts, Unani on Galenic and Islamic medicine, and Siddha on South Indian humoralism. In addition to 95 biomedical schools, India has 92 Ayurvedic colleges, 15 Yunani colleges, and a college of Siddha medicine. Although homeopathy entered India as a European import, the opposition to it by the British-dominated biomedical profession spared it association with colonialism. Homeopathic practices have become a standard component of Ayurveda. Although the Indian state continued to support biomedicine after independence, in 1970 it established the Central Council of Indian Medicine as a branch of the Ministry of Health in an effort to legitimize the traditional professionalized medical systems and for the purposes of registering traditional physicians, regulating education and practice, and fostering research (Leslie, 1974). According to Leslie (1992, p. 205), “[Traditional] physicians ... are sometimes painfully aware that cosmopolitan medicine [or biomedicine] dominates the Indian medical system, yet a substantial market exists for commercial Ayurvedic products and for consultation with practitioners.”

Zaire

Janzen (1978) presents an account of how patients in a region of Lower Zaire engage in “therapy management” and how they resort to various medical systems in addressing illness. The “therapy management group,” consisting of kinspeople, friends, and colleagues, serves to broker the relationship between physicians, nurses, indigenous and

religious healers, on the one hand, and the patient, on the other hand. The plural medical system in Lower Zaire consists of the following levels: (1) biomedical physicians and nurses (most of whom initially were European expatriates but in time were Africans); (2) various *banganga* or indigenous healers; (3) kinship therapy; and (4) *bangunza* or diviners and prophets. Whereas some indigenous healers, such as the *naganga mbuki* or the herbalist, treat natural illnesses, others, such as the *nganga nkisi* or magician treat illness emanating from supernatural causes or emotional states, such as anger. The clan meeting serves as the focus of kinship therapy in which several diagnostic sessions are followed by therapeutic sessions. African Christian missionary leaders, referred to as *bangunza*, engage in laying-on-of-hands and other religious healing techniques. Although the people of Lower Zaire recognize the advantages of biomedicine, they continue to subscribe to traditional views of health, illness, and curing.

The Bolivian Altiplano

Crandon-Malamud (1991) conducted fieldwork between 1976 and 1978 on medical pluralism in Kachitu (pseudonym), a rural town on the Bolivian *altiplano*. Kachitu is the center for a canton consisting of some 16,000 Aymara Indians over 36 *comunidades*. The town proper has a population of about 1,000 people consisting of three ethnoreligious groups: (1) Aymara peasants, (2) the Methodist Aymara, and (3) Catholic *mestizos*. Prior to the Revolution of 1952, the *mestizos*, which constitute about one third of the population of Kachitu, supervised the Aymara for national elites who generally resided in La Paz and other cities. Since the Revolution, the *mestizos* have been seeking to avoid poverty in a shrinking population and are a socially fragmented ethnic category that includes teachers, small shopkeepers, and poor occasional agricultural laborers. Prior to 1952, the Aymara, which make up another third of the village, lived in Indian communities that were heavily taxed or on haciendas. Some Aymara were miners and performed personal services. Many Aymara peasants migrated to Kachitu from the haciendas upon acquiring land through fictive ties with *mestizos*. Following the Revolution and land reform, others moved to town and claimed land on the outskirts that had been confiscated from the *mestizos*. The Methodist Aymara are converts or descendants of converts to the Methodist church which established a mission in the early 1930s. The Methodist Aymara

attended mission schools and became entrepreneurs who took over local administrative and political offices when the revolutionary government threw the *mestizos* out of these positions. They function as the economic and political backbone of Kachitu. Crandon-Malamud (1991, p. x) tends to conflate ethnicity and social class, noting that Aymara-ness, *mestizo*-ness, and even Methodism constitute “masks for social class.”

She situates four themes that permeate the dialogue about medical etiology and diagnosis in Kachitu—pervasive hunger, subordination, victimization, and exploitation—within the context of the Bolivian political economy. The first one—that of race—differentiates the purportedly white elites from *mestizos* and Indians as a means to justify unequal access to the political process; the second one entails an economic system that exploits Indian labor; the third one consists of *caudillo* political structures that suppress dissent on the part of rural *mestizos* and Indians; and the fourth one is conflict that exists between *mestizos* and Indians.

Crandon-Malamud delineates five domains of medical resources utilized by Kachitu depending upon the diagnosis: Aymara home care, shamanistic or *yatiri* care, *mestizo* folk home care, biomedical clinical care, and hospital care in La Paz. She examines the intricate ways that residents of Kachitu utilize the local plural medical system for purposes of establishing their sense of cultural identity and obtaining the few resources available to them. Contrary to the wishes of biomedical practitioners and indigenous healers, decisions concerning illness etiology and diagnosis tend to be made primarily by patients themselves, their families, and other interested parties. Biomedical physicians who practice in Kachitu must abandon many of their preconceptions and adapt themselves to the local belief systems if they expect to establish rapport with their patients. The medical ideologies in Kachitu function as options that address different types of ailments. As Crandon-Malamud (1991, pp. 202–203) observes, “All things being equal, if one has tuberculosis, one goes to the physician in the Methodist clinic; if one suffers from *khan achachi*, one goes to the *yatiri*; if one has a stomach upset, one resorts to *medicinas caseras*.” [Note: *khan achachi* refers to a sickness stemming from a phantom, *khan achachi*, who consumes meat, alcohol, and other gifts that it demands from people; *medicinas caseras* means home care.]

Kachitunos, regardless of their social standing, tend to be pragmatists when it comes to seeking medical

treatment. Medical dialogue serves as an idiom by which a person identifies his or her ethnic identity within the larger context of Bolivian society—one that is characterized by frequent economic crises, unstable governments, and military coups. Mestizos in Kachitu who find themselves downwardly mobile may in essence gain access to greater health care by turning to Indian indigenous medicine. Crandon-Malamud argues that they employ medical dialogue as a mechanism of empowerment in the face of external hegemonic forces. Unfortunately, this medical dialogue has served as a rather limited form of empowerment and in reality more as a coping mechanism within the larger Bolivian political economy.

Haiti

Like Crandon-Malamud, Brodwin (1996) conducted ethnographic research on medical pluralism at the village level, namely in the Haitian village of Jeanty (pseudonym). In addition to access to biomedicine or “metropolitan medicine,” the villagers turn to various other practitioners and healing systems in their search for better health. These include herbalists, bonesetters, midwives, the cult of Roman Catholic saints, Vodou priests, and Pentecostal ministers. Morality and medicine are intricately intertwined in rural Haiti and pose questions of innocence or guilt. People in Jeanty debate among themselves as to which healing system they should resort to in an effort to achieve moral balance in their lives. While recognizing its value in treating certain diseases, they regard the biomedical dispensary in their village “as yet another site where local representatives of powerful outside forces provide valued resources and techniques for ordering life” (Brodwin, 1996, p. 67). For the problems of everyday life, the villagers can turn to the *houngan* and *mambo* (male and female Vodou religious healer), Catholic lay exorcists, or Pentecostal healers. Whereas Vodou and Catholicism coexist in a complementary and somewhat tense relationship, Pentecostals tend to regard them systems as diabolic. Regardless of the healing system that the villagers employ, as Brodwin argues, each of them to address pressing moral dilemmas.

Kyoto, Japan

In 1973–74, Margaret Lock (1984) conducted ethnographic research on medical pluralism in Kyoto, Japan.

In addition to biomedicine, modern Japan has a wide variety of East Asian medical systems and has undergone a revival of these systems, much in the same way that the United States, Canada, European societies, Australia, and New Zealand have seen the emergence of the holistic health/New Age movement. The most popular of these is *kanpo* (“the Chinese method”), a form of herbal medicine that was imported to Japan from China in the sixth century. In addition to prescribing herbs, *kanpo* doctors administer acupuncture, body manipulation, and moxibustion. *Kanpo* doctors are M.D.s who combine biomedicine and East Asian medicine. They tend to treat psychosomatic ailments in which the patients’ chief complaints are tiredness, headaches, occasional dizziness, or numbness, typical symptoms emanating for the somatization of distress. Lock also reports the existence of herbal pharmacies, acupuncture clinics, moxibustion clinics, and *amma* (massage) parlors in Kyoto. She reports, however, that East Asian healers in Kyoto by and large do not apply them holistically. Conversely, Lock (1984, p. v) maintains that “in the majority of clinics, practitioners appeared to be engaged in an attempt to remove physical symptoms in a fashion reminiscent of that of most biomedical physicians, although their tools were those of traditional medicine.”

The United States

Based upon historical and ethnographical research, Baer has written an overview of medical pluralism in the United States (Baer, 2001). He argues that medical pluralism has historically reflected and continues to reflect class, racial/ethnic, and gender relations in U.S. society. U.S. medicine during the nineteenth century was highly pluralistic in that regular medicine shared the stage with a wide array of competing and sometimes alternative medical systems, including homeopathy, botanic medicine, eclecticism, hydrotherapy, Christian Science, osteopathy, and chiropractic. Although regular medicine constituted the most widespread medical subsystem, it did not completely dominate its rivals economically, politically, or socially.

As U.S. capitalism evolved from competitive to a monopoly form after the Civil War, the corporate class found it necessary to exert control over an increasingly restless populace. Along with the state and education, medicine became another hegemonic vehicle by which members of the corporate class indirectly came to

legitimate capital accumulation and to filter their view of reality down to the masses. The corporate class acquired an effective tool around 1900, with the development of a germ theory and the transition to “scientific medicine,” or biomedicine, a medical system based on systematic research and controlled experimentation. With its emphasis upon pathogens as the cause of disease, biomedicine provided corporate leaders with a paradigm that allowed them to neglect the social origins of disease while at the same time, in some instances, restoring workers back to a level of functional health essential to capital accumulation. Consequently, the emerging alliance between the American Medical Association, which consisted primarily of elite practitioners and medical researchers in prestigious universities, and the corporate class ultimately permitted biomedicine to achieve dominance over rival medical systems. Biomedicine quickly co-opted most homeopaths and eclectics by admitting them into their state medical societies.

The U.S. dominative medical system consists of several layers that tend to reflect class, racial/ethnic, and gender relations in the larger society. In rank order of prestige, these include: (1) biomedicine; (2) osteopathic medicine as a parallel medical system focusing on primary care; (3) professionalized heterodox medical systems (namely chiropractic, naturopathy, and acupuncture and Oriental medicine); (4) partially professionalized or lay heterodox medical systems (e.g., homeopathy, massage therapy, herbalism, and midwifery); (5) Anglo-American religious healing systems (e.g., Spiritualism, Christian Science, Unity, Pentecostalism, and New Age healing); and (6) folk medical systems (e.g., Appalachian herbalism, African-American folk medicine, *curanderismo*, Native American healing systems).

As a result of corporate support for biomedicine, its practitioners came to consist primarily of white, upper- and upper-middle-class males. As professionalized heterodox medical systems, osteopathy, chiropractic, and naturopathy held out the promise of improved social mobility for thousands of white lower-middle- and working-class individuals, most of whom were males, who were denied access to biomedicine due to the structural barriers created by the Flexner Report of 1910. Osteopathic medicine eventually evolved into a parallel medical system with full practice rights as a result of the paucity in primary care physicians created by the increasing trend toward specialization in biomedicine. Anglo-American religious healing systems provided outlets for

white women seeking therapeutic roles. Whereas Christian Science served this role largely for upper-middle-class women, Spiritualism and Unity did so for lower-middle-class women and Pentecostalism did so for lower-class women. Finally, folk medical systems have enabled working-class people from various ethnic groups, particularly people of color, to provide low-cost and culturally appropriate therapy for individuals at the lowest echelons of U.S. society.

A California Holistic/New Age Healing Center

English-Lueck (1990) conducted an ethnography of the holistic health/New Age movement in Paraiso (pseudonym), a California community consisting largely of white upper-middle- and upper-class residents. Despite its relative ethnic homogeneity, Paraiso’s residents adhered to a variety of lifestyles. These included millionaires, university students, and members of unconventional congregations, such as the Unitarian Universalist Church, the Unity School of Christianity, and the Church of Religious Science. Paraiso has numerous self-help groups, 36 schools that offer workshops and lectures on alternative medicine, and three schools that offer training in various alternative therapies, including massage, acupuncture, and hypnosis. The local community college, the university extension program, the YMCA, herbal stores, a Taoist sanctuary, and a Yogic Institute/ashram also offer workshops on alternative therapies.

Of the estimated 790–830 alternative practitioners in the Paraiso area, only 253 practice publicly. Many certified practitioners do not advertise, preferring to treat clients belonging to small, intimate networks in order to avoid legal prosecution. Alternative practitioners often exhibit therapeutic eclecticism and combine different therapies depending upon the needs and desires of their clients. Bodyworkers incorporate massage, yoga, Alexander technique, reflexology, and zone therapy. In its diversity of practitioners, Paraiso constitutes a microcosm of the holistic health movement.

BRINGING POWER RELATIONS INTO THE STUDY OF MEDICAL PLURALISM

Whereas the early work on medical pluralism tended to focus on levels in plural medical systems, more recent

research on this phenomenon has to recognize that, as Stoner (1986, p. 47) asserts, “[p]luralism can now be examined as a multiplicity of healing techniques, rather than of medical systems.” Indeed, in its response to the growing popularity of the holistic health movement, biomedical physicians in the United States have increasingly been incorporating various therapeutic techniques, from homeopathy, herbalism, acupuncture, and bodywork, into their regimen of treatment in an effort to create an “integrative medicine.” Brodwin (1996) asserts that the “study of medical pluralism had reached a theoretical impasse” because efforts to categorize plural medical systems “often produced rigid functionalist typologies or broke down in a welter of incomparable terms.” Medical anthropologists turned to concerns such as the political economy of health, biomedical hegemony, alternative medical systems in Western societies, reproduction, the mindful body, the social dynamics of clinical encounters, biotechnology, substance abuse, and AIDS.

Despite the validity of Brodwin’s comments on the shortcomings of much of the research on medical pluralism, not all scholars interested in new theoretical concerns dropped their interest in medical pluralism. Indeed, various anthropologists interested in the political economy of health, including Crandon-Malamud, Brodwin, and Baer, developed an interest in how power relations shape plural medical systems. While within the context of complex societies, one medical system tends to exert, with the support of strategic elites, dominance over other medical systems, people are quite capable of dual use of distinct medical subsystems. Subaltern groups, including lower social classes, racial and ethnic minorities, and women, have often utilized and continue to utilize alternative medical systems as a forum for challenging not only biomedical dominance but also, to a degree, the hegemony of ruling groups around the world. Unfortunately, according to Elling (1981, p. 97), “Traditional medicine has been used to obfuscate native peoples and working classes.” Folk healers in the modern world have shown an increasing interest in acquiring new skills and use certain biomedical-like treatments or technologies in their work, a process in which they often inadvertently adopt the reductionist perspective of biomedicine. Many Third World peoples receive regular treatment from “injection doctors” and advice from pharmacists who indiscriminately sell antibiotics and other drugs over the counter. Among the indigenous people in the highlands of Papua New Guinea, the “shoot” is

perceived as “strong medicine” for a wide range of conditions, even if they do not require an injection, because it was “introduced by colonial powers who brought other ‘strong’ things” (Strathern & Stewart, 1999, p. 101). In essence, biomedicine and traditional medicine, despite antagonistic relations between them, exhibit a great deal of overlap and even fusion.

The growing interest of corporate and governmental elites in alternative medicine is related to the cost of high-technology medicine. Even in countries where explicit financial and/or legal support for indigenous or alternative medicine is absent, governments prefer to support traditional healers because they recognize that the latter take some of the strain off biomedical physicians in dealing with self-limiting diseases or diseases that tend to run their course without treatment. Furthermore, in the urban setting, traditional medicine minimizes the trauma of acculturation associated with the familiar cycle of capital penetration, import-substituting industrialization, and rural to urban migration of the peasant population.

Medicalization and the Naturalization of Social Control

Margaret Lock

Although medicalization is a concept that has been widely taken up and used by medical anthropologists, it was sociologists who first coined the term and put it into circulation. One of the abiding interests of sociologists concerned with modernization and its effects, particularly those who followed in the legacy of Emile Durkheim and Talcott Parsons, has been to show how social order is produced and sustained in contemporary society. In this vein the sociologist Irving Zola (1972) argued in the early 1970s that medicine had become a major institution of social control, replacing the more “traditional” institutions of religion and law, resulting in the “medicalizing” of many aspects of daily life in the name of health. Zola’s publication, in which he makes it clear that he is by no means totally opposed to the process he highlights, gave birth to a genre of research in which the cumbersome word medicalization—“to make medical”—was adopted as a key concept.

It can be argued that medicalization commenced many hundreds of years before Zola’s observation, from the time that specialists devoted to healing were first recognized among human groups. With the consolidation of the several literate medical traditions of Europe and Asia between approximately 250 BC and 600 AD, professional healers made themselves available for treatment

in connection with the stresses of everyday life and life-cycle-related problems, notably infertility, in addition to dealing with obvious physical malfunctions. Nevertheless, it is usually assumed, particularly in the sociological literature, that medicalization is a recent phenomenon and that it is inextricably associated with modernization as it unfolded in the “West.” This entry will review this literature, drawing on research findings from both the “developed” and the “developing” world, giving emphasis to the contribution made by medical anthropologists.

MODERNIZATION AND MEDICALIZATION

Commencing in the 17th century, European and North American modernization fostered an “engineering mentality,” one manifestation of which was a concerted effort to establish increased control over the vagaries of the natural world through the application of science. As a result, by the 18th century, health came to be understood by numerous physicians and by the emerging middle classes alike as a commodity, and the physical body as something that could be improved upon. At the same time, legitimized through state support, the consolidation

of medicine as a profession was taking place, together with the formation of medical specialties and the systematic accumulation, compilation, and distribution of new medical knowledge. Systematization of the medical domain, in turn, was part of a more general process of modernization to which industrial capitalism and technological production was central, both intimately associated with the bureaucratization and rationalization of everyday life.

Medical interests expanded in several directions during the 18th and 19th centuries. First, there was an increased involvement on the part of medical professionals in the management not only of individual pathology but of life-cycle events. Attending birth had been entirely the provenance of women, but from the early 18th century in Europe and North America, male midwives trained and worked at the lying-in hospitals located in major urban centers to deliver the babies of well-off women. These *accoucheurs* later consolidated themselves as the profession of obstetrics. By the mid-19th century other life-cycle transitions, including adolescence, menopause, aging, and death had been medicalized, followed by infancy in the first years of the 20th century. In practice, however, large segments of the population remained unaffected by these changes until the mid-20th century.

Another aspect of medicalization can be glossed in the idiom of “governmentality” proposed by Michel Foucault. With the pervasive moves throughout the 19th century by the state, the law, and professional associations to increase standardization through the rational application of science to everyday life, medicine was integrated into an extensive network whose function was to regulate the health and moral behavior of entire populations. These disciplines of surveillance, population “bio-politics” as Foucault (1979) described it, function in two ways. First, everyday behaviors are normalized so that, for example, emotions and sexuality become targets of medical technology, with the result that reproduction of populations and even of the species are medicalized. Similarly, other activities, including breastfeeding, hygiene, exercise, deportment, and numerous other aspects of daily life are medicalized—largely by means of public health initiatives and with the assistance of the popular media.

The medical and public health management of everyday life is evident not only in Europe and North America, but also in 19th-century Japan and to a lesser extent in China. In India, Africa, South East Asia, and

parts of the Americas, medicalization was intimately associated with colonization (Comaroff, 1993). Activities of military doctors and medical missionaries, the development of tropical medicine and of public health initiatives, designed more to protect the colonizers and to “civilize” the colonized than to ameliorate their health, were integral to colonizing regimes. As with medicalization everywhere, large segments of the population remained untouched by these activities until well into the 20th century (Arnold, 1993).

From the late 18th century, yet another aspect of medicalization became evident. Those populations labeled as mentally ill, individuals designated as morally unsound, together with targeted individuals living in poverty were for the first time incarcerated in asylums and penitentiaries where they were subjected to what Foucault termed “panopticism.” Inspired by Jeremy Bentham’s plans for the perfect prison in which prisoners are in constant view of the authorities, the Panopticon was, for Foucault, a mechanism of power reduced to its ideal form—an institution devoted to surveillance.

These changes could not have taken place without several innovations in medical technologies, knowledge, and practice, among which four are prominent. First, the consolidation of the anatomical pathological sciences whereby the older humoral pathology is all but eclipsed so that belief in individualized pathologies is essentially abandoned in favor of a universal representation of the “normal” body from which sick bodies deviate. Second, introduction of the autopsy enabling systematization of pathological science. Third, the routinization of the physical examination and of the collection of case studies. Fourth, the application of the concept of “population” as a means to monitor and control the health of society, central to which is the idea of a norm about which variation, which can be measured statistically, is distributed. The belief that disease can be understood as both individual pathology and as a statistical deviation from a norm of health becomes engrained in medical thinking as a result of these changes. Treatment of pathology remains, as was formerly the case, the core activity of clinical medicine, but the new epistemology of disease causation based on numeration gradually gained ground. Public health and preventive medicine, always closely allied with the state, made the overseeing of the health of populations its domain.

Other related characteristics of medicalization, well established by the late 19th century, and still evident

today, can be summarized following Rose (1994), into “dividing practices,” whereby sickness is distinguished from health, illness from crime, madness from sanity, and so on. With this type of reasoning certain persons and populations are made into objects of medical attention and distinguished from others who are subjected to different authorities including the law, religion, or education. At the same time various “assemblages” are deployed: a combination of spaces, persons, and techniques that constitute the domain of medicine. These assemblages include hospitals, dispensaries, and clinics, in addition to which are government offices, the home, schools, the army, communities, and so on. Recognized medical experts function in these spaces making use of instruments and technologies to assess and measure the condition of both body and mind. The stethoscope, invented in the early 19th century, was one such major innovation, the first of many technologies that permit experts to assess the condition of the interior of the body directly, rendering the patient’s subjective account of malaise secondary to the “truth” of science.

Several noted historians and social scientists argue that from the mid-19th century, with the placement in hospitals for the first time not only of wealthy individuals but of citizens of all classes, the medical profession was able to exert power over passive patients in a way never before possible. This transition, aided by the production of new technologies, has been described as medical “imperialism.” Certain researchers limit the use of the term medicalization to these particular changes, whereas other scholars insist that the development of hospitalized patient populations is just one aspect of a more pervasive process of medicalization, to which both major institutional and conceptual changes contribute. Included are fundamentally transformed ideas about the body, health, and illness, not only among experts, but also among populations at large.

THE MEDICALIZATION CRITIQUE

In writing a review article about medicalization Conrad (1992) argues that during the 1970s and 1980s the term was used most often as a critique of inappropriate medicalization, rather than simply to convey the idea that something had been made medical. The sociological and anthropological literature of this period argued uniformly that health professionals had become agents of social

control. This position was influenced by the publications of Szasz (1961) and Laing (1960) in connection with psychiatry where they insisted that the social determinants of irrational behavior were being neglected in favor of an approach dominated by a biologically deterministic medical model. Zola (1972), Conrad, and others argued in turn that alcoholism, homosexuality, hyperactivity, and other behaviors were increasingly being “biologized” and labeled as diseases. While in theory this move from “badness to sickness” no longer made patients morally culpable for their condition, it nevertheless permitted medical professionals to make judgments about the labeling and care of such patients that inevitably had profound moral repercussions.

Once it became clear that life-cycle transitions and everyday behaviors were increasingly being represented as diseases or disease-like, a reaction set in during the late 1970s against medicalization. It was Ivan Illich’s stinging critique of scientific medicine in his book *Medical Nemesis* (1976) that had the greatest effect on health care professionals and the public at large. Illich argued that, through overmedication, biomedicine inadvertently produces iatrogenesis, creating negative side-effects in the body (an argument that no one denies today) and, further, that the autonomy of ordinary people in dealing with health and illnesses is compromised by medicalization.

At the same time certain feminists, among them anthropologists, publicly characterized medicine as a patriarchal institution because, in their estimation, the female body was increasingly being made into a site for technological intervention in connection with childbirth and the reproductive life cycle in general (Oakley, 1980, 1984; Romalis, 1981). Similarly to what had happened in 18th-century Europe, medical anthropologists, including Fiedler (1997), Fraser (1992), Jordan (1978), Laderman (1983), O’Neil and Kaufert (1990), Pigg (1997), and Sargent (1989), among many others, have documented the ways in which midwifery has been forcibly professionalized, systematized, and placed under the authoritative knowledge (Jordan, 1997) of governments and the medical profession.

Much of this literature has also paid attention to women’s responses to medicalization. In contemporary writing it is common to assert that to cast women in a passive role with respect to medicalization is to perpetuate the very kind of assumptions that feminists have been trying to challenge. It is recognized that an active resistance to medicalization has contributed to the rise of

the home-birth movement and to widespread use of alternative therapies and remedies of numerous kinds. But empirical research has also made clear that the responses of individuals to the availability of biomedical interventions are pragmatic, and based upon what are perceived to be in the best interests of women themselves, often their families, and at times their communities (Lock & Kaufert, 1998).

Martin's cultural analysis of reproduction was one of the first attempts to show how women are not simply victims of medical ascendancy, but exhibit resistance and create alternate meanings about the body and reproduction than those that are dominant among the medical profession (Martin, 1987). Davis-Floyd uncovers two cultural models about the pregnant body in America: technocratic and holistic. She finds that, for professional women, keeping control of their bodies during pregnancy and birth is crucial, and to this end they subscribe heavily to technological interventions. On the other hand, for those women who adhere to the holistic model giving up control is laudable, pain is acceptable, and "nature knows best" (Davis-Floyd, 1988, 1996). Lazarus (1997) has shown how middle-class women are better able to manage their own births, even in a medicalized hospital setting, than are poor women.

It is clear that the majority of women studied globally internalize the norm that their prime task in life is to reproduce a family of the ideal size and composition, and that failure to do so diminishes them in the eyes of others. Under these circumstances it is not surprising that a pragmatic approach to medical technology and medical services is much more common than is outright resistance to these products of modernization. For Egyptian women seeking to overcome infertility through resort to medical interventions, both indigenous and biomedical (Inhorn, 1994), Chinese women making use of IVF, despite the county's one-child policy (Handwerker, 1998), lesbian couples using reproductive technologies in order to create a family (Lewin, 1998), and Americans who are labeled as infertile (Becker, 2000), selective, calculated acceptance of medicalization is much more apparent than is outright resistance. Nevertheless, in certain situations the majority of women apparently think that medicalization coincides with their own best interest. Browner and Press (1996) have shown how, until relatively recently American women valued subjective knowledge over biomedical recommendations during pre-natal care even though during labor technological intervention was

welcomed. Over the past several years this situation has changed, and as the state of California (in common with other locations) has become increasingly involved in the promotion of pre-natal genetic screening, many women now think of these tests as indispensable to the high-quality pre-natal care they desire (Browner & Press, 1995). On the other hand, the Inuit strongly resist medicalization when they give birth, in large part because this has usually involved routine "evacuation" from the Arctic to urban tertiary care hospitals in the Canadian south (O'Neil & Kaufert, 1995).

Documenting the pragmatism of individuals is not to argue that the micro-physics of power, dominant ideologies, culturally constructed orthodoxies, and hegemonies are not at work. Numerous informants, wherever their location, exhibit pragmatism, cynicism, or ambivalence about medical interventions, at least some of the time. But unquestioned participation in medicalization is also visible everywhere.

Individual desire is frequently informed—sometimes over-determined—by the mystification associated with political regimes, religious organizations, nationalistic interests, or cultural esthetics. Perhaps the most pervasive example of this is that worldwide governments of all kinds are deeply involved in the politics of contraception, abortion, population management, birth, and sexually related diseases, in particular AIDS. Sometimes women and their partners resist the normative order with respect to these interventions; at other times they comply because they have no choice (Anagnost, 1995; Barroso & Corrêa, 1995; Kligman, 1995). But people are increasingly able to reflect critically on their own situation and that of those around them. Paradoxically, medicalization has actually promoted such reflection by presenting people with choice, although globalization rather than medicalization per se has no doubt been the major driving force for change. The result is that older hegemonies have crumbled, only to give way to new ones, most often in the form of knowledge that comes under the rubric of science.

It is evident that an era of new nationalisms has set in, often as a result of the self-conscious development of post-colonial identities, or else as a response to feelings of being over-run by values associated with the West. In such circumstances the fostering by governments of pluralistic medical practices is very common (Leslie, 1980, 1989), but more often than not indigenous medications, knowledge, and technologies are subjected to commodification,

rationalization, and sometimes wholesale restructuring based on globalized biomedical standards and local interests (Adams, 2001, 2002; Farquhar, 1995; Ferzacca, 2002; Nichter, 1996; Pigg, 2002). Under these circumstances medicalization is itself diversified and pluralized, and the associated moral discourse is similarly diverse and dependent upon the specific medical traditions involved (Brodwin, 1996). The misapplication of medicalized interventions, notably pharmaceuticals, is also evident in situations where governments are chronically short of money (Nichter, 2001).

At times, as in the cases of the breast cancer movement, AIDS activists, support groups for children with rare genetic diseases that demand more research on these problems, or where toxic environments are at issue, people unite to fight for more effective medical surveillance (Kaufert, 1998; Rapp, Heath, & Taussig, 2001). Under these circumstances, the knowledge and interests of users results in an expansion of medicalization.

Recent research has emphasized the way in which people are at times active “consumers” of medicine, notably in connection with the new reproductive technologies, genetic testing, and direct-to-consumer advertising of medication (Becker, 2000; Hogle, in press; Lock, 1998). What is clear from this research is that without the ethnographic approach the complexity of selective acceptance and resistance, and how this changes over time and in light of new medical technologies, will not be well understood.

MEDICALIZED IDENTITIES AND CONDITIONS

Social science critiques of medicalization, whether associated more closely with labeling theory and the social control of deviance, or with Foucauldian theory and the relationship of power to knowledge, have documented the way in which identities and subjectivity are shaped through this process. When individuals are publicly labeled as schizophrenic, anorexic, infertile, menopausal, a heart transplant, a trauma victim, and so on, transformations of subjectivity are readily apparent (Ablon, 1984; Becker, 2000; Estroff, 1993; Kaufman, 1988). At times medicalization may function to exculpate individuals from responsibility for being sick, and individuals may then actively participate in this process (Lock, 1990; Nichter, 1998).

A large body of anthropological research has focused on Zola’s original intent in creating the concept of medicalization and has revealed how a range of behaviors and distress are constructed by the medical world as diseases. Robert Barrett shows how the institutional practices of psychiatry first created in the 19th century made possible the production of a new category of knowledge—schizophrenia. Prior to institutionalization, the kind of “crazy” behavior involving disorders of cognition and perception that we now associate with schizophrenia would have elicited a range of responses, not all of them indicating that pathology was involved. Barrett interprets schizophrenia as we know it today as a “polysemic symbol” in which various meanings and values are condensed, including stigma, weakness, inner degeneration, a diseased brain, and chronicity. Without this associated constellation of meanings, schizophrenia as we understand it would not exist. Barrett goes on to argue that the individualistic concept of personhood so characteristic of Euro-America has also contributed to our understanding of this disease. He shows how a theme of a divided, split, or disintegrated individual runs through 19th-century psychiatric discourse, and continues to the present day. Schizophrenia is not the only disease associated with splitting and dissociation, but it has been the prototypical example of such a condition. The perceived loss of autonomy and boundedness taken as characteristic of schizophrenia are signs of the breakdown of the individual, and thus of the person, and, further, the classification and treatment of schizophrenic patients as broken people with “permeable ego boundaries” profoundly influences the subjective experience of the disease (Barrett, 1988).

Barrett, himself a psychiatrist, argues that categorizing patients as suffering from schizophrenia implies a specific ideological stance which may highlight, problematize, and reinforce certain experiences, such as auditory hallucinations, for example. Barrett’s argument is neither one of simple social construction, nor of schizophrenia as a myth, but a more subtle argument in which he does not dispute at all the reality of symptoms, or the horror of the disease. He points out, however, that a careful review of the cross-cultural literature indicates that some of the constitutional components of what we understand as schizophrenia may be virtually absent in certain non-Western settings: “Thus, in some cultures, especially those that do not employ concept of ‘mind’ as opposed to ‘body,’ the closest equivalents to schizophrenia are not concerned with ‘mental experiences’ at all, but employ

criteria related to impairment in social functioning or persistent rule violation” (Barrett, 1988, p. 379). Similar arguments to that of Barrett have been developed for clinical depression as it is currently defined, that is, as being a psychiatric ethno-category characteristic of Euro-America society (Kleinman & Good, 1985).

The literature of medical anthropology is replete with examples in which arguments about bodily ills are essentially moral disputes about the boundaries between normal and abnormal, and their social significance. Ong (1988), for example, interpreted attacks of spirit possession on the shop floors of multinational factories in Malaysia as complex and ambivalent, but not abnormal, responses of young women to violations of their gendered sense of self, difficult work conditions, and the process of modernization. The psychologization and medicalization of these attacks by consultant medical professionals permitted a different moral interpretation of the problem by employers: one of “primitive minds” disrupting the creation of capital.

Similarly, the refusal of many Japanese adolescents to go to school is labeled by certain psychiatrists in that country (but not all) as deviant, and as behavior that should be medicalized. In a few cases the children are clearly mentally ill, but this behavior can also be interpreted as an individualized, muted form of resistance to manipulation by families, peers, and teachers and to larger stresses associated with the education system and Japanese modernization (Lock, 1991). Similarly, Kleinman and Kleinman (1991) have analyzed narratives about chronic pain in China as in effect normal responses to chaotic political change at the national level. These changes are associated with collective and personal delegitimation of the daily life of thousands of ordinary people, and the subjective experience of physical malaise, that in the clinical situation are interpreted as and reduced to physical disorder. In a Brazilian shantytown, Scheper-Hughes interprets what she describes as an epidemic of *nervoso* as having multiple meanings: at times a refusal of men to continue demeaning and debilitating labor, at times a response of women to violent shock or tragedy, and also in part a response to the ongoing state of emergency in everyday life. The epidemic signals a nervous agitation, “a state of disequilibrium”—the only means of expressing dissent in a truly repressive society. Individuals are often quite conscious of the injustice of their situation, but at the same time exhibit ambivalence and describe their own bodies as “worthless” or “used up”

(Scheper-Hughes, 1992, p. 187). She concludes that the semi-willingness of people to participate in the medicalization of their bodies is the result of participating in the same moral world as their oppressors.

Swartz and Levett (1987, p. 747) note that, not surprisingly, “psychological sequelae” have been frequently reported in connection with the impact of massive long-term political repression of children in South Africa. They go on to argue that this psychologization is too narrowly defined, and that “the costs of generations of oppression of children cannot be offset simply by interventions of mental health workers.” Further, these researchers argue, “it is a serious fallacy to assume that if something is wrong within the society, then this must be reflected necessarily in the *psychopathological* make-up of individuals” (p. 747, emphasis added). In common with those authors cited above, Swartz and Levett oppose the normalization and transformation of political and social repression into individual pathology, and its management solely through medical interventions.

Allan Young, researching the invention of post-traumatic stress disorder, shows just how powerful is the current psychiatric model in the creation of this new disease. Psychiatrists assume that the uncovering and reliving of a single traumatic episode during the course of therapy will open the door to relief from chronic debilitating stress and postulated pathological changes in the neuroendocrinological system (Young, 1995). Thus, even the atrocities of the Vietnam war and moral condemnation of them are individualized and depoliticized.

MEDICALIZATION OF WELLNESS

Medicalization is not limited to sickness and “deviance.” Wellness—the avoidance of disease and illness, and the “improvement” of health—is today a widespread “virtue,” notably among the middle classes. As part of modernity, practices designed to support individual health have been actively promoted for over a century, and are now widely followed. The individual body, separated from mind and society, is “managed” according to criteria elaborated in the biomedical sciences, and this activity becomes one form of self-expression. Body-aesthetics are clearly the prime goal of some individuals (Sullivan, 2001), but a worry about the “risk” of becoming sick is at work for the majority. By taking personal responsibility for health, individuals display a desire for

autonomy and in so doing they actively cooperate in the creation of “normal,” healthy citizens, thus validating the dominant moral order (Crawford, 1984). Health is medicalized and commoditized.

As evidence is amassed to demonstrate conclusively how social inequity and discrimination of various kinds contribute massively to disease, ranging from infections to cancer, the idea of health as virtue appears increasingly out of place. Owing to poverty, large segments of the population in most countries of the world have shorter life expectancies and a greater burden of ill-health than do their compatriots. The pervasive value of individual responsibility for health enables governments to narrow their interests to economic development, while ignoring redistribution of wealth and the associated cost for those individuals who, no matter how virtuous they may be, are unable to thrive.

RISK AS SELF-GOVERNANCE

Activities designed to assist with the avoidance of misfortune and danger are ubiquitous in the history of humankind, but the idea of being at “risk” in its technical, epidemiological meaning is a construct of modernity. In theory, morally neutral risk provides a means whereby experts can distance themselves from direct intervention into people’s lives while employing the agency of subjects in their own self-regulation through “risk-management.” Among the numerous examples of this process, the transformation of aging, in particular female aging, into a discourse of risk is illustrative. Given that women live longer than men it seems odd that female aging has been targeted for medicalization, but this move is in part driven by a fear of the enormous expense to health care budgets that very old infirm people, the majority of them women, are believed to incur.

Medicalization of female middle age, and in particular the end of menstruation, commenced early in the 19th century but it was not until the 1930s, after the discovery of the endocrine system, that menopause came to be represented in North America and Europe as a disease-like state characterized by a deficiency of estrogen. In order to sustain this argument, the bodies of young pre-menopausal women must be set up as the standard by which all female bodies will be measured. Post-menopausal, post-reproductive life can then be understood as deviant. This “expert knowledge” is buttressed through comparisons made with human populations where

post-menopausal life is less common, and with primate populations in which post-reproductive life is very unusual. The arguments of biological anthropologists that older women are essential to the survival of highly dependant human infants and their mothers in early hominid life are ignored. Moreover, it is argued erroneously that women have lived past the age of 50 only since the turn of the 20th century, and that post-reproductive life is due entirely to improved medical care and living conditions.

Today older women are warned repeatedly about heart disease, osteoporosis, memory loss, and Alzheimer’s disease, and numerous other conditions for which they are said to be at increased risk due to their estrogen-deficient condition. Misleading interpretations of often poorly executed epidemiological research create confusion about estimates of risk for major disease in women who are past menopause. Even so, daily medication on a permanent basis with regular medical monitoring has been recommended by gynecological organizations in many countries for virtually all older women, although reversals of these blanket suggestions are now taking place in light of recent evidence from longitudinal research trials. Few commentators deny that drug company interests have contributed to this situation.

The situation is made yet more problematic because cross-cultural research suggests that the common bodily experiences of populations of middle-class North Americans at menopause are significantly different from those of some women in other parts of the world. Local biologies and cultures contribute inextricably to this situation, making medicalization of this part of the life cycle exceedingly problematic (Lock, 1993). Nevertheless, hundreds of thousands of women willingly medicate themselves daily in the firm belief that aging is pathology. Among them a few, but we cannot predict who exactly, may avert or postpone the onset of debilitating and life-threatening diseases, while others may well hasten their own death. Medicalization on a prophylactic basis of diseases statistically projected as probabilities is in itself a risky business, but even so is on the increase, particularly as the new genetics become increasingly routinized.

The combination of the emerging technologies of the new molecular genetics with those of population genetics is currently opening the door to an exponential growth in medicalization in the form of what has been termed “geneticization.” As genetic testing and screening of fetuses, newborns, and adults becomes increasingly institutionalized, the possibilities for surveillance are boundless, particularly so because proponents of genetic

determinism promote the idea that genes are destiny. Our genes are increasingly thought of as “quasi-pathogens” that place us at increased risk for a spectrum of diseases. Rapp (1999) has shown the way in which decisions made by women and their partners in connection with pregnancy and its termination are increasingly informed by genetic testing, the results of which are often based on probabilities (Lock, 1998).

This biomedicalization of life itself comes with extravagant promises about our ability in the near future to harness nature as we wish, the enhancement of human potential, and access to the knowledge that makes it possible to know what it is that makes us uniquely human. Based on the results of genetic testing, a *laissez-faire* eugenics, grounded in individual choice and the inalienable right to “health” for our offspring, is already taking place (Lock, 2002). Of course, suffering is reduced when, for example, families choose to abort fetuses with Tay Sachs’s disease. On the other hand, how can discrimination on the basis of genetics, already evident in some workplaces, insurance companies, and the police force, be controlled? Should entrepreneurial enterprises have a monopoly over the development of testing for multifactorial diseases such as breast and prostate cancer as is currently the case? How should the findings of these tests be interpreted by clinicians and the public when all that can be surmised if the results are positive is the possibility of elevated risk for disease in the future? Negative results do not indicate that individuals will not contract the disease. Who will store and have access to genetic information, and under what conditions? And who, if anyone, may patent and commodify genetic materials and for what purpose? The new genetics and geneticization make answers to such questions an urgent matter.

It has been proposed that we are currently witnessing a new “biomedicalization” associated with late modernity or post-modernity (Clarke, Mamo, Shim, Fishman, & Fosket, 2000). A technoscientific revolution is taking place involving increased molecularization, geneticization, digitization, computerization, and globalization, and these changes are in turn associated with a complete transformation of the organization (including the privatization of a great deal of research), expertise, and practices associated with the medical enterprise. In this milieu the potential exists to make the body increasingly a site of control and modification, much of it carried out, in the West at least, in the name of individual rights or desire.

Such modifications are often highly profitable to involved companies and frequently correspond to the utilitarian interests of contemporary society; one prime objective is to save on health care expenditure. A danger exists of overestimating the consequences of technological innovation and associated biomedicalization. A large proportion of the world’s population effectively remains outside the reach of biomedicine. That medication for HIV/AIDS is not universally available is a gross injustice, as is the increasing incidence of antibiotic-resistant tuberculosis that could be controlled efficiently if biomedicine was competently practiced. At the other extreme, despite an enormous promotion of hormone-replacement therapy, research shows that less than a quarter of the targeted female population takes this medication, and even then not consistently. It is also clear that many women do not make use of selective abortion should a fetal “flaw” be found through genetic testing.

Medicalization, understood as enforced surveillance, is misleading. So too is an argument that emphasizes the social construction of disease at the expense of recognizing the very real, debilitating condition of individuals who seek out medical help. Rather, an investigation of the forms taken by political economies, technological complexes, and the values embedded in biomedical discourse and practice and in popular knowledge about the body, health, and illness that situate various states and conditions as residing within the purview of medicine better indicates the complexity at work.

Phenomenology of Health and Illness

Gay Becker

INTRODUCTION

The last quarter of the 20th century has seen a shift in the social sciences, especially in anthropology, from objectified descriptions of the body in health and illness to

subjective, in-depth explications of the body as lived. The experience of health and illness has been a central theme in medical anthropology in particular, and has been mirrored in other social and health science disciplines as well, including sociology, philosophy, nursing, and social

medicine (Benner, 1994; A. Frank, 1995, Toombs, 1987, 1993; Turner, 1992, 1996; Williams & Bendelow, 1998). This shift in how health is viewed by social scientists is part of a broader interpretive turn within the social sciences that has heralded a focus on experience of all sorts. Within this interpretive, phenomenological realm, medical anthropology and cultural anthropology have been closely entwined since the rise of this perspective. In cultural anthropology Bruner (1986, p. 5) has characterized the anthropology of experience: "Lived experience ... as thought and desire, word and image, is the primary reality."

Illness can be seen as one type of experience. A variety of terms have been used to describe work that falls within the domain of the phenomenology of health and illness, including lived experience, embodied experience, and bodily distress. Some of this work examines experience, or sensation, within the immediate cultural context, while other work seeks to connect experience with its political and economic implications. What all of this work has in common is an emphasis on how some sort of distress is experienced and expressed through the body and in everyday life. Thus, a key element of a phenomenological approach is not only on experience but on the meanings that attach to that experience, as well.

The phenomenology of health and illness encompasses many topics within medical anthropology such as healing, death and dying, and violence, to name only a few. In this entry I will touch on work in a wide range of areas, including relevant work in cultural anthropology that cross-fertilizes with medical anthropology.

THEORETICAL AND METHODOLOGICAL PERSPECTIVES

The roots of the current emphasis on the phenomenology of health and illness lie in the field of philosophy. Numerous philosophers have addressed questions that are phenomenological in nature, including Dilthey, Hegel, Husserl, Heidegger, James, Merleau-Ponty, Peirce, Sartre, and Schutz. Central to the phenomenological approach has been an effort to incorporate notions of culture into phenomenological constructs. The term *phenomenology* refers to the distinction introduced by Kant between *phenomena*, which are the appearances of reality in consciousness, and *noumena*, which are the things-in-themselves, independent of consciousness (Bidney, 1973). The term itself was first used by Hegel

in his *Phenomenology of Mind* in 1807, a record of the "spiritual anthropology of man derived from a comparative study of the history of human culture" (Bidney, 1973, p. 110).

Edmund Husserl, widely credited with the rise of phenomenology, viewed all modern philosophy as originating in the Cartesian Meditations. He regarded the task of philosophy as providing a view to understanding how an autonomous philosophy and science are possible, and sought to develop a rigorous science of transcendental phenomenology. Unlike Descartes' temporary suspension of the certitude of existence implicit in the experience of the world, based on the Cartesian ego who doubts the existence of the world, Husserl viewed this suspension as a permanent attitude toward the world in which the existential world was reduced through the "phenomenological reduction." He used this concept to describe a basic phenomenological procedure of bracketing all judgments about the ontological nature of perceived objects and reducing what is given in cognitive experience to the essentials of its form (eidetic reduction), ultimately bracketing the knower him or herself, and leading to transcendental reduction (Husserl, 1960). (For anthropological discussions, see Bidney, 1973; M. Jackson, 1996; Watson & Watson-Franke, 1985).

The concept of the lifeworld, or *lebenswelt*, introduced by Husserl, is the world as given in experience prior to critical reflection, the world as experienced, including the experience of the world of nature as well as the world of culture (Husserl, 1970). Husserl gave ontological priority to the lifeworld over the world of theoretical thought and explanations (*Weltanschauung*) in an effort to make philosophy more responsive to the demands of human life and to break down the division between explanatory models and everyday life (M. Jackson, 1996, p. 13). In addressing the lifeworld as he formulated phenomenological sociology, Schutz (1967) developed the concept of intersubjectivity, which refers to what is common to individuals. Arguing for the critical place of the lifeworld in ethnography, M. Jackson (1996, pp. 7–8) describes it as "that domain of everyday, immediate social existence and practical activity, with all its habituality, its crises, its vernacular and idiomatic character, its biographical particularities, its decisive events and indecisive strategies, which theoretical knowledge addresses but does not determine." In developing his theoretical approach in medical anthropology, Kleinman (1992, p. 172) has coined the term, "local moral worlds" to capture the lived experience of the lifeworld.

The concept of radical empiricism, as discussed by James and Husserl, includes cultural phenomena. In radical empiricism, experience of the essence of a cultural phenomenon is combined with experience of subjective existence to yield the meaning of the phenomenon in the life of the subject (Bidney, 1973, pp. 126–127). In applying radical empiricism to anthropology, M. Jackson (1989, p. 3) differentiates radical empiricism from traditional empiricism by the emphasis in the former on intersubjective experience, stressing the importance of the ethnographer's interactions with those he or she lives with and studies, and clarifying the ways in which anthropological knowledge is grounded in practical, personal, and participatory experience in the field as much as in detached observations.

Embodiment, as one aspect of phenomenology, can be construed both as a method and also as an emerging theoretical perspective in anthropology. Merleau-Ponty (1962) viewed phenomenology as a method, with embodiment as one aspect of that method. Embodiment refers to being, to living through the body, to the state of being embodied. Merleau-Ponty attributes a transcendental function to the body-subject: the body is the basis of the constitution of the human world. He refers to automatic bodily functioning as the preobjective self, a culturally constituted way of being-in-the-world. In interpreting Merleau-Ponty's work, Dillon (1991, Preface, p. xv), observes: "the body contributes to the world we live in but the reverse is also true: the world contributes to the constitution of our body." Bourdieu's work (1977, 1984, 1990) represents a shift from a focus on the body as a source of symbolism to an awareness of the body as the locus of social practice. Recent work in anthropology examines embodiment and social practice (for example, A. Becker, 1995; G. Becker, 1997, 2000; Csordas, 1990, 1993, 1994a, 1994b, 1997; Desjarlais, 1992a; Devisch, 1993; G. Frank, 2000; M. Jackson, 1989, 1996, 1998; Roseman, 1991; Stoller, 1989b, 1995, 1997).

PHENOMENOLOGY OF THE BODY

Accompanying the interpretive turn of the last 25 years has been a growing emphasis on the body as a topic of social investigation. The work of Mauss (1935) has been rediscovered in this shift, with his conceptualization of habitus, the way social structure leaves its imprint on individuals through bodily training. Mauss maintained that bodily sensations and movements are affected by

culture through acquired habits and somatic tacts. Elias's (1939/1978) work on the social development of bodily comportment and physical correctness was both a complement to and demonstration of bodily processes described by Mauss.

Today the body is a central focus of work in medical anthropology. The first step in addressing the body is to differentiate between representations of the body and the experiencing body. Turner (1992, p. 43) notes that anthropologists were traditionally concerned primarily with using the body as part of a social classificatory scheme rather than with understanding the phenomenology of the lived body, emphasizing how the body is represented and how culture is "inscribed" on the body rather than focus on the lived body. Scheper-Hughes and Lock (1987) captured a shift in the emerging emphasis on the body when they identified three bodies, or three different theoretical approaches and epistemologies: phenomenology (individual body, the lived self), structuralism and symbolism (the social body), and poststructuralism (the body politic). (For reviews of literature on the body, see Csordas, 1999; A. Frank, 1990; Lock, 1993; Lock & Scheper-Hughes, 1993; Scheper-Hughes & Lock, 1987; Turner, 1991, 1992.)

Concurrent with the interpretive turn that began some 40 years following the work of Mauss and Elias, anthropologists began turning in greater numbers to embodiment as a theoretical framework for the study of experience, and a wealth of literature has subsequently emerged on the experiencing body. A number of theoretical developments have emerged in phenomenological anthropology. Csordas (1994a, 1994b) articulated an approach grounded in Merleau-Ponty's concept of embodiment, which he designated *cultural phenomenology*, to refer to the synthesis of embodied experience and cultural meanings. In his extrapolation of Merleau-Ponty's concept of embodiment, Csordas emphasized its particularly anthropological application, viewing as a basic premise the necessity of understanding the body as the existential ground of culture, and that to use this model one must take "embodied experience [as] the starting point for analyzing human participation in a cultural world" (Csordas, 1993, p. 135).

Interrogating what is meant by experience has been one aspect of the development of a phenomenological approach. Although there is an extensive literature on the anthropology of experience (for example, Turner & Bruner, 1986), questions of what constitutes experience have recently been revisited by Desjarlais (1996), who

questions whether “experience,” as used by most social scientists, is a universal phenomenon. Tracing what experience has meant to social scientists, he concludes that it has come to convey “an aesthetic of integration, coherence, renewal, and transcendent meaning—of tying things together through time” (p. 87), and juxtaposes this characterization with the disjointed existence of mentally ill, homeless people.

Taking the embodiment construct beyond the individual into social collectivities has been an important feature of recent work in anthropology. Csordas (1993, pp. 137–139) has argued that embodiment forms the intersection between individual and collective experience, combining it with Bourdieu’s understanding of the habitus as an unself-conscious orchestration of practices: “embodiment need not be restricted to the personal or dyadic micro-analysis customarily associated with phenomenology, but is relevant as well to social collectivities.” This idea has also been developed by numerous ethnographers (see, for example, A. Becker, 1994, 1995; G. Becker, 1997, 2000; Csordas, 1994b, 1997; Desjarlais, 1992a; Devisch, 1993; Roseman, 1991; Scheper-Hughes, 1992; Stoller, 1995).

The use of metaphor has been an important focus of anthropological work. According to Fernandez (1974), metaphors frame and structure meaning: they have the ability to bind the past and future together and the ability to give the impression of coherence or “return to the whole” when exploration of the metaphor is fulfilled. The body is metaphor’s ground: body metaphors provide a way to communicate bodily sensation, as well as social, cultural, and political meaning (G. Becker, 1997; M. Jackson, 1989). M. Jackson (1983, 1989) developed the idea of metaphor as praxis in his work on the Kuranko, and the embodied nature of metaphor has been explored by medical anthropologists (G. Becker, 1997; Csordas, 2000; Kirmayer, 1992; Low, 1994).

The linkage between embodiment and narrative has also received considerable attention in anthropology. The embodied aspects of narrative as expressed through the life story have received in-depth treatment by G. Frank (1979, 2000) and by Watson and Watson-Franke (1985). An overall approach to biography in anthropology has been rooted in phenomenology (Langness & Frank, 1981). Csordas (1994a) has drawn on Merleau-Ponty’s (1962) idea that language is one way of disclosing the phenomenological essence of embodiment, to suggest that the body be placed in a paradigmatic position complementary to the

text rather than subsumed under the text metaphor; by doing so, body and textuality can be viewed as corresponding methodological fields, a suggestion also made by Stoller (1994). Similarly, M. Jackson (1996, p. 39) views narrative as a form of being as much as a way of saying, a crucial and constitutive part of the ongoing activity of the lifeworld. Kirmayer (1992) calls attention to the inescapable circularity between the order of the body and the order of the text, or narrative. Although narrative can be understood as only a partial expression of experience, it does provide one avenue for the exploration of emotion and the inchoate (G. Becker, 1997). Addressing the experience of illness and its narrative expressions has been a particular focus of phenomenological work, in particular individuals’ efforts to reconcile or make sense of suffering (Ablon, 1999; G. Becker, 1997; Bluebond-Langner, 1996; Crossley & Crossley, 2001; Farmer, 1988; A. Frank, 1995; Garro, 1992; B. Good, 1977, 1994; Gordon, 1990; Gordon & Paci, 1997; Kleinman, 1988, 1992; Kleinman & Kleinman, 1994; Mattingly, 1998; Mattingly & Garro, 2000).

The literature on performance uses theories of embodiment and narrative in anthropology in its discussions, but these works emphasize the performative aspects of embodiment rather than embodiment itself. Performances are viewed as constituting action, that is, they are a tangible expression of embodiment (G. Becker, 1997; Bruner, 1986; Laderman & Roseman, 1996; Palmer & Jankowiak, 1996; Stoller, 1994). Work on performance is relevant to a larger discussion of phenomenology as it links to imagination, and several streams of research have been identified that contribute to a theory of performance (Csordas, 1996). (For examples of phenomenological work that emphasize performance see Csordas, 1997; Laderman & Roseman, 1996; Roseman, 1991; Stoller, 1989a, 1995.) Examined as a cohesive body of research, phenomenological emphases on narrative, metaphor, performance, and the bridge to social collectivities represent a rich, cohesive, and rapidly expanding assemblage of scholarship in medical anthropology.

ETHNOGRAPHIC USES OF THE LIVED BODY

The body, as it is culturally conceptualized, directly affects understandings of self, and ultimately of health and illness. In keeping with Merleau-Ponty’s (1962)

concept of being-in-the-world as culturally constituted, phenomenologically oriented ethnography has examined the body as cultural and its implications for self and society. In *Do Kamo* (1979, p. 24), Maurice Leenhardt's study of the Canaque, one of two early ethnographies written from a phenomenological perspective (see also Levy-Bruhl, 1979), the Canaque "fails to delimit his body and to circumscribe it to separate it from the world." The body is mythic, a support for the "living one," and is linked to all the person's relatives, "attached by all the fibers of his being to the group" (1979, p. 94). Leenhardt suggests that it was only with the coming of missionaries and their religion that the Canaque recognized the body and thus the self, or person, as individual. A. Becker (1994, 1995), studying Fiji Islanders, observes a similar community orientation of the body, in which the body is the responsibility of the feeding and caring microcommunity, and its form consequently shows the work of the community rather than of the self. She notes that body shape not only suggests personal abilities, but reflects connection to the social network and its ability to nourish, as well. Desjarlais (1992a, pp. 31–32), in describing a Yolmo shaman in Nepal, notes that he not only *has* a body, he *is* a body, and thus feels, knows, tastes, acts, and remembers. Among the Yolmo, the imagery of the body parallels the workings of Yolmo social groups. Embodied esthetics of everyday life encompass Yolmo epistemology (how one goes about knowing self and other) and the local ethos (dominant cultural styles of experiencing and expressing felt experience) (Desjarlais, 1992a).

Such views of the body contrast with the individualized body of U.S. society and its linkage to sense of self, with its emphasis on individual responsibility, thinking rather than feeling, and bodily control (G. Becker, 1997). Myerhoff's (1978, p. 1) classic work, *Number Our Days*, opens with an ode to bodily knowledge, with the words of Basha, an old Jewish woman living in California: "Every morning I wake up in pain. I wiggle my toes. Good. They still obey. I open my eyes. Good. I can see. Everything hurts but I get dressed. I walk down to the ocean. Good. It's still there. Now my day can start. About tomorrow I never know. After all, I'm eighty-nine. I can't live forever." This statement is a direct illustration of Csordas' (1993, p. 138) term, somatic modes of attention, which he defines as "culturally elaborated ways of attending to and with one's body in surroundings that include the embodied presence of others." Csordas' (1994b) work on the Charismatic Renewal in the United States is a

testament to this U.S. emphasis on self, in which self processes operate within an organized ritual system. A. Becker (1994) contrasts these differing emphases: whereas the cultivation of the body is an expression of self in the United States, in Fiji it is the cultivation of social relations that is given emphasis.

Examination of the role of sensory perception has been one focus of a phenomenological approach (Stoller, 1989b), and in particular with respect to health and illness, including music and everyday sounds (Chuengsatiansup, 1999; Daniel, 1991; Desjarlais, 1992a; Kleinman, 1995; Roseman, 1990, 1991; Stoller, 1996). Chuengsatiansup (1999, p. 281), in a study of Kui women in Thailand, introduces a new theme into work on sensory perception, with an emphasis on how power relations of domination embedded in everyday sounds create a specific form of illness experience among politically vulnerable people.

THE BODY IN DISTRESS

Understanding of oneself and one's world begins with the orderly functioning of the body (G. Becker, 1997). This known body has been described by Leder (1990) as "the absent body" that is taken for granted. But when the body and embodied knowledge become disordered through physical or emotional distress, the body is experienced in its immediacy, whether through pain, physical or emotional discomfort, or even through the absence of expected bodily feeling, such as Sacks (1984) and Murphy (1987) have described for their own experiences. Examining the body in distress has been a central motif in the burgeoning phenomenologically based literature in medical anthropology on a wide range of topics (for example, G. Becker, 1997; B. Good, 1994; Gordon, 1990; Gordon & Paci, 1997; Jenkins & Valiente, 1994; Kaufman, 1988a, 1988b; Kleinman, 1988, 1992; Kleinman & Kleinman, 1991; Ots, 1990, 1994; Pandolfi, 1990; Scheper-Hughes, 1992).

Illness disrupts embodied knowledge. G. Becker (1997) observes that when a serious illness occurs, sense of bodily wholeness disintegrates and individuals struggle to recreate a sense of bodily continuity in order to restore meaning to life. This disruption of taken-for-granted embodied knowledge challenges one's known and seemingly predictable world. Suffering arises not only from the experience of bodily disruption but

from the effort to articulate that disruption, as well (G. Becker, 1997). The difficulty of putting suffering into words is especially noted in the literature on chronic pain (Garro, 1992; M. J. Good, Brodwin, Good, & Kleinman, 1992; J. Jackson, 1994; Kleinman, 1992). Phenomenological approaches have also been used to interpret the experience of specific illness syndromes such as *nervios* (Low, 1994), *susto* and *fallen fontanelle* (Castro & Eroza, 1998), and *calor* (Jenkins & Valiente, 1994).

Phenomenologically oriented work emphasizes the relationship between the esthetics of the known body and healing. Desjarlais (1992a, 1992b, p. 1105) demonstrates how healing by Yolmo shamans is directly tied to the experiencing body and “works to reinstate a visceral sense of harmony, completion, and vitality.” Similarly, Roseman (1990, 1991) and Devisch (1993, 1996) trace embodied understandings of selves directly to healing practices, especially to dance forms, while Boddy (1988) finds that women regenerate sense of self and recontextualize experience through a diagnosis of possession and participation in curing rites such as *trance*. (Other phenomenological studies of healing include Briggs, 1996; Csordas, 1994b, 1996; Laderman & Roseman, 1996; McCallum, 1996.)

Considerable phenomenologically oriented work has been done on the interface between the lived body and biomedicine. A phenomenological approach highlights disjunctures between the practice and philosophy of biomedicine and the experiencing body, and especially the effects of these encounters on people in delegitimizing or destabilizing bodily knowledge and experience (for example, G. Becker, 1997, 2000; Becker & Kaufman, 1995; Estroff, 1991; M. J. Good et al., 1992; B. Good, 1994; Gordon & Paci, 1997; Kaufman, 1988b; Kleinman, 1988; Mattingly, 1998; Mattingly & Lawlor, 2001; Rhodes, McPhillips-Tangum, Markham, & Klenk, 1999; Toombs, 1987, 1993; K. Young, 1997). For example, K. Young (1997) provides a detailed description of how biomedicine intervenes and disregards the known body, and Mattingly (1998) demonstrates how therapeutic plots reshape people’s understandings of their bodies and their health. This body of work also addresses the construct of resistance (Kleinman, 1995) and illustrates how people resist biomedical interpretations and how they act on their own behalf (G. Becker, 1997, 2000; Becker & Kaufman, 1995; Kleinman, 1988; Mattingly, 1998; Root & Browner, 2001). Most recently, a phenomenological approach has been applied to biotechnology (G. Becker, 2000; Csordas, 2000; Goslinga-Roy, 2000).

THE GENDERED BODY

Phenomenological perspectives on the gendered body and feminist perspectives, with their emphasis on gender practices as sites of political struggle and critical agency, have coalesced in the recent past to produce work in medical anthropology. Rethinking the gendered body has entailed a feminist critique of philosophical phenomenology. Feminists argue that there is an implicit bias in classic phenomenology, that the body in question is the male body, and that the phenomenology portrayed is one of maleness; in response, they have developed new conceptualizations that greatly expand the usefulness of the phenomenological approach for ethnography (for example, Bigwood, 1991; Butler, 1989, 1993, 1997; Davis, 1997; Grosz, 1994; I. Young, 1989).

Feminist standpoints with perspectives on embodiment can be found in work on people’s everyday lives, as well as in work specific to general health, reproductive health, and sexuality. Lee (1999) views the struggle of Chinese women with fat and fatigue as women’s attempt to straddle two moral worlds, by trying to satisfy traditional expectations while simultaneously subscribing to new images of womanhood, resulting for these women in being disempowered. G. Becker (1997, 2000) applies a phenomenological approach to gender to demonstrate how societal ideals about gender pervade the lived body and the political and economic consequences when women and men discover infertility and turn to reproductive technologies. Embodied knowledge is reshaped through the use of technology, but at the same time, technologies become instruments of gender performance (G. Becker, 2000). Goslinga-Roy (2000), in studying embodied experience and surrogacy, illustrates how a notion of embodiment as ending at the skin enables the abstract language of ownership that frames surrogacy debates. She develops the idea of biographical embodiment to address how embodiment extends beyond the individual body. (Other phenomenologically oriented work on gender includes Behar, 1993; Behar & Gordon, 1995; Davis, 1997; G. Frank, 2000; Green, 1999; Inhorn, 1994, 1996; Scheper-Hughes, 1992; Shuttleworth, 2000, 2001, in press.)

THE BODY OF DIFFERENCE

Since its inception in medical anthropology, a phenomenological approach has been applied to the study of

physical difference and disability with great originality, by challenging conventional ideas about the body and about what being “normal” means. For example, Ablon (1984) has pointed out that the dwarf body is different but not disabled: dwarfs experience their bodies as complete and normal. G. Frank (1986, 2000), in her phenomenological life history study of a woman who was born without arms or legs, questions a view of this woman as missing body parts and describes how she asserts her fundamental normalcy. Other phenomenological work that addresses difference or disability include blindness (Ainlay, 1989), deafness (G. Becker, 1980; Preston, 1994), post-polio syndrome (Kaufert & Locker, 1990; Scheer & Luborsky, 1991), mobility impairments (Luborsky, 1995; Murphy, 1987), and disability more generally (Luborsky, 1994; Zola, 1982).

These works challenge not only societal ideas about physical difference or disability but hegemonic ideals about gender and sexuality, as well (see also Ablon, 1996; G. Frank, 2000). Shuttleworth (2000, 2001, in press) combines phenomenology with a post-structural approach to explore the experience of severely disabled men seeking sexual intimacy, while Willis, Miller, and Wyn (2001) develop the construct of gendered embodiment in their work on the differential meanings of cystic fibrosis for young men and women.

EMBODIED MEMORY IN STUDIES OF AGE AND TERROR/VIOLENCE

The temporal dimension of people’s lives plays an important part in understanding embodied health and illness. Phenomenology is less concerned with establishing what actually happened in the past than in exploring the past as a mode of present experience (M. Jackson, 1996, p. 38). People’s historical experiences of their bodies is expressed through embodiment (Connerton, 1989). Memory not only reflects personal, subjective experience, it is socially constructed and present oriented, reshaping experience (Halbwachs, 1992). Lambek (1996, p. 235) suggests that memory be viewed as a cultural practice. Memories are powerful symbols of the self (Csordas, 1994b), permeated by people’s views of how life has been and should be (G. Becker, 1997). Memories can be seen as incomplete, reshaped interpretations made in an effort to create a world that makes sense (Becker, Beyene, & Ken, 2000b). Memory is thus a critical aspect of embodiment.

Several distinct realms in medical anthropology in which embodied memory plays a central role are in the distressed body (discussed earlier), the lived experience of aging, and the experience of terror and violence. Phenomenological approaches to the aging body address the body both in health and in illness (G. Becker, 1994, 1997; Gadow, 1986; Hennessy, 1989; Rubinstein, 1989, 1990). In old age, embodied knowledge represents the accumulation of a lifetime of self-understanding. Kaufman (1986) characterizes this process among elders in the United States as “the ageless self.” Luborsky (1995, p. 1457) notes, “The experience of present-day impairment is infused with a sense of being seamlessly connected to past, present, and future experiences and identities, both actual and idealized or expected.” For those who have been healthy most of their lives, embodied knowledge is of a healthy body, but culture-specific views inform bodily expressions (Lamb, 2000; Mimica, 1996). Rubinstein (1989, 1990) found that for frail elders in the United States, their long-time homes had become embodied extensions of themselves.

Current infirmities represent obstacles to be worked around but also signal the approach of the end of life and bring about the contemplation of death, a phenomenological process that is rooted in the body and its memories (G. Becker, 1997, 2002). These processes are mediated through biographical work, for example after a stroke (Kaufman, 1988a, 1988b), or following the onset of blindness (Ainlay, 1989). The intimate connection between memory and preparation for death has been examined in work on a variety of cultural groups (G. Becker, 1994, 2002; Becker, Beyene, & Canalita, 2000; Becker et al., 2000b; Desjarlais, 1992a, 1992b; Myerhoff, 1978). Questions about embodiment have also been addressed for memory loss (Chatterji, 1998; Herskovits, 1995).

Embodied memory is a critical component of trauma arising out of terror and violence. Those memories refract the world through a lens altered by fear and mistrust and by physical and emotional pain (Daniel & Knudsen, 1995; Green, 1998). Traumatic memories revise the world people experience as an unspeakable, hostile, and death-ridden place; the experiencing body becomes the site of conflicted memories, encompassing the need to remember as well as the desire to forget (Becker et al., 2000b).

A burgeoning literature has recently emerged in medical anthropology that addresses the complexity of embodied violence (Green, 1998), including, for example,

the effects of fear on widows in war-torn Guatemala (Green, 1999); martyrdom in Palestine (Pitcher, 1998); crimes against women in Croatia and Bosnia-Herzegovina (Olujic, 1998); the effects of war and deprivation on children (Quesada, 1998; Scheper-Hughes, 1992); human rights politics in Tibet (Adams, 1998); terror warfare in Mozambique (Nordstrom, 1998); the cultural revolution in China (Kleinman & Kleinman, 1994); the experience of violence and its aftermath for Tamils (Daniel, 1994, 1996; Gronseth, 2001); the aftermath of genocide in Cambodia (Becker et al., 2000b; Hinton, 1998); rape in the United States (Winkler, 1994); and violence among HIV drug users (Bourgois, 1998).

FROM PHENOMENOLOGY TO THE POLITICS OF HUMAN SUFFERING

Although the phenomenology of health and illness has been a central strand in medical anthropology's development over the past 25 years, in recent times there has been a decided shift in emphasis, away from studies that are limited to immediate experience and toward studies that encompass the political and economic ramifications of human suffering. M. Jackson (1989, 1996) and Abu-Lughod (1991) have used phenomenology to challenge basic constructs associated with Western thinking by questioning their relevance for cross-cultural work. M. Jackson (1996, p. 18) asks how might European thought (such as phenomenology) address a non-European world, and how might phenomenology outstrip its European origins by revalidating the everyday life of ordinary people and thus contribute to cross-cultural understanding, with direct implications for subaltern studies. Examples of such work include a focus on the toll in human suffering created by conflict, war, and hegemonic structures (Bourgois, 1995; Bourgois & Schonberg, 2000; Daniel, 1996; Das, Kleinman, Ramphele, & Reynolds, 2000; Das, Kleinman, Lock, Ramphele, & Reynolds, 2001; Farmer, 1996; Kleinman, Das, & Lock, 1997; Scheper-Hughes, 1992); an emphasis on collectivities, resistance, and action (G. Becker, 1997, 2000; Csordas, 1993, 1994b; Green, 1999; Ong, 1995; Root & Browner, 2001), the effects of public policies (Becker, Beyene, & Ken, 2000a), and recommendations for the alleviation of suffering in specific situations (Ablon, 1999; Bluebond-Langner, 1996).

In conclusion, conceptions of what constitutes a phenomenological approach in medical anthropology have emerged within a short period of time, with many theoretical developments. There has been a burgeoning of work in a great variety of directions. As medical anthropologists rethink and reshape the phenomenology construct, further theoretical developments are likely to be concentrated increasingly on the linkages between embodiment, the political subject, and political and economic effects, in both their global and local contexts.

Possession and Trance

Erika Bourguignon

INTRODUCTION

The English term “possession” includes both the concept of ownership and of control and domination. Belief in possession by spirits, that is, the possibility that an individual’s actions and behavior may be controlled by spirits or demons, is attested in English usage from the 16th century. These beliefs have left their traces in everyday language. Belief in spirit possession is both ancient and very widespread as seen in the historical and ethnographic record. One of the remarkable features of this system of beliefs and associated ritual practices is its very great flexibility and innovative potential. This is demonstrated by its expansion and diffusion, where decline and indeed disappearance might have been expected. In a large-scale, cross-cultural study, some form of such beliefs was found to be present in 77% of 488 sample societies (Bourguignon, 1973). Given the terminological confusion at the time of this research and a great deal of ad hoc generalization in the literature on the basis of single ethnographic cases, such systems of belief needed to be studied in the larger context of their behavioral and sociocultural correlates. Once the geographic distributions and the cultural linkages had been identified, the special features of specific ethnographic instances could be studied in depth. A distinction between beliefs and behaviors revealed that certain types of behaviors reflect general human physiological and psychological features and that these are not necessarily associated with possession beliefs. A broad sampling of human societies made it clear that what may be considered pathological in Western bio-medicine is often conceptualized in radically different ways in other cultures.

SOURCES AND TYPES OF BELIEFS

Possession beliefs are rooted in conceptions of the human being as consisting of several elements (such as body, mind, personhood, self, name, identity, soul or souls, even part souls), where one or more of these may be

replaced, temporarily or permanently, by another entity. More rarely, a second entity may also be thought to enter the body without displacing the first, even though the behavioral manifestations are those of this additional presence. Such an explanation for possession by the spirit of a dead sinner (*dybbuk*) is found in the Jewish tradition. A belief in entities that may possess individuals is also required, be they hostile or benevolent, spirits of the dead, sometimes of animals or witchcraft beings. High gods are rare among the spirits that are believed to possess humans. It is apparent that beliefs in spirit possession are linked to complex cosmologies, although the details of such esoteric systems may be known only to ritual specialists. For the ritual participants, such cosmologies may be more implicit than explicit. The behavior acted out is largely learned and structured by local expectations.

Understanding the human being as consisting of several potentially separable parts may be used to account not only for “spirit possession,” but also for dreams, hallucinations, seizures, and death.

BEHAVIORAL MANIFESTATIONS

The behavioral manifestations of such “possessions,” or displacement of a person’s soul or other key element by another entity, vary widely but fall into two main groups: (1) negative changes in physical health or behavior or, on the other hand, enhanced powers, and (2) alterations in state of consciousness and behavior. Bourguignon (1973) refers to the second type as Possession Trance and to the former simply as Possession (or non-Trance Possession). These two types have different geographic distributions and are linked to different sociocultural and economic variables. Also, where they occur in the same society, they are likely to have different distributions within the population. The second type, Possession Trance, is significantly linked to female participation.

Trance (or dissociation), not linked to possession belief (non-Possession Trance), may be sought intentionally, as in the vision quest of North American Indians.

As such it refers to communication with spirits, usually in visions. These may be auditory rather than visual in nature. Although at times women have sought visions, the typical seeker was a young man. Austerities (isolation, exposure, fasting, and so forth) were used to induce the trance state.

Trance may also occur spontaneously. How it will be interpreted and evaluated will depend on the particular cultural context. A distinction between Possession Trance and non-Possession Trance corresponds roughly to a distinction between possession religions and shamanism (e.g., de Heusch, 1981). Others (e.g., Lewis, 1989) generalize the term more widely, applying it to all who control spirits, regardless of their manner of interaction. The terms “shaman” and “shamanism” are also used differently in different ethnographic regions. Since these terms are used quite inconsistently in the ethnographic and historical literature, shamanism is currently a contested category (Bourguignon, 1989a; Kehoe, 2000).

As noted, for physical or behavioral changes to be interpreted as due to possession, a belief in possession must be available. Such beliefs, if not traditional in a given community, may be adopted in contact situations. It should be emphasized that “possession” is not directly observable; it is an interpretation of behavior made by participants, and it is statements of participants that must be obtained by an outside observer or researcher to discover it. There are situations in which it may appear that an entity speaks through an individual—that is, an example of “possession”—but where, upon investigation, the individual may claim to be repeating what he hears, and fully remembers the message after the event (for a description of this situation among the Hunza of Northern Pakistan, see Sidky, 1994). Amnesia, actual or normative, full or partial, is frequently associated with Possession Trance, but not with Trance where Possession is absent. In this case, what the trancer sees or hears must be remembered in order to be communicated to the group. Ritual trancing is not idiosyncratic behavior, but is carried out in a group context, often on behalf of the group.

GEOGRAPHIC DISTRIBUTIONS AND SOCIOCULTURAL CORRELATES

In the study cited above, Bourguignon (1973) found that 90% of sample societies had institutionalized Trance

(or altered state of consciousness) and/or Possession Trance in a sacred context. That is to say, Trance states interpreted as due to possession, or interpreted in some other way, are here grouped together. For the remaining 10%, evidence on the subject was unavailable or inadequate. There were significant differences among ethnographic regions in the utilization of trance states: they ranged from a high of 97% of societies in Native North America, to 94% each in the Insular Pacific and East Eurasia, 84% in South America, 83% in Sub-Saharan Africa, and to a low of 80% in the Circum-Mediterranean region. A belief in spirit possession was found in 74% of the world sample. Again, there was wide variation between world regions, ranging from 88% of the societies of the Insular Pacific and East Eurasia, to 81% of Sub-Saharan societies, 80% in the Circum-Mediterranean, to 65% in South America, and finally North America with a low of 52%. Here we are counting both societies that either have a possession belief linked to trance states and those where possession refers to some other change in the host. With regard to possession beliefs, one might say that the New World is indeed a world apart.

Possession Trance is significantly correlated with Sub-Saharan Africa, where it appears in 45% of societies. By contrast, non-Possession Trance is highly correlated with North America, where it is found in 72% of sample societies. In addition, both Possession Trance and Trance are found in 20% of African societies. In North America, both are found in 21% of societies. In other words, while the most prominent form of sacred altered state of consciousness in North America is Visionary Trance, in Africa it is Possession Trance. Visionary Trance is more likely to be found among men, Possession Trance among women.

Belief in spirit possession is also widespread (Bourguignon, 1976). It appears in 74% of sample societies. Because of the difference between the near universality of institutionalized trance and the much lower incidence of possession beliefs, as well as other evidence, such as the widespread existence of nonsacred forms of trance, it may be argued that trance has its roots in human physiology, whereas possession beliefs, which are highly variable, are cultural phenomena. The human capacity for trancing (or dissociation) thus may be seen as raw material for cultural utilization.

It may be noted that Possession Trance involves the enactment of multiple roles by human actors. This is more likely to be the case in complex societies, where

there exists a varied repertory of roles for individuals. It is then not surprising that correlations were found between the presence of Possession Trance and four variables showing degrees of societal complexity: estimated population size over 100,000; present or recent presence of slavery; permanent or semi-permanent settlements; and a jurisdictional hierarchy above the local level. Societies with Trance only were significantly less likely to have these characteristics. Societies having both Trance and Possession Trance were found to be intermediary between the other two types or to be the most complex of all. These correlations have been confirmed by restudies by other scholars (Shaara & Strathern, 1992; Winkelman, 1992).

Where both Possession Trance and non-Possession Trance are found in the same society, it is often the case that they involve different types of persons and different contexts. The same applies to Possession and Possession Trance. For example, among the Azande (Evans-Pritchard, 1937) there is a belief in possession: certain people—mostly men—have a witchcraft creature residing in their bodies which they can activate to cause harm to others. There are also “witch doctors,” most of whom also are men. They take “medicines which give them power to see the unseen and to resist great fatigue” (Evans-Pritchard, 1937, p.178). It is not known whether these “medicines” are pharmacologically active. They are taken in conjunction with drumming, singing, and active dancing during which the witch doctors achieve a state of dissociation in which they prophecy, and identify witches. That is, there exists a ritual Trance state among the Azande, which is not linked to a belief in possession. However, Possession Trance did exist among the Azande, for Evans-Pritchard (1962) tells us that they also had women ghost diviners who went into trance and were possessed.

In a study of a sample of African societies, Greenbaum (1973) has found support for a hypothesis suggesting a relationship between the presence of Possession Trance and societal rigidity.

Winkelman (1992), focusing his attention on various types of “trance-based healers”—that is, healers employing trance states—offers a four-fold classification: Shaman; shaman/healer; healer; medium. These four types are found linked to levels of societal complexity.

The difference between Sub-Saharan Africa and Native North America suggests some explanatory hypotheses: the ethnographic record of these two regions

shows major differences in the predominant economy (hunting and gathering vs. agriculture), small versus large population size, simple versus complex political structures, etc. as well as the differential participation of men and women in religious rituals. In an early cross-cultural statistical study, D’Andrade (1961) studied the use of dreams (and visionary trances—the two are not clearly distinguished in the literature) to seek and control supernatural powers. He found that about 80% of hunting and fishing societies use dreams in this way and only 20% of societies that depend on agriculture and animal husbandry do. But hunting and fishing was the predominant type of economy in native North America and relatively rare in Sub-Saharan Africa. Moreover, the seekers were primarily men. D’Andrade (1961, p. 326) speaks of “anxiety about being isolated and under pressure to be self-reliant” and suggests that this may create “an involvement with a type of fantasy about magical helpers.” That the vision quest takes place at a time in the lives of young men when they needed to become independent and self-reliant in societies where self-reliance and independence were necessary for the male role, is also noteworthy. On the other hand, in the agricultural, sedentary societies of Africa, Possession Trance, practiced in groups, addressed the concerns of women with striking frequency. They often involve diagnoses of problems, by means of divination, concern for long-term relationship with spirits, as well as the opportunity to act out various roles. When women are possessed by powerful male spirits, these may be their spirit husbands.

POSSESSION BELIEFS IN WESTERN THOUGHT

A difficulty with the concept of “possession” arises from its history in the Western tradition, since ideas of some types of demonic and other possessions come to us from both Hebrew and Greek sources. For example, the New Testament (Mark 5:1–17) describes Jesus exorcising a mad man, whose possessing spirits then went into a herd of swine who drowned themselves. This account has been related to its political context: the Roman occupation of Palestine (Crossan, 1994, p. 89). Luke (11:14–15) tells of a mute man who was able to speak once the spirit that possessed him was driven out. Numerous exorcists were active in Galilee at the time, where there was probably a mass of manuals and other literature available to them.

The popular view of the day, as expressed in the New Testament, was that evil spirits caused illness, physical and mental, by possessing people (Guinebert, 1959). The sophisticated view of the time, expressed by Jewish writers such as Flavius Josephus and Philo Judaeus, was rather that it was the souls of evildoers who possessed individuals, a view that was elaborated later in Jewish history, where a tradition of negative spontaneous possession and exorcism continued.

As for the Greek tradition, where evidence is also limited, sources available to scholars have been interpreted as dealing with Possession Trance, rather than possession as evidenced in mental or physical illness. The examples given by Dodds (1957) refer to the *Pythia*, that is, the Delphic oracle of Apollo, whose prophecies were believed to be coming from the god (see also Maurizio, 1995). Dodds also considers the cult of Dionysius, particularly as reflected in Euripides' play, the *Bacchae*. The French classicist, Jeanmaire (1951), compares the fragmentary evidence on Greek Dyonesian religions with the zar cult of modern Ethiopia. In both cases there appears to be a curative function, and women are put into Possession Trance with the use of drum rhythms. Here, rather than exorcism, we find rituals of initiation and attempts at meeting the demands of the possessing spirit, thus turning a negative presence into an ally. In addition, Johnston (2001) describes a form of Greek divination using child mediums.

In the Christian tradition, demonic possession and exorcism have, at times, played a significant role, sometimes involving important political issues. The case of the possessed nuns of London in 17th-century France represents a dramatic example (de Certeau, 2000).

As a result of this background, Western observers at times have been tempted to read evidence of "possession," where, in fact, such an understanding may not have corresponded to the particular local tradition.

POSSESSION RELIGIONS, WOMEN, AND MORALITY

It has been observed consistently that in most instances of possession illness and Possession Trance, the majority of spirit hosts are women. This was true of 19th-century European spirit mediums as well as contemporary leaders of Spiritualist churches in the United States, of Balinese and Zulu healers and diviners, of possession trancers in Haitian *vodou*, and Brazilian Afro-Catholic religions.

A variety of explanations have been offered, both by the people themselves and by outside observers.

Lewis (1989) sees possession trance religions as consisting of two types. He distinguishes between central morality cults and amoral peripheral cults. The central cults are dominated by men and support the official morality of the society; the peripheral ones are amoral and the possessed are mostly women and other deprived persons. He argues that "for all their concern with disease and its treatment, such women's possession cults... are thinly disguised protest movements directed against the dominant sex" (Lewis, 1989, p. 31). Kendall (1985) has challenged Lewis's thesis, arguing that in Korea the healing and Possession Trance activities primarily controlled by women are complementary to the male-dominated ancestor cult, and do not represent a peripheral cult, nor are they amoral or protest movements directed against men. Consequently, the Korean religious and ritual system involves both sets of activities. Lewis also claims that Possession Trance of the socially deprived constitutes a means of manipulating the powerful through supernatural sanctions. He speaks of this as an expression of the war between the sexes. He gives Haiti as an example where, he claims, *vodou* is an amoral peripheral cult. This is an inappropriate example. Manipulation through supernatural sanctions can work only if the powerful share the belief system of those who would so manipulate them.

Brazilians explain the greater disposition of women to become mediums by their view that the process of developing their mediumistic capacities requires suffering, and women have a greater capacity for suffering than men.

Nutritional explanations have also been proposed, particularly with regard to calcium metabolism. The most elegant model has been proposed by Raybeck et al. (1989). These authors relate the problems encountered by individual women at the sociocultural level on the one hand to existing beliefs in possession by spirits, and to stress and anxiety at the psychological level on the other. This leads to physiological changes, notably a depressed level of calcium in the blood, independent of dietary calcium intake. It is known from substantial physiological research that women's calcium metabolism differs from that of men. The resulting symptoms, such as dizziness, tremors, convulsions, and dissociation are then interpreted as spirit possession at the cultural level. This interesting model, however, remains to be tested in field studies.

POSSESSION AND HEALING

In recent years there has been a great and continuous increase in the literature dealing with possession, both descriptively and analytically. This corresponds also to the worldwide distribution of the phenomena in question, as well as to greater interest in various aspects of this complex subject by researchers. Beginning in the 1960s, with the development of transcultural psychiatry, Possession Trance religions and shamanism have been considered with regard to their functions as healing systems (e.g., Kiev, 1964; Prince, 1964). More recent studies have focused on a broad range of other issues, such as communication, discourse analysis, women's position, political resistance, reflections of history, and social change. Not only do new Possession Trance religions spring up, but even among established religions, such as Haitian *vodou*, new spirits make themselves known. The focus of analysis varies with the individual researcher and the specific local situation.

The rather rough grouping into two types of possession (see above) includes a variety of subtypes—for example, the concerns with healing are much more prominent in East Africa than in West Africa. The African Diaspora, as in Brazil, has produced an emphasis on mediumistic capacities, in which suffering—though not necessarily illness—is seen as leading to spiritual development. The Jewish, Christian, and Moslem traditions see possession almost entirely as negative, due to demonic or other hostile forces, and as requiring exorcism—that is, the driving out of the invading spirit that produces manifestations that are interpreted as hostile to religion. There are, however, some exceptions. For example, the Protestant tradition understands glossolalia (speaking in tongues) as a sign of possession by the Holy Ghost. The Anastenaria ritual of Northern Greece (Greek Macedonia and formerly also Thrace) involves a healing tradition in which participants are possessed by Saints Constantine and Helen while they dance on burning embers. This practice is sanctioned within the Greek Orthodox Church (Danforth, 1989).

In mystical Judaism, some scholars (Goldish, personal communication, 2003) read the voice of a supernatural entity (*maggid*), that speaks to or through mystics and prophets as possessions, while others do not (e.g., Bilu, 1996).

Islam, on the whole, has been tolerant of local spirit beliefs. Thus, in various parts of North Africa as well as in Sub-Saharan Africa, spirit cults are active in which

Possession Trance is part of the ritual activity, and initially harmful spirits are transformed into allies and helping spirits through the ritual process. This is true of the zar cult in Sudan (e.g., Boddy, 1989), Egypt (e.g., Salima, 1902), and the Gnawa of Morocco (Chlyeh, 1999; Welte, 1990). This last is one of many groups whose history reveals it to be a cult of the Sub-Saharan Diaspora. Traditionally, men have been primarily drummers and women mediums and healers. However, Welte (1999) argues that, as a result of the worldwide pauperization of peoples, men are now expressing depression in psychosomatic symptoms interpreted, and treated, as possession and requiring exorcism.

As noted earlier, there is a frequent linkage between possession beliefs and altered states of consciousness (trance). However, its precise nature varies substantially. If we consider possession belief, trance state, and a third variable, illness, then the following examples show this variation very clearly. Thus, in the zar cult of Eastern Africa (Egypt, Sudan, Ethiopia, Somalia), as mentioned earlier, various types of illness or strange behavior may be diagnosed as spirit possession. These include fugue states, stomach aches, infertility, apathy, seizures, and many other symptoms. On the basis of divination, the possessing spirit is identified and will then be invited; that is, possession trance is ritually induced. Over time, through cult initiation, the spirit is placated and turned into an ally. The result is a life-long cult membership. In Possession Trance, the women enact complex personalities of individual zar spirits.

By contrast, Corin (1998) describes the Zebola cult of the Congo, and particularly of Kinshasa. Here illness is explained as due to the malevolence of others. It is redefined as spirit possession by means of divination. During divination, the spirit manifests itself, speaks through the woman in Possession Trance, identifies itself, and reveals the causes of the illness. A lengthy process of initiation follows; it seeks to control the spirit by inhibiting manifestations of trance. This is accomplished, among other things, through medications, as well as the teaching of complex dance performances. The woman then maintains a relationship with the spirit which is now her protector.

Haitian *vodou* presents quite a different picture. Here illness and bad dreams are seen as harassment by *vodou* spirits (*lwa*) to encourage the victim to seek initiation. Possession Trance may also occur spontaneously, and then require divination for the identification of the spirit. Initiation and ritual participation are seen as

religious and familial obligations. Possession Trance, in which the complex characters of spirits are acted out, are part of long-term relationships between humans and their spirits who need to be fed, as well as entertained, in order to give humans the support they need in their difficult lives.

THE RETURN OF EXORCISM

While exorcism had virtually disappeared as a practice in Catholicism and mainstream Protestantism through most of the 20th century, it has made a significant come back in the last 30 years. It received great popular attention with the publication of the book and the film *The Exorcist* in the 1970s. In the same period, the exorcism of a German girl attracted worldwide attention. When she died, the priests/exorcists and the girl's parents were convicted of unintended manslaughter. While the exorcisms had continued over an extended period of time, she was also diagnosed and treated for epilepsy by a physician (Goodman, 1981). The Archbishop of New York permitted an exorcism of a teenage girl to be broadcast on the ABC program 20/20. In this case the girl had been diagnosed and was under treatment for schizophrenia.

What is interpreted as possession requiring exorcism in a given situation varies widely but seems to involve some common features. One of these is uncharacteristic behavior. Hensely (1993) tells the story of a man, in the Ohio–Kentucky border area, who is believed by an exorcizing minister to be possessed. Carl, a humble and meek man, has outbursts of violence. This is said to be due to people who died violent deaths in a club location Carl frequented, and whose spirits have not moved on.

As of 2001, there are frequent reports of exorcisms in national newspapers and magazines; a Seattle radio station reportedly conducts exorcisms over the air. (See also Cuneo's, 2001, review of the current state of exorcism in America.)

POSSESSION RELIGIONS ARE INCREASING IN NUMBERS

The great increase in the reporting of the phenomena in question is likely to be due to both a growth of interest and awareness by researchers, but also to an actual increase in incidence. This in turn seems to be partly due to displacement/diffusion of populations, and spread to others, partly due to health crises (including both traditional healing and

searches for alternatives) and partly due to crises in identity. Examples include the presence of Caribbean religions in the United States and in the United Kingdom. These were syncretic religions developed in the areas from which the migrants have come. In Trinidad, for example, we find both South Indian Kali religion and Afro-Protestant groups, both of which are at this time represented in Britain. In a different vein, the development of and interest in Channeling in the United States speaks to a concern with identity and self help (M. Brown, 1997). This pattern of mediumistic behavior is distinct from earlier Spiritualism of the 19th and early 20th century, where the spirits called up through mediums were those of the recently dead. The spirits called on by channelers address more distant, impersonal spirit guides. There is also a belief in reincarnation and previous lives. Most channelers are women; most spirits male.

Although Spiritualism was first developed in the United States, it rapidly spread to Europe. A French variety, as developed by Alain Kardec (pseudonym of H. L. D. Rivail), has been most influential in Latin America. Spiritistic religions and Protestant Evangelical religions which encourage ecstatic experiences are the most rapidly spreading forms of religion worldwide.

POSSESSION RELIGIONS AS WORSHIP AND TRADITION

To see Possession Trance only in medical terms would be a mistake. Behavior that might be seen as pathological in the Western or bio-medical system, may be seen in terms of a mythico-religious system in a traditional society. Hollan (2000, pp. 546–547) notes that “possession behavior that is culturally normative, no matter how bizarre or irrational it appears from a Western point of view, should never be considered pathological or psychotic [It] is culturally constituted symbolic behavior”

As Suryani and Jensen (1993, p. 46) write: “In Bali, ritual possession is common, controlled, desirable, socially useful, highly valued, socially reinforced by society and individually satisfying.” Balinese Possession Trance occurs in numerous contexts: the work of traditional healers (*balian*), masked ritual dramas, kris dancers, hobby horse dancers, little girl trance dancers, and so forth. Among forms of Possession Trance considered aberrant and sometimes requiring biomedical intervention are incidents of collective dissociation among school girls and attacks of *amok* among men.

Traditional people may be caught in a conflict between two different explanatory systems (Kleinman, 1980). Possession Trance linked to long-term relationships with one or more spirits involves the development of what appear to be secondary or alternative personalities. This may be seen by psychiatrists as D(issociative) I(dentity) D(isorder), often referred to as Multiple Personality (Bourguignon, 1989b; Suryani & Jensen, 1993). Bizarre behavior and speech may be diagnosed as psychotic by psychiatrists. It might be noted that Suryani herself is both a Western-trained physician and psychiatrist and a *balian*, a Balinese trance healer.

In recent years, for example, zar beliefs and practices have been brought to Israel by Jewish immigrants from Ethiopia. As reported by Witzum, Grizaru, and Budowski (1996), some women who had brought zar illness behavior from Ethiopia were inappropriately referred to mental health clinics, hospitalized, and treated with anti-psychotic medications. By contrast, having their behavior labeled as zar possession provided them and their families means of coping with distress and avoided the stigma of mental illness. The zar ritual serves as a curing ceremonial.

Kahn and Kelly (2001) conducted a study of Xhosa-speaking psychiatric nurses in South Africa and note "their dual allegiance to apparently competing and largely incommensurate mental health paradigms" (pp. 34–35). Here it is health care workers, as well as patients, who are involved in the conflict between competing explanatory systems. A major category of Xhosa traditional healers are diviners, who are "called" to their profession by an initiatory illness, involving possession by ancestor spirits and who in their divination practices go into Possession Trance.

Possession Trance rituals, however, do not necessarily deal with illness and curing. They may serve to alleviate many different kinds of stress, such as marital or financial problems or concern over school examinations. They may also be experienced as forms of devotion and fulfillment of obligations to the spirits inherited in family lines or revealed to specific individuals. As such they reflect participants' sense of self and of belonging.

For Caribbean people in the United States, for example Haitians, Cubans, and Jamaicans, their Afro-Christian religions, in which rituals center around various forms of Possession Trance, have become significant elements in their reaffirmation of their ethnic identities. This is illustrated by the fact that, in the United States, some

members of the educated middle class among these groups are now identifying themselves with religious practices that were primarily linked to the poor in their homelands. These were negatively sanctioned and often denied by the earlier generations of their families (see K. Brown, 1991; Palmié, 1991).

Pentecostal and Charismatic churches have a long and variable history in this country. Here the faithful experience possession by the Holy Spirit, speak in tongues (glossolalia), and manifest other "Gifts of the Spirit." They are associated with healing only to a limited extent. They have widespread appeal as well in Latin America and Africa, where they may be in competition with established Possession Trance religions.

Any consideration of rituals of Possession Trance and, often also of Trance, must not neglect the esthetic aspects of what are more or less complex performances. The most famous are to be found in Bali, but also in India on the one hand and in the Afro-American traditions of Brazil. Possession Trance rituals only rarely involve the use of masks, as in the trance dramas of Bali. More frequently the possessed individuals act out the personalities and activities of the possessing spirits in interactions with the audience, in dance, and costumes, all of it accompanied by music, frequently drumming, the whole constituting a dramatic performance.

Moore (1982) discusses music and dance as expressions of religious worship, with specific reference to Cumina and Revival, two religious groups in Jamaica. He notes that to participants these art forms are vehicles "for self expression and release of inner tensions...[a]psychic outpouring [that] restores vitality and refreshes the whole person" (p. 299).

SUMMARY AND SOME CONCLUSIONS

Beliefs in the possibility of possession by spirits or other entities has been found to be very widespread among the societies of the world. However, there are regional variations in the percentage of societies that have such beliefs and the manner in which these beliefs are formulated. Such variations are not random or arbitrary but are related to other sociocultural features predominant in a given region or characteristic of particular societies. As the societies change under impact of modernization and globalization some of the beliefs and ritual practices change also.

A study of ideas of possession by spirits and other beings necessarily leads to an investigation of how this possession is experienced and therefore to a study of the ritualization of possession states and to trance (altered states of consciousness, dissociation). It also leads to a study of the relationship to other features of the societies in which these occur, how they are distributed throughout the world, who the participants are, how the states are diagnosed and evaluated, and what social uses are made of possession states.

Historically, the approach to both possession and trance has reflected the interests of the investigators. In Haiti, for example, the initial writings had to do with demonology and then with ideas of pathology, specifically hysteria. These were inherited from French psychiatry, where Janet compared his hysterical patients to the cases of possession and exorcism in French history. Anthropologists, such as Herskovits (1937), emphasized cultural relativism, and since the Haitians induced Possession Trance in their rituals and valued these states, he argued that they were normal and not to be seen as pathology. In the 1960s some psychiatrists began to see Possession Trance as therapeutic rather than pathological, and sometimes also a prophylactic. There also developed a view of possession as political phenomenon, whether as resistance to existing circumstances and conditions or as a means of mobilization in a liberation struggle. More generally, the relationship between possession and social change has become a topic of great interest (e.g., Kenyon, 1995).

When computer analysis of data became possible, the statistical comparative method could be utilized to test hypotheses with regard to spirit possession beliefs. Because of women's strong presence in Possession Trance religions, research into these groups became relevant to gender studies. When still other approaches developed in anthropology, these have been utilized in related research, so that Lambeck (1989) speaks of a move from disease to discourse. At that point the emphasis again turned to the workings of individual societies rather than to comparative analysis. With the development of New Age religions in the United States, still another field of research on possession and trance opened up, as took place when migrants from distant places brought their Possession Trance religions to metropolitan centers. In sum, the research reflects the reality on the ground as well as the interests of the investigators. Although much has been accomplished in the last 40 years, there is much that remains to be done.

Shamanism

Michael Winkelman

INTRODUCTION

The term shaman entered English from other cultures (Flaherty, 1992) and has been attributed to practices around the world (Vitebsky, 2001). Shamanism received widespread academic attention following Eliade's (1964) *Shamanism: Archaic techniques of ecstasy*, which considered shamanism a worldwide healing practice involving ecstatic communication with the spirit world on behalf of the community (cf. Halifax, 1979; Hultkrantz, 1973). Whether shamanism is cross-cultural or regionally specific, and consequently an etic or emic phenomenon, is

contentious. Some consider shamanism specific to Siberia (e.g., Siikala, 1978), while others considered shamans to be any practitioners who voluntarily enter altered states of consciousness (Peters & Price-Williams, 1981).

Cross-cultural and interdisciplinary research indicates shamanism is an etic phenomenon involving psychobiological adaptations to the adaptive capacities of altered states of consciousness (ASC) or the integrative mode of consciousness (Winkelman, 2000). Shamanism was a central cultural institution at the dawn of modern humans some 40,000 years ago (Clottes & Lewis-Williams, 1998; Ryan, 1999). Shamanism is a fundamental aspect of

human evolutionary psychology that was transformed by sociocultural evolution, but persisted in other forms of shamanistic healing (Winkelman, 1992, 2000). This entry addresses both the specific aspects of shamanism and the universal therapeutic mechanisms of shamanistic healers, and focuses upon the generic aspects of, rather than the numerous, culturally specific forms.

CROSS-CULTURAL PERSPECTIVES ON SHAMANS

The problems of a definitional approach to shamanism (e.g., see Jakobsen, 1999; Townsend, 1997) are overcome by a cross-cultural approach that provides an empirical basis for characterizing shamans. Cross-cultural research reveals an etic shamanism world-wide in hunter-gatherer societies and universal practices using ASC for healing (Winkelman, 1986a, 1990, 1992; see Winkelman & White, 1987 for data and methods). Shamanism was an ecological-psychobiological adaptation of hunter-gatherer societies to biological structures, psychosocial processes, and therapeutic needs (Winkelman, 2000). This psychobiological foundation for the hunter-gatherer shaman also provided the basis for the persistence of similar ASC-based healing practices in more complex societies; these have been referred to as shamanistic healers (Winkelman, 1990), recognizing their continuity with shamanism.

The foundations of shamanism are derived from: (1) ASC induction activities that elicit the relaxation response and produce theta wave synchronization across levels of the brain; (2) analogic and visual symbolic systems involving a presentational symbolism and other innate representational modules for self, "others," mind, and nature; and (3) socioemotional and psychodynamic ritual processes and their physiological, social, psychological, and cognitive effects. Shamanistic ASC involve a biological mode of consciousness with many adaptive physiological consequences directly related to healing (e.g., relaxation, psychological integration, opioid, and serotonin-mediated effects). Shamanism uses presentational symbolic systems (Hunt, 1995) and analogical thought processes produced through integration of innate representational systems of the brain, specialized adaptations for processing perceptions of social relations (self/others), their intentionalities ("mind reading"), and animal knowledge (natural history representations)

(see also Mithen, 1996). Shamanic universals of animism, animal spirits, totemism, soul flight, and the guardian spirit complex involve manipulation of information regarding personal, social, and natural identities through analogical and visual representations (Winkelman, 2000). These use innate brain processing modules for knowledge about mind, self, and others to understand nature; and reciprocally internalizes these natural models for development of self and social representations (Winkelman, 2000). These community ritual activities manipulate and strengthen social identity, using psychosocial processes for emotional healing.

UNIVERSALS OF SHAMANS

Cross-cultural research (Winkelman 1986a, 1990, 1992) indicates a core set of characteristics associated with healing practitioners of hunter-gatherer societies. In addition to the ecstasy (ASC), spirit world interaction, and community relations emphasized by Eliade, other characteristics of shamans include soul journey or flight, soul loss and recovery, death and rebirth, hunting magic, and other therapeutic processes.

Shamans are found among hunter-gatherers and societies with limited agriculture or pastoral subsistence patterns and political integration limited to the local community. Shamans provide healing, divination, and charismatic leadership. Shamans are also capable of malevolent acts, or sorcery. Characteristics of shamans include: training and professional practice based upon the use of ASC; a soul flight ASC and soul recovery; their transformation into animals and control of animal spirits; death and rebirth experiences; and the provision of hunting magic and assistance in food procurement. Predominant shamanic illnesses result from soul loss, attacks by spirits and sorcerers, and the intrusion of foreign objects and entities into the body. Shamanic world views include a multileveled universe including upper and lower worlds connected by an *axis mundi*, often a "sacred tree" through which the shaman travels between worlds. The shamanic ritual was the most significant social event in these societies. In an all-night ritual attended by the entire community, the shaman engaged in ritual interactions that brought the community into direct experience of the spirit world. Shamans are selected through the outcomes of spirit encounters that occur in deliberately induced ASC (e.g., vision quests) or through spontaneous

or accidental ASC experiences interpreted as signs of selection by spirits. Shamans often come from shaman families, but in most cultures anyone may be selected by the spirits through successful training experiences. These often involve an extension of vision questing experiences undertaken by the entire population (or all males) during the adult transition. Shamans are mostly males, but most cultures also allow females to be shamans before or after child-bearing years (Winkelman, 1992).

Shamanic ASC

Ecstasy, trance, or ASC are central to selection, training, and practice, and induced through many procedures that have physiological effects (Winkelman, 1986b, 1992, 2000; cf. below). Shamanic ASC occur in a dramatic ritual encounter within the spirit world. After extensive singing, chanting, drumming, and dancing, shamans collapse into apparent unconsciousness, but have an intact memory of the ensuing visionary experience upon returning to ordinary reality. Shamans experience flying to other worlds with spirit allies, or encountering spiritual or supernatural entities. Sometimes shamans' ASC involve an internal focus of attention without extensive induction procedures. The typical procedures used by shamans to induce an ASC involve extreme activation of the sympathetic nervous system through drumming and dancing until exhaustion of the sympathetic system from extreme exertion leads to collapse into a parasympathetic dominant state characterized by intense visual activity. Shamans also induce ASC through fasting, other forms of auditory stimulation (e.g., clapping, singing, and chanting), prolonged periods of sleeplessness, temperature extremes, and painful austerities. Hallucinogens are used in some traditions (see Furst, 1976; Harner, 1973; Winkelman, 1996). Deliberate periods of sleep and dream incubation may also be used for inducing ASC.

Soul Journey

The soul journey or flight is a universal feature of shamanism, although not characteristic of all of the shamans' ASC. The shaman's interaction with spirits may take the form of a journey into the spirit worlds, a visit from the spirit world, or a transformation into an animal. Shamans' ASC are typically referred to as flights or journeys, and share visual experiences in which some aspect of the practitioner (i.e., soul, spirit, or animal familiar)

interacts with spirits in a non-ordinary reality. The cross-cultural distribution of experiences similar to shamanic flight has an innate basis in psychophysiological structures that reflect homologies across symbolic, somatic, and physiological systems (Hunt, 1995; Laughlin, 1997; Winkelman, 2000). The visionary experiences of the soul journey reflect a natural phenomenon of the human nervous system and occur as a consequence of the dysinhibition of the visual centers of the brain. Soul journey involves "taking the role of the other" in the visual spatial modality involving a presentational symbolism (Hunt, 1995). These externalized self-representations provide new forms of self-awareness and subjective experience, maximizing the symbolic self-referential capacity in the imagetic-intuitive mode. The shamanic soul flight is a representation of the shaman's transcendence. Shamans' ASC normally do not involve possession (spirit takes over and dominates consciousness), but rather the control of spirits, particularly animal spirits.

Death and Rebirth

Shamans' training generally includes a "death and rebirth" experience, an initiatory crisis typically involving illness and suffering from attacks by spirits that lead to the experience of death. This is followed by descent to a lower world where spirits and animals attack and destroy the victim's body. The initiate is then reconstructed with the addition of spirit allies that provide powers. The death and rebirth experience reflects processes of self-transformation that occur under conditions of overwhelming stress and conflicts that result in fragmentation of the conscious ego (Walsh, 1990). The experiences are "autosymbolic images" reflecting the breakdown and disintegration of psychological structures (Laughlin, McManus, & d'Aquili, 1992). The death and rebirth cycle reflects a fragmentation of the conscious ego and self, experienced symbolically as death; and their reformation guided by innate drives toward psychological integration. Shamanic ritual processes manipulate symbolic constructs and neurological structures to restructure the ego, producing a new level of self and identity. The restructuring of the ego is promoted by holistic imperatives toward psychointegration (Laughlin et al., 1992), providing a dramatic alleviation of psychosomatic, emotional, and interpersonal problems. This self-transformation is core to the exceptional health of shamans, providing a basis for individuation and

self-actualization. Although pathological interpretations of the shaman have been offered, Noll's (1983) application of diagnostic criteria of the Diagnostic and Statistical Manual of the American Psychological Association (DSM) rejects this; nonetheless, the initiatory phase may involve conditions akin to acute psychosis (Walsh, 1990).

Soul Loss

A central shamanic illness is soul loss, which Achterberg (1985) characterizes as an injury to the core or essence of one's being. Soul loss reflects concerns with the essence of crucial aspects of the self (Ingerman, 1991), involving the loss of, or injury to, fundamental aspects of personal identity. This injury to one's essence is manifested as despair, disharmony, and loss of meaning in life and feelings of belonging and connection with others. "Soul" constitutes a vital essence of self-emotions. Soul loss occurs from trauma that causes an aspect of one's self to dissociate. This separated aspect of the self carries with it the impact of the traumatic experiences that are unavailable to the rest of the self, arresting ego and emotional development. Reintegration of these dissociated aspects of self is central to healing. Soul recovery involves the shaman's dramatic enactment of battles with terrifying and threatening spirit images that symbolize disowned and repressed aspects of the self (Walsh, 1990). Through their recovery one regains a sense of a social self alienated by trauma and feelings of disharmony and disconnectedness (Ingerman, 1991). Community is significant in soul retrieval, with social support vital to the healing processes and re-integration of self. Community participation facilitates social bonding and release of the body's opioids, producing a sense of well-being. The shaman's dramatic struggles with the spirit world to realize soul recovery and power animal recovery produce powerful experiences, transforming self and altering social relationships.

Therapeutic Processes

The psychodramatic ritual encounter with the spirits is a foundation of shamanic therapeutics. Therapeutic effects derive from physiological and psychological effects of ASC, manipulation of spirit world constructs, and community relations discussed below. Shamanic therapeutics are mediated through song, chants, music, and percussion, eliciting the ancient audio-vocal systems of the brain (Oubré, 1997). Music has a number of different therapeutic effects through physiological and psychological actions,

including stress reduction, affecting access to unconscious information, and elicitation of emotional and cognitive processes (Winn, Crowe, & Moreno, 1989). Visualization, or mental imagery cultivation, is also employed as a principal shamanic technique (Noll, 1985). Shamans also use physical therapeutic practices, including: rubbing or massaging the body; laying on of hands to transfer healing energies; sucking on the patient's body to extract objects and infections; incisions to extract foreign objects; washing and cleansing the body; and herbal or other natural substances (Winkelman & Winkelman, 1991).

SHAMANISTIC HEALERS

All societies have healers who use ASC in community rituals to interact with the spirit world (Winkelman, 1986b, 1992). These *shamanistic healers* share core characteristics of shamans—ecstasy (ASC), community, and spirits—reflecting psychobiological principles of the brain that are manifested universally (Winkelman, 1992, 2000). The biologically based ASC central to shamanism is also the foundation of shamanistic healers' training and practices. ASC enhance integration of lower brain processes with frontal processes through induction of synchronized theta wave patterns that entrain the brain with common patterns across the neuraxis (nerve bundle running from the base of the brain to the frontal cortex). Community has a variety of psychosocial functions and psychobiological effects in healing, including eliciting opioid-mediated immune system enhancement. The spirit world is a symbol system for social identification and self-development and differentiation. Shamanistic healers share other characteristics, including: beliefs that spirits and humans cause illness; using spirits in therapeutic processes; and ritual manipulations for the restoration of health (Winkelman & Winkelman, 1991). Other types of shamanistic healers (e.g., mediums and healers) differ from shamans because of the effects of their respective societies (agricultural, politically integrated) (Winkelman, 1986a, 1990, 1992).

Psychobiological Structures of Shamanistic ASC

All cultures have procedures for accessing ASC but differ in their attitudes toward these states and the means for controlled access (Laughlin et al., 1992). These universals of shamanistic practices reflect underlying

brain structures and functions that elicit operations of an *integrative* mode of consciousness (Winkelman, 2000). This integrative mode of consciousness reflects the ubiquitous response of the brain to diverse conditions that induce synchronized limbic system discharge patterns. These discharges entrain across the neuraxis of the brain, synchronizing the frontal cortex with coherent slow wave EEG patterns in the alpha and theta range (Mandell, 1980; Winkelman, 1986b, 1992, 2000). Physiological mechanisms underlying the integrative mode of consciousness are based in neurobiochemical pathways involving activation of the temporal lobe and limbic system serotonergic pathways to the lower brain (Mandell, 1980). These limbic system processes integrate information from the whole organism into emotion and memory, and mediate self-preservation, family behavior, novel sensory information, and control of the sleeping/waking cycles.

ASC of other shamanistic healers may involve soul journey, but typically have other psychophysiological and experiential dynamics. Possession ASC of mediums have characteristics of a “take over” of the person by spirits (Bourguignon, 1976; cf. Goodman, 1988; Lewis, 1988) and temporal lobe symptomatology (tremors, seizures, convulsions, and amnesia) (Winkelman, 1986b, 1992). Possession is not a unitary phenomenon, but involves a variety of different psychodynamic processes including dissociation, illness, communication, role enactment, and political struggle (Boddy, 1994; Shekar, 1989). Possession ASCs predominantly occur in complex societies with hierarchical political integration and reflect the psychodynamics of oppression and powerlessness (Bourguignon, 1976; Winkelman, 1986b, 1992). Meditative ASC are characterized by deliberate relaxation (direct parasympathetic activation) and focus of attention. Castillo (1991) characterizes meditative practices as involving the differentiation of a participating self engaged in the world from a detached observing self. The neuroendocrine mechanisms of meditative effects on physiology and psychology involve stress reduction through enhancement of serotonin functioning (Walton & Levitsky, 1994) and stimulation of theta brain-wave production. Meditation intervenes in the stress cycle, inducing relaxation, lowering autonomic arousal, and enhancing brain-wave coherence in theta frequencies. Meditation increases serotonin levels, reducing cortisol levels and the limbic system’s anger and fear reactions. This mirrors Mandell’s (1980) serotonergic model of ASC and suggests serotonin’s generic role in the therapeutic mechanisms of ASC, manifested in synchro-

nous high-voltage, slow frequency brain-waves (alpha, theta, and delta activity, especially 3–6 cycles/s).

SHAMANISTIC THERAPEUTIC PROCESSES

Therapeutic mechanisms of shamanistic healing derive from ASC, community relations, and ritual spirit-world interactions. ASC have physiological effects, including the relaxation response, the elicitation of opioid release, and enhanced serotonergic action. The spirit world plays a role as “sacred others,” representing personal and community identity models and aspects of the psyche. The spirit world and community’s therapeutic roles include models for development, social support, and community bonding. Ritual processes manipulate physiology, psychology, and social relationships for therapeutic processes.

ASC Bases of Shamanistic Therapies

Therapeutic mechanisms of ASC involve parasympathetic dominance, interhemispheric synchronization, and limbic–frontal integration (Winkelman, 1992, 1996, 1997, 2000). These physiological processes facilitate healing through a variety of mechanisms, including: inducing physiological relaxation and reducing tension and stress; regulation and balance of psychophysiological processes; reducing anxiety and phobic reactions and psychosomatic effects; accessing normally unconscious information; enhancing behavioral–emotional–cognitive integration; enhancing social bonding and affiliation; and regulating emotions, self, and social attachments.

The parasympathetic dominant state evokes the relaxation response, a generalized decrease in sympathetic nervous system activity, and enhanced alpha and theta brain-wave activity. The relaxation response has therapeutic value in addressing stress-related physical and psychological conditions. Rapid collapse into a parasympathetic dominant state can have therapeutic effects involving erasure of conditioned responses, dramatic changes in beliefs, and increased suggestibility, enhancing placebo and positive psychosomatic effects. ASC activate typically unconscious processes, integrating into the conscious mind material that is normally inaccessible. These repressed dynamics are sources of

conflicts that affect emotions, behavior, and physiological responses. ASC enhance expression of repressed aspects of self by reducing habitual screening processes and giving expression to non-verbal information.

ASC evoke paleomammalian brain or limbic system functions that manage autonomic nervous system balance, emotional mentation, self and social identity processes, bonding and attachment, and the integration of information. These contribute to healing, producing an integration of personal and social consciousness. The theta wave entrainment characteristic of ASC produces integration across hierarchical brain levels, an integration of pre- or unconscious functions into conscious awareness. ASC and ritual enhance integration of cognitive and emotional processes and information from different functional systems of the brain, providing optimal conditions for learning, attention, memory, and adaptation to novel situations (Mandell, 1980).

Therapeutic Aspects of Community Relations

Shamanistic healing typically occurs in a community context. Community participation facilitates therapeutic effects derived from psychosocial influences (positive expectation and social support). These collective rituals strengthen group identity and commitment, enhancing community cohesion by reintegrating patients into the group. Communal healing practices reinforce attachment needs in the mammalian biosocial system (Kirkpatrick, 1997). Attachments and affectional bonds that evolved to maintain proximity between infants and care-givers provide a secure basis for the self, feelings of comfort, and protection from powerful figures (e.g., shamans, spirit allies).

Shamanistic practices enhancing social cohesion elicit psychosociophysiological mechanisms that release endogenous opiates. Frecska and Kulcsar (1989) review evidence that shamanistic practices elicit psychobiologically mediated attachment based in opioid mechanisms. Opioid release is produced through cultural symbols that have been cross-conditioned with patterns of attachment and their physiological and emotional responses. Emotionally charged cultural symbols associated with physiological systems during attachment socialization link mythological and somatic spheres, providing a basis for elicitation of the opioid system in shamanistic ritual. Endogenous opioids are also stimulated by a variety of physical aspects of shamanic ritual (Prince, 1982;

Winkelman, 1997), including: extensive dancing and other exhaustive rhythmic physical activities (e.g., clapping); temperature extremes (e.g., sweat lodges); stressful procedures such as fasting, flagellation, and self-inflicted wounds; emotional manipulations, especially fear and the elicitation of positive expectations; and night-time activities when endogenous opioids are naturally highest. Opioid release stimulates emotions and physiological processes, including endocrine and immunological systems (Frecka & Kulcsar, 1989), enhancing psychoneuroimmunological responses. The euphoria from activation of the body's opioid system produces a sense of certainty and belongingness. These dynamic functions of the psyche provide coping skills and mechanisms for maintenance of bodily homeostasis (Valle & Prince, 1989). Endogenous opioids facilitate environmental adaptation, enhance biological synchronization within a group, reduce pain, and enhance tolerance of stress. These experiences strengthen social relationships in an experience of *communitas*, the essential bonds among group members. This community identity induces dissolution of self-boundaries, identification with others, and the development of an integrated self that can heal others, exemplified in shamanic healing.

Meaning and Emotions

Shamanistic healing addresses the needs met by all of religious healing systems, the provision of meaning and explanations that meet needs for assurance, instilling confidence and a sense of certainty that counteracts anxiety and its physiological effects. Shamanistic healing rituals manipulate meaning to elicit placebo responses and their physiological effects. Symbolic manipulations can intervene in relieving the stress mechanisms of the general adaptation syndrome, providing explanations that alleviate anxiety. Ritual and social support can alleviate the high level of pituitary/adrenal activity of the resistance stage of the stress reaction through changing emotional responses and the balance in the autonomic nervous system, through integration of the emotional and egoic levels, and by resolution of social conflicts. These symbolic manipulations also elicit emotions and their physiological consequences, linking body and mind through effects on the limbic system.

All shamanistic healing processes address emotions, but the emotional psychodynamics of soul journey, possession, and meditation differ significantly (Winkelman, 1999). Shamanistic healing processes share approaches,

however, in addressing emotional distress through the provision of explanations and mechanisms for obtaining relief, and in eliciting community support systems that meet fundamental human needs for belonging, comfort, and bonding with others. Shamanistic healing effects emotions through: elicitation of repressed memories, restructuring painful memories, confession and forgiveness, resolving intrapsychic conflict, alleviating repressions, and giving expression to unconscious concerns. Explanations provided in shamanistic healing processes typically minimize personal guilt, negative emotional process, intrapsychic conflict, and internal discrepancies through attributing responsibility to external agents (i.e., spirits). Ritual controls attitudes through metaphoric and affective processes operating independently of higher cognitive processing, providing mechanisms for manipulating affective responses independent of habitual resistances. Emotions and unconscious structures are typically addressed by attributing these to external forces (spirits). Shamanic ritual also provides psychoemotional and mental reprogramming of lower brain processes in the material embodied in the chants, songs, and psychodramatic enactments that change perception of self, social relations, and emotions.

Shamanism produces meaning through universal aspects of symbolic healing (Dow, 1986), particularizing the patient's circumstances within a cultural mythology, and manipulating that system to emotionally transform the self-system of the patient. Ritual manipulation of the spirit world enables shamans to symbolically transform individual psychophysiological processes through emotions related to well-being and attachment. Shamanistic ritual activities access innate drives toward self-differentiation and identification with "other," promoting reorganization at higher levels of integration. Through ritual manipulation of psychophysiological structures not directly accessible to the conscious ego, shamans evoke cognitive and emotional responses that cause physiological changes. These are achieved by the manipulation of cultural symbols associated with autonomic responses and through activities that cause physiological changes (e.g., drumming, fasting).

Spirit as Biopsychosocial Dynamics of Self and Other

The spirit relations of shamanism are part of a broader animistic framework. Animism involves beliefs in a soul or vital principle animating entities and producing their behaviors and observed properties. Animism is

exemplified in a universal anthropomorphism, the attribution of human characteristics, particularly those associated with self and mind, to non-humans (Guthrie, 1993). This human tendency to animate the natural world involves a relational epistemology that situates humans in the environment and plays a fundamental role in the construction of personhood and communal identity (Bird-David, 1999). Spirits provide a language of intrapsychic and psychosocial dynamics and relationships, and consequently a system for manipulating self, identity, and relations with others.

The shamanic spirit world is a conceptual framework representing aspects of self; ritual symbolic manipulation of these spirit constructs can affect attachments and emotions by operating on structures functioning outside of conscious awareness. Spirits are the most fundamental cause of shamanistic illness, and are also fundamental structures of self and others, representing generic aspects of human thought. Ritual interactions with spirits elicit these primordial psychocognitive processes and forms of representation and communication that manage the relationships of self-concept, social "others," and emotional well-being.

Shamanistic meanings involve attributions to a spirit world, embodied in animism, the belief that spiritual beings motivate the behavior of humans, animals, and natural phenomena. Animistic meaning systems involve projected cognitive similarity—a belief that the world's unseen forces are like humans' cognitive, emotional, and social capacities. Spirits are attributions based in metaphoric extensions of the self for modeling the unknown other. Spirit beliefs reflect social structures, social and interpersonal relations, group and individual psychodynamics, and cognitive processes. Shamanistic healing makes maladies meaningful in the context of both cultural life, and in relationship to innate structures of self-perception. Shamanic healing uses psychobiologically based references for understanding personal psychodynamics in terms of a body-based system of meaning (Laughlin, 1997) and innate representational systems (Winkelman, 2000). These innate structures are entrained by symbolic processes, allowing satisfactory meanings to emerge from symbolic ritual manipulation of unconscious structures.

Spirits are symbolic systems, representing complexes, organized perceptual, behavioral, and personality dynamics dissociated from ordinary awareness, normal and social identity. These complexes are dissociated

aspects of the personality. Shamanistic healing practices elicit a holistic imperative (Laughlin et al., 1992), a drive toward integration across levels of consciousness. These disowned, un-integrated or unconscious aspects of self are symbolically manipulated through spirit concepts, producing healing by re-structuring the interactions among personal and collective dynamics. The ritual elicitation of the emotional unconscious and transference of control of intentional processes to the shaman and spirit world enables individual alignment with social expectations and meaning systems. Shamanic healing integrates the self through visual and corporeal processes, uniting conscious and unconscious information.

Spirit Relations as Role-Taking

Shamanism provides therapeutic processes through role-taking (Peters & Price-Williams, 1981). Role-taking is exemplified in spirit world interaction where shamans adopt the personalities of the spirits. Spirit world dynamics are representations of personal and social psychodynamics (emotions, attachments, complexes, and social forces), permitting ritual affects on the psychodynamics of the patient. Manipulation of spirit constructs is therapeutic because they represent fundamental aspects of self and others. Dramatic enactments of interactions with spirit “others” provide mechanisms for personal self-development and roles for individual re-socialization in the spirit symbolic systems. Identity modification occurs through internalization of social expectations, exemplified in animal allies and powers. These self-development activities are exemplified in the vision quest (or guardian spirit quest), which involves seeking a personal relationship with the spiritual world. These personal relations with spirit allies, powers, and guardians were central to the development of adult skills and competencies, providing personal powers, strength, and assistance in personal and social choices for adult life (Swanson, 1973). Animism, totemism, and guardian spirits are natural symbolic systems that differentiate and constitute the self in relation to others. Incorporating animal spirits as part of identity and powers reflects self-representation through “sacred other” (Pandian, 1997). Attribution enables reciprocal internalization of the other’s superior qualities, enhancing one’s self-esteem. These provide cultural processes for production of the symbolic self and self models for the resolution of social contradictions in the representation of the self. Shamanic dynamics

produce alternate forms of self for problem-solving and psychosocial adaptation. Spirit allies and identities provide variable agents to mediate conflict among social and personal goals.

CONTEMPORARY SHAMANIC ILLNESS AND HEALING

The psychobiological basis of the shamanistic paradigm is revealed in its persistence in contemporary religious experiences (Stark, 1997) and psychological crises. Shamanic dynamics are reflected in the DSM-IV category “spiritual emergencies,” which includes: spontaneous shamanic journeys; possession; the death and rebirth experience; mystical experiences with psychotic features; and experiences of psychic abilities (Walsh, 1990). The shamanic paradigm provides a useful framework for addressing these experiences as natural manifestations of human consciousness, and as developmental opportunities rather than pathologies. This reformulation permits addressing these powerful unconscious dynamics as opportunities for transformation to greater health, just as the shamanic initiatory crisis provides transformational potentials. Crisis experiences associated with shamanism—attacks by spirits, death and dismemberment, depersonalization, and out-of-body experiences—can be interpreted within the shamanic world view as growth opportunities. The shamanic paradigm re-interprets symptoms of acute psychosis, emotional disturbance, hallucinations, ASC, and interaction with spirits as symbolic communications for personal development. These can be managed by integrating shamanic healing principles into counseling and psychotherapy (Krippner & Welch, 1992). The psychobiological basis of these experiences within a model of evolutionary psychology permits treating these conditions as natural rather than aberrant. Shamanistic procedures elicit brain processes and structures that provide opportunities to develop control over these experiences, providing an alternative to traditional psychiatric treatment approaches with drugs that repress these experiences. Rituals and deliberate access to ASC allow for management of these distressing intrusions with experiences mediated by natural healing symbol systems. One aspect of contemporary shamanic healing involves “core shamanism” popularized by anthropologist Michael Harner (1990) and the Foundation for Shamanic Studies. This system is based in common principles and practices

of shamanism found worldwide. It acts upon the assumption that there is a non-ordinary reality that involves spirits and souls, and that compassionate spirits can be elicited to assist in human healing. Shamanic therapies are eclectic, taking a holistic approach in which they complement other approaches. They address soul loss, guardian spirit and power loss, spirit and object intrusion, and possession (Harner & Harner, 2000); shamanic treatments are also considered particularly effective for the treatment of the consequences of trauma, drug dependence, and mental and emotional illness. Shamanic therapies involve restoring and maintaining personal power through an alliance between the shaman and client that requires the latter's self-discipline and dedication. Relationships with the spirit world, particularly animal powers, are central to maintaining personal well-being.

Central aspects of the classic shamanic vision quest involved processes for self-empowerment. A similar approach underlies contemporary shamanic counseling and the training of the client to make a shamanic journey on his own to acquire or restore his personal power. This active aspect of shamanic journeying induces a sense of mastery and control. Harner (1988) characterizes shamanic counseling as "a method of personal empowerment wherein one comes to acquire respect for one's own ability to obtain spiritual wisdom without relying on external mediators" (p. 181). The shamanic healing approaches encompass virtually all spiritual healing practices (Harner & Harner, 2001); their emphases include using soul journey to treat spiritual aspects of illness through the assistance of spirit allies while in an ASC. Shamanism's biopsychosocial approach to healing integrates emotional, mental, spiritual, and social dimensions within a physiological framework.

SUMMARY

Shamanistic practices reflect ancient human traditions of healing through altering consciousness, manipulating identity and psychosocial dynamics through constructs represented in the spirit world, and eliciting the biopsychosocial dynamics of community support. These traditions are rooted in human psychobiology and brain dynamics, giving them a continued relevance in the contemporary world. The widespread persistence of these practices and their resurgence in the modern world is vibrant testimony to the continued relevance of shamanic

healing. These community-based spiritual practices may provide important antidotes to the contemporary malaise, alienation, and anomie among modern populations afflicted by violence, trauma, dislocation, and meaninglessness.

Political, Economic, and Social Issues

Disasters

Jody Glittenberg

IMPORTANCE OF UNDERSTANDING DISASTERS

Disasters, no doubt, have always been part of human history, long before literate societies emerged to record them, yet, in the 21st century they have become increasingly significant in shaping human societies. The ever-increasing global population tends to cluster around points of geophysical niches prone to natural disasters such as earthquakes, hurricanes, tornados, flooding, and droughts. And, the ever-increasing industrial use of energy, much of it non-renewable, promotes destruction of vital resources leading to potential catastrophes, such as global warming. The vulnerability of marginalized populations, such as refugees and migrants, has increased as many people are separated from long-standing socio-cultural support systems. Indeed, massive and rapid global communication and transportation capabilities make us, as a human village, more urgently in need of understanding disasters. Recognizing the importance and urgency of dealing with disasters wherever they occur, the United Nations declared the 1990s as the Decade for Disaster Reduction.

HISTORY OF RESEARCH ON DISASTERS

An early study in 1915 of two munition ships' collision in the harbor of Halifax, Nova Scotia, marks the beginning of disaster research in the United States by Samuel Henry Prince, a sociologist, who studied the process of recovery from the devastation that left 2,000 people dead and another 6,000 injured. When newspapers resumed publication it was used by Prince (1920) as a marker of the process. No attention was given to the pre-existing conditions nor to the cultural patterns surrounding the catastrophic event. In 1932 Carr suggested that a classification system of typing disasters as "localized" or "diffused," and whether they were "instantaneous" or "progressive," would be helpful in the study of the

nature and scale of such physical and social disruptions (Carr, 1932). Until after World War II, disaster research remained largely focused on the traumatic event and the geological and atmospheric causes. Most studies investigated ways to forewarn citizens and to control or reduce the damage.

A broader interest in the social aspects of disasters followed the human destruction resulting from the impact of atomic bombs at Hiroshima and Nagasaki. For instance, Anthony Wallace, an anthropologist, focused upon the organization of the community and the formal organization of the rescue and relief organizations. Using a time-space conceptual model, Wallace viewed a destructive tornado in Worcester, Pennsylvania, as a behavioral event in which the dynamics of the cultural system were enacted at both the individual and the community levels. He saw the interactive processes of the relief efforts as promoting conflict and transformation (Wallace, 1954). Fritz and Williams (1957), sociologists, and Wolfenstein (1957), a psychologist, related their studies to the collective behavior of human beings in disasters, and Baker and Chapman (1964), sociologists, pressed forward in viewing the interaction between man and society as it related to disasters. Drabek (1970), a sociologist, began studies of past patterns as important in research disasters, and Turner (1981) viewed collective behaviors and social movements in his disaster studies. Also important were the early and multiple contributions of Quarantelli, a sociologist who researched people and organizations under stress (Quarantelli, 1957, 1978). Medical systems emerged as a 20th century disaster relief force by transporting medical units of rapid, efficient aid to all parts of the world, and set into practice readiness training and triaging principles to reduce loss of life and destruction in times of catastrophe (Glittenberg, 1989). Stress and coping, so much a part of human adaptation to disaster, became important models for treating post-traumatic stress syndromes as sequelae of devastating events (Glittenberg, 1981).

Studies done during the early post-war era were concerned primarily with prediction of disasters, warning

systems, the immediate impact and the aftermath of catastrophes with little or no attention given to examining historical precursors or sociocultural patterns. Due in part to anthropologists such as Doughty (1971), Glittenberg (1981), and Oliver-Smith (1986), who each studied earthquake destruction in Central and South America, a new direction in disaster research emerged. Using diachronic and comparative methodologies of anthropology, they and other scientists began to view such catastrophic events within an ecological framework (Hewitt, 1983). Current research addresses human societies and their environments—physical, biological, and sociocultural—as inseparable entities in constant flux, and trying to retain equilibrium (Moore, Van Ardsdale, Glittenberg, & Aldrich, 1987). This mutually interactive ecological model is the most promising approach used in today's research of disasters.

DEFINITION OF DISASTER

“What is a disaster?” asked Quarantelli (1998), and 12 scientists responded; their views fall within two categories: (1) a disaster is an objectively identifiable phenomenon; or (2) a subjective, socially constructed process (Oliver-Smith, 1999, p. 22). The subjective definition is more useful to anthropology as it views a disaster as a socially constructed crisis in which the significance to the survival of the society is more important than the physical structures that were destroyed. This definition allows for a wide variety of disrupting events to be considered as disasters, such as a flu epidemic, a major earthquake, or the collapse of a banking system. Within the disruptive process, culturally prescribed ways in which people deal with the system collapse or societal readjustment can be studied and understood.

PERSPECTIVES FROM ANTHROPOLOGY

Anthropology as a holistic discipline includes several important concepts in its perspective on disasters, such as: (1) diachronicity, adaptation, and evolution; (2) the comparative nature of affected units including both micro and macro levels; and (3) the vulnerability and resilience of individuals and groups that are affected. Also, it is important to acknowledge that it is the groups' ethos that shapes the ways in which people respond to crises.

When under conditions of stress, it is the culture of a group that overrides individual reactions, as it builds group alliances in order to avert overwhelming stress. Hoffman (1999a) points out that disasters are instigators of essential change. She concludes that through anthropological research it is possible to gain a greater understanding of the basic sociocultural structure of a group in crisis, as deep cultural values and norms are exposed and made explicit.

Diachronicity, adaptation, and evolution are concepts that reveal conditions and processes adopted by populations to manipulate and use physical and social surroundings for their benefit. Making shelter, developing subsistence methods, evolving social institutions, and use of power are some processes that develop slowly over time in ways that have an adaptive ecological “fit.” However, a rapid shift in conditions, such as in a flood or earthquake, can quickly destroy those adaptive environments, so that immediate change is critical for survival. Long-held mores or beliefs may no longer be adaptive, and resistance to change can prove harmful or fatal. On the other hand, dangerous, shifting conditions may go unheeded by the people as they continue in their long-standing cultural, non-adaptive ways until the processes are so out of balance that dire conditions exist. Global warming is such a process that has been predicted by many scientists to be potentially harmful and perhaps fatal, yet the condition manifests itself so subtly on a daily basis that few seem to feel the need to alter their ways of using the environment.

Comparative nature of anthropological research is an important perspective as the nature and scale of physical events and sociocultural disruptions vary at the micro and macro levels of different social groups. Understanding the social forces at these levels can aid in understanding differential responses to catastrophe. The holistic nature of anthropology allows for comparison, analysis, and explanation of variation in response to a similar disastrous event. A good example of such a comparison is the Glittenberg study from 1977 to 1987 of four squatter settlements of about 15,000 inhabitants in each, following the 1976 Guatemala earthquake. Glittenberg (1987) found variation over the 10-year period in the lives of very poor, marginalized people who were all uprooted by the earthquake and needed to start new existences in squatter settlements. One highly energized, chaotic settlement leaped forward, raising their level of living to a new high, while another languished in anomie until outside assistance was

received. Another settlement suffered further demise as a new river (a result of the shifting land from the earthquake) further destroyed roads and agricultural land. The fourth settlement had mixed starts and stops depending upon the whims of unreliable leadership. Glittenberg concludes in this comparative study that a higher level of living, harmony, and balance were due to social forces including: democratic leadership, access to economic opportunity, and outside aid assistance (Glittenberg, 1989).

Vulnerability and resilience are characteristics that are key to understanding the consequences of disasters. These characteristics can be identified at the individual, household, and community levels, and the factors that contribute to these states of being include physical, cultural, political, and economic conditions. As Zaman (1999) points out, the vulnerability of a social system to natural disaster is determined by complex socioeconomic characteristics of a population that are not merely the physical or natural factors alone (p. 208). Glittenberg uses both the concepts of vulnerability and resilience in determining the protective and non-protective sociocultural factors in a small Mexican-American town, a center of drug-trafficking and violence. In exploring these concepts further, she urges sociohistorical forces that shape and create such communities be investigated. As a discipline, anthropology is at the forefront in studying such at-risk populations. For example, Glittenberg found that ethnic minorities, elders, female-headed households, refugees, and new immigrants, were all at-risk households (Glittenberg, 2001). The economic differences between classes are increasing and put the poorest class as the most vulnerable. Recent changes in corporate holdings, take-overs, and neoliberal economic policies have further increased the income gap between the poor and the rich in the United States. Oliver-Smith (1999, p. 91) notes, "It is well-documented that in the U.S. environmental risks and disasters' effects are distributed unequally by class, race, ethnicity, gender, and age."

Glittenberg found interesting patterns among the resilient households in the 1997–2001 National Institute on Drug Abuse funded study, noting that

resilient households are not more economically wealthy but rather they have more sociocultural support, as they are not among the migrating, undocumented people who live within the shadows of their uncertain shelters, looking for ways to counter their catastrophic displacement and fears of deportation. These vulnerable people are easy targets for the drug lords who are trafficking their own disasters. (Glittenberg, 2001., p. 2)

Such a description fits the definition of a disaster by Bates and Pelanda (1994, p. 149) who state, "Disasters occur when the limits of vulnerability of a system are exceeded." Thus, the perspective of anthropology in viewing the patterns of society that promote vulnerability is important as it permits finding ways to resolve the disaster by countering vulnerability and/or building resilience. It is the sociocultural process/event that when combined with conditions of vulnerability in a social group can result in a disruption that is viewed as a catastrophe or disaster. A society that continues to perpetuate vulnerability is indeed a target for disaster and this persistence may be seen as a condition of a society's total adaptational capability (Oliver-Smith, 1998b).

Aptekar (1994) in his monumental global perspective on disasters raises numerous moral issues related to bringing international relief to the most vulnerable states, the developing countries. As he notes, there are insufficient resources to reduce vulnerability in developing countries, and decisions are based on political factors regarding which disasters will receive relief. Aptekar claims there are 15 deaths related to disasters in developing countries to every one death in a developed country. For instance, a single flood killed almost 4 million people who lived on the Yellow River in China. This dangerous abode, he notes, was not occupied because the people were ignorant of the danger, but because the river was a source of their livelihood (Aptekar, 1994, p. 159).

METHODOLOGIES USED IN ANTHROPOLOGICAL DISASTER RESEARCH

Archeology, an anthropological method, provides an in-depth historical account by rebuilding the event through scientific reconstruction of the material culture. Through such material, social structure, political economic vulnerabilities, terrain, habitat, mortuary, and belief systems can be reconstructed through evidence left by the people. Material evidence sheds much light on how the group coped or met their demise. Chronicles and archives also bring to light how segments of the society compromised, coped, and evolved. These documents may reveal in minute detail how societies interpreted the meaning of these disruptive events.

Ethnography is the major anthropological research method used in disaster studies. Researching a society's pre-disaster conditions as well as its post-disaster ones has been part of ethnographic research, and although most disasters by their very nature are unpredictable, there are examples of data collected prior to a disaster that are used within the ethnography. Some of the known examples of pre-disaster ethnographic data are the Doughtys' long involvement and research in the Andes prior to the 1970 500-year earthquake (Doughty & the Doughty, 1968). And, another is Sheets' (1979) study of the volcanic activity prior to the eruption of Ilopango Volcano in 1987 or his other experiences in Mexico's volcanic regions in 1992 (Sheets, 1987, 1992). Glittenberg's study of fertility in Guatemala became the pre-disaster study upon which the level of living data were used to measure change following the 1976 earthquake in the highlands of Guatemala (Glittenberg, 1976). Ethnography as a research method is diachronic and holistic. The social life of a cultural group is documented by extensive fieldwork gained from living with the people and studying their patterns of coping, and expressions of meaning. Glittenberg documents in her 1994 ethnography some of the myths and legends that appeared following the 1976 earthquake as examples of peoples' interpretations of and meanings given to these events (Glittenberg, 1994).

Decontextualizing the narratives gained from ethnographic interviews is another source of data in the study of disasters. Hoffman's vivid picture of her own experience of being a victim of a firestorm that swept the hills where she resided in Oakland, California, on October 20, 1991, is an emic view that adds interpretation to the phases of individual coping and recovery. Her sensitivity to the conflicts and frustrations encountered by victims contributes a unique model for understanding cross-culturally and by gender the phases of coping with a catastrophic event (Hoffman, 1999b).

A CASE STUDY: THE 1976 NSF GUATEMALA EARTHQUAKE

Case studies are often used in anthropology to elucidate theory and illustrate practical applications. There are numerous case studies that could be used in this entry, such as Oliver-Smith's study of Peru's 500-year earthquake, as also written about by Doughty (1999) in his 18-year coverage of that same earthquake. Another

important viewpoint is found in Button's study of the media response to oil spills in Great Britain. In respect to the brevity of this entry, it is suggested that the reader accesses a very comprehensive, excellent book edited by Oliver-Smith and Hoffman in which these and other case studies are described. The title is *The Angry Earth* published by Routledge Press in 1999.

The case study that will be described is the 1976 Guatemala earthquake, as I, Glittenberg, was a Co-Principal Investigator along with Frederick L. Bates, a rural sociologist, Principal Investigator, and Timothy Farrell, also an anthropologist and a Co-Principal Investigator. The study was funded for over \$1 million dollars in 1977 and extended through 1982. Following the termination of the NSF study little formal work was done due to the civil war that was growing in intensity, especially in the highland research sites. I returned to selected sites to update my findings on three occasions, 1987, 1992, and 1998. The official title of the NSF Study was *A Longitudinal and Cross-Cultural Study of the Post Impact Phases of a Major National Disaster, 1977–82*. The study was housed at the Instituto Nutricion de Centro America y Panama (INCAP) in Guatemala City, the University of Georgia (Bates), and the University of Colorado (Glittenberg).

Synopsis of the Event

Sleeping Guatemalans were unprepared for the massive natural disaster that struck at 3:04 a.m., February 4, 1976, measuring 7.5 on the Richter scale. In a Republic with 5.2 million people, within 35 seconds nearly 25,000 lost their lives and 75,000 were seriously injured. A million people were left homeless as the deadly earthquake demolished their adobe houses. Throughout the Republic, few families were unaffected. Heaviest damage was in the western highlands and along the Motagua River leading to the Caribbean coast. In Guatemala City, the capital, with a population of almost one million, 200,000 were left homeless, and many other houses were severely damaged. Tents and makeshift shelters of plastic sheeting, tin, and cardboard became home for many, well into the first year after the disaster. As the disaster struck in the middle of winter, cold weather was an ever-present reality, and the monsoons began by mid-May. Mortalities related indirectly to the disaster occurred long into the second year, including drowning of infants in the rushing monsoons when their flimsy shelters left them unprotected,

and others died as the result of various infections carried through contaminated water systems.

Glittenberg, who had done field work in the western highlands for her doctoral dissertation only months before, returned two days following the earthquake as part of the Salvation Army rescue team. This team was one of over 100 relief agencies that sent people and tons of emergency supplies immediately into Guatemala City. The influx of relief workers was seen by some local people as another “disaster.” Many left after delivering their emergency supplies, but others stayed, some as long as five years, to give long-term recovery aid.

Guatemala had been the scene of many natural disasters in the past, and so it had an Emergency Plan in place to deal with such events. This Plan proved to be invaluable, and it could be used as a model for other disaster-prone areas. At the first warning of the earthquake, the Plan went into action, and all electricity in the capital was shut down; this action probably prevented many fires. However, an electrical generator at INCAP, used to ensure that fragile research projects would not be affected by the whims of an unreliable public electricity system, remained running and unfortunately a major fire resulted, destroying valuable research projects as well as the superb research library.

The Emergency Committee (eventually renamed the Committee for Reconstruction) had a far-sighted, long-term plan as to how relief aid could reach the most needy and in an equitable fashion. Each town and village, each departmental center, and sections within the capital were given a sponsorship, drawn by lottery, of a country or relief agency, such as Norwegian Red Cross, or a country, such as Puerto Rico, to assist them in reconstructing their habitats. That country or agency then became the donor and manager of the recovery process of their assigned unit. The Committee for Reconstruction centralized information, and through this process held weekly meetings in the capital to which an elected representative from each unit, such as a town, came. Each unit had its own elected committee of reconstruction and the elected representative for the national Committee. As the plan was carried out, this process led to strengthening civil participation in decision-making and had far-reaching repercussions beyond the disaster event.

Structure of the Research Team

Glittenberg and Farrell met at INCAP during the first week following the earthquake; they had not known each

other before, but both were deeply involved in the lives of Guatemalans and saw the disaster as an opportunity to study the process of recovery. Bates, a seasoned disaster researcher, was quickly recruited to be the Principal Investigator and thanks to the enthusiasm of another disaster researcher, George Baker, a Program Manager at NSF, the study was funded. Baker saw great potential in such a study of how aid was sent, received, and the overall benefit to a developing country. A research team of 25 Guatemalans was hired and trained, and all but one (who left to marry in Spain) remained for the full course of the five-year study. These researchers included a field supervisor, household interviewers, mappers, and data entry people. Numerous doctoral students were given field work opportunities. The original data are still held at the University of Georgia, Athens, Georgia.

The research plan was to test the hypothesis presented by Prince in 1920 that a disaster would stimulate change. The major research question was: Is the level of living increased following a disaster? The level of living was defined as a composite score of culturally appropriate material goods/wages or income, found/or not found in the households over a five-year period of time. The amount of damage to the dwelling as well as the amount and type of aid received were also figured within the index of the level of living of each household. Numerous research strategies were used to build a case study of how a nation coped and recovered from a devastating national disaster. The following research strategies were used in the study: a 1,400 random household survey with three waves of interviewing; ethnographies, including community inventories, of each research site; in-depth interviews of relief agency leaders; and collection of life histories and narratives of the earthquake.

A representative sample was purposively set up to match the characteristics of the population of Guatemala. There were 19 research sites (where damage and loss of life were heavy) and seven control sites (where there was no notable damage or loss of life). Inhabitants within Guatemala City, the capital, had no comparative control site, so four squatter settlements, of about 15,000 each, were chosen for comparison, as two were largely Indian and two were Ladino. Other characteristics of the random sample were equal units of Ladino and Indian populations in both highland and lowland areas. Pre-disaster data were available in a few sites from a recent INCAP study and from Glittenberg’s dissertation data. Three waves of interviews were done on the 1,400 household random sample

in order to study diachronically the process of recovery. The units of population matched from small village, small town, medium to large towns along the parameters of ethnicity, and geographical location.

A short summary of the findings is all that is possible here, but they are significant in understanding the principles of effective disaster relief. The size of the population did affect the changes in level of living, as the smallest units, the villages, and the large towns fared the least well in recovery. It was reasoned that these units simply did not receive an equal amount of outside relief aid, and it was speculated that the remoteness of some villages and the lack of organization in the large towns prevented intimate, face-to-face linkages with relief agencies. Small towns and the capital received the most aid, probably because of access to roads, and to frequent relationships with relief agencies. These factors probably made cooperation and commitment more focused and accountable. Leadership in the sites was a critical factor, and although recovery was continuous, the interruptions due to conflict resolution were often barriers to a smooth process of recovery. Sites where a democratic process was retained were the most progressive, but also where individual liberties were supported. One example was Sanarate, a small Ladino town in the lowlands supported by Jewish Relief Services. This town progressed rapidly as supplies were plentiful and equally distributed, and they had good access to public roads. New roles were found as Sanarate Ladino women became actively involved in rebuilding their homes, as modeled by Israeli women builders.

The question of interfering with the local economy through disaster relief was answered clearly by the study. All supplies were needed; food and shelter, in particular, were in short supply well into the second year. People were hungry and the local food supply, such as beans, was insufficient to feed them. The local bean production was undiminished and profits remained at a pre-disaster level. Strong controls were in place by the government in order to keep the prices of materials and foods from sky-rocketing. The study concluded that the disaster relief food and shelter supplies were needed. The types of housing that proved the best investments over a five-year period were the stronger, earthquake-resistant dwellings that were culturally appropriate. The quickly built wooden shacks and the tent cities were meant only for short-term shelter, and in the long run, the wooden shacks were the least cost-effective.

The way the relief supplies were delivered was found to be more important than the actual supplies. For

instance, those relief agencies that gave away supplies were found not to be as effective over the long haul, as they did not build the infrastructure essential for long-term functioning. One of the most effective groups worked carefully with a local planning committee over a six-month period of time before building *one single house*. The infrastructure of the settlement was carefully laid out, and the lotteries drawn openly for the individual lots. Grants permitted the people to buy their own land and dwelling with a 20-year payback system at very low interest rates. The local governing board was headed by women and much of the construction was done by them while their husbands worked a long distance from their homes. In 2001 the settlement, *Carolingia*, was a thriving suburb of the capital with high schools, a technical college, a television station, and two factories. The homes were all occupied and most have been improved upon, showing a sense of pride in ownership. The actual household survey did confirm the hypothesis made by Prince, in 1920, that a disaster does stimulate change, and in this case an increase in the level of living.

Other changes spawned by the disaster clearly are visible as one studies Guatemala in the 21st century. Some writers conclude that the earthquake was a watershed event that increased a disaster of another kind—the 35-year civil war, a scorched land, and a reign of terrorism (Green, 1999). Others have claimed that the earthquake brought new religions into awareness and created a new evangelism. From seeing the vast number of factories and new industries that were spawned and the agribusinesses in the highlands, the earthquake did spawn conflict and transformation (Annis, 1987; Brydon & Grant, 1989; Petersen, 1992; Watanabe, 1992). Other changes include the indigenous rights movement, with the Nobel Peace Prize awarded to Rigoberta Menchu, an indigenous Guatemalan woman, for her role in drawing attention to the abuse of human rights not only in Guatemala but throughout the world (Menchu, 1992). Analysis of all these changes is beyond the scope of this entry, but it can be noted that the disaster brought into play new leaders and new ideas came from outside relief workers.

CONCLUSION

A disaster occurs when the sociocultural structure of a group is vulnerable and an event overwhelms the limits

of that system. Looking at such an event cross-culturally, holistically, and diachronically through a cultural meaning lens is the approach anthropology takes to investigate disasters of all types. The study of disasters and the processes of recovering is a fertile field for anthropologists who can use such situations to develop theory and practice related to adaptation and survival.

Health and Economic Development

Arachu Castro and Paul Farmer

WHAT IS ECONOMIC DEVELOPMENT?

Development

A bridge with no river.

A tall facade with no building.

A sprinkler on a plastic lawn.

An escalator to nowhere.

A highway to the places

the highway destroyed.

An image on TV of a TV

showing another TV

on which there is yet another TV.

Eduardo Galeano

Most development paradigms are evolutionist and rest on a belief in the inseparability of a number of processes. As societies “evolve” toward higher degrees of technical, economic, demographic, and political complexity, improvements in health and education necessarily follow for the majority of the population.

The roots of modern theories of economic development can be traced to European social theory of the 18th century. In the early part of the century, Claude Henri de Rouvroy, Comte de Saint-Simon, set forth an organicist theory of social order. Blending scientific naturalism and the rationalism of the Enlightenment, this theory introduces the concept of an orderly progression of civilizations toward increasing levels of technological and economic advancement. Later in the century, a number of economists and philosophers—including Adam Smith, Thomas Malthus, Friedrich Hegel, and Jeremy Bentham—further promoted the idea of the

teleological evolution of societies. They were followed in the 19th century by figures such as Auguste Comte (1830), Herbert Spencer (1852), Karl Marx (1857/1964), Lewis Henry Morgan (1864/1965), and Fredrick Engels (1884/1902), who classified societies into different stages of development: evolution from one level to the next was considered a necessary step toward progress. This concept of evolutionary determinism was further developed by Darwin (1859/1964) in the biological sciences.

Development, originally grounded in these ideas of progress and social evolution, could be achieved through technological achievements that could bring poverty—which was often termed “underdevelopment”—to an end. The management of poverty, as Escobar has noted, “called for interventions in education, health, hygiene, morality, and employment and the instilment of good habits of association, savings, child rearing, and so on” (Escobar, 1995, p. 23). In Europe, Asia, and in parts of the Americas, this new domain of social intervention (often at the national level) laid the groundwork for the developmentalist projects of an emerging social field: “international development.”

International development endeavors have deep roots in the colonial projects of several European societies, but many such endeavors had an internal logic of their own. In Europe and the United States, only a few private institutions (such as the International Red Cross) had begun foreign assistance programs by the 19th century. The early 20th century saw the emergence of a number of philanthropic institutions, including the

Rockefeller Foundation, the Near East Foundation, and the Institute of Inter-American Affairs, with the express goal of promoting development (Cueto, 1994; Pillsbury, 1986, p. 21).

The real proliferation of international development programs began in the aftermath of World War II (Foster, 1962, p. 177). As the 20th century proceeded, a number of events and processes reshaped the foreign-policy objectives of wealthy countries: the rapid industrialization of Europe and North America, the reconfiguration of world powers and the dissolution of colonial empires in the aftermath of World War II, and the changing economic and political relations between newly independent nations and former colonizers. International assistance programs to promote economic development in poor countries became a common mechanism through which industrial powers were able to maintain strong ties with their former colonies. These ties of dependency enabled wealthy countries to continue exerting geopolitical leverage over, extracting natural resources from, and securing favorable trade ties with formerly colonized poor countries.

Today, tens of thousands of economic development programs operate in countries throughout the world. These include programs created and funded by international agencies or non-governmental organizations (NGOs); programs initiated, paid for, and implemented by a single country donor or private foundations; and internally funded domestic programs. A large number of community-based organizations and solidarity projects also engage in health and development efforts.

The United Nations, created in 1945, established the Economic and Social Council as the chief institution to promote

higher standards of living, full employment, and conditions of economic and social progress, and development; solutions of international economic, social, health, and related problems; and international cultural and educational cooperation; and universal respect for, and observance of, human rights and fundamental freedoms for all without distinction as to race, sex, language, or religion. (ECOSOC, 1945)

Since its inception, the United Nations has officially recognized the link between health and economic development in pragmatic terms. However, this link is not always made explicit, nor are the goals of major health and development organizations always compatible. Institutions affiliated to the United Nations, such as the World Bank, the World Health Organization (WHO), or

the United Nations Development Program, operate independently and often with discordant aims.

The World Bank, although originally established to help rebuild Europe after World War II, began focusing its efforts in the 1960s on economic development in low-income countries. With developmentalist ideologies rooted in evolutionary notions of progress, such as those proposed by Rostow (1960), the World Bank's principal indicators of economic development and well-being became annual per capita income and gross domestic product (GDP). The assumption was that improving the GDP of poor countries would lead directly to improvements in health and education. Addressing social inequalities within and between nations—redistribution of resources—was not part of the equation.

Other UN agencies looked at the problem of economic development from different perspectives. In 1978, WHO and UNICEF organized an international conference on Primary Health Care with the stated aim of placing health indices, rather than GDP, at the center of the development process. The primary health care (PHC) movement sought to promote community-based responses to common health problems, especially maternal and child health, nutrition, family planning, water and sanitation, control of infectious diseases, and health planning. By the 1980s, primary health care became one of the primary recipients of funding from donors in North America and Europe.

In part as a reaction to the World Bank's uncritical promotion of economic growth—measured in terms of GDP—as the solution to poverty, and drawing on Amartya Sen's economic theory (Sen, 1975, 1981, 1984, 1985), the UN Development Program (UNDP) launched, in 1990, the *Human Development Report*. The report suggests that social and health measures, including literacy and life expectancy, must be considered in conjunction with GDP, since that latter index tells little about the health and well-being of the poor or about the distribution of wealth within a given society or nation. The report demonstrated that, in some settings, GDP might rise even as did the percentage of people living in poverty. In 1993, the World Bank's *World Development Report* acknowledged that economic growth per se did not necessarily improve health indicators; instead, good health was identified as a prerequisite to economic development. This understanding has gained ground in recent years. The WHO's landmark study *Macroeconomics and Health: Investing in Health for*

Economic Development spells out the consequences of skimpy investments in public health:

as with the economic well-being of individual households, good population health is a critical input into poverty reduction, economic growth, and long-term economic development at the scale of whole societies. This point is widely acknowledged by analysts and policy makers, but is greatly underestimated in its qualitative and quantitative significance, and in the investment allocations of many developing-country and donor governments. (WHO, 2001, pp. 21–22)

The British Development Act of the 1940s, created to restructure relations between colonial powers and newly formed nations, was a precursor to the international assistance programs developed after World War II. The French government established the *Agence Française de Développement* at the same time, and focused initially on their colonies, which were soon to declare independence but remain recipients of such aid. As Japan recovered from World War II, it too began using international aid to maintain political and economic influence in former colonies or administered territories. Gradually, Japan has expanded its aid beyond Asia to become, since 1989, a major bilateral donor. In 1957, the European Community launched its international assistance programs to sub-Saharan Africa, the Caribbean, and the Pacific. Shortly thereafter, the United States and the Soviet Union began using development assistance as foreign-policy instruments with the geopolitical goals of gaining increased international power and fostering “capitalist” and “socialist” spheres of influence, respectively. In 1964, the U.S. government launched the International Cooperation Administration, the predecessor of the Agency for International Development (USAID).

Several countries now provide aid earmarked specifically for the health sector. Ranked by annual average commitments in health for the period 1996–98, these include Japan, the United Kingdom, Germany, the Netherlands, Spain, France, Denmark, Sweden, Australia, Belgium, Norway, Canada, Switzerland, Italy, Austria, Finland, and the United States (OECD, 2000, p. 6). For the same period, the top 10 recipients of health-specific aid were India, Bangladesh, Vietnam, China, Ethiopia, Egypt, Tanzania, Indonesia, Uganda, and Kenya (OECD, 2000, p. 9). Of the 22 countries on the OECD’s Development Assistance Committee, 17 give less than 0.5% of their gross national product (GNP) in foreign aid, and 11 give less than 0.3%—and most gave less in 2000 than in 1990 (UNDP, 2002, p. 30).

Currently, the private foundations most influential in the area of international health are the Bill & Melinda Gates Foundation, the Wellcome Trust, the Open Society Institute, the Rockefeller Foundation, and the Ford Foundation. In addition, although it operates almost exclusively in Asia and East Africa, the Aga Khan Foundation, established in 1967, is another influential international development agency seeking to promote social development by concentrating on health, education, and rural development.

The shortcomings of basing development solely on economic growth became most evident in the 1980s, particularly in Latin America and Africa. During this “lost decade,” economic growth in many countries in Latin America decreased (Escobar, 1995). Structural adjustment programs (SAPs), imposed by the International Monetary Fund and the World Bank, led to sharp cuts in social spending, including health outlays. Consequently, many countries in Latin America and many in Africa underwent “health sector reform, including a revamping of the resources, actors and institutions related to the financing, regulation, and provision of health and other activities whose primary intent is to improve or maintain health” (Murray & Frenk, 2000, p. 718). These reforms, distinct in each country, were often influenced by neoliberal ideologies, which tended to depict health services as a private good. These ideologies justify their focus on the cost-containment of public health spending and the promotion of increased private sector involvement in the provision of health services (Castro et al., 2003; Iriart, Merhy, & Waitzkin, 2001; Laurell, 2001). Instead of helping to improve the health of populations, these health privatization efforts often increased social inequalities and worsened health outcomes, especially among the poorest (Kim, Millen, Irwin, & Gershman, 2000). At the same time, economic crises in much of the developing world exacerbated social inequalities and increased the demand for health care services, especially among the newly impoverished lower-middle classes. Displaced by this group, the poorest of the poor were, in many instances, denied access to basic health services. Nonetheless, many developing governments increased spending in services that met the demand of higher income groups (Vinocur, 1997, p. 12), partly through U.S.-based health care corporations that are exporting managed care as they come under increased scrutiny at home (Waitzkin & Iriart, 2001, p. 497, cited in Rylko-Bauer & Farmer, 2002).

ANTHROPOLOGISTS IN HEALTH AND ECONOMIC DEVELOPMENT

During the 1930s, many anthropologists worked in educational and medical welfare programs within colonial administrations (Montgomery & Bennett, 1979, p. 128; see also Asad, 1973) in Africa and Asia. Their express goal was, often enough, to protect the health of English and French colonial administrators. In the 1940s, these early projects were expanded into development assistance programs linked to the idea that technology would solve the economic underdevelopment of poor countries. Public health professionals expected that people in poor countries would accept the medical interventions of the colonial powers. When such efforts failed to yield results, many European health experts began seeking the assistance of anthropologists in order to comprehend native cosmologies and local understandings of health and healing. The stated goal was to understand why biomedical ideas and therapies were not readily accepted (Moore, Van Arsdale, Glittenberg, & Aldrich, 1987, p. 9; see also Paul, 1955).

In the 1950s, applied medical anthropologists were engaged in international public health to examine “cultural barriers” to health promotion and health campaigns and to design health programs that would be deemed culturally appropriate by local populations (“the natives”). Their role was to interpret community structures and help foreign or foreign-trained health technicians to implement top-down development programs (Farmer & Good, 1991, p. 137). There was, at the time, little critical reflection on the purpose of such programs or on the perceived needs of the populations the programs sought to serve. Studies of traditional healers, including birth attendants, proliferated at this time. Later, the anthropologists who produced such work were criticized as being “handmaidens” of biomedicine and cheerleaders of the Western “medical industrial complex.”

By the 1960s, it was acknowledged that development work involved social processes so complex that technology alone was insufficient to solve the “underdevelopment” of poor countries (Foster, 1962). Soon, macro-economic growth became the professed solution, and the urban and industrial sectors became the focus of many development programs. Because anthropologists had been working largely on rural and community development programs, few of them remained involved in development

work, although the field of medical anthropology was growing rapidly, especially in the United States (Pillsbury, 1986, p. 12).

During the 1970s, an exclusive emphasis on economic growth revealed itself to have its own limitations. Many actors—from policy-makers to researchers to peasant populations—argued that increasing social inequalities often followed increases of GDP. Some medical anthropologists were very critical of development programs, and directed their critiques at both the technical and the economic growth “solutions” to development.

A second strain of criticism of the “economic growth solution” came from dependency theory (Cardoso & Faletto, 1969/1978; Dos Santos, 1970; Prebisch, 1949) and world systems theory (Wallerstein, 1974). Both models allowed that the end of colonialism changed the political structures of relations between citizens of former colonies and administrators. However, the structure of economic relations, based on “free trade” and limited governmental involvement, was maintained and contributed to persisting inequalities between and within countries. Critics argued that the “economic growth solution” relied on several mistaken assumptions. One of the symptoms of growing economic inequalities was the persistence or “reemergence” of diseases that had been previously slated for eradication.

At the same time, the primary health care movement, based on community involvement and upon the concept of rights, opened the door for participation on the part of anthropologists in the design, implementation, and evaluation of PHC (Pillsbury, 1991, p. 66). George Foster encouraged the involvement of anthropologists in the health-policy arena by studying the bureaucratic structures and personnel of the development agencies themselves (see Foster, 1977; Tandler, 1975). The contributions of anthropologists to the development field were enhanced by improvements in the theory and methodology of anthropology, mainly the emergence of subfields devoted to problem solving in the areas of health, education, or agriculture. Studies of the impact on poor or otherwise marginalized groups of central decisions about health and social policies were also initiated.

In the 1980s, the participatory approach, enhanced by the primary health care movement, became a cornerstone of many development programs designed to be equitable. It was based on the idea that the lived experience of people (“putting people first”), and not GDP indicators, needed to be central to the conduct and evaluation

of development programs (Cernea, 1985; Justice, 1989). People-centered development became one anthropological approach to economic development (Pillsbury, 1986, p. 22), a heterogeneous social process often informed by an interest in human rights (Bennett, 1996, p. S32) or in redressing gender inequalities (see Boserup, 1986).

By that time it had become increasingly clear that many of the health and social problems facing the world's poor populations were not in fact due to endogenous cultural factors but rather a complex series of push-pull forces that were undermining rural and small-scale economies, leading to urbanization and a decline in health status even as poor people took up wage labor. Furthermore, it also became clear that integration of poor communities into national and international economies does not necessarily improve their living conditions, and that economic prosperity and the ability to become consumers in a global market are not universal human goals. Finally, the growing social inequalities between and within countries have, in the absence of a social justice agenda, proven to be formidable barriers to the promotion of modern sanitation and health care. At the close of the last century, there was often more interest in studying inequalities of access to technologies than in remediating them.

In the 1990s, critical medical anthropologists started to explore current and past socioeconomic and political processes, to examine "how illness representations serve to represent and misrepresent power relations within a society" (Farmer & Good, 1991, p. 144), and to identify and expose structural forces that undermine the health of poor and marginalized groups. Anthropologists also began to study the role of international health institutions "managing inequality" rather than addressing the growing gap between rich and poor and the "outcome gap" necessarily associated with growing inequality (see Baer, Singer, & Susser, 1997; Donahue, 1989, 1990; Farmer, 1992, 1994, 1999; Farmer & Castro, 2002; Farmer, Connors, & Simmons, 1996; Farmer et al., 2001; Kim et al., 2000; Morgan, 1993, 1998; Singer, 1997; Stebbins, 1993; Whiteford, 1992, 1993, 1998; Whiteford & Manderson, 2000).

WHERE TO GO FROM HERE?

Many models of economic development rest on unexamined colonial and neocolonial assumptions and should be

interrogated by research able to link local social processes to large-scale structures long in the making. Alternative models of transformation based on social justice with cooperative, collaborative approaches have been advanced. In such models, success is measured in terms of health and education outcomes as well as equitable distribution of and access to resources. The health of the poor is given priority, and the language of social and economic rights is central to this model.

With deep knowledge of local health effects of many economic development endeavors and approaches, as well as local systems of meaning, medical anthropologists are in a position to encourage novel ways of promoting just, equitable development. The dimensions of the global AIDS pandemic, which has in the course of the past two decades become the leading single infectious cause of young adult death in much of the world, brings the shortcomings of past approaches into sharp relief.

Homelessness

Irene Glasser and Rae Bridgman

The field of anthropology has contributed much to documenting the condition of homelessness, with the goals of easing the lives of those who are homeless, and pointing to ways of preventing and eradicating homelessness. Anthropology's theories, methodologies, and modes of analysis make it especially suited to unearthing the subtleties of homelessness. As one of the most visible indicators of poverty, homelessness confronts communities with their inability to offer everyone the most basic conditions for a healthy and productive life.

DEFINITIONS AND THEORIES OF HOMELESSNESS

A widely used conceptualization of homelessness developed by Peter Rossi (Rossi, Wright, Fisher, & Willis, 1987) distinguishes between the *literally homeless* (persons who obviously have no access to a conventional dwelling and who would be considered homeless by any conceivable definition of the term) and the *precariously or marginally housed* (persons with tenuous or very temporary claims to a more or less conventional dwelling

or housing). This distinction can be used in studies of the visibly homeless (those in homeless shelters and living on the streets, in encampments, in abandoned buildings, and in places such as subway stations) and the precariously housed (those doubled-up temporarily with other, usually poor, families, or those paying daily or weekly for inexpensive lodging). How widely one casts the "homeless net" has a tremendous impact on the numbers and characteristics of the people included in the definition of homelessness.

Anthropologists try to use the self-appellation of the group under study. However, there are many individuals without permanent housing who would not necessarily define themselves as "homeless," a term which suggests the stereotype of an elderly man or woman, alone in the streets, with their shopping carts and wearing layers of clothing. In addition, cultures have different words for the concept *homeless*, each with different and sometimes subtle connotations.

Industrialized nations tend to view homelessness as a result of *personal* problems (chronic alcoholism or drug misuse), or as a result of the deinstitutionalization of the mentally ill, in concert with the gentrification of urban

housing and decreased government support for social housing and welfare (Glasser, 1994). Developing countries view the etiology of squatter settlements as rural-to-urban migration. In India, for example, the term for people living outside without shelter is *roofless*, a term that does not imply the social pathology so often associated with the word *home-less*. On the other hand, for many years in Finland the word for homeless was *puliukko*, which implies alcoholic.

One way to confront the problem of defining homelessness is to think of homelessness as the opposite of having adequate housing—shelter that is physically adequate and affordable, where people are free from forced eviction, with protection from the elements, potable water in or close to the house, provision for the removal of household and human wastes, site drainage, emergency life-saving services, easy access to health care, and within easy reach of social and economic opportunities (the Limuru Declaration cited in Turner, 1988).

METHODOLOGIES FOR THE STUDY OF HOMELESSNESS

Through undertaking extended fieldwork and using holistic and cross-perspectives, anthropologists attempt to understand what drives individuals to life on the streets and to shelters, and what prevents them from gaining permanent and secure housing.

Ethnography, a hallmark of anthropology, involves entering a culture, learning about it, and, as much as possible, communicating a “native” point of view to a wider public. The “insider’s” ethnographic approach attempts to avoid the a priori categories of other disciplines, and therefore enables us to see the world through the eyes of the homeless themselves. Anthropological research on homelessness then becomes a good complement to the research of sociologists, psychologists, and public health professionals who often utilize the one-time interview method.

In order to enter the world of the homeless, it is necessary to develop various approaches to the challenging task of invading the private space of a person whose life is conducted so often in public view. For example, working in a metropolitan airport, Kim Hopper would offer food and coffee to the individuals who slept in the airports and who tried to blend in with the travelers there. He was especially interested in why people preferred the

airport to the public shelter and how they managed to survive. Sometimes, for those who were badly disoriented and sick, Hopper would arrange for placements with agencies in the city, but most of the time he concentrated on understanding “the native’s point of view” (Hopper, 1991).

A very useful technique that has been employed in homelessness research is *triangulation* or obtaining multiple perspectives about the same person (e.g., interviews complemented by extensive observations). A good example from the work of Koegel (1992) is the self-report of a homeless man on the street who maintained that he used no services, despite living on the street full-time. As a member of the research team tagged along with him one Sunday, they observed him obtaining an entire week’s worth of food from a mobile feeding program, which he put in his ice chest (well-camouflaged inside a tattered box), thoroughly belying his claim of “no contact.”

DOCUMENTING SURVIVAL STRATEGIES

Perhaps anthropology’s greatest contribution to our knowledge of homelessness has been in describing and understanding the methods of adaptation and survival in life on the streets and in the shelters. The thick, ethnographic descriptions of the daily rounds of the homeless have brought the concept of “the street” to life in these studies.

Skid Row Studies

One of the first contemporary examples of homelessness research was the work of Spradley (1970). Utilizing participant observation and methods of linguistic anthropology, Spradley was able to document the broad array of adaptive strategies used by men on the streets of Skid Row in Seattle, Washington. He sought to understand why the men who spent so much time in the “drunk tank” of the local jails, immediately returned to drinking and to the streets upon their release. Twenty years after Spradley, Cohen, and Sokolovsky (1989) turned their attention to the survival strategies of older men on the Bowery. Their study was characterized by more statistical rigor than earlier skid row studies: approximately 10% of the estimated 2,700 men over age 50 living in flophouses, apartments, and on the surrounding streets of the Bowery were sampled during the study period of 1982–83.

The methodology of the study involved participant observation, intensive interviewing, and semi-structured questionnaires utilizing previously tested measures of physical, mental, and socioeconomic well-being, as well as measuring the degree of social interaction of older people. They were most impressed by the intense reciprocal sharing of resources among the men on the Bowery. The social and material support the men got from each other served as a buffer to the harsh life on the streets and in the flophouses.

Life on the Streets

Contemporary studies of the life on the streets of homeless people can be said to have begun with the work of Ellen Baxter, a psychologist, and Kim Hopper, an anthropologist (Baxter & Hopper, 1981) in New York City. Although many of the people on the street interviewed in this study appeared to have mental health problems (e.g., talking loudly to themselves, telling the interviewers about imaginary people), Baxter and Hopper pointed out that the daily stresses of life on the street can themselves be mentally exhausting and disorienting. Rather than seeing mental illness as a *cause* of homelessness, Baxter and Hopper see symptoms as the *effect* of life on the streets and in shelters. In fact, the symptoms of mental illness expressed by many homeless (e.g., pacing, rummaging through the garbage, talking to oneself) can be difficult to distinguish from behaviors that may arise as survival adaptations to homelessness. Acting “crazy” may be an effective adaptive strategy for keeping other people at a distance.

Jennifer Wolch, a geographer, and Stacy Rowe, an anthropologist, documented the mobility paths of the homeless in the Los Angeles area as they made their way in search of food, income, social support, and rudimentary shelter (Wolch & Rowe, 1992). Their time-space maps could then be used as a guide about where to position services for the homeless. This research indicates that when the person was not successful in meeting daily needs for food, shelter, and camaraderie, long-term goals were often sacrificed.

Panhandling

A common method of survival on the street is panhandling, or begging for money. There are few anthropological studies on begging, which is perhaps surprising given the attention of anthropologists to life on

the streets. An early and excellent study of begging in Chiapas, Mexico, was conducted by Horacio Fabrega, a psychiatrist and anthropologist (Fabrega, 1971).

Fabrega studied the phenomenon of begging in San Cristóbal by means of participant observation, interviews, gathering life histories, and, in some cases, performing medical evaluations on over 80 beggars. There appeared to be a relationship between a person’s physical disability and his characteristic manner of asking for alms. The people with obvious physical disabilities needed only to sit or stand next to the doorway of a church, with hand extended or a plate next to them. Those without an obvious disability had to do more to convince a potential donor of their need for charity.

Twenty-five years after the San Cristóbal study, Williams (1995) sought to observe begging in two U.S. cities, New York and Tucson, Arizona. Her mission was not to conduct a systematic study, but rather to become a more informed “fellow citizen” in a society where panhandling is no longer confined to skid row. Williams described three types of beggars: the “character beggars” who impressed listeners with their stories and personalities; the “brother-can-you-spare-a-dime” beggars, whose interactions with fellow urbanites were brief and whose stories were minimal; and the “will-work-for-food beggars.” As in Fabrega’s observations, beggars underlined their lack of any alternatives, had an obvious disability (though not necessarily a permanent one), and invoked God in their expression of gratitude.

Getting Food

By the 1980s, soup kitchens and food banks, once called “emergency” feeding programs, had dropped the word emergency from their titles and become a part of the contemporary landscape in North America. Soup kitchens, serving a hot noontime meal or evening dinner, and sometimes serving breakfast as well, have come to be relied upon by people who live on the streets and in shelters (shelters typically do not serve meals during the day).

Soup kitchens and food banks have become so institutionalized that levels of government now depend on them to supplement meager social assistance, people in need of doing community service and charity work depend upon their existence to fulfill their commitments, and poor people (most of whom are *not* homeless) depend on them for a hot meal and food supplies. Glasser (1988) described a soup kitchen that served a daily hot meal to

over 100 “guests” (as soup kitchen clients are typically called) each day in a “no-questions-asked” setting. With very few staff members and many hours of operation during which guests could drink coffee, smoke cigarettes, and socialize, this was a setting in which poor people created their own set of rules and ambiance, and help in times of crisis.

Working in food banks and soup kitchens in Delaware, Curtis (1996) noted that some food policies and programs directed at the poor originated not because of the nutritional needs of the poor, but out of a quest to find nonmarket outlets for surplus agricultural products, in order to sustain farm prices and incomes. Therefore, if one wants to understand how the homeless meet their needs for sustenance by studying the feeding programs of shelters, soup kitchens, and food banks, it is useful to look not only at what is happening in the dining room—from the recipients’ point of view—but also, as Curtis pointed out, at the total context of the feeding program and how it is delivered.

Squatting

In the developing world, millions of people live in squatter settlements, which are self-made housing units, often at the edge of a city, inhabited by poor people who have “invaded” the land, often at night, and built structures. From the *pueblos jóvenes* (young towns) of Lima, Peru, to the *bidonvilles* (tin cities) of Africa, these examples of self-help are seen as incipient communities that could, with the assistance of clean water, security of tenure, and some basic services, become stable communities of productive citizens (see Turner, 1976, for a full discussion of the potential of squatter settlements). In the industrialized world, squatting usually refers to homeless people taking over a vacant building or creating an encampment on a vacant lot.

Shelter Life

When anthropologists have focused their attention on shelter living, they have, for the most part, been struck by the corrosive effects of shelter life on the homeless person. Desjarlais (1997) spent time in a mid-size (52 beds) shelter for the homeless mentally ill. Although the staff regarded the shelter as the “Rolls Royce” of shelters, the place was in fact noisy and distracting. The clients just *struggling along*, as they put it, can be seen as

a shelter-induced adaptation, and may not be due primarily to the mental illness suffered by most of the residents. According to Desjarlais, struggling along contrasts to *experiencing* life, which implies active engagement with the world, including the ability to perceive, reflect, and act. Residents of the shelter spent much of the day pacing, bumming and smoking cigarettes, and drinking coffee.

The description is reminiscent of Murray’s (1984) contrast between linear time, where people make long-term plans, and cyclical time, associated with survival goals. Life on the streets is often associated with immediate, daily, weekly, and monthly cycles of time: the hours of opening and closing of the soup kitchens and shelters, the weekly appointments with social workers and doctors, and monthly check days.

In a study of a large (600 beds) New York City shelter (Franklin Avenue shelter in the South Bronx), Gounis (1992) hypothesized that the institutionalized atmosphere of the shelter eventually resulted in the *shelterization* or dependency of the occupants. For example, rules governing time and space kept the men on the move (to leave during the day, to be in by early afternoon) or kept them waiting in line (e.g., the ubiquitous lines for food, the shower, seeing the caseworker). The men were not allowed to sleep in a bed or on the floor during the day and so resorted to sleeping on top of pool tables and ping-pong tables, a sight reminiscent of the large mental hospitals before the era of deinstitutionalization.

Observers of shelter life have noticed the great variability among shelters. Liebow (1993), in a richly descriptive ethnographic account of his 10 years of participant observation in two women’s shelters in the Washington, DC, area, notes major differences. One shelter, he calls “The Refuge,” was staffed mostly by volunteers, and was housed in the fellowship hall of a church. It was a “low-demand” (for the shelter users) albeit bare-bones shelter. Liebow found that women appeared to be comfortable there, despite the physical limitations of the space. On the other hand, “The Bridge” was conceptualized as a therapeutic house, providing shelter for women, but with the understanding that the women would be actively working on a case plan to return to permanent housing. The staff were paid and well educated, and, according to Liebow’s observations, were more burned out than the volunteer staff of “The Refuge.” The book, *Tell Them Who I Am*, was written in part in collaboration with the homeless women and staff of the two shelters, who read and commented on the

manuscript. Liebow prints this commentary on his insights in footnotes which occur throughout the book. His is one of the few works in contemporary anthropology which takes the idea of collaboration with the community under study seriously and literally.

Doubling-Up

Probably the least researched type of adaptation to homelessness is that of living with another family, usually another poor family, on a very temporary basis. This is referred to as “doubling-up” and is often a precursor to life on the streets, or in encampments and shelters.

In Janet Fitchen’s pioneering work on rural homelessness in New York state (Fitchen, 1991), she found that the most frequent form of lack of adequate shelter among the rural poor was to squeeze two families into a trailer or apartment that was already too small for one. These arrangements were often short-lived, as the strain of the situation made life unbearable. Fitchen found that doubling-up was associated not with mental illness or substance abuse, but a worsening economy in rural areas due in part to the great loss of manufacturing jobs. Another factor that led to doubling-up was the rise of single motherhood in which income (through work or welfare) was not adequate to pay rent.

If a realistic portrayal of homelessness is to be achieved, it is incumbent upon the researcher to capture the *dynamic* quality of life on the streets as people cycle through the various alternative places to sleep (the street, shelters, hotels, and rehabilitation programs). For example, interview someone after a long hotel stay and they may discuss the loneliness and danger of their life. Interview the same person after a stint in a rehabilitation program (e.g., detoxification, or alcohol, or drug treatment), and they may bitterly complain about the regimentation and lack of privacy. It is important to know where in the cycle we are meeting the person (Koegel, 1992). Cycles of living on the streets may be seasonal, as has been observed among some groups of aboriginal people in Canadian cities who spend several months living on the streets, interspersed with several months “up North” on a reserve.

HEALTH AND HOMELESSNESS

The health problems experienced by homeless people may be conceptualized as those contributing to the etiology

of homelessness; those arising as a direct consequence of homelessness; and those conditions exacerbated by homelessness. From a large U.S. study of homelessness and health (Institute of Medicine, 1988), conditions that contributed significantly to a person’s inability to work—mental illness, AIDS, and injuries—may be seen as resulting in homelessness for those without other means of support. Other conditions (e.g., skin disorders, trauma, malnutrition, and parasitic diseases) increase and are exacerbated, or even actually caused by homelessness. Also, homelessness makes the treatment of diseases much more complicated. For example, prescribing bed rest or a special diet is impossible for individuals living in most shelters or for people relying on soup kitchens for their meals.

Physical Health

In a study of men using homeless shelters in Toronto, homeless men’s mortality rate was 8.3 times the mortality rate of the general male population in the same city in the 18–24 year old age group, 3.7 in the 25–44 year old group, and 2.3 times the 45–64 year old group (Hwang, 2000). The rates of traumatic disorders, skin and blood vessel disorders, respiratory diseases, and chronic diseases such as hypertension, diabetes, and chronic obstructive pulmonary disease are higher in the homeless population than in the general population (Institute for Medicine, 1988). Of great concern are homeless individuals with infectious tuberculosis who sleep in crowded shelters and are not able to adhere to their medication regimen.

Mental Illness

For many people in North America the issue of homelessness is closely tied to the phenomenon of *deinstitutionalization*, which refers to the process of having people who were hospitalized with psychiatric problems leave the hospital in order to live in the community. In the United States and Canada, the movement away from long-term hospital stays in favor of short-term, crisis-oriented hospitalizations and then community placements occurred in force during the 1960s and 1970s. Life in the community was considered more humane than life in the large psychiatric institutions. However, approximately 10 years after the community placements began, there appeared to be a visible segment of former patients

wandering the streets and generally not being cared for by “the community.” The early placements in group homes, boarding houses, and apartments fell into disarray (or were tenuous at best in the first place). The former patients wandered away from the placements, and many stopped taking their medications. How many of the homeless population really are mentally ill became an object of great interest in the research community and in the general public during this time period.

When rates of mental illness among the homeless are contrasted with rates in the general population, we find that most studies with good methodology report that 20–50% of the homeless population in the United States suffer from severe mental illness (i.e., schizophrenia, major affective disorders, paranoia and other psychoses, and personality disorders) in contrast to 1% in the general population (Burt, 1992, pp. 108–109). Although much attention has been given to the effect of the deinstitutionalization of the mentally ill on rates of homelessness, researchers were reporting a 20% rate of severe mental illness among skid row residents even in the 1950s, before the era of returning the hospitalized mentally ill to the community (Burt, 1992, p. 109).

Substance Abuse

The relationship of alcohol and drug use to homelessness is interactive, in that it is very difficult for an individual with limited financial resources to remain in housing when much of his/her money is spent on substances, and it is difficult for an individual to focus on substance abuse treatment when his/her basic survival needs for shelter, food, and warmth are only precariously met. A recurring question is whether substance use disorders precede homelessness or are precipitated by it (Glasser & Zywiak, 2003).

There is substantial evidence that alcoholism is the most pervasive health problem of the homeless in the United States (Fischer & Breakey, 1991). The rate of alcohol abuse has been estimated to be 58–68% for homeless men; 30% for homeless single women; and 10% for mothers in homeless families. In the general population, the rates for alcohol abuse are estimated to be 10% for men and between 3% and 5% for women.

Determining the rate of drug use among the homeless has been especially fraught with problems, since many studies do not distinguish between drug and alcohol use or between occasional use and a regular drug habit. An estimated rate of between 25% and 50% of the homeless

population use illicit drugs, and this exceeds the rate of the general population in the United States. Intravenous drug use is one of the primary transmitters of the HIV virus.

In their study of homeless youth in Hollywood, California, Robertson, Koegel, and Ferguson (1989) found that almost half (48.4%) of their respondents could be diagnosed as being either alcohol users or being alcohol dependent at some point in their lives, and that even the nonabusers drank and were at high risk of becoming problem drinkers. The authors found that being on the street exacerbated the amount of drinking. Interestingly, very few of the total sample (6.5%) said that their drinking was a contributing factor to their homelessness, although almost one quarter (23.7%) said that alcohol-related problems (including alcohol-induced violence) had led to their leaving home. Very few of the youth had had any kind of alcohol treatment.

In an excellent study examining the *overlap* of mental health and substance abuse problems among the homeless, 1,260 shelter residents in New York City were surveyed (Struening & Padgett, 1990). How, the researchers asked, is health status related to the individual’s involvement with alcohol, drugs, mental disorder, and a combination of all three? It is not surprising that the coexistence of heavy substance use with symptoms (or a history) of mental disorder resulted in very high rates of poor health, disability, and worsening health conditions. The often-cited health problems were hypertension, stomach and liver problems, and respiratory disease. The implication of this study is again that medical and mental health care (including substance-abuse treatment) need to be integrated with services for the homeless. Especially important is early and effective intervention with substance abusers in order to circumvent a lifetime of health consequences of alcohol and/or drug abuse.

Beyond the epidemiology of substance use among the alcohol- and drug-using homeless population, advocates for the homeless argue that providing housing is a first step in rehabilitation. Given the episodic nature of much of the homelessness of the population, it is also important to consider providing adequate support to individuals during their *housed* periods.

ENDING HOMELESSNESS

What do we know about ending homelessness? If many of the homeless shelters in North America have not been

effective in leading people to permanent housing, then what programs and strategies have proven helpful? How has the voluminous research on the cultures of the homeless been translated into action that leads to secure housing? We review here only a few of the exemplary programs that address homelessness. (For a full review, including other strategies such as outreach, self-help housing and advocacy on behalf of homeless communities, see Glasser & Bridgman, 1999.)

Daytime Respite

While on the street, there is an intermediate step of service between outreach efforts and permanent shelter which may be termed a “daytime respite,” or a place of rest and refuge for the homeless person. One successful daytime respite is Chez Doris, a multilingual (French, English, and, increasingly, Inuktitut, the language of the Inuit) daytime shelter for women in Montreal. The center was named after Doris, a destitute young woman murdered on the street in 1974. Chez Doris is the gathering spot for over 60 women a day; they come for food, clothing, baths, laundry facilities and, most of all, the companionship of the other women and the staff. The center is funded by a combination of government and private donations, and the women who utilize Chez Doris also provide much of the labor needed to run the place. It is a “low demand, no-questions-asked” service that accepts women who are poor, on the street, and may have psychiatric and/or substance-abuse problems.

Utilizing Indigenous Leadership

There are many examples of leadership and social support among the homeless, whether they are in encampments, single-room-occupancy hotels, or shelters. These examples can prefigure projects that seek to provide permanent and safe housing for the homeless.

Shapiro (1969) documented the dominant leaders within three different single-room-occupancy hotels. All three were women who were able to provide emotional and material aid to the other hotel residents. They were also able to be a link to the professionals who came to the hotel to provide health and social services. Almost 20 years later, Glasser (1988) documented the social networks and leadership exhibited within the dining room of a soup kitchen. The leaders among the soup kitchen guests were seen as *more* effective at sharing information

and making referrals than were the staff. A program that taught accurate information about community resources to groups of soup-kitchen leaders, who were chosen from the various social networks within the dining room, appeared to be effective in increasing the fund of knowledge of these leaders.

Transitional and Supportive Housing

Many people are not able to make the transition from shelter to apartment living. They require support in order to maintain permanent housing. Transitional housing generally consists of housing with two years of services, while supportive housing offers services for an open-ended period of time. Such housing may be provided within one physical space (e.g., apartment units built in former warehouses), or it may be provided in scattered apartments in publicly or privately owned buildings, with services brought in to individuals or families. In many communities, transitional and supportive housing is much preferred over building more shelters, which are often viewed with fear and suspicion. Increasingly, it is also being recognized that transitional and supportive housing models offer far more economical options than emergency shelters or institutions such as psychiatric hospitals or detention centers.

The Native Women’s Transition Centre (opened in 1981) in Winnipeg, Manitoba, for example, provides long-term residential services for aboriginal women experiencing family violence, abuse, addiction, involvement with Child and Family Services, and inadequate housing (Canada Mortgage and Housing Corporation, 1999, pp. 45–55). This long-term residential facility is staffed 24 hours a day, and provides a safe home for native women and their children. Staff are all aboriginal women. There are ex-residents among the full- and part-time staff, and on the Board of Directors. The program respects traditional native practices with a healing circle as an integral part of its program and a healing room built to resemble a teepee. Generally the maximum length of stay is one year. Then residents may choose to move on to second-stage housing at Memengwaa Place (“Home of the Butterfly”).

CONCLUSION

Anthropologists have been able to offer the “thick” description of homeless communities that are so often

missing from more statistical approaches, and have helped us comprehend the pathways into and out of homelessness. Anthropology's holistic approach of integrating the large, macro-level societal movements, as well as the family and personal level dynamics, offers a complex understanding. Some of the most compelling work in the field utilizes an understanding of the culture that is created by the homeless themselves in order to create employment, housing, health and social service programs, and policies that are culturally compatible with the world views of homeless people.

Nutrition and Health

Gun Roos

INTRODUCTION

Patterns of diet and activity, and nutritional and health status vary across cultures and historical periods. For example, currently there are populations living as hunter-gatherers and also groups subsisting on diets high in fat and refined carbohydrates. The nutrition and health situations in developing countries have been exemplified by nutrient deficiencies, such as protein-energy malnutrition, iron deficiency anemia, vitamin A deficiency, and iodine deficiency, in addition to periodic famine and high prevalence of infectious diseases. In contrast, over the past 100 years nutrition-related non-communicable diseases (obesity, cardiovascular disease, diabetes, some types of cancer) have mainly been a challenge in Western industrialized countries. However, today changes in work patterns, lifestyles, and food systems (e.g., global availability of cheap vegetable oils and fats) are contributing to an increase in non-communicable diseases also in developing countries, particularly countries in rapid economic transition. As a result these countries are facing a growing risk of a double burden: the persisting problem of undernutrition plus the rising prevalence of obesity (Drewnowski & Popkin, 1997; Popkin, 2002).

The relationships of food, nutrition, society, and culture are highly relevant for population health and welfare. Food is integrated into all aspects of life, and is, therefore, also studied in a wide range of disciplines. In nutritional sciences food is mainly viewed in terms of its nutrient composition and effects upon the body's metabolic processes and health status. There has been a special interest in developing methods for measuring nutrient intake and defining essential, adequate, and optimal intakes of nutrients. Anthropological perspectives, which are broad and holistic, tend to look at food and nutrition in populations as complex systems influenced by many factors, including the environment, genetic inheritance, culture, and socioeconomic circumstances. Anthropological research on food and nutrition examines the origin, development, and diversity of the human diet and tries to understand how and what people in different

cultures and contexts eat. Food is often viewed as a system of communication; it conveys meanings and social relations. Cultures distinguish themselves from one another in part through their different eating habits, manners, and conceptions of eating. Class, gender, age, and ethnic distinctions are also manifested through food practices and rules about eating.

Food and nutrition within anthropology is a diverse field, which broadly can be divided into two groups based on the main focus: nutritional anthropology and anthropology of food. Nutritional anthropology is a subfield of medical anthropology in which nutritional implications of food intake, food as carrier of nutrients, nutritional status, human growth, and health are the focus. Studies in nutritional anthropology draw on theories and methods from both biological and social sciences. In contrast, anthropology of food focuses on the cultural and social significance of food and eating. Food is studied as a way of understanding social and cultural processes and to reveal symbolic structures. For example, anthropologists have examined the reasons why only a limited selection of all that is theoretically edible in a culture is actually consumed as food and how individuals learn culturally defined rules of what and how to eat. A number of authors have undertaken reviews of the most significant perspectives in anthropology and sociology of food (e.g., Beardsworth & Keil, 1997; Caplan, 1994; Murcott, 1988). Classic pieces by Claude Levi-Strauss and Mary Douglas in addition to more recent anthropological texts from social, symbolic, and political-economic perspectives have been collected into a reader on food and culture (Counihan & Van Esterik, 1997). In addition to anthropology of food and nutritional anthropology, a third subfield, food systems and food policy studies, has been suggested (Pelto, 1996). Food systems research focuses on the linkages between economic and social policy and food production and distribution, as well as food and nutrition policy implementation and program evaluation.

The objective of this entry is to provide an overview of the anthropological literature on nutrition and health. Because nutritional anthropology is the most

health-oriented subfield of food and nutrition within anthropology, the focus will be on nutritional anthropology. This entry has three goals. First, to describe briefly the history of nutritional anthropology. Second, to present the main theoretical orientations and methods used in nutritional anthropology. Finally, to provide examples of themes that have occupied nutritional anthropologists.

HISTORY OF NUTRITIONAL ANTHROPOLOGY

The early history of nutritional anthropology dates back to studies of food and social organization in non-industrial societies in the 1930s. The British anthropologist Audrey Richards (1939) is often described as the first one who explicitly focused on food. She studied economic and social factors affecting food among the Bemba in central Africa. Her work was part of the British applied anthropology movement, which was associated with colonial governance and welfare.

In the 1940s, studies of nutrition and the culture of eating were stimulated by the circumstances related to World War II. Committees that included anthropologists and nutritionists were set up in the United States and the United Kingdom to plan food rationing and to ensure adequate nutrition for the troops and support personnel. The U.S. Committee on Food Habits was directed by a well-known anthropologist, Margaret Mead (Wilson, 2002). Between 1950 and 1970 food- and nutrition-related themes were included in some anthropological studies, but nutrition was not in generally a central focus of anthropological study.

In the 1970s food and nutrition within anthropology was revived as nutritional anthropology in the United States. Pelto (1986) traces the development of the field to four social forces: the world energy and food crisis in the early 1970s; growing interest in the role of nutrition in health and diseases; the emergence of ethnicity as a social and political phenomenon; and an interest in gourmet food and cooking in affluent societies. The rise of cultural ecology as a theoretical perspective in anthropology was also central to the development of nutritional anthropology. The American Anthropological Association organized sessions on the biocultural perspective of nutrition in response to the increased interest in the 1970s and this resulted in a widely used publication (Jerome, Kandel, & Pelto, 1980). The Committee on Nutritional Anthropology

was established in 1974 as a special interest group within the Society for Medical Anthropology. The committee became the Council on Nutritional Anthropology (CNA), which has been a separate unit of the American Anthropological Association since 1987. There has been and still is a broad diversity of interests within the group ranging from theory to application.

THEORETICAL ORIENTATIONS AND METHODS IN NUTRITIONAL ANTHROPOLOGY

As with other fields of anthropology a wide variety of theoretical perspectives and methods are used in nutritional anthropology. A range of ecological, symbolic, materialist, and political perspectives has been used to explain patterns of food selection, nutritional consequences, and the relationships of nutrition to sociocultural, economic, and ecological processes.

What foods people eat and how much they eat are determined not simply by physiological needs, but also by political and ecological factors that determine the availability of food, and cultural factors that shape the acceptability and preparation of food. Therefore, it is not surprising that the biocultural approach has been widely used in nutritional anthropology. This is also reflected in the title of a recent edited volume on nutritional anthropology *Nutritional Anthropology: Biocultural Perspectives on Food and Nutrition* (Goodman, Dufour, & Pelto, 2000). Evolution and adaptation are central theoretical concepts in the biocultural or ecological approaches. Biological anthropologists have tried to assess the role of nutrition in human evolution and adaptation to different physical environments and climates. They have attempted to understand subsistence patterns and nutrition, population differences in nutrient utilization, and the evolution of favorable nutritional patterns, cooking methods, and dietary preferences. Focus on energy flow and the systems framework have given rise to studies on the problems of the food system, including inadequacies in the food supply or specific nutrient deficits (Haas & Harrison, 1977). However, the ecological approach has been criticized for ignoring political and economic factors and, as a consequence, political economy has more recently been given increased attention (Himmelgreen, 2002).

Pelto (1996) has provided a framework for organizing nutritional anthropology research. She has grouped research questions in nutritional anthropology into the following main headings: (1) sociocultural processes and nutrition; (2) social epidemiology of nutrition; (3) belief structures and nutrition; and (4) physiological adaptation, population genetics, and nutrition. Nutritional anthropological research on sociocultural processes and nutrition examines the nutritional consequences of social and cultural forces. The basic question is: What is the impact of sociocultural processes on nutrition? Sociocultural processes refer to both long-term and short-term evolutionary changes, such as transformation of subsistence from hunting–gathering to agriculture, the introduction of new technologies, modernization, or migration from rural to urban areas. In studies classified as the social epidemiology of nutrition the central issue is the identification of the determinants of, or the factors associated with, food intake and nutritional status. The emphasis is on the nutritional condition, and anthropologists aim to recognize the role of social factors in the etiology of that condition. For example, they have studied the factors that determine malnutrition or deficient levels of intakes of specific nutrients. Some of the nutritional anthropology research focuses on the relationships between cultural beliefs and nutritional outcomes. By examining the links between cultural idea systems (e.g., the humoral medicine system of hot/cold beliefs or modern rational models of diet) and nutrient intake, the strengths and weaknesses of dietary systems can be assessed and sociocultural barriers to change and potential avenues for facilitating improvement in dietary practices can be revealed. The group of studies labeled physiological adaptation, population genetics, and nutrition include research that addresses how the nutritional history of a population has formed or affected its physiological or genetic characteristics (e.g., low birth weight, growth, obesity). For example, nutritional anthropologists have studied the differences in the capacity to maintain production of lactase, an enzyme required for the digestion of milk, beyond early childhood from one population to another.

A considerable part of the work in nutritional anthropology is applied in nature; anthropological theories and methods are used to understand and improve specific nutritional problems and alleviate malnutrition. In the 1940s, work focused on solving the nutritional problems of feeding the army and populations during war. Since the 1970s a growing number of anthropologists

have participated in the planning, implementation, and evaluation of nutrition and health programs and policies. For example, anthropologists have played a part in identifying the social and cultural variables that have the greatest impact on nutrition and health. In the 1990s anthropology moved from critique to greater involvement in action, and this can also be seen in applied nutritional anthropology (Pelto, 2000).

When the research problem, ethnographic context, and theoretical orientation are set, an appropriate methodology is selected. Over recent years, flexible and eclectic combinations of theoretical approaches and methods have become more common. Nutritional anthropologists utilize a wide variety of data-collection methods drawn from anthropology as well as from the nutritional sciences. Special training manuals and guides provide assistance on methodological issues for nutritional anthropologists (Pelto, Pelto, & Messer, 1989; Quandt & Ritenbaugh, 1986). To understand nutritional problems, anthropologists tend to examine the problems at several levels: the individual, the household, the society, and the region. The unit of data collection is often the individual, but the primary focus has traditionally been the community.

Often more than one technique is used; qualitative and quantitative methods are combined in a holistic approach. Dietary intake usually is measured by food record methods (weighed or estimated) and food recall methods (diet history, food frequency, 24-hour food recall). An individual's nutritional status is measured using anthropometric methods (measurements of the human biology, such as height, weight, and skin folds), energy expenditure, and growth. For example, measures of childhood growth and development are used to reflect the biological consequences of nutritional intake.

Data on cultural practices and rules related to diet and nutrition are collected by anthropological methods, including traditional fieldwork, archival research and the use of observational techniques, interview techniques, and written respondent records (questionnaires, diaries). Anthropologists have participated in the development of improved methods to measure food and nutrition-related variables, and tools and manuals for rapid or focused ethnographic investigation and assessment have also been developed (Pelto, 2000). However, it is important to consider that rapid assessments may provide only a limited understanding of a problem and may not be the best choice of method in studying some complex problems, such as malnutrition (Dettwyler, 1998).

THEMES IN NUTRITIONAL ANTHROPOLOGY

The anthropological literature on nutrition- and health-related issues has become vast over the last decades and it also has a broad geographic spread. Nutritional anthropologists have covered a wide variety of topics, ranging from nutritional adequacy in prehistoric populations to various forms of malnutrition in late modernity. The different types of malnutrition studies include protein-calorie malnutrition, micronutrient malnutrition, and overnutrition. Next, two themes have been selected to illustrate some of the variation in nutritional anthropology research and the contribution of anthropology to advancing our understanding of nutrition and health: (1) hunger and malnutrition in low-income countries, and (2) the possible effects of our nutritious past on human health and well-being today.

Hunger and Malnutrition in Low-income Countries

The production and distribution of adequate food is a serious health problem facing the world's population. The concept of food insecurity is often used to describe the limited or uncertain access to nutritionally adequate and safe foods for households and individuals. Hunger and food insecurity are highly relevant problems for health policies and intervention programs because malnutrition has functional consequences both at the individual and societal levels. Women and young children represent a large section of the chronically undernourished and are especially vulnerable groups.

Anthropological research on hunger and malnutrition indicates strong links between low household income and undernutrition, but it is evident that most of the malnutrition in low-income populations does not have one single cause. Research has suggested complex relationships between nutritional status and a wide variety of macro-level and micro-level factors, such as agricultural production, economic strategies, women's roles and time allocation, nature of local diet, food availability, intra-household allocation of food, breast-feeding, weaning practices, sanitation, and infections. Therefore, there are no easy solutions and strategies for preventing malnutrition and hunger; programs to improve health need to address the various causes of malnutrition.

The first two years of a child's life is the time of rapid growth and the nutrient requirements are therefore great. Good growth is an indicator of good health in children, and stunting and wasting are measures of lack of adequate food in childhood. Stunting often occurs in association with the weaning period. The question Is being short a sign of unhealthiness? caused a debate in the 1980s. David Seckler, an economist, proposed a "small but healthy" hypothesis, namely that a short but not thin child or a stunted but not wasted child is healthy. According to Seckler only those children who show clinical signs of malnutrition are malnourished. If the "small but healthy" hypothesis were true, the prevalence of malnutrition would be smaller, and this would have political implications. However, the hypothesis was heavily criticized and others showed that the process of stunting is not healthy. Research has shown that child growth deficits and deficiencies of iodine or vitamin A may have permanent effects on cognitive development and work capacity in adulthood (Martorell, 1998).

Today Sub-Saharan Africa is among the poorest regions in the world. Dettwyler (1994, 1998) studied child malnutrition in Mali in the 1980s, a country with very high rates of child malnutrition and mortality. She applied a biocultural approach and used both anthropometric measurements and sociocultural ethnographic data (e.g., socioeconomic status, cultural infant/child feeding practices, and beliefs) to study the relationships between growth and development of children and the sociocultural environment in Mali. The data indicated that the relationship between socioeconomic status and malnutrition is not simple; some children from relatively poor families grew well while some children from relatively well-off families grew poorly. Dettwyler's research suggested that growth status was not just a consequence of dietary quantity or quality but resulted from the interaction of a number of complex biological, social, and cultural factors, which also have to be considered. Local agricultural production and the marketing of food were central factors, but in addition cultural beliefs and rules led to the late introduction of solid food to children in Mali and feeding those in the household who had to work was prioritized.

Nutritional anthropologists have been interested in understanding the role of domestic life or intra-household processes in explaining variations in diet, nutrition, and health found within groups and households (Messer, 1997; Sharman, Theophano, Curtis, & Messer, 1991). Interrelationships between several factors, such as

cultural beliefs and practices, a shift to a market economy, women's work, time allocation, cash income, child care, and dietary planning in specific ecological and economic settings have been studied. Anthropological research can help to predict or identify the nutritionally vulnerable within households and help others design more effective interventions. Messer (1997) compared ethnographic studies in India, Nepal, Madagascar, Mexico, and Peru for an analysis of intra-household allocation of food and health care. Her aim was to clarify the cultural, economic, and biological factors that contribute to discrimination or neglect based on gender and age within households. The studies included in the analysis indicated non-egalitarian allocation of food within the household. However, according to Messer, the data suggest that there is no intent to discriminate, but culturally prescribed rules may have a negative impact on nutritional outcome. Allocation rules seemed to mainly aim toward "household maximization"; those members who were perceived to be more active (often male income-earners) were generally perceived to have greater nutritional needs. Messer concluded that household food security might not be a good predictor of adequate individual intake, especially among children and women.

Baer (1998) studied social factors related to malnutrition among Cacti households in Sonora in northwestern Mexico, which is an area of contrast between old and new and with unexpectedly high rates of stunted, malnourished children. Data were collected through a combination of qualitative methods (ethnographic and archival research) and quantitative analyses of income, diet, and nutritional status. The study suggests that income level does not explain differences in the quantity and quality of foods consumed in households, but that the "invisible variable of available income," the amount of money actually available to those responsible for household expenditures, may be important in understanding dietary patterns. Available income incorporates the effects of several social and cultural variables (e.g., rural to urban migration, ethnicity, prestige, women's roles) on the amount and allocation of available income. Baer shows that households with similar available incomes may differ in their food expenditures and consumption due to context and culturally acceptable ways of allocation of available income. She underlines the relevance of identifying the social and cultural variables that have the greatest effects on available income in a particular area in developing food policy and intervention programs.

Anthropologists have studied development policy and food policy issues related to food production, supply, distribution, and consumption. Changes in traditional food production and distribution in the developing countries have resulted in decreases in the diversity of available foods, nutritional status, and food security in general. For example, the effects of agricultural commercialization (increasing production of cash crops, i.e. crops produced to be sold for cash) on food consumption and nutritional status have been examined (DeWalt, 1993). Kathleen DeWalt reviewed 14 studies of the impact of commercialization conducted at the micro level in various locations (e.g., Kenya, Swaziland, Guatemala, Mexico, Philippines) in the late 1980s. The review shows that impacts vary because they depend on a mix of "intervening" variables, such as the nature of the crop, the control of production and income, allocation of household labor, land tenure, and pricing policies for cash crops and foods. These intervening variables have more effect than crop choice on the nutritional status of rural people. DeWalt suggests that policies and programs that focus on the most vulnerable population instead of commercialization are more likely to have a positive effect on food security and nutritional status.

Nutritional anthropologists have especially contributed to our understanding of malnutrition by addressing and showing the importance of the underlying conditions of nutritional risk and by providing descriptions of economic and cultural factors and processes that influence malnutrition.

Our Nutritious Past and Today's Health

The major diseases and health problems affecting people in the modern world, such as cardiovascular disease, hypertension, obesity, diabetes, and some forms of cancer, are related to diet. This implies that present-day Western dietary habits, characterized by high intakes of fat and low intakes of fiber, may have a role in causing modern health problems. It has been suggested that humans may not be well adapted to eating dairy products and grains because we have lived as hunter-gatherers for almost all of our history. It was approximately 12,000 years ago that the first human populations shifted to agriculture. Some have proposed that contemporary human health could be improved if we were to imitate our hunter-gatherer ancestors' diets. In the food and nutrition literature there is currently considerable interest in

exploring what our ancestors' nutrition might mean for our health and if our bodies' physiology and genes are suited for the contemporary patterns of diet and activity (Kiple, 2000).

Nutritional anthropologists have developed biocultural evolutionary models that offer holistic explanations for the interaction of genes and culture in an evolutionary context. They have described what our prehistoric ancestors may have eaten based on archeological skeletal remains and through cross-cultural comparison of what currently living hunter-gatherer populations eat. For example, diet and activity patterns of !Kung San modern-day hunter-gatherers who live in the Kalahari Desert in southern Africa have been studied. They consume mostly plants (approximately 70%–80% of the food by weight), have high levels of physical fitness, low blood-cholesterol levels, and adequate and well-balanced nutrition. Stone age diets have been estimated to have consisted of wild game meat and wild plants. Compared with modern diets in industrialized societies they probably included more protein and dietary fiber and less fat (Eaton & Konner, 1985; Eaton, Shostak, & Konner, 1998).

Food shortages have been common in human prehistory and history. Nutrition was often a matter of feast and famine, and, therefore, those individuals who during times of feasting were able to store energy reserves in the form of fat to survive famines would have enjoyed a considerable survival advantage over those who did not have this capacity. But today this genetic adaptation for coping with a very small supply of nutritional glucose is blamed for causing health problems. The “thrifty genotype” was introduced in the 1960s by the geneticist James Neel and has since been debated. In the 1980s anthropologists demonstrated the lack of fit between the “thriftness” of the glucose metabolism system and a diet characterized by a lot of carbohydrates. This was identified as a “New World Syndrome.” Studies of Native Americans, Australian Aborigines, Pacific islanders, and Alaskan Eskimos have reported higher rates of type II diabetes and obesity when traditional diets and patterns of physical activity have changed (Ritenbaugh & Goodby, 1998).

Obesity is an increasing problem in low-income countries. Both genes and lifestyle are involved in the etiology of obesity. Most research on obesity has focused on medical issues, but it is also a focus of anthropological, sociological, and psychological approaches. An anthropological approach to obesity involves both an evolutionary and a cross-cultural dimension. Brown and

Konner (1998) argue that traits that cause obesity were selected because they improved the chances of survival and that fatness may have been directly selected because it is a cultural symbol of social prestige and reflects general health.

Nutritional anthropologists have demonstrated the complexity of eating worldwide, and the relevance of context and cultural and social factors on nutrition and health. They tend to view nutritional health as shaped by the interaction of social and biological forces operating in different physical environments.

Post-Colonial Development and Health

Steve Ferzacca

Decolonization is always a violent phenomenon.
Frantz Fanon, *The Wretched of the Earth*, 1963

INTRODUCTION

The post-World War II era marked the rise of new nation-states. Released from the shackles of European colonialism, the former colonies as newly emerging nations began to chart their own courses toward becoming modern global partners with and for their former colonizers. Manifestos of various political persuasions and economic strategies became blueprints for transforming colonialist architectures of rule into nationalist administrations. One important manifesto that spoke a common language across the globe was development ideology. For newly emerging nation-states in search of an international language to legitimate their status as democratic nations among democracies, development ideology, based on the

authoritative ground of “scientific” theory and technique, provided immediate entry into an international network of power, knowledge, and finance. The health of the population and the state of its health care provisions were, after forming a government, a top priority for these youthful nation-states. South and Southeast Asian countries, various African states, governments in the Middle East and the Americas, in the spirit of self-determination, guided by the ideology of developmentalism, prepared for take-off into the atmosphere of the modern world by turning their attentions to improving health. In many cases, after centuries of colonial rule, standards of health and health care remained dismal, especially for those segments of the population already marginalized by colonial practices.

Medical anthropology found itself as a sub-field of anthropology at this historical moment of post-coloniality. The research concerns and methodological approaches of medical anthropology emerged within a post-colonial

context for which “development” and the urge to develop were integral features of political and social life. Medical anthropology as applied to theory and practice shaped and was shaped by the “essential binaries” that are central organizing principles for colonial theories of human diversity formulated to justify inequality and relations of domination and control. Such binaries include distinctions made between primitive and modern, simple and complex, small scale and large scale, undeveloped (or developing) and developed, Third World and First World. However, medical anthropology as a problem-oriented research activity also reflected the real actualities of colonial history manifest in conditions of health and health care. Medical anthropology continues to reflect and contribute to the unfolding history of post-coloniality and the post-colonial condition.

COLONIALISM, EARLY POST-COLONIALISM, AND HEALTH

The health consequences of colonialism immediately faced by post-colonial regimes cannot be characterized by any one set of health problems, health practices, and perceptions. Rather, differences in health and health care reflect regional, class, ethnic, gender, age, rural and/or urban circumstances, posing a myriad of challenges for post-colonial development efforts. The withdrawal of colonial powers left behind a mixed legacy of health conditions and health care provisions. Where one lived in terms of geography, and where one stood in terms of colonial social structure were significant determinants of health for emerging post-colonial societies. Janzen (1978) in his groundbreaking ethnography on medical pluralism among the BaKongo in Lower Zaire (today’s Democratic Republic of the Congo), describes the social and geographic distributions of various health problems faced by available medicine at the time of his study (1969). The Belgian colonial government played a central role in the increasing prevalence of post-colonial “endemic killers” among populations in the Lower Zaire river region. Colonial expansion into the region disrupted an ecological balance among settlement patterns, subsistence strategies, and economic arrangements. Colonial infrastructure projects, for example the building of the railroad, required a local labor force. Colonial recruitment activities resulted in the displacement of people and settlements. Before the intrusion of colonial expansion,

villages had been built on top of hills and mountains which provided some immunity to the insect vectors that carried malaria, sleeping sickness, and dysentery. As peoples of the Lower Zaire moved to the valleys and sheltered forests, either as colonial laborers or in an attempt to escape labor recruitment, whole villages were exposed to endemic killers such as malaria, gastrointestinal parasites, and sleeping sickness.

At the time of his study Janzen noted that while “endemic killers” had been “brought under control” the persistence of these health problems continued after the arrival of “modern” colonial medicine. He outlined a post-colonial social geography of disease and illness that followed social divisions established by poverty, access to adequate food supplies, “inadequate knowledge” of health care and disease prevention, and in the case of children, stage of human development. For BaKongo children their conditions of life in Lower Zaire remained plagued by respiratory infections, chronic diarrhea, polio, measles, and sickle-cell anemia. For the poor and ill-educated, life was one of chronic malnutrition and diseases related to vitamin deficiencies, as well as outbreaks of smallpox, and yellow fever.

In Southeast Asia, Indonesia provides a similar set of circumstances and health conditions after Independence from Dutch colonial rule. Gardiner and Oey (1987) document a disease profile for Java before independence dominated by infectious and communicable diseases, notably cholera, smallpox, malaria, typhoid, dysentery, and tuberculosis. The *Handbook of the Netherlands East-Indies, 1924* warns Dutch colonialists of the persistence of “the contagious abdominal troubles ... enteric fever, amebic and bacillary dysentery, cholera, malaria” as well as hookworm disease, yaws, beri-beri, leprosy, plague, and smallpox that affect health in the Dutch colonies. In 1966, nearly two decades after Indonesian Independence, President Suharto gave birth to the Seven Health Efforts program instituted in order to cope with the “return of epidemics,” especially malaria and the poxes. Indonesian post-colonial development projects meant to eradicate epidemic infectious diseases targeted the improvement of conditions surrounding food, clothing, housing, preventive medicine, curative medicine, pharmaceuticals, and education (Ferzacca, 1996). In 1967, with help from the World Health Organization (WHO) and UNICEF, the first national Master Plan for the development of national health care services in Indonesia was born with these issues in mind and at hand.

In addition to the presence of the “traditional hazards associated with lack of development” (WHO, 1997) post-colonial development efforts had to face and were stalled by millions of deaths and other health problems in the newly emerging nations related to violence, wars, and military coups. At the dawn of post-coloniality guns and other weaponry were often the most abundant forms of technology used in nation-building and becoming a developed country. The costs due to these violent national awakenings were felt in terms of health. Nigeria, a British colony until 1963, as a newly emerging Republic was wracked by ethnic conflict and warfare that in 1967 led to the Biafran War. By 1970 it was estimated that the number of dead from violence, disease, and starvation was between 1 and 3 million. Moreover, the infrastructure of health care was destroyed in the region of Biafra. The hostilities and destruction of the Biafran War resulted in severe shortages of food, medicine, clothing, and housing. One of the military tactics of the Nigerian government against the successionist Republic of Biafra was to impose blockages that were effective in cutting off food supplies. Famine was widespread in the region. The images of Biafran children sick with *kwashiorkor*, an extreme form of protein-energy malnutrition, appeared worldwide. Before the fighting ended about 1 million children had died of starvation.

In the former colonies post-colonial health care provisions were pieced together from remnants of colonial era medicine. European colonial experiences in and perceptions of the disease environments of the colonies along with experiences with and perceptions of colonial populations shaped post-colonial strategies toward health care. For European colonizers medicine as a “tool of empire” was employed to civilize the natives as well as environments hostile to the health of both colonizers and colonized (Arnold, 1988). The “local health care system” of colonial medicine generally included an array of clinics, hospitals, and rural dispensaries as well as medical care provided by missionaries, local individuals who received some training in this import of medical technique and knowledge, and indigenous healers and medicines.

In the Congo the advent of colonial medicine is directly related to the sleeping sickness epidemic (Lyons, 1988). In the first part of the 20th century the population struck by endemic sleeping sickness dropped to half the level of the 15th century. Belgian colonial medical services dispatched to confront sleeping sickness evolved into

the system of hospitals, rural clinics, missions, patterns of research activity, and bureaucratic health administration that some claimed by the 1950s “was without a doubt the best in the whole tropical world” (Grinker, 1994, p. 50). In June 1960 independence was achieved and the First Republic of the Congo inherited a medical pluralism that included the colonial medical services along with “indigenous therapy” and medical perception (Janzen, 1978).

The appearance of colonial medicine in Indonesia began late in the Dutch colonial enterprise. Boomgaard (1993) notes that the “popularity of shots” in Java began with the anti-yaws campaigns after 1900, and left a “lasting impression” of the efficacy of scientific medicine on local medical perception and practices in colonial Indonesia. These public health campaigns in conjunction with the “Javanization of medical personnel,” particularly in the *Dokter Djawa* schools that provided medical training for the natives, and increasing urbanization, was the context from which the Dutch Colonial Public Health Service in 1925 was launched (Boomgaard, 1993). Many scholars agree that early in the 20th century scientific models of health and disease, especially as these models pertain to hygiene and germ theory, made their way into the consciousness of certain segments of the Indonesian population, most likely through public health campaigns aimed at eradicating malaria, cholera, typhoid fever, smallpox, and the plague (Gardiner & Oey, 1987). An equally important urgent health condition in the natural history of scientific medicine in Indonesia was the influenza pandemic of 1918 (Brown, 1987). The availability of post-colonial medical services based on biomedical practices and perceptions of illness and disease increased after Independence, and especially after the mid-1960s with the emergence of President Suharto’s New Order government. The Indonesian National Health Care System was organized from a pre-existing Dutch colonial network of hospitals, public health centers, rural health centers, and mobile units.

The medical architectures that grew out of these strategies for which European medicine was dominant provided the foundation, often times a skeletal one at that, for post-colonial health care. The technologies and architecture of health care, found to be in varying states of order and decay, along with the cultural logic that in the colonial context had informed their use, were adopted by newly emerging nations in the desire to remedy the ill-health of their national populations and to begin the

path toward development. The cultural logic of European colonial medicine not only reflected an emerging science of medicine. In addition, the cultural logic of colonial medicine reflected the views of European colonizers of the environments and populations under their control. Medicine and medical technique were arranged and employed within hierarchically arranged categories and sets of “essential binaries” that represented the colonial world view in general ways beyond the realm of medicine (Bhabha, 1994). The “humane imperialism” (Comaroff & Comaroff, 1992) of colonial era medicine produced and reproduced conceptual frameworks of the natives and their environments in terms of body, hygiene, person, society, medical perception, and technique. Native bodies were closer to nature than the cultured ones of Europeans, and their wild, filthy, animal-like, traditional, magical bodies, hygiene, persons, societies, *materia medica*, respectively stood in contrast to civilized, clean, human, modern, scientific European ones.

As post-colonial national developments begin, these common binaries incorporated into development ideology, are appropriated by governments as they apply this ideology for purposes of nation-building and state-making. Ironically, the very categories of rule imposed by colonial regimes became measures of progress and development for post-colonial states, albeit within a language of development that was little more than a revision of the scientific racism of colonialism. Gone were the references to evolutionary models of human difference to be replaced with a language of economic change in which binary oppositions between First World and Third World, traditional and modern societies, developed and developing, represented the before and after results of development efforts, strategies, and programs.

For example, in 1949 as the New Republic of Indonesia wrestled its independence from a returning and obsessed Netherlands East Indies colonial regime there was already a vibrant discussion among various Indonesian nationalist leaders and future social engineers concerned with the appropriate directions for this new nation toward becoming modern while maintaining the authentic traditions unique to the peoples of this archipelago. Ethnic groups, their practices and beliefs, including their medicines and medical knowledge, were organized by their proximity in both time and space to modernity using the contrasting category of tradition. Typically, Indonesian ethnic groups who foraged in the forests or lived rural agricultural lives were characterized

as peoples ruled by customs and traditions with levels of technology, medical or otherwise, that were equally traditional compared with Indonesians living in cities who had adopted city ways, medical or otherwise, that were modern. Likewise, the health problems that plagued peoples categorized along these lines were also described as either traditional or modern. Since the majority of the Indonesia population lived as agricultural peasants the nation-state itself, determined by international standards that were also adopted by the Indonesian government, was in need of development in order to progress from a post-coloniality stuck in tradition toward modern ways of life.

These “essential binaries” of development ideology that offer contrasting portraits of “modern” in terms of the “traditional,” “Western” in terms of “non-Western,” “urban” in terms of “rural,” provided the necessary parameters for post-colonial development projects targeting health. In the Indonesian case local knowledge incorporated in the health plans for a nation formed around the essential binaries of development ideology identified *tradisi*, or the traditional, *adat*, or custom, *desa*, or the village, and *daerah*, or a place outside urban landscapes as potential sites for development. *Tradisi*, *adat*, *the desa*, and *daerah* had been important categories since Dutch colonial efforts to account for and standardize ethnic diversity in the colony. These categories for the post-colonial regime became important markers of the potential presence of under-development and traditional patterns of illness and disease.

In the newly emerging nation-states poised between remedying the health hazards of colonialism and traditional lifeways, most Westerners began practicing what was to become medical anthropology (Janzen, 2001). Medical anthropology of the time did little to reflect critically on these ethnocentric categories of distinction. Medical anthropologists often operated as cultural brokers, bridging gaps of translation thought to plague interactions and development efforts taking place between the modernity of aid and assistance and the traditions of the needy. Moreover, as advocates, medical anthropologists often reified these distinctive features of contact and change when calling attention in relativist terms to the logic of native medical perceptions and practices. In what follows, post-colonial developments are explored in terms of continuing health conditions, emerging health issues related to development, and the conceptual schema of development that continued to locate

that “external discourse” (Gupta, 1998) of modernity based in “western experience” (Escobar, 1994) within images, activities, and associations related to health and health care.

POST-COLONIAL DEVELOPMENTS AND HEALTH

Post-colonial development met and continues to meet the challenges of high fertility and mortality rates, health environmental issues, poverty and its impact on segments of post-colonial populations, acute respiratory infections, diarrheal diseases, vaccine-preventable infectious diseases, malaria, and other tropical vector-borne diseases. In fact, the persistence of these health issues is considered the bio-historical facts of under-development that are also the targets of development. Any positive changes in these and other health measures of progress brought about by development signal successful movement toward take-off. Post-colonial governments, along with a wide variety of other governments, international aid agencies, and non-governmental organizations have targeted the health and demographic measures of progress for which Europe and the United States provide the gold standards in terms of achieving their pinnacle stage of development.

The health profiles of developing countries bore out in demographic profiles are based on national census data collected by post-colonial state bureaucracies. This important activity of the state provided the targets toward which development projects could be applied. The demographic profiles of non-Western industrialized countries were and continue to be the comparative measures used to track a developing country's movement toward becoming a developed country. Returning to the Congo, relying on statistics collected in 1959, Janzen reveals a demographic profile for the Lower Zaire in which life expectancy at birth only reached 37.64 years for males and 40 years for females. The infant mortality rate stood at 180 deaths per 1,000, half of what it had been 20 years earlier, but nevertheless still a high rate of death. He noted constant but high fertility rates, and a declining mortality rate overall. Similarly, Indonesia just after Independence (1950) experienced life expectancy rates at birth of 35–40 years. Infant mortality rates at this time stood at 200 deaths per 1,000 (Ananta & Arifin, 1990). As in the case of central Africa, Indonesia also continued to exhibit high fertility rates as well as high rates of maternal mortality.

Demographic measures and profiles are significant in that they become the measures of development, or lack thereof, for post-colonial regimes on the pathway toward becoming developed nations. The Indonesian government's National Census Bureau (*Biro Pusat Statistik*) figures document various demographic changes that indicate the changing shape of Indonesian society—a development the New Order regime in Indonesia was proud to take credit for. Demographic profiles appear to be at the point of “transition.” Life expectancy at birth has increased from a 1950 expected age of death between 35 and 40 years to a 1990–95 rate of 61–64 years (Ananta & Arifin, 1990). Infant mortality rates have fallen from a 1950 rate of 200 deaths per 1,000 to a 1993 rate of 65 deaths per 1,000, with projected rates continuing to decrease (Ananta & Arifin, 1990). Fertility rates have declined as health care measures and family planning campaigns take effect. The distribution of population in Indonesia by age is changing rapidly, becoming older overall, and beginning to mirror the population distributions of developed countries.

This demographic transition, often referred to as the epidemiological transition, the health transition, or in some cases the risk transition, is the result of post-colonial development efforts brought about through family planning programs, public health and sanitation programs, wider access to health as well as shifts in economic conditions and improvements in nutrition for national populations overall. The health costs of development are the “Western diseases” of affluence and “civilization” that include the chronic degenerative diseases associated with over-nutrition, increasing age, and other behaviors, for example smoking and alcohol consumption.

Of course, not all segments of post-colonial society experience the health benefits and costs of development. In the “least developed countries” 20% of children still die before age 5 compared with 1% in “developed countries” (WHO, 1997). Women in developing countries face high risks for iron deficiency anemia, protein-energy malnutrition, death from pregnancy-related complications, and health conditions related to increasing poverty especially among rural communities (WHO, 2000). In spite of trends toward risk transition from “traditional hazards associated with lack of development” to “modern hazards” related to development, vital statistics indicate that public health efforts should be maintained toward reducing poverty, improving the provision of sanitary

services, improving water supplies, providing adequate housing, insuring safety in the workplace, and decreasing exposure to pathogens and toxins from foods and in soils. Medical anthropology continues to play an applied role in addressing and documenting the persistence of these “traditional” health hazards.

Development organizations, and especially the WHO, have identified three diseases that now dominate the “global burden of disease” causing more than 5 million deaths every year. These include HIV/AIDS, tuberculosis, and malaria which, as a group, represent a disease profile of newly emerging infectious diseases. For post-colonial societies these diseases represent a mix of the old and the new as the HIV/AIDS pandemic has taken hold in developing countries with tragic and devastating consequences. In Africa and Asia, HIV/AIDS has become a major health problem that has motivated the marshaling of health care provisions in the same way that colonial medicine was provided to treat epidemics such as sleeping sickness in the Congo.

POST-COLONIAL MEDICINE

Post-colonial health provisions are an admixture of medical practices and perceptions that reflect the colonial experience. These local health care systems continue to include a combination of hospitals, clinics, health posts, pharmacies, nurse paramedical practitioners, and health cadres as well as a multitude of government-sponsored health programs, for example family planning programs, family nutrition improvement programs, village community health development programs, advanced age programs, and programs that train local level health promoters, to name just a few. Mention should also be made of the increasing number of magazines on health, or articles and newspaper columns, television and radio programs, and advertisements that all promote health from the perspective of scientific medicine.

In addition, indigenous medicine, often referred to as traditional medicine, is vibrantly apparent as well. Anthropologist Charles Leslie (1974), in his work on Asian medical systems, noted that in the context of modernization medical revivals of traditional medicine constituted a “looking forward–looking backward” for many nations in their quest to become modern developed countries. Particularly in China and India, medical revivalism was a significant “aspect of cultural

nationalism in these societies” (Leslie, 1976, p. 319). Indonesia provides an illustration of post-colonial medicine which reproduces colonial categories while at the same time producing something different.

The popularity of *pengobatan tradisional*, or traditional medicine, in Indonesia indexes a concern with tradition at a time when Indonesian nationalist rhetoric portrayed the nation on the brink of becoming modern. This modernist revival marked a heightened attention toward traditional medicine within a vibrant and powerful national discourse on contemporary life and citizenship in Indonesia. The Indonesian government considers *pengobatan tradisional* an essential resource in the cause of development (*pembangunan*) (Ferzacca, 2002). As a consequence, traditional medicine becomes a progressive tradition. The logistical issues inherent in the Indonesian engineering of an Indonesian-flavored modernization have set limits on the ability of the government to provide “modern” scientific medicine to a diverse and dispersed national citizenship. For a developing country such as Indonesia, modernist technologies of health embodied by scientific medicine cannot always be made available to the Indonesian population overall. Nor, given the diversity of ethnic groups and their nearness to or distance from the centers of modernity, is scientific medicine always an appropriate technologic intervention.

Therefore, safe and rationalized forms of traditional medicine and practice are promoted until the time when progress toward an advanced social–cultural–economic stage is reached. For Indonesian governance, standard Western modernization theory that advocates breaking down tradition as an obstacle to development is replaced with one that produces, reproduces, and so re-distributes tradition. Tradition and its authenticity, then, are not just artifacts, images, and activities, but a mark of social relations and identities.

From the perspective of Indonesians traditional medicine includes a wide variety of shaman who practice as curers, sorcerers, and ceremonial specialists. In addition to this varied group of shaman are the roving sellers of health elixirs, entrepreneurs who make and sell elixirs and other medicines out of their homes and in the markets. Practitioners of traditional medicine also include: masseuse; Chinese herbalists and acupuncturists; healers who practice South Asian Ayurvedic and Arab Unani medicine; particularly potent teachers of Islam who have the ability to heal; persons who exhibit a particular talent for healing and other shamanistic practices such as

divination; spirit mediums; medical doctors who include traditional medicine in their practices; a wide variety of dentists, optometrists, and surgeons who use traditional medical techniques and medicines; and entrepreneurs who sell manufactured and prepared traditional medicines. Practitioners of traditional medicine are often referred to simply as *dukun*, even though with more frequency there are those who prefer other terms such as the currently popular *paranormal*.

While the availability of traditional medicine in Indonesia represents the contingencies of health care provision in a developing country, medicine is also anchored in historically contingent social forms and practices as well as environmental circumstances. Health and medicine also provide “idioms” and forms of agency for which Indonesians can come to say something of the conditions of their lives and the state of things as they see it. The use of traditional medicine engages communities of sense and sentiment that are experienced as re-enactments of an authentic culture situated within the emergent communities of Indonesian modernity. The continued post-colonial use of colonial categories and essential binaries embedded in development ideology and practice reproduces “partial presence” of these practices and structures of thought (Bhabha, 1994, p. 86). Medical pluralism in post-colonial societies such as Indonesia offers a “complex border zone of hybridity and impurity” (Gupta, 1998, p. 6) within which post-colonial identities are produced through the use of medicine.

Post-colonial development promises many benefits for societies embarking on the road toward prosperity and an improved quality of life. Under the gaze of development ideology and technique the health status of a society serves as one indicator of where it stands in the process of developing. The demographic, health, and nutritional profiles measured by the instrumentalities of government bureaucracies and evaluated from enumerated collections by statistical examination are considered the objective realities of individual and social conditions at a particular historical moment for a segment of society or for an entire nation-state. Under the ideological gaze of development these objective measures become moral barometers that mark both the degree and kind of conditions underway in the process of development. Medical anthropology concerned with post-colonial development has operated within the context of development ideology to apply anthropological approaches and knowledge toward problem-solving—problems that appear in

development encounters. At the same time medical anthropology of post-colonial development has also been concerned with the structural aspects and cultural politics of development. In this way medical anthropologies of post-colonial development are also subject to and so reflect the complex border zone of hybridity and impurity that is post-coloniality.

Refugee Health

Pascale A. Allotey

INTRODUCTION

The study of refugees as a population invites a multi-disciplinary approach because their very existence often is a result of history, politics, economics, conflict and, more recently, globalization; their protection is a matter of international, refugee, humanitarian, and human rights law; their settlement involves immigration, citizenship, and national sovereignty; and their long-term outcomes involve multi-sectoral collaboration between providers of education, health, and welfare. As a population, refugees are influenced directly by the culture of the countries of origin, the culture of conflict and instability, and the culture of the countries in which they resettle. This entry provides a brief overview of the health of the world's refugees. It covers the cultural issues affecting health and the provision of health care from conflict through to settlement. It also examines a range of cross-cultural approaches to the health of refugees in a number of countries.

BACKGROUND

The international community, initially through the League of Nations, and subsequently the United Nations (UN), recognized that priority needed to be given to addressing the vulnerability of the many displaced individuals living within a context where governments were unwilling or unable to enforce laws and protect their

basic rights. Refugee protection on a large scale first occurred with the setting up of the United Nations Relief and Works Agency for almost 1,000,000 Palestinian Refugees in 1950 and culminated in the establishment of the United Nations High Commissioner for Refugees (UNHCR) and the drafting and passage of the Convention on the Status of Refugees in 1951 (hereafter referred to as The Convention). The Convention and the subsequent Protocol in 1967, defined refugees as individuals who (1) face threats of or experience torture, trauma or other forms of persecution by virtue of their race, religion, nationality or membership of a particular social group, or their political opinion; (2) were outside their country of origin; and (3) for these reasons were unable to return (UNHCR, 1951, 1967). Governments that are signatories to The Convention have a number of obligations. These include to support the work of UN agencies that deal with refugee crisis situations, to respond to people who request and are found to be in genuine need of asylum under The Convention, and to protect the human rights of refugees within their borders. A critical component of the obligation is not to return a refugee or asylum seeker to the country from which they fear persecution, a principle known as non-refoulement.

The circumstances that lead to displacement today vary significantly from the circumstances held at the time the definition of a refugee was first drafted. Today, situations that create refugees are more likely to involve mass movements of people. Most of the recent mass displacements have been caused, for instance, by ethnic wars and

political insurgency, with a few occurrences of natural and environmental disasters. The mass displacement of populations comes about, in part, because of the changing nature of warfare, where civilians are increasingly becoming the targets for negotiating political agendas. Approximately 75% of deaths and injuries in recent wars were recorded in the civilian population (Benjamin, 2001) compared with less than 5% of civilian casualties in World War I. In addition, women are deliberately targeted for rape, torture and sex slavery, trafficking, forced marriages, and pregnancies (Benjamin, 2001; Goldstein, 2001). The numbers of refugees rose from 2.5 million in 1970 to current figures of over 12 million registered through formal agencies; over three quarters of these are women and children (UNHCR, 2000). The most recent significant flows were from Afghanistan and the Former Yugoslav Republics.

Another population of concern to the UNHCR is the internally displaced. Mass movements of people can occur as a result of the situations described above; however, the populations are unable to flee outside the national borders and are displaced or homeless within their own countries. While internally displaced persons (IDPs) are unable to return to their homes, they are not legally refugees within the definition of The Convention and therefore are not officially the responsibility of the international community. However, like refugees, conditions for IDPs are characterized by insecurity affecting civilians and noncombatants, the destruction of social networks, infrastructure, and ecosystems and human rights abuses. Recent figures indicate that there are 20–25 million IDPs; that is, there are around two IDPs for every refugee (UNHCR, 2000).

Refugees and IDPs typically experience high mortality, especially in the period immediately after their displacement or migration (Toole & Waldman, 1990). Deaths occur from malnutrition, diarrhea, and infectious diseases, especially in children, with recorded increases in communicable diseases such as malaria, tuberculosis, and HIV infection. Injuries from land mines and direct conflict-related violence typically affect adults. The prior health status of the population, their access to key determinants of health (housing, food, shelter, water and sanitation, health services), the extent to which they are exposed to new diseases, and the level of resource availability, all affect health status (World Health Organization, 2002). A recent session of the General Assembly (June 2001) noted that populations

destabilized by armed conflict, natural disasters, and humanitarian emergencies are at increased risk of exposure to HIV infection because of sexual abuse, coercion, forced high-risk sexual behavior, and rape (United Nations, 2001).

Under The Convention, the immediate response of the international community through the UNHCR is primarily to provide refugees with basic necessities such as shelter, food, water, and medicine. Longer term solutions are sought and include settlement in neighboring countries, voluntary return to country of origin once the threat ceases, or resettlement in a new (third) country. Neighboring nations in Africa and Asia host most of the world's refugees because of the importance of geopolitical considerations and family links (UNHCR, 2001a). It is argued that repatriation is easier from neighboring countries and the similar culture and social structure make the settlement process, even if temporary, less traumatic (UNHCR, 2001b). This argument, however, oversimplifies the complexities of social cohesion and political relationships within regions and overlooks the real potential for continuing ethnic conflict where tribal groups and therefore tensions may occur across borders. It also fails to take account of the potential hostility that may result from the need to redistribute the usually scarce resources in order to cater for the refugees. In South Africa, for instance, significant antagonism and prejudice, especially from black South Africans toward black refugees from other parts of Africa, has become a major issue because of high rates of poverty, unemployment, and poor access to health care for the local, disenfranchised black population (Morris, 1998).

The final option is resettlement in countries, usually in the West, through established procedures coordinated by the host countries and the UNHCR. Unfortunately, the increase in refugee numbers has coincided with an increasing reluctance from countries that are signatories to The Convention, particularly in Europe, North America, and Australia, to respond to the resettlement needs of refugees. The major concern has been the mixed nature of migratory movements, the misuse of the asylum processing system by people wanting to migrate to more affluent countries due to economic hardship, the growth in an industry of people smuggling and trafficking, and an inability to garner international support to prevent and resolve refugee situations (United Nations, 2001). In Europe alone annual political asylum applicants increased over a 10-year period from 60,000 to 600,000

(Steiner, 2000, p. 2). Furthermore, the response of nations to refugees and asylum seekers is based not only on the magnitude of the crisis and humanitarianism, but also on the internal economic interests and political agenda of the potential host country (Shacknové, 1993). More recently hostility toward refugees has been exacerbated by the perceived need by many countries for stricter border control and immigration policies following the terrorist attacks in the United States on September 11, 2001.

Tighter border control and an asylum review process that is increasingly unable to cope with the numbers of applicants has led to an increase in the numbers of asylum seekers attempting to circumvent the resettlement process by applying for asylum “on-shore.” That is, the application for asylum is lodged following arrival in the country with a valid visa and legal documents or through attempting to enter the country without legal documents or visas. The Convention makes provision for this in recognition of the vulnerable positions in which asylum seekers find themselves, and the general lack of choices they have in seeking asylum (UNHCR, 1951).¹ The response from several countries, however, has been the mandatory detention of asylum seekers who do not have valid documentation, for the duration of the processing of their applications (McMaster, 2001a). In addition, there has been a tightening of the definition of persecution with a greater onus lying on an asylum seeker to prove a threat to life, torture, or trauma (Lambert, 2001). Rigorous debates have occurred between human rights and refugee advocates on the one hand and immigration authorities and governments on the other about what is perceived by some to be harsh treatment of traumatized and vulnerable populations. Refugee advocates have argued for a broader definition of persecution to include nonpolitical but potentially life-threatening events such as gender-related persecution (Copelon, 2000; Kelley, 2001). The case of Togolese Fauziya Kasinga receiving asylum in the United States in 1996 based on her fear of female genital mutilation provided an opportunity to set precedence in this. “Diminished livelihoods” as a result of conflict has also been proposed as justification for asylum (International Catholic Migration Commission, 2001). Advocates maintain that it is often difficult to unravel human rights abuses from economic marginalization as causes of forced displacement (United Nations, 2001). Arguments based on equity have also been presented to justify an increase in the quota of humanitarian entrants to cope with the numbers of applicants waiting processing for resettlement

(Steiner, 2000). The anti-refugee lobby and, increasingly, governments in hosting countries have politicized the asylum issue in response to community perceptions of insecurity (de Bousingen, 2002; Mares, 2001; Steiner, 2000) with the result that the humanitarian spirit that embodied The Convention is often lost. Discussions about the causes of conflict and displacement are more often than not neglected in public discourse in favor of highlighting the importance of border sovereignty and disadvantages of multiculturalism (Mares, 2001; Mateen & Titemore, 1999; McMaster, 2001a). A real danger identified by the United Nations is the potential for acts of racism and xenophobia against asylum seekers (de Bousingen, 2002; United Nations, 2001).

IMPLICATIONS OF CONFLICT AND DISPLACEMENT

In addition to the direct effects on ill health previously highlighted, an important characteristic of current conflicts that indirectly impacts on health is the destruction of social networks and cultural institutions that provide populations with a sense of identity. This is particularly relevant in conflicts against particular ethnic groups such as the Iraqi government’s targeting of the Kurdish population (Middle East Watch and Physicians for Human Rights, 1993), the Indonesian government’s killing of large numbers of East Timorese, and the Serbs’ targeting of ethnic Albanians. There has been documentation of the systematic suppression of cultures through the ban of the use of ethnic languages within oppressed groups. Examples are the violent protests in Soweto as a result of the government’s insistence on the exclusive use of Afrikaans during the apartheid period in South Africa and the Iraqi assault against the Shia culture and religion (Makiya, 1993).

The intentional destruction of social, economic, and cultural realities has been described as the primary psychic obstacle that needs to be overcome by survivors (Summerfield, 2000). Communities subjected to frequent harassment, particularly in protracted situations, “forget” concepts of trust and innocence and the ability to predict or explain their sociocultural context. Just as traumatic is the destruction of livelihoods, for instance of subsistence farmers that know no other way of life, and other social structures, community networks, and traditional mechanisms that are relied on in times of crisis. Harrell-Bond and Wilson (1990) describe the effects on Sudanese

refugees of the inability to perform traditional burial rituals for relatives who lost their lives during the conflict, a critical part of the grieving process. They reported being haunted constantly by the spirits of the dead family members.

The refugee experience is therefore mediated by a wide range of circumstances. How refugees overcome these to rebuild their lives and regain their health and well-being depends to a large extent on the post-conflict outcomes and the opportunity for a stable environment in which “normal” life can resume. Consequently, the opportunities that present through voluntary repatriation or resettlement are critical to long-term outcomes.

Recent repatriation programs have acknowledged the importance of rebuilding all aspects of the country and communities that have been affected by conflict and instability. Program activities for reintegration and resettlement of conflict areas involve not only the returning refugees, but also the local population in areas to which refugees will be returning in order to create and sustain viable social units. There is an increasing focus on active participation, which is important to short-term success and long-term sustainability. In addition, following a recent UN resolution¹ on the impact of war on women, findings from studies on gender and empowerment have been incorporated into planning, implementation, and evaluation to ensure women’s active participation in the peace and repatriation processes. While the voluntary repatriation of refugees may be the ideal solution, systematic evaluation is fairly recent and therefore “best practice models” by which successful reintegration and re-establishment of livelihoods are not clear. A body of literature is gradually building up from lessons of countries such as Albania, Eritrea, and Ethiopia.

THIRD COUNTRY RESETTLEMENT

Experiences of refugees resettled in countries that are culturally different are much better documented. Refugee resettlement is controversial and increasingly emotive, as previously described. For the refugees, the resettlement experience is shaped by the conflict and post-conflict period as well as by the receptiveness of the host community. The receptiveness of the broader community in host countries depends to a large extent on the political climate, the media, and historical experience with engaging with refugee communities. Images of refugees presented in

many Western countries are of victims, powerless against rebel forces fighting for or against the incumbent government, of living conditions within refugee camps that harbor diseases long eradicated or unknown in developed societies, and of miserable and malnourished children (Mares, 2001). These refugees are perceived as people who are vulnerable and reliant on the goodwill of the receiving nation (McMaster, 2001c). Also featured in the media are people taking perilous journeys to cross national borders without legal documentation; people taking the initiative to seek out peace and stability instead of waiting on the benevolence of wealthier countries through an established process that is nonetheless protracted and not necessarily equitable.² Further images present similar looking people responsible for terrorist attacks on civilian populations. The overall picture drawn from these representations is important to the perception and reception of refugees and asylum seekers. The power of media images in providing and interpreting information and swaying public opinion cannot be over-stated (Kleinman & Kleinman, 1997) and the media has come under a great deal of criticism for fuelling the disquiet in the perception that industrialized countries need to be concerned with the potential of being overwhelmed by asylum seekers (UNHCR, 2001a). It is not uncommon for descriptions of refugees, asylum seekers, and illegal immigrants to be used interchangeably (Steiner, 2000). In reality, however, much of the blame for the disquiet of host communities rests with the political leadership in these countries (de Bousingen, 2002; Mares, 2001; McMaster, 2001a). A recent UN review on international protection stressed the need for the political will to de-dramatize and depoliticize the humanitarian challenge of protecting refugees in order to promote the public’s understanding of the right of refugees to seek asylum (United Nations, 2001).

In Australia, asylum seekers who arrive without documentation are subject to indefinite mandatory detention while awaiting determination on the outcomes of their applications. When they are found to have a genuine claim for asylum, they are issued with temporary protection visas, a classification that restricts their rights and access to social and public goods within the community and differentiates them publicly from other citizens and refugees in the community. This policy establishes a hierarchy of the vulnerable who deserve support. Importantly, it institutionalizes their marginalization and creates an attribute for stigmatization. This subsequently

contributes to the barriers to accessing health care (Silove & Steel, 2002; Silove, Steel, & Mollica, 2001; Sinnerbrink et al., 1996).

A recent review of alleged human rights violations in the immigration detention centers by a special envoy of the UNHCR raised serious concerns about the length of and conditions under which asylum seekers were detained in Australia (Bhagwati, 2002). For these asylum seekers, experiences within detention, and subsequently the temporary protection visas (which can be revoked on review), add to the interruptions in their search for stable and peaceful environments in which to rebuild shattered lives (Silove, Franzcp, Steel, & Watters, 2000). In contrast, in Sweden, asylum seekers are housed in geographically isolated hostels with a full provision of services on-site while they wait for their claims to be processed (Summerfield, 1999). Refugees who arrive through the procedures laid out through the Department of Immigration of Australia and the UNHCR are housed in state-funded housing on arrival and their settlement officially coordinated for the first few months following arrival. Refugees in the United Kingdom are largely required to fend for themselves in the community (Dean, 1998).

Specific effects on health of these contextual issues during resettlement have been well documented (Shrestha et al., 1998; Silove & Kinzie, 2001; Silove, McIntosh & Becker, 1993; Silove & Steel, 2002; Sinnerbrink et al., 1996; Sundquist & Johansson, 1996). Most consistent are the mental health problems, which correlate highly with torture and trauma experiences, post-migration stressors such as detention, unemployment, family disharmony, social isolation, and other acculturation difficulties. The inability to trust has an important impact on the establishment of social capital which in turn has negative effects on health. The most common conditions reported include post-traumatic stress disorder, anxiety, and depression (Shalev et al., 2001; Silove & Kinzie, 2001; Silove et al., 1997; Silove et al., 1998). Debates in cross-cultural mental health, however, have raised questions about the universal application of diagnoses based on psychiatric conditions that may not translate well cross-culturally (Kleinman, Das, & Lock, 1997a; Summerfield, 2001; Szasz, 1991). Summerfield describes the medicalized trauma discourse of Kurdish asylum seekers when reinterpreting their experiences with Turkish authorities when they seek asylum in the West. According to Summerfield (1999), it was unlikely that the asylum seekers would have subscribed to a label of torture or

mental health pathology within the country of origin. However, they learn to adopt the expected illness label within the dominant medical discourse of the services they access (Christianson & Safer, 1996; Herlihy, Scragg, & Turner, 2002; Van der Kolk & Fislser, 1995).

There has also been some exploration of alternative explanations for mental ill health in refugees. Kleinman, Vas, and Lock (1997a) describe cultural notions of suffering as a result of political, economic, and institutional power and the influence of this power on social responses and health (pp. ix–xxvii). Grønseth (2001) combines theories of embodiment by Csordas (1994) with social suffering (Kleinman et al., 1997b) to describe the complexity of how the process of suffering manifests as diffuse aches, pains, and fatigue among resettling Tamil refugees in Norway. Others describe the somatization in terms of culture specific syndromes such as *susto*, which indicate a loss of soul, detachment from place, and general disquiet within oneself (Allotey, 1998; Eckersley, 2001; Simpson, 1993).

The perception of unfriendly host communities (Steiner, 2000) and prior experiences that affect trust provide an important context for refugee resettlement. It is not uncommon for resettling refugee groups to embrace and revive traditional cultural practices within the host country as an important part of re-establishing a sense of identity, particularly where they feel unable or, for a range of reasons, are unwilling to integrate within the host community. Women who were nonpracticing Moslems or liberal in their practice have reinvented themselves, taking to traditional forms of dress (*hijab*) as a bold statement of their identity (Brooks, 1995; Manderson & Allotey, 2003b). It is important to highlight the heterogeneity of refugee groups and the diversity in levels of education, professional, and socioeconomic status within groups. However, it would be reasonable to state that there is usually a strong imperative, based on a perception of incongruity of the dominant culture, to foster social networks within their own or other minority groups. There is a tendency, for instance, for information on health and services to be sought from established social groups who share the refugee experience (Manderson & Allotey, 2003a, 2002b).

PROVISION OF HEALTH CARE

Unfamiliarity with mainstream health systems, lack of ability to communicate in the language of the host

community, cultural differences, poverty, and marginalization combined with pre-migration and settlement stressors all contribute to social and health disadvantage identified in many refugee groups. These factors are also the main barriers to accessing health services (Jones & Gill, 1998; Palmer & Short, 2000).

The provision of health care to resettling refugees in a third country depends to a large extent on the policy environment towards migrants. Over time and in various contexts, governments have adopted policies broadly based on philosophies of assimilation, integration, or multi-culturalism (Palmer & Short, 2000). Assimilation, which reflects current trends in Europe, is based on an expectation that migrants and refugees will blend in with the dominant culture with no significant change expected from the host community. There is little recognition of or tolerance for diversity under policies of assimilation. Integration recognizes and respects differences in culture and provision is made for language and cultural differences. Integration policies provide assistance to refugees to function within the dominant culture. Multi-culturalism or cultural pluralism is based on total participation of all cultural and ethnic groups in the political process in recognition of their contribution to the development of a dynamic, evolving culture of diversity.

In reality, there is a broad variation in the implementation of these policies into service provision. In broad terms, the policy environment dictates the allocation of resources that enable health services to respond in one way or another. However, services also need to some degree to reflect the needs of their client group. Within health service provision for refugees, service delivery models have ranged from specialized ethno-specific services to mainstream services with no clear agreement of the advantages of either. The debate is ongoing in part because of the differences in outcome indicators, which may be based on efficiency in health service provision or on specific outcomes for the patient. The most desirable would achieve both.

Ethno-specific models provide targeted services to ethnic groups, ensuring that the providers of the service are either from the same ethnic backgrounds or are culturally sensitive to the needs of the specific groups. Other refugee-targeted services include dedicated clinics that recognize the special health needs of this group such as particular parasitic conditions that are not endemic within the host population and, more commonly, specialized trauma counseling services for survivors of torture and trauma (Palmer & Short, 2000). It has been argued,

however, that while these services may meet a need, they are not an efficient use of health care resources and they further marginalize refugees from the host community, especially in a policy environment of multi-culturalism (Kelaher & Manderson, 2000). On the other hand, providing refugee care within a mainstream service risks the failure to identify and respond to special needs due to the cultural chasm between service providers and refugees. There has been some attempt to address this failure through a growing body of resources, the aim of which is to increase the cultural awareness and sensitivity of staff to the range of issues that may affect the health, presentation and symptoms, attitudes, response to and compliance with treatment within the health care system (Allotey et al., 1998; Geissler, 1998; Jones & Gill, 1998; Kirkwood, 1993; Levenson & Coker, 1999; Lipson, Dibble, & Minarik, 1996). Under this model, some training is also provided to refugee groups on the available services and negotiation of the health system.

CONCLUSION

It would be unduly optimistic to make projections about the elimination of conflict, particularly under current global circumstances. Anthropologists have an important role to play in the exploration and analysis of situations that create refugees, enable them to survive and maintain resilience in spite of significant trauma, and rebuild their lives post conflict both through repatriation and resettlement. There is a particular dearth of knowledge on the health of refugees within protracted conflict situations where there is long-term uncertainty, a lack of cultural and social infrastructure which we generally understand to be necessary for human societies, and the application of that information to build structures to support and maintain health.

NOTE

1. Article 31 of the convention states that The Contracting States shall not impose penalties, on account of their illegal entry or presence, on refugees who, coming directly from a territory where their life or freedom was threatened in the sense of article 1, enter or are present in their territory without authorization, provided they present themselves without delay to the authorities and show good cause for their illegal entry or presence (UNHCR, 1951).
2. The screening process for the resettlement of refugees for many countries gives priority to the well educated, healthy applicants; a further occasion for the disadvantaged to be further marginalized.

Social Stratification and Health in the Western Context

Arushi Sinha and Tyson Gibbs

INTRODUCTION AND DEFINITIONS

The concept of social stratification and the concept of health embody two areas of research interest to social scientists. Social stratification is a commonly accepted term in the social sciences, particularly in examining of the ways that humans organize themselves into various cultural and social groupings. For the purposes of this discussion, social stratification is:

plurality of strata within a single society, with some sense of their internal identity, of their internal similarity, of their external differences

vis a vis other strata...These qualities by which strata identify themselves and others, are frequently referred to by shorthand terminology such as wealth or poverty, or rulers or people, or workers or bosses. These terms refer to positions on particular distributions such as wealth...income, power and occupational role...The connections between positions of the individual on different distribution are of two sorts. One is...through life chances, opportunities to enter into a higher position on any distribution from lower position in that distribution. [The other is the ideal that]...there is widely experienced aspirations to bring positions on a series of distributions into an appropriate correspondence with each other. (Shils, 1970, pp. 446–447)

The behavior of humans is not rooted in our genetic structure to the degree that it cannot be changed,

modified, or otherwise channel behavior. As Krauss (1976, p. 3) states, “the way we act is based on the meaning we attach to things...physical objects, specific individuals, categories of persons and other activities such as commands and requests. The meanings are not intrinsic but social products.” Social stratification is the term that describes the way humans group themselves, based on characteristics ascribed to one another or passed from one generation to the next. Such characteristics take on a life of their own in the day-to-day functioning of human beings within a cultural and social context.

Everything that humans do is part of a social construct, attaching meaning to the objects, people, and activities in which they engage. The meaning becomes part of the process by which places are created in the fabric of human organization. Each culture and social group emphasizes different components of the human existence. For some cultures, the critical element separating one person from another might be the family of origin. In another group, it could be access to wealth. And in yet another group, gender affiliation may determine where one is placed in that society. Religion, appearance, body type, and many other human attributes determine where one is placed. Also, each society differs on when the placement of that person is made, for example, such placements might be made across the life spectrum—at birth, at puberty, at adulthood, at old age.

Whatever the basis for classifying people into various groupings, such judgments are made in each society, and these classifications result in creating differential levels of human interaction. And these groupings are not equal for each person. As Tumin (1994, p. 47) commenting on the ubiquity of social inequality writes, “Every known society (above the band level of organization) distributes its scarce and demanded goods and services unequally. And there are attached to the positions which command unequal amounts of such goods and services certain highly morally tinted evaluations of their importance to society.”

The types of groups that result from the need to place individuals within a social hierarchy are complex in their manifestation. That is to say, one’s position can change depending on the circumstance. Humans can play the roles of mother, father, husband, wife, sister, brother, lover, friend; each role carries certain responsibilities and can occur in activities outside of the family. Each group requires that individual members understand these various roles thrust upon them, and the expectation is that

each person will fulfill certain responsibilities ascribed to those roles. The socialization process of each human within a culture does not always adequately prepare one to assume the responsibilities that accrue to these roles. Thus, the concept of social stratification offers researchers the opportunity to understand how people function within a given culture.

The area of health is one component of human existence. Each society has created a mechanism for explaining the changes to their biological functioning. The explanations for these changes range the gamut of possibilities. For example, in many Chinese groups the presence of energy bands within the body, called meridians, along with the balance of yin and yang dominate the explanation for health status. In Mexico, one can have a hot or cold illnesses based on humoral explanations. And in parts of Africa, the presence of witchcraft can explain many sicknesses that befall the individual. Because the world is changing as a result of globalization, and the interaction of cultures across previously closely guarded borders, many societies have adopted a mixture of explanations for changes in body function that include their own local explanation, plus the more Western explanation that focuses on disease at the cellular level.

The question is: How does social stratification in a group have an impact on issues of health? The definition of health, like the definition of social stratification, is not one on which researchers readily agree. The concept of health is not easily defined. Mascie-Taylor (1995, pp. 101–102), quoting Talcott Parsons, defines health as “the state of optimum capacity of an individual for the effective performance of the roles and tasks for which he has been socialized.” The World Health Organization defines health as the state of complete physical, mental, and social well-being, and not merely the absence of disease (Brearley et al., 1978, p. 7). *The American Heritage Dictionary* describes health as the state of an organism with respect to functioning, disease, and abnormality; the state of an organism functioning normally without disease (Pickett et al., 2000). Health can also mean that the chakras are balanced, the absence of malevolent spirits, or the flow of positive *Qi*. These multiple definitions necessarily imply that cultural groups manage health on many levels, depending on what has been identified as having changed body function. Such management also connotes that defining the state of health of an individual may require multiple players, each with his/her role—the individual, the family, the health practitioner,

and the care-givers. It is this mixture of local and other health practices that has created a health system structure worldwide. As Wilkerson (1996, p. 1) states,

research findings focused attention on the wider features of the social and economic structure...we have, in effect, been learning about the interface between the individual and society, and the structural factors on health; about how people are affected, by social position, by wealth and poverty, by job insecurity and un/(under) employment, by education, by social mobility; about why taller people move up the social hierarchy; about the importance of social networks... and about social organization of work.

HEALTH AND SOCIAL STRATIFICATION

One could argue, quite cogently, that social stratification clearly delineates human activity and behavior on multiple levels in a society. Linking social stratification to health issues constitutes a structural approach to understanding health issues at the local and global, public and private sector levels. It also means understanding the ways in which patients' and health care providers' choices are circumscribed (Anagnost, 1995; Morsy, 1995; Navarro, 1981; Pearce, 1995; Singer, 1990). At the individual level, as Gramsci (1971) argues, the healer, like the priest, is a mediator between the elite and the non-elite, and health and disease are defined by the elite for the purposes of controlling the non-elite. Others have described healing systems as the meeting ground between the elites and the proletariat (Waitzkin, 1979) and as "the locus of hegemony" (Csordas, 1988). Medicine often defines the "Other" as diseased or unhygienic, and in doing so, places it under medical control, the realm of the elites (Comaroff & Comaroff, 1992; Douglas, 1966).

Because health is negotiated at so many different levels, it is important not only to identify the different levels but also to understand their interaction. What are the tools available to anthropology to examine the structural determinants of health care? Health care at the macro level is determined by the confluence of politics, economics, and ideology. Such interactions determine the path governments choose in determining health standards, in providing health for their populous, and in endorsing one health care system over another. The macro, structural, is separated from the micro, experiential, phenomena only as matter of analysis (Singer, 1990, p. 191). In practice, individual and structural features work simultaneously to determine health decision-making.

As Morsy states, "the political economic orientation forces anthropology to redefine its field of inquiry in global processual and relational terms" (Morsy, 1990, p. 27). As such, the political economy of health addresses the issue of power in the production of health. For example, in Egypt *uzr* is described as a sickness that preys upon young brides and younger sons in the family. The disease is understood as being induced by the powerlessness of these familial positions, and the sick role is seen as an embodiment of this inefficacy. In a Nigerian example, the uncertain political future of the nation-state has prompted people to utilize simultaneously a variety of health solutions, including reliance upon familial "therapy managing groups" and a renewed interest in faith healing and indigenous medicine, in addition to the state-supported biomedical system (Pearce, 1993). Wilkerson further demonstrates the linkage between social position and health. He writes about a study of electoral wards in Northern England in which death rates were four times higher in the poorest 10% of the wards, as in the richest 10% (Wilkerson, 1996, p. 53). He writes, "numerous studies have shown health differences are not confined to differences between the poor and the rest of society, but instead run across society with every level of society having worse health than the one above it" (Wilkerson, 1996, p. 53).

BIOMEDICINE AND MEDICALIZATION

In the Western context, and in the United States specifically, biomedicine has assumed the role of the dominant health system (Singer & Baer, 1995). By focusing on the modes of biomedical production, anthropologists can look at the ways in which capitalism has been resisted or transformed by the individual participants (Morgan, 1987). Foster and Anderson (1978) define biomedicine as an ethno-medical system which has both its genesis and its sustenance within Western political, economic, and ideological institution. It is variously called cosmopolitan medicine, capitalist medicine, Western medicine, and urban medicine. Importantly, Foster and Anderson (1978) point out that biomedicine is an ethno-medical system, just like *curanderismo* in Latin America, *Ayurveda* in India, and *Qi*-based systems in China. Biomedically informed health providers blame the victim. Indeed, in capitalist medicine (Navarro, 1986) the system is rarely implicated, while the worker is further burdened. Among

migrant agricultural workers in the United States, public health researchers conclude that the way to alleviate cancer among this population is to provide cancer screening clinics (Lantz, Dupuis, Reding, Kerauska & Lappe, 1994) instead of enforcing the occupational safety laws already in place.

In an effort to emulate the capitalist world and its institutions, non-Western governments may further the causes of Westernization. In the Egyptian experience, this has allowed pharmaceutical companies access to human subjects for drug testing, such as Norplant (Morsy, 1993). In the Indian example, the state policy of controlling overpopulation, a Western definition (Sowell, 1983) espoused by elite Indians, led to the forced sterilization of several thousand men during the 1977 emergency. The memory still haunts the Indian rural populous today and makes them wary of government-sponsored health intervention programs (Banerji, 1982).

Given biomedicine's historical influences, its spread has definite implications for the negotiation of health care both within and outside the industrialized world.

NEGOTIATING HEALTH AND SOCIAL STRATIFICATION

What are the factors that influence the ways in which people understand and express their health/illness behavior? The anthropological record shows that expressions of the sick role are mediated by individual determinants, such as ethnicity, age, education, "racial" classification, class, gender, and occupation, and structural determinants such as health policy, economic policy, and national policy.

If health is a negotiated process by which a standard of values is defined as "health," then communication lies at the base of determining the health of individuals within a society. Because the definition of health is a collective determination, it must have room for debate and negotiation of the standard by which individuals are to be judged (Habermas, 1970, p. 372). In biomedicine, as in other healing cultures, it is often the case that a small, but powerful minority decides definitions of health and the standard for a "healthy" individual.

Kleinman's (1980) was the first model that acknowledged that definitions of health and disease are arbitrary, culturally conditioned, and vary across space and time. The model could thus be used for analysis of culture-bound

syndromes (such as premenstrual syndrome) as well as biomedically defined diseases such as tuberculosis. The model did not distinguish between biomedically and non-biomedically constructed illness and imparted the same legitimacy to each. Secondly, the explanatory model took into account and legitimated both patient and practitioner (healer) roles and participation in the health process. By demonstrating that health and disease are negotiated by individuals in the context of cultural and social experience, the explanatory model also provided a theoretical foundation, establishing communication as the crux of the health care encounter. At its simplest, the health experience is the meeting of patient and healer; at its most complex, health care is where biomedicine meets the global marketplace. Each of these represents points of articulation and communication.

The sick role is a mode of communication and the first step in the healing process because it is the acknowledgment of illness or abnormality. In assuming the sick role, the individual communicates several important messages: the first is a wish to be absolved of regular duties; second, a desire to validate illness via a healer; and third, an acknowledgment that this is not a normal or usual state. The patient might visit the doctor, ensuring "formal medical validation, and the submission of the sick person to the ministrations of the physician" (Foster & Anderson, 1978, p. 146). The sick role may be undertaken for utilitarian purposes. *Nervios*, *susto*, and stress may be excuses individuals use to separate themselves from expected social roles. Sufferers from legitimate illness are often excused from daily duties, including housework, occupational responsibilities, and child care.

CONSTRUCTING HIERARCHY

Structural forces are implicated in the production of illness as well as with the provision of health care and treatment. There is a variety of socioeconomic and structural parameters on which health care is not only defined but also delivered. These parameters may be ethnicity (including "racial" classification), sexual orientation, class, and gender.

Ethnicity

Though issues of discrimination based on skin color were the foundations of political activism in the 1960s and

1970s, “race” did not constitute a central focus of anthropological study until much more recently (Harrison, 1999). It is only within the last two decades or so that anthropologists have taken the position that “race” is a social category, not a meaningful biological category as applied to humans. By focusing attention on the perceived ethnic differences, the physician defers attention from clinical shortcomings (Stein, 1985). For example, the African American experience has been well studied (e.g., Powdermaker, 1939; Stack, 1974). Among the medical community, the importance of ethnicity and race as a basis for the provision of health care are only now becoming apparent. In the case of cardiovascular disease, recent studies document that African Americans are less likely to receive the same types of preventive screening measures as European Americans, resulting in a higher morbidity and mortality rates, with African American women being the most disadvantaged group. As Brown (2002) states, “Overall, the general pattern of care suggests that African-American women may receive high-technology cardiac treatment significantly less often than all other race and sex categories.” Racial disparities in the provision of health care are corroborated by other researchers (e.g., Funk et al., 2002) and represent the tip of the iceberg into the inquiry of ethnicity and race and as a determinant of health care status.

By demonstrating the different socialization patterns of European American and African American youth, anthropology has provided a context for understanding variances in health behavior and practice based on racial categories (Boone, 1989; Heurtin-Roberts & Reisin, 1993; Wilson, 1985). For instance, young African American women have a less stereotypical body image, and they are more comfortable with their own bodies (Parker et al., 1995). In addition, among African American women condom use is motivated not by economic considerations but by affective ties and notions of self-esteem (Sobo, 1995). Self-supporting women with strong kinship ties demonstrate a higher incidence of condom use, while those women who depended upon their male partners for both affection and/or income are less likely to insist upon condom use. Variation in such behavior has definite implications for health status.

Another more recent example is an analysis of the push-pull factors influencing alcoholism among Native Americans (Spicer, 1997). Among members of this group, alcohol is considered a communal commodity and is thus shared freely; drinkers must be willing to provide

alcohol in a reciprocal manner. Those who partake of this communal resource without contributing to it are publicly shamed and ridiculed, though they may still be allowed to drink. Individuals may go to great lengths to contribute to this communal resource, selling household items in order to obtain money for liquor, which is then shared among friends. Anthropological research has demonstrated that health is inextricably linked to the social indices of “racial” categories and class in the American experience.

Sexual Orientation

While pre-Boasian anthropology was interested in maintaining Victorian morality, contemporary research has little use for such prudery, and actively lobbies against it (e.g., Deacon, 1997; Hare, 1985; Jacobus, 1990; Mead, 1928; Roscoe, 1995). AIDS was and continues to be a controversial issue, not just because of the politics of identification and prevention, but also of treatment, such as in the case of needle exchange programs. In activist gay communities, alternative therapies for AIDS—that is, those that do not conform to the standards of the medical community—became normal and no longer “alternative” (Eisenberg et al., 1993). AIDS has the highest percentage of alternative therapy use of any chronic ailments. Estimates of alternative therapy use among AIDS patients range from 36% to 73%, compared with 7% for cancer patients, and 5% among the general population (Furin, 1997). The disease came to be identified as a punishment for unacceptable lifestyles, and disease as caused by “sin” re-entered mainstream discourse about the disease. Because of the AIDS epidemic, anthropological research focused upon and found encouragement for studying the drug subculture and the subculture of the homosexual community within the United States (Furin, 1997; Singer & Baer, 1995; Whitehead, 1997). Since AIDS was initially categorized as a gay disease, and because some men who engaged in homosexual activity did not necessarily think of themselves as gay, they did not think the warnings about AIDS applied to them. This has resulted in the high frequency of AIDS among men who are members of “racial” minorities. In the American context, African American men who engage in homosexual behavior use the term “gay” only in reference to homosexual European American men (Whitehead, 1997). In the Washington, DC, area, 66% of the new AIDS cases are African American men who have low survival rates after diagnosis (Whitehead, 1997, p. 412). Whitehead (1997)

argues that contemporary sexual behavior has historical precedent in the plantation system. The northward migration of slaves meant the transportation of plantation lifestyles. One of the features of plantation culture was the idea that “the more children a man has, the more of a man he is” (Whitehead, 1997, p. 414). By examining the roots of social behavior, Whitehead joins historical to present-day health indices, a process that has been borne out by Caribbean research (i.e., Jones, 1994). Similarly, Latino men are also hesitant to display openly homosexual behavior because it constitutes grounds for violent attacks (Singer, 1996; Singer & Marxuach-Rodriguez, 1996).

Class

Strickland and Shetty (1998, pp. 25–26) posit that “measures of health status, a relatively long-term property of the individual...tend to show more marked social class differences.” In the American context, the medical marketplace is the primary mode of health care delivery. As a consequence, Heurtin-Roberts and Reisin (1993, p. 223) point out that just as “American affluence is not equitably distributed, neither are our basic health care services.”

In the American context, Appalachia is often described as enamored of “folk” remedies. Cavendar and Beck (1995, p. 140) argue that in fact, members of this community are pragmatic, and though pious, are not overly given to superstition or faith healing. “Traditional” remedies, such as turpentine or onion poultices to treat upper respiratory ailments, have slowly been replaced with commodities available in today’s health market, namely pharmaceuticals and professional services. Younger generations may express disdain for the backward ways of their parents and grandparents because they have internalized the “primitive” characterization of this type of healing as it has been expressed to them by outsiders (Cavendar & Beck, 1995, p. 140). The changing health practices, namely a preference for health commodities, are reflective of the changing subsistence base of this area.

As a class structure, incarcerated criminals constitute the lowest social order in society. They are deprived of rights, privileges, and often personhood itself (Foucault, 1975). Prisons are a particularly intriguing area of study, especially from an anthropological perspective. Coupled with the legal mandate of 1976 which required prisons to provide adequate and timely medical care to inmates, correctional systems have been searching for ways to

provide both safe and timely response to inmate health care. Federal prisons alone held over one million inmates, and the incarceration rate increased from 139 per 100,000 in 1980 to 373 per 100,000 in 1994, a tripling in just over a decade (Hipkins, 1997, p. 375). Disease is endemic in the prison system because prisoners have lower health indicators to begin with and are exposed to highly potent and communicable diseases such as AIDS. Endemic also are high rates of mental illness among inmates as they are shunted out of a shrinking mental health system and into the prison system (Hipkins, 1997). Given the large numbers of individuals living in prisons in the United States and around the world, a systematic analysis of the articulation of health and social control as it is expressed in the criminal justice system is long overdue.

Gender

Perhaps one of the foremost determinants of social status in the cross-cultural record is gender. The contemporary feminist movement in anthropology dates to the 1970s when Rosaldo and Lamphere (1974) published their revolutionary work, and Ehrenreich and English (1978) realized the feminist agenda through a meticulous critique of the biomedical establishment. Their work added to the existing literature on the health of minority groups, but underscored the notion of biomedicine as a means to enforce an amassed set of Euro-American values (Jacobus, 1990). After examining the historical relationship between women and biomedicine, they proposed that the goal of medicine was to legitimate a “masculinist society, dressed up as objective truth” (Ehrenreich & English, 1978, p. 5; also Keller, 1985; Martin, 1991). As patients, women are subordinate to physicians and also to medical technology (e.g., Frank et al., 1998). With respect to pharmaceuticals, women are more likely to be prescribed psychotropic drugs than men, owing to a higher incidence of what Estroff (1993) terms “I am” diseases, such as anorexia. Thus, women not only suffer from such diseases, but also from complete identification with them (see also Davis-Floyd, 1992). In the genetic counseling industry, Rapp (1988) describes the process from the points of view of the patient and provider. The people who work in this industry tend to be young women. However, because the job requires a fair bit of emotional involvement with parents and helping them to understand the meaning of genetic assay in their unborn child, the rate of employee turnover tends to be fairly high.

In another examination of biomedicine, Cassell (1996) described the role of women, not as patients, but as health care providers. In the accounts of female surgeons, their femaleness provided a basis for vilification, continually reinforced and frowned upon. Snide remarks (“Surgery is no good when a woman is in the room”) and questions about sexual orientation (“Put on lipstick, or people will think you’re a lesbian”) undermine the self-esteem and effectiveness of these professionals (Cassell, 1996). It is an atmosphere of belittling confirmed by women doctors themselves (Levy, 1987, p. 536).

The dominion of masculine over feminine and its effects upon health has been extensively covered in the medical anthropology literature, and any discussion here will be cursory at best. Some of the earliest accounts are those by Gilman (1993). First published in 1891, Gilman describes the way in which women are confined and coerced by biomedicine. Since that time, many writers have commented upon their mistreatment at the hands of the biomedical establishment (Davis-Floyd, 1992; Ehrenreich & English, 1978; Laurence & Weinhouse, 1994; Martin, 1991; Rapp, 1988).

While women are more susceptible than men to the sick role, they may use their illness experience to their advantage (Low, 1989). Using the example of *nervios* or “nerves,” Rebhun finds that “a woman’s manipulations are more or less successful depending upon her skill at orchestrating perceptions of her situation” (Rebhun, 1993, p. 131). A woman may somatize an unhappy marital relationship, using it as a tool by which to bring about favorable behavior on the part of her husband while simultaneously mobilizing community support for her cause. In Andean Ecuador, women use the *nervios* sick role as a “coping mechanism for excessive responsibility and unrealistic social expectation,” namely trying to successfully manage home, family, livestock, and cultivation duties (Finerman, 1989). This type of approach to lived experience enters the realm of definitions of resistance (e.g., Coplan, 1992; Foucault, 1963, 1975), where resistance is described as a bargaining and coping tool for the overtly disenfranchised members of the group. In these cases, illness provides a mode of escape, a temporary empowerment, or a method for dealing with powerlessness.

The examination of reproduction and reproductive technologies also affords a window into the “politics of reproduction,” synthesizing local (birth and parenting) and global (socioeconomic) structures. Just as contraception made possible sex without reproduction, so reproductive

technologies offer the possibility of reproduction without sex (Whiteford & Poland, 1989). The danger is that the flow is unilateral, where infertile women are used as guinea pigs for drug testing, and poor, but fertile women may rent out their wombs for bearing others’ children. Birth technologies have also altered the birthing process itself. Thousands of years of women kneeling or squatting during childbirth gave way to women lying on their backs in hospital gurneys, their legs elevated by stirrups. This unnatural, iatrogenic posture was pioneered by Louis XIV, so that he could have a royal ringside seat at one of his “favorite events” (Whiteford & Poland, 1989, p. 2).

Aging studies are another avenue of examining the effects of medicalization. Lock’s work illuminating the experience of menopause in women cross-culturally, ranging from its absence in Japan to its over-medicalization in the United States, has shown us that the latter is the result of two confluent forces: the medicalization of women as the “other” and the medicalization of aging (Lock, 1993). Martin describes that for women, aging is a derogatory process, causing atrophy (Martin, 1991). In medical advertisements, women are described as having “outlived her ovaries” (Martin, 1991).

CONCLUSIONS

In taking a structural approach to the production of health and disease, medical anthropology brings together socioeconomic determinants and clinical practice in the analysis of biomedicine. The result of this approach demonstrates that definitions of health and health care have a correlation with ethnicity, class, sexual orientation, and gender that serve as lenses through which the biomedical establishment may be viewed. If good health is a scarce commodity in a complex society such as the United States, its distribution is necessarily dependent upon social status. Anthropological contributions to discussions of health and disease demonstrate that the administration of health care is a means of social control. Despite new health technologies and methods of health care delivery, their patterns of use are largely informed by entrenched social and political mores (e.g., Sinha, 2000). The advantage to the anthropological approach is that issues of power and agency are inserted into the dialogue of clinical biomedicine that otherwise narrowly focuses on pathogens and individual biological processes. By using the tools of social analysis, medical anthropology

broadens the discussion forum to include issues of social control and social process into the realm of health care and disease treatment.

The Urban Poor

Health Issues

Delia Easton

INTRODUCTION

Health outcomes are inextricably linked to poverty (Farmer, Conners, & Simmons, 1996), and as a result anthropologists studying urban populations have devoted considerable attention to understanding and representing the health conditions of the urban poor. Anthropological portrayals of the poor have altered over time. Despite earlier social science research documenting the disturbing health outcomes among the urban poor (e.g., Engels, 1892; Liebow, 1967; Spradley, 1970), there was relatively little ethnographic research that integrated theory from both urban and medical anthropology prior to the 1980s (Foster & Kemper, 1996). Even then, wary of misrepresenting the poor through reductionist stereotypes, anthropologists have often evaded focused analysis of urban poverty (Bourgois, 1995). The intent of this entry is to both summarize the health challenges faced by people living in urban poverty and briefly trace theoretical approaches to the urban poor.

Anthropologists have variously referred to poor urban areas as “ghettos” (e.g., Hannerz, 1969) “urban slums” (Whyte, 1943), “squatter settlements” (Glasser, 1994), or “inner-cities” (Singer, 1994; Wallace et al., 1994). The nuanced meaning of each of the above terms, and the appropriateness of each to describe poor urban populations, has been previously discussed and debated (Hannerz, 1969, 1980), and will not be covered here. For the purposes of this entry, I will use the term used to describe the locale by the authors at the time of their research, with the caveat that each term clearly reflects the historical and political setting of the research. For lack of a better general term, I will use “urban poor” to refer to those most often vulnerable to disease in urban settings.¹ The review will also look at what anthropology has brought to the study of the health of the urban poor, and what it can potentially contribute in the future. Physical, cultural, and medical anthropologists have all contributed

to aspects of understanding how the processes of urbanization, industrialization, and globalization affect health among the poor worldwide. Because of shared topics of research and approaches to understanding health, there is an obvious overlap between epidemiological, medical anthropological, and public health studies on health among the urban poor. If relevant to the topic, formative work in fields other than anthropology is noted.

THREATS TO HEALTH AMONG THE URBAN POOR

The topic of health among urban poor is a critical global issue since approximately one third of the world’s poor live in cities (McDade & Adair, 2001). At least 80% of urban areas are in underdeveloped areas of the world that often lack adequate infrastructures (Kendall et al., 1991), meaning that there are too few or sufficiently developed public health care, sanitation, and transportation systems in these areas to provide people with basic living necessities and consistent health care. Health among the urban poor in the United States and other developed countries is in some ways distinct from health in poor urban areas in the developing world. Yet the experiences of the urban poor in industrialized and developing countries have commonalities, particularly in regards to morbidity and mortality rates. For example, Fullilove, Green, and Fullilove (1999) cite research demonstrating that survival rates among inner city men over the age of 40 in the United States are lower than those of similarly aged men in Bangladesh. In this section, I will briefly synthesize findings on compromised health and disease among the urban poor. The following health issues are not all specific to urban health, but considered in concert with other biological, cultural, and structural variables, are salient to the holistic picture of health among the urban poor.

The population density found most often in closely inhabited urban centers and settlements is a critical condition for epidemics such as the plague, measles, influenza, poliomyelitis, tuberculosis, and the HIV/AIDS pandemic to thrive, spread, and exist at endemic levels (Armelagos, Ryan, & Leatherman, 1990). The devastating spread of HIV/AIDS through both urban and rural areas of the world has been further facilitated by factors including migration for employment, and the interconnection between sex work, and high-mobility occupations such as truck driving (e.g., Decosas & Padian, 2002; Voeten, Egesah, Ondiege, Varkevisser, & Habbema, 2002). Large-scale societies with high birth rates permit a rapid production and replacement of disease hosts (Schell, 1996). Because of the dense concentration of people in urban centers, sanitation has been a past problem for now-industrialized countries, and remains a persistent problem for less developed countries. Although all urban dwellers are exposed to environmental pollutants and toxins (Schell, 1996), the poor do not always have the option of living in asbestos-free or lead-free housing. The most obvious result of burgeoning populations in urban areas worldwide is the lack of habitable, economically priced shelter, forcing the poor into overcrowded conditions (Bashem, 1978). Overcrowding has been linked to health problems stemming from inadequate sanitation services, the rapid spread of communicable disease, and stress. Research done among African Americans in the United States has demonstrated that stress levels, high among poor groups experiencing the effects of racism, have a noticeably negative effect on health (Dressler, 1990, 1993).

Homelessness

Homelessness is not a problem exclusive to urban areas, but the poor living in cities are especially vulnerable to being left without shelter. Overcrowding, inadequate housing, unemployment, policies directed against the poor and working class, gentrification, and, in the United States, the de-institutionalization of mental hospitals in the 1970s have all been cited as factors contributing to urban homelessness (Baer, Singer, & Susser, 1997; Glasser, 1994; Hopper, 1988). In particular, poor urban youth are at risk for homelessness. Facing sexual or physical abuse, inadequate family resources, or rejection because of sexual identity, some youth may choose to or be forced to leave home (Clatts, Davis, Sotheran, & Atillasoy, 1998; Glasser, 1994).

In developing countries, the number of homeless people in urban areas has grown exponentially in the last few decades: the result of forced rural to urban migration due to the increasing precariousness of subsistence farming (Baer et al., 1997), and to population increases in rural areas (McDade & Adair, 2001). Often homeless people in developing and industrialized countries occupy settlements or squatter settlements, which lack adequate sanitation, infrastructure, or basic health care systems (Baer et al., 1997; Rubenstein & Lane, 1990). Being homeless, or having inadequate shelter has been linked to heightened vulnerability to infectious disease, especially HIV and tuberculosis, alcoholism, malnutrition, and exposure to violence (Clatts & Davis, 1999; Farmer et al., 1996). Lacking shelter, food, resources, or all three, homeless people may resort to activities such as theft, robbery, selling illicit drugs, or sex trading for survival (Bourgois, 1995; Clatts et al., 1998; Clatts & Davis, 1999; Glasser, 1994; Schoepf, 1992; Waterston, 1993).

Violence

Exposure to violence is another widely acknowledged problem for the poor living in urban settings, especially the homeless (Glasser, 1994). Researchers have conceptualized the proliferation of violence in cities as the result of: (1) clashes between ethnic and social boundaries (Merry, 1981, 1996); (2) rapid social disintegration (Wallace, 1990); (3) the result of familial stigma and the misuse of state power (Glasser, 1994; Hecht, 1998); (4) gender power differences and homophobia (Asencio, 1999); and (5) as the byproduct of the inherent danger of operating in an underground economy (Bourgois, 1995, 1998). Violence is also closely associated with illicit substance use and alcoholism (Singer, 1994; Wallace, 1990), both of which are linked to HIV risk directly through the sharing of contaminated needles (Singer, 1996), trading sex for drugs (Sterk, Elifson, & German, 2000), and indirectly through decreases in inhibition (Stall, Heurтин-Roberts, McKusick, Hoff, & Wanner-Lang, 1990).

Malnutrition

Malnutrition is a threat for both rural and urban dwellers worldwide (Schell, 1996). As already noted, malnutrition is one of many issues in the web of health problems facing the urban poor and homeless. Although the inability to purchase basic foodstuffs is a critical factor in

malnutrition, the availability of nutritious, economically priced food is also a factor. In many U.S. cities, for example, grocery stores are scarce in poor neighborhoods and public transportation systems are highly inadequate. The result of these combination of factors is that residents of these communities are compelled to shop for groceries at bodegas or convenience stores, which have very limited selection and high prices. Himmelgreen et al. (2000) note that in the United States, food insecurity—the limited or uncertain availability of nutritious food—is most experienced in the inner city, in households with children, among the homeless, and among African Americans and Latinos.

Infectious Disease

Infectious disease is a focal point of urban medical anthropological literature in developing countries, and international health research. The poor in urban areas of developed countries and developing countries, often malnourished or with compromised immune systems, are vulnerable to infectious disease because of inadequate shelter, sanitation, and inaccess to basic health care or lack of health insurance. For example, despite heightened attention, education, and improvements in sanitation, acute diarrhea remains a health threat, and a leading cause of death for young children worldwide (Kendall, 1991). Children with inadequate or no housing are especially at risk for diarrheal disease because of the unavailability of clean water and sanitation services (Glasser, 1994). Describing her ethnographic work in Brazilian favelas, Scheper-Hughes (1984, 1985) argues that rates of infant mortality are so common, and resources so scarce, that mothers have developed emotional strategies for coping with the awareness that some of their children may die. For example, mothers may not name their children immediately to prevent bonding to a child who may not survive, or they may favor children perceived as hardier and thus more likely to survive to the detriment of weaker more vulnerable children. Nation and Rebhun (1988) argue that mothers were far from inured to the death of children, but simply did not have the economic means of obtaining adequate health care for their children. The structural constraints influencing infant mortality are addressed in detail by Scheper-Hughes (1992). Tuberculosis, medically manageable with access to adequate health care, is often fatal to the poor in both rural and urban areas of the developing world (Farmer, 1999).

Increasingly, the impact of globalization, rapid sociocultural change, and increased mobility has proven ideal conditions for the global spread of relatively “new” diseases, such as HIV/AIDS (Jochelson, Mothibeli, & Leger, 1991). Increased mobility through air travel and the development of highways and local roads resulted in the rapid transmission of HIV worldwide (Armelagos et al., 1990). Despite some improvements to the infrastructures of developing countries, overall the rural and urban poor are still highly vulnerable to disease. Migration patterns based on availability of employment illustrate that the health of the rural poor is now fundamentally linked to the health of the urban poor. This heightened mobility—though at one level increasing job opportunities for the unemployed, and theoretically, access to health care—is disruptive to local economies and family structure. In addition, structural adjustment programs in developing countries, predicated on the export of locally produced goods and the increasing importation of corporate products, has often resulted in the decreased availability of health care, social services, and HIV-prevention tools such as condoms (Parker, Easton, & Klein, 2000). In the United States, undocumented immigrants may resort to underground or street economies for survival (Baer et al., 1997). Street youth, homeless men, and women trying to support themselves or their children sometimes resort to trading sex or selling drugs—high-risk activities for HIV (Clatts et al., 1998; Clatts & Davis, 1999; Schoepf, 1992; Schoepf, Engundu, Wa Nkera, Ntsomo, & Schoepf, 1991; Susser & Stein, 2000).

Recounting data from over 12 years of fieldwork in Yabucoa, Puerto Rico, Susser and Kreniske (1997) describe how some Puerto Rican migrants looking for greater financial opportunity may experience urban U.S. living when they have no relatives for emotional or financial support. Unable to find profitable work, some migrants began using drugs, and sometimes supporting drug use through commercial sex work. Clearly, HIV can be rapidly transmitted among these migrants, both on the mainland and upon return trips to Puerto Rico.

ANTHROPOLOGICAL THEORY AND URBAN POVERTY: WAYS OF REPRESENTING THE URBAN POOR

Paradigmatic shifts in urban anthropology have influenced representations of the urban poor. Urban anthropology is

considered to have its early roots in the Chicago school in the 1920s and 1930s (Merry, 1996). Elijah Anderson's work typifies research done from an urban ecological perspective (Low, 1999). During the 1950s, research on slum clearance was conducted in London and Laos through the Institute of Community Studies (Low, 1999). Drawing on theories of kinship and social networks, Stack's US-based research among urban African Americans demonstrates that extended kinship networks and social reciprocity are practical adaptations to scarcity of resources, high unemployment rates, and overall poverty (Stack, 1974). Social networks can be viewed as a form of social capital for the urban poor. Stack is careful to point out that the African American community was fully aware of middle-class values and aspirations, but congruent lifestyles were unattainable to them. Their poverty was not a chosen, self-perpetuating state, but a result of real social economic constraints

The concept of the "culture of poverty" is worth noting here because of the impact it has had on discussions of urban poverty in the 1970s and 1980s, and because of its enormous influence on social policy. Oscar Lewis concentrated his ethnographic work on Mexican, Puerto Rican, and Latin American populations in the 1950s and 1960s toward understanding how poverty is perpetuated within certain communities. This question was most concretely addressed in his 1968 work, *La Vida*, a richly detailed description of Puerto Rican Barrios in New York and San Juan after World War II. Lewis contended that, in populations such as Puerto Ricans and urban Mexicans, exposure to poverty and oppression inevitably resulted in the acquisition of largely self-destructive learned behaviors that perpetuate impoverishment. Waterston (1993) contends that the notion of a "culture of poverty" was an idea that first surfaced around the time of the Irish immigration of the 1840s and 1850s, as speculation was made about the cultural origins of "deviant" behavior among immigrants. Nonetheless, Lewis, who is most closely associated with the culture of poverty construct, theorized that poverty is a cultural trait developed over time in response to oppressive life circumstances. Although Lewis theorized that the culture of poverty also had some protective aspects to it, such as creating a greater sense of inter-connectedness among those joined in poverty, his construct has been widely criticized for its reductionism and the negative impact it has

had on public policy to this day (Goode & Eames, 1996). The theory of the culture of poverty assumes a middle-class notion of deviant culture, and conflates class with ethnicity (Goode & Eames, 1996). Later historians have suggested that the notion of the culture of poverty later resurfaced as Wilson's "underclass" (Marks, 1991). Countering criticism, Wilson later re-termed the underclass the "urban poor" (Susser, 1999).

In the 1980s, urban anthropology gradually oriented itself less toward micro-level analyses, and away from Lewis's psychologically grounded theory of poverty, and more toward research exploring political, economic, and historical structures of urban living (Low, 1999; Sanjak, 1990). Examples include Hannerz's (1969) ethnography of an African American ghetto in Washington, DC, illustrating intra-group variation and offering an alternative view to the relatively monolithic culture of poverty (Goode & Eames, 1996). Similarly, Susser's detailed ethnographic account shows how working class families in a Brooklyn neighborhood actively respond to the limited economic possibilities available to them (Susser, 1982). At the same time, reflecting a broader trend in anthropology overall, medical anthropologists writing about health and the urban poor began to offer alternatives to primarily relativistic, ahistorical, and apolitical traditions (Morsy, 1990). Schensul and Borerro (1982), for example, describe the death of a Puerto Rican infant in an urban U.S. hospital because of language and cultural differences, the critical event determining the formation of a health organization devoted to advocating for the health of the city's urban Latinos. Urban ethnographies focusing on poverty in the 1990s represent the urban poor as inhabiting discretely bounded areas of cities, where commonalities of class, ethnicity, and the absence of political voice form a unified spatial identity (Low, 1999). In these ethnographies, the urban poor take on a distinct social identity through their locale in the city. In Brazil, Hecht (1998) and Scheper-Hughes (1992) also describe similarly youth and communities effectively segregated through poverty and violence. In the United States considerable anthropological attention has also been devoted to the societal marginalization of drug users (Baer et al., 1997; Singer, 1996; Waterston, 1993). For example, crack-cocaine dealers occupy a marginal and deteriorated area of Harlem, with few or no avenues for supporting themselves in the mainstream economy (Bourgois, 1995, 1996).

INTEGRATING LOCAL AND GLOBAL ANTHROPOLOGICAL PERSPECTIVES ON THE HEALTH OF THE URBAN POOR

Structural Violence

Farmer and colleagues argue that the poor, through their experience of social inequality, discrimination, and limited choice endure a structural violence that concretely manifests on a local level (Farmer, 1999; Farmer et al., 1996). Central to the concept of structural violence is an evaluation of how disease is linked to social inequality, class, and ethnicity. Dressler's (1993) research, for example, demonstrates that skin color is significantly associated with hypertension mediated socially through experiences of racism and not genetically. Singer argues that the high rates of drug use among urban minorities reflects an attempt to alleviate the depression and low self-esteem engendered by the frustration of enduring perpetual racism and poverty (Baer et al., 1997; Singer, 1994).

Urban Syndemics

The idea of structural violence is premised, in part, on Wallace's analysis of the multiple layers of societal and structural factors that place individuals at risk for HIV (Wallace, 1988, 1990). Capturing a wider trend in urban areas with systemic implications for poverty and health, Wallace recounts how urban deterioration in the Bronx, loss of municipal and public health sector funds, in conjunction with widespread fires, combined to result in an environment conducive to the rapid spread of HIV. Singer (1994) first described what he termed "syndemics" of the urban poor. Syndemics, fully explained by Baer, Singer, and Susser (1997) below, are intertwined and mutually reinforcing health issues and social conditions of the urban poor:

Health in the inner-city is a product of a particular set of closely interrelated endemic and epidemic diseases, all of which are strongly influenced by a broader set of political-economic and social factors, including high rates of unemployment, poverty, homelessness, and residential overcrowding, substandard nutrition, environmental toxins, and related health risks, infrastructural deterioration and loss of housing stock, forced geographic mobility, family breakup and disruption of social support networks, youth gangs and drug-related violence, and health care inequality. (Baer et al., 1997, p. 174)

Singer illustrated this idea by describing the substance abuse, violence, and AIDS (SAVA) syndemic, a constellation of experiences, symptoms, and behaviors among study participants that appeared to be synergistically linked: substance use, experience of abuse or violence, and current infection with HIV/AIDS.

The concept of syndemics is useful for understanding how sociocultural, historical, and geographic realities in urban areas interact with and compound the adverse consequences of disease. Fullilove, Green, & Fullilove, (1999a) describe the inevitable increase of violence, addictive disorders, and HIV rates in urban U.S. areas following the high unemployment rates, increase in drug trade, and urban flight of the 1970s and 1980s. Similarly, the forced migration of rural dwellers to urban areas in large parts of Africa, Latin America, and Asia subsequent to loss of viable work, economic development programs, and political flux has resulted in overcrowding, challenges to already inadequate infrastructures, and the rapid transmission of HIV in parts of Africa, South America, and Asia (Farmer et al., 1995; Parker, 1995; Romero-Daza & Himmelgreen, 1998; Sabatier, 1996). The lack of basic sanitation alone in squatter settlements that surround large cities in as much as 20–50% of the developing world (Rubenstein & Lane, 1990) is a considerable barrier to health and overall survival. Dehydration from diarrheal disease, for example, is a direct result of inadequate sanitation and contaminated water supply sources. Feasible and sustainable interventions for reducing rates of infectious disease among the urban poor must be geared not only toward individual behavior, but toward the reality of the multiple and concurrent health threats in impoverished urban areas and the systemic, structural, and institutional components of disease (Manderson, 1998).

CONCLUSION

Clearly, anthropology has much to bring to the task of comprehending and effectively addressing health problems related to urban poverty. Anthropological research has effectively represented and portrayed the sociocultural, biological, and structural components of health and disease for the urban poor. Rich ethnographic descriptions illuminate the complexities of the daily struggles of the urban poor, while capturing the historical processes and political and economic roots of their vulnerability to

unnecessarily high rates of morbidity and mortality. The concept of urban syndemics permits an understanding of the compounding and mutually interactive effects of poverty and exposure to multiple health threats. An integrated anthropological analysis of individual experience, local level knowledge, and broader societal and structural factors clarifies exactly how disease devastates the urban poor. It also demonstrates the immense challenges to providing effective and sustainable health care, affordable treatment, and health therapy to the urban poor worldwide. Continued rigorous anthropological research on urban poverty that documents the micro- and macro-determinants of health and disease is necessary:

- (1) to advocate for the urban poor
- (2) facilitate their empowerment, and
- (3) influence policy change

NOTE

1. Susser, however, cautions that a limitation of the term “urban poor” is its implication that the poor are separate and not an integral component of dynamic economic systems.

Sexuality, Reproduction, and the Life Cycle

Aging

Jay Sokolovsky

AN ANTHROPOLOGY OF AGING

Despite the early seminal book by Leo Simmons, *The Role of the Aged in Primitive Society* (1945), and articles by such luminaries as Gregory Bateson (1950), and Margaret Mead (1967), a concern for a worldwide, cross-cultural analysis of aging has developed late in anthropology. It was anthropologists such as Otto von Mering, Jules Henry, Margaret Clark, and Barbara Anderson who first turned the ethnographic approach into a valuable tool for understanding the relationship of aging, local culture, and well-being. In the late 1950s von Mering conducted fieldwork in the geriatric wards of psychiatric hospitals, illustrating how the cultural devaluing of old age led to a withdrawal of psychosocial care for older patients (von Mering, 1957). Jules Henry followed this (1963) with a disturbing ethnographic account of life in three American nursing homes. However, it was only with Margaret Clark's, "The Anthropology of Aging, A New Area for Studies of Culture and Personality (1967)" that a clear direction was offered for anthropological research on aging. This was followed up with *Culture and Aging: An Anthropological Study of Older Americans* co-authored with Barbara Anderson (Clark & Anderson, 1967). Their work examined the cultural dynamics of San Francisco's community-based care of mentally impaired older citizens. Since that time there has been a literal explosion of anthropological works dealing with aging and the aged.

Access to this rapidly expanding literature on aging can be found in several edited compilations and texts: *The Politics of Age and Gerontocracy in Africa* (Aguilar, 1998); *The Cultural Context of Aging, 2nd edition* (Sokolovsky, 1997); *Other Cultures, Elder Years, 2nd edition* (Rhodes & Holmes, 1995); *Old Age in Global Perspective* (Albert & Cattell, 1994); *The Aging Experience* (Keith et al., 1994); *Anthropology and Aging: Comprehensive Reviews* (Rubinstein, 1990); *Aging and Its Transformations* (Counts & Counts, 1985); *Other Ways of Growing Old* (Amoss & Harrell, 1981); *Dimensions: Aging Culture and Health* (Fry, 1981); *Aging in Culture and Society*

(Fry, 1980); and *Life's Career, Aging* (Myerhoff & Simic, 1978). There has also been a proliferation of ethnographies illuminating the general cultural dynamics of old age in India (Cohen, 1998; Lamb, 2000; van Willigan & Chadha, 1999); China (Bossen, 2002; Davis-Friedman, 1991); Africa (Bledsoe, 2002; Rasmussen, 1997); Japan (Kinoshita & Keifer, 1992; Thang, 2001; Traphagan, 2003); and the United States (Freidenberg, 2000; Guo, 2000; Myerhoff, 1978; Savishinsky, 2000; Shenk, 1998; Vesperi, 1998). Of particular interest to medical anthropology has been books focusing on health issues and long-term care such as Becker (1980); Foner (1994); Hazan (1980); Henderson and Vesperi (1995); Kaufman (1986); Savishinsky (1991); and Woolfson (1997).¹

Importantly, the maturing of an anthropological specialty in aging has unfolded through several works, *New Methods for Old Age Research* (Fry & Keith, 1986); *Age and Anthropological Theory* (Kertzner & Keith, 1984); *Old Age in Global Perspective* (Albert & Cattell, 1994); and *The Aging Experience* (Keith et al., 1994). These volumes have brought to bear the distinct realm of anthropological methods and theory on questions of aging and the aged. The last mentioned of these books reports on Project AGE, the first effort to combine long-term fieldwork with a precise and consistent research protocol to study aging in a variety of cultural settings. This was done in two American communities as well as among residents of Hong Kong, Botswana, and rural Ireland. The research shows how both "system wide" community features (such as social inequality) and "internal mechanisms" (such as values) create distinct contexts for conceptualizing the life cycle, establishing age norms, and influencing the perception of well-being in old age (Fry, 2000).²

AGING, ELDERHOOD, AND OLD AGE

From a biological standpoint aging involves structural and functional changes over time, both maturational

and senescent, which normally occur among males and females when they pass puberty. Maturing over a prolonged life span is one of the species-specific traits of *Homo sapiens* (Crews & Garruto, 1994). While most other primates live in multi-aged communities, only human societies have developed systems that require high levels of prolonged material and social interdependence between generations. Moreover, humans are the only primate species where substantial numbers of females survive well past their reproductive span and where surviving older adults past the fifth and sixth decades of life are supported by kin and community when their functional capacity declines. A recent study of Hadza foragers in Africa showed that it was in fact grandmothers and elderly aunts who had the most to do with assuring the survival of children into early adulthood (Hawkes, O'Connell, Blurton Jones, Alvarez, & Charnov, 1998).

The cultural construction of the human life cycle creates substantial variation in how aging and a society's most aged individuals are perceived and treated (Ikels & Beall, 2000). Human cultural systems recognize the importance of life cycle patterns by linguistically creating labels delineating a stage of late adulthood. The conception of being "old" is a near human universal and is culturally constructed by a variety of measures. Only one study to date has systematically used worldwide data to examine this issue. Anthropologists Anthony Glascock and Susan Feinman (1981) found that in a random sample of 60 societies there were three basic means of identifying a category of "old": change of social/economic role; chronology; and change in physical characteristics. Their study produced the following conclusions:

1. A shift in social/economic roles was the most common marker of being designated as old. Typical examples are: one's children having their own kids; changes in a person's productive activities; or beginning to receive more goods and services than you give.
2. A change in physical capabilities is the least common marker. Severe frailty or dementia are quite rare as initial indicators of being called old. This surprising result happened because sampled societies typically create a category of old starting before many people encounter much radical signs of physical decline.
3. About half of the societies use multiple definitions of being aged. Such varied markers of aging are commonly applied to distinct categories of the "old" itself, which can include a phase of oldness linked to images associated with a movement toward death and the loss of normal functioning.

THE CULTURAL CONSTRUCTION OF ELDERHOOD AND OLDER ADULTHOOD

Steve Albert and Maria Cattell in *Old Age in Global Perspective* (1994) make a helpful distinction between elders, old age, and ancients. A notion of elderhood appears to exist in most non-Western societies and is largely based on combining social and functional definitions of one's place in the life cycle. It is used as a marker of social maturity for population cohorts in relation to others in the community. This is contrasted to boundaries of old age which can take some of the criteria of elderhood and combine them with how a person's individual physical being and behavior reflect the biological aging process. In many tribally organized societies elderhood is accomplished by passing through ritual transitions and is not necessarily tied to extended chronological years. Persons who do not pass these ritual markers will not be considered elders, no matter what their age. Among Australian aboriginal tribes as well as in Africa's pastoral peoples, persons could enter the beginning ranks of elderhood in their early 30s, and proceed over time and through ritual passage into different elder statuses.

Cultural perceptions of older adulthood or old age link changes in the person's physical being (reduction of work capacity, beginning of menopause) with social changes (such as the birth of grandchildren) to create a culturally defined sense of oldness. Like elderhood, this social boundary can have various gradations that can even extend beyond the point of death into a category of ancestors (Kopytoff, 1971). However, many societies also recognize those truly *ancient* adults who show sharp declines in functioning as a different category of old. For example, to the *Ju'hoansi* people of Botswana old age is perceived to begin relatively early and can start in a person's mid-40s when and if changes in physical capabilities begin to diminish functional ability. Here there are three levels of "old," a beginning early stage, a frail but functional stage, and a physically disabled designation. Counterbalancing the *Ju'hoansi* linkage of older adults with physical decline is a powerful association with greater spiritual and emotional strength often put to use by the aged in healing rituals or settling disputes (Rosenberg, 1997).

GENDER AND AGING

A global view of aging shows that women age somewhat differently than men (Cattell, 1995). Although there are slightly more males born than females in most populations, almost universally it is the latter gender which on average survives the longest. At age 15, women in the United States have a life expectancy eight years greater than men, and when they reach age 65 they can expect to survive four more years than their male counterparts. For Third World nations, there is typically about half this difference in life expectancies. Here, for those over age 60 the gender ratio is relatively close, about 90 men for every 100 women, contrasted to a full 20% fewer males still alive than females in more developed nations.

Various writers have noted that for women, the fourth and fifth decades of life, in its association with menopause, often provide a key turning point in both the biological and social worlds of females and may mark the beginning of a label of old. Cross-cultural work in this area has shown the need for sophisticated research that takes a bio-cultural approach to this issue (du Toit, 1990; Flint & Samil, 1990; Kaufert & Lock, 1992; Lock, 1993). The complex interplay of biology, nutrition, and culture in shaping women's experience of menopause is analyzed by Yewoubdar Beyene's in *From Menarche to Menopause: Reproductive Lives of Peasant Women in Two Cultures* (1989). She compares Mayan and Greek women living in rural villages and finds that their experience of menopause and aging strongly differed, despite similar values and behaviors regarding menstruation and childbearing. Greek women had a substantial, well-balanced diet, married late, and averaged only two pregnancies. Here, menopause was associated with growing old and the start of a "downhill course in life." A strong majority reported hot flash or cold sweat symptoms. The Mayan women, in contrast, consumed a much poorer inconsistent diet, married early, and had many closely spaced pregnancies. Females here looked forward to aging citing anticipated new freedoms and social passage to higher status in old age. She found that *none* of these women reported symptoms of hot flashes or cold sweats and they welcomed menopause.

In terms of social transformation many authors have begun to document a common pattern in non-industrial societies of dramatic positive changes of role, power, and status by women as they pass into the middle and latter

adult years (Brown, Subbaiah, & Therese, 1994; Kerns & Brown, 1992). Gutmann (1987) has suggested that universal intrapsychic personality development best explains the frequent reversals observed among older adult women, while other theorists have stressed the cultural turning points linked to procreative and family cycles. For example, Rasmussen in studying the Tuareg in Africa argues that female androgyny in late adulthood is not simply being more male but part of expressing transformations of female personhood through time, involving realignment of kin hierarchies and other social strata affecting both males and females (Rasmussen, 1987, p. 29).

STATUS OF THE AGED

In many traditional societies studied by anthropologists, older adults commonly function as a storehouse of knowledge about such things as kin ties, health, religious rituals, lore, and myth which explain tribal origins as well as in-depth knowledge about the environment. Among many African tribal peoples, older adults are the gatekeepers for the ritual management of life, from the naming of children to the planting songs chanted by West African village women to assure the younger female farmers that the harvest will be good.

It is clear from the ethnographic literature that great age does not guarantee good treatment. Pamela Amoss and Steven Harrell propose that there are two key factors that determine how older adults fare in their particular cultural settings. First is the relative balance between the contributions older persons make to the costs they represent. Second is the control over resources important to younger members of the community. They sum this up succinctly by predicting that:

The position of the aged in a given society can be expressed in terms of how much old people contribute to the resources of the group, balanced by the cost they exact, and compounded by the degree of control they have over valuable resources. (Amoss & Harrell, 1981, p. 6)

Various studies using the Human Relations Area Files (HRAF) have corroborated in many respects the association of status and deference with the control of informational and administrative roles as well as valued activities and extended family integration (Silverman, 1987). Silverman's analysis finds that in terms of

resource and information control, only certain types of control, particularly administration and consultation, correlate with beneficent treatment of the elderly. Some forms of supernatural information control, especially transformational powers, were in fact a potential threat to the elderly. Under conditions of rapid change, older women who are linked to esoteric power such as witchcraft, may be seen as great liabilities and put to death. This happened in great numbers in Europe during the middle ages (Bever, 1982) and in certain areas of East Africa during the mid-1990s (“Witchcraft—a violent threat,” 2000).

This darker side of aging—various types of non-supportive and even harsh treatment directed toward the elderly—has been studied in worldwide statistical studies (Glascock, 1997; Silverman, 1987). These studies make clear that being old in a small-scale, face-to-face community does not necessarily prevent cultural variants of severe neglect and abuse from occurring. In Glascock’s study killing of the aged was found in about one fifth of his global sample, finding 84% of the societies exhibiting various forms of *non-supportive* treatment. This was defined as involving either killing, abandonment, or forsaking of the elderly. In a similar study Silverman and Maxwell (1987) noted “negative deference” (harsh treatment) in 62% of their cases. Importantly, it was commonly found that both supportive as well as death-hastening behavior co-exist in the same social setting. Both studies found that cultural distinctions drawn between *intact*, fully functioning aged and *decrepit* individuals who find it difficult to carry out even the most basic tasks are critical. As Barker’s (1997) ethnographic analysis of the frail aged on Niue Island also shows, it is persons placed in the decrepit category toward which geronticide or death-hastening is most frequently applied.

AGING AND SOCIETAL TRANSFORMATION

The dramatic upsurge in the longevity of older citizens in Third World countries is a legacy of the last two decades. This demographic change has been intertwined with powerful modernizing events including alterations in economic production, wealth distribution, an explosion of super-sized cities, and the often violent devolution of large states into smaller successor nations (Lloyd-Sherlock, 2000). Modernization theory is the primary model for considering the impact of major worldwide

changes on the elderly. Donald Cowgill, the first to suggest a number of discrete postulates and later in developing a more elaborate model, has been the most dominant writer on this subject (Cowgill, 1974, 1986). The hypothesized decline in valued roles, resources, and respect available to older persons in modernizing societies is said to stem from four main factors: modern health technology; economies based on scientific technology; urbanization; and mass education and literacy. There has been a very lively debate over the validation of this model (see Rhoads & Holmes, 1995, pp. 251–285 for an excellent review). Historians in particular have sharply questioned the model, saying it is not only ahistorical but that, by idealizing the past, an inappropriate “world we lost syndrome” has been created (Kertzer & Laslett, 1994; Laslett, 1976). For example, summing up research on the elderly living in Western Europe several hundred years ago, historian Andrejs Plakans states, “There is something like a consensus that the treatment of the old was harsh and decidedly pragmatic: dislike and suspicion, it is said, characterized the attitudes of both sides” (Plakans, 1989).

A study by Vincentnathan and Vincentnathan (1994) of three untouchable communities in the South Tamil Nadu area of India illustrates the complexity of this issue. In the poorest communities, the assumption of respect and high status as a prior condition did not hold. Elders here had no resources to pass on. Providing material resources for the elders through new modernization programs became a basis for binding together the young and old. However, increased education of the young led many children and young adults to feel superior to parents. Over time, generational relations deteriorated—sometimes involving high levels of abuse and killing of the aged—closer to the predictions of modernization theory.

AGING POPULATIONS IN A GLOBAL CONTEXT

Until the very end of the last millennia, much of the world’s population had an *average* expectancy of life less than half the *potential* years humans could live, namely about 120 years. Moreover, adolescents under age 15 were much more numerous than adults over age 60. This is changing very rapidly. Since 2000, in industrialized nations the older segment of the population has exceeded

Table 1. Some Demographic Comparisons Between More and Less Developed Regions

Region	Population aged 60 years or older. Percentage of total population		Percentage 80 years or older		Potential Support Ratio (number of persons aged 15–64 years per aged 65 years or older)	
	1999	2050	1999	2050	1999	2050
More developed regions	19	33	16	27	5	2
Less developed regions	8	21	9	17	12	4
Least developed regions	5	12	7	10	18	8

those under age 15, a transformation to be replicated in other regions by 2050 (Kinsella & Velkoff, 2001). By 2030 most Third and Fourth World regions will still not have reached the level of "societal aging" now faced by North America, much of Europe, and Japan. However, "young/youthful" nations such as Brazil, Indonesia, and Mexico will witness the oldest part of their population (over age 65) at least double—and even quadruple in the case of Indonesia.

Despite the oncoming rapidity of aging in many developing nations, their demographic profile, especially for the least developed nations, will still show a relatively youthful population by 2050 (see Table 1) and maintain a moderately high Potential Support Ratio (eight younger adults for each person over age 65). In some areas, especially in Sub-Saharan Africa, the AIDS epidemic has caused the overall life expectancy to drop precipitously over the past 10 years and consequently has played havoc with traditional systems of intergenerational support and exchange (Sankar, Luborsky, Rwabuhemba, & Songwathana, 1998).

Population aging is of more demographic concern in the middle range countries ("less developed regions") which will see a near doubling of the portion of the elderly over age 80 occurring at the same time as a three-fold drop in the Potential Support Ratio. In Latin American and Asian nations in this category, by mid-century, populations will present a demographic aging profile that is similar to the one found in more developed nations today.

Such changes are already causing China to rethink some of its policy stressing patrilineal based family support and care of elders (Arnsberger et al., 2000; Ikels, 1997). Part of the reason for the rapid aging in such Third World nations is the dramatic drop in overall fertility rates. In Asia and Latin America birth rates have fallen about 50% during the period from 1965 to 1995, from 6 to 3 children per woman (Kinsella & Gist, 1995; World Bank, 1999). Over the first two decades of the 21st century, Mexico, Ghana, India, Indonesia, and most of the Caribbean nations will actually have minimal or even negative annual growth among 0–14 year olds, while persons over age 65 will grow at rates between 2.1% and 3.2% each year (World Bank, 1999). Such changes will have an enormous impact on the nature of communities which anthropologists study and force medical anthropologists to more seriously examine midlife and late adulthood.

NOTES

1. There have also been a good number of recent special issues of journals which have focused on the anthropology of aging. These include: "Positive Adaptations to Aging in Cross-Cultural Perspective." Special Issue of *Journal of Cross-Cultural Gerontology*, 16(1), 2001; "Aging and ElderCare," *Journal of Family Issues*, 21(6), 2000; "Home Health Care and Elders: International Perspectives." Special Issue of *Journal of Cross-Cultural Gerontology*, 8(4), 1993; "Cultural Contexts of Aging and Health," Special Issue of *Medical Anthropology Quarterly*, 9(2), 1995.

2. The most comprehensive bibliography on the anthropology of aging is Schweitzer (1991). However, new information about ongoing ethnographic aging research and related publications can be followed through the *Cultural Context of Aging* web site at <http://www.stpt.usf.edu/~jsokolov>.

Birth

Carolyn Sargent

INTRODUCTION

Birth, the physiological process of childbearing, is both a biological and cultural event. In all societies, the universal physiology of birth is culturally shaped and managed. Jordan's (1978, 1993) groundbreaking work *Birth in Four Cultures* initiated the field of study now known as the anthropology of birth, or more broadly, the anthropology of reproduction. Following Jordan, anthropologists have focused on the study of birthing systems rather than on the comparison of individual and isolated "birth practices" which characterized the earliest anthropological references on this topic. The cross-cultural analysis of birthing systems has documented that birth is globally a culturally marked life crisis event that is socially patterned as well as being a biological phenomenon. The cultural patterning of birth includes beliefs and practices surrounding pregnancy; expectations regarding the circumstances in which pregnancy may occur and who may legitimately reproduce; prescriptions and proscriptions affecting expectant mothers, their partners, and families; the management of labor, including the circumstances under which interventions occur and the characteristics of such interventions; and treatment during the postpartum period. Birthing systems range from low-technology systems exemplified by the Maya of Central America (Jordan, 1978) or the Bariba of West Africa (Sargent, 1982, 1989) to the high-technology biomedical systems of most industrialized societies. Generally, birth practices within a particular society are consensually shaped, with a low level of variation within any given system, but considerable variation across different societies. As Jordan (1978) observed, "we find that within any given system, birth practices appear packaged into a relatively uniform, systematic, standardized, ritualized, even morally required routine" (p. 2).

EARLY ETHNOGRAPHIES AND SURVEYS

The earliest anthropological attention to birth is contained within ethnographies devoted to other topics, rather than

studies focusing directly on birthing systems (for further discussion, see Browner & Sargent, 1996). Exceptions include Montagu's (1949) discussion of Australian aboriginal understandings of fetal development and Malinowski's (1932) commentary on ideas and practices concerning birth among Trobriand Islanders. A few comparative surveys on human reproduction such as that by Ford (1964) basically provide lists of reproductive customs from societies around the world, and include some detail on pregnancy, delivery, and the postpartum period. For example, references to pregnancy in Ford's compilation on 64 societies include mention of seemingly illogical food taboos, sexual regulations, and tabooed acts to prevent miscarriage, birth defects, or stillbirth. With reference to birth, world surveys such as Ford's offer brief descriptions of techniques of delivery in preindustrial societies, noting such details as delivery position (women may sit, kneel, or squat; occasionally a standing position is reported); the role of the birth attendant in providing physical support to the parturient; restrictions on who may attend the delivery; and the location of delivery. Reflections on the topic of pain in childbirth are found from the earliest ethnographic reports, perhaps indicating widespread interest in the question of pain management as well as the speculation that childbirth may be less painful in some societies than others. Key among these is Freedman and Ferguson's (1950) consideration of painless childbirth in "primitive cultures." Principle means of addressing pain and suffering during labor include ritual performances, prayer, and sacrifice. However, in the early ethnographic accounts and surveys, little mention is made of herbal or other techniques of accelerating labor or intervening in complicated births.

In contrast, more interest is expressed in the widespread concern with disposal of the placenta, or afterbirth. Dating from early reports such as that by Malinowski (1929), anthropological publications from numerous societies include reference to the powerful meanings associated with the placenta. Techniques of expelling the placenta, such as massage or pressure, and the ritual disposal of the placenta, have been widely described. Disposal of the

placenta is rarely random or careless. Often it is burned, or buried in a significant location. Sometimes the placenta is preserved to later create a medicine or to use in ritual practice. Early discussions of the placenta also mention methods of cutting the umbilical cord (knife, arrow, other sharp implement), preferred timing of cord-cutting (after the placenta is expelled, for instance), and means of tying the cord. Little information is available in the earliest studies regarding treatment of the mother postpartum, except to indicate that she may wash, and is often secluded for a ritualized period of time. A few societies are described as employing techniques to prevent excessive bleeding. Dietary proscriptions and prescriptions are also noted, as are sexual restrictions during the postpartum period. Approximately half the world's societies in the ethnographic record have lengthy postpartum sex taboos, sometimes encouraging abstinence for as long as two years (Whiting, 1964).

Regarding the regulation of postpartum sexuality, Whiting notes that in many societies, a brief period following the birth of a child is identified during which sexual intercourse is taboo, to allow the mother to recover from childbirth (Whiting, 1964, p. 518). In those societies practicing a more extended period of sexual abstinence, the explanation usually focuses on the well-being of the infant, suggesting that if a nursing mother were to become pregnant, her breastmilk would be contaminated, thus placing the infant at risk. The prolonged postpartum sex taboo may thus represent a cultural means of protecting the well-being of infants by prolonging the nursing period and encouraging adequate spacing between births.

TOWARD AN ANTHROPOLOGY OF BIRTH

Subsequent to 1970, increased anthropological interest in birth assistance and midwifery practice moved the field beyond brief ethnographic accounts and surveys to more contextualized analyses of birth. This growing attention to the ways in which pregnancy and delivery are culturally shaped generated an important literature on the management of birth in industrialized societies. From the 1970s, more women anthropologists entered the field. Inspired by the second wave of feminism and with greater access to information about birth practices derived from empirical observations, they began to explore birthing systems as local systems of knowledge and praxis, grounded in broader cultural and social contexts

(see Davis-Floyd & Sargent, 1997, for a thorough review of this literature). Among the cutting-edge research from this phase in the anthropology of birth is McClain's (1975) work on cognition and behavior regarding pregnancy and birth in Mexico in which she introduced the term "ethno-obstetrics" and approached birth as a cultural system in the process of transformation.

One aspect of the cultural patterning of birth that elicited attention in the emergence of the anthropological study of birth was the issue of variations that exist in the characteristics of those who are allowed to attend births and offer specialized assistance to the parturient. In most societies, a woman is attended by other women, often kin, who provide emotional support and generalized knowledge regarding labor and delivery. Some societies also have a specialist to assist at birth. In the anthropological literature, this specialist is usually referred to as a midwife, although the World Health Organization has favored the term "traditional birth attendant," to differentiate those who are biomedically trained from other birth specialists. A few societies encourage women to deliver alone, without the participation of a midwife or indeed any companions (see, e.g., Sargent, 1982, 1989; Trevathan, 1987).

Cross-cultural comparison of the characteristics of midwives has focused on recruitment to the role, acquisition of skills and knowledge, status, and the midwife's role in prenatal care, at delivery, and in the postpartum. Cosminsky (1976) provided the first substantial review of existing data on this topic. Cosminsky's review, based on a variety of secondary ethnographic and medical sources, surveys the role of the midwife in providing prenatal care, delivery assistance, treatment of the newborn, and postnatal care. Subsequently, her own ethnographic research provided systematic and in-depth analyses of Guatemalan midwifery (Cosminsky, 1976, 1982).

Cosminsky found that worldwide, most midwives are female, postmenopausal, and have had children of their own. Recruitment to the role of midwife may be based on spiritual calling, inheritance, or personal inclination. Dreams or visions are sometimes used as signs that a woman should be a midwife. For example, in Guatemala, Cosminsky reports that a midwife usually has suffered ill health and a shaman may divine the cause as a warning to take up the calling of midwifery or risk severe consequences from God. Most commonly, midwives acquire training by means of apprenticeship, a pattern documented in Africa, Latin America, Asia, and the

United States. While midwives usually occupy a respected position in society (e.g., in Jamaica, peninsular Malaysia, and much of Africa), exceptions exist; in India, for instance, the position of midwife (*dai*) is allocated to low-caste women, because of the association of birth and bodily fluids (Jeffery & Jeffery, 1993). Similarly, Rozario describes the position of the *dai* in Bangladesh as very low status. The *dai* is usually very poor, elderly, with no formal education or training (Rozario, 1998, p. 161). There is often little or no remuneration for her work, although the *dai* are recognized as experienced and useful as birth attendants. The case studies Rozario presents indicate that the *dai* does not provide prenatal or postpartum care, but initiates her involvement during labor. She suggests that the Bangladeshi pattern is typical of the region, and probably of most of South Asia. Worldwide, proliferation of biomedical facilities has often resulted in a decline in respect for local midwives, as women increasingly seek care from biomedical practitioners.

The landmark 1978 publication of Jordan's *Birth in Four Cultures* inspired a generation of anthropologists to pursue empirically based comparative studies of birth and legitimized the grounded study of human reproduction (Ginsburg & Rapp, 1991). Jordan referred to her own approach as "biosocial," with an emphasis on the feedback between biology and culture. Prior to Jordan's work, there was a distinct lack of data useful for a holistic comparison of childbirth, and almost no research based on direct observation of normal births. Medical reports presenting cross-cultural examples tend to focus on physiology, and often on abnormal features of birth. Jordan sought to emphasize the social interactional aspects of birth, such as the nature of the decision-making process during parturition, and the extent of material and emotional support for the woman during pregnancy and labor. Broadly, she proposed a biosocial framework for the collection and analysis of data, that would integrate local meanings of birth with associated "biobehaviors." Accordingly, she developed a methodology to isolate features of the birth process that would serve as units for cross-cultural comparison.

As the specific cases employed in her book, she compared birthing systems in Sweden, Holland, Yucatan, and the United States, thus illustrating the possibility of cross-cultural analysis in this domain of inquiry. Methodologically, she proposed that the study of birth requires direct observation. Given that birth involves bodily functions and bodily displays, collecting data

by survey or primarily by structured interviews is fundamentally inadequate. In contrast, anthropological participation is recommended as an explicit methodological device "intended to give the investigator access to the *knowing how* of birth, that is to say, to the behaviors in which participants engage as competent performers of system-specific ways of doing birth" (Jordan, 1978, p. 8). Participant observation, combined with standard structured means of data collection, provide the foundations for a holistic representation of the birth process.

In addition to providing ethnographic detail about each system, Jordan's research offered policy recommendations to encourage accommodation between biomedical and indigenous birthing systems that would acknowledge the perspectives of both systems. Most significantly, she argued that birth is always a cultural production. She applied this perspective to biomedicine as well as to local birthing systems, thus generating an enduring interest among anthropologists of reproduction in the cultural shaping of biomedical obstetrics.

During the 1980s, anthropologists followed Jordan's groundbreaking work with detailed ethnographic studies conducted in many parts of the world. The first edited collections focusing on pregnancy and birth in cross-cultural perspective date from this period (Kay, 1982; MacCormack, 1982/1994). Ethnographic research in this phase portrays viable local birthing systems, confronted with challenges from an imported biomedical system, usually legitimized by the state. Correspondingly, numerous anthropologists have detailed the resistance and accommodation of local practitioners and women seeking maternity care. A substantial body of research examines the impact of birth technology on local practice, and the global exporting of the biomedical (American), technocratic model of birth (Davis-Floyd, 1992; Davis-Floyd & Sargent, 1997).

CONTEXTUALIZING BIRTHING SYSTEMS: GLOBAL AND LOCAL PERSPECTIVES

Among the principal studies of local birthing systems from the decade of the 1980s are those by Sargent, Laderman, and MacCormack. These studies are characterized by ethnographic detail as well as careful articulation of childbirth as an event with broader sociocultural issues such as gender ideology, domestic power relations, professional specialization, and the components of

particular ethnomedical systems. Sargent's (1982, 1989) monographs on birth among the Bariba of Benin contextualize Bariba understandings and behaviors surrounding birth by detailing Bariba religion and cosmology, gender roles and ideology, occupational hierarchies, local medicine, and the structure of state-sponsored health services. Local ideas concerning the order of the universe are linked to diagnosis and management of problematic births. Sargent uses case studies of Bariba births that she attended to analyse patterns of delivery assistance, the meaning of therapeutic "efficacy" for clients and midwives, and features of the decision-making process for pregnant women.

In one case, for example, Ganigi, a woman experiencing her tenth pregnancy, confronted complications during labor that challenged local healers. Ganigi initially adhered to the Bariba ideal of delivering alone but called her mother when she delivered the umbilical cord prior to the birth of the baby. Her labor then stopped. This unusual circumstance led the family to call a respected local midwife, known for her spiritual powers. The midwife diagnosed the protrusion as a woman's affliction known as *tigpiru*, and offered a herbal remedy. When that failed to accelerate labor, a second midwife and the anthropologist were called. The second midwife tried abdominal massage, herbal smelling salts, and a herbal drink served in a gourd, to no avail. Ganigi, in a state of great anxiety that her problems might result from witchcraft, finally allowed the anthropologist to transport her to the nearest maternity clinic, where the nurse diagnosed a prolapsed cord and assisted Ganigi in delivering twins, one of which was stillborn. The consensus of the family and community was that witchcraft—fortunately thwarted by the involvement of the anthropologist—was at the root of the problem (Sargent, 1982). This case illustrates important Bariba concepts, such as the widespread understanding that witches can take the form of unborn children who may kill their mother. Birth serves as the occasion to detect witchcraft, by identifying signs of abnormality such as breech births or other anomalies such as the prolapsed cord. Childbirth is therefore a time of ritual danger as well as physical risk. Extended case analyses of Bariba birth not only generate an ethnography of the local birthing system, but also shed light on broader aspects of Bariba culture and society.

Similarly, Laderman (1983) uses extended case studies, survey research, and nutrient analyses to illustrate the management of birth in Malay culture, as well as to

illuminate broader Malay cultural and social principles. Laderman describes the Malay humoral system, beliefs, and behavior surrounding food in relation to ecology, ideas about conception and pregnancy, and the management of birth by traditional and government midwives. The Malay birthing system is thus carefully contextualized. In one case, for example, Laderman describes how an unborn child is thought to be afflicted with a wasting disease, caused by the destructive spiritual influence of a corpse. Early in her pregnancy, Rohani was startled by the sight of a young cousin's corpse. When her month-old baby began to lose weight and became increasingly sickly, retrospective analysis led to the suspicion that the infant's sickness resulted from her mother's prenatal experience. An alternative diagnosis by a local healer attributed the sickness to a birth trauma (the baby was born with the umbilical cord around its neck) which can cause ritual danger to the child. The healer also suspected another affliction caused by disembodied spirits associated with the placenta, amniotic fluid, and the blood of childbirth. In spite of several therapeutic efforts—the baby's name was changed to another more harmonious one, ritual acts were performed to symbolize a spiritual rebirth, and on the anthropologist's advice, the family eventually consulted a pediatrician—ultimately the baby died (Laderman, 1983, pp. 96–101).

In her discussion, Laderman addresses issues of generalized anthropological concern by means of the analysis of childbirth. She explores the relationship between belief and behavior as she investigates Malay food restrictions during pregnancy and the postpartum period. In addition, as the case of Rohani indicates, important features of Malay ideology emerge from the ethnography of birth.

In her edited volume, *Ethnography of Fertility and Birth*, MacCormack (1982/1994) presents an ethnographic collection that illustrates state-of-the-art research in this time period. Her own research on midwifery in coastal Sierra Leone analyses the Sande society, a women's organization concerned with maintaining health and fertility. Sande practitioners provide maternal and child healthcare, including midwifery. Like other anthropologists of this decade, MacCormack was interested in demonstrating that birth is a cultural and social, as well as a "natural" or medical process. Thus she examines the role of the Sande society initiation, including clitoridectomy and ritual adolescent fattening, folk meanings of fertility, midwifery practice, social support during childbirth, and

infant mortality. In addition, she discusses the flexibility of the local conceptual framework in order to propose that Sande midwives are open to adopting theoretical tenets about birth drawn from biomedicine. She suggests that an effective primary healthcare system should draw on biomedical as well as local models of health, fertility, and birth.

AN ANTHROPOLOGY OF WESTERN CHILDBIRTH

The anthropology of Western childbirth has represented a core element in studies of birthing systems from Jordan's comparative research through the 1990s. A consistent theme in this body of research emphasizes that the dominant cultural definition of birth in the United States is a medical one, in which pregnancy is viewed as a pathological state, requiring specialist attention and hospital delivery. Accordingly, the medicalization of childbirth, characterized by use of technological interventions during birth, such as episiotomy (a surgical incision of the vagina to widen the birth outlet), intravenous medication, and the lithotomy (supine) position for delivery, have become standard procedures (Davis-Floyd, 1992; Jordan, 1978; Romalis, 1981). This widespread use of technology has led Davis-Floyd to suggest the term "technocratic birth," in her classic study of birth as an American rite of passage. Technocratic birth predominates in the United States, where 98% of women give birth in hospitals. In many hospitals more than 80% of women receive epidural anesthesia, and at least 90% receive episiotomies (Davis-Floyd & Sargent, 1997, p. 11). In some hospitals, the cesarean, or surgical birth rate has reached 30% or higher (Sargent & Stark, 1987). A minority of American women—less than 2%—rely on midwifery and home birth. A revival of interest in midwifery in industrialized societies has generated research on such topics as the history of midwifery, regional traditions of midwifery in the United States, and the politics and professionalization of midwifery (Fraser, 1995; see Davis-Floyd & Sargent, 1997 and Ginsburg & Rapp, 1991, for specific citations).

The impact of the medicalization of birth in the United States is illuminated in Emily Martin's (1987) exploration of how women talk about their birth experiences. Martin examines scientific and medical representations of women's bodies and reproductive processes. She analyses the medical treatment of birth in relation to

the development of Western thought and medicine, in particular the emergence of the notion of the body as a machine and the doctor as the technician who repairs it. Based on semi-structured interviews with a sample including working-class and middle-class women ranging in age and racially diverse, Martin presents women's narratives about pregnancy, labor, and delivery. In talking about their birth experiences, women describe a sense of alienation and fragmentation, produced by the reliance on technological interventions and specialist monitoring. She documents both acceptance of biomedical control and acts of resistance and opposition.

Correspondingly, a principal theme in the anthropology of Western birth has been women's progressive loss of control over birth in conjunction with the transfer of childbirth from home to hospital, and the shift from reliance on midwives as birth assistants to obstetric specialists. An alternative perspective focuses on the limits of the "control model," and argues that the narrative of personal control reflects 20th century Anglo-European notions of individualism. However, infertility, pregnancy loss, and disability exemplify experiences that test the limitations of models that emphasize individual decision-making and control, as several anthropologists have argued, building on personal narratives of pregnancy or neonatal loss (cf. Ginsburg & Rapp, 1999; Layne, 1999).

BIRTH AND AUTHORITATIVE KNOWLEDGE

The American biomedical model of birth has been exported to much of the developing world, and anthropologists have documented the accommodation and resistance of local birthing systems to encounters with imported biomedical obstetrics. Following Jordan's comparative approach, anthropologists have explored variations in the use of obstetric technology in numerous countries, and have documented cross-national variation in the ways birth is managed within European medical systems. The persistence of midwifery in the Netherlands, where midwives attend 70% of births, the home birth rate is still 30%, and maternal and child health outcomes exceed those of neighboring countries, has attracted considerable anthropological interest. As Jordan initially documented, the comparison of biomedical systems among industrialized societies effectively illustrates the ways in which obstetrics is culturally influenced and shaped.

In the context of contested power relationships, a number of anthropologists have employed Jordan's concept of authoritative knowledge, the interactionally displayed knowledge on the basis of which decisions are made and actions taken, to investigate birth as a social process (see Davis-Floyd & Sargent, 1997, for a collection of ethnographic accounts; also Ginsburg & Rapp, 1991, for a review of related literature).

The anthropological interest in contested power relations surrounding pregnancy and birth evident in theoretical discussions of authoritative knowledge reflects a longstanding focus in the field on the politics of childbirth. Since the 1970s, influenced by the feminist movement, anthropologists studying birth have explored the shifting power relations implicated in struggles for control over childbirth, in both industrialized and pre-industrial societies (cf. Handwerker, 1990). Within the United States, Lazarus (1996) describes a two-class system, in which poor women and middle-class women experience pregnancy and childbirth under different circumstances. Her work serves as a reminder that social class generates differences in power, authority, and resources among women that structure access to knowledge about birth and shape the birthing process.

Diverse ethnographies of birth demonstrate how authoritative knowledge about birth is produced, displayed, and challenged. Trevathan's (1987, 1996) work is unique in proposing an evolutionary perspective on human birth. She argues that for millions of years the birthing female was the most important figure at the time of birth, although today her knowledge about her body is likely to be suppressed and devalued.

LOCAL/GLOBAL PERSPECTIVES

Three decades of ethnographic and theoretical work on birthing systems have produced a substantial and empirically grounded anthropological literature. Case studies from North America, Europe, and societies of Asia, Africa, and Latin America have generated the material for anthropological analyses of multiple "ways of knowing" about birth. Anthropologists have begun to address not only the encounter between low- and high-technology birth systems, but also the diverse paradigms of maternity and birth held by different categories of women within heterogeneous societies (Browner & Sargent, 1996, p. 232). In addition, a scant but important literature explores the topic of men in relation to

childbirth (e.g., Ebin, 1994; Romalis, 1981; Whiteford & Sharinus, 1988).

In spite of the global spread of biomedical obstetrics, a substantial body of research illustrates the continued viability of midwifery and low-technology birthing systems. Biomedicine has emerged as the dominant state-sponsored system worldwide; local midwives are often subordinated to government nurse-midwives and hospital births increasingly have supplanted home births. Nonetheless, local birthing systems have demonstrated remarkable resilience in contesting high-technology obstetrics (Daviss, 1997; Kaufert & O'Neil, 1993). While much of the anthropology of birth has worked to validate midwifery and low-technology birthing systems, the risk of an anthropological romanticizing of traditional childbirth has also been identified (Rozario, 1998). In the 1990s, influenced by post-modernism and feminism, the anthropology of birth has moved to include reflexive narratives that represent birth as a subjective experience, in addition to continuing empirical and theoretical investigations of birthing systems in relation to broader social structures and ideology.

Breast-Feeding

Wenda R. Trevathan

PHYSIOLOGICAL, CROSS SPECIES, AND EVOLUTIONARY PERSPECTIVE

For most women in the world nursing an infant is such a routine and normal part of life that they would be surprised to

see an entry for this activity in an encyclopedia. But as with similar life cycle phenomena such as pregnancy, childbirth, and puberty, breast-feeding for contemporary humans is never simply a biological phenomenon, but is typically embedded in a dense context of beliefs, values, and traditions.

The physiological ability and requirement to nurse infants from mammary glands is, in fact, what defines us as mammals, members of the class Mammalia. Indeed, not all mammals have mammary glands (e.g., the monotremes who nurse their young, but do not have mammary glands) so this class might actually be better defined by noting that all members possess body hair, but it is mammary glands that catch our attention when we examine the characteristics of mammals. That, in itself, tells us something about the importance of breast-feeding to human observers who describe animal characteristics.

Two hormones are involved in breast-feeding: prolactin, which promotes milk production, and oxytocin, which enables the milk to move from the mammary glands into the infant's mouth. When an infant suckles, a signal is sent from the breast to the pituitary gland, which, in turn, stimulates the release of prolactin and oxytocin. Oxytocin is also involved in uterine repair after birth and in suppression of ovulation during the period of intense nursing, thus delaying the start of another pregnancy. Certainly the most important contribution of breast-feeding is nutritional, but breast milk also contains antibodies from the mother that protect the nursing infant from a number of pathogens to which it is exposed in the first few weeks of life.

Nutritionally, mammalian breast milk has co-evolved with and is tailored to the physiological and growth needs of infants of each species. Furthermore, the content of milk is closely related to behavioral factors in the nursing relationship in a system that might be described as the "behavioral ecology of breastfeeding." For example, milk of most whale species is very high in fat (up to 50%), which is important for infant survival in cold waters. Mammals that leave their young in nests for long periods of time have milk that is high in fat and protein, whereas mammals that are in near-constant contact with their young have relatively dilute milk. Most primates, including humans, fit into this latter category, and are known as "on demand" feeders. Human milk, like that of apes and monkeys, is low in fat (4%) and protein (less than 2%) and unusually high in carbohydrates (more than 6%). Milk high in carbohydrates contributes to brain development, certainly an important feature for human infants whose brain size more than doubles in the first year of life. In fact, primate milk has a higher carbohydrate content than other mammalian species, a fact clearly related to the relatively large brains characteristic of primates.

Although high-quality breast milk substitutes are available today for those with the knowledge and financial means to use them correctly, the importance of breast-feeding in human prehistory and for mothers and infants in most cultures today cannot be overemphasized. There is no question that, under most conditions and in most parts of the world, breast-fed babies are healthier than their bottle-fed counterparts. In addition to the immunological protection afforded by mother's milk, breast-fed babies are less likely to be exposed to environmental pathogens associated with unclean water, unsterilized bottles, and other equipment used in infant feeding. Even later in life, children and adults who were breast-fed as infants seem to be protected from a number of health insults, including otitis media (earache), sudden infant death syndrome (SIDS), gastrointestinal illnesses, atherosclerosis, and some cancers (Anonymous, 1997). Furthermore, cognitive and motor skill development seem to proceed more rapidly in breast-fed infants, and children who were breast-fed as infants score higher on intelligence tests.

Also, as noted above, highly frequent nursing, especially when coupled with low caloric intake in the mother, usually leads to inhibition of ovulation in the first few months of nursing (Ellison, 2001). A longer birth interval is associated with lower infant mortality, providing another link between breast-feeding and child survival. Certainly in populations in which alternative means of birth control are absent or ineffective, nursing an infant enhances family and community health, as well. When examined statistically, populations in which breast-feeding is prolonged have longer birth intervals than those in which nursing is terminated soon after birth or not practiced at all.

Breast-feeding also seems to provide benefits for the mother. Nursing an infant soon after birth speeds a woman's recovery from the stresses of childbirth. Breast and ovarian cancer rates and osteoporosis are lower among women who breast-fed their infants. Certainly one can argue that having a healthy infant is advantageous to a mother's health, as well.

Breast milk is also much cheaper than milk substitutes when one considers financial costs. Regarding metabolic costs for the mother, however, milk production requires an additional 500 calories per day beyond what she would need for normal body maintenance and activities. For women who are marginally nourished, these additional calories may be difficult to come by. Furthermore, milk production is given high priority in

a nursing woman's metabolic budget, so her own needs may be further compromised by lactation (Ellison, 2001). Because marginal nutrition for the mother is most often associated with poverty, a woman whose own nutritional needs are difficult to meet would likely find that her infant's needs were impossible to meet without breast milk. In fact, in economically impoverished populations, mother's milk may be the only healthful option for very young infants.

In most discussions of breast-feeding in industrialized nations the emphasis is placed upon the health of the mother and infant. In many parts of the world, however, breast-feeding involves the entire family or a community. For example, Katherine Dettwyler (1995a) reports that in Mali, nursing an infant reinforces the kinship relationship between a genetically related mother and infant and creates kinship bonds between unrelated people when a woman nurses an infant that is not her own. She notes that if a woman does not nurse her child, then it calls into question her kinship with the child.

INITIATION AND MAINTENANCE OF BREAST-FEEDING

As noted above, breast-feeding a child is a somewhat predictable part of the life course for most women. That does not mean that initiation of nursing is routine and easy. Most populations also have cultural rules that women must follow during pregnancy to prepare for and ensure successful breast-feeding. These may include specific foods to eat or avoid, the wearing of special clothing and amulets, and other prescribed or restricted behaviors. Following birth, cultural practices relating to breast-feeding a child may include avoiding sexual relations, food restrictions, and performing ritual acts. Dana Raphael describes the tradition of the *doula*, a family member or friend whose primary role is to assist a new mother in breast-feeding her child (Raphael, 1973). Although the word itself is Greek and describes a person who assists women after childbirth ("mothering the mother"), the practice is found throughout the world, evidence that breast-feeding is not something that comes easily to every new mother.

One way of ensuring nursing success in a number of cultures is the custom of enforced inactivity and partial isolation of the mother and infant for periods up to 40 days following birth. In parts of Southeast Asia, this is often referred to as "roasting" the mother

(Laderman, 1983). During this time the mother and infant are kept warm, well fed, rested, and massaged. Although the primary goal of this resting period is recovery from childbirth, it also gives the mother time to initiate and establish breast-feeding before she has to return to her routine activities in the home and fields. Among the Ilocanos of the Philippines, a five-month period known as *tangad* includes a set of regulations that ensure sufficient milk supply and successful nursing (Nydegger & Nydegger, 1966). The most important of these are specific food recommendations and restrictions.

Another place where cultural practices come into play is in the initiation of breast-feeding after birth. In humans, a substance known as colostrum is secreted for the first two or three days following birth. Although colostrum is not nutrient-dense, it provides antibodies and other properties that enhance infant health during a particularly vulnerable period after birth. In many cultures, however, the colostrum is perceived to be inappropriate for infants and is discarded, meaning that the infant is not allowed access to the breast until the true milk comes in, often two or three days after birth. In the meantime, the infant may be fed water or another milk substitute. In contrast, a recent trend in North America is the emphasis on initiating breast-feeding as soon after birth as possible, in the belief that early nursing is positively associated with successful long-term nursing. To some extent, early nursing is important in that the hormonal changes at birth trigger milk production, but if suckling does not occur within a day or two of birth, production shuts down and it is very difficult to re-initiate lactation.

Much variation in the cultural patterning of breast-feeding is apparent in the ethnographic and medical literature. In some cultures, feeding an infant is truly "on demand" in that infants have access to the breast at all times of day and night. In others, including most Western nations, breast-feeding most commonly occurs in private and is more scheduled than spontaneous. Where infants do not sleep with their mothers, nursing through the night "on demand" is not easily achieved.

The most ancient breast-feeding pattern is likely that followed by our close primate relatives, one that permits the infant to nurse whenever he or she wants and for reasons that are not always nutritional. For example, monkey and chimpanzee infants have been observed latching on to their mothers' breasts when they are frightened or otherwise need comforting, even when no milk is taken in. At the opposite extreme is the "nurse every four

hours” pattern formerly recommended by Western medical practitioners. In between are women in the vast majority of world cultures whose work patterns may dictate when breast-feeding can occur. In some settings a woman may carry her infant in a sling and continue working with little interruption when the infant nurses. In other settings, breast-feeding may be restricted to rest periods. Among the Gusii of Kenya, where women are involved in strenuous agricultural work, a young child is charged with carrying the infant to the fields with the nursing mother. When the infant cries, the child caretaker brings the infant to the mother for nursing (LeVine & LeVine, 1966).

SUPPLEMENTATION AND WEANING

In the West, medical specialists and lactation consultants recommend that infants who are exclusively breastfed receive iron supplements at six months of age. Human milk is low in iron, so by the time the infant is that age, anemia may occur if breast-feeding is not supplemented. This is the age that is most commonly cited for supplementation in other cultures as well (e.g., Minturn & Hitchcock, 1966). Food supplements may include a gruel made from a common grain such as rice or millet, cow’s or goat’s milk, or finely ground meat.

Just as there is variation in beliefs about breast-feeding, there is variation in beliefs about the timing and method of weaning. Commonly, an infant is weaned when the mother becomes aware of another pregnancy. Milk from a pregnant woman may be seen as dangerous for the nursing infant, or nursing may be seen as dangerous to the developing fetus. Women may choose to terminate breast-feeding in order to increase their fertility. In much of West Africa, sexual intercourse during the nursing period is believed to be dangerous to the infant, so women may choose to terminate breast-feeding to end the postpartum sex taboo and resume sexual relations with their partners.

One of the most common reasons given for termination of breast-feeding is “insufficient milk.” Certainly there are rare instances when a woman is limited physiologically in her ability to produce sufficient milk for her infant, but under most circumstances, milk production is a supply-and-demand phenomenon, which means that the more an infant suckles, the more milk is produced. In fact, “insufficient milk” is often associated with food

supplementation. If an infant is satiated because of other foods and liquids it is given, then it is less likely to suckle when placed at the mother’s breast. If the infant suckles less, less milk is produced, and soon the mother finds that the infant is not getting sufficient nutrients from the breast alone and that food supplements are required to maintain a healthy weight. Thus begins a cycle that usually terminates with weaning from the breast and permanent transfer to infant foods other than breast milk.

The marketing of milk substitutes has had a profound effect on breast-feeding practices worldwide. Some women believe that canned or powdered milk is better for their infants and that, at the very least, they should supplement their breast-feeding with bottle feeding. As noted above, this often leads to “insufficient milk,” and women find they cannot continue to nurse even if they want to. In some cases, particularly among urban populations, work in the public sector and breast-feeding are incompatible and infants may be weaned when a woman returns to work following childbirth. This is one of the most frequently cited reasons for terminating breast-feeding in the West.

Methods of weaning a child are highly variable across cultures. In some cases the child is said to wean himself or herself, choosing to nurse less and less often until complete cessation. When mothers take the lead in weaning, there is usually stress associated with the transition from breast to solid foods. Mothers may place bitter or pungent substances on their breasts to discourage nursing. For example, the !Kung woman Nisa recalls her mother putting a bitter paste on her breasts to discourage Nisa from nursing after she became pregnant again. Nisa was told that the milk was for the new baby and that it would make her sick if she continued to nurse (Shostak, 1981). Weaning is apparently quite traumatic for the !Kung, and several people that Shostak interviewed in her fieldwork had vivid memories of the unhappiness they experienced at that time. Among the !Kung and in other cultures, an older child may be shamed into terminating breast-feeding.

The Gusii believe that an infant should be nursed until it is walking well and is able to take care of other basic needs. Thus, weaning begins in the second year of life, although it may occur earlier if the mother becomes pregnant. The severity of the weaning process is illustrated by the word used, which means “to stamp on” or “step on” (LeVine & LeVine, 1966). Mothers may put noxious substances on their nipples, or they may actually hit the child who attempts to nurse once the weaning

process begins. The child may even be sent to live with grandparents or may be given great quantities of solid food in order to decrease hunger.

As noted, cultural practices most often determine how long an infant should be breast-fed. Evolutionary anthropologists, however, have tackled the question of how long the human nursing period is expected to be when placed in an evolutionary and cross-species context. Four years is the most common figure cited for the nursing duration for our close relatives, chimpanzees, gorillas, orangutans, and for women in foraging societies. Other factors that have been used to assess the “natural” age of weaning in humans include life history variables such as adult body size, gestation length, and tooth eruption, all of which point to an approximate 4- or 5-year nursing period for humans (Dettwyler, 1995b). But no matter what criteria are used to estimate nursing length in humans, it is clearly much longer than the six months commonly reported in industrialized nations.

BREAST-FEEDING PRACTICES IN THE WEST

In the United States, the number of mothers who chose to breast-feed their infants had declined by the middle part of the 20th century, with the decline being most rapid in the middle and upper classes, in association with the economic ability to purchase breast milk substitutes. By the end of World War II, most American women bottle-fed their babies (Raphael, 1973). One of the factors behind the decrease in breast-feeding was active promotion of infant formula by food and drug manufacturing companies. Initially, promotion efforts were aimed at educated women in industrialized nations, but as the birth rate began to fall in the early 1960s, manufacturers turned to developing nations for their markets. Outraged at what were viewed as unethical marketing practices resulting in “commerciogenic malnutrition” in infants of developing nations, advocacy groups in Europe and North America began what has been called the most successful international boycott in history against Nestlé and other manufacturers of milk substitutes (Van Esterik, 1989). As a result of the boycott and publicity surrounding it, the World Health Organization produced the WHO/UNICEF Code of Marketing for Breastmilk Substitutes in 1981. (The United States was the only member of the 122-nation World Health Assembly to vote against

the Code at the time, although the United States endorsed it in 1994.) The Code primarily encourages regulation of advertising and marketing, but it also encourages the provision of information about the benefits of breast-feeding.

The international boycott drew attention to breast-feeding at a time when American and European women were turning away from technological and medical ways of dealing with pregnancy, childbirth, and childcare. The result was a gradual increase in the numbers of women choosing to nurse their infants and by the second part of the century, natural childbirth and natural mothering began to come back in style, with middle- and upper-class women again taking the lead. By 1998, 64% of women breast-fed upon leaving the hospital, 29% were still breast-feeding at six months, and 16% at one year. The Healthy People 2010 Objectives for the Nation (United States) targets 75% at birth, 50% at 6 months, and 25% at one year (US Department of Health and Human Services, 2000). At all three points, African American women are far behind Hispanic and “White” women in meeting those targets.

In 1997 the American Academy of Pediatrics produced a policy statement promoting breast-feeding for all infants, including those born prematurely, and urged that nursing begin within the first hour after birth whenever possible. Furthermore, the Academy agreed that the infant be nursed whenever it shows signs of hunger and that breast-feeding should be exclusive for the first six months (Anonymous, 1997). This policy statement is followed by more than 100 scientific references in support of the view that “breast is best” for human infants. It seems that the pendulum of breast-feeding fashion has swung widely in the past 50 years.

Contemporary research on breast-feeding in the West emphasizes the importance of social support in promoting successful breast-feeding, not only through direct assistance with techniques for nursing an infant, but also through promotion of positive attitudes toward breast-feeding. The formation in 1956 in Chicago of a group of nursing mothers known as the La Leche League was a response to the need for social support for breast-feeding that was not being provided by the medical establishment. Today, La Leche League chapters are found all over the world and there are dozens of other organizations devoted to providing support to nursing mothers. Breast-feeding does not come easily to women in industrialized nations, as evidenced by hundreds of websites devoted to

providing education and support for breast-feeding, including those with titles like “Breastfeeding Online,” “Breastfeeding Basics,” “A Woman’s Guide to Breast-feeding,” and “Breastfeeding and Parenting Resources on the Internet.” One site promised more than 500 links to sites providing breast-feeding information.

Breast-feeding is part of our heritage as mammals, but as culturally embedded human beings, we have an array of choices about infant feeding that no other species or past human population has ever had. Current scientific research has led educated women to choose to feed their infants in the same way that all other mammals do. Similar choices are often out of the hands of poor women in much of the world, but renewed efforts on the part of international organizations target breast-feeding as the single best and least expensive way to improve the health of infants worldwide.

Child Growth

Barry Bogin

WHY DO ANTHROPOLOGISTS STUDY HUMAN GROWTH?¹

The study of human growth has been a part of anthropology since the founding of the discipline. European anthropology of the early to mid-19th century was basically anatomy and anthropometry, the science of human body measurements (Tanner, 1981). Early practitioners of American anthropology, especially Franz Boas (1892, 1940) are known as much for their studies of human growth as for work in cultural studies, archeology, or linguistics. Boas was especially interested in the changes in body size and shape following migration from Europe to the United States. At the time of those studies, around

1890–1920, most anthropologists and anatomists believed that stature, and other measurable dimensions of the body such as head shape, could be used as “racial” markers.

The word “race” is set in inverted commas here because it refers to the scientifically discredited notion that human beings can be organized into biologically distinct groups based on phenotypes (the physical appearance and behavior of a person). According to this fallacious idea, northern European “races” were tall and had relatively long and narrow heads, while southern European races were shorter and had relatively round skulls. Boas found that, generally, the children of Italian and Jewish European migrants to the United States were

significantly taller and heavier than their parents. The children of the migrants even changed the shape of their heads; they grew up to have long narrow heads. In the new environment of the United States, the children of recent southern European migrants grew up to look more like northern Europeans than their own parents.

Boas used the changes in body size and shape to argue that environment and culture are more important than genes in determining the physical appearance of people. In terms of environment, life in the United States afforded better nutrition, both in terms of the quantity and the variety of food. There were also greater opportunities for education and wage-paying labor. These nutritional and socioeconomic gains are now known to correlate with larger body size. In terms of culture, in particular child-rearing practices, there were other changes. In much of Europe infants usually were wrapped up tightly and placed on their backs to sleep, but the American practice at the turn of the century was to place infants in the prone position. In order to be “modern” the European immigrant parents often adopted the American practice. One effect on the infant was a change in skull shape, since pressure applied to the back of the infant’s skull produces a rounder head, while pressure applied to the side of the skull produces a longer and narrower head (Walcher, 1905).

The work of Boas and his colleagues shows that an interest in human growth is natural for anthropologists. This is because the way in which a human being grows is the product of an interaction between the biology of our species, the physical environment in which we live, and the social/economic/political environment that every human culture creates. Moreover, all living people share the basic pattern of human growth. That pattern is the outcome of the four million year evolutionary history of the hominids (i.e., living human beings and our fossil ancestors). Thus, human growth and development reflect the biocultural nature and evolutionary history of our species.

Human Growth and Medical Anthropology

Boas argued for nearly 50 years that the study of human growth provides a mirror of the human condition. It is widely accepted today that the patterns of growth of human populations reflect the “material and moral conditions of that society” (Tanner, 1986). Those material and moral conditions are, in large parts, determinants of human health, in terms of physical, social, and emotional

well-being. Viewed in this perspective, the study of human growth in its cultural context contributes to many interests of medical anthropology.

Biocultural Models of Human Growth

Human growth is part of the biocultural nature of our species. Since the late 19th century, anthropologists (such as Boas) have used biocultural models of human development. By the mid-20th century, the discovery of the nature of DNA and other fundamentals of developmental biology led to a biocultural model that considered human development as, basically, a biological process which could be influenced to a greater or lesser extent by the social and cultural environment.

By the late 20th century, the biocultural model was revised to show that there is a recurring interaction between the biology of human development and the socio-cultural environment. Not only does the latter influence the former, but human developmental biology modifies social and cultural processes as well. Global trends toward taller stature over the past 150 years and toward overweight and obesity in the past 20 years are just two examples of these interactions. Increases in the average height and weight of human individuals and populations have consequences for health, the manufacture of clothing and furniture, physical work capacity, perceptions of desired or ideal body shapes, food production and consumption, demographic structure (fertility, migration, and mortality), and social behavior (Bogin, 2001).

Furthermore, it is now understood that environmental forces, including the social, economic, and political environment, regulate the expression of DNA as much, or more so, than DNA regulates the growth process. One example of this type of biocultural interaction is the evolution of bipedalism, the method of human locomotion unique among the primates. Bipedalism is made possible, in part, by a pattern of growth that alters the size and shape of the skeleton (e.g., legs longer than arms and a relative short and broad pelvis) without adding or deleting any bones found in our ape cousins. It is hypothesized that many crucial feeding, reproductive, social, and cultural adaptations of our species are both a consequence and cause of bipedalism (Morbeck, Galloway, & Zihlman, 1997). These behavioral adaptations selected for the expression and regulation of genes that bring about the human pattern of growth allowing for bipedalism. In a medical sense, bipedalism also brings about many physical

ailments, including lower back pain, fallen arches of the feet, and inguinal hernias. People respond to these liabilities of bipedalism with a wide variety of medical and cultural behaviors, ranging from diet to surgery to psychological and spiritual counseling.

LIFE HISTORY THEORY AND HUMAN GROWTH

The biocultural nature of human growth is best viewed from a life history perspective. The field of life history theory is the scientific study of life cycle strategies and their evolution (Stearns, 1992). Life history refers to major events that occur between the conception and death of an organism. It is defined as the strategy an organism uses to allocate its energy toward growth, maintenance, reproduction, raising offspring to independence, and avoiding death. Living things on earth have greatly different life history strategies, and differences in life history characteristics can have profound effects on the growth dynamics, ecology, and evolution of populations.

Some key elements of life history theory are shown in Table 1. These key points are divided into two columns in the table. The left column lists the basic principles that guide the evolution of life history for any species. The right column lists the trade-offs that shape the particular life history strategy of a species or members of a species. A trade-off may be thought of as the competition between two biological or behavioral traits. An example of the first type of trade-off is competition between organs or tissues of the body during growth. For example, should energy and materials be devoted to growing a large set of muscles or a larger brain? An example of the second type of trade-off is the choice of producing one large offspring or many, smaller offspring. All living things face these trade-off decisions. Some occur on a day-to-day basis, others occur over longer periods of time. Those that have reproductive consequences and occur over generations are subject to natural selection, and the effected traits may evolve over time.

Human beings are no exception to the dynamics of life history. People share many life history traits and trade-offs with other mammals. As for all mammals, people have evolved strategies of when to be born, when to be weaned, how many and what type of pre-reproductive stages of development to pass through, when to reproduce, and when to die. Human growth serves as a good example of life history traits and trade-offs. In contrast to most

Table 1. Life History Principal Traits and Trade-offs

Principles	Trade-offs
1. Size at birth	1. Current reproduction vs. future reproduction.
2. Growth patterns <ul style="list-style-type: none"> • Number of life cycle stages • Duration of each stage 	2. Current reproduction vs. survival
3. Age at maturity <ul style="list-style-type: none"> • Age at first reproduction 	3. Number, size, and sex of offspring
4. Sexuality: asexual, sexual, parthenogenesis?	4. Parental reproduction vs. growth
5. Size at maturity	5. Number vs. size of offspring
6. Number, size, and sex ratio of offspring	6. Parental condition vs. offspring growth
7. Age-, sex-, and size-specific reproductive investments	7. Offspring growth, condition, and survival
8. Age-, sex-, and size-specific mortality schedules	8. Parental vs. offspring reproduction
9. Length of life <ul style="list-style-type: none"> • Reproductive lifespan • Rate of aging/senescence 	

^aFrom Bogin (2001). This is a partial list of the most important traits. The list is based on the discussion in Cole (1954) and Stearns (1992), who provide additional traits.

other mammals, people grow slowly and take almost 20 years to reach maturity. The lag between conception and maturity is, in part, a trade-off between speed and quality. Slow human growth delays both the independence of the young and the age at reproduction, but it may pay-off in adults with better health and reproductive fitness.

The evolution of human life history can be studied in many ways. One way is to examine the stages of the life cycle. One of the many possible orderings of the events in the human life cycle is shown in Table 2. The remaining discussion is confined to the postnatal life cycle stages, with an emphasis on childhood. These stages are defined in terms of functional biological, behavioral, social, and cognitive characteristics. One of these is change in the rate of growth, as shown in Figure 1. The human “distance” curve, showing the amount of growth in height from birth to age 22 years, is labeled on the right side of the graph. This curve has three phases: an initial phase of rapid growth during infancy, a second prolonged phase of moderate and near-constant growth during the childhood and juvenile stages, and a third phase with the adolescent growth spurt.

These phases are more clearly seen in the velocity curves. The increment of the velocity curve, which

Table 2. Stages in the Human Life Cycle

Stage	Growth events/duration (approximate or average)
<i>Prenatal Life</i>	
Fertilization	
First trimester	Fertilization to 12th week: embryogenesis
Second trimester	Fourth through sixth lunar month: rapid growth in length
Third trimester	Seventh lunar month to birth: rapid growth in weight and organ maturation
Birth	Transition to extra-uterine life
<i>Postnatal Life</i>	
Neonatal period	Birth to 28 days: extrauterine adaptation, most rapid rate of postnatal growth and maturation
Infancy	Second month to end of lactation, usually by age 36 months: rapid growth velocity, steep deceleration in velocity with time, feeding by lactation, deciduous tooth eruption, many developmental milestones in physiology, behavior, and cognition
Childhood	Third to seventh year: moderate growth rate, dependency for and feeding, mid-growth spurt, eruption of first permanent molar and incisor, cessation of brain growth by end of stage
Juvenile	Ages seven to 10 for girls, or 12 for boys: slower growth rate, most permanent teeth erupt, capable of self-feeding, cognitive transition leading to learning of economic and social skills
Adolescence	Five to eight years after the onset of puberty: Adolescent growth spurt in height and weight, permanent tooth eruption virtually complete, development of secondary sexual characteristics, sociosexual maturation, intensification of interest and practice adult social, economic, and sexual activities
<i>Adulthood</i>	
Prime and transition	From 20 years of age to end of child-bearing years: homeostasis in physiology, behavior, and cognition, menopause for women by age 50 years
Old age and senescence	From end of child-bearing years to death: decline in the function of many body tissues or systems

^aFrom Bogin (1999).

represents the rate of growth in height during any year, is labeled on the left side. Changes in the velocity of growth may be divided into five phases, or stages, of human development. These are: (1) infancy; (2) childhood; (3) juvenile; (4) adolescent; and (5) adult stages. Below the velocity curve are symbols indicating the average duration of each stage of development.

Infancy begins at birth and lasts until about age three years. The infant's rate of growth is initially rapid but

Figure 1. Distance and velocity curves of growth for human beings. Boy—solid line, girls—broken line. The stages of postnatal growth are abbreviated as follows: I = infancy, C = childhood, J = juvenile, A = adolescence, M = mature adult (Bogin, 1999).

decelerates quickly. The infant's growth curve is a continuation of the fetal pattern, in which the rate of growth in length actually reaches a peak in the second trimester of gestation, and then begins a deceleration that lasts until childhood. The childhood stage encompasses the ages of about three to seven years. The growth deceleration of infancy ends at the beginning of childhood, and the rate of growth levels off at about 6 cm per year. This leveling-off in growth rate is unusual for mammals, as virtually all other species continue a pattern of deceleration after infancy. This slower and steady rate of human growth maintains a relatively small-sized body during the childhood years. About 60% of children have a small acceleration in growth rate, called the mid-growth spurt, at the end of childhood.

The human juvenile stage begins at about age seven years, and is characterized by the slowest rate of growth since birth. In girls, the juvenile period ends, on average, at about the age of 10, two years before it usually ends in boys. The difference reflects the earlier onset of adolescence in girls. Human adolescence is the stage of life when social and sexual maturation takes place. In terms of growth, both boys and girls experience a rapid acceleration in the growth velocity of virtually all of the bones of the body. This is called the adolescent growth spurt. Adolescence ends when skeletal growth is complete. This usually marks the achievement of full reproductive maturity, meaning both physical and psychosocial maturity.

In addition to changes in growth rate, each stage may also be defined by characteristics of the dentition,

by changes related to methods of feeding, by physical and mental competencies, and by maturation of the reproductive system and sexual behavior. Details on the development of these characteristics may be found in Bogin (1999).

WHY GROW AND DEVELOP?

Organisms grow and develop if they are mortal. Reproduction is necessary to replace those organisms that die, and sexual reproduction requires cell division, the formation of tissues, and other forms of growth. Some forms of life reproduce asexually, in which one or a few cells are contributed by a parent and those cells eventually grow and develop into a new mature individual that is, in many ways, almost identical to the parent. Most species reproduce sexually, requiring a single cell with some biological material from each of two parents. In either case, the initial contribution of cells cannot look or behave in any way like the parent. To be like their parents, "... the new organisms will have to suffer changes before they become something approaching replicas of the old" (Newth, 1970).

Plasticity and Continuity during Human Development

Sexual reproduction and time for growth allow new organisms to develop differences from their parents—the offspring may display plasticity. The term plasticity means a potential for change in the phenotype of the individual caused by a change in the environment (Mascie-Taylor & Bogin, 1995; Stearns, 1992). The fitness of a given phenotype varies across an environment's range of variation. When phenotypes are fixed early in development, such as in mammals that mature sexually soon after infancy, environmental change is positively correlated with high mortality. Examples are mice, rats, and other rodents, which may mature only a few weeks after birth. However, fewer than one out of a thousand newborns survive to maturity.

The process of growth and development is arduous, often prolonged, and generally hazardous. The high rates of death for sex cells, fertilized eggs, embryos, fetuses, newborns, and young attest to these hazards. The pattern of human growth is one of the most prolonged of any mammals and this entails many hazards. In traditional

societies of both historic and prehistoric eras, including hunter-gatherers and horticulturists, about 35% of live-born humans die by age seven years, and less than 60% reach adulthood (Bogin, 1999; Lancaster & Lancaster, 1983). Despite the risks for death, more human beings reach adulthood than any other animal species. The next most successful species after humans is the chimpanzee, but only 35% of live-born chimpanzees reach adulthood. Part of the success of humans is due to the prolonged process of human growth, which allows for greater plasticity in development.

Social mammals such as some carnivores, elephants, and primates, prolong the developmental period by adding a juvenile stage (a period of feeding independence prior to sexual maturation) between infancy and adulthood. Adult phenotypes develop more slowly in these mammals. They experience a wider range of environmental variation, and the result is a better conformation between the individual and the environment. This plasticity leads to an increase in evolutionary fitness, meaning that more offspring can survive to reproductive age. In large mammalian species without a juvenile stage, less than 10% of live-born offspring survive to reproductive age, while between 12% and 30% survive in the social mammals with a juvenile growth stage (Pereira & Fairbanks, 1993).

Human beings have a juvenile stage and add a childhood stage of growth between infancy and the juvenile period. Evidence for the evolution of the childhood growth stage is provided in Bogin (1999). Childhood allows for an additional four years of relatively slow physical growth and behavioral experiences that further enhance developmental plasticity.

The Five "Themes" of Human Childhood

Listed in Table 3 are some of the biosocial traits of human children. Many of these traits are shared with other social

Table 3. Biosocial Traits of Human Children

-
1. Slow and steady rate of growth and relatively small body size
 2. A large, fast-growing brain
 3. Higher resting metabolic rate than any other mammalian species
 4. Immature dentition
 5. Sensitive period for maturation of fundamental motor patterns
 6. Sensitive period for cognitive and language development
 7. Weaned, with dependence on older people for care and feeding
-

mammals, but no other mammalian species has all of these traits. By these criteria, childhood is a stage of growth found only in the human species.

Five “themes” help us to understand the place of childhood in human biology and culture.

1. Childhood is a reproductive and feeding adaptation. By the time the childhood growth stage begins at age three years the infant is weaned, meaning that all breast-feeding is finished. Weaning frees the mother from the demands of nursing and the inhibition of ovulation related to continuous nursing. This decreases the interbirth interval and increases reproductive fitness, as human women can reproduce successfully every three years or less, but ape females require four to seven years between successful pregnancies. A trade-off is that human children are still dependent on older individuals for feeding and protection because they do not have the permanent teeth, digestive systems, or motor skills to fend for themselves. The reproductive benefits are so great, however, that on balance childhood and child support social systems may have evolved as a means to provide dependent offspring with food and care while allowing the mother to reproduce new infants.
2. The allometry of the growth of the human child releases nurturing and care-giving behaviors in older individuals. Allometry refers to different rates of growth for different parts of the body. At birth, the human head is about 25% of total body length (Figure 2). By age seven years, the brain and cranium achieve almost adult size, but body growth is only 40% complete, dental maturation is only 58% complete, and reproductive maturation is only 10% complete. A series of ethological observations (Lorenz, 1971) and psychological experiments (Alley, 1983; Todd, Mark, Shaw, & Pittenger, 1980) demonstrate that these growth patterns of body, face, and brain allow the human child to maintain a superficially infantile (i.e., “cute”) appearance longer than any other mammalian species. The infantile appearance of children facilitates parental investment by maintaining the potential for nurturing behavior of older individuals toward both infants and dependent children (Bogin, 1999; McCabe, 1988).
3. Children are relatively inexpensive to feed. The relatively slow rate of body growth and small body size of children reduces competition with adults for food resources, because slow-growing, small children require less food than bigger individuals. A five year old child of average size (the 50th centile of the NCHS reference curves for growth) and activity, for example, requires 22.7% less dietary energy per day for maintenance and growth than a 10 year old juvenile on the 50th growth centile (Ulijaszek & Strickland, 1993). Thus, provisioning children, though time consuming, is not as onerous a task of investment as it would be, for instance, if both brain and body growth were both progressing at the same rapid rate. Moreover, in times of food scarcity children are protected from starvation by this unique pattern of brain and body growth.
4. “Babysitting” and adoption are possible. As children do not require nursing, any competent member of a social group can provide food and care for them. Cross-culturally, juveniles, adolescents, grandmothers, and other kin, both male and

Figure 2. Changes in body proportion from birth to adult. The newborn's relatively large head, with large eyes and small chin (not shown) combined with small arms and legs is perceived as “helpless,” “cute,” or “in need of care” in many human cultures. Infants and children retain these body proportions until at least seven years of age.

female, may provide care for children (Bogin, 1994a; Bogin & Smith, 1996). This type of care-taking is rare in other primates, even for apes. Adoptions of orphaned infants by females do occur in chimpanzee social groups, but only infants older than four years and able to forage for themselves survive more than a few weeks (Goodall, 1983). It seems that the human infant can more easily make new attachments to other caretakers than the chimpanzee infant. The ability of a variety of human caretakers to attach to one or several human infants may also be an important factor. The psychological and social roots of this difference between human and non-human species in attachment behavior are not known. However, this flexibility in attachment behavior allowed, in part, for the evolution of childhood and the reproductive efficiency of the human species.

5. Childhood allows for developmental plasticity. The value of this plasticity was discussed above. Cross-cultural examples of plasticity in human growth are given below.

CROSS-CULTURAL EXAMPLES OF CHILD GROWTH

A great deal of data on human physical growth exist in the literature and some of this has been collected into

two volumes by Eveleth and Tanner (1976, 1990). Also see Ulijaszek, Johnston, and Preece (1998). There is relatively little difference between individuals cross-culturally in growth before birth, as birth length clusters at 50 cm and mean birth weight ranges from 2.4 kg to 3.4 kg. To be sure, infants born to smaller, undernourished, or ill mothers may be shorter and weigh less than infants born to taller, heavier, or healthier mothers. Indeed, birth weight serves as an indication of the overall health of the infant, and epidemiologists use the mean birth weight of a social group as an indication of its general quality of life. Even so, more variation between individuals and populations develops with time after birth. By adulthood, the range in stature is from 184 cm for young men in the Netherlands (Fredriks et al., 2000) to 145 cm for Efe Pygmy men (Dietz, Marino, Peacock, & Bailey, 1989). In these and other populations, adult women are from 8 cm to 14 cm shorter than men. Population variation in many other body measurements is detailed in the Eveleth and Tanner volumes cited above.

The African pygmies are short for genetic reasons: they do not produce enough growth hormones or their cells are not sensitive to these hormones. Genetic causes cannot easily explain growth variation between other human populations. The research concerning growth variation is far too copious to review here (see Bogin, 1999; Gray & Wolfe, 1998). Much attention is focused on specific determinants, such as disease and nutrition. Some cross-cultural work cites physical and emotional stress, or child-rearing practices. Children and adults tend to be taller in societies that practice some sort of painful ritual (e.g., scarification, piercing, vaccination) early in life or separate infants from their parents by swaddling or crèching them (Landauer & Whiting, 1981).

These individual factors are important, but the consensus of research is converging on the total quality of life as the main explanation for growth variation. This is because nutritional status and disease are highly correlated with the social, economic, and political conditions of life. The poverty rate, the infant mortality rate, the literacy rate for adults, the school attendance rate for girls, and the mean birth weight of any society may predict child and adult stature as well or better than measures of specific diseases or food intake. Conversely economic and social historians use growth data to assess the quality of life in past centuries, when standard indicators of health and economic development were unavailable.

Since 1992, my own research has focused on the social, economic, and political conditions that influence the growth and health of children of Guatemala Maya immigrants to the United States. Some scholars have called the Maya "Pygmies of the Americas" or otherwise asserted that the Maya are genetically shorter in stature. Our research finds that Maya children between the ages of five to 12 years old, living in Los Angeles, California, and Indiantown, Florida, average 10–11 cm taller than their age-mates living in Guatemala (Bogin, Smith, Orden, Varela Silva, & Loucky, 2002). Our Los Angeles and Indiantown sample includes children born in Guatemala and Mexico, and Maya Americans born in the United States. Greater time in the United States results in greater stature, meaning that the Maya American children are the tallest of all the Maya. This height increase following migration is the largest that has ever been recorded for any human population, and expands the known range of plasticity in human growth. The height increases show that the social, economic, and political conditions of Guatemala holding back human growth are very severe. The increase in stature attests to improvements in nutrition, healthcare, water quality, education, reduced physical labor, and increased physical and emotional security in the United States. However, the Maya children are still, on average, shorter than European Americans, African Americans, and Mexican Americans living in Indiantown, Florida (ethnic group names are based on self-identification by the people of Indiantown). We predict that it will take three or four generations of growth in the United States until Maya Americans achieve the same average height as these other ethnic groups.

RISKS FOR CHILDREN

The pattern of child growth, including dependency on older individuals for food and protection, small body size, slow rate of growth, and delayed reproductive maturation, entails liabilities. Mild-to-moderate energy undernutrition is, perhaps, the most common risk, with estimates that 28% of all children, equaling 150 million, are undernourished in developing nations (UNICEF, 2001). Undernutrition may be due to food shortages alone, but equally likely it is due to work loads and infectious disease loads placed on children that compromise their energy balance (Worthman, 1993). Viewed in historical perspective, unreasonable work loads for

children and many childhood diseases are products of the agricultural and industrial revolutions (Sommerville, 1982; Tanner, 1981). Overnutrition, resulting in overweight and obesity, is also a problem in both the poor and rich nations. The World Health Organization estimates that worldwide, about one billion people are overweight or obese. Between 20 and 25 million are infants and children. Under- or overnutrition are serious threats to adequate growth, physical and cognitive development, health, and performance at school or work.

Another risk for children in the contemporary world is that of abuse and neglect. One estimate of the worldwide mortality from abuse and neglect is between 13 and 20 infants and children per 1,000 live births (Belsey, 1993). The incidence of all suffering from abuse and neglect is probably higher, but very difficult to estimate since data are not reported by most nations. Some industrialized nations do maintain statistics for non-fatal abuse and neglect of children. In the United States, for example, "in 1991 2.7 million abused or neglected children were reported to child protection agencies" (Kliegman, 1995). This is a rate of 38.6 children per 1,000.

One reason for child abuse and neglect is that the biology of infancy and childhood may not keep pace with the rapidity of technological, social, and ideological change relating to families and their offspring. It is now technologically possible to safely nourish infants without breast-feeding and this allows parents (mothers) an opportunity to pursue activities that separate the mother and her infant. Of course, mothers working away from their infants, be it in agriculture, industry, or other services, do not usually desire to neglect or abuse their infants. Where qualified caretakers are available, such as grandparents or older siblings, the infant may be well attended when the mother is working. When families live under difficult social, economic, and political conditions, especially poverty conditions, mothers may have no alternative but to leave an infant with unqualified caretakers, or even alone.

Reduced or absent breast-feeding may also allow a woman to have another baby sooner. Among the poor populations of the developing countries, short birth intervals (less than 23 months) compromise the health of both the infant and the mother (Huttly, Victoria, Barros, & Vaughn, 1992). A major negative effect on the infant is low birth weight, which is known to impair both physical growth and cognitive development during childhood and later life stages (Crooks, 1995; Garn, Pesick, & Pilkington, 1984; Kliegman, 1995).

In the populations of the more developed nations, such as among the U.S. middle-class, fewer than 20% of infants are breast-fed. In these same countries, the weaning process—from bottles and formula to solid "baby foods"—may begin by three months of age (Detwyller, 1995). This severely curtails the infancy stage of life history, when feeding is evolutionarily designed to be done mostly by breast or bottle. These "premature children" present a problem for care, as they are still biologically within the infancy stage of development and do not possess the physical or emotional capabilities of children. Societies in the developed nations have many programs and devices (e.g., day care for the infants, parent education classes, play equipment) to handle this conflict between biology and culture. Some arrangements work well, but when they do not succeed, and the infant reacts poorly, the frustrated parents or caregivers may respond with abusive or neglectful behavior.

A final example of the consequences of a changing world on the development of children concerns violence and warfare. In 1985 14% of all childhood deaths in the United States were due to violence, up from 4% in the 1960s. Nearly half of all childhood mortality in the United States was due to accidents (Fingerhut & Kleinman, 1989). The accident rate (due to motor vehicles, fires, and drowning) also represents a type of violence to which children are susceptible. Several studies have noted strong associations between socioeconomic status and childhood accidents, including research in the United States (Fingerhut & Kleinman, 1989) and England and Wales (Fox, 1977). Lower social class, especially poverty, is linked with a significantly higher death rate from all types of accidents (Kliegman, 1992).

CONCLUSION

Childhood is a unique stage in the life history of human beings. Prior to the late 1980s standard "textbook" explanations for the value of childhood held that it provides "extra" time for brain development and learning. This is true, but advances in life history theory and analysis of the fossil record of human evolution are now used to associate the initial selective value of childhood more closely to parental strategies to give birth to new offspring and provide care for existing dependent young. Additionally, the childhood stage allows for increased developmental plasticity and fitness for the young. The dependency of

childhood also entails risks. Deviant behavior by older individuals, social groups, and political institutions can adversely and permanently affect children.

A troubled childhood has long-term consequences. The problems of adults who were abused, neglected, subjected to warfare, or poverty as children are often cited. Less openly discussed are undernutrition in the poor nations and overnutrition in the wealthy nations. These are, arguably, the major health threats to the world's children. Both types of malnutrition often lead to severe and costly physical and psychological complications in adulthood. To paraphrase William Wordsworth, the child is father and mother to the adult. It is certainly easier to produce physically healthy and psychologically well-adjusted adults if their development conforms to the bioculturally based needs of infancy, childhood, and the other stages of human life history. Medical anthropology has the resources to elucidate the needs of children and the responsibility to promulgate them widely.

NOTE

1. This entry focuses on theoretical issues of interest to medical anthropology. Detailed treatments of the biology of child growth, techniques of measurement, behavioral and cognitive development, body shape and composition, clinical issues, and the evolution of human growth may be found in Ulijaszek et al. (1998) and Bogin (1999).

Dying and Death

Sharon R. Kaufman

INTRODUCTION

Dying and death are profound aspects of human experience whose definitions and meanings are fabricated through cultural and historical lenses. Though death is biologically inevitable, it is also a social fact; knowledge about it is made. It is understood through frameworks of religion and social structure, science and medicine, loss and disruption that are available to individuals within societies. There is no such thing as a *natural* death, that is, a death that occurs beyond the boundaries of culture and historical moment, social norms and expectations, tradition and innovation.

The anthropology of dying and death itself, considered from the early days of ethnographic practice, illustrates a major shift in how those terms have been situated and employed. Late 19th and early 20th century studies of death were conducted within the frameworks of the anthropology and sociology of religion, ritual practice, and structural–functionalism. Recent critiques of early studies note their attention to normative practices surrounding the corpse, the funeral, and the bereaved to the exclusion of acknowledgement of the dying person and the intense emotions surrounding the dying transition. Late 20th century and contemporary studies focus

primarily on controversies that emerge from biomedical understandings about the physiologic body, the brain and the idea of consciousness, and how the cessation of life can be measured or unequivocally known, especially in the contexts of organ transplantation and values about life prolongation. Social and cultural studies of the body, medicalized death, and biotechnologies point to a double problematic: first, that death is negotiable terrain, rather than an absolute status; and second, that the separation and opposition of *life-and-death* is a culturally produced dualism, rather than a natural fact. Exploration of forms of biopower, influenced by the work of Foucault and Agamben, underscore ways in which *life* and *death* are politicized concepts that acquire meaning through law, science, and state practices.

World events throughout the 20th century, especially the Nazi holocaust and more recent genocides, displacements and political violence, and AIDS and other epidemics have fostered anthropological studies of the normalization of violence, ways in which the effects of war and terror are embodied, emerging considerations of risk in the face of disease and natural and human-made disasters, narratives of illness, dying, trauma, and how death is lived, and ethnographic explorations of social suffering. In much of this work, *death* is central to the events which are

considered ethnographically, yet, as a biopolitical topic, it hovers in the background and is not taken up analytically.

Within anthropology and medical anthropology, the subjects of dying and death must be placed, too, in the changing shape of disciplinary knowledge and practice. Early investigations of death were undertaken in an anthropological enterprise that conceived the object of study to be discrete cultural groups whose native practices were considered perduring. The framework for approaching death was the individual within a bounded cultural group, the threat of death to social stability, and the role of ritualized, generalized mortuary practices in the re-stabilization and re-integration of small-scale societies. Studies of war and violence were not conceptually connected with studies of death or their associated rituals. Critiques of colonialism, the deconstruction of “the native,” and the impacts of migration and globalization have forever altered earlier conceptions of culture as static and territorially demarcated. Thus, ideas about death as an easily identifiable part of some cultural whole, and the singular disruptive or integrative role death plays, have been dismantled as well.

The addition of interpretive methods and experiments in ethnographic writing also have changed the ways in which ethnographic facts come to be established. Highly complex notions such as life, death, and dying are viewed, in contemporary investigations, as subjects without clear boundaries, and any analytic exploration of those themes now problematizes their definition. Subjects of longstanding anthropological interest foundational to contemporary death studies include: personhood, identity, liminality, and the relationship between the sacred and the secular. Of more recent interest to medical anthropologists are three lines of inquiry: (1) studies of death situated in social science analyses of technoscience are concerned with biopower, body commodification, bioethics, and a rethinking of the culture/nature and human/non-human dichotomies; (2) AIDS/HIV has fostered anthropological work on the social underpinnings of disease acquisition and its spread, the political economy of epidemics, and the culture of risk; and (3) the anthropology of violence, war, and terror explores ways in which death is “lived” in memory, in illness, in the body, and in everyday practices. Critical, narrative, and phenomenological analytic approaches come to the fore in these contemporary explorations. Death is now a site where investigations of technology, medicine, and science; epidemics, poverty, and structural inequality; state and ethnic conflict and

genocide; intersections of person, community, and the state; and traditional and innovative approaches to “culture” and “nature” come together.

THE CLASSIC STUDIES: RELIGION, RITUAL, AND THE SOCIAL

Grounded in the work of Tylor, Frazer, and Durkheim on the origins and social function of religion, the anthropology of death developed around the task of describing normative funeral and mourning rituals in pre-literate societies. Analysis aimed to illustrate ways in which particular rites enabled the transfer of the soul from one realm to another and reinforced social solidarity. Durkheim’s student, Robert Hertz (1907/1960) in his study of secondary burial rituals, set the standard for anthropological considerations of the corpse and its treatment, the soul, ritual practices of mourners, and relationships among them. His work emphasized the following: death does not coincide with the destruction of an individual’s life; death is a social event and the beginning of a ceremonial process by which the dead person becomes an ancestor; and finally, death is an initiation into an afterlife, a rebirth. His insights about death as passage from one classificatory status to another remained central subjects in the anthropology of death through most of the 20th century.

The studies of Malinowski and Radcliffe-Brown, while influenced by Durkheim and Hertz, focused not on the corpse, but instead on the problem of death as a social crisis for society. (See Palgi & Abramovitch, 1984, for a review of the classic studies.) The impact of functionalist theory on anthropological studies of death, especially regarding the social implications of mortuary rituals, was felt well into the 1970s and 1980s. The period from the 1960s to the 1980s saw a profusion of ethnographic accounts of rituals surrounding death, in both their symbolic and structural aspects (e.g., Block & Parry, 1982; Danforth, 1982; Douglass, 1969; Goody, 1962; Gorer, 1965; Huntington & Metcalf, 1979; LeVine, 1982; Metcalf, 1982). Rosenblatt, Walsh, and Jackson (1976) surveyed grief and mourning practices in 78 cultural groups to identify universal or near-universal cultural responses to the death of someone close. They compared death customs from around the world—behavior surrounding the bereaved, taboos, ritual practice, and the role of anger and aggression, for example—with customs in the United States.

CRITIQUE AND INNOVATION

While Hertz noted that death rituals tapped deep emotions, his study and those that followed emphasized the socially determined nature of emotional responses to death. Indeed, Block and Parry (1982, p. 41) describe emotion only in the service of sociality, stating that mortuary practices anchor the social group, “not just by political power, but by some of the deepest emotions, beliefs and fears of people everywhere.” An exception is the work of LeVine (1982) in psychological anthropology on grief, anger, and fear among the bereaved in Gusii funerals. In their comprehensive cross-cultural review of death studies up to 1984, Palgi and Abramovitch (1984, p. 385) comment: “When reading through the anthropological literature in one large sweep, one is left with the impression of coolness and remoteness. The focus is on the bereaved and on the corpse but never on the dying.” Agreeing with and extending that assessment of observer detachment and an absence of an engagement with powerful emotion, Rosaldo (1989a, 1989b) and Fabian (1974) both develop critiques of the state of the anthropology of death. Rosaldo characterizes ethnographic representations of death by their formality, externality, and generality, while ignoring lived experience, subjectivity, and particularity. Seeking to describe broad cultural patterns, anthropologists “flatten their accounts, distancing themselves from the tears and agony as they seek out the lowest common denominators that make all funerals not different from one another but the same” (Rosaldo, 1989a, p. 173). He calls for a shift from ritual to bereavement as the unit of analysis and a move in ethnographic writing from distanced witnessing of visual spectacle to an engagement with the subjective experience and intense emotion of mourners. Fabian, in a more scathing claim, asserts that the historical representation of death in self-contained rituals, performed for the sake of social solidarity in bounded societies, has had an “intellectually disastrous effect” on anthropology. The discipline has looked only at visible behaviors surrounding death—“parochialization and folklorization”—rather than addressing the supreme social reality of the final dilemma of life. The study of “how others die,” Fabian notes, has placed death at a safe distance from one’s own society and one’s self.

A number of pathbreaking ethnographies emerged from scholars trained in and following the 1960s. While maintaining the tradition of employing ritual as a central

theme, those texts are influenced by the turn to interpretive techniques in ethnographic writing. They move well beyond strategies of generalization to explore the impact of individual deaths on particular communities and to consider the topic of death from the perspectives of poetics and politics, gender, emotion, the body, the self, memory, and modernity. For example, Myerhoff (1978), following Van Gennep and Victor Turner, describes the social drama and performative aspects of death as a life cycle passage ritual in a fading community of elderly Jews in California. Battaglia (1990) in an ethnography of cultural responses to mortality, explores the ways in which personhood is performed and experienced in rituals of commemoration in Sabarl society. Serematakis (1991) uses women’s laments as her point of departure to examine the social uses of pain and methods of emotional communication and resistance in women’s experience in modern Greece. Desjarlais (1992) focuses on sensory practices among the Yolmo Sherpa to develop an esthetics of experience that encompasses ways of understanding and writing about death, illness, and healing.

Moving beyond ritual as the guiding analytic frame, Cohen (1998) uses the themes of senility and old age in India, the United States, and in European social thought to ponder ways in which the decay of the body comes to be enacted and interpreted as decline and as reflection of family and community relations, the culture of the state, and scientific practices. The anticipation and location of death emerge as major preoccupations for elderly immigrants and refugees to the United States in Becker’s (2002) study of transnationality and ethnic identity in late life. Biehl (1999) documents the interplay of science, government, poverty, and subjectivity in his study of AIDS and the experience of dying in Brazil’s “zones of abandonment.” The cemetery is a site of cultural production for Francis, Kellaher, and Neophytou (2004) in their cross-cultural study of memory-making, ethnic identity, and the incorporation of the dead into everyday life.

FROM THRESHOLD TO EVENT, PROCESS, AND EXPERIENCE

In his comprehensive history of death in the Western world, Philippe Aries (1974, p. 28) writes of the Middle Ages, “In death man encountered one of the great laws of the species, and he had no thought of escaping it or glorifying it. He merely accepted it with just the proper

amount of solemnity due one of the important thresholds which each generation always has to cross." For well over a thousand years, death was a public event rather than the private family matter it now has become. Death was visible everywhere in life; it was intermingled with life and not conceived to be in opposition to life. "Thus death was not a personal drama but an ordeal for the community, which was responsible for maintaining the continuity of the race," Aries (1981, p. 603) writes. Death was "tamed" by ceremonies "both Christian and customary" (Aries, 1974, p. 12). The dying person's bedchamber was a place that the community could and did freely enter, where "each man would discover the secret of his individuality" (Aries, 1974, pp. 51–52). That individuality was built not on the psycho-emotional terms we associate it with today, but was instead a relationship between the worldly acts and passions of a lifetime and fate. Dying well, the *artes moriendi* of the 15th century, provided the model, until the 19th century, of how a spiritual passage, a crossing of a critical threshold from life into the unknown, should unfold. Though the deathbed scene was a public drama that encapsulated the fight of good against evil for the soul, it also embodied a private, intimate relationship between the act of crossing that threshold and the dying individual: "the fate of the dying man was decided for the last time, in which his whole life and all his passions and attachments were called into question" (Aries, 1981, p. 108).

For millennia, doctors were rare at the bedside and death was not conceived in a medical idiom. By the end of the 18th century, death began to be understood as located in the body, as resulting from something that happened to the body. Foucault (1975) describes the emergence of anatomic understandings of the body together with clinical understandings of disease in his history of modern medicine's "gaze," its apprehension of relationships among disease symptoms and internal organs. Then death came to be seen not as something that arrives from outside this world, but as a disease or a natural process to be known and attended to by doctors. The dying person became the patient. Medicine made death visible to the doctor who could see everything about disease and the body. In that transformation, the dying person became alienated from knowing, in the spiritual sense of an earlier era, his own death. By the 19th century, the terms in which death was understood had shifted from religion and the invisible, fateful crossing at the deathbed to medicine, a disease process, and

the analyzable body. By the mid-20th century, that understanding came to include as well the "truth" of the dying patient as witness to and creator of his own identity (Armstrong, 1987; Arney & Bergen, 1984) and the fact that the biology of death itself could be negotiated for political purposes. Death became a process that encompassed life. Dying was a form, a style of living and its end-point was open both to varieties of psychological expression and to medical debate.

In their studies of death in the modern American hospital (which followed the unprecedented rise in hospital deaths in the United States), sociologists Glaser, Strauss, and Sudnow were the first to investigate how late 20th century *dying* is organized and understood through structural features of the hospital, especially medical and nursing staff interactions with patients and families. Who can speak about death and to whom, the ways in which emotions are revealed or concealed, and expectations about the timing and certainty of death all were shown to be socially elaborated, bureaucratically determined. Glaser and Strauss (1965, 1968) found that dying had a "trajectory," a duration and shape, which was conceptually useful in knowing how the passage from life to death was constituted. The work of psychiatrist Kubler-Ross (1969), published in the same period as the sociological studies, articulated and mapped the patient's voice through the dying transition so that it could be conceptually isolated as a process that lends itself to, and in fact needs, management by health professionals. A dying person, Kubler-Ross informed us, is a self-aware being with expressive needs. *Dying* came into its late-modern form as an *experience* that could be evaluated and inflected with value by the dying person and by others.

The modern hospice movement, generally considered to have started with the founding of St. Christopher's Hospice in Great Britain in 1967, arose during that same period. Fueled by the then widely acknowledged desire for individual control over the dying experience, the psychological staging of dying, and symptom management techniques, the hospice became a means of combining modern medical knowledge and practice with an imagined tradition of family and community that was thought to be an alternative to the growing bureaucratization and use of technology found in the hospital. Although less than 20% of persons in the United States and Great Britain die in hospice programs, hospice has become the symbol of the Western idea of "a good death," that is, a patient and family-centered process in which spiritual,

emotional, and psychological labor are the focus of attention and in which symptom control is in the service of personal growth and awareness at the very end of life. Hospice has become a site of “healthy dying,” moral order, and ultimate individualism (Seale, 1998; Walter, 1994). Yet the elderly, for whom biological death often follows social death, and for whom dying is frequently without reflexivity, lie outside the “good death” cultural ideal.

DEATH AS A PROBLEM OF LIFE AND BIOPOLITICS

The historical shift in conceptions of dying—from something powerful, metaphysical, and inevitable, to an event to stave off, an act over which one must assert control, a process one can observe, a clinical dilemma, and a technical decision—occurred gradually from the 1960s with the confluence of a number of changes in the medical and social landscape. In 1968 a Harvard Medical School committee, responding to the medical demand for a way to preserve organs for transplantation, created a new definition of death, *brain death*, in which they determined that a person crosses the threshold from life to death when there is irreversible and permanent cessation of function of the entire brain. With this new definition the artificial respirator or ventilator, which was coming into widespread use in intensive care units in industrialized countries, could keep the heart pumping and the lungs breathing so that organs would continue to receive oxygenated blood and would not “die.” The Harvard committee decision was followed by the creation of The Uniform Determination of Death Act, passed by the U.S. Congress in 1981 (and was followed by similar legislation in European countries), which outlined the clinical criteria that determine brain death. The formal, new definition of brain death moved, blurred, and troubled the traditional boundary between life and death, a boundary which had never before been publicly questioned or clinically debated. The absence of breath and heartbeat, historically the defining features of death which anyone could note, were no longer the only, or the most comprehensive, or the correct criteria. Lock (2002) described the differential reaction to the concept of brain death in Japan and North America, illustrating how the redefinition of death was perceived as an affront to the natural and the traditional in Japan. As a result, organ transplants

were not allowed there until the year 2000, following considerable public debate.

A moral uneasiness began to appear in American and European studies of healthcare professionals who worked with organ donors. Physicians and nurses questioned whether potential donors on respirators were really dead. They sometimes noted that donors died twice—first from trauma or disease and then again when respirators were removed. The existence of dead persons kept in life-like conditions of ongoing respiration suggested that there was more than one kind of death or that brain death was not actual, final death. Rather than specifying and clarifying the moment and conditions of death, the notion of brain death made death more indeterminate and troubling because it became an epiphenomenon of transplant technology or an event that could be decided through political deliberation (Agamben, 1998). Sharp (1995) describes health professional unease over definitions of death and how mixed messages about rights to body parts that “live on” impact the sense of self of organ recipients. In interviews with transplant and intensive care specialists and physicians who treat long-term comatose patients in North America, Britain, and Japan, Lock (2000) describes the extent of the “brain death problem” that now extends to debates about the nature of consciousness, the degree to which brain dead persons can be distinguished from corpses, and the moral ambiguity of bodies that are neither persons nor cadavers. The global traffic in organ sales (mostly kidneys) from poor live donors to more affluent buyers, studied by Cohen (1999) and Scheper-Hughes (2000), extends the anthropology of transplantation from medico-legal definitions of death and the person to the political economy of exploitation, the relationship of bodily risk and harm to survival, and the question of what constitutes ethical medical practice (Finkel, 2001).

The use of the positive pressure mechanical respirator, invented as a means for maintaining respiratory function during heart and lung surgery, quickly spread in the United States to non-surgical and non-transplant patients, including the elderly, the comatose, and the dying. On those persons life-extending technologies collided with medicine’s unclear sense of its role in death. Biomedical ethics, by then a well-established professional domain as well as an intellectual field, scrutinized this place of uncertainty in its attempt to find solutions both to the uses of technologies that prolong dying or keep the “dead” alive and to the ambiguous obligations of contemporary

clinical medicine. Timmermans' (1999, p. 53) ethnographic study of the history, politics, routinization, and rationalization of resuscitation in Western Europe and the United States shows that while resuscitation rarely saves lives, it frames death as a socio-medical failure, a roadblock "to be cleared by modern medicine." The disjunction between the societal quest for "death with dignity"—that is, a death without medical intervention to prolong dying—and the regular use of life-extending/death-prolonging technologies in the acute-care hospital and emergency room setting became a central preoccupation of American, and to a lesser extent Western European, medicine by the mid-1980s (Kaufman, 1998; Muller & Koenig, 1988).

The making of post-modern or late modern subjects, described in ethnographies of reproductive, transplant, and other biomedical technologies, is explored by Kaufman (2000) in regard to persons/bodies who are betwixt and between life and death, culture, and nature. The permanent comatose condition and the institutions and practices that enable that form of life to exist are extreme manifestations of the life extension enterprise and they create further cultural remappings of the notions of life, person, and death. Shifting understandings of "natural death," "life prolongation," and "suffering," for example, impact and are informed by cultural quandaries (especially American) about approaching, negotiating, and accepting death, the value of any form of life, and what social practices constitute dignity.

A number of recent studies focus on relationships among medical care, death, the enactment of dignity, and notions of suffering in cross-cultural comparison (see, e.g., Kleinman, Das, & Lock, 1997). Farmer and Kleinman (1989) compare the stories of two persons dying from AIDS, one at a Harvard teaching hospital and the other in a poor, rural community in Haiti, to highlight ways in which the powers of biomedicine are limited to diagnosis and treatment and ignore the suffering of the dying. Gordon and Paci (1997), in a juxtaposition of the "autonomy-control" narrative of North America with the "social embeddedness" narrative of Tuscany, Italy, show how cultural assumptions underlying visions of "the good" guide medical practices surrounding the disclosure or concealment of life-threatening illness. Informed consent, self-determination, and autonomy, guiding principles of biomedical ethics that are of primary importance in the delivery of American medicine and that are now circulating the globe and gaining ascendance, seem harsh, irresponsible, and naive from the

framework of the Italian narrative in which protection, tranquility, family, and relationships assume the greatest importance in the face of death. The rise, limits, and irrelevance of bioethics as a cultural paradigm for structuring problems and solutions to the end of life, the interpretation of death, and the organization and gaze of clinical medicine in general are described by Bosk (1999), Fox (1991), Kleinman (1999), and others.

THE SOCIAL INEQUALITY OF DISEASE DISTRIBUTION

Seeking to move beyond the analysis of individual risk-taking behaviors and psychosocial variables in the study of epidemics, critical medical anthropologists (beginning in the 1980s) have called attention to the ways in which political economy, class, and gender create unequal vulnerabilities and responses to disease and death. Poverty, racism, and oppression are shown to shape the contours of morbidity and death statistics through the unbalanced distribution of medical services and political and economic barriers to prevention and care. In those studies, disease control programs are critically appraised. Linkages are made between global capitalism and individual affliction and between individual human agency and the structural factors that constrain it (e.g., Farmer, 1992, 2001; Farmer, Connors, & Simmons, 1996; Kim, Millen, Irwin, & Gershman, 2000; Singer, 1998). This body of work extends the social medicine tradition of Rudolf Virchow into ethnographic practice:

Medical statistics will be our standard of measurement: we will weigh life for life and see where the dead lie thicker, among the workers or among the privileged. (Virchow, 1848, quoted in Farmer, 2001)

The social roots of mass death from disease and the conditions that place individuals at risk in the first place are structural. Power relations, an important source of disease affliction, are slow to be acknowledged in public health discourse and action.

SPACES OF VIOLENT DEATH: NORMAL, PATHOLOGICAL, EXCEPTIONAL

The legal sanctioning of violence in state politics and the merging of violence and the law (Agamben, 1998) has

become, according to the surge in publications beginning in the 1990s, a growing focus for anthropological work. Prior to this trend, Taussig (1984, 1987) described the ways in which “terror and torture became the form of life... an organized culture with its systematized rules, imagery, procedures and meanings...” (Taussig, 1984, p. 495), in his ethnography of the colonial “heart of darkness” of Colombia. More recently, Desjarlais and Kleinman (1994) note the worldwide rise both in conflicts between and within states and in civilian casualties resulting from nationalist struggles, ethnic rivalries, and political insurgencies. Nagengast (1994, p. 110) reports that since the end of the Cold War and the fall of the Berlin Wall in 1989, more than 50 ethnic conflicts are in progress, “a veritable explosion of violence with the state lending the force of arms to one side or the other.” Robben and Nordstrom (1995, p. 2) state, “if we expand our definition of [war] to include the pressing conflicts in many people’s lives—riots, gang warfare, tribal genocide, and forms of terror warfare such as rape and torture—then we find that the number of people directly affected by violence extends into the hundreds of millions.” Death and destruction—of lives, homelands, families, identities, traditions, in short, “the death of a way-of-being-in-the-world” (Daniel, 1996, p. 68)—are the fundamental reality in examinations of war, ethnic strife, and their aftermath. They are the ground on which ethnographers stand to write about the lived experience of those who witness, suffer from, and perpetrate violence and massive death and the kind of culture(s) that an unrelenting exposure to violent death creates. Victims and victimizers are not always dichotomous; relations of power and lines of authority are not always clear (Robben & Nordstrom, 1995, p. 8).

A major theme connecting the various anthropological investigations of violence and its ramifications throughout the world is its insidiousness, its enactment in everyday life, and its effects on the routine tasks of living as well as on the personal and cultural meanings imputed to the past and the future. Political, structural, symbolic, and everyday violence are the concepts employed most in critical analyses of the devastating consequences of extreme conflict, mass death, and interpersonal aggression in order to identify particular ways in which the political-economic organization of social inequality is linked to and implicated in individual lives—both in internalized legitimations of hierarchy and in the contexts of family and community disruption and distress (Bourgeois, 2001).

The ways in which violence, war, and acts of terror become embodied are of special interest to medical anthropologists (Green, 1998), who have explored the ramifications of massacres, genocides, and oppression along with their associated displacements and deprivations on memory, illness, and the body, as well as the relationship of forms of embodiment to cultural production. In a detailed analysis of a child’s wish to die so others might live, Quesada (1998) provides a moving portrait of how a decade of war in Nicaragua is inscribed in the body and life of a 10 year old boy. Quesada (1998, pp. 62–64) writes that his is “a body charged with social and family responsibility... colonized through filial piety and loyalty... to the struggle not to succumb to the extreme social, economic, and physical duress” created by the impact of political upheavals on his very physicality and his rational assessment of what would be best for himself and his family. Quesada’s description of one child’s desire for death gives voice to the effects of fear, combat, continuous food shortages, inadequate housing, and “the space of death” (Taussig, 1984) on young victims and survivors of revolution and powerful political forces beyond their control.

Everyday violence, in the form of commonplace, expected infant death and maternal practices of passive infanticide and indifference are the subjects of Scheper-Hughes’ (1992) work in the shantytowns of Northeastern Brazil, where approximately a quarter of the babies born die in infancy. Scheper-Hughes traces the ultimate sources of the extreme deprivation there to political and economic neglect perpetrated by the post-colonial state, including the police, death squads, and the medical establishment. The institutionalized and normalized practices women employ in that context of scarcity include: the withdrawal of food from babies thought to be too weak to live so that they might die more quickly; and the withholding of emotional attachment from apathetic infants so that their mothers will not mourn their loss.

The dead body is a site for delineating relationships between the person and the state and for representations of social fact. In his study of the 1995 Chicago heat wave, Klinenberg (1999, 2002) discovered how the science of the medical autopsy became the lens through which deaths “caused by natural disaster” were viewed. Journalists focused on the aftermath of the problem—the carnivalesque quality of refrigerating and storing corpses in the city center—rather than on its source—the deplorable housing conditions that endanger frail, poor,

isolated elderly, the majority of the victims. The quantity of the dead was important in the public narrative, as was the need for health, esthetics, and order in processing the dead. But the bodies remained nameless, unconnected to specific families and neighborhoods. The politics surrounding the identification and counting of the dead is taken up as well by Scheper-Hughes (1996) in her comparison of how street children in Brazil and “Black” township youth in South Africa come to be known as “dangerous” while they are alive, and how their dead bodies are de-personalized and devalued in social representation.

CONCLUSION

In the context of medical technologies that simultaneously extend life and prolong dying, the commodification of poor bodies in a global economy of scarcity, debt, and demand, and the proliferation of violent conflict into everyday life, *death and life* enter a zone of indistinction in which biopolitics determines their precise definition (Agamben, 1998). The ways in which law, medicine, the market, concepts of the body, private life, and political existence come together in new cultural formations will continue to be a rich ground for anthropological investigation.

Female Genital Cutting

Social and Cultural Dimensions of the Practice and the Debates¹

Bettina Shell-Duncan and Ylva Hernlund

INTRODUCTION

Having little parallel in its ability to arouse an emotional response, the practice of female genital cutting (FGC) has come under increasingly intense international scrutiny from news media, feminist and human rights

organizations, health practitioners, and legislators. A reclassification has taken place: the local has become a global concern, "female circumcision" has become "female genital mutilation," and a "traditional practice" has become a "human rights violation." Under the gaze of international attention, this issue has come to constitute a

site for a number of emotionally charged debates around cultural relativism, international human rights, racism and Western imperialism, medicalization, sexuality, and patriarchal oppression of women, resulting in an onslaught of discussion and writing on the topic. Yet misunderstanding, confusion, and controversy over the complex dimensions of this issue have not been resolved.

The intervention of outsiders has been sharply criticized by both African and Western scholars. It has been argued that African people affected by this practice ought to be allowed to “argue this one out for themselves” (Scheper-Hughes, 1991, p. 26). Yet, it is important to bear in mind that many people in Africa are already aware that their “traditions” have come under intense scrutiny. The debate over FGC has throughout much of Africa become impossible to escape and is not likely to fade away, but only continue to increase in intensity. Knowing that African “traditions” have fallen under attack, many Africans have a growing awareness that the practice of female “circumcision” will—for better or worse—be talked about worldwide.

Just as the debate over female “circumcision” will not simply go away, the increasing pressures being put on African governments, communities, and individuals to eliminate what has come to be perceived as a “harmful tradition” are not likely to be reversed. In many African countries local initiatives opposing the practice are well established and often inextricably linked with international projects. Such intervention efforts have not, however, been received in unequivocally positive ways. A number of researchers report instances of “backlash” reactions on the ground (e.g., Hernlund, 2000, p. 243; Johnson, 2000, p. 231; Leigh, 1997), as communities respond to anti-FGM campaigns with an increase in genital cutting. In the literature, as well, opinions diverge. Fuambai Ahmadu, Sierra Leonean/American anthropologist and herself an initiate into Bundu secret society, argues that although protecting the rights of a “minority of women who oppose the practice is a legitimate and noble cause... mounting an international campaign to coerce 80 million adult African women to give up their tradition is unjustified” (Abusharaf, 1995, p. 45). Others do not object to such campaigns per se, but stress that any action taken to prevent female “circumcision” must originate with the women and communities among whom it is practiced and be grounded in an understanding of the cultural and political contexts in which the practice is situated.

On the levels of both action and discourse, practices of FGC are currently undergoing rapid and dramatic change. This change, we argue, is irreversible. As one of us was once told in an interview about attitudes to the international campaigns against “FGM”: “It is like when you mix water and sand and you get mud. You can never separate them into sand and water again.” On the level of practice there remains a diminishing amount of choice for communities and individuals whose “traditions” have become irrevocably situated in the public arena. On the level of discourse, silence on the topic seems no longer to be an option and the choice that remains is between informed and non-informed discussion.

THE TRIVIALIZATION OF CULTURE²

Discussions of the cultural context of FGC, in both the academic and activist literatures, as well as in popular media, often describe the practice as an “entrenched” and “deeply-rooted” tradition, practiced for thousands of years in parts of Africa. Much of the existing literature conveniently overlooks the dynamic cultural, political, and historical contexts of the various types of genital cutting performed by different actors in widely varying contexts. As Leonard (2000, p. 161) notes, these narratives contribute to the idea that FGC is “a relatively fixed and static practice firmly anchored in social institutions and relationships both difficult and slow to change.” Empirical evidence, however, does not support assumptions about the immutability of FGC practices. Scattered reports indicate that in some areas in which female “circumcision” was formerly universally practiced, it is gradually falling from favor (e.g., Caldwell, Orbuloye, & Caldwell, 1997). In other groups, where FGC has not historically been practiced or had been abandoned, it is being introduced or revived. Some of these cases involve the constantly evolving borrowing and influence from one ethnic group to another (see, e.g., Hernlund, 2000; Leonard, 2000; Lightfoot-Klein, 1989), others the resurgence of previously discarded traditions (see, for e.g., Nypan’s, 1991, article discussing “neo-traditionalism” among the Meru of Tanzania).

In societies that do, indeed, have a long-standing tradition of practicing FGC, descriptions of a “deep-seated” practice imply that the meanings and nature of the custom are locked in place by convention. Some scholars, however, maintain that the conditions that led to the

initial adoption of female “circumcision” are not static, nor are they required for understanding the perpetuation of the practice. For instance, Janice Boddy has argued that knowledge of this “custom’s remote historical origins [does not]... contribute to our understanding of its present significance” (Boddy, 1982, p. 685). Gruenbaum (2000, pp. 50–51) adds that “views of outsiders fail to recognize the dynamic nature of cultural patterns, imagining ‘the other’ perhaps as frozen in time ... and as ‘prisoners of ritual’ ” (Lightfoot-Klein, 1989). An increasing body of work by anthropologists highlights the fact that female “circumcision” is a response to complex social concerns; yet social conditions are dynamic, and so is the nature and meaning of the practice.³ “Culture is always dynamic,” argues Gruenbaum, “and that is even more the case when the issue at hand is the subject of international controversy, health education, and political discord” (Gruenbaum, 2000, p. 51).

Nonetheless, in the voluminous literature on female “circumcision” there can be found a recurring narrative surrounding meaning, often appearing as a generalized list of “reasons for the practice.” Gosselin argues that the repeated recitation of this list contributes to the “trivialization of culture in the political literature” (Gosselin, 2000, p. 48). While we do not wish to recreate here such a “laundry list” of rationales, we hope instead to highlight a wide range of local discourses and assumptions surrounding practices of FGC that, as James notes, “must be revisited and revised within the specifics of cultural context” (James, 1998, p. 1043). With Ahmadu, we caution that although each of the “explanations” for practicing FGC are discussed distinctly, they are in fact “interconnected and mutually reinforcing and, taken together, form overwhelming unconscious and conscious motivations” for its continuation (Ahmadu, 2000, p. 295).

A wide continuum of approaches to the question of “meaning” can be found. At one extreme, Mackie (2000) argues that all FGC ultimately stems from a concern with pre-marital female chastity, paternity assurance, and marriageability, although this association may no longer be explicit in all practicing societies. On the other extreme, Leonard found among the Sara of Chad—who have only recently adopted the practice, much in the manner of a “fad”—that their “narratives force us to ask not what it means, but, rather, whether it means anything at all.” After repeated probing about the “meaning” of female “circumcision” among Sara today, Leonard was finally

told by one impatient informant: “You are looking too hard—there is nothing!” (Leonard, 2000, p. 190).

Between these two poles, of a singular universal meta-theory and the dearth of any meaning at all beyond the desire to be fashionable, lies a multiplicity of reported local understandings of female “circumcision.” The Special Report issued by the UN Sub-Commission for the Prevention of Discrimination and the Protection of Minorities (henceforth Special Report) found that, in a compilation of studies of attitudes to FGC, over 54% of respondents stated that “tradition” was their primary reason for performing female “circumcision” (United Nations, 1986, p. 13) and Carr, analyzing Demographic and Health Survey data on FGC, concurs that the vast majority of women state that they favor the continuation of the practice because it is “custom” and “tradition” (Carr, 1997). Hernlund, as well, found in the Gambia that respect for what was “found from the grandmothers” was the most strongly and commonly stated reason for performing FGC (Hernlund, 2000, p. 237; see also Skramstad, 1990). Mackie discusses this sort of response which “perplexes outsiders who suspect that the appeal to custom is merely obscurantist” but goes on to argue that “the respondents are absolutely correct: FGC is a certain type of convention, involving reciprocal expectations about an interdependent choice, and that is exactly why it continues” (Mackie, 2000, p. 265). Leonard’s comparison of two communities at different stages of adoption of FGC, demonstrates how quickly such significance can accrue (p. 190).

A number of observers have commented on the often powerful nature of peer convention in perpetuating FGC, as girls and young women pressure each other to “join” in the practice (see, e.g., Ahmadu, 2000; Hernlund, 2000; Leonard, 2000). A particularly powerful account provided by Thomas (2000), describes the “*Ngaitana*” movement during which Kenyan girls defied a 1956 ban on excision, and took it upon themselves to circumcize themselves and each other. Such conventions, Mackie argues further, often come to be seen, as well, as ethnic markers, but this is, he argues, “a consequence, not a cause, of the practice” (Mackie, 2000, p. 266). As pointed out by Hernlund, however, these often become over time mutually reinforcing (Hernlund, 2000, p. 239). This is demonstrated, for example, in Johnson’s discussion of Guinea-Bissau where the practice of female “circumcision” has come to be perceived as intrinsically linked to the construction of Mandingka identity (Johnson, 2000).

According to Mackie (1996, 2000) the main force perpetuating the custom is the link between genital cutting and marriageability (but for a critique of the marriageability perspective, see Obiora, 1997, p. 318). He argues that even if the originating conditions change, “as soon as women believed that men would not marry an unmutated woman, and men believed that an unmutated woman would not be a faithful partner in marriage, the convention was locked in place” (Mackie, 2000, p. 264). While many scholars describe an association between FGC and marriageability, others emphasize that the significance of “circumcision” extends well beyond conferring marriageability, but also to the legitimization of reproduction, as is the case in the Kono women’s societies described by Ahmadu (2000); see also Shell-Duncan, Obiero, & Muruli, 2000).

Boddy, as well, has noted that in the Sudan the procedure not only renders a girl marriageable, but that undergoing it is “a necessary condition of becoming a woman, of being enabled to use her one great gift, fertility” (Boddy, 1982, p. 683). Boddy argues that infibulation is used to symbolically and physically enclose the womb, thus emphasizing the protection and sacredness of a woman’s reproductive center. Moreover, Boddy articulates what many anthropologists have identified as the distinction between sexuality as procreation versus recreation. Infibulation, Boddy argues, is to many Sudanese women an “assertive, highly meaningful act that emphasizes female fertility by de-emphasizing female sexuality” (Boddy, 1982, p. 682).

A complete polarization of the sexes permeates Sudanese society, Boddy has argued, and genital cutting reinforces this polarity by making women *less* like men—physically, sexually, and socially. Women are not so much preventing their own sexual pleasure, she argues, as “enhancing their femininity” (Boddy, 1982, p. 687). Boddy’s analysis mirrors the work of anthropologists Nancy Lutkehaus and Marilyn Strathern who, although they do not write specifically about female “circumcision,” have done extensive research on female initiations in New Guinea. Lutkehaus, with Strathern, argues that these rites are concerned with promoting the transition of boys and girls from an androgynous state of childhood to the genderized, and hence sexually differentiated, state of masculine or feminine adulthood (Lutkehaus & Roscoe, 1995, p. 196). Support for this theory has been drawn, as well, from widespread ethnographic reports of male and female “circumcision” (see, for example, Griaule, 1965;

Hansen, 1972–73; Meinardus, 1967).⁴ Similarly, Ahmadu maintains that Kono women of Sierra Leone “equate the female clitoris with the male penis, and hence, promiscuity, sexual aggressiveness, instability ... Removing the clitoris is ultimately what symbolizes the separation of women from men physically, psychologically, and spiritually” (Ahmadu, 1995, p. 44). Moreover, she argues that excision is “the negation of the masculine in feminine creative potential” (Ahmadu, 2000, p. 285).

The broad range of responses to the alteration of female genitalia reflects the widely differing views of meanings associated with women’s bodies and women’s sexuality. While the procedure of genital cutting is seen by many as essential to the creation of femininity and full adult status, others view it as the obliteration of these very principles. For many Western feminists, the clitoris has become a powerful symbol of women’s emancipation. In the wake of Shere Hite’s influential *Hite Report* (Hite, 1976) and the fight for the right to clitoral orgasms and sexual satisfaction, “female genital mutilation” became for many Western feminists the symbol *par excellence* of patriarchal control over women and their sexuality (Gosselin, 2000; Obiora, 1997). Through rhetoric such as Mary Daly’s essay “African Genital Mutilation: The Unspeakable Atrocities” (Daly, 1978), FGC was cast as a violent cruel act of patriarchal oppression. It is an undeniable fact, however, that in many cultures the practice is carried out by and remains firmly within the control of other women, and is often integral to and evidence of the power relations amongst women. Fuambai Ahmadu (2000), who herself underwent excision in the context of her initiation into a secret women’s society in Sierra Leone, argues that female initiation, including genital cutting, is an event which can be highly empowering to women and is in many contexts wholly unrelated to Western feminist ideas about patriarchal oppression (see also Hernlund, 2000, who reports a similar assertion regarding initiation in the Gambia). Ahmadu argues against the standard anthropological view of “ritual officials as colluding with patriarchy in order to maintain the subordination of women in society,” and asserts that “what Bundu teaches first and foremost is the subordination of young girls and women to female elders” (Ahmadu, 2000, p. 299). Similarly, Thomas (2000) points to the importance of initiation events in bolstering the power of elder women over those from younger age groups (see also Lutkehaus & Roscoe, 1995).

A Western feminist approach has been sharply criticized by some African feminists who argue that by letting sexuality become “assumed as an a priori issue around which ‘all women’ should organize... the specificity of women’s experience is conveniently overlooked” (Abusharaf, 1996, pp. 5–6). According to Abusharaf, “some Western feminist representational discourses on female ‘circumcision’ as a signifier for sexual oppression have come under considerable critical reflection for their ethnocentrism and reductionism” (Abusharaf, 2000, p. 160). She cautions that “by overemphasizing the effects of female ‘circumcision’ on sexual pleasure” much of the Western anti-circumcision literature has distanced itself from the socioeconomic contexts of broader violations of women’s rights (p. 161).

Other anthropologists have pointed, as well, to the way in which ideas on female sexual pleasure are culturally constructed and historically situated. Hansen, in 1972, wrote: “The most accepted view today is that sensitivity is concentrated in the clitoris. This contrasts with the older view, maintained by Freud and his pupils, that the erogenous zone is confined to the clitoris in the child and the young girl, while sensitivity in the adult woman is and should be vaginal” (Hansen, 1972–73, p. 22). Leonard (2000) offers an extensive analysis of such psychoanalytic theories regarding the effect of FGC on female sexuality. Interestingly, a similar view on the immaturity of clitoral and maturity of vaginal orgasms appears, as well, in Ahmadu’s (2000) discussion of Kono women’s thoughts on excision.

Several scholars (e.g., Abusharaf, 2000; Ahmadu, 2000; Gosselin, 2000; Leonard, 2000; Obermeyer, 1999; Skramstad, 1990) discuss the Western preoccupation with the clitoris as the primary site of female sexual pleasure, which has become incorporated into much of the “anti-FGM” literature. Inevitably, Western feminist discourses on sexuality are becoming incorporated into local anti-FGC campaigns throughout Africa, thus giving rise to new debates. Researchers often find, however, that perceptions vary widely, with supporters and opponents of the practice claiming alternately that FGC has no effect on sexuality; that it decreases or even annihilates a woman’s ability to feel pleasure; or that it in fact causes more uncontrolled sexual behavior (see, e.g., Johnson, 2000). One anthropologist points, as well, to the contents of sexual education often accompanying “circumcision,” arguing that “if any linkage exists between control of female sexuality and female ‘circumcision’ this linkage seems

to be stronger within the transmission of knowledge about proper gendered behavior rather than through the removal of the clitoris” (Skramstad, 1990, p. 18).

Just as female genital cutting cannot, then, be linked in any simplistic, causal way to female sexual desire or pleasure, a similar ambivalence characterizes its perceived association with religious practice. Female “circumcision” is in particular often seen as somehow associated with Islam. This is perhaps not surprising, considering Islam’s compulsory circumcision of males and the frequency with which FGC is practiced among Muslim groups. It is important to note, however, that the Qur’an does not require female “circumcision,” that not all Islamic groups practice FGC, and that many non-Islamic ones do (see also Abusharaf, 2000; Assaad, 1980). Attention, however, has been drawn to the wide range of variation in the extent to which the practice of FGC corresponds with adherence to Islam. At one end of the continuum, Shell-Duncan et al. (2000), Leonard (2000), and Thomas (2000), among others, describe the practice of FGC among non-Islamic groups. At the other extreme, Johnson (2000) points to the near complete correspondence between female “circumcision” and Islamic identity formation among Mandingkas in Guinea-Bissau, where the practice has come to be seen as a prerequisite for the ritual purity necessary to pray as well as a marker of belonging to an Islamic community.

In between these two extremes lie many specific contexts in which Islam is to various degrees invoked as associated with the continuance of the practice. It has been suggested that “religion” is often offered, “almost reflexively,” as a reason for performing FGC (see Gordon, 1991, p. 9). In response, Boddy argues that “the question of what is meant by ‘religion’ remains obscure” and she points out that for many women “religion is nothing less than their entire way of life; religion and tradition are not merely intertwined, they are one and the same” (Boddy, 1991, p. 15; see also Coleman, 1998). A great deal of effort by scholars and activists has been concentrated on demonstrating the lack of scriptural support for enforcing FGC (see in particular Abu-Sahlieh, 1994). It must, however, be emphasized that the “absence of clear textual dictates... does not automatically undermine the religious motivation” (Lewis, 1995, p. 22) of those who practice FGC.

Clearly, meanings and importance associated with FGC vary not only across time and cultural contexts, but also within societies whose members have diverse

motives for preserving the practice. Writing on rural Sudan, Gruenbaum (2000, p. 49) “found the interests in preservation or change in the practices vary starkly depending on gender, age, education, status, ethnicity and religious background.”

STRATEGIES TOWARD THE ELIMINATION OF FGC: DOES MEANING MATTER?

Identifying the most effective and appropriate strategies for eliminating FGC is among the most bitterly contested issues surrounding this practice, and the choice of approach determines the importance of understanding the cultural construction of “meaning.” Two established paradigms for combating FGC are the *moral* model and the *disease* model. In the moral model, FGC is condemned and often criminalized, while motives and meanings of the practice are deemed irrelevant. This approach can be traced back to the early 20th century when, as discussed by Thomas (Thomas, 1996, 2000), missionaries and early colonial administrators identified FGC as a moral shortfall, framing the practice as uncivilized, barbaric, and unacceptable in the eyes of Christianity. Such campaigns have reappeared several times throughout the last century, each time with a slightly different focus. In a series of conferences honoring the United Nations Decade for Women (1975–1985), the practice increasingly became attacked as a violation of women’s rights. A decade later, at the United Nations Fourth World Conference on Women, “FGM” was classified as a form of violence against women along with battering, rape, sexual abuse, and prostitution.

Adopting a universalist stance, some activists argued that “FGM” should be subject to condemnation, and, in certain instances, punishment through legislative force. Legal scholar Bashir, for example, argues that criminalization will assist in deterring the practice by “fostering an environment . . . that is clearly intolerant to FGM” (Bashir, 1996, p. 13). This view is receiving increasing support from Western nations, whose influence through economic means is perceived to threaten countries that do not outlaw or formally denounce all forms of genital cutting. There have been rumors, both on the ground in Africa and in U.S. media, of U.S. legislation tying international aid conditionally to a nation’s steps to criminalize and combat “FGM,” much as with conditions tied to, for example, drug trafficking, terrorism, or forced abortions.⁵ Although

a 1996 Treasury Department Bill requires the United States to oppose loans to countries that have not “taken steps to implement educational programs designed to prevent the practice” of FGM, this bill has, as far as we know, never resulted in denial of funds to any African country. Nonetheless, it clearly shows evidence of the U.S. government’s opposition to FGC in an economic context and clarifies the rationale of countries that pass legislation to “please American sensitivities” (*The Economist*, February 13, 1999).

Formal legislation has proven, however, to be a poor instrument of cultural change. The few attempts to outlaw clitoridectomy or infibulation in Africa have been largely unenforceable (Thomas, 1996). For example, the 1946 law criminalizing infibulation in the Sudan caused public uprisings, and following its enactment the prevalence has actually increased (Gruenbaum, 1982; van der Kwaak, 1992). Moreover, such efforts have triggered unexpected incidents of backlash, both in anticipation of and in response to legislation. When the British in 1945 made it known that infibulation would soon become illegal in the Sudan, “parents rushed to have their daughters infibulated, resulting in what one British observer reported as an unprecedented orgy of bloodletting” (Boddy, 1991, p. 16). Similarly, communities in varied locales that have been targeted by anti-circumcision campaigns following film and media exposure have feared the enactment of legislation, and have responded by performing excisions on all uncut females, including newborn infants (Eliah, 1996; Herlund, 2000; Johnson, 2000). Mackie (2000) emphasizes the limited utility of legislative action: “You simply can’t outlaw cultural practices . . . It is not possible to criminalize the entirety of a population, or the entirety of a discrete and insular minority of the population, without methods of mass terror. People have to decide to stop on their own” (*The Economist*, February 13, 1999).

Problematic, as well, is defining the legal stance for opposing and criminalizing FGC. The practice of female “circumcision” is not universally recognized as a violation of basic human rights (see, e.g., Brennan, 1989). Hence, debate has centered on the challenge of balancing cultural values and autonomy against international standards of human rights. As outlined in an article by U.S. legal scholar Kay Boulware-Miller (1985), the human rights approach can be broken down into claims based on: (1) the rights of the child; (2) the rights of women; (3) freedom from torture; and (4) the right to health and bodily integrity. As Boulware-Miller and

others point out, however, each of these approaches carries with it potential problems.

A number of scholars and activists have come to the conclusion that the most reasonable angle from which to argue for the elimination of genital cutting is that of health. Boulware-Miller concludes that the right-to-health argument “integrates the issues of physical, mental, and sexual health as well as child development,” and that it may be seen as less exclusive and more politically acceptable than any other approach (Boulware-Miller, 1985, p. 177). This is the same conclusion that was reached by the UN Working Group on Traditional Practices in 1986 (United Nations, 1986). The UN Working Group did not, in the end, conclude that the practice of FGC constitutes a human rights violation. Instead, the sub-commission chose to frame the issue in terms of weighing the health consequences of the practice against its “cultural functions” (United Nations, 1986). This conclusion is, in essence, the replacement of a universalist stance with a cultural relativist position, and consequently, meaning does indeed matter.

Arguing that FGC has become “obsolete” due to changing economic and social conditions, the Special Report concluded that the health risks can be deemed unwarranted (United Nations, 1986). Two issues are problematic with this conclusion. First, numerous cases exist in which the practice is not “obsolete” for the persons involved. Second, as Obermeyer (1999) and Shell-Duncan (2001) have pointed out, reliable information on the health risks of different types of FGC is limited, making it difficult to weigh health consequences against “cultural function.” The *a priori* assumption of cultural irrelevance of FGC means, however, that no true weighing need ever occur. Nonetheless, trade-offs involved in choosing to cut—or not cut—are central in individual and family decision-making processes.

It has long been assumed that as people are made aware of the potential health risks they will abandon the practice. Anthropologist Carolyn Sargent, however, points out that health hazards are often recognized by women themselves and that basing a public health program on informing women about the risks of FGC would not alter their perceptions of its relevance (Sargent, 1989, 1995; see also Obiora, 1997, p. 359). Toubia asserts that the cultural pressures on a girl to be circumcized in order to obtain the status of an adult—and thus marriageable—woman leads to a situation in which the “loss of a woman’s genitalia is not too high a price to pay”

(Toubia, 1988, p. 102). Shell-Duncan et al., writing on the Rendille of Kenya, concur: “Awareness of the fact that female circumcision is associated with adverse health consequences is widespread, yet the Rendille view the risks as worth taking in light of the implications for marriageability” (Shell-Duncan et al., 2000, p. 126).

Nonetheless, a medical argument has come to form the cornerstone of opposition in many anti-circumcision campaigns, framing the issue through a disease model. In the 1970s and early 1980s, when anti-circumcision activists identified female genital cutting as “female genital mutilation,” the practice was described as an “epidemic,” and was singled out to be “treated as a public health problem and an impediment to development that can be prevented” (Hosken, 1978, p. 155). Consequently, in a disease model, the practice was targeted to be “eradicated much like any disease” (Hosken, 1978, p. 155).

In the early 1980s, anthropologist Ellen Gruenbaum warned that the adoption of the medical view “implies not only that the practice is ‘pathological,’ but that its solution might lie in a sort of campaign-style attack on the problem. Social customs, however, are not ‘pathologies’; and such a view is a poor starting point for change, since it is not one necessarily shared by the people whose customs are under attack” (Gruenbaum, 1982, p. 6). Nahid Toubia has argued, as well, that female “circumcision” is not a medical problem, but “essentially a social phenomenon reflecting the position of women” (Toubia, 1988, p. 102). Toubia adds that “to argue against this practice on the grounds of physical damage and to attempt to eradicate it through health awareness and education are futile” (Toubia, 1988, p. 102).

Simple education campaigns designed to improve knowledge of the potential adverse health outcomes of genital cutting can, in fact, be problematic. When communities practicing clitoridectomy and excision become targeted by anti-FGM campaigns, medical “facts” derived from reports on infibulation are often not supported by the experience of community members, and the incongruity between propaganda and lived experience has the potential to undermine the credibility of campaigns. Shell-Duncan’s (2001) review of the literature on the medical aspects of FGC points to the limited quality of empirical evidence of serious harm from non-infibulating types of genital cutting, and concurs with Obermeyer’s (1999, p. 92) conclusion that “evidence on complications is very scarce.” We are concerned, however, that a recent trend in writing goes to unwarranted extremes in trivializing the

potential health effects of FGC, interpreting the lack of data as evidence of no harm (Shweder, 2000).

Despite these challenges, a number of innovative educational campaigns have been met with some degree of success. Mackie (2000) stresses the importance of educational campaigns being non-directive, and describes the process by which Senegalese women involved in the Tostan project themselves came to identify FGC as an issue needing to be addressed. He describes the process by which villagers first look at what they and others are doing now and understand why they are doing it, next receive new, relevant, and often technical information, before finally working as a group to discuss the information and decide whether it is useful. "People are *never told what to do*," he emphasizes (Mackie, 2000, p. 259).

Although many scholars do argue that the right-to-health approach is the most tenable human rights approach for opposing FGC, practical application is faced by contradictions as well. One of the most contested areas of the debate over efforts to eliminate FGC concerns its potential medicalization (Shell-Duncan, 2001). Opposition to all forms of medicalization has been central in efforts to eliminate FGC, a stance supported by the World Health Organization as well as numerous medical associations, and upheld by policy or legislation in many countries. This staunch opposition to medical intervention rests on one central assumption: that medicalization will counteract efforts to eliminate FGC. Shell-Duncan (2001) has argued that this assumption is not based on empirical evidence, and deserves critical examination. This need is underscored by the fact that, regardless of legislation or international opinion, FGC is, and will likely continue to become, increasingly medicalized throughout Africa. Shell-Duncan (2001) has suggested that an alternative to moral and disease models is a *harm reduction* model. "Harm reduction" is a new paradigm in the field of public health that seeks to minimize the health hazards of risky behaviors, such as intravenous drug use, high-risk sexual behaviors, and smoking, by encouraging safer alternatives including, but not limited to, abstinence (Marlatt, 1998). Harm reduction considers a wide range of alternatives and promotes the alternative that is culturally acceptable and bears the least amount of harm. In the case of FGC, abstinence is clearly the most harm-reductive solution. However, when abstinence is not attainable, a harm reduction approach would promote reduced cutting and/or other forms of medicalization as an interim strategy to reduce adverse health outcomes (Shell-Duncan, 2001).

Toubia and Izett (1998, p. 33) argue against medicalization since the cause of harm is "human behavior, which can be changed." What is not emphasized in this statement is the inherent difficulty in changing this human behavior. FGC is often connected with complex and dynamic meanings, and it is well recognized that change efforts must take into account the broader social meanings, and may take decades to take hold (see, e.g., Boddy, 1982; Gruenbaum, 1982).

Mackie (1996, 2000) has argued that marriageability is the key factor promoting the practice of FGC in intramarrying groups, and that the abandonment of the practice rests upon altering this mutually supported convention. He suggests that if a critical mass of people publicly pledges to abandon FGC, then the convention shifts, and uncircumcized girls are not excluded from future marriageability and group support. Consequently, Mackie argues that when FGC ends, it will do so quickly. Recent events in Senegal support this theory. Through a non-directive education program designed and implemented by Tostan, Senegalese women identified FGC as an area of improvement, and resulted in 1998 in 31 villages publicly pledging to end the practice of female "circumcision" (Mackie, 2000). While this event is one of the most promising initiatives for eliminating FGC, it does not indicate that rapid abandonment of FGC is imminent across Africa. The amount of time required to "set the stage" for convention shifts will likely vary considerably in different settings. Consequently, we must consider a crucial question: What is the fate of women in societies not yet willing to abandon the practice of FGC?

Shell-Duncan (2001) has argued that the medicalization of FGC, if guided by harm reduction principles, may have the potential to reduce harm and serve as an engine of change in societies not yet willing to abandon the practice. However, several important questions about harm reduction and the medicalization of FGC remain. First, are communities in which FGC is practiced less likely to abandon the practice if harm reduction policies are implemented? Clearly, the elimination of any form of cutting is the most harm reductive of all. Would the existence and support of medicalization slow the process of changing attitudes of supporters of FGC, or might it act as an engine of change? Second, would implementing medicalization as harm reduction encourage others to adopt the practice? And finally, would pursuing a policy of harm reduction overburden health care systems and spread resources for research, education, and intervention

too thinly? The answers to these questions are, however, empirical, and studies examining these issues are within the scope and capacity of social scientific and public health research. Defining and promoting a range of culturally acceptable means of protecting women's health may, in the end, be a sound and compassionate approach, underscoring, once again, that meaning does, in fact, matter.

IN LIEU OF CONCLUSIONS

The practices of FGC appear to—more than just about any other issue—capture the popular imagination, trigger emotional responses, and reduce the complex to the unnegotiably absolute. Regardless of one's stance on the appropriate level of the West's involvement with the practice of FGC, encounters are becoming increasingly common in which a completely hands-off approach is untenable. On a legal and political level, the recent granting of political asylum to a Togolese woman on the basis of her fear of returning to Africa and being forced to undergo FGC has established a legal precedent which—at least in theory—could apply to millions of women (but see Bashir, 1996, for an argument against the fear of opening “the floodgates” of immigration). In the context of Western biomedicine, the recent influx of immigrants from communities that practice female “circumcision” has forced health practitioners, when confronted with the practice, to come face to face with issues of autonomy and multiculturalism (Schwartz, 1994, p. 431). Ethics committees are facing newly articulated “rights and wrongs” as they seek to adopt policies toward a procedure which has alternatively been described as a barbaric practice, an extreme act of misogyny, and an “affirmation of the value of women in traditional society” (Schwartz, 1994, p. 431).

While many scholars correctly argue that the issue of determining the future of FGC is best resolved by members of the communities in which the practice is found, the undeniable reality is that this has already—irreversibly—become a global political issue. Western governments have reclassified female “circumcision” as a “human rights violation,” and the implied threat of withholding economic assistance to countries where the practice persists must be perceived as coercion for countries already reeling from structural adjustment programs. Morsy has offered a scathing critique of such global “rescue missions” and

warns that “Western compassion can be nothing less than the kiss of death” (Morsy, 1991, p. 22).

Clearly, it is an inescapable reality that the choice whether to continue or to eliminate the practice of FGC is no longer solely in the hands of those who currently engage in this practice. Consequently, any resolution of debated issues and the development of culturally sensitive approaches to eliminating FGC require that we do not focus on this practice in isolation, but rather that we consider the lives and opinions of the people affected by it, and the local and global domain of discourse and domination in which they are embedded.

NOTES

1. A longer version of this paper previously appeared as the introduction to *Female “Circumcision” in Africa: Culture, controversy, and change*, edited by Shell-Duncan and Hernlund (2000).
2. The expression “the trivialization of culture” was coined by Canadian anthropologist Claudie Gosselin (Gosselin, 2000).
3. For instance, Shell-Duncan et al. (2000) report that among Rendille pastoralists in northern Kenya, excision was, in the past, performed at the time of marriage, legitimizing reproduction. Within the past 20 years, it has become increasingly common for girls to attend school, and a rising number of girls have eloped without being excised. A solution to avoid illegitimate childbearing has been to uncouple excision and marriage, circumcizing girls instead before attending secondary school.
4. Accounts in the literature refer to ancient Egyptian beliefs about the bisexuality of the gods, which possibly merged with pre-existing African ideas that identify the feminine “soul” of a man as located in the foreskin and the male “soul” of a woman in the clitoris (Meinardus, 1967). Although such a discussion is beyond the scope of this entry, interesting parallels can also be drawn to the well-documented Western discomfort with gender ambiguity that has resulted in routinely performing surgery on “hermaphroditic” infants.
5. For example, *The Economist* (February 13, 1999, p. 45) reported that the U.S. State Department's Human Rights report “lists those African governments that have banned female circumcision, and is used as a guide to allocating American aid.”

Immunization

Global Programs, Local Acceptance and Resistance

Anita Hardon

INTRODUCTION

Until recently immunization as object of investigation was limited to public health researchers and historians of science and medicine (Basch, 1994; Greenough, 1980). Immunization became a more popular topic for anthropological enquiry in the 1970s, when global immunization programs aimed at “universal coverage” were launched. Anthropologists were invited by global health agencies such as the World Health Organization (WHO) to help identify structural and cultural barriers to achieving increased immunization coverage. More recently there has been attention to broader issues, including the processes through which immunization comes to be institutionalized as a routine practice in public health management, at the global, national, and local levels; and there are wider issues pertaining to popular conceptions of immunity, the role of global institutions,

and notions of citizenship and consent (Das, Das, & Coutinho, 2000).

THE HISTORY OF IMMUNIZATION

The history of modern vaccination goes back to the late 18th century when Jenner developed a smallpox vaccine based on cowpox. Before that time in Asia and Europe, the practice of variolation prevailed. Variolation means deliberately inoculating a susceptible person with smallpox virus, usually with matter taken from pustules of someone who had caught the disease by natural contagion. For reasons not well understood, the inoculee got an attenuated case of smallpox with less severe illness symptoms which was very rarely fatal and conferred immunity from further infections (Greenough, 1980). Native variolators were reported in Bengal from at least 1731. Modern vaccination

was probably the most important reason behind the disappearance of smallpox as an endemic disease in Europe during the course of the 19th century. In developing countries, smallpox remained a leading cause of death.

In the 19th and 20th centuries a wide range of vaccines, based either on live or attenuated bacterial matter, were developed (Basch, 1994). Until the 1960s, however, the use of vaccines was limited mainly to industrializing countries. Globally orchestrated mass immunization programs were set up in the 1970s starting with the Smallpox Eradication Campaign which was implemented under the auspices of the WHO. Building on the success of this campaign the WHO launched the Expanded Program on Immunization (EPI) in 1974. At the time less than 5% of the world's children were immunized against the six target diseases selected for inclusion in the EPI. For each of these six—diphtheria, tetanus, whooping cough, polio, measles, and tuberculosis—vaccines could be procured at very low cost. The six vaccines were already established as safe and effective. Through acceleration of the EPI in the 1980s 80% of the world's children under 13 months of age globally were provided with BCG, OPV3, and measles vaccines by 1990 (Basch, 1994; UNICEF, 1996; WHO, 1992).

STUDYING GLOBAL IMMUNIZATION EFFORTS

The assumption underlying the global immunization efforts was that interventions and knowledge developed globally are applicable in diverse local contexts. The EPI developed blueprints that were to be implemented top-down by national governments. The EPI established standard vaccination schedules and surveillance procedures. It provided training and managerial support to national programs and developed promotional materials. Anthropologists were involved in the EPI by investigating why people in diverse sociocultural settings do not comply with the global immunization regimes (Heggenhougen & Clements, 1987). Very little anthropological enquiry has been done on the immunization policy-making process itself. Anthropologists tend to define policies as context, or macro structures which influence people's lives (Justice, 1987; Shore & Wright, 1997).

Global immunization policies such as smallpox eradication and the EPI are guided by powerful cultural

assumptions and political interests. They make use of catch phrases such as “universal coverage” which have important political functions: ideologically they provide a shared aim behind which different stakeholders can rally, whilst in practice they help mobilize support from various global actors, including UN agencies, donors, private foundations, and industry. They help mobilize collective energies behind collective goals and they help sustain the hope that the aims can be achieved and project an imagery of possible and intrinsically beneficial public health programs. Policies change over time in response to changes in global public health paradigms and resource flows. The EPI, for example, was followed in 1988 by a new initiative which aimed to *eradicate polio by the year 2000*, partly in response to increased resources available for this campaign from Rotary International at a time when a more disease-control-oriented Director General took over the leadership of the WHO (Walt, 1993; WHO, 1997).

In the 1990s there was a growing emphasis on technical approaches to the problems confronting immunization programs (Children's Vaccination Initiative, 1997; Hardon, 2001; Starling, Brugha, Walt, Heaton, & Keith, 2002). Interesting analysis of the trend toward technological innovations has been done by the medical historian Muraskin (1990, 1998). He describes how the Children's Vaccine Initiative (CVI) was created as an attempt to revolutionize the way vaccines were developed for the developing world. It was formed, in part, out of optimism that the scientific advances of the biotechnology revolution could be harnessed to create new and improved vaccines. Initially the CVI aimed to develop a single childhood vaccine that would combine all the necessary antigens. Muraskin looked at the indispensable role played by pivotal individuals (William Foege of the Task Force for Child Survival, Kenneth Warren & Scott Halstead of the Rockefeller Foundation, James Grant & James Sherry of UNICEF, & D. A. Henderson of Johns Hopkins University) without whom the CVI would not have come into existence. While these individuals worked within the confines created by the large social, economic, and political changes that shaped the 1980s, their goals, often targeted at fairly limited objectives, were crucial in determining the final outcome. Muraskin points to the role of individual choice and serendipity in determining major policy decisions and argues that these are underestimated in the social science literature.

VACCINATION PROGRAMS, THEIR CULTURE AND CONTEXT

Global policy-making processes have been studied more by medical historians and health policy scientists than by medical anthropologists. Medical anthropologists have focused on the implementation of immunization programs and the acceptability of vaccines in diverse socio-cultural settings. They have shown how at the local level immunization programs are characterized by a target-oriented approach and emphasis on strict adherence to vaccination rules and procedures that have been developed in an international setting (Banjeri, 1990). Usually, the organizational culture of vaccination programs combines an emphasis on strict adherence to many rules with strong social control through monitoring of the achievement of targets (Nichter, 1990; Onta, Sabroe, & Hansen, 1998; Streefland, 1989). Onta et al. (1998) report that Primary Health Care Service Outlets (PHSOs) and the district health office in Nepal responded to the target-orientation by exaggerating coverage. The PHSOs reported numbers of immunized children to the district health office even in months when no children were entered in the immunization register in the outlets. Similarly, the district health office reported the number of immunized children to the national government even in months when no report had been received from the PHSOs. Nichter (1990) describes how mid-level health personnel and their superiors in South India associated immunization programs with military campaigns. It did not matter what people knew or did not know about vaccines, they said. The effort depends on good logistics, and compliance. As one South Asian planner comments: "The beauty of vaccination programs is that they require little from the community beyond lining up and holding out their arm at the proper time ... it matters little whether a soldier understands how the rifle he uses works as long as he knows how to aim, load and shoot. It is the same with vaccinations" (Nichter, 1990, p.197).

Another anthropological enquiry in India focused on the introduction of a new vaccine, hepatitis B, in the East Delhi Immunization program (Addlakha & Grover, 2000). This program was launched with the WHO in 1996. Addlakha and Grover did ethnographic fieldwork with an aim of (1) understanding the way in which the discourses of public health officials are framed within a meta-discourse of population regulation or biopower, and (2) exploring the lived experiences of actual users

negotiating with health problems in specific local settings. They argue that immunization programs regulate populations through a strategic alliance between the "immunizing state," multinational pharmaceutical companies, and the medical profession. In the case of hepatitis B vaccination, clinicians from different medical specialities, multinational pharmaceutical companies, and international organizations were trying to persuade the entire population of India that it was in the grip of a potentially fatal health crisis (liver cancer due to the hepatitis B virus) for which the vaccine is the only preventative. A sense of urgency was conveyed by comparing the hepatitis B threat to that of HIV/AIDS. The authors question the rationale for the introduction of hepatitis B vaccine given that there were in fact no accurate prevalence figures in India, and that small-scale studies showed moderate levels of endemicity (4–5%). They also revealed a controversy about the selection of vaccine-product. While a local company in India produced hepatitis B vaccine and could provide it to government at low cost, a multinational company was found to be pressuring the government to include its hepatitis B vaccine in the Indian immunization program. Conducting multi-sited ethnography, the researchers examined notions of hepatitis in East Delhi communities. They find that most people were not aware of "hepatitis" as an illness category. Only 17/50 respondents had heard of the term through newspapers or mass-media reports. They could not delineate symptoms or treatment. The public health officials overcame this problem by promoting the vaccine as treatment for *pilia*, a local term for jaundice, literally meaning yellowness in Hindi. Nurses described the vaccine as *pilia ka teeka*, injection for jaundice (*pilia* is treated in the communities with herbal medicines).

Nichter (1990) and Addlakha and Grover (2000) analyzed immunization programs as modes of surveillance and control of populations, which could be defined as biopower (Foucault, 1979). In the area of immunization, bodily states such as *pilia* are defined as being "vaccine-preventable," opening up the way for legitimate intervention by the "immunizing" state. Most anthropological studies on immunization aim not to analyze the role of the "immunizing state" and mechanisms of biopower, but rather focus on ways in which the operations of the immunization programs can be facilitated, and the target populations more effectively and efficiently reached. Such studies focus on health beliefs and structural factors that act as barriers for acceptance of vaccinations.

In a review of social science studies on childhood immunization Heggenuhoun and Clements (1987) recommended that in order to achieve a high level of coverage, the global immunization program blueprint would have to be adjusted to its sociocultural environment. Sustained high levels of vaccination coverage, they argued, are only possible when vaccination services are easily accessible and when parents take their children there at the time indicated by the immunization schedule. Whether the children attend regularly and on time will partly depend on the perceived quality of the services, including whether or not outreach clinics are held on time, mothers are treated with respect, and vaccines are available. Parents' confidence in vaccination technology, their calculation of the chance of harm through side-effects and of health protection through vaccination, and the social control of the community are other determining factors. Seasonal working schedules, nomadic travel patterns, and local ideas about risk are among the sociocultural elements which vaccinators and program managers need to take into consideration when implementing their vaccination program.

OVERCOMING STRUCTURAL BARRIERS

Such applied studies have specifically pointed at the need to consider service-level factors, which matter to people in their day-to-day interactions with immunization programs (Heggenuhoun & Clements, 1987; Salkever, 1976; Streefland, Chowdury, & Ramos-Jiminez, 1999), including:

1. *Convenience of time and space:* Many studies have pointed to the need to provide immunization services at convenient times and places that are easy for the "target" population to reach. In the EPI blueprint, vaccination services were designed to be vertical programs, which from a programmatic point of view are easier to manage and control (Walsh & Warren, 1980). However, from the perspective of users a more multi-pronged approach is more appropriate, offering community-based immunization, schools vaccination programs, and opportunities for vaccination during curative consultations, in addition to the routine vaccinations events (Dietz & Cutts, 1997). Waiting and travel times are also relevant factors. A study in Bangladesh found that poor women could not pay the fares to local static vaccination facilities. In Ethiopia women of unimmunized children complained that they could not carry their children the long distance between their home and the clinics (Streefland et al., 1999). A combination of static services, mobile outreach efforts, and school programs is suggested to be the most
2. *Staff attitudes:* The sociocultural difference between staff and recipient, and the general attitude of staff toward recipients were found to be significant. A multi-country study (Streefland et al., 1999) found that health workers often behave impolitely. In Malawi, for example, health workers were reported to shout at women who arrived late. They worked slowly and stopped at midday even if there was still a long line of women waiting for the services (Chilowa & Munthali, 1999). In the Philippines, health workers reportedly were angry if mothers forgot to bring their vaccination cards (Ramos-Jiminez, Rodrigues, Patino, & Lim, 1999).
3. *Social exclusion processes:* Several studies have pointed to the low immunization rates in marginalized population groups. A study in Britain found that severely handicapped or disadvantaged groups were less frequently immunized (Berkeley, 1983). A study in India found that scheduled caste women and their children were denied access to a community home where vaccination sessions were held until the children of higher caste women had been vaccinated. Scheduled castes are groups in India with a very low position in the social hierarchy based on their supposed ritual impurity (SSIM/India, 1998).
4. *Communication on effects:* An emphasis on coverage has meant that immunization programs have emphasized the benefits of immunization over risks. Anthropological studies have shown that experiences with side-effects such as fever, abscesses, and pain can limit future acceptability of vaccines. Mothers also do not want to have immunizations given to their sick children. Sick children are considered especially vulnerable. Health workers know about the concern of their clients, and they know that they will be blamed if side-effects occur. In practice, they therefore do warn about side-effects, and are reluctant to immunize sick children (Heggenuhoun & Clements, 1987; WHO, 1998).

ACTIVE DEMAND, PASSIVE ACCEPTANCE

Apart from structural barriers, health belief studies also aim at identifying and finding solutions to cultural barriers to vaccination acceptance. Acceptance of vaccinations can, according to Nichter (1995), be differentiated into active demand and passive acceptance. Active demand "entails adherence to vaccination programs by an informed public which perceives the benefits of and need for specific vaccinations. Passive acceptance denotes compliance: passive acceptance of vaccinations by a public which yields to the recommendations and social

pressure, if not prodding, of health workers and community leaders” (Nichter, 1995, p.617). Others (Streefland et al., 1999) have suggested that such a dichotomy is not sensitive enough to variations in actual vaccination behavior. Acceptance, it is argued, can be more or less active. Despite efforts to deliver vaccines virtually to every child’s doorstep worldwide, empirical studies suggest that mothers have to overcome substantial barriers to get their children vaccinated. As mentioned above, they have to walk far, or wait for a long time before being attended to. Is such acceptance passive? Or is it active demand?

Insight into vaccination acceptance and demand requires an understanding of local notions of disease etiology. Very few studies have explored these in relation to interpretations of vaccine efficacy, reflecting perhaps a neglect in medical anthropology for preventive medicine. Many more studies have been done on indigenous notions of therapeutic medicine (Van der Geest, Reynolds, Whyte, & Hardon, 1996). In their study among the Bambara of Mali, Imperato and Traore (1969) point out that the Bambara perceived a vaccination to be an amulet that works if Koranic charms and diviners’ incantations have failed. Just as amulets need to be renewed, so vaccinations are seen to be timebound. In Indonesia mothers who do not fully vaccinate their children were found to believe that their children are healthy, and therefore not in need of further vaccinations (Nichter, 1995). In the view of the mothers it was the quantity, and not the quality of the distinct vaccinations that mattered. And, Mull, Anderson, and Mull (1990) describe how in the Hindu Kush region of Pakistan, tetanus-toxoid (TT) vaccines given to mothers are seen to prevent or cure Khudakan, an illness associated with neonatal tetanus. Khudakan, according to their respondents, is caused by spirits passed on from the mother to the child. One reason that TT vaccination was accepted is that it is congruent with local beliefs. Others have reported that mothers do not have faith in the power of the vaccine to prevent disease; rather they expect the vaccine to reduce the severity of the disorder (Odebisi & Ekong, 1982).

Congruence with local notions of disease etiology and vaccine efficacy clearly affects the extent to which people accept and demand vaccines. When they believe that the vaccines have a general protective effect, and serious illness still occurs, individual mothers may decide against further vaccination of their children. Refusal to vaccinate is then based on individual weighing of costs and benefits. In the above cited case on the promotion of

hepatitis B vaccine in Delhi as protection against *pilia* (jaundice), the authors note that medically, jaundice can be caused by different types of hepatitis. Hepatitis A is common in the community and this vaccine does not protect against it. The authors argue that a future problem for the hepatitis B immunization program is that it will in fact not prevent jaundice from occurring. If a child, despite having been vaccinated, falls ill with *pilia* (caused by hepatitis A) then the mother’s faith in the immunization program may be shattered (Addlakha & Grover, 2000).

RESISTANCE TO VACCINATION REGIMES

When vaccination was introduced by colonial governments in the last century resistance was a rather common response. Presently, collective resistance occurs for religious reasons: when parents reject protection through vaccination because they consider this unjustified interference with God’s will or because their explanatory model of how a child ought to gain resistance against a disease is at odds with the biomedical model. Collective resistance may also occur when the population distrusts the state (Streefland, 2001), when the media report adverse effects or undisclosed aims (e.g., sterilization of pregnant women by way of the TT vaccination).

A survey on the acceptance of vaccination among different ethnic groups in the Netherlands found more informed resistance among highly educated white populations (Hardon, Streefland, Egers, & Gerrits, 1998). Reasons for non-acceptance are the belief that childhood illnesses play a role in the development of children. Parents specifically refuse the MMR (measles, mumps, and rubella) vaccination because the diseases against which the vaccine works are not considered life-threatening. Ploch and van Staa (2002) have labeled this view as a “balancing attitude.” For each vaccine, parents make a balance of risks and benefits. Their critical attitude is part of a more general lifestyle in which organic food is preferred and environmental pollution avoided. It also reflects a more informed and critical attitude toward health services. Increasingly through the Internet, patients are finding their own information sources and confronting health workers with alternative paradigms for health, such as the hygiene hypothesis, which suggests that vaccines can in fact distort the development of the immune system.

In the Philippines, Ramos-Jimenez et al. (1999) report how the TT vaccination campaign ran into difficulties

when a rumor spread that the vaccinations were aimed at reducing the fertility of women. The rumors were spread by pro-life nun, Sr. Pilar Versoza, who had read reports from Mexico where the TT vaccine was reportedly contaminated with human chorionic gonadotropin (HCG), the hormone which is released during pregnancy. The nun demanded that the TT vaccines be tested, and “minimal traces” of HCG were found by one of the two testing centers. The controversy led to much unrest about the safety of TT vaccines, which at the time were included in the mass-immunization campaigns against polio. Women believed that TT vaccination could cause miscarriages and immunization coverage went down from 80% to as low as 20%–25%. The controversy also affected the coverage of measles vaccines. Underlying the controversy in the Philippines is distrust in the benevolence of the state’s public health programs.

Media reports on adverse effects are often the cause for collective resistance to vaccination. Banerjea and Coutinho (2000) report that resistance against polio vaccine grew in India when three children died during the first phase of the polio-eradication campaign. The authors examine the blame-assigning discourses, while attempting to map the varied and plural responses to the events in the media, state, and community. One of the mothers reported how her child had been ill prior to receiving the vaccine. She had doubted whether it was good to have the vaccine. All parents of the children who had become ill and died did not blame the vaccine, the authors note, but the administration procedure. The competence of the vaccinators was in question. The events led to refusal to have children vaccinated in the subsequent phases of the campaign. The health planners blamed the resistance on the people’s ignorance. As one active participant in the polio campaign commented: “People are ignorant. Our religious leaders are against pulse polio. They say if you have pulse polio, you will become sterile. People are thus scared.” And another comments “I constantly let them know about the benefits of immunization. . . . but they don’t understand” (Banerjea & Coutinho, 2000, pp.715–716).

IN ANTICIPATION OF FUTURE RESISTANCE

Vaccine administrators fear that with the increased flows of information accompanying globalization, immunization resistance will increase. Such resistance is considered

especially problematic when new vaccines are introduced. In contrast, existing vaccines tend to become part of local health cultures and are viewed with less suspicion. Hardon (1998) describes how a global network of women’s health organizations successfully opposed experiments with anti-fertility vaccines. The women’s health groups feared that the vaccines would disrupt their immune systems and lead to menstrual disorders. Anticipating resistance, anthropologists have been asked to conduct cultural feasibility studies in preparation for AIDS vaccine trials. The aim of such studies is to investigate AIDS-related beliefs, acceptability of the vaccine to trial participants, and community reactions and repercussions to the trial (Coreil et al., 1998). In the conclusions of such studies, anthropologists recommend in-depth educational preparations of trial populations ensuring that the effects of the vaccine, and the design of trials (including placebo groups), are understood. Streefland (2002), reviewing findings on acceptability of vaccines, suggests that the most important determinant of future acceptance of AIDS vaccines is better quality vaccination practices by health staff. When a vaccine is introduced for a prevailing deadly disease such as AIDS, vaccination demand is likely to be great.

Population Control

Robert J. Meier

HISTORICAL BACKGROUND

Evolutionary Perspective—Malthus and Darwin

Thomas Robert Malthus, in his major work originally published in 1816, “*Essay on the Principle of Population*” (1968), projected a gloom and doom scenario for the human race in what he surmised to be a losing battle between population growth and an adequate food supply. Simply put, humans would multiply at an exponential rate (2, 4, 8, 16, etc.) while increasing food production only would occur at an arithmetic rate (1, 2, 3, 4, etc.). As a dire consequence, the human species would far outstrip its subsistence capacity, unless population growth was checked by such agents as famine and disease. We will have a closer look at the Malthusian doctrine later on, but for now it is important to note that it was Malthus who helped clarify for Charles Darwin a vexing problem he had regarding evolution. Darwin was searching for an understanding of how change would take place over time in a population, and in 1838 it was the writing of Malthus that led him to the notion of “struggle for existence,” possibly due to limited food resources. Given that the reproductive potential of a population exceeded what appeared to him to be more or less stable population numbers, Darwin theorized that a selection process was operating to remove those individuals who were less able to successfully compete for restricted resources. He eventually published his theory of Natural Selection in 1859 (Darwin, 1892).

Malthus and Darwin established what to this day are considered to be natural “checks” that help to maintain or restore populations within the boundaries of resource availability. Resources, of course, come in many forms, not the least of which are an adequate food supply, mates, and a measure of secure habitat, or safe living environment. In terms of Darwinian evolution, then, population control was part and parcel of a natural process.

Cultural Revolution and Population Control Responses

Were humans under the same constraint? Obviously Malthus must have thought that effective control was not yet in place, and from his perspective it was only going to get worse. He was correct given the subsequent unfolding of major events in human history, such as the Industrial Revolution, that led to high concentrations of people living in crowded, unsanitary cities.

However, looking over the long course of human history, now reckoned in terms of several million years, foraging populations lived in small, scattered groups, and local pressures on resources could be relieved temporarily at least through out-migration. In fact, it is quite likely that movements of precursor human groups within and between continents in early time periods were in part due to successful cultural and biological adaptation and reproduction. Population growth spurred outward expansion.

A clear picture of the number and timing of migrations has not yet emerged. One intriguing notion is that there was a major population bottleneck some hundreds of thousands of years ago, when it is projected that the source population from which all of present-day humans stem consisted of only 10,000 adults (Harpending, Sherry, Rogers, & Stoneking, 1993). It was from this base in Africa that principal migrations populated Eurasia. If this conjecture holds up under continued examination, then it would appear that population control for the human species did conform to natural evolutionary processes until relatively recently. Early human groups were subjected to the same kinds of adversities as other animals, that is, “struggles for existence,” in the form of food and shelter shortages, some degree of predation, injuries and deaths from accidents, natural calamities, etc. However, there also was a growing advantage and environmental buffering in the form of cultural adaptation and evolution that would have begun making its impact. Cultural development along lines of improved

tool-making technologies and more complex social organization, which may have been biologically grounded in brain evolution, provided the means of dispersal and also the capability of replacing or displacing earlier established precursor humans (Stringer, 1994). An alternative view is that the latest wave of human migrants interbred with some of the existing groups, and these subsequently evolved into modern *Homo sapiens* (Wolpoff & Caspari, 1997). It might be noted that within the scenario of population replacement, and to the extent that this action was intentional and confrontational, this possibly would represent the first instance of population control in human history whereby earlier inhabitants became extinct. The final version on this aspect of human history is yet to be written, however.

Picking up the story around tens of thousands of years ago, humans at that point had managed to disperse throughout all of the areas of their current distribution, in what some have conjectured to be a period of explosive population growth. For instance, Sherry et al. (1994), using mtDNA estimates, base the timing of this spectacular growth in the 40,000 to 60,000 year range, seemingly coinciding with major new cultural developments (Klein, 2000). Total world population size at this time could run into millions of individuals, which would be a rather remarkable recovery following the presumed bottleneck noted above. While there may have been local checks on population, such as periodic episodes of high mortality due to natural calamity and starvation (infectious disease would not likely to be present at this time because of the small groups and their scattered, intermittent contacts), the principal population dynamics seem to have involved high levels of reproduction followed by population expansion, that is, migration based on necessity and opportunity. To be sure, early, partially effective forms of birth control were probably being practiced, and these will be discussed shortly.

This picture of relatively small, mobile groups subsisting on a mixed foraging/hunting strategy characterizes much of human history. It was not until population density reached a critical mass, either through abundant local resources such as in certain riverine or coastal environments or through the development of plant and animal domestication (the “agricultural revolution” and associated market systems that brought large numbers of people together on a regular basis), that highly contagious and parasitic diseases found densely populated regions to be maintained and spread, and thereby exert death control

on population growth. It can be conjectured that death control via infectious agents did occur during the past several thousand years of human history, but it was not until the Middle Ages that more precise accounting was done. For example, it is estimated that one third of the European population died during the bubonic plague (“Black Death”) of the latter half of the 14th century, a catastrophe from which it did not recover until the mid-16th century (Livi-Bacci, 2001). Considering a more recent episode, it is reported that up to 500 million people died from smallpox epidemics during the 20th century (CBSHealthWatch, 2001). However, a large question does remain as to what long-lasting effect infectious disease, or any form of disease for that matter, has had on the overall growth of the human population? (The same question will be addressed later with respect to warfare.) Given the complete recovery of numbers following the cited events, and other similar epidemics, it can be argued that if there was any effect it has been for fairly restricted areas and only for relatively brief periods of time.

THEORIES AND METHODS

Basics of Demography

Demography studies the size, composition, distribution, and dynamics of populations. Size refers to the number of persons, usually counted in a census, which can be more or less accurate depending on the method and thoroughness of counting. Composition deals with a breakdown of total population in terms of sex and age categories, and can also include other categories such as race/ethnic group and SES. Distribution primarily maps the placement and density of populations. Finally, and most importantly for the topic of population control, dynamics covers the changes that take place within and between populations. In simple terms, population size change can occur depending upon the number of births versus the number of deaths, plus or minus the number of persons who migrate into or away from a population. Birth, fertility, reproductive, and death/mortality rates are more formally defined than will be utilized here. A highly useful presentation of demographic rates can be found in Gage (2000). Suffice it to say that this discussion on population control will be oriented toward some rather broad aspects of human endeavors to maintain, reduce, or increase total population size, or to restrict/promote

certain subsets of a population, both in terms of number and quality. Reference will be made to particular countries or cultures to help illustrate certain features of population control efforts.

A widely cited demographic measure is the doubling rate. The doubling rate is the number of years it would take for a population to reach a two-fold size increase. For example, given the current size of the world's population at more than six billion people, and given the current rate of increase at almost 1.8%, then the world is projected to have around 12 billion persons in about 40 years. This population size is predicted by some estimates to be beyond the maximum number of persons that can be accommodated on earth. A directed interest in the doubling rate is obvious to anyone concerned about overpopulation, which will be considered later.

Demographic Transition Theory

In tracing the demographic history of developed countries it became apparent that a rather regular pattern of change in population growth had taken place. Historical demographers devised a theory to account for this pattern, referred to as the demographic transition model. In its purest application, populations experienced three stages; initially represented by high levels of births (largely through short birth intervals) and deaths (largely through high infant and childhood mortality) that for the most part offset one another, so that there was little or no population growth. At a second stage, spurred on by improved quality of life through medical advancement, food production, and distribution, death rates declined while birth rates remained high. This, of course, led to an increase in population size. For the third stage, the theory stated that with continued economic and technological development, which brought about more opportunities and incentives to control family size, birth rates declined (mainly through longer birth spacing), and populations once again resumed a slow or no rate of growth. This traditional theory of the demographic transition model does not seem to apply universally; for instance, some developing countries seem to be caught in the second stage. Furthermore, anthropological research done on non-industrial societies shows that fertility levels are highly variable (Nag, 1973) and high mortality is not always found in hunting-gathering societies (Polgar, 1972). It may mean that social and cultural changes that precipitate or accompany the transition to lower birth and death rates are just too

variable for the general model to handle. Indeed, an alternative demographic transition model (Social Justice Theory) has been proposed by Ratcliffe that does not rely on population control but rather on changing economic and social policies that would reduce poverty which in turn would reduce fertility levels (Hartmann, 1995).

Ecological Models

Imbedded within population ecology is the notion of carrying capacity, which basically asserts that there is a maximum population size for a particular set of environmental conditions. One population growth model, out of several that have been postulated, asserts that exceeding the maximum would result in degrees of environmental degradation, ultimately leading to a collapse of the entire ecosystem. This issue will be taken up in the next section.

It is generally assumed that during the period of exclusive foraging/hunting economy of our past, human groups could and did live in a "state of harmony" with nature, that is, within the constraints of carrying capacity. Whether this was intentional through a realized and understood concept of conservation of resources, or whether it was simply a matter of having a relatively low level of exploitative technology, is not always clear. Probably it was some of each. Certainly there was and still is a recognition by a numerous cultures of the connectedness between people and the environment through cosmology, subsistence, and even sophisticated understanding of ecological concepts. There is, of course, the highly practical understanding that living too long in one place can raise the risk of certain diseases and parasitic infections due to accumulated wastes. Hence, it might be argued that migrating to avoid pollution was one impetus for human population expansion.

The shifting of subsistence patterns from hunting/foraging to that of sedentary agriculture very likely occurred during continuous periods of population growth. Whether or not population growth was a key stimulus to the development of agriculture, or whether agriculture was the base from which rapid population growth could take place, has been subject to theoretical dispute (Bogin, 2001). On the one hand, the Boserup theory of positive demographic pressure contends that increasing population brought forth increasing demand for food, followed by more intense efforts for food procurement through evermore effective agricultural technology (Livi-Bacci, 2001). The "classic" theory

proposed by Childe argued that population growth was proceeded by discoveries and diffusion of new ideas concerning animal and plant domestication that resulted in a more secure, predictive food base (Livi-Bacci, 2001). Yet a third theory proposed by Cohen (1977) would explain the origins of agriculture somewhat along the lines of Boserup in that population pressure did contribute to an increasing reliance upon agricultural pursuits. In more specific terms, Cohen proposed that as hunting–gathering groups had begun to occupy the more productive areas, then under a model of continuous growth, subsequent groups would be relegated to making a living in areas that were nutritionally less adequate but yielded higher amounts of calories. Under this regime, populations increased in size while decreasing in quality of life, at least as measured by dietary intake. It is well known that deficiencies in diet can lead to a higher risk of contracting infectious and parasitic diseases. Hence, early sedentary populations are likely to have maintained a high level of mortality, to go along with an even higher level of fertility.

As noted earlier, it also seems likely that earlier human groups might well have avoided major problems in exceeding carrying capacity by migrating to new areas whenever pressure on local areas became too great. In more recent times, however, opportunities for migration were not very open, and this has prompted some new thinking and theory-building that promoted development and consumption on a sustainable level.

Sustainable development has its roots in Malthus of the late 1700s, but it was not until 1970 and thereafter that the concept was fully formed in bringing attention to excessive human exploitation of resources along with detrimental environmental consequences. Stemming from the 1992 Earth Summit held in Rio de Janeiro, goals and objectives of sustainable development were drafted to incorporate social, economic, and ecological concerns. Fundamental to any action taken was to insure human rights and needs for the present without compromising those of future generations. At the Rio Earth Summit, all countries were called on to formulate their own National Strategies for Sustainable Development (NSSD) and two target dates were proposed—2002, when NSSD was to be introduced, and 2005, when NSSD would begin implementation (NSSD, 2001).

How does NSSD deal with population growth and control? Conceptually, it does clearly recognize the impact uncontrolled development has on the environment,

but maintains that this is not solely due to population size but to local concentrations of people who garner unequal exploitation and distribution of resources. The concept of sustainable development, if it is to have worldwide application, must deal with a number of interconnected issues plaguing developing countries such as economic disparity and political unrest, severe poverty and inadequate food supply, and highly fatal diseases, notably HIV/AIDS and malaria.

Sustainable development also has to marshal strategies that deal with loss of biodiversity in many plant and animal communities, as well as a corresponding form of diversity reduction observed in human communities that seems to characterize globalization. Effective population regulation in ecological systems depends on maintaining diversity in life forms that offer resilience, flexibility, and stability in the face of changing conditions. There is good reason to make the same claim for maintaining cultural diversity. Yet worldwide trends clearly indicate that consumerism, especially of Western goods and behaviors, is eroding once unique cultural identities. There is the recognition of this in the NSSD strategy statement as it calls for a balance between globalization and decentralization, the latter being an effort to maintain lower levels of control and influence (NSSD, 2001).

On theoretical grounds, sustainable development appears to provide a set of sound strategies for correcting current problems in population–environment interactions that will ensure a brighter future for generations ahead. Implementation of the NSSD plan, for example, presents challenging but hopefully not insurmountable difficulties.

Developments in Medicine

Population growth, expressed as natural increase, is dependent upon the differential rate of births and deaths, more births than deaths results in a population increase, and of course, a decrease occurs when deaths overtake births. This section will summarize methods that have been developed to control causes of human mortality and factors that influence fertility.

Death Control. As noted above, causes of deaths in pre-industrial peoples likely centered on periodic episodes of starvation and repeated occurrences of serious injuries, from both man-made and natural events. The question as to whether compassion and care was extended to injured, physically disabled or aged persons has been

addressed (Dettwyler, 1991). While it can be conjectured that behaviors were devised and selected for if they reduced the death toll from accidents and mishaps, it was probably mainly in the area of food production, storage, and distribution that most control was exerted. That is, there were attempts to reduce the vagaries of nutritional intake.

With increasing industrialization and urbanization, involving larger and more densely settled populations, infectious disease could and did rise to become the leading cause of death. The bubonic plague that occurred in Europe in the first half of the 14th century was mentioned earlier. Improvements in sanitation and recognition by Louis Pasteur of the germ theory of disease toward the end of the 19th century meant that death control over infectious diseases could advance. Pasteurization of milk and vaccination against infectious agents may be partially responsible for major reductions in morbidity and mortality. However, as shown by McKeown's epidemiological research (cited in Hertzman, 2001), the death rate from TB in England and Wales experienced a sharp drop well before the introduction of antibiotics and administering of vaccinations. The explanation seems to rest along social and economic lines. Indeed, Hertzman (2001) presents a strong argument for death control by way of psychosocial determinants (quality of the social environment), along with socioeconomic indicators, expressed in terms of a gradient of health status determined, for example, by the equality/inequality of income within a society. A steeper gradient in wealth leads to marked differences in health. Gage (2000) provides an illuminating discussion of the historical variation in mortality by making a distinction between proximate causes (the disease itself) and ultimate causes (the psychosocial support system).

The leading causes of death in America have now shifted to "lifestyle" diseases, notably heart disease and cancer. For clarification, recent genomic research has allowed scientists to claim they have discovered the "gene" for some of these chronic conditions. This too is an oversimplification in that genetic predisposition triggered by certain environmental events, including once again the social environment, combine and interact to make the risk for contracting and dying from these "lifestyle" diseases rather more complex. It is the case that a substantial portion of medical research is devoted toward finding treatments and cures, somewhat less for preventive measures. In short, Western medicine runs its

course of attempting to gain as near as possible full control over the modern causes of death. Medical advancements in surgical techniques, nuclear medicine, medications, and the like do offer great promise for sustaining human life at a high level of vitality throughout the later years. Yet, if this advanced medicine is restricted to only those who can afford it, and if inequalities of health provision (Hertzman, 2001) are not addressed, then the general picture of health will not likely improve for a substantial number of humans. Beyond that, much of the world still must contend with childhood diarrhea, malaria, and infectious diseases. HIV/AIDS has reached crisis levels in some countries, while outbreaks of the ebola virus and bubonic plague are distinct threats.

Birth Control. Reproduction is of course the vital force of any ongoing population. Differential reproduction, wherein some adults are more successful at leaving offspring than others, is the hallmark of Darwin's theory of natural selection. Accordingly, some populations persist, perhaps to grow, while others undergo extinction. To be sure, the human population is among the former. As discussed earlier, ancestral human groups had the opportunity to undergo major expansions and migrations seemingly without any lasting effect of natural checks on their population growth. Indeed, highly successful adaptation as measured by reproductive output might well have been one impetus for these groups to migrate. At that time period, intentional limiting of births was not likely so relevant. Hence, natural fertility may well have been in place, but this would not preclude such practices as postpartum abstinence since this may have been done more for the health of the mother and her nursing baby (Whiting, 1964) than to deliberately limit births (Wood, 1994). Then too, the concept of natural fertility has been clarified with regard to postpartum "contact" in the Gambia (Bledsoe & Hill, 1998) while Ellison (2001) offers a different perspective regarding the role of lactation in postpartum fecundity.

There was, of course, a time when human groups did devise more or less effective measures to control the number and spacing of births, in part at least as a necessity or desire to control population growth, for both personal and communal reasons. Some traditional birth control methods that are documented in the ethnographic record include ingested noxious herbal agents, aggressive massage, ligatures and mechanical devices for aborting ongoing pregnancies. Infanticide/infant abandonment,

and fatalities from child abuse or neglect, also were present. Selective survival of children born with disabilities has always been a cold fact of evolution. Birth defects would increase the risk of mortality on its own, along with added economic, medical, and social pressures on parents to provide reduced childcare investment, often manifested by neglect and abuse. However, given their relative rarity (approximately 5% of total live births), deaths due to birth defects, directly or indirectly, are not likely to have been a significant contributor to overall mortality rates.

Still later, presumably after the recognition of paternity, abstinence (through celibacy, delayed marriage, and postpartum taboos) and *coitus interruptus* (withdrawal) were practiced. These were followed by increasing reproduction knowledge that led to the timing of sexual intercourse—the “rhythm method.” Together, the rhythm and withdrawal methods make up 15% of overall contraceptive use according to a worldwide survey (Fathalla, 1994). These methods are much more likely to be used in developed countries. The now well-studied temporary loss of fecundity or lower risk of pregnancy during lactation and breast-feeding, “postpartum amenorrhea” (Ellison, 2001; Ellison & O’Rourke, 2000; Wood, 1994) may have been partially understood for some time into the past (Ramos, Kennedy, & Visness, 1996). Some of these methods might be considered “low tech,” perhaps to reflect their relatively high failure rate. Others, such as infanticide, while totally effective, must have exacted a terrible blow to emotional well-being, as well as considerable energy expenditure incurred by the mother who experienced the death of her infant.

The birth control industry has developed over time to a point where monetary costs, failure rate, ease of use, side-effects, as well as moral and religious attitudes, all lead into decisions of whether or not and which method/s to use. A brief survey of these methods follows, some will receive further attention in the Issues section.

Contraception. Preventing a pregnancy can take many forms, some of which were mentioned as part of earlier attempts at birth control such as periodic abstinence, the “rhythm” method, *coitus interruptus*, etc. In fact, it was not until after 1820 in England that any preventative measure other than delaying marriage (abstinence) was openly considered (Field, 1968). The next century was to see major advancements toward fertility control through contraception, notably by gaining knowledge about female

reproductive hormones. By 1960, the FDA approved marketing in the United States of “the pill.” Its action was based on administering progestin (an artificially synthesized progesterone) as an ovulation suppressor. Depo-Provera is an injectable form of ovulation inhibitor. Hormonal pills account for about 16% of all contraceptive use worldwide (Fathalla, 1994).

Barrier contraceptives, many accompanied by spermicide, include the condom, diaphragm, and the cervical cap. Condoms alone make up 10% of worldwide contraceptive use (Fathalla, 1994). Of course, in addition to birth control, condoms are also used for greatly reducing the risk of contracting sexually transmitted diseases (STDs).

All of the contraceptive methods mentioned above are seen as temporary. On the other hand, voluntary sterilization (tubal ligation for females and vasectomy for males), is generally considered permanent, although limited success of reversal has been reported. On a worldwide basis, sterilization is the most frequently practiced method. For females it occurs 26% and males 10% of total contraceptive use (Fathalla, 1994). It is important to note that roughly two thirds of sterilization is done in developing countries.

Contraceptin. Physical and chemical means to interrupt a pregnancy at its earliest stages define the action of contraceptins, that is, they prevent gestation. One of the most prominently used devices is the intra-uterine device (IUD), while hormones that block implantation are found in Norplant and the “morning after” pill. Most recently introduced to the U.S. market is RU486, which serves as a non-surgical means of abortion, cleared by the Food and Drug Administration (FDA) for use up through about 7–9 weeks of gestation. The IUD method is practiced 19% of the time for those using some form of birth control (Fathalla, 1994).

Elective surgical abortion technically might be classed as a contraceptin form of reproductive management. When applied for this purpose it is customarily carried out during the early stages of gestation, notably the first trimester. This topic will be given extended coverage in the next section.

Contranatals. As this term implies, fertility control is exerted after the child is born, by way of infanticide shortly after birth, or instances of child abuse/abandonment and benign neglect (cf. Cassidy, 1980, 1987) that result in death. Dettwyler, in her widely acclaimed book,

Dancing Skeletons, Life and Death in West Africa (1994), offers a heart rendering glimpse into how poverty and lack of some basic nutritional knowledge can be a lethal combination for a young child. It was mentioned earlier that some populations have regulated birth spacing or a desired son-preference outcome through female infanticide (Miller, 1987; Segal, 2001). As might be expected, precise numbers on contranatal practices are not readily available. One study indicated that as many as 38 million abortions are done each year in Southern countries, with perhaps 20 million of these carried out without proper medical supervision (Germain, Nowrojee, & Pyne, 1994). On the other hand, it is reported that in 25 countries, which contain about 40% of the world's population, abortion is permitted and properly performed through certain stages of gestation without requiring specific grounds (Fathalla, 1994).

The Population Establishment

Various groups have participated in population matters. Below is a listing of some of the more prominent of these governmental and private organizations. For a more complete description and critique see Hartmann (1995).

- AID—The U.S. Agency for International Development
- UNFPA—The United Nations Fund for Population Activities
- The World Bank
- IPPF—The International Planned Parenthood Federation
- The Population Council
- Foundations—Ford, Hewlitt, MacArthur, Mellon, and Rockefeller

ISSUES AND CONTROVERSIES

This section will briefly present some major issues that have come up with respect to population control. It is not possible to cover all of the nuances of the arguments or to represent every position. And it certainly is not possible to resolve any of these issues or controversies here.

Overpopulation

Alarming demographic projections regarding ineffectively controlled human population growth and consequent environmental catastrophes have spawned several literary warnings with ominous titles (e.g., Ehrlich, *The Population Bomb*, 1968; Carson, *Silent Spring* 1962). Perhaps no sentinel in this camp is better known

than Garrett Hardin who, for more than four decades, sounded the clarion for those so inclined to heed the call. His numerous works (e.g., 1968 (“Tragedy”); 1969 (*Population, Evolution and Birth Control*); 1974 (“Living in a Lifeboat”); 1993 (*Living within Limits*) pose educated scenarios and optional solutions with respect to the future of humankind. Essentially, the message is that, given finite resources and limited space (he argues that interstellar colonization will not work), human population growth must be contained or a default resolution will be imposed by natural selection, that is, nature will exact its toll. On a broader scale, The Club of Rome was organized in 1968 by a group of 30 persons from 10 countries (later expanded to include 25 nations) to present warnings of what they thought would happen if population growth and economic production continued at the same pace (cf. Meadows et al., 1974; Neurath, 1994). Zero Population Growth (ZPG) was a private organization that used the slogan, “Stop at Two!” (Hardin, 1993). ZPG would be achieved if fertility remained at an average of 2.1 births per woman, the so-called replacement rate (Adamson, Belden, DaVanzo, & Patteron, 2000). Of course, any lower average fertility and a population would decline.

Countering the ZPG and Hardin positions also has been a highly active endeavor by those who purported to show in various connected themes that resources are not as limited nor population growth so detrimental (e.g., Simon & Kahn, 1984, *The Resourceful Earth*). The crux of their argument is that technological and economic developments will continue to expand whatever might be the current limits of carrying capacity, so that resources will not be depleted, and in fact, continued population growth will be a stimulus for future development. One branch of anti-Malthusian followers were called Cornucopians (Hartmann, 1995).

Is there a meeting ground for these opposing viewpoints? While any disagreement may be in the realm of “only time will tell,” cautioned optimism has been voiced by some (e.g., Livi-Bacci, 2001).

Northern Country OverConsumption

This issue is basically a contest of quantity versus quality. The focal points are that even though a larger population requires an ever-increasing share of the resources, the available resources are not, and perhaps rarely ever have been, equitably distributed. To the point,

Northern countries, due to certain historical outcomes, have managed to control most of the earth's resources as well as the technology for future energy capture. It has been reported that the industrialized nations, which comprise only 22% of the world's population, actually consume 70% of the world's resources (Hartmann, 1995). This favored position allows for a standard of living that far exceeds that of the developing Southern countries. However, there is a high cost that goes along with a high standard. First, currently available resources are being drained to maintain the high standard, some would argue at an alarming rate. Additionally, the very nature of much of current energy conversion and consumption (notably through fossil fuels and nuclear power) yield large amounts of pollution and toxic/radioactive wastes. These effects are hardly conducive to a healthy planet or its inhabitants.

It seems doubtful that a stable, long-term resolution to this "haves versus have-nots" problem would be achieved solely through a more equitable redistribution of resources, although certainly that would relieve the plight of those many who now endure a poor quality of life. Realistically, it does not appear possible to raise the quality of life for all to that high level presently enjoyed throughout the Northern countries. Hence, a more permanent fix calls for a reduction at the high end of the quality of life scale to go along with an elevation at the low end.

Forced Migration and Immigration Restrictions

Human migration was viewed in an earlier section to be a way out for hunting–foraging groups in order to allow for continued population growth without placing undue pressure for survival on the limited resources of a given area. However, at some point in human history most of the productive areas of the world were occupied, and as a consequence competition was waged between individuals and groups for inhabitable space. Some might argue that the demise of Neanderthals came about as they encountered more modern humans, but that outcome is not yet proved to everyone's satisfaction. Displacement and/or replacement that far back in time provide academically interesting points of departure for research, but jumping forward to more contemporary periods brings out some of the most troubling events in human history involving involuntary movement of peoples. One need only

mention the forced transport of African slaves to the New World and the Holocaust of World War II to bring home painful reminders of just how horrible population control can be.

Unfortunately, history is not finished in providing these painful lessons. At the present time refugees and their makeshift camps can be found in many parts of the world. Large numbers of people have been forced to leave their homelands in such examples as some African countries, former Yugoslavia, and Central Eurasia. Tragically, instances of forced movements of people are often accompanied by acts of genocide, recently termed, "ethnic cleansing" (Bok, 1994). Although the geopolitics are complex and do of course vary by region, there is an underlying commonality in the resultant very poor quality of life for these masses of suffering people. Controversies abound as to what should be done, and by whom. One action that has led to even greater concern is that of restricted immigration policies where oppressed peoples find borders closed to them.

Warfare and Population Control

The controversial nature of this topic seems patently obvious. After all, the killing of our own species seems morally repugnant to most people. Nonetheless, deeply imbedded in human acts of war there exist primal responses that at times characterize the competitive behavior found throughout the animal world. To say that warfare is our evolutionary heritage probably is not truly appropriate, since cooperation must have been at least as important as competition over the long haul of human history. Yet, it is important to acknowledge that more recent wars among humans do have a long history of engaged groups as they competed for space, resources, and ideologies. From an evolutionary perspective, inter-group selection is a model that has been applied to human population genetics (Cavalli-Sforza & Bodmer, 1999). The question posed here is: Has warfare served to check population growth among humans?

In an earlier appraisal of this matter, Bates (1968) stated that while it was difficult to accurately document by numbers, recurring wars between 1650 and 1950 did not effectively slow the rate of worldwide human growth. He reasoned that there was indeed a decline in birth rate due to disruption of families, and of course there were wartime casualties and attendant mortality due to famine and disease. But postwar "baby booms" seem to

have allowed populations to rapidly recover their wartime losses. On the other hand, Bates (1968) also argued, based on research done by Alfred Kroeber, that some Eastern Native American tribes may have had their population growth limited due to sustained war. But once again this kind of conjecture is unencumbered with clear numerical documentation.

While this very brief discussion does not delve very thoroughly into the matter, it does seem probable that warfare per se has not systematically resulted in checking human population growth, at least in terms of worldwide trends. This does not mean that in more localized areas, and perhaps in much earlier times, war and warlike activities were not limiting the rate of population growth, and in some cases could well have precipitated massive depopulation and even extinction of some groups. As pointed out by Harris and Ross (1987), it is important to distinguish between warfare as carried out at the village and band level, which likely did restrain population growth, from war and conquests in imperial contexts which were carried out for territorial expansion. And then, in either case, it is important to note that numbers do not tell the whole story of the misery and suffering connected with warfare.

Biological Warfare—Present, Future, and Past

Concerns about bioterrorists' attacks recently have heightened, for good reason. Outbreaks of anthrax disease and bacterial exposure have placed the United States and portions of Europe on high alert. The alarm has sounded to include other, even more deadly pathogens such as the smallpox virus that possibly are being prepared for attacks on the public. The present status of high alert prompts the same question that goes back to World War I and then repeated at times during subsequent wars and conflicts: Are nations or terrorist groups planning to engage in biological or chemical warfare? While no large-scale offensive attack has occurred as yet (there are recorded or suspected contained incidents), the very question led to stock-piling and testing by some countries purportedly as defensive moves. The very grave future threat that these weapons of mass mortality pose could lead to loss of life that far exceeds that from prior use of conventional, or even until now, nuclear warfare. Unfortunately, warfare as a check to population growth may take on new meaning in the future.

But perhaps the past can serve here as a guide and warning. Historical records are replete with examples of peoples who underwent major depopulation, some to extinction, following initial contacts with European colonists (Livi-Bacci, 2001). It has been estimated that in the three centuries following initial European contact, the native population that inhabited the area that later would become the United States was reduced from 5 million to 60,000 (Thornton, 1987). The affected populations were vulnerable to what has been called the "virgin soil" theory, which presumes that there was little natural immunity to contagious agents, so that epidemics raged and mass mortality ensued both directly from the pathogen itself but also from overwhelming the native systems of health care and daily functioning. Native healers and traditional medicine had little experience from which to counter these foreign microbial attacks. Devastated groups included the Maoris of New Zealand, the Taino of the Dominican Republic, the Tierra del Fuegians, and the Tasmanians, all of which experienced major population loss, in major part due to infectious disease (Livi-Bacci, 2001).

These particular instances may not be biological warfare, simply because it cannot be shown conclusively that there was deliberate use of pathogens as weapons against native peoples. This probably also applies to assertions that smallpox-contaminated blankets were passed along to American Indian tribes. However, it is well documented that the wrath of infectious disease among Native Americans took a massive toll on life. Numerous tribes buckled under the more advanced technology of the colonists, who progressively replaced and displaced them (Livi-Bacci, 2001).

Eugenics and Sterilization Programs

The historical practice of eugenics has indelibly scarred attempts at reproductive control that was based upon both reducing the number of people and also eliminating certain kinds. Thus, race/ethnicity, sex, mental status, physical ability, and income-level all have served to identify those who were involuntarily sterilized and, in more extreme cases, put to death. Technically, this is referred to as negative eugenics, since it prohibited the reproduction by those so identified. The converse practice, that of positive eugenics, was also applied, where once again selected groups were promoted for their reproductive contribution. Shapiro (1985) has provided an account,

based on case studies as well as broader studies, of sterilization abuse among U.S. women, as does Hartmann (1995) with respect to Native women. As will be discussed below, procreative rights stand in most people's eyes as a foundation of humanity. Hence, forced sterilization is seen to violate reproductive freedom, irrespective of the good intention as defined by those who carry out the act.

A voiced concern in more recent times is whether certain biomedical developments might constitute a new form of eugenics. This issue centers on the growing capability of identifying genes that are in part responsible for determining such behavioral traits as intelligence and personality, or desired physical attributes such as stature. When this capability is realized there will be the potential for abuse in either selecting prenatally for these traits, or postnatally under the guise of gene therapy. Nonmedical (in certain instances this could be termed "cosmetic") applications of the new genetics obviously fall within the purview of quality control of humans, and they raise the specter of earlier eugenics movements. Certainly the stakes have been raised now that human cloning may be added to the controversial mix. However, in spite of the danger of potential abuse, it does seem that there is a place for legitimate medical uses of gene therapy.

Abortion as Birth Control

Few topics engender more heated discussion than that of abortion. It seems fair to say that much of this rancor stems from strong religious and moral prohibitions to the practice of intentionally terminating viable pregnancies. Some concern might also be expressed from a strictly pragmatic point of view that abortion is a costly (in terms of fetal wastage) practice. Here we will focus on non-therapeutic abortion which is meant to limit the number of births, rather than those abortions that occur spontaneously, that is, miscarriages, and those resulting from surgical procedures that are medically indicated when the health and well-being of mother and/or fetus are compromised by a continued pregnancy.

It already has been mentioned that hunting-foraging groups had practiced abortion, along with infanticide, in order to control both the timing and number of children being born. Too many children in a short period of time could be a liability. On the other hand, children born into a subsistence agricultural setting could be deemed an asset rather than a burden. Additional children might well

improve household economy. While subsistence livelihoods are still prevalent throughout the world today, the controversial nature of abortion as a population control measure centers on particular countries, perhaps exemplified by the United States and China.

Abortion in the United States is legal and may be used as part of family planning. In this application it appears that parents mostly carry out their decision to terminate a pregnancy at the personal or family level, often dealing with "unwanted" pregnancies. Anti-abortion groups have marshaled forces to thwart the practice of abortion, and have made attempts to overthrow the *Roe v. Wade* decision. One highly visible group, the Center for Bio-Ethical Reform, denounces abortion as an act of genocide through its display of highly graphic posters. This action is countered by Pro-Choice advocates, and organizations such as Planned Parenthood maintain that safe, readily available abortions should be contained within a broad framework of family planning. Not surprisingly, there is little likelihood that the abortion controversy in the United States will be resolved in the near future.

The situation in China offers a different perspective on the abortion controversy. China instituted a national population policy in the 1970s that employed abortion within its highly coercive family planning program that established birth quotas. In the 1980s, both incentives (in the form of wage and pension increases, medical and educational benefits, etc.) as well as disincentives (such as salary cuts and loss of benefits) were imposed on Chinese couples (Livi-Bacci, 2001). China's population policy has been viewed as an attack on basic human rights as well as a targeted assault on women's rights, since forced abortions often selected female fetuses (Hartmann, 1994). More recently the one-child policy has been relaxed somewhat, and the coercive program is being phased out as China has been able to realize some of its demographic goals by sharply reducing fertility (Livi-Bacci, 2001).

Another controversy concerning abortion has arisen in its use to selectively abort female fetuses in favor of son-preference (Hartmann, 1995). This practice has been documented in India and other developing countries (Miller, 1987; Segal, 2001), where initially amniocentesis and now ultrasound are done to ascertain sex. Selective abortion combined with neglect have resulted in a low female to male sex ratio among children in India (Segal, 2001).

Procreative and Reproductive Rights and Responsibilities

As might be expected, whenever restrictions are placed on people's actions or activities, there will be resistance, particularly if these restrictions are seen to violate fundamental human rights. Does this apply to reproduction and procreative rights? There are at least three issues that are raised.

1. Individual/Human Rights versus Public Good. This matter boils down to parental rights to have as many children as desired (cf. Adamson et al., 2000) in opposition to one or more levels of the government placing limits on family size. China was discussed earlier in this regard.
2. Women's Health and Fertility. Some of the most cogent discussion of reproductive rights has come from a position that argues for empowerment of women generally. For instance, Hartmann (1995) succinctly presents this argument for government policy to address women's reproductive health needs rather than attempting to impose population control measures, which she stated often have denied women's rights in the area of fertility and family planning.
3. Men's Responsibility in Family Planning. This takes on the issue of more actively involving men in family planning, such as a consistent use of condoms, undergoing vasectomy (which is less risky than tubal ligation), and being receptive to research development that may lead to a male contraceptive pill (Ren et al., 2001).

Family Planning and/or Maternal–Child Health Care

The matter becomes controversial as governmental agencies, as well as nongovernment organizations (NGOs), prepare budgets, when their assets are not sufficient to adequately fund both areas. In some instances, AID and other programs have interceded on behalf of mothers and their children, in meeting their nutritional and medical needs, but have neglected to provide family planning services, perhaps due to sensitivity issues.

Human Population Control on Other Species

Efforts to control our own population have obviously been a stormy sea of consequences. Good intentions have been morally questionable at times, and there are those who would argue that any attempt at human population control is wrong. This issue carries over to other life forms which humans have either directly (as in domestication)

or indirectly (as in habitat destruction) altered the course of evolution. Like it or not, we are the species that will largely determine the fate of other creatures, large and small. How we do this, of course, is the nature of the controversy.

Reproductive Health

Andrea Whittaker

INTRODUCTION

Research on reproductive health within medical anthropology encompasses people's emic perspectives on all matters related to sexuality and reproductive processes

and functions. Some of the earliest works to describe ethnophysiological understandings include Ashley Montagu's (1949) work on understandings of conception, fetal development, and embryology among Australian indigenous peoples. Likewise, Malinowski's (1932) work

in the Solomon Islands and Margaret Mead's (1928) work in Samoa may be seen as antecedents to modern work on the subject of sexuality. Early work on reproductive customs include Ford's (1964) comparative work listing beliefs and practices in 64 societies.

In the last 30 years studies focusing upon reproductive health have grown exponentially. Concern over the issue of world population growth in the late 1960s and 1970s spurred increased interest among anthropologists toward involvement into population issues. Anthropologists Steven Polgar and Moni Nag led a movement encouraging anthropologists into "population anthropology" researching fertility in Third World settings and promoting the need for anthropological research within high fertility societies (Nag, 1972; Polgar, 1972). The spread of international public health programs concentrating upon family planning, maternal and child health also promoted anthropologists' involvement in applied research on reproductive health issues. This coincided with the growth of feminist scholarship documenting the experiences of women and the nature of sex and gender, and the development of sexual research and gay studies. The HIV/AIDS pandemic has also demanded better understandings of sexual behaviors and the management of sexual health.

Anthropological work on reproductive health draws upon disciplines of public health, demography, biosocial approaches, post-structuralism, feminist theories, political economy, and historical approaches. The proliferation of studies on gender and sexuality across various disciplines has produced a rich literature that has greatly influenced anthropological approaches to sex and reproduction. Methodologically work on reproductive health has also highlighted the difficulty of gathering data on tacit knowledge and sensitive issues such as sexuality, forcing the development of innovative techniques. Two observations may be made about this body of work in general. First, the majority of work concerned with issues of reproductive health is by women anthropologists, and correspondingly, there remains a paucity of studies devoted to understandings of male reproductive health.

MENSTRUATION AND THE REPRODUCTIVE LIFE CYCLE

In all cultures, women and men's reproductive health is invested with complex meanings that refer to their

potency, fertility, and sexuality. Studies from Papua New Guinea and Australia provide notable cases where high values are placed upon both male and female roles in reproduction and nurturance and emphasize reproduction as a cosmological principle (e.g., Suggs & Marshall, 1971). Societies differ in the degrees to which they mark the commencement of young women and men's reproductive lives. Initiation ceremonies have long been a focus of anthropological interest exploring the links between social and moral order and the sexual and social maturity of youth. Ritual circumcision and sexual instruction may occur as part of these rites (Herdt, 1982; Richards, 1956).

Early studies emphasized the symbolic elaborations of menstruation. A re-evaluation argued for studies of menstrual ritual to be contextualized within the larger cultural system (Buckley & Gottlieb, 1988). For example, early ethnocentric works on menstruation analyzed Native American menstrual taboos as signs of female defilement and degradation. Buckley's (1988) reanalysis of Yurok data and Wright's (1982) work among the Navaho show that menstrual blood is a generative substance of enormous power which is considered dangerous when not involved in reproduction. Secluding menstruating women is not necessarily a mark of defilement and pollution, but can mark women's power. In contrast, in Turkey, menstruation is considered polluting, reflecting the subordination of women's interests (Delaney, 1988).

The quality and regularity of menstrual flows may also be understood to be related to a woman's moral and social status (Rasmussen, 1991; Sobo, 1992). In rural Thailand, a regular heavy menstrual flow of red blood is indicative of a healthy body and indicates the expulsion of "bad" blood. Irregular menstruation, or blood that is "thin" or "black, bruised and congealed," or any discharges, are signs of ill-health and bodily imbalance. The retention of bad blood within a woman's body may cause varied bodily and emotional states: weakness, bad moods, irritability, insanity, skin rashes, headache, dizziness, ulcers, and paleness (Chirawatkul, 1996; Whittaker, 2000). Likewise, understandings about the function of blood in provincial Iran are associated with beliefs about the nurturing and polluting qualities and the physical weakness of women and highlight how emic definitions of reproductive health may include aspects not considered by biomedicine to be associated with reproduction. Menstrual blood is believed to be "dirty" blood that must be released so as to cleanse the body each month

(DelVecchio Good, 1980). Any disruption to menstrual flow due to the use of contraceptives such as the pill is understood to cause heart distress, weak nerves, lack of blood, aches and pains, and is frequently cited as a reason for discontinuing use.

Similarly, the experience of menopause depends on the ways in which cultures label the event and the assumptions made about women's lives (Beyene, 1989). Studies indicate that in some cultures the cessation of menstrual cycles is considered unremarkable and not necessarily the most important marker of female aging, nor associated with the same bodily symptoms associated with menopause in many industrial societies (Rasmussen, 2000). The meanings of menopause differ between cultures. Menopause is understood as a time of enhanced social status, and freedom for women in some cultures (Chirawatkul & Manderson, 1994; Kerns, 1985; Vatuk, 1985), and associated with enhanced sexual pleasure released from the fear of pregnancy (Beyene, 1989; Brown, 1982; Brown & Kerns, 1985). In the United States, menopause is associated negatively as a time of biological atrophy (Martin, 1987). In Japan, Lock has described the ways in which menopausal symptoms are labeled as signs of selfishness (Lock, 1988). Beliefs about the production of menstrual blood also impact upon understandings of the menopause. In Iran, menstrual blood signifies a woman's fertility and its loss is considered a sign of loss of youth, fertility, and physical attractiveness, because of the drying out of the womb (DelVecchio Good, 1980). The introduction and widespread use of hormone replacement therapies (HRT) as a treatment for "menopausal syndrome" in both industrialized and developing countries raises new issues as to the medicalization of menopause and the impact upon local understandings of older women and their lives.

A controversial issue addressed by some medical anthropologists is that of female genital surgery (also known as female circumcision or female genital mutilation), which involves the injury to, or partial, or total removal of external genitalia for cultural reasons practiced in many parts of the world, including some countries of the Horn of Africa and the Middle East, parts of Southeast Asia, especially Indonesia and Malaysia, and among immigrant communities from these areas. Campaigns against female genital surgery have been emotionally charged. Anthropological studies have provided understandings of the meanings and context of these practices (Gruenbaum, 1996, 1999; Obermeyer,

1999; Shell-Duncan & Hernlund, 2000). For example, in the Northern Sudan, Boddy explains infibulation within local values of beauty, enclosedness, and culturalized fertility. Girls are "veiled" through infibulation, men are "unveiled" at circumcision (Boddy, 1982). Ellen Gruenbaum argues that factors that perpetuate female circumcision and inhibit change can only be understood by examining the broader social, economic, and political context of the practice (Gruenbaum, 2001).

FERTILITY REGULATION

Cultures differ in their understandings of fertility and the process of conception. For example, work on Sri Lanka (Nichter & Nichter, 1987) has found the first few days immediately following the cessation of menstruation is considered the most fertile, due to perceptions that the womb is most open to conception before and immediately after menstruation. Likewise, women are considered fertile immediately following childbirth due to the open state of the womb. Humoral notions of hot/cold and wet/dry also affect fertility. Given that the "safe period" is a common means of family planning in Sri Lanka, the provision of fertility cycle education combined with the use of condoms could result in a more effective usage of the "safe period" both for those wishing to postpone or space their children, or for those wishing to fall pregnant.

Many cultures have detailed knowledge of herbs, foods, and medicines for fertility regulation. Newman's edited work (1985) documents herbal medicines and other techniques used for menstrual regulation, the management of pregnancy, and assistance with labor in seven cultures, including Chinese-Malay, Afghanistan, Egypt, Colombia, Peru, Costa Rica, and Jamaica. Indigenous means of fertility regulation remain popular even when modern means of contraceptives are available, because they coincide with local understandings of the body, are controlled by women, are readily available and are socially and culturally acceptable. Humoral rationales underlie many cultures' understanding of reproductive processes and many of the indigenous medicines used in fertility regulation involve manipulating the body's humoral balance to enhance fertility or to delay it. In Cali, Colombia, one cause of menstrual delay is understood to be impurities in the womb or menstrual blood, or the accumulation of cold in the vagina. Remedies that purify the womb and restore humoral balance or others defined

as purgatives are used to cure delayed menstrual periods (Browner, 1985).

Anthropological studies show how contraceptives are understood to work on women's and men's bodies in a wide variety of perceived ways and with a wide range of effects, and are mediated by a variety of social relationships, institutions, knowledges, beliefs, and practices (Russell, Sobo, & Thompson, 2000). Access to and use of modern contraceptive technologies has had a dramatic impact upon women's reproductive health, not least of which is a decrease in maternal mortality due to childbirth and induced abortion. It has had a major impact upon women's lives and bodies, enabling women to play greater roles as producers and allowed couples greater control over the timing of children and the number of children they may have. For many women and men this has had positive effects allowing them to express their sexuality free from the anxiety of pregnancy. At the same time, the use of modern contraceptives also involves a range of negative side-effects, of variable severity. These have primarily affected women who are the main users of contraceptives. An important debate within studies of fertility regulation by feminist anthropologists has been the extent to which modern contraceptives enhance women's empowerment and reproductive choice and rights (Petchesky & Judd, 1998).

Medical anthropologists have been involved in a range of "acceptability studies" to assess how local beliefs, social and cultural contexts, and behaviors will affect the acceptability of various fertility regulation methods (Polgar & Marshall, 1978). Across different cultures, the modes of action of various contraceptives differ and reveal local understandings of the workings of the body and factors influencing fertility. Neither the physiological responses nor attitudes toward any contraceptive technology can be distinguished from the wider context in which it is used (Gammeltoft, 1999). McCormack (1985) notes how in Jamaica the contraceptive pill is thought to work by mechanically blocking sperm from reaching the uterus. Pills are believed to build up within the body over time, requiring the use of a castor oil "wash-out" to cleanse the body, or periodic cessation of the pill. Other studies have suggested other modes of action of the pill, from weakening the body and blood, or through heating and drying out the womb (DeVecchio Good, 1980). In Northeast Thailand, injectable contraceptives are frequently associated with side-effects, such as tired arms, amenorrhoea, thinness, weakness, and

chills, as the "bad" blood that is normally expelled through menstruation accumulates in the body causing a cold state (Whittaker, 2000). In Vietnam, the intra-uterine device (IUD) is understood to weaken a woman's blood and be detrimental to her health (Gammeltoft, 1999). In many places, such as Peru, the IUD is understood to be capable of moving through the body and cause injury to the heart or lungs (Maynard Tucker, 1986).

Contraception is associated with increased weakness and vulnerability to ill health in many cultures, which may be mitigated by following other folk medical practices and dietary regimes. For example, Morsy (1980) and Nichter (1996b) report that in Sri Lanka and Egypt, respectively, the ingestion of powerful drugs such as oral contraceptives is understood to require the consumption of nourishing foods to strengthen the body. Only rich women who can afford a "nourishing" diet are considered able to take the oral pill. In this way, side-effects from contraception may also be mediated by class.

The meanings of contraceptives and the negotiation of their use are influenced by and influence local economic values, ethical and religious concerns, political ideologies, gender relations, and kinship systems (Russell et al., 2000). Decisions whether to adopt family planning methods also entail considerations of social and economic constraints. Sobo's work in Jamaica highlights the importance of issues of power, gender relations, and trust involved in the use of contraceptives (Sobo, 1993a, 1993b). In other contexts, such as Bangladesh, where use of contraceptives may invoke a husband's anger and violence, women may prefer to use contraceptives that can be administered clandestinely and infrequently (Stark, 2000).

Studies of contraception have also entailed the study of the health care systems delivering services. Anthropologists have studied the ways in which delivery of services reflects the broader social and political context and the quality of the relationships between health workers and their clients. Maternowska's (2000) study of a family planning clinic in Haiti provides an analysis of the power relations and how these reflect and perpetuate the ideologies and political and economic realities of wider society. Thompson (2000) describes how in Chiapas, Mexico, within the context of an ongoing guerilla campaign by indigenous people against the state, family planning is suspected of being part of a genocidal campaign to limit the number of indigenous people. As local elites, health care workers can reinforce the views of local people as ignorant and ignore or deride the fears

and side-effects reported by users (Nichter, 1996b; Whittaker, 1996).

PREGNANCY OUTCOMES

In parallel with public health interest in maternal and child health during the 1960s and 1970s, ethnographic studies drew attention to the diverse ways of managing pregnancy, childbirth, and mothering (see the entry Birth). The management of pregnancy, birth, and the postpartum period has important consequences for women's reproductive health. Long-term complications of pregnancy and childbirth include uterine prolapse, fistulae (holes in the birth canal that allow leakage of urine or feces from the bladder or rectum) incontinence, painful intercourse, and infertility. Obstructed labor can cause permanent nerve damage causing loss of sensation in the feet and legs, and infections can cause pelvic inflammatory disease, damaging the reproductive system. Although there is a large anthropological literature on birth and maternity, there remains scant material on women's experiences of such conditions.

In many cultures, the postpartum period is defined as one of vulnerability for both mother and child and is characterized by a reduction of household and work responsibilities, minimal social interactions, and support from female kin. Appropriate actions taken through the postpartum period are also believed to ensure a woman's continued reproductive health, strength, and beauty in many cultures. In a number of Southeast Asian cultures, the practice of "mother roasting" following birth involves a period during which the new mother rests close to a constantly burning fire for a period that varies from several days to several weeks as part of a measure to restore the humoral balance to a woman's body. Childbirth causes a "cold" state requiring the gradual restoration of heat to her body (Manderson, 1981; Mougne, 1978; Rice & Manderson, 1996; Sich, 1981; Whittaker, 1999).

Postpartum practices also involve dietary restrictions. Foods may be avoided due to their humoral status as "cold" foods, or for metaphorical reasons, for example some strong smelling foods are believed to affect the quality of the breastmilk. Anthropological studies of dietary practices and restrictions during pregnancy and in the postpartum period have also helped clarify to what extent such practices may negatively impact upon women's health and the pregnancy outcome (Laderman,

1983; Manderson, 1986; Nichter, 1996a). Laderman (1983, p. 70) found in her study of Malay postpartum diets that many foods in the unmarked, "safe" categories are those essential for life, whereas foods in the "dangerous" categories are supplementary foods that are easily removed or reduced in the diet.

Despite an enormous literature on family planning, birth, and maternity, there is little written about the distressing events of miscarriages, stillbirths, and neonatal deaths. As Cecil suggests, this lack of anthropological interest in pregnancy loss is surprising given that it highlights fundamental issues such as the definition of when life begins, when and how a fetus/baby is defined as human, and at what point a child is admitted into the social order (Cecil, 1996; Morgan, 1990). A number of studies in Western countries highlight the difficulty in defining pregnancy loss in Western cultures which assume successful outcomes to pregnancies, glorify motherhood, and evade the experience of death (Hey, Itzin, Saunders, & Speakman, 1989; Lovell, 1983; Oakley, McPherson, & Roberts, 1984). Common themes run through accounts of pregnancy loss cross-culturally (Cecil, 1996). First is the emphasis upon women's responsibility to maintain a healthy pregnancy. Across many societies greater emphasis is placed upon prohibitions on activities and diet by women, providing commentary on existing notions of gender in a given society. Another common theme is the relationship between the fetus and the supernatural. In many cultures the fetus is defined as between the two worlds, with complete human status not ascribed until some later point, sometimes years after birth. Finally, pregnancy loss draws out the importance of understanding social and gender relations, as miscarriage is commonly defined as caused by the intentional or unintentional actions or desires of another human agent.

The ferocious debate over abortion raging in the United States inspired a number of studies analyzing abortion as a practice and as a political and social construction and its relationship to the social and economic context, transformations in gender relations, and changing sexual culture. Feminist analyses of abortion history, practice, and politics within the United States (Luker, 1984; Petchesky, 1990) demonstrate how control over reproduction is a critical site of contest, reflecting broader economic, social, and ideological concerns over women's status and roles, and competing constructions of gender relations, sexuality, and motherhood. Luker (1984) and Ginsburg (1989) gave insight into the worldviews and

social circumstances of activists on both sides of the abortion debate and the reformulation and redefinition of gender oppositions. Until recently few ethnographic studies considered the meanings of abortion in other cultures. Exceptions include studies on the *mizuko kuyo* rituals for aborted fetuses of Japan (LaFleur, 1992), and edited volumes detailing emic understandings of abortion and menstrual regulation within various social contexts (Githens & Stetson, 1996; Indriso & Fathalla, 1999; Rylko-Bauer, 1996). Whether in countries with restrictive abortion laws or not, the studies in these collections highlight the relationship between the social and ideological context, the economic situation of women, and the quality of abortion care they can access.

INFERTILITY AND FERTILITY ENHANCEMENT

The links between the moral order and reproductive health are particularly marked in cases of infertility. The inability to bear a child is understood to reflect moral status, and in particular is usually blamed upon the woman who may suffer abuse and ostracism. In Africa, infertility carries a grave social stigma, and there is an elaborate range of traditional remedies used to address it (Ebin, 1994; Kielmann, 1998). Likewise, Chinese medicine reflects the cultural emphasis placed upon fertility (Farquhar, 1991) and women are often subjected to intense traditional and biomedical interventions to conceive (Handwerker, 1998).

The dissemination of new technologies for prenatal testing, fertility enhancement, selective reproduction, and cloning technologies, as well as new contraceptive technologies, including male contraceptives, pose new examples of the intervention of biomedicine into reproduction and its social impact. Feminist researchers have questioned the value and effects of some new reproductive technologies and the complex ways in which women are positioned in their use of these technologies and how they gain and lose power over reproduction in the process (Birke Himmelweit, & Vines, 1990; Franklin, 1990; Rapp, 1990, 1991, 1999; Sandelowski, 1990, 1991). For example, women's access to and choices about prenatal testing is mediated by differences in class position, racial-ethnic, and religious backgrounds and provides another example of "stratified reproduction" (Lock, 1998; Rapp, 1999). Surrogacy arrangements are also

challenging kinship relationships and definitions (Kaplan, 1999; Modell, 1989). Although these technologies are increasingly available in developing countries, there is little work on the practices and meanings of amniocentesis and other reproductive technologies such as in-vitro fertilization (IVF) in these settings.

REPRODUCTIVE TRACT INFECTIONS

Reproductive tract infections, including sexually transmitted diseases (STDs) are a major cause of infertility, genital cancers, pelvic inflammatory disease, ectopic pregnancy, poor pregnancy outcomes, and infections in neonates, and are often less symptomatic, more easily contracted, and have more serious and life-threatening consequences for women than for men. For example, chlamydia infection is a common STD with serious consequences for women's health including increasing risk of ectopic pregnancies, infertility, and neonatal morbidity (Millar, 1987). Human papilloma virus, the causative agent of genital warts, is associated with cervical cancer. STDs are socially influenced by such factors as the number of sexual partners, use of contraceptives, sexual behaviors, and general health care practices. Beliefs and meanings surrounding gender and sexuality, fertility, STDs, hygiene, and health care are all crucial to developing prevention strategies and reducing the impact of STDs, along with studies of the psychosocial consequences of infection and its economic consequences.

There is a relatively small literature relating to reproductive tract infections in men and women. In part this is because these topics are extremely sensitive and in many cultures associated with shame and social stigma. While the incidence of reproductive tract infections and other conditions in developing countries is substantial, many women do not seek treatment from the formal health sector for these problems, or else postpone treatment until the condition is acute. Work conducted in Vietnam (Gammeltoft, 1999; Whittaker, 2002), in Thailand (Boonmongkon Nichter & Pylypa, 2001; Whittaker, 2000), and among Vietnamese migrants (Kendall, 1987), concentrates upon the ethnophysiology of vaginal discharge and its relationship to ideas of strength, humoral balance, and cleanliness. The presence of vaginal discharge may be associated with a "dirty" womb and may be believed to indicate a transgression against the moral order. Sobo's (1993a, 1993b) study of

Jamaican ethnophysiology explores how the body and culturally constructed idioms of health and sickness serve as metaphors for the social and moral order. In Thailand, understandings of the causation and detection of cervical cancers are linked to ideas about the strength of the womb, its cleanliness and dryness, and the presence of an injury or infection which is understood to develop into an ulcer (Boonmongkon et al., 2001). Such understandings have public health ramifications for cervical cancer screening programs and notions of risk (Chavez, Hubbell, McMullin, Martinez, & Mishra, 1995). In South Africa, pap smears to check for cervical cancer are believed to be a preventive measure to clean the womb (Wood, Jewkes, & Abrahams, 1997). In Northeastern Brazil, campaign messages linking cervical cancer with sexual activity are interpreted by many women to mean that once a woman is no longer sexually active she need not continue to be screened (Gregg, 2000).

There remains little anthropological research on male reproductive health. Apart from early studies on ritual or informal couvades (Browner, 1983; Riviere, 1974) and male initiation, there has been little attention paid to male ethnophysiology, attitudes toward infertility, their roles in sexual negotiation, and reproductive decision-making (Rosen & Benson, 1982; Whiteford & Sharinus, 1988), roles in birth (Ebin, 1994), experience of paternity (Katz & Konner, 1981), and practices surrounding STDs. For example, Nichter describes men's use of self-medication for the treatment of suspected STDs (Nichter, 1996c) and prophylactic practices to avoid infection, such as washing the penis in disinfectives and the consumption of purges. Recent programs promoting male involvement in family planning and HIV/AIDS programs have encouraged research in these fields.

SEXUALITY AND HIV/AIDS

In their review, Davis and Whitten note that anthropological approaches to the cross-cultural study of sexuality typically reflect prevailing values in the West at the time (Davis & Whitten, 1987). Sexuality remains a provocative subject area with a range of ethical and methodological difficulties. There remain few detailed ethnographic studies on sexuality and sexual health (Vance, 1991), especially in relation to aging and sexuality, youth sexuality (Burbank, 1988; Manderson & Rice, 2002), homosexual practices (Taylor, 1985), sexual violence, transsexualism,

or other cross-gender behavior/third gender identification in cross-cultural settings (Nanda, 1985; Nanda & Francher, 1980; Shah, 1961). Little anthropological work has explored gender reassignment and sex change surgery.

Much of the recent work on sexuality is in response to the advent of HIV/AIDS (see the entry HIV/AIDS). How people categorize the disease affects their perceptions of risk and preventive behaviors (Ingstad, 1990; Lyttleton, 2000). Farmer's influential ethnography traced the emergent collective representations of AIDS in a rural village in Haiti across six years (Farmer, 1992). From associations with outsiders, villagers gradually incorporated AIDS into local understandings of illnesses produced by dirty blood, to a more severe form of a locally defined illness. As villagers had direct experience of the illness through infected people, AIDS became defined as a "sent illness" and associated with TB. He traces the increased politicization of AIDS within the discourse of Haitian people and the political economy of AIDS through which poor people are at greater risk.

How people categorize their sexual encounters also affects their perceptions of risk. Parker (1987) shows how the sexual categories of Brazil are based on notions of passivity and activity and are not absolute. He noted that the very notion of safe sex runs counter to Brazilian notions of eroticism and that campaigns that depend on homosexual identity would be limited in their impact. Studies of commercial sex workers also point to the need to understand sexual networking and how sex workers differentiate between clients and intimate others and factors contributing to the use of condoms (Renaud, 1997).

Studies of HIV/AIDS also include attention to the social consequences of the disease for people infected, but also their families and communities (Barnett & Blaikie, 1992). Because of its associations with sex, particularly non-monogamous, commercial, or homosexual sex, intravenous drug use and blood, HIV/AIDS has evoked stigmatization and fear (Quam, 1990; Songwathana & Manderson, 2001).

CONCLUSION

The meanings, beliefs, and practices surrounding reproduction are structured historically and culturally by local and global forces (Ginsburg & Rapp, 1991, 1995; Greenhalgh, 1995; Jolly & Ram, 2001; Ram & Jolly, 1998). Reproductive experiences are structured by

macro- and micro-relations of power, class, and gender politics in which relationships of power act selectively to encourage and empower certain groups of people to reproduce (Ginsburg & Rapp, 1991, 1995; Handwerker, 1990). An anthropology of reproductive health draws the researcher into the fundamental anthropological question of the problem and process of people's agency in daily life (Carter, 1995; Lock & Kaufert, 1998) and the degree to which intimate decisions, behavior, and practice are structured by social institutions, and the political economy. As demonstrated in the studies above, understanding of reproductive health behaviors and practices requires familiarity with the social, economic and cultural context, general therapeutic understandings, notions of embodiment, and core cultural concepts within a cultural setting. Large gaps remain in our knowledge of cultures of reproductive health and pose epistemological and methodological challenges for the discipline of medical anthropology.

Health Conditions and Diseases

Alcohol Use

Dwight B. Heath and Irene Glasser

The use of alcohol is a part of the social fabric of many cultures in the world and has been so since ancient times. There are many and varied uses and outcomes of such use, some of which are closely related to the health beliefs and practices. Ethnographers have long described these, and medical anthropologists in recent years are actively engaged in dealing with the subject in practical and applied ways.

It is important at the outset to recognize that there is much more to alcohol than *alcoholism* and that much drinking has nothing to do with drunkenness or alcohol-related problems. Furthermore, even colleagues in other disciplines generally agree that nothing less than a biopsychosocial perspective is necessary if one is to understand alcohol and its effects. Nevertheless, there are important implications that are specific to the field of medical anthropology.

ALCOHOL AND ALCOHOL USE

Several types of alcohol are known, but ethanol is of special interest to anthropologists, having long been an influential component of many beverages among a large portion of the world's population. A relatively simple chemical compound (C_2H_5OH), it often occurs naturally without human intervention, although the hominid imagination has resulted in manifold elaborations and refinements of the basic processes of fermentation and distillation. In fermentation, it is microorganisms that convert carbohydrates to sugars, with ethanol as a by-product. Distillation results from the heating of a fermented liquid, whereby ethanol can be further concentrated because it has a boiling-point lower than that of water.

Although we routinely speak as if people drank alcohol, it is widely recognized that fermented beverages (beers, ales, wines, pulque, chicha, hard cider, and a variety of other brews) contain less than 20% ethanol (by volume), usually less than half that much. Distilled beverages (spirits or liquor) contain between 40% and 90%, usually in the lower part of that range. There is an

enormous variety of beverages that contain alcohol based on a vast range of raw materials, additives, aging, and other considerations.

Ethanol readily diffuses into the blood and hence through the body. A psychoactive (or mind-altering) effect is commonplace with minute concentrations; such changes in thought and action are usually recognized and often actively sought and valued. There are marked differences in those effects depending on the dose, the drinker, and the setting. In terms of dose, the overall volume of a drink and the concentration of ethanol within it determine how much alcohol has been ingested. Being water-soluble, a given amount is more readily dispersed through a small body, or one with less fat. Because of adaptive changes that occur in the brain, previous repeated alcohol experience can enhance the body's tolerance to alcohol, lessening its behavioral impact. The presence of food delays absorption, and carbonation, exercise, or altitude accelerate it.

The psychoactive quality of alcohol relates to its effect on neurotransmitters in the brain. This can result from a minute concentration of ethanol in the blood. For most individuals, the effect is biphasic, stimulant for the first few drinks, and then depressant. Endogenous processes of metabolism can reduce ethanol within the body; various enzymes and the liver gradually convert it to carbon dioxide and water.

From an anthropological perspective, it is noteworthy that there are customary uses, attitudes, and behavior patterns associated with alcohol, even when it is ingested at levels that do not significantly affect the physiology. Drinks containing ethanol often serve as basic beverages, integral to the diet; others tend to have important symbolic or ritualistic uses and associations. Drinking may be an accompaniment to a meal or it may be an act valued and practiced in itself. Solitary drinking occurs, although drinking is usually a social act, often viewed as enhancing sociability and symbolizing camaraderie. It is the very diversity of drinking and its outcomes that have made it a subject of intense ethnographic study.

Although acute observers had long commented on alcohol, there was little systematic investigation of its uses, misuses, and outcomes until the mid-20th century. At that time, isolated chemical, biological, and physiological studies began to be published in a handful of journals, and within a decade a few introductory textbooks appeared. Such studies often were presumed to have universal relevance, although they were conducted on small samples of undergraduate students, homeless men in industrialized cities, institutionalized patients, prisoners, or other unrepresentative categories, usually with “White” males predominating. These marked the beginnings of what has grown to be a multidisciplinary field of alcohol studies (or, some would even say “alcoholology”).

ANTHROPOLOGY AND ALCOHOL STUDIES

The ethnographic or cross-cultural perspective was important early in establishing the simple fact that differences in attitudes, behaviors, and outcomes exist and are important among different populations. Interested observers had long been writing some insightful descriptions but they tended to be fragmentary and scattered in recondite sources. The rapidly expanding cadres of social and cultural anthropologists in the 1950s and 1960s brought a sharper focus to what they called drinking patterns, not defining that term precisely but implicitly referring to who drank, what they drank, when, where, how, in the company of whom, while doing what else, and with what apparent consequences. In addition to providing ethnographic descriptions and analyses of drinking patterns, they have spelled out the sociocultural model (emphasizing the importance of meanings and values as well as consumption), offered some constructive comments about typologies and diagnostic criteria, studied populations that are difficult to survey, developed survey instruments that are appropriate to specific subcultures, evaluated various policies and their effectiveness, and worked on expanding and improving various modalities of prevention and treatment.

Another way in which anthropology had a major impact on alcohol studies in those early years was in providing some broad theories about the roles of drinking in various cultures. A number of studies were conducted that were hologetic in nature, in which scholars used a

sample of societies from throughout the world to test general theoretical hypotheses at the societal level. The data most often came from ethnographies in which drinking behavior was described, along with other aspects of the culture. Among the associations found through the hologetic method were that drinking and or drunkenness appears to have served to relieve anxiety, to cope with feelings of dependency related to child rearing practices, or to feel powerful. Communal sobriety was found to be associated with corporate kin groups, residence near the husband’s family, bride price, and a concentrated form of settlement. Such cross-cultural studies and their associated models were especially appreciated at a time when there were few alternative conceptualizations available.

The vast and varied experience in the cross-cultural record raised serious questions about findings that treated drinking as if it were uniform and alcohol as if it were a universally invariant variable. Notably, the voice of anthropologists has been influential in countering or at least tempering several kinds of determinism that prevailed at various times in relation to drinking and a few such deserve to be mentioned. It was long believed that alcohol had a rapid pharmacological impact, supposedly deadening “higher levels” of the brain that were said to be the centers of control over inhibitions. A brief but convincing review of ethnographic and historical sources, MacAndrew and Edgerton’s *Drunken Comportment*, appears to have successfully helped convince scientists that some environmental factors (beyond chemistry, physiology, and personality) are important in understanding how people behave during or after drinking. Another success for anthropologists in the field of alcohol studies was the increasing recognition that uniform modalities of diagnosis, prevention, and treatment, whether for alcoholism or for a variety of alcohol-related problems, were neither efficient nor effective, especially when populations with different cultures or subcultures were concerned.

Within the broad field of alcohol studies, many different kinds of work progressed at different rates. Early efforts at definition and classification often preceded compilation of data, and considerable effort was devoted to practical applications from the outset. Because long-term heavy drinking harms many organ systems and because extreme intoxication is both highly visible and often harmful to the drinker as well as to others, that aspect of use attracted attention out of all proportion to its actual occurrence. Alcoholics, alcoholism, and types of each continue

for some to be more interesting than other aspects of alcohol, and funding for research is overwhelmingly focused on attempts to counter negative outcomes.

From a psychological perspective, there were efforts to identify the causal roots of heavy drinking, and to characterize an “alcoholic personality” type. Studies of twins were of special interest in the hope that investigators could differentiate between hereditary and environmental factors, isolating nature from nurture; the findings from these studies in fact implicate both. Tracing the association of psychological factors such as motives, and expectancies with alcohol and drinking continues to attract attention. Social psychologists also study the effects of media and advertising of alcohol.

Sociological studies of drinking behavior have specialized in the following ways: using questionnaires and surveys, they attempt to assess quantity and frequency of drinking among populations as large as entire nations; categories are differentiated and compared on the basis of age, gender, socioeconomic class, and other variables; and linkages are made between such data and reports of alcohol-related problems.

Biological studies of alcohol have become increasingly specialized as knowledge has increased and techniques have been refined. From early questioning about whether alcoholism was a disease, we have progressed to the point of knowing which allele triggers facial flushing in some when exposed to ethanol. Much work is done at the neurological level, and the long-term effects of different beverages are often attributed to trace elements.

A number of issues of definition have occupied the field of alcohol studies in its short history, and an anthropologist should be aware of them because some of the implications still reverberate (if only implicitly) in views that are expressed by others who address similar situations from various disciplinary perspectives. There was considerable controversy over whether alcoholism was a disease and then over whether it was unitary or of various types. The concept of addiction was largely supplanted by dependence, and much attention has been paid to progressive delineation of special observable criteria for the diagnosis of different kinds of disorders.

Now the international community of scholars, many of whom are also outstanding in more traditional academic disciplines, are able in recent decades to take part in international conferences and to publish in books and journals in the fields of alcohol or addiction studies.

There is often overlap with studies of illegal drugs, partly because poly-drug use is increasing among individuals, partly because drinking often tends to be treated socially in terms that are similar to drug-taking, and because the effects of alcohol and drugs on brain neurobiology are similar.

When a few interested social scientists organized an Alcohol and Drug Study Group (ADSG), they did so within the American Anthropological Association, and when that underwent major reorganization requiring that each of the many interest groups become affiliated with an intermediate sub-disciplinary society, ADSG was accommodated within the Society for Medical Anthropology.

Alcohol as a Window on Culture

In reviewing the vast and scattered anthropological literature on drinking, it becomes readily apparent that alcohol can serve as a convenient window through which to appreciate the many and varied aspects of cultures. A few brief examples illustrate such linkages; to diet, medicine, religion, children-rearing, gender differences, attitudes, economics, and age-stratification.

To be specific, alcohol is often an integral part of diet or shows close links thereto. Homebrews throughout Africa, Asia, and much of South and Central America are not only the predominant beverages for people of all ages but also provide vitamins and minerals that are otherwise lacking. Medical values were attributed to drinking long before they were amply documented in scientific terms. Alcohol was served to spirits of the ancestors in China 3,500 years ago, as it still is there and elsewhere. Although some groups insist that drinking is a prerogative of adults, Zulus in Africa (like many groups) favor beer for infants, supposedly to build strong bones and to clean the blood. Although men almost everywhere drink more than women do, there are specific contexts in which females are expected or even required to drink. Whereas Muslims are exhorted in the Koran not to drink, wine is a sacrament among some Christian groups. In czarist Russia, as in many jurisdictions today, a major portion of the government’s budget derived from the production and sale of drink. In many societies, drinking should be done only in sequence of descending age when men are in a group; in others, drinking together (often with a toast) is important. There are innumerable instances in which paying attention to alcohol, its manufacture, distribution,

consumption, and meaning articulate in significant ways with many other aspects of culture.

The inclination to put great weight on emic statements (what the “insiders” say), combined with a slant toward cultural relativism that characterized many social and cultural anthropologists in the 1960s, and a strongly functionalist perspective (attending to how the parts of a cultural system work together) resulted in interpretations of the roles of alcohol among various populations as being predominantly beneficent. A striking example is the Camba of Bolivia, among whom nearly all adult males routinely drink to the point of drunkenness for days at a time, using an extremely strong beverage. Nevertheless, they claim that doing so does no harm to them or to others.

As we look at the place that such drinks hold in various societies, a striking ambivalence can be noted. We have already seen that different populations have diverse—often diametrically opposed—views about alcohol. Apart from that, often, within the same society, it is enjoyed as an adjunct to celebration at some times and sought out as a consoling refuge at others. Even while convincing scientific evidence in recent years demonstrates that moderate use of alcohol is healthful for most people, it is equally recognized that long-term or immoderate use results in many accidents as well as grave damage to a number of organs through the body.

Alcohol Abuse and Alcohol-Related Problems

There is ample justification for ambivalence about alcohol. Even while appreciating the many benefits derived from some of kinds of drinking, one may realistically fear the harms or risks that are associated with others. Recent studies suggest that intoxication is often highly correlated with a wide range of alcohol-related problems, ranging from headaches and hangovers to absenteeism at school or work; from generalized aggression to spouse or child abuse, including homicide, suicide, illnesses, accidents, and fetal alcohol effects. Drinking and driving is of special concern because its consequences affect not only the driver but also others on the road. Specifically, a blood-alcohol concentration of over 0.10% can realistically be viewed as risky at any given time, and chronic drinking at that level tends to be injurious to the body.

In recent years some anthropologists have joined laypersons in being ambivalent about alcohol use.

The reportorial ethnographic perspective on drinking was derided by some as a case of “problem deflation,” especially in contrast with the epidemiological or public health perspective, which some of the same scholars warn about as “problem amplification.” By paying special attention to dominant patterns within populations, ethnographers tended to emphasize the integration of drinking with other aspects of culture, often noting associated social and individual benefits. It is not that they failed to recognize that some risks or harm were occasionally associated with drinking, but that they chose not to emphasize them. What some misconstrue as a controversy between pro- and anti-alcohol researchers can more accurately be described as equally valid emphases on alternate aspects of the complex reality of drinking behavior and its outcomes.

RECENT TRENDS AND PRACTICAL IMPLICATIONS

In the 1970s, anthropologists increasingly turned from descriptive ethnographic work to more applied or practical studies in many fields, and this was especially true with respect to alcohol. Sources of funding also increased markedly in fields of public health and social welfare, while simultaneously decreasing for non-problem-oriented ethnography. Anthropologists have increasingly been employed by institutions that emphasize the costs rather than an impartial view of drinking, so that more recent anthropological writings on the subject have similarly tended to emphasize the abuse rather than use of alcohol, various kinds of risks and harm of alcohol consumption, the prevention or lessening of such problems, and treatment to help problem drinkers.

Anthropologists have never played a dominant role in the emerging field of alcohol studies, but they continuously provided minority views that have been important reminders to others who have a less global or holistic approach. At the outset, a confrontation with the reality of cultural differences provided a salutary challenge to understandings that had been built up on the basis of “mainstream Middle Americans.” Critical analysis of drunken comportment in historical and ethnographic perspective disproved the dominant pharmacological interpretation of disinhibition. Transnational studies showed that how people drink must be considered in looking at problems, and not merely how much they drink.

Some Milestones

In one sense it is disappointing that anthropology has not had more impact on how people use and think about alcohol. In another sense, it is gratifying that so much has been accomplished by so few in a field long dominated by biomedical interests.

Openness to considering cultural differences with respect to alcohol is often stated as a goal although many in the field must be reminded of it when dealing with specific issues. A bibliography, a periodic newsletter, and a few anthologies and occasional review articles, or special issues of journals on various topics, make it easier now to keep abreast of the diverse and scattered literature.

Epidemiology and Public Policies

The problem aspect of alcohol use was a focus of interest not only for scientists but also for practitioners in the fields of health and welfare, and for administrators seeking appropriate policies. To demonstrate that it should be of broad social concern, epidemiological studies were undertaken on a rapidly increasing scale. That became a major part of a combination of influences that converged to shape alcohol studies in the 1980s. Most psychological and social problems became increasingly medicalized as physicians extended their influence and assumed new importance throughout Western cultures.

Social and cultural research was generally marginalized by government and other funding agencies. Biochemistry, neurology, and genetics came to dominate the field of alcohol research.

The World Health Organization (WHO) was active in promulgating the idea that alcohol-related problems occurred universally in a direct and invariant proportion to the consumption of alcohol. They posited that not only for individuals but also, using average per capita consumption per month or year, among populations. Data from their own survey often contradicted that axiom, as when Luxembourg, France, Portugal, and some other countries that rated at the top of the international list for consumption tended to have low rates of most alcohol-related problems, whereas Ireland, the United States, and some others with much lower consumption reported higher rates of most problems. Nevertheless, a "control of consumption" model emerged as dominant among those constituencies who

recommend policies. They continue to emphasize adoption of a bundle of measures intended to lessen such problems. These include increasing taxes on beverage alcohol, restricting advertising, mandating health-warning labels, increasing the minimum legal drinking age, curtailing sales outlets and hours of business, and other measures aimed at decreasing the overall consumption of alcohol.

Many individuals abstain and even so-called moderate drinkers generally consume very little. It should not be surprising that most control measures cut drinking among non-abusers while hardly affecting those who engage in heavy drinking. It is a concern that so little has been achieved in the way of reducing harm or preventing problems.

The inordinate emphasis on the consumption model has resulted in an imbalance in research and writing about alcohol by those who claim to have a primarily social or cultural interest. By far the greatest portion of such work is epidemiological, correlating the quantity and frequency of drinking with various alcohol-related problems and compiling quantitative data on alcohol as used by diverse demographic categories. Most such studies are conducted by means of social surveys, with close attention to the exact wording of the instrument or questionnaire, and to the process of sampling within the large population. Such studies can be conducted by unskilled personnel using standard survey instruments, and they yield quantitative data that can be tabulated and statistically manipulated, have the superficial appearance of "hard science," and are easily communicated in visual format. Unfortunately, too often even the principal investigator is at a loss to explain or to interpret findings in terms that would have meaning to the subjects or to colleagues.

By contrast, most ethnographic studies require close and sustained work by skilled observers and yield qualitative data that do not easily lend themselves to tabulation or visual presentation. Brief papers based on such qualitative studies too often are regarded as little more than interesting anecdotes and few bother to read the expository style that is often judged to be "soft" in comparison with numerical findings. Those who mistakenly confuse numbers with science give credibility to quantification, even while many methodological issues remain questionable among survey practitioners.

It is becoming commonplace to give lip service to the ideal of combining qualitative with quantitative

methods and data in alcohol studies, but only a few pioneers are doing it systematically. One encouraging example is the use of ethnographic observation and interviewing as a preliminary to survey work. In that way, it is possible to get a good feel for what issues are important to the population and what terms are appropriate in the formation of questions before the instrument is created. Another imaginative combination is the subjecting of open-ended interviews to detailed content analysis, so that it is possible to quantify what the respondents said in their own words, rather than relying on a few pre-coded forced choices among alternatives worded by someone else.

Education as Prevention

It is primarily anthropologists who proposed the socio-cultural model (as an alternative to the consumption model discussed above) as a means of preventing or lessening alcohol-related problems. Centuries of experience demonstrate that (contrary to what many believe) drinking at an early age, drinking every day, or drinking more than two drinks at a sitting, are not major factors in identifying who will have alcohol-related problems (as throughout southern Europe), suggesting instead that familiarity with alcohol and its effects, an unglamorous view of drinking, and learning to do so with food and in the company of kin may be protective.

On the assumption that sociocultural integration of alcohol is preventive, education about it seems to be called for to remedy widespread ignorance and inaccurate stereotypes about drinking and its outcomes. Numerous experiments with brief educational efforts, often unrelated to other topics and taught by people who are not knowledgeable, relying heavily on scare tactics, have been discredited, but there have been few attempts at long-term accurate teaching in ways that relate alcohol in credible ways to other things people care about. Rather than attempting to diminish drinking by everyone, such an approach would probably help abstainers to understand their choice as well as help some of those who might otherwise drink inappropriately, creating problems for themselves and others.

Alcoholics Anonymous

Alcoholics Anonymous (AA) is a fellowship of individuals whose primary concern is to stop drinking.

An anomalous organization with no dues, formal membership, or budget, it has millions of attendees and a meeting can be found in most countries around the world almost anytime. AA has served as the model for numerous other “self-help” (or 12-step or mutual support) groups involving addicts, overeaters, gamblers, and others. An outgrowth of an evangelical group, AA early dropped references to “God” in order not to alienate prospective affiliates, and substituted “Higher power” as that to which one should surrender. In socialist Poland, even that allusion was deleted. Other striking adaptations have occurred in different cultural contexts. Far from protecting anonymity, many Mexican AA groups share meals and other social services with poor and ill neighbors. In France, some forgo anonymity, finding a sense of liberation in declaring their freedom from alcohol. It is not surprising that AA has become the object of many interesting studies; special contributions of anthropologists to that literature relate largely to discourse analysis, ritual, folklore, and group dynamics.

Treatment and Alternatives

Drinkers who feel that they have been harmed by alcohol have access to a broad range of treatments, under the best of circumstances. These range from month-long in-patient medical programs to psychiatric analysis, aversion therapy, pharmaceutical interventions, or brief counseling. An enormous literature describes and evaluates most such treatments, and it appears as if each is about equally successful—for different individuals. What anthropologists have contributed to the subject varies depending on the setting. When halfway houses were numerous, they were often sites of intensive ethnographic observation. Asian alternatives emphasizing prayer and monastic asceticism have been studied, as have some Native American initiatives that combine spirituality, traditional rituals, and cultural pride.

Suspicion about stereotypes and openness to considering minority adaptations have involved anthropologists in some controversies that are peculiar to alcohol studies: evolution of the concept that alcoholism is a disease, challenging the presumption that anyone who once has a problem with drinking can never again drink without becoming drunk, and investigating the otherwise ignored phenomenon of “spontaneous recovery” (abandonment of heavy drinking without any help from others).

Only early in the 1970s did a few individuals and organizations that focus on prevention and treatment of problem drinking begin to recognize that there was a need to make programs “culturally appropriate” or “culturally sensitive” if they were to achieve any success, especially with minority populations. It was some time before those new code-words were translated into action, but there has been gradual improvement from the time when all such programs were based on simplistic views of a supposedly mainstream shared culture. At first, there was little more than an attempt to hire a few token individuals who spoke languages other than English, or to pay some attention to various forms of family, different gender roles, or attitudes toward work and leisure.

Another flurry of activity was intended to identify and characterize various patterns of belief and behavior, and to adapt schedules in minor ways in order to improve communication and cooperation with various minority populations. Unfortunately, the few categories of ethnicity that were identified in the U.S. census (“White,” “Black,” Hispanic, American Indian/Alaska Native, Asian/Pacific Islanders) became widely adopted as if they were meaningful, even though those terms have little to do with self-identification or cultural or demographic regularities. It is noteworthy that anthropologists were among the first and most persistent in challenging those supposedly “ethnic” categories, and the census now permits self-identification rather than implying broad cultural uniformities that do not exist.

Much has been written about the prevalence of drinking and drinking problems among so-called marginal populations, with “culture-loss,” “acculturative stress,” “sociocultural deprivation,” or simply “acculturation” glibly cited as the causal factor. As we have learned more about drinking, attitudes, and the great variety of problem drinkers and drinking problems, it has become increasingly clear that such oversimplification tended to obscure rather than to resolve the real issues. For example, acculturation has been variously measured on surveys by place of birth, national heritage of father, mother, or friends, or neighbors, years of residence in the country, language used at home, or other indices that bear little relation to stress, identity, or culture change. Of the many meanings that are applied to “anomie,” the one that does appear to have relevance, with reference both to individuals and to communities, implies a combination of loss or repudiation of traditional skills and values, major restriction of choices in terms of workaday activities,

disruption of channels and means of socialization, and a feeling that elders have little to contribute that is relevant to the present situation. First Nations in North America and Australia have been explicitly compared in those terms where major communal disruption is linked with alcohol abuse, and other populations around the world seem to fit the model. Subsequently, as various reference groups became better organized, secured funding, and developed their own programs, cultural appropriateness became an occasional reality. National and other local traditions came into play; significant tribal differences were recognized; earlier stereotypes were disproved and rejected. Among Native Americans, a number of forms of native healing have been adapted in effective ways, such as Sweatlodge, Sundance, and others. Often these combine traditional purification and healing rituals to provide strengthening of self-concept, pride in heritage, and a return to a world-view that had been abandoned or rejected.

There exist some examples of approaches to treatment of alcohol-related problems that depend on knowledge of cultural and subcultural groups. For example, anthropologists have played a major role in engaging traditional healers such as spiritists, shamans, clerics, and elders as treatment providers for those with drinking problems; spiritists for some, shamans for others, clerics, elders, and others. Commonly there is also some brokering so that such specialists may collaborate with social workers and practitioners of Western medical methods. Clients and their kin often have greater comfort and confidence in dealing with familiar healers, even if some specific procedures are syncretic.

Attempts to Universalize Discourse

Since its inception, the WHO has paid considerable attention to alcohol and related problems as pertinent to public health. That organization encouraged the broad dissemination of epidemiological studies using translations (and later, adaptations) of survey instruments that had been developed in major Western research centers. In an attempt at standardization, workgroups and special committees often labored over defining terms, and spelling out objective diagnostic criteria. Because English has become the universal language of science and because so many non-Western practitioners and scientists are trained in the United States and the United Kingdom, there was heavy international reliance on conceptualization and terminology that were inextricably imbedded in

thought-patterns of the metropole. It recently became evident that many of those meanings were being significantly misunderstood abroad, even by those who had studied them in English, and WHO has engaged some anthropologists and others in efforts to ensure that research and communication on the subject be better understood transculturally and transnationally.

Anthropology's Contribution to the Understanding of Alcohol Use

Two major continuing contributions of anthropology to the study of alcohol use are in the areas of qualitative methodologies and cross-cultural and cross-national understanding. Anthropology has already pioneered the use of observation, participant observation, focus groups, in-depth interviews, and life histories as methodologies that seek to understand alcohol use from an insider's point of view and in the broadest cultural context.

The qualitative approach is especially useful when investigators seek to understand cultures and subcultures that are different from their own. Studies that link qualitative approaches with quantitative and epidemiological studies can offer us better methods for understanding alcohol use, abuse, and possible culturally compatible treatments.

Long before the field of alcohol studies was recognized anthropologists were contributing to our understanding of alcohol use and its outcomes by observing, analyzing, and reporting drinking patterns among different peoples. There was a brief period when drinking patterns tended to be viewed by those in other disciplines as irrelevant except inasmuch as they related to sheer volume of consumption. At the beginning of the 21st century, drinking patterns have re-emerged in the consciousness of alcohol researchers. They are now being recognized as important by survey-investigators who no longer claim that only consumption matters. There is a scramble to devise quick and easy ways to count and measure drinking patterns in ways compatible with the social survey format.

A few spokespersons for critical medical anthropology have been careful to demonstrate that many alcohol-related problems do not result from specifically individual, constitutional, or personality issues but can be better understood in relation to the historical context emphasizing political economy, that is, primarily relations

of power and wealth. Recurrently, around the world such problems tend to be especially prevalent among the homeless, unemployed or underemployed, migrant workers, minorities who are subject to racial and other forms of discrimination; in sum: the poor and powerless within societies, even those societies that are ostensibly open and allowing mobility. It is as if heavy drinking and drunkenness were an adaptation to systemic frustrations, providing relief from stress, opportunities to act or speak in ways that would otherwise be censored. Such an interpretation has important implications in terms of both prevention and treatment.

Perhaps a breakthrough can be achieved now that drinking patterns have been explicitly identified as crucial intervening variables between sheer consumption and the occurrence of alcohol-related problems. This came about through qualitative studies by anthropologists in which they have identified specific patterns—some behavioral and some ideational—that are associated with the harms and risks of alcohol abuse. Of special importance with reference to populations that are thought to be difficult to study, the traditional methods of participant-observation and non- or semi-directed interviewing are often streamlined to allow short-term assessments that are more congenial to the timetables and budgets of agencies concerned with public health and social welfare. Similarly, greater attention to political economy and relations of power access within social systems promise to enhance our understanding of causes, consequences, and alternatives to problem drinking and drinking problems.

Child Abuse and Neglect

Jill E. Korbin

INTRODUCTION

Child abuse and neglect violate some of our most cherished views of human relationships. Parents are expected to nurture and care for their offspring, providing the foundation for families and societies. Nevertheless, child abuse and neglect have occurred throughout history and across cultures. Child maltreatment became a concerted field of inquiry and a matter of public and professional attention in the United States in the early 1960s (Kempe, Silverman, Droegmueller, & Silver, 1962). Many nations had similar experiences of first denying the existence of child maltreatment within their boundaries, only to later “discover” its existence. This stimulated interest in the broader cross-cultural record (Hrdy, 1999; Korbin, 1981; Levinson, 1989; Scheper-Hughes, 1987; Scheper-Hughes & Sargent, 1998).

DEFINITIONS

Definitional ambiguity has been a major stumbling block in child abuse and neglect research and practice. There has been considerable difficulty in formulating valid and reliable definitions of child maltreatment. Definitions are critical because they influence case identification and thereby knowledge about child maltreatment. Identification of child maltreatment relies on a complex interaction of (1) harm to the child; (2) caretaker behaviors that produced or contributed to that harm; and (3) societal or cultural assignment of responsibility or culpability.

Child maltreatment was initially defined in the medical and social welfare literature in the United States

and Europe during the 1960s and 1970s. Definitions centered on physical harm resulting from acts of omission or commission by parents and other caretakers. Two diagnostic criteria were particularly important. First, child abuse was identified when children had injuries that did not match with their caretaker’s explanations of how the injuries occurred. Second, because child abuse is rarely a one-time occurrence, an important diagnostic sign was the identification of multiple injuries in various stages of healing. The early work on child abuse and neglect focused on children who had been seriously harmed, either by being physically assaulted with resulting injuries or by being neglected with tangible evidence, such as severe malnutrition.

Over the next 40 years, definitions expanded in both the national and international literatures to encompass a broad range of harms to children. The four basic categories of child maltreatment are: *physical abuse*, *physical neglect*, *emotional maltreatment*, and *child sexual abuse*. Neglect may also include *medical neglect* or *educational neglect* if a parent or caretaker does not meet the child’s basic needs in these two areas. Neglect may also include *non-organic failure to thrive*, which involves sustained subnormal growth in an infant that can be attributed to parental deprivation of the infant’s nutritional and emotional needs. A type of child maltreatment that was identified primarily in medical settings, *Munchausen’s Syndrome by Proxy*, is a facetious illness fabricated by a parent, usually a mother with previous medical knowledge and experience. The induced symptoms may be damaging, or even fatal, to the child. *Fatal maltreatment*, in which a child dies from a repetitive pattern of abuse and/or neglect, is often a separate category in the professional literature.

International child abuse efforts have resulted in additional definitional categories. Even though these problems exist in Euro-American nations, the international literature brought them more to the forefront. First, *child labor* is a matter of some controversy in that the anthropological literature has documented the positive effects of children socialized while working alongside their families in agricultural, gathering and hunting, or other subsistence activities. When children's labor becomes exploitive, however, most often with children laboring away from their families in factories or industries making exports, international advocacy groups may include this as a category of child maltreatment. Second, *child prostitution* has been included under the definitional category of child sexual abuse. And, third, *selective neglect*, or *underinvestment*, has been identified in international demographic data through patterns of differential mortality in which some categories of children are less likely to thrive or survive due to medical, nutritional, and other forms of inattention and neglect. One example would be female children in societies with high son preference (Scrimshaw, 1983).

Establishing cross-cultural definitions of child maltreatment has been complex. Just as there is no absolute standard for optimal child-rearing that would be considered valid cross-culturally, there has been difficulty in establishing a universal definition of abusive or neglectful child-rearing. Standards for child abuse and neglect originated in European and North American societies. A long history of anthropological research on cross-cultural child-rearing patterns has shown that European and American cultures are often at odds with child-care practices and patterns in a broader sample of the world's cultures. Defining child maltreatment cross-culturally involves issues of human universals, cultural relativity, and human rights.

Three definitional levels have been suggested for culturally informed definitions of child maltreatment. First, cultural practices vary and what one group considers abusive, another group may consider well within the normative range of behavior. Differences in definitions of child maltreatment that can be ascribed to differences in normative cultural beliefs and practices are not, strictly speaking, abuse since they are not proscribed, at least by the group in question. This does not preclude discussions and evaluations of the relative harm and benefit of different practices, but acknowledges that there is not currently a universally accepted standard for optimal or for deficient child-rearing. Second, idiosyncratic departure

from cultural standards and norms affords an intracultural view that highlights those individuals who violate the continuum of acceptable behavior. And third, societal-level maltreatment of children is sometimes confused with culturally acceptable behaviors. Societal neglect refers to the level of harm or deprivation that a larger political body (e.g., nation) is willing to tolerate for its children (Korbin, 1981, 1997). Because child maltreatment has not always been labeled as such in other cultures, some anthropological works have examined physical punishment (Levinson, 1989) or emotional climate as accepting or rejecting (Rohner, 1986).

INCIDENCE AND DEMOGRAPHICS

In the United States, between 800,000 and one million children are identified as abused or neglected each year as a result of reports to child protection agencies. Between three and five children die from fatal maltreatment each day, and homicide by parents is a leading cause of trauma-related death for children under four years of age. Between one half and two thirds of child maltreatment cases are neglect. Children under three years of age have the highest rates of victimization. Victimization rates are similar for males and females, with the exception of child sexual abuse, in which approximately three to four times more girls than boys are involved.

There is limited data on incidence and prevalence of child maltreatment cross-culturally. While the available evidence suggests that child maltreatment occurs, or has the potential to occur, in all societies, the differential distribution is difficult to estimate. Definitional issues discussed above increase the difficulties in making valid cross-cultural or cross-national comparisons. Despite increasing international awareness, child abuse and neglect are often difficult to recognize or make sense of in the small populations often studied by anthropologists. Because child maltreatment is a low base rate behavior, it may be rare in a small population during a single year of fieldwork. Rare cases that seem at odds with more general cultural patterns, then, may not find their way into the literature. Additionally, it often is difficult to estimate the incidence or prevalence of child maltreatment in societies with high infant and child mortality rates due to disease or malnutrition.

In the United States, there is controversy about whether there are differential rates of child maltreatment

across ethnically diverse populations. Questions remain as to whether a higher proportion of reports in poor ethnic minority populations is due to stresses associated with poverty leading to maltreatment or due to increased scrutiny by public welfare agencies leading to higher reports.

A major difficulty is that categories of “race” or ethnicity are not consistently disentangled from socioeconomic status. Both official report and self-report data indicate that impoverished families are at increased risk of child maltreatment. Because ethnic minority groups are at the greatest risk of poverty, they then appear to have a disproportionate incidence and prevalence of child maltreatment. Additionally, poor and ethnic minority families are more likely to be reported for child abuse and neglect than are European American families even if the severity of the incident is equivalent. Several studies have found that socioeconomic class and ethnicity are the best predictors of whether an incident is considered maltreatment and reported. This pattern has been found in New Zealand as well as in the United States.

ETIOLOGY

The etiology of child abuse and neglect is poorly understood, even within those nations that have the longest history of research and policy attention to the problem. More sophisticated etiological models stress the importance of an ecological framework, with risk and protective factors transacting across the ecological levels of individual factors, family factors, community factors, and factors in the larger sociocultural environment. These complex theoretical models, however, have rarely been adequately subjected to empirical testing and research (Cicchetti & Lynch, 1993; National Research Council, 1993).

A cross-cultural perspective has the potential to enhance understanding of the complex interaction of risk and protective factors that contribute to or prevent the occurrence of child maltreatment. It is not currently known whether common or divergent pathways lead to child maltreatment across diverse populations. For example, does the interaction of poverty and an individual history of child maltreatment have different consequences in different community contexts? Etiological factors should have explanatory power both within and between cultures.

The cross-cultural record sheds some light on categories of children at risk for maltreatment. Even in

cultures in which children are highly valued and rarely punished, some children may receive a lesser standard of care than other children. These categories of children may be identifiable through demographic analyses that suggest differential survival by factors such as gender or birth order. Identification of categories of children at risk also requires knowledge of cultural values on specific child behaviors or traits (Korbin, 1987a).

Circumstances in which children have diminished social supports or in which social networks are lacking or deficient have also been suggested as increasing the risk of maltreatment. Social networks can act either to prevent child maltreatment or to exacerbate the risk of its occurrence. Social networks, on the one hand, provide the context for assistance with child care, for redistribution of children who may be at risk for maltreatment, and for the establishment, scrutiny, and enforcement of standards of child care and treatment. These functions of social networks should diminish the likelihood of child abuse and neglect. On the other hand, some abusive or neglectful families may be embedded in closely knit, but maladaptive networks (Korbin, 1998). Abusive parents may engage with others whose child-rearing attitudes and behaviors are similar to their own. Networks in which attitudes and behaviors toward children tend toward the aggressive or neglectful may provide precisely the kind of role models that facilitate abuse. Network members may be hesitant to intervene or to report maltreatment because their own behavior is similar. They may be fearful that if they report others, they risk report themselves. In addition, network members may be isolated from community facilities and supports and therefore may not know how to access supports or services for themselves or for an abusive parent in their midst. Inequality of power between parents has also been implicated in the etiology of child abuse (Handwerker, 2001).

BREAKING THE CYCLE OF CHILD ABUSE AND NEGLECT

The most frequently cited risk factor in the child abuse and neglect literature is a childhood history of maltreatment. Adults who were abused as children are at increased risk of abusing their own children. However, this “cycle of violence” is not inevitable, and estimates vary as to the precise risk of repeating abuse with one’s own children. Retrospective studies of abusive parents

yield a much higher rate of a cycle of abuse than do prospective studies of abused children. As with other risk factors, abuse in childhood alone is not sufficient to predict problematic later behavior, including becoming an abusive parent. Research has suggested that protective factors, including an important significant other in childhood, good therapeutic intervention, and/or a supportive spouse can decrease the risk of repeating the cycle of abuse.

CONSEQUENCES OF CHILD ABUSE AND NEGLECT

Child abuse and neglect has been associated with increased risk of adverse outcomes. Not all abused and neglected children suffer immediate or lasting consequences beyond their immediate injuries. Nevertheless, abused and neglected children are at increased risk for a range of physical, mental/emotional, and social/behavioral difficulties. The pathways to these outcomes are currently unclear, but involve a combination of compromised brain development and long-term psychological and emotional sequelae associated with their abuse and neglect. Abused and neglected children are at increased risk of school-related difficulties resulting from cognitive and learning difficulties or from emotional adjustment problems. Abused and neglected children are at increased risk of relationship problems stemming from low-self esteem or aggressive tendencies. Abused children are also at increased risk of juvenile delinquency. Girls who have been sexually abused are at increased risk for violence in dating relationships, teen pregnancy, spousal violence, and abuse of their own children. Abused children, particularly sexually abused children, may exhibit symptoms of Post-traumatic Stress Disorder. Abuse in childhood has also been associated with a range of risky health behaviors and suicidal behavior. Cross-culturally, children who are treated with rejection rather than with warmth and acceptance by their parents and care-givers display negative psychological outcomes (Rohner, 1986).

While child abuse and neglect confers increased risk of a variety of problems, much less is known about those factors that promote a healthy or positive development despite the occurrence of abuse. Adults who experienced abuse as children may prefer the term "survivor" over "victim," particularly those who were sexually abused. The term survivor connotes a more active process of

healing than does the term victim which is thought to convey helplessness.

INTERVENTION AND PREVENTION

Different nations have taken different approaches to child maltreatment. In some countries, the emphasis has been one of enhanced social services and resources for families experiencing difficulties. In others, child maltreatment is handled primarily through the health care system, such as the "confidential doctor" in the Netherlands. In the United States, all 50 states have mandatory reporting legislation that requires professionals working with children to report all cases of suspected abuse or neglect. The categories of professionals required to report varies across states. Child abuse and neglect is reported to child protection agencies who investigate. Depending on the judgment of the child protection agency, cases may or may not proceed to legal intervention and possible removal of the child to foster care. Treatment is not necessarily provided to children or to families through child protection service agencies. When treatment is provided, a variety of modalities have been employed.

In the United States and other Western nations, prevention programs have shown some success in reducing the occurrence of child abuse and neglect. Prevention programs have focused on providing support to new and at-risk parents, particularly through home visitation.

Cholera and other Water-Borne Diseases

Linda M. Whiteford

INTRODUCTION

Cholera—A Water-Borne Disease

The practically invisible bacterium *Vibrio cholerae* made millions of people sick and die before it was first recognized in 1503 (Kiple, 1993). Easily transmitted through water and food, sudden large outbreaks of cholera can occur through fecal contamination of a water supply. Cholera outbreaks are often associated with a breakdown in sanitary conditions such as those following a hurricane or flood where drinking water systems are contaminated with fecal matter as pipes break and raw sewage spills out. Political and economic forces are also implicated in the spread of cholera; its spread is most often associated with inadequate sanitation and hygiene conditions.

The World Health Organization (WHO, 2001) estimates that every 8 seconds a child dies of a water-related disease and probably more than five million people die from diseases associated with contaminated water and poor sanitary conditions. Cholera and other water-borne and water-washed illnesses are particularly relevant for social science research because their control depends on understanding the human decisions and behaviors surrounding the continual transmission of the bacterium. Medical anthropologists' contributions to the

study of cholera and other water-borne and water-washed diseases include research on food-handling and food-preparation practices, the ubiquitous street vending of foods, household health traditions, ethnomedical understandings of disease transmission, indigenous curing practices and beliefs, patterns of land tenure and agricultural traditions, community participation interventions, analysis of political and economic forces, and national water policy recommendations.

Cholera: Disease History

Cholera is an acute intestinal infection with a short incubation period (from 1 to 5 days), and produces an enterotoxin causing copious amounts of watery diarrhea (WHO, 2001). Untreated, cholera can quickly result in severe dehydration and death. Treatment includes oral rehydration salts (ORS) and, for severe cases, both intravenous fluids and antibiotics. Prevention is based on the public health infrastructure of safe water and sanitation, and cultural beliefs and behavioral practices based on a reliable supply of water and security in its use. Once cholera is introduced into a community, endemic control necessitates the hygienic removal and disposal of feces, the provision of a reliable supply of clean water, and an understanding and the practice of safe food hygiene.

While cholera is an ancient disease, it continues to emerge and re-emerge. In 1991, the cholera epidemic that began in Peru and for two years spread across South America, was the first time in 100 years that cholera was diagnosed on that continent. Before it was over, more than 9,000 people had died and many more were sickened by it (Guthman, 1995). During an earlier cholera pandemic, a London physician named John Snow identified the mode of transmission. In his classic 1853 study, Snow demonstrated that a single source of water was implicated in the cholera outbreak in a particular neighborhood. The people who became sick drank water from a common public water source, the Broad Street pump. Others living in the same neighborhood did not become sick when they used water sources other than the Broad Street pump. Snow decided that the water being pumped from the Broad Street well was contaminated and had the pump handle removed. Within days the number of cases was reduced, and the outbreak was over. Snow correctly deduced that the well was contaminated and that the contaminated water was making people sick, even though it was not until later that they learned a contaminated cesspool had leaked cholera bacteria into the well (Diamond, 1992).

TYPOLOGY OF WATER-RELATED DISEASES

While cholera may be one of the most widely recognized examples of a water-borne disease, the list of illnesses associated with water is extensive. Several of the terms commonly used help clarify the relationships between water and various pathogens follow. *Water-borne diseases* are those such as cholera which are caused by the ingestion of water contaminated with human or animal feces or urine containing the pathogen. The pathogen may be bacterial or viral. Typhoid, diarrhea, and dysentery, as well as cholera, are examples of water-borne diseases.

Water-washed diseases are those associated with poor hygiene and are often associated with unreliable access to clean water. Water-washed pathogens can cause diseases such as scabies, trachoma, and flea, lice, and tick-borne diseases when contaminated water is brought into contact with human skin and eyes.

Water-based diseases are caused by parasites found in non-human hosts living in water, and are transmitted

when humans come into contact with the intermediate organisms while wading, swimming, bathing, washing clothes, or other water-based activities. Schistosomiasis, dracunculiasis, and other helminths are such examples.

Water-related diseases are caused by insect vectors that use water as breeding grounds. Yellow fever, malaria, and dengue fever are some of the best-known examples, but onchocerciasis and trypanosomiasis, while less well known, are also examples.

Human activities such as the building of dams for water and electricity, the creation of irrigation systems, the flooding of land for agriculture, and the construction of human dwellings in pristine forests, savannas, and flood plains each change the balance between hosts and vectors by changing the proximity of common reservoirs. The Aswan Dam in Egypt, for instance, provided water and electricity but also increased rates of schistosomiasis (a water-based disease) (Kloos, 1985). In the Dominican Republic, crowded urban living conditions and an unreliable water supply system created a perfect breeding ground for *Aedes aegypti* mosquitoes and resulted in increased rates of dengue fever (a water-related disease) in the urban areas (Whiteford, 1997). In rural communities in the Andes, labor migration patterns continue to influence the re-introduction of cholera when laborers return home to celebrate holidays with traditional food- and drink-sharing practices (Whiteford, 1998; Whiteford, Laspina, & Torres, 1996). As these examples suggest, central to any in-depth understanding of the distribution of water-borne and water-washed diseases is a social science analysis of the underlying sociopolitical and economic variables that effect changing patterns of human contact with non-human vectors and pathogens.

ANTHROPOLOGICAL CONTRIBUTIONS TO THE STUDY OF WATER-RELATED DISEASES

Much of the anthropological research on cholera builds on the extensive body of literature created between the 1980s and 2000 by medical anthropologists studying diarrheal disease (Bentley, 1988; Chen & Scrimshaw, 1983; Green, 1986; Kendall, Foote, & Martorell, 1983, 1984; Nitcher, 1988; Whiteford, 1999; Yoder, 1995). The world-wide scale of Child Survival intervention programs, and in

particular, the mass distribution of oral rehydration salts as part of oral rehydration therapy (ORT) regimens for the treatment of diarrhea provided excellent opportunities for medical anthropological studies (reviewed in the Diarrhea entry). While the provision of rehydration salts does not break the cycle of disease transmission, it saves lives by replacing the water, sugar, and salts commonly lost through diarrhea. In addition, the ability to produce the oral rehydration salts locally made the application of anthropological knowledge a necessity. Anthropological research findings were used to facilitate the introduction and acceptance of ORT by building on the classic features of anthropological theory and methods: the respect for local beliefs, the understanding of local social organization, the need to integrate new knowledge within existing knowledge frameworks, and the recognition of the power of history and politics. Communities where oral rehydration therapy has successfully been adopted are often those where the process was based on the integration of indigenous knowledge and local resources with lessons learned from biomedicine.

Three Anthropological Perspectives to Interpret Disease

Donald Joralemon (1999) succinctly demonstrates how anthropological perspectives deepen our understanding of a disease such as cholera. He identifies three anthropological perspectives which he applies to an analysis of cholera: (1) ecological/evolutionary; (2) political/economic; and (3) interpretive. Joralemon concludes by suggesting a fourth and more inclusive and synergistic point of view. The central concepts within these three identified frameworks provide valuable ways to identify anthropological contributions to the study of water-borne and water-washed diseases. The concept of *natural selection* is central to the ecological/evolutionary perspective; associated with natural selection are the concepts of adaptation and fitness. When applied to understanding a disease such as cholera, this perspective emphasizes the biological and evolutionary relationship between the human hosts and the cholera bacteria.

The ecological/evolutionary analysis of cholera highlights the impact of changing human demographic, economic, and medical patterns on the bacteria's evolutionary trajectory. The combination of evolutionary theory with the ecological model has also provided insights into the long-term genetic implications for human hosts of exposure to other epidemic agents (Joralemon, 1999, p. 40).

The second perspective Joralemon refers to as the political/economic perspective and is often discussed as critical medical anthropology (Baer, Singer, & Johnson, 1986; Frankenburg, 1988; Singer, 1989a, 1989b), or the political economy of health (Morsy, 1979, 1981, 1993), and more recently as the critical anthropology of health. Regardless of the variants of the name, they all share a focus on the underlying political and economic forces that affect the distribution and experience of disease. Central to this view is the idea that resources are not equally distributed, and the lack of equity is generated by *political and economic forces*, resulting in a concentration of poor health and health resources among marginalized populations.

A political/economic perspective on the cholera epidemic might question, for instance, what are the social class and resource variables that account for a country such as Ecuador having recurring outbreaks of endemic cholera in the rural highlands but not in the cities. Such an orientation would question why once the epidemic was controlled in the urban centers, and whether it continued to re-occur in the rural highlands. What structural variables influence the continued re-emergence of a communicable disease where low population densities make its endemicity unexpected? Employing a political/economic analysis suggests that part of the answer lies in Ecuadorian international economic policies, national racism, and local cultural traditions. The structural adjustment policies (SAPs), for instance, that Ecuador experienced as part of the re-negotiation of loans with the World Bank, required the removal of many price subsidies that unequally affected the poor. As gasoline prices rose, farmers distant from central markets were strongly affected, and some farmers were forced to give up farming and move to urban areas to engage in wage labor. One of the highland states with the highest incidence of cholera was the state of Chimborazo, and is composed of small-scale farmers and craftspeople. It also has the largest number of indigenous people in the country. People in the small towns in Chimborazo were forced to leave the land and migrate to cities such as Quito or Guayaquil (the largest city in Ecuador, located on the Pacific coast) for work, often returning to their home communities only for ritual occasions. Anti-Indian sentiment also pushes labor migrants into the large urban areas by reducing the number of jobs available to them in mid-sized cities. As people migrate to coastal cities such as Guayaquil, and are forced through economic circumstances to live in conditions lacking

basic hygiene and sanitation, and come in contact with the water-borne cholera bacteria, fresh outbreaks of cholera frequently follow their return to their highland home communities. Traditional cultural activities often require actions that lend themselves to the transmission of communicable diseases. Such activities might be the sharing of drinks, common handling of shared food, and often inadequate or no running water or sanitary facilities. Therefore, local traditions facilitate the spread of cholera once a migrant carrying the bacterium returns home. To understand the endemicity of cholera in the rural highlands of Ecuador using a political/economic perspective, then, one needs to understand the international lending practices that force people into labor migration, the racist beliefs that impede access to jobs for indigenous people, and the local cultural traditions that facilitate the transmission of water-borne diseases (Whiteford et al., 1996).

The third perspective identified by Joralemon is the Interpretive, or meaning-centered approach. A number of anthropologists have been identified with this approach (Good, 1977; Good & DelVecchio Good, 1980, 1981; Lock & Scheper-Hughes, 1990;³ Scheper-Hughes & Lock, 1986, 1987). In essence, the Interpretive approach centers on the *experience of the illness for the sufferer*, with all of its permutations. This perspective has been said to put the person back into the analysis and focuses on personal accounts of experience, its meanings and metaphors, members of networks of the sufferer, and interactions with friends, family, and physicians. As an example of this approach, Joralemon uses an article by Nations and Monte (1996) on cholera in a poor community in Brazil as an example of this perspective applied to an understanding of experience of cholera. One remarkable insight derived from the analysis demonstrates how the Brazilian cholera health education campaign came to be seen by those most affected by it as a direct attack on them and on their living conditions—without a concomitant recognition of the forces responsible for creating and maintaining those very conditions.

While these three perspectives are not as exclusive as I have suggested in these few paragraphs, they do offer a glimpse at ways in which anthropological conceptualizations shape the kinds of understanding we have about a disease such as cholera and other water-washed and water-borne pathogens. In addition to the well-known areas of medical anthropological research, new research is further developing our understanding of how cultural practices intersect with biological pathogens to cause

human illness. In the remainder of the entry I turn to a discussion of water insecurity and disease, looking at water and its culturally constructed use as an emerging area useful to our understanding of the cultural concomitants of water-washed and water-borne disease transmission.

Water Insecurity and its Relationship to Water-Related Diseases

While medical anthropology has contributed to a significant and recognized portion of the literature on behaviors and beliefs associated with water-borne diseases, anthropologists have also begun to study the relationship between water scarcity and water insecurity and the intransigence of certain water-borne diseases such as endemic cholera. Following the 1991 cholera epidemic that swept across northern South America, massive public health aid controlled the epidemic in most of the urban areas. However, outbreaks continued to occur in the rural areas where cholera was endemic. Caused in part by lack of access to a constant source of clean water, water insecurity caused people to use their limited water for multiple uses—some of which were counter-indicated in the elimination of the *Vibrio cholerae* pathogen. Anthropological studies demonstrated that families who raised pigs, for instance, were reluctant to use soap (an intervention recommended by public health authorities) to wash their hands because the wastewater was used as slop for the pigs, and the pigs refused the slops with soap in the water. Traditional cultural practices and land tenure patterns were also identified through anthropological research as implicated in the spread or re-introduction of cholera in indigenous communities. Land use and ownership practices caused thousands of people to migrate to urban and often coastal cities to find employment. During peak periods in the calendar of traditional obligations when urban migrants returned to their rural communities and shared festival drinks from common bowls and water sources, cholera was spread. The same anthropological techniques applied to an analysis of the behavioral consequences of water insecurity provide some unexpected insights into water-washed and water-borne disease transmission.

Water insecurity, like food insecurity, results when people do not have access to a reliable water supply. While the underlying causes for the lack of a reliable water supply may be due to a wide variety of factors, it results in behaviors to conserve water through multiple

means, such as water storage, re-use, and a hierarchy of use often placing personal hygiene activities such as hand-washing at the bottom of the scale (Cairncross & Kinnear, 1992; Esrey & Habicht, 1986; Whiteford, 1999). Patterns of water storage in the Dominican Republic due to water insecurity have been implicated in the increased rates of dengue fever (Whiteford, 1999), while Starkloff (1998) showed that in a village in Sri Lanka families were dependent on river water polluted with feces and pesticides during extended dry periods. Trachoma, another water-borne disease (sometimes referred to as “river blindness”), is also associated with water scarcity. When people must conserve water or travel considerable distances to obtain water they are less likely to use it for activities that are not economically productive—such as face or hand washing. And yet, according to public health officials, the easiest and most effective intervention against trachoma is to wash away the larvae deposited on the skin around the eyes (West et al., 1989).

The relationship between personal hygiene and enteric diseases such as diarrhea have long been noted by public health officials. However, in a 1998 study on cultural responses to water shortage among Palestinians in Jordan, Arar (1998) documented that as the availability of water was reduced and with it the frequency of personal hygiene behaviors (such as hand-washing and bathing), increased levels of diarrhea were noted. Lack of access to a reliable source of water impacts what people eat and may also affect the amount they eat, since water is a basic component for cooking many foods such as rice or beans. The cost of water, either in the formal or informal economy, can also influence patterns of water usage. In marginalized peri-urban neighborhoods in Guayaquil, Ecuador, where the public infrastructure to provide water did not extend, people paid an informal network of water trucks to deliver their water. The cost for one month of water delivery exceeded the government minimum wage covering the same period of time. Just paying for water could consume a wage-earner’s entire monthly salary—and that’s assuming that he or she was paid the minimum wage and not less (Whiteford et al., 1993). When people pay more than they earn for water, they learn to conserve it in as many ways as they can, often at the expense of their health.

Water insecurity and its associated water-borne diseases are not equally distributed. As was mentioned above, the poor, living outside of the city services, are disproportionately affected, as are women and girls (Ahmed, Hoque, & Mahmud, 1998; Cairncross & Cliff,

1987; Starkloff, 1998; West et al., 1989). In many societies, women are the prime users of water. They cook and clean with water, as well as treat the sick or the infirm. They may also be responsible for the collection and storage of water (Whiteford & Coreil, 1997). Women in many parts of the world spend between 10 minutes and 2 hours daily collecting water; this translates into less time to spend on other household-related activities.

Water scarcity is implicated in the diminution of health status through a reduction in consumption of water, the energy expended in its collection and storage, the loss of time from other health-related and family hygiene activities, the reliance on contaminated water sources, the multiple household use of a single water source, and the sharing of water-borne diseases through that source.

CONCLUSION

Understanding the Determinants of Water-Related Diseases

Understanding the cultural beliefs and behaviors related to water use, as well as the underlying reasons for water scarcity, are central to any attempt to reduce morbidity and mortality due to cholera and other water-borne diseases. Untangling the complex set of relationships between determinants of water supply, personal and household hygiene behaviors, and exposures to water-borne diseases has benefited from the work of medical anthropologists and their application of concepts, skills, and techniques. The synergistic effect of expanding our understanding of the underlying determinants of the changing rates of water-borne and water-washed diseases to include behaviors and beliefs associated with water insecurity enhances our ability to facilitate the interruption of transmission of water-borne and water-washed disease such as cholera, trachoma, schistosomiasis, amoebic dysentery, malaria, and hepatitis.

Chronic Diseases of Aging

Catherine Hagan Hennessy

THE AGING PROCESS AND DISEASE

Chronic diseases of aging are the result of pathogenic changes in physiological systems and physical structures that manifest during senescence (Solomon, 1999). Decline in elasticity of the large arteries, for example, predisposes the aging individual to systolic hypertension, while increased insulin resistance is the basis for the development of adult-onset diabetes. A wide range of conditions may be categorized as chronic degenerative diseases including many, such as sickle cell anemia and cystic fibrosis, that have an onset earlier in life. Those conditions recognized as aging-related include the leading causes of mortality among older adults in developed countries—cardiovascular disease, cancer, and type II diabetes—as well as other non-fatal conditions with a high prevalence and burden of morbidity and disability in late life—osteoarthritis, Alzheimer’s disease, osteoporosis, hearing and visual impairment, and urinary incontinence (Crews & Gerber, 1994; Solomon, 1999). Older adults also frequently experience comorbidity or multiple coexisting chronic conditions (Thorpe, Widman, Wallin, Beiswanger, & Blumenthal, 1994; Yancik et al., 1996).

Risk factors for these chronic diseases include a host of genetic, behavioral, and environmental influences acting throughout the life course to contribute to disease outcomes in old age (Kuh & Ben-Shlomo, 1997). There is growing evidence that many chronic diseases of aging may be “programmed” in utero and in infancy, and that preadult influences are further modified by exposures

in adulthood to produce eventual disease (Leon & Ben-Shlomo, 1997). From an evolutionary perspective, many of the chronic diseases of aging are considered to represent gene–environment interactions that were previously adaptive in human and hominid populations but are maladaptive in present ecocultural contexts (Crews & Gerber, 1994). Type II diabetes, for example, occurs more frequently in populations where, historically, fluctuating food supplies might have genetically favored individuals with a more efficient calorie metabolism, that is, a “thrifty genotype” (Neel, 1962, 1982). In contemporary environments under conditions of high caloric intake and reduced physical activity with lower energy expenditure, however, individuals with these genotypes are prone to obesity, hyperinsulinemia, and diabetes.

THE IMPACT OF GLOBAL AGING ON POPULATION HEALTH STATUS

The prevalence of chronic conditions is expected to increase dramatically as a result of global population aging over the next several decades. It is estimated that the number of persons aged 60 and over worldwide will increase from 550 million in 1996 to 1.2 billion in 2025 (National Institute on Aging, 1996). In at least 50 industrialized countries in Europe, North America, and Asia, 15% or more of the population is in this age group, and in most countries, the rate of growth of the elderly population exceeds that of the population as a whole

(National Institute on Aging, 1996). Moreover, the number of elderly persons in developing countries is increasing more rapidly than in developed countries, and by 2020 will account for 70% of the world's population aged 60 and over (Roca & Amaducci, 1991). Worldwide prevalence projections for diabetes illustrate the impact of population aging on the burden of chronic diseases. The number of persons aged 65 and over with diabetes is estimated to increase from about 54 million in the year 2000 to 105 million by 2025. This latter figure represents 35% of all cases among adults aged 20 and over, and the majority (58%) of older adults with diabetes in 2025 will be in developing countries (King, Aubert, & Herman, 1998).

The extension in life expectancy underlying population aging has been the result of decreased infant and maternal mortality and delayed mortality among persons aged 65 and over due to improvements in nutrition, sanitation, control of communicable diseases, and medical services (Miles & Brody, 1994). Developing countries are currently undergoing various stages of the "epidemiologic transition," that is, the shift in the major causes of morbidity and mortality from infectious and parasitic diseases to chronic diseases (Omram, 1971) that typically occurred in industrialized countries from the 19th century onward (Levison, Hastings, & Harrison, 1981; Rogers & Hackenberg, 1987; Wolleswinkel-Van den Bosch, Looman, Poppel, & Mackenbach, 1997). Modernization has also spread risk factors for many chronic diseases of aging through the "nutrition transition" to a Westernized high-fat, low-fiber diet (Popkin, 1994), increased sedentarism, obesity, and smoking, that contribute to the growing epidemics of these diseases in developing regions of the world (Bovet, 1995; Pearson, 1996, 1999).

ANTHROPOLOGICAL PERSPECTIVES ON CHRONIC DISEASES OF AGING

Age-related chronic diseases have been the subject of investigations by both biological and cultural anthropologists. Research within biological anthropology has focused on the population burden and distribution of chronic diseases including related genetic and environmental risk factors, and the occurrence of these diseases in paleopopulations and in non-human primates (Crews, 1990; Crews & Gerber, 1994; DeRousseau, 1994). Studies from a sociocultural framework, on the other hand, have examined older individuals' perceptions and meanings of

the experience of chronic disease (e.g., Kaufmann, 1988; Silverman, Musa, Kirsch, & Siminoff, 1999; Silverman, Smola, & Musa, 2000), their psychological and behavioral strategies for self-management of a chronic condition (e.g., Mittness, 1987), and cultural values and activities related to the care of chronically ill aged persons (e.g., Gubrium & Sankar, 1994; Henderson, 1990). Because a detailed description of the range of chronic diseases of aging is not possible here, this review focuses on two prototypical diseases of aging—osteoporosis and Alzheimer's disease.

TWO PROTOTYPICAL DISEASES OF AGING

Osteoporosis

Osteoporosis is a disease characterized by loss in bone mass and degeneration of bone microarchitecture resulting in increased bone fragility and vulnerability to fracture (Consensus Development Conference, 1993). Bone tissue is dynamic and is produced through a continuous "remodeling" process of formation and resorption throughout life. Growth and development during childhood and adolescence involve large increases in bone size and volume (Plato, Fox, & Tobin, 1994), and peak bone mass is achieved by approximately age 30. Age-related loss of bone begins in both men and women about ages 40 to 45 as bone resorption starts to exceed formation, and significant bone loss continues into the ninth decade (Murray, Luckey, & Meier, 1996). In women this loss occurs most rapidly for 5–10 years following menopause when bone mass can decrease at a rate up to 2% per year primarily due to decreased estrogen levels (Eisman, 1999).

Diagnosis. Osteoporosis is generally asymptomatic until fractures occur and, in the case of vertebral fractures, may go undiagnosed if medical attention is not sought for pain. Diagnosis of osteoporosis is based on bone mineral density (BMD) which is the most accurate measurable risk factor for fracture in the elderly (Murray et al., 1996). Existing technologies for determining BMD are based on bone scanning with gamma-ray or X-ray densitometry and ultrasound (Gunby & Morley, 1994), and include single-photon and single X-ray absorptiometry (SPA/SXA), dual photon and dual X-ray absorptiometry (DPA/DXA),

quantitative computed tomography (QCT), quantitative ultrasound (QUS), and radiographic absorptiometry (RA). Of these, DXA is the most widely used method for spine and hip measurements, while SXA/SPA are the most frequently used techniques for determining BMD in the limbs (Center & Eisman, 1997).

Cross-Cultural Distribution and Risk Factors.

The World Health Organization (WHO) has developed a definition of osteoporosis based on a BMD measurement of greater than 2.5 standard deviations below the young adult mean (WHO Study Group, 1994). Normative values for BMD are based on Caucasian women, and their validity for other racial groups and for men remains to be determined (Melton, 1997; Samsioe, 1997). However, there is a growing number of cross-cultural studies on the population distribution of BMD among older adults in Asia (Hashimoto, Sakata, & Yoshimura, 1997; Lau, 1997; Lau et al., 1999; Liu, Zhao, Ding, & Zhou, 1997; Rowe, Jung, & Lee, 1997; Taechakraichana, Angkawanich, Panyakhamlerd, & Limpaphayom, 1998; Tsai & Tai, 1997; Yoshimura et al., 1998), South America (Mautalen & Pumarino, 1997), and Africa (Daniels, Pettifor, Schnitzler, Moodley, & Zachen, 1997) which, in combination with fracture incidence data, can be used to set population-specific cutoff values for diagnosing osteoporosis.

In the absence of large-scale population studies of BMD, incidence rates of hip fracture have been used as proxy indicators for the population distribution of osteoporosis. In general, this research suggests that osteoporosis is most common in Caucasians, followed by Asians, and populations of African ancestry, respectively (Samsioe, 1997). Fractures of the hip, vertebrae, and distal forearm (wrist) are the most prevalent types of osteoporotic fractures, with hip fractures having the highest associated mortality, morbidity, and costs (Melton, 1995). Worldwide, there were an estimated 1.7 million incident hip fractures in 1990, with almost half of these occurring in Europe and North America. This number is expected to reach 6.3 million by the year 2050 (Cooper, Campion, & Melton, 1992), and consistent with the aging of populations in less-developed countries, over 70% of these hip fractures will be in Asia, Latin America, the Middle East, and Africa.

Risk factors for the development of osteoporosis include genetic, hormonal, and environmental and lifestyle causes (Khoury, 1998; Nguyen, Howard, Kelly, &

Eisman, 1998; Salamone et al., 1996) although the relative contributions of these influences have yet to be quantified (Center & Eisman, 1997; Samsioe, 1997). A number of genetic factors have been implicated in determining peak bone mass and possibly in bone turnover. These include genes for the receptors for vitamin D and estrogen, the transforming growth factor-B, type I collagen, and the regulation of cytokines involved in bone turnover. Leanness and other features of body composition are other genetically mediated influences on bone mass (Daniels et al., 1997; Nelson, Feingold, Bolin, & Parfitt, 1991; Yoshimura et al., 1998). Differences in bone metabolism have been demonstrated, for example, between Blacks and Whites in the United States with Blacks having lower bone turnover and higher bone mass (Weinstein & Bell, 1988). Overall, hereditary factors are estimated to account for up to 80% of population variability in peak bone mass (Center & Eisman, 1997).

Other known risk factors for low BMD include late onset of menarche, a diet low in calcium and Vitamin D, sedentary lifestyle, excessive consumption of alcohol and caffeine, smoking, and the use of certain medications, that is, corticosteroids (Gamble, 1995). From a historical perspective, archeological evidence indicates that a reduction in bone density accompanied the shift from hunter-gathering to agriculture, presumably from a reduction in levels of physical activity and a change in diet that may have reduced the absorption of calcium (Agerwal & Grynpas, 1996). Age-related bone loss is also evident in the paleopathological record (Plato et al., 1994), although various examples of excessive bone rarefaction in pre-menopausal women point to factors such as multiple pregnancies and prolonged lactation combined with chronic dietary deficiency as possible etiologic factors (MacLennan, 1999). Findings on age-dependent bone loss in female skeletons from two more recent historical populations in Britain indicate that their rate of bone loss was less than in their contemporary counterparts, presumably due to their higher levels of physical activity (MacLennan, 1999).

Prevention and Treatment. Strategies for the prevention of osteoporosis include maximizing the attainment of peak bone mass beginning in childhood and adolescence through adequate consumption of dietary calcium and regular, weight-bearing physical activity, and slowing the rate of age-related bone loss (Scott & Hochberg, 1998). Bone density measurement is recommended for persons

with risk factors for osteoporosis, and treatment is indicated for those meeting the WHO criteria for osteoporosis (Juby, 1999). The principal treatment for osteoporosis is the use of agents that retard bone resorption, including calcium, estrogen, calcitonin, and bisphosphonates. Hormone replacement therapy (estrogen and estrogen/progestogen combinations) has been shown to be effective for both the prevention and treatment of osteoporosis with a demonstrated decrease in the risk of fractures (Murray et al., 1995).

Sociocultural Studies of Osteoporosis. Despite the frequent disability and physical disfigurement associated with this condition, little attention has been given to osteoporosis from a sociocultural viewpoint (Gold & Drezner, 1995). Seanne (2000) has examined behavioral and psychological strategies used by elderly women with osteoporosis to negotiate and protect their sense of self in the face of meanings associated with aging and with the disease. Other qualitative research (Paier, 1996) has documented the negative psychosocial impact of vertebral osteoporotic fractures on older women's self-perceived physical functioning, appearance, and social connectedness.

Alzheimer's Disease

Alzheimer's disease (AD) is the most common adult onset neurodegenerative disorder and accounts for up to 60% of all age-related cases of dementia in Western societies (Woodruff-Pak & Papka, 1999). The disease is characterized by a progressive decline in cognitive abilities, personality, and psychomotor functioning over a period averaging from 8 to 10 years (Filley, 1995; Morris, 1994). Memory impairment is the principal feature of AD and several distinct stages of the disease, often classified as mild, moderate, and severe, are recognized (Morris, 1994). Early manifestations of the disease include the inability to recall recent events, difficulties with word-finding, and geographic or temporal disorientation. As memory loss grows over the course of the disease, the individual's ability to carry out even simple routine activities is affected, language output and comprehension decline, and behavioral problems, such as wandering and restlessness, aggression, and suspiciousness appear. In advanced AD, the affected individual is totally functionally dependent due to severe dementia, and is typically mute and incontinent.

Diagnosis. Definitive diagnosis of AD requires cerebral biopsy or postmortem examination. Neuropathological changes associated with AD include loss of neurons in the medial temporal and frontal cortices, neuritic plaques and neurofibrillary tangles, and B-amyloid deposits (Franklin & Nelson, 1998). A decrease in the neurotransmitter acetylcholine has also been correlated with decline in memory and cognition in AD. Clinical criteria for the differential diagnosis of probable AD include progressive deficits in memory and other cognitive functions or personality that are sufficient to interfere with the person's ability to conduct usual daily activities in the absence of any other systemic or brain diseases (Morris, 1994). These deficits are identified through neurologic examination, brain imaging, and neuropsychological testing (Filley, 1995). Considerable methodologic work has been done on the development of culturally appropriate diagnostic instruments for AD (e.g., Chandra, Ganguli, Ratcliff et al., 1998).

Cross-Cultural Distribution and Risk Factors.

Research on AD suggests a complex etiology involving interactions of biological and genetic variables with a range of environmental and lifestyle exposures (Radebaugh, Buckholtz, & Khachaturian 1996). Age is the most widely recognized risk factor for AD: the prevalence and incidence of AD increase with age in all populations in which it has been investigated. Varying prevalence rates for dementia among older adults have been reported for North American, European, and Asian populations with estimates ranging from 2% to 11% in persons aged 65 and over and 30%–50% in those aged 85 and over (Larson & Imai, 1996). These populations differ, moreover, in the relative proportions of AD and vascular dementia. Among the Western, predominantly Caucasian study populations, between 50% and 70% of the rate is attributed to AD and 12%–20% to vascular disease (Graves et al., 1996). Most studies of Asian populations, on the other hand, have ascribed between 30% and 60% of dementia cases to vascular disease, and approximately 15%–30% to AD (Graves et al., 1996). Information about the incidence of AD worldwide is generally limited (Roca, 1994).

A confirmed genetic risk factor for AD in some populations is the E-4 allele of the gene for apolipoprotein E (APOE), a serum cholesterol carrier protein which has been associated with increased B-amyloid deposition. APOE4 has been associated with early-onset AD and with both sporadic and familial forms of late-onset AD.

The distribution of the APOE4 allele has been shown to vary both within and among populations (Kalaria et al., 1997; Pericak-Vance et al., 1996). A comparison of APOE4 frequencies in various developed and African countries showed relatively high frequencies in African populations (up to 37% in South African Bushmen) compared with Caucasian American, European, and Asian populations (Kalaria et al., 1997). In addition, the effect of the allele may vary across environments. Relatively high frequencies of APOE4 were found among elderly non-demented East Africans, for example (Kalaria et al., 1997). A number of cross-cultural epidemiologic studies aimed at disentangling genetic and environmental risk factors for AD are currently underway (Chandra, Ganguli, Pandav et al., 1998; Hendrie et al., 1995; White et al., 1996). A study of the incidence of AD in persons aged 65 and over of common genetic heritage—African Americans in Indiana and Africans in Ibadan, Nigeria (Hendrie et al., 2001) revealed higher rates of dementia, including AD, among the former than the latter. In addition, there was only a marginally significant association between AD and APOE4 among the African Americans, and no significant association between the gene and the disease among the Africans.

Other possible risk factors that have been evaluated for their association with AD include head trauma with a loss of consciousness, history of depression, family history of certain disorders (dementia, Down's syndrome, Parkinson's disease), low level of education, late maternal age, hypothyroidism, and environmental exposure to toxins (Roca, 1994). A definitive list of risk factors for AD remains to be established, however, and the relationship of many of these risk factors with AD in non-Western populations has yet to be investigated.

Prevention and Treatment. Currently, curative treatment is not available for AD. A number of drugs designed to enhance cholinergic function, however, have been successful in producing a temporary slowing in cognitive decline with an improvement of behavioral symptoms in some patients with early AD (Giacobini, 2000). Three of these cholinesterase inhibitors, tacrine, rivastigmine, and donepezil, are currently registered for use in the United States and Europe. Estrogen, which also affects several neurotransmitter systems, is thought to improve cognitive function in women with AD, although findings on its ability to prevent or delay AD are still inconclusive (Hirai, 2000). Based on the observation that patients with

rheumatoid arthritis have a very low prevalence of AD, non-steroidal anti-inflammatory drugs are being evaluated for their effectiveness against AD in which areas of the brain most affected by neurodegenerative changes also show evidence of inflammation (Hirai, 2000). Various antioxidants, such as Vitamin E and ginkgo biloba, a herbal extract with effects on cholinergic function, are used as complementary medical treatments for memory problems, and have been shown to have modest efficacy in slowing the progression of cognitive symptoms (LeBars, Kieser, & Itil, 2000; Mix & Crews, 2000; Wettstein, 2000). Future treatment modalities for AD will likely involve combining several of these pharmacotherapies (Giacobini, 2000).

Sociocultural Studies of Alzheimer's Disease.

The sociocultural context of AD has been investigated from several perspectives. A social constructionist framework has been used in a number of studies (Chatterji, 1998; Gubrium, 1986, 1987, 1991; Saunders, 1998; Vittoria, 1999) to examine the processes of identity maintenance in older adults with dementia by the patients themselves, by health care providers, and by family caregivers. Variations in ethnomedical beliefs about the causation of AD have also been documented among different groups within the United States (Elliott, DiMinno, Lam, & Tu, 1996; Henderson, 1989; Olson, 1999). Beliefs about dementia prevalent among traditionally oriented Chinese Americans, for example, include the interpretation of dementia as retribution for the sins of one's ancestors, spirit possession, fate, an imbalance of energy within the body, or the lack of proper orientation of important physical sites and objects with the forces of nature (Elliott et al., 1996). Henderson (1987) has also considered how the sociocultural environment in which AD exists in contemporary America acts to generate or exacerbate illness problems and how these problems are culturally managed. He discusses AD support groups as fictive kinship forms that have emerged to provide assistance to members faced with an acute care medical care system and a nuclear family kinship system that are unable to meet the needs of elders with a chronic, debilitating brain disease.

CONCLUSION

With the global aging of populations, the worldwide impact of age-related chronic diseases on quality of life

and societal resources will continue to grow throughout the 21st century. The holistic and cross-cultural perspective of anthropology, including biological and sociocultural research, has much to offer in terms of identifying genetic and environmental risk factors for these diseases and examining the cultural patterning of values, meanings, and activities related to older adults with these conditions and their care.

Culture-Bound Syndromes

L. A. Rebhun

Every known cultural group has ways of describing things that go wrong in body and mind. Although biological causes can be identified for many sicknesses, the way local groups identify, understand, classify, interpret, and respond to conditions is cultural, not biological (Kleinman, 1980). Differences in how local groups understand normality and abnormality are particularly marked for psychological and behavioral syndromes. The term “culture-bound syndrome” developed out of the attempts of psychiatrists and anthropologists to make sense of named syndromes observed in groups outside the middle class, Western European, and North American setting in which contemporary medicine developed.

Pow Ming Yap, a psychiatrist, coined the term “culture-bound syndrome” in the 1960s (Yap, 1962, 1969) when he noted that scholars working in Asian, Pacific, and tribal societies described behavioral syndromes unknown to mainstream psychiatry at the time and denominated only by terms in local languages. Describing these as “atypical psychogenic psychoses” (1962) and later “atypical culture-bound reactive syndromes” (1969), he argued for their inclusion in psychiatric literature as local variations of universal psychiatric disease categories described in psychiatric manuals, and urged his colleagues to work on their organized classification. Although he believed that local beliefs, values, and social structure influenced the symptomatic presentation of such ailments, at base, they reflected universal disorders of the human mind (Yap, 1969).

Since the 1960s, the way theorists have used the term “culture-bound” and interpreted the various syndromes falling under that category has reflected not only different approaches of disparate disciplines to medical classification but also disputes over the meaning and significance of the concept of culture itself as well as greater attention by theorists to both intra-cultural variation and inter-cultural connections. While the term has been attacked as inaccurate and ethnocentric by some, others have sought to expand its use to a greater range of phenomena, including behavioral syndromes described by U.S. and international psychiatry. Anthropologists,

sociologists, psychologists, and psychiatrists use and argue over the term, and debates on its meaning and use reflect not only theoretical changes within disciplines but conflicts in orientations of these different disciplines. Definitional debates bring up thorny issues of the philosophical relationship between culture and biology as well as of the universality of medical categories.

A CONTROVERSIAL TERM

In 1994 the American Psychiatric Association decided to include an appendix on culture-bound syndromes in its *Diagnostic and Statistical Manual*, version Four (*DSM-IV*). This marked a turning point in psychiatry’s treatment of culture, and together with revisions in other parts of the *DSM* to use more culturally and ethnically inclusive language (Good, 1996), constituted a major step in attempts to reconcile the approaches of anthropology and psychiatry to human psychological variation. This reconciliation remains an on-going and controversial process.

At the same time as anthropologists have increasingly attacked what they see as problems in the basic concept of culture-boundedness, psychiatrists have shown increasing interest in cultural variation and made greater attempts to include awareness of cultural variation within official diagnostic categories. The *DSM-IV* defines culture-bound syndromes as follows:

Recurrent, locality-specific patterns of aberrant behavior and troubling experience that may or may not be linked to a particular DSM-IV diagnostic category. Many of these patterns are indigenously considered to be “illnesses,” or at least afflictions, and most have local names [C]ulture-bound syndromes are generally limited to specific societies or culture areas, and are localized, folk, diagnostic categories that frame coherent meanings for certain repetitive, patterned, and troubling sets of experiences and observations (American Psychiatric Association, 2000).

Anthropologists have challenged this definition on a number of grounds, while recognizing that the inclusion of culture-bound syndromes within the *DSM-IV*

represents a positive step toward greater cultural inclusiveness in otherwise ethnocentric diagnostic definitions. One problem arises with the idea of cultures as bounded entities: contemporary anthropology regards culture as both internally differentiated and constantly changing, and has a strong focus on how members of different cultures and subcultures interact with and adapt ideas and practices from one another. Anthropologists have also debated whether the various phenomena described in the literature are properly conceived as syndromes.

Regarding the boundedness of cultures, some syndromes originally described as culture-bound in the literature turn out on further investigation to appear in a variety of sometimes loosely related cultural settings, but not to actually be confined to just one local area or language group. For example, *koro*, in which men (and sometimes women) believe their sexual organs are shrinking or disappearing, was originally described as a South Chinese culture-bound syndrome, but has also been reported among other Asian groups. The term *koro* itself is of Malayo-Indonesian origin and the syndrome has been observed in Indonesia as well as Singapore, Hong Kong, Thailand, and parts of India (Jilek & Jilek-Aal, 1985). Similarly, “nerves” first described as a Guatemalan syndrome has been described all over the Mediterranean and the Americas as well as in the Middle East (see below for more detail). Jilek and Jilek-Aal (1985) reject attempts to classify human behavior as either universal or culturally specific, arguing that what get defined as “culture-bound syndromes” in the literature reflect reactions to geopolitical, and socio-economic conditions in local areas in reaction to local ideologies, and that groups in similar situations will manifest similar reactions under different names.

Theorists have also disputed whether the concept of a “syndrome” occurs in all cultural settings. Anthropologists often use the word “emic” to describe phenomena as viewed from within a particular cultural perspective and “etic” to describe phenomena as viewed from an imposed non-native perspective, especially when an imported definitional or interpretive category is used to describe some local phenomenon. The very concept of a syndrome can be seen as etic for it reflects the ways in which the psychiatry of Western Europe, the United States, Canada, Australia, and similar societies classify experience and behavior.

Some theorists dispute the possibility of direct translation from one cultural setting to another. Yap (1969) saw the phenomena he discussed as local variations of

universal human psychiatric disorders, all translatable into some variety of schizophrenia or depression or mania or hysteria, etc. as defined in Western medical nosologies. Arthur Kleinman (1977), a psychiatrist who has also had a major influence on medical anthropology, calls this a “category fallacy,” arguing instead that such local psychiatric phenomena cannot be understood outside of the cultural context in which they occur. Similarly, Nichter (1981), in a discussion of cases from South India, argues that many types of sickness are best understood as “idioms of distress” rather than as syndromes per se: each describing local reactions to particular forms of psychiatric distress that arise in the differing situations of disparate cultures. Some of these ways of expressing distress become formalized with names in local languages, but do not necessarily become as rigidly defined as are psychiatric diagnoses.

An example of this can be found in *kitsune-tsuki* (fox possession), first described by that name in written sources in 12th century Japan. Unlike medically defined syndromes, the symptoms of fox possession vary widely, and seem to encompass any deviant behavior (night terrors, dizziness, jumping into rivers, making piles of stones, eating gravel, chewing hair, wandering, etc.) as well as experiences of communication from fox entities not perceptible to others (Eguchi, 1991). The central diagnostic criteria of fox possession is the declaration by a religious specialist that the patient is possessed by the spirit of a wild fox or a fox-deity, both common figures in Japanese folklore (Etsuko, 1991).

In the past, when most Japanese lived in small rural villages, a person possessed by fox spirits might become a religious leader, for the signs of possession would have been taken as indications of contact with the divine. However, in contemporary Japan, with a decline in folkloric beliefs, the signs of possession are defined as deviant. Eguchi (1991) argues that the historical change in significance of fox possession indicates that scholars should approach illness as an event or series of events rather than as a rigidly defined thing. He takes issue both with those who try to universalize such phenomena, as in the argument that fox possession constitutes a local form of schizophrenia, and also with particularist arguments that claim that fox possession is unique to its setting and incomparable with any other psychiatric phenomenon. Diagnosis and analysis, in this approach, is more complex than simple labeling with a disease name, but requires a careful delineation of context and meaning as well as presentation.

In addition to defining “culture-bound syndrome” in general, the *DSM-IV* gives examples of named syndromes that have been mentioned in the anthropological and psychiatric literature. Some have only one or two articles devoted to their description, while others inspire extensive literatures. These may also be described by more than one name in the literature. For example, the *DSM-IV* lists *taijin kyofusho* as a Japanese syndrome of intense fear of offending others through bodily appearance or function (American Psychiatric Association, 2000). The International Classification of Mental and Behavioral Disorders (ICD-10) calls the same phenomenon “anthrophobia” (World Health Organization, 1992), emphasizing a particular avoidance of eye contact among sufferers (Zhang, Yu, Zhang, Tang, & Draguns, 2001). In general, the literature on culture-bound syndromes suffers from these kinds of irregularities, complicating attempts to characterize it as a whole, and adding to inconsistencies in descriptions of phenomena.

TYPES OF SYNDROMES

Despite controversies over the term “culture-bound syndrome” the concept remains important in the medical anthropology literature. A number of theorists have attempted to classify syndromes named in the anthropological and psychiatric literature into types. For example, Simons and Hughes (1985) divide culture-bound syndromes into:

- startle matching (as in *latah*)
- sleep paralysis (a reference to a number of syndromes in which people experience choking and/or paralysis during sleep or while falling asleep, often attributed to attack by spirits and possibly related to sleep disorders of physiological origin) (Hufford, 1982; Simons & Hughes, 1985)
- genital retraction (*koro*)
- sudden mass assault (*amok*)
- running (*pibloctoq* or “arctic hysteria” in which sufferers tear off their clothes and run about in a state of high agitation)
- fright illness (*susto*), and
- cannibal compulsion (*windigo*) (see below for discussions of syndromes).

Simons and Hughes (1985) posit that startle matching (*latah*) and sleep paralysis have a neurophysiological basis, whereas genital retraction (*koro*), sudden mass assault (*amok*), and running (*pibloctoq*) do not, and they further state that fright illness (*susto*) and cannibal

compulsion (*windigo*) probably ought not to be considered culture-bound syndromes, because they do not have specific enough descriptions to be useful as psychiatric terms and because they make the category “culture-bound syndrome” too heterogeneous to be really useful. In addition, the theorists mark *windigo* as a problematic term because of controversies over whether it ever actually existed. This division of phenomena remains in line with Yap’s original idea (1962, 1969) that culture-bound syndromes constitute local variations of universal phenomena, and adds a more critical appraisal of existing literature by rejecting some terms as non-specific or inaccurate.

In the case of *windigo*, Marano (1985), in Simons and Hughes’ collected volume, claims that despite an extensive literature on the phenomenon, in fact there never has been such a syndrome among Northern Algonquin peoples. Literary descriptions posit that some Northern Algonquins suffer from fits in which they experience a compulsion to kill and eat human beings. Marano claims that some Algonquin peoples believed that compulsive cannibals lived among them as part of their understanding of witchcraft, and that some individuals were accused of being *windigo*, and even executed on the basis of that accusation.

But just in the same way that the majority of people accused of witchcraft in Western and Southern Europe in the 16th century actually were not casting spells, cavorting with demons, or holding black masses, and the majority of people accused of vampirism in Eastern Europe at the time were not in fact undead blood suckers, the unfortunates accused of being *windigo* were not really cannibals. At the time that many Algonquins were fearing *windigos*, and many anthropologists were collecting data, Native Americans were undergoing severe hardships from disease, conquest, and both political and economic domination. Like other societies under stress, they expressed their trauma through fear of attack by witches. The Algonquin belief that witchcraft took the form of cannibalism was mistaken by early researchers for the presence of actual cannibalism (Marano, 1985).

Hall (2001) provides an even more critical typology of how the term “culture-bound syndrome” is used. He posits that theorists use the term to refer to:

1. apparent psychiatric illnesses not attributable to an identifiable organic cause or corresponding to a Western disease category;
2. locally recognized and named psychiatric syndromes;

3. discrete disease entities not or not yet recognized by Western medicine;
4. named local illnesses which elaborate symptoms found in Western populations but not named as syndromes in the West;
5. culturally accepted explanatory models of sickness not matching allopathic categories and which in Western settings might indicate delusions;
6. states or sets of behaviors involving communing with spirits, or possession by spirits, or loss of one's soul not necessarily seen as pathological within their own cultural setting, but indicating delusion, psychosis, or hallucination in Western nosology;
7. syndromes reported to anthropologists or other foreigners but not directly observed, which may be used to justify punishment or execution of an outcast.

Hall's formulation more clearly presents the idea of "culture-bound syndromes" as a result of theorists in the United States, the British Commonwealth, and Western Europe looking at societies they consider exotic and trying to make sense of what they categorize as foreign illness categories and bizarre behaviors. Although an exhaustive list is beyond the scope of this entry, I now turn to more extended considerations of particular syndromes named in the literature to more fully elucidate the points made above.

"NERVES"

Although there are cross-cultural differences in the description of "nerves," there are also so many cross-cultural similarities that it can no longer be considered so much a culture-bound phenomenon as a widespread label for similar experiences in cultures with sometimes tenuous historical links (Finkler, 1989; Low, 1985, 1989). The syndrome appears in the literature in various languages: "nervios" in Spanish, "nervos" in Portuguese, "nevra" in Greek, etc. The African American "worriation" can also be considered a variant of "nerves" (Camino, 1989). In English, it is usually written within quotation marks to distinguish it from the anatomical word.

Patients with "nerves" usually complain of headache, dizziness, fatigue, weakness, and abdominal pain and attribute their symptoms to sadness, anger, fear, or worry (Davis & Guarnaccia, 1989), although symptoms and etiology vary. While some theorists discuss "nerves" among men (Duarte, 1986; Koss-Chioino, 1989; Low, 1985, 1989), others see it as either a specifically feminine disorder (Barnett, 1989; Davis, 1983, 1989; Finerman, 1989; Kay & Portillo, 1989; Low, 1989;

Slutka, 1989) or the female presentation of stresses expressed differently by men (Camino, 1989; Davis & Low, 1989; Rebhun, 1999; Slutka, 1989). Anthropologists have put forth interpretations of "nerves" which may reflect differences in the local communities in which they work. For example, Low sees "nervios" in Guatemala as a folk illness of strong emotion related to family stresses (Low, 1985, 1989; see also Guarnaccia, DeLaCancela, & Crillo, 1989), whereas both Barnett (1989) and Davis (1983) see connections with menopause. Finerman emphasizes the stresses of female over-responsibility (Finerman, 1989), while both Rebhun and Krieger analyze how women may use "nerves" as part of interpersonal manipulation (Krieger, 1989; Rebhun, 1993). Scheper-Hughes (1988, 1992) prefers to emphasize the symptoms of hunger and the stresses of economic deprivation (see also Dunk, 1989), while other theorists see "nerves" as a means for women to express socially unacceptable emotions (Clark, 1989; Lock, 1990, Rebhun, 1999), and as a folk model of anxiety or depression (Kay & Portillo 1989; Koss-Chioino, 1989).

Although today a folk category, "nerves" has its origins in the same ancient Greco-Arabic forms of medicine that lie in the history of biomedicine as well. Related to such categories as hysteria, neurasthenia, and melancholia, it reflects the idea that the body possesses a finite amount of "nervous energy" which can be exhausted if too excited, especially in women (Cayleff, 1988; Davis & Whitten, 1988). As such it is similar to such concepts as "stress." While mainstream medicine moved away from older concepts in the late 19th and early 20th centuries, the ideas that underlie the various presentations of "nerves" were retained in the folk medicine of Western Europe, the Mediterranean, the Middle East, the Americas, and historically related areas.

SUSTO

The Spanish word *susto* means "fright" or "fear." Although Simons and Hughes (1985) argue that *susto* ought no longer be considered a culture-bound syndrome because it is too non-specific in its description, nonetheless the DSM-IV lists it in its appendix. The basic idea in *susto* is that either a sudden shock as in being startled, or an emotional shock, or a series of traumatic events, or a frightening encounter with a ghost have damaged a person, often by startling their soul out of their body.

Other terms used similarly include *espanto*, *perdida del alma*, *pasmo*, *tripa ida*, and *chibih*. Typically a sufferer has trouble sleeping or sleeps too much, feels sad and listless, may stop eating, and experiences headaches, diarrhea, and assorted aches and pains, similar to depression or post-traumatic stress disorder (American Psychiatric Association, 2000). Although most associated with Latin America, similar fright complexes have been reported in other areas of the world as disparate as the Phillipines and New Guinea (Simons & Hughes, 1985). In Latin America, *susto* is often connected with “nerves” as when a person’s problems with “nerves” start because of a *susto* (Rebhun, 1993).

Simons and Hughes (1985) express discomfort with the broad, non-specific nature of *susto*, but many anthropologists have found that very characteristic valuable, allowing them to understand how the people they study think about adversity through their use of all-encompassing terms such as *susto* and “nerves.” Crandon (1983), for example, in a study of how mothers in an Andean community come to label their sick infants with the term *susto*, concludes that designating a particular infant as *assustado* (shocked) rather than corresponding to any specific symptomatology, is a way for the community to comment upon the particular vulnerability of specific infants due to the social and economic conditions of their families.

In another study, Baer and Bustillo (1993) found that even though folk terms such as *susto* and *mal de ojo* (evil eye) do not correspond to specific biomedical conditions in infants, mothers in a community of Mexican migrant farmworkers in Florida who brought children to doctors for treatment of these complaints in fact were identifying serious maladies such as infectious diarrheas, severe dehydration, fevers, etc. They conclude that even if doctors regard folk syndromes as superstitions, they should still regard mothers who ask about their sick infants in such terms as able diagnosticians of potentially serious medical conditions. The difference between the doctors’ and the mothers’ or folk healers’ approaches lies in the explanatory model (Kleinman, 1980) applied to the condition rather than in the ability to recognize potentially serious illness (Baer & Bustillo, 1993). Terms such as “nerves” and *susto* express philosophical attitudes about human vulnerability and emotional suffering in the face of misfortune (Rebhun, 1999; Rubel, O’Neill, & Collado, 1984, 1985; Dobkin de Rios, 1985). Both are better understood in terms of Nichter’s (1981) idea of “idioms of distress” rather than as discrete disease entities.

KORO

Like “nerves”, *koro* has been described in a variety of locales mostly in Asia and among Asian immigrants to other areas. A few individual cases of men panicked that their genitals are shrinking have also been recorded in other cultural settings, but here the phenomenon does not seem to have become formalized as a widespread belief (Chowdhury & Bera, 1994; Earleywine, 2001; Fishbain, Barsky, & Goldberg, 1989). *Koro* sufferers are usually male, and during episodes they become convinced that their genitals are shrinking up inside their bodies. *Koro* sufferers also manifest acute anxiety, and often believe that full genital retraction will result in death. Cases of women fearing breast and genital shrinkage have also been recorded, but more rarely (Cheng, 1996; Jilek & Jilek-Aal, 1985). *Koro* was first mentioned in Western medical texts in 1895, although its mention did not become widespread until the 1960s (Chowdhury, 1998). Although often described as a Chinese culture-bound syndrome, the word *koro* itself is of Malay origin, and refers to the head of a turtle. The equivalent term in Mandarin would be *suoyang*, but that is not the term commonly used in English language literature (Cheng, 1996).

In addition to reports of individuals manifesting *koro*, some researchers have reported on widespread outbreaks or “epidemics” of *koro* (Bartholomew, 1994; Cheng, 1996; Jilek & Jilek-Aal, 1985). Jilek and Jilek-Aal posit that the epidemics of *koro* they analyze in Thailand and India were related to the movement of ethnically distinct political refugees into new areas or anticipated military attacks from ethnic rivals, where local people feared engulfment or destruction from their adversaries. They theorize that the belief in disappearing sexual organs is a metaphor for the fear of being unable to reproduce and sustain families, to dying as a people due to perceived aggression from ethnically distinct others, and compare *koro* epidemics to the ghost dance religion of the Coast Salish people under military attack from colonists as a reaction to the stresses of conquest. Rather than look at *koro* as an individual phenomenon related to Oedipal castration fears, they argue for its comprehension as an idiom of distress (Nichter, 1981), incomprehensible outside its political setting (Jilek & Jilek-Aal, 1985).

Interestingly, some theorists have adopted the term *koro* to refer to any case of believed genital shrinkage or disappearance, no matter the cultural setting (Earleywine,

2001; Fishbain et al., 1989; Moodley, 1985; Yap, 1965). The increased use of the term *koro* by physicians to describe patients outside its historical cultural settings seems a further development of Hall's "named local illnesses which elaborate symptoms found in Western populations but not named as syndromes in the West" (Hall, 2001) in which the non-English term has been usurped to fill a nosological need.

AMOK

British colonial officials in Malaysia were so impressed with the idea that native Malays might suddenly grab a weapon and embark on a frenzied homicidal attack, that they adopted the Malay word *amok* into the English language to refer to any sudden, violent, chaotic behavior. Such attacks, usually following a period of brooding, may have their origin in forms of warfare in historical Malaysia, although by the time they were described by the British, they had become individual attacks (Carr, 1985). Historical accounts from Southern India, Malaysia, and Indonesia describe elite warriors known by a variety of names including *amouco*, *amok*, and *amokos* and famous for their willingness to die in furious attacks. However as early as the 15th century, historical accounts describe civilian men who suddenly took on an apparently indiscriminate homicidal fury (Spores, 1988). John Spores points out, however, that *amoks* often attack members of their immediate family (Spores, 1988) and is among those theorists who question whether *amok* attacks are in fact indiscriminate and whether *amoks* do not actually remember their actions, as claimed (Burton-Bradley, 1985; Carr, 1985; Hughes, 1985; Spores, 1988).

Although Carr (1985) argues that *amok* is properly understood as a specifically Malay phenomenon, others see similarities with sudden, homicidal attacks in other parts of the world, as in mass shootings in schools and workplaces in the United States, for example (Arboleda-Florez, 1985). Theorists who like to compare similar events in disparate settings might also ask whether ostensibly politically motivated attacks such as suicide bombings in Israel, Palestine, and other world areas share similarities with these other described assaults. Although Simons and Hughes (1985) argue to retain *amok* within the culture-bound syndromes, the frequency of mass homicidal and homicidal/suicidal attacks in a variety of world

areas tends to indicate, once again, that the idea of culture-bounding remains problematic. However, the proliferation of sudden homicidal and homicidal/suicidal attacks in many parts of the world indicates that understanding such behavior, however classified, should remain a priority.

KURU

Unlike other culture-bound syndromes, *kuru* has been identified with a biomedical condition. First appearing among Fore tribal people in New Guinea in the late 1920s, *kuru* (meaning shaking with fear) manifested with tremors and progressive dementia concluding in inevitable early death and was most common among women. The Fore at first attributed it to assault by ghosts, but eventually concluded that it was caused by sorcery. By the early 1960s, the Fore were a community in crisis with increasing numbers of women dying from *kuru*, and they responded with community meetings to denounce sorcery and increasing attempts to identify the witches they believed were killing their wives and mothers (Lindenbaum, 1979, 2001). However, by the 1990s the incidence of *kuru* had dropped to the point where it is today a rare condition (Lindenbaum, 2001).

In 1979, physician D. Carleton Gadjusek won the Nobel Prize in medicine for his discovery of an infectious origin for *kuru*, which his research revealed to be caused by what he called a "slow virus" but later researchers call a prion similar to those that cause Creutzfeldt-Jakob disease, scrapie, and, more recently, bovine spongiform encephalitis ("mad cow disease"). In combination with research by anthropologist Shirley Lindenbaum, his work showed a possible transmission path through the practice of consuming parts of the remains of deceased relatives as an aspect of funerary practices, allegedly an increasing practice in the early 20th century, but ceasing by the 1960s (Lindenbaum, 1979). This contention has attracted controversy because there has been no first-hand observation of endo-cannibalism among the Fore (Lindenbaum, 2001).

Kuru fits two of Hall's classifications of culture-bound syndromes (Hall, 2001): "culturally accepted explanatory models of sickness not matching allopathic categories and which in Western settings might indicate delusions" (the attribution of witchcraft) and "discrete disease entities not or not yet recognized by

Western medicine” (during the time before Gadjuzek’s discovery).

LATAH

Latah, from the Malay word for “ticklish,” denotes a person who responds to being startled by temporarily entering an altered state in which she or he will obey commands, imitate movements or sounds repeatedly, utter rude or obscene language, and/or act in sexually inappropriate ways (Winzeler, 1995). Like *amok*, *latah* has been described in English language literature for some time, with earliest mentions dating from the 19th century. From the late 1960s to the present, anthropologists have debated the significance of *latah*. Starting with Hildred Geertz’s discussion of the “latah paradox,” which she described as the problem that while *latah* is culturally specific to Malaysia, similar forms of hyperstartling behavior have been observed in other cultures (Geertz, 1968), anthropologists have tried to account for both generalizability and specificity in *latah* behavior (similar to problems with the definition of other culture-bound syndromes). Together with *amok* and *koro*, *latah* became a common literary topic that some have seen as part of the making of stereotypes of both exoticism and uncivilizability about Malays and similar peoples by Western colonialists (Winzeler, 1995).

Simons (1985) posits that although individuals in all cultures vary in how they respond to startling, and some individuals respond with brief periods of *latah*-like behavior, in Malaysia, popular amusement with hyperstartling has led to a cultural complex around this behavior, which establishes a social role for people who exhibit it, and encourages people to induce it by deliberately startling *latahs* repeatedly until they perform as expected. While English-language commentary tends to refer to *latah* as a problem, Malaysian villagers studied seem to regard it as an amusing personality quirk instead (Simons, 1985).

However, Kenny (1985) finds this explanation too limitingly biomedical in nature, preferring to see *latah* as only lightly related to cultural elaborations of hyperstartling. Instead, he posits that the behavior finds meaning within a complex of beliefs about marginality and distress, in the context of culturally specific notions of spirit possession and shamanism. The hilarity with which villagers address *latahs* and their clowning social role

reflect their state of marginality, according to Kenny (1978, 1985).

CULTURE-BOUND SYNDROMES AND SOCIAL CHANGE

Although the term “culture-bound” refers to a concept of culture that comes from an earlier period in anthropological theory in which culture was seen as relatively unchanging and localized, contemporary anthropologists increasingly see such syndromes as not only characterized by the same historical changes and globalization that affect all cultural phenomena, but as derived from such changes directly. For example, Carr posits that the incidence of *amok* may have risen under colonialism and with urbanization in Malaysia because Malaysian rural culture had insufficient ways of dealing with the sharp rise in interpersonal conflict when the society came under stress (Carr, 1985). Eguchi (1991) theorizes that phenomena such as fox possession became psychiatric syndromes, defined as disease, only when the religious context in which they originally appeared changed. When most people no longer believed in fox spirits, those who did were labeled as delusional, and therefore sick. Jilek and Jilek-Aal (1985) discuss *koro* epidemics as manifestations of anxiety about violent ethnic conflicts, and Lindenbaum (1979) describes how the Fore people responded to an epidemic in their midst through concepts of sorcery. Marano (1985) believes that the whole concern of Western observers with *windigo* psychosis derives from a misunderstanding of a rise in witchcraft accusation within a colonial context, and Winzeler (1995) discusses early descriptions of both *amok* and *latah* as part of the creation of stereotypes of deficiency in colonized Malaysians.

These approaches suggest that culture-bound syndromes are involved with culture change in several ways. For one, the incidence and types of expressions of distress may rise with rapid and forced cultural change. In addition, as beliefs change, those who hold to older patterns may become newly classified as sick within their home communities. And in addition, the very concept of culture-bound syndromes may result from misunderstandings that ensue when members of politically dominant groups attempt to study dominated groups and classify their behaviors.

Theorists of diverse disciplines do not agree on how to understand behavior and emotion cross-culturally and debates over culture-bound syndromes in the current literature reflect their differences. Theorists continue to debate which named syndromes ought to be included in the category “culture-bound syndrome,” whether such a theoretical category has any utility, and how to understand cross-cultural differences and both how and whether to include more cultural diversity within biomedical disease classifications. These debates as well as the interest of the ethnographic material itself make the field of “culture-bound syndromes,” whether one accepts or rejects the term, continually lively.

Culture, Stress, and Cardiovascular Disease

William W. Dressler

INTRODUCTION

For the past half-century medical anthropology has been guided by various theoretical orientations. These include (but are not exhausted by) interpretive orientations, political-economic orientations, and biocultural orientations. The latter approach to research, which is allied with ecological and adaptation perspectives, has been productive for the field through the explicit effort to link the biological and the cultural. Research in some areas of medical anthropology can proceed with scant reference to human biology (e.g., interactions of patients and healers). There are, however, some questions of cultural significance that require taking account of biological variation within and between populations. A biocultural orientation provides theory and method for approaching these problems and for unpacking the complex interactions of culture and biology.

Cardiovascular disease, as a general term, refers to any pathology of the cardiovascular system, which would include diseases of the heart as well as vascular disease affecting other parts of the body (such as stroke). Medical anthropologists have studied this broad category of diseases in a variety of ways, but this entry will focus primarily on a condition that is less disease per se but rather a kind of barometer of the system as a whole: blood pressure. A regular cycle of pressure in the cardiovascular system is necessary for basic tissue nutrition. Oxygen and nutrients must be transported across cell membranes. A relatively low level of blood pressure is required for this tissue perfusion; yet, it is not unusual for a person's blood pressure to be considerably higher than that required for system maintenance. At even modest levels of blood pressure (e.g., those considered "normal" in biomedicine, such as 130/80 mmHg, or millimeters of mercury) the risk of serious cardiovascular events such as myocardial infarction (or heart attack) increases significantly.

Cross-cultural research on blood pressure has been carried out for over 30 years, sometimes by medical anthropologists, sometimes by epidemiologists and other researchers. One reason that much research on blood

pressure has been conducted is because of the relative ease of measuring it. No more elaborate equipment is required than a sphygmomanometer and a stethoscope. It is true, however, that blood pressure can be measured with deceptive ease; a number of conditions of its measurement must be standardized, and the observer must be experienced and aware of the common mistakes in its measurement. Nevertheless, given the ease of measurement of blood pressure, and its strong relationship to other disease outcomes, cross-cultural studies on the distribution of blood pressure provide a rich source of data for understanding biocultural processes.

BLOOD PRESSURE DIFFERENCES BETWEEN SOCIETIES

Henry and Cassel (1969) noted that the observation that there are mean blood pressure differences between societies goes back at least to the 1930s. There are a number of papers appearing in the medical literature in the 1950s and 1960s that provide descriptive data on mean blood pressures and the distribution of blood pressure by age and sex in societies dramatically different from the industrial societies that were home to the researchers. Implicitly, and even sometimes explicitly, comparisons were uncritically made between, for example, foragers such as the Hadza of Africa and data from the United States and Europe. Typically, researchers were surprised by two results. First, mean blood pressures were usually found to be much lower in the "traditional" society than in a "modern" society like the United States. Second, rarely were blood pressures observed to increase with age or to differ between genders in the traditional societies, while in modern societies increasing blood pressure with age and differences between men and women (that change with age) were the norm.

With accumulating studies of this kind, in the late 1970s Ingrid Waldron and her associates (Waldron et al., 1982) were able to collate over 80 different studies of

blood pressure, and to link characteristics of the communities studied with data from the Human Relations Area Files. A number of interesting results emerged from this exercise. First, community mean blood pressures increase along a continuum of sociocultural complexity, with societies arrayed according to the familiar sequence of foraging, pastoral, horticultural, agricultural, and industrial modes of adaptation. Second, the increase of community mean blood pressures is not smooth and linear along this continuum; rather, there is a sharp increase in mean blood pressure between horticultural and agricultural societies, which then stays high in industrial societies. And third, controlling for community average levels of obesity does not alter the pattern, which is consistent by age and sex as well. It is unlikely that these patterns are artifacts of differences between observers in the measurement of blood pressure, since such differences would be more likely to obscure patterns rather than produce them. Furthermore, these differences are not an artifact of treated cases, since measurements were carried out on (at least roughly) representative samples of the communities.

The work of Waldron and associates probably represents the most convincing evidence for societal differences in disease risk.

BLOOD PRESSURE DIFFERENCES WITHIN SOCIETIES

As noted above, in the data collated by Waldron and her associates, there was a sharp increase in community average blood pressures between societies practicing foraging and pastoral/horticultural modes of adaptation, and those societies based on systems of extensive agriculture and industrial economies. There is a sudden change in health status at one point along the continuum, suggesting that something associated with the increasing sociocultural complexity of these societies is associated with changing human biology. The term “the epidemiologic transition” has been used to describe this pattern. The epidemiologic transition refers to the shift in patterns of morbidity and mortality within a population from one dominated by infectious and parasitic diseases (compounded by nutritional deficiencies) to one dominated by chronic diseases (compounded by nutritional imbalances and excessive caloric intake).

Evidence consistent with this observation comes from studies of differences in blood pressure within

societies. Many of these studies were guided by the “modernization” hypothesis. In this research, communities are ordered along a continuum from “traditional” to “modern.” Traditional communities are those in which the local economy is still based on production for local consumption; there is little formal education; national languages are not frequently used; social structure emphasizes extended family relationships; and, there is little penetration by global supernatural belief systems. Modern communities are those in which wage-labor has replaced local production; formal education is present; national language supplants local dialects; the nuclear family becomes a more important unit of social structure; and, individuals adopt one of the global supernatural belief systems. There is a gradient of increasing risk of chronic disease, as indicated by increasing blood pressure (as well as increasing serum glucose, serum cholesterol, obesity, and symptoms of psychiatric disorder) that is associated with a gradient of increasing modernization (Dressler, 1999).

The modernization hypothesis has been investigated in two ways. First, aggregate data (e.g., proportion of persons employed in subsistence agriculture; proportion of nuclear family households) have been used to assign whole communities to a point along the continuum. Then, mean differences in blood pressure have been calculated for each community and variation within and between the communities has been examined. Second, modernization has been measured at the individual level, in terms of a person’s occupation or living arrangements. Then, the correlation between these modern characteristics and blood pressure has been calculated. There are reliable and consistent blood pressure differences between communities arrayed along a continuum of modernization. The associations of blood pressure and individual-level variables are much less consistent.

Changing diets have been investigated as a major contributor to this pattern. These hypotheses take two forms. First, increasing caloric intake and decreasing physical activity associated with modernization can lead to higher levels of obesity and risk of high blood pressure. This explanation is fairly easily dealt with by adjusting for measures of body composition such as the body mass index. This is routinely done in this kind of research, and the effects of modernization on blood pressure are independent of body mass. Second, changing patterns of dietary intake have been found to be associated with modernization, consisting of increasing intake of sodium

and saturated fats, both of which are thought to be associated with increasing blood pressure. But again, when investigated closely, changing patterns of dietary intake do not account entirely for increasing blood pressure levels.

Attention therefore turned to social, psychological, and cultural factors that might account for these differences. In the late 1950s and early 1960s there was a remarkable burst of activity in thinking about this issue, culminating in an article by Cassel, Patrick, and Jenkins (1960). These investigators were particularly interested in what happened to migrants from rural areas to urban areas, although the same reasoning can be applied to culture change occurring within any community. They offered the following hypothesis: the migrant to a novel setting carries with her a particular understanding of how the world works, in every sense (i.e., what it means to work, how marriages are constituted, how families treat themselves and their neighbors, how to worship—everything). She is confronted, however, with a system for which her understanding may not work. The novel and dominant culture of the new setting must be learned for everyone else's behavior to be understood, and indeed for her to behave in ways that are understandable to others. She must, in other words, culturally adapt to the new setting. Even if she is successful, such adaptation can be costly. Indeed, this is precisely what Hans Selye meant by the General Adaptation Syndrome when he gave the concept of stress its first scientific respectability in the 1930s. Adaptation is costly, and the cost of adaptation is written on the body in terms of what we call health. So, Cassel et al. argued that the less successfully the migrant culturally adapts to the new setting, the higher her stress levels and the higher her blood pressure.

This introduced the concept of stress, and the idea of the stress of culture change, to the literature on modernization and disease. There were, however, certain theoretical and methodological difficulties that limited this as an area of inquiry. First, there was increasing disenchantment within anthropology, especially cultural anthropology, with the whole idea of modernization. The theoretical orientation guiding this work came out of the linear models of economic development that guided post-World War II thinking. All societies were seen as moving along a trajectory of development that would culminate in an industrial mode of production, accompanied by a predictable set of social and cultural changes. This has turned out to be dramatically wrong; instead, a world

systems theory posits a continuing state of underdevelopment within some societies, as these occupy positions on the periphery of that world system. Regardless of which specific variant of this theory is used, some kind of world systems view appears to describe more accurately what is going on with respect to economic development (or continuing under-development) than does a modernization perspective. Therefore, some other way of thinking about the epidemiologic transition is needed.

Second, while Cassel et al. developed a very useful theory of the health effects of culture change, it proved to be very difficult to actually test. This research group was extremely productive, but the logic of the tests of these ideas remained an epidemiologic logic. In epidemiology, the logic of making inferences about the operation of disease processes generally involves the comparison of population groups, one of which is thought to have been exposed to a particular set of risk factors, while the other has not. In the work of Cassel et al. this logic involved comparing groups thought to have been exposed to a set of sociocultural stressors (e.g., migrants to a novel cultural setting) versus those who have not been exposed to this set of stressors (e.g., sedentes), with differences interpreted in terms of the contradictions of cultural systems described by the theory. There never was, however, any direct evidence that these cultural contradictions actually occurred. In other words, methodological developments for assessing in a precise and rigorous way the differences in shared culture between groups, and how these differences may enter into individual behaviors, which in turn are associated with higher blood pressure, were not forthcoming. Therefore the theory remained essentially untested.

Third, anthropologists increasingly turned their attentions to advances occurring in cognate fields (psychology, sociology, and epidemiology, principally) with respect to the stress model. The period of the 1960s and 1970s was an extremely fertile one in terms both of theory and method in the evolution of the stress model. Ethnographers drew on these developments and integrated these concepts and methods with anthropological concerns to derive models of stress relevant in the context of developing societies. This enabled these researchers to avoid the pitfalls of the concept of modernization, while at the same time employing measures that could be directly linked to individual behaviors and health outcomes. This served as a major direction in research throughout this period.

MODELS OF STRESS

Research on stress and disease in sociology, psychology, and epidemiology paralleled work on modernization and disease in anthropology. By the late 1970s, a rough synthesis had emerged that could be used in the development of research models that would be useful cross-culturally. The term “stress” can be used to as a shorthand description for a general area of inquiry. Stress research or the stress model takes as subject-matter the direct link of thought, emotion, and behavior to physiologic changes and hence to disease. In early usage, the term referred to a specific physiologic pathway, although contemporary physiologic research recognizes that there are multiple pathways hormonally mediated by the hypothalamo–pituitary–adrenal axis, the hypothalamo–pituitary–gonadal axis, and the hypothalamo–pituitary–thyroid axis (as well as others; Worthman, 1999).

From the standpoint of social and culture theory, the aim was to identify factors that could be anticipated to be reliably associated with the activation of efforts at adaptation on the part of individuals, that would in turn be associated with a particular pattern of physiologic responses, that in turn could lead to sustained disease. Until recently, the major empirical link made was from social–environmental factors to disease, with the intervening links of physiology posited by analogy with laboratory experiments. More recently, some techniques have been developed that make it possible to measure hormonal mediators in the field and link them to disease outcomes (Panter-Brick & Worthman, 1999). The opportunity to study the physiologic mediators of the stress process is an important addition to the research in this area. At the same time, a principal aim of research continues to be the identification and measurement of factors in the social environment that tax individual adaptive capabilities.

There are two broad classes of social factors thought to influence risk of disease. Stressors are those factors that are (or are understood to be) problematic for individuals. These are events or circumstances that must be dealt with at some level for life to proceed smoothly. Stressors can be further divided into two categories. Acute stressors are typically events that occur suddenly with little warning, or if they are anticipated, their occurrence is limited in time. Chronic stressors are problematic circumstances that persist through time. Both chronic and acute stressors are associated with an increased risk of disease.

A second broad category of social factors can be referred to as resistance resources. Resistance resources are factors that enable the individual to avoid, withstand, or alter the stressful events and circumstances to which she is exposed. These again can be divided into two categories. Social support refers to the help or assistance that an individual can anticipate or receive by virtue of her membership in a network of social relationships. Coping styles refer to relatively stable individual dispositions to approach stressful circumstances in particular ways. On the one hand, individuals may actively seek out ways of coping with the occurrence of a stressor; on the other hand, individuals may more passively withdraw from a stressful circumstance and attempt to emotionally alter the meaning of the stressor.

One of the more influential models of the way in which these factors influence disease risk is the stress buffering model. It is argued that stresses in life are a more-or-less ubiquitous part of human existence, yet not everyone succumbs to the effects of stressors. Rather, individuals, even though they may be exposed to stressors, may not suffer the effects of those stressors because of their available social or psychological resources. Stressors will then have two different patterns of associations with disease risk. On the one hand, where resources are low, stressors will have a substantial effect on disease risk. On the other hand, where resources are high, individuals may be insulated from the stressor effects. That is, resistance resources may buffer the effects of stressors. Actually, one of the most influential papers in this area was also authored by Cassel (1976), who turned to stress models of this kind in search of operationally more explicit ways of examining stress processes.

The question then became one of how this general model might be applied in various ethnographic settings. Scotch (1963) was one of the first anthropologists to look at blood pressure from an explicit stress model. He compared samples of Zulu in South Africa, one sample living in a traditional homeland, the other living in an urban area. He found a variety of factors to be associated differently with high blood pressure in each area. For example, women who were past childbearing age were more likely to have high blood pressure in the rural area, while they were more likely to have low blood pressure in the urban area. Similarly, individuals who were members of Christian churches were more likely to have high blood pressure in the rural area, and low blood pressure in the urban area. Scotch interpreted this pattern of associations

as evidence of stress, due to the incongruity between behaviors and context. Women past childbearing age experienced a loss of valued social status in the rural area, while they were relieved of onerous economic burdens in the urban area. Similarly, members of Christian churches were viewed with a certain suspicion in the more traditional and conservative rural areas, while in the urban areas this opened up the possibility of greater social participation. While Scotch's work is still broadly interpretive (i.e., there is little operational specificity to support his arguments), his research was groundbreaking and set the stage for later studies of blood pressure.

Dressler (1982) developed a specific model of stress and culture change on the island of St. Lucia, in the eastern Caribbean, using the theoretical synthesis described above, and building on Scotch's work. By the mid-1970s, St. Lucia had experienced some 20 years of very modest, but sustained economic growth as a result of innovations in the banana industry, which in turn spurred development in other areas. An increasing exposure of people to media representations of North American and European middle-class lifestyles accompanied this growth. The accumulation of consumer goods (e.g., radios, stereos, imported furniture) was emerging as a primary definer of local social status. At the same time, the real potential for increasing incomes to sustain such lifestyle aspirations did not grow at the same rate (economic growth may trickle down, but it does so very slowly and very incompletely). This meant that for a substantial portion of the population the economic resources necessary to fuel the high status lifestyle were absent, although this hardly altered lifestyle aspirations. Drawing on theories of status inconsistency, Dressler argued that individuals who presented themselves in mundane social interaction as having attained the valued lifestyles, but who did not have the economic standing consistent with that claim, would not receive confirmation of their status claims by others. This inconsistency in social status, referred to as "lifestyle incongruity," was predicted to be a chronically stressful circumstance which would be associated with higher blood pressure, and this hypothesis was confirmed (after controlling for age, sex, and the body mass index).

At the same time, the social and psychological resources that could support coping with stressful circumstances were investigated. In St. Lucia, social support took a very specific form, relative to patterns of family and household formation that have been well described for the West Indies. It is unusual for persons to marry

prior to beginning a family, and frequently individuals will have children by two or more other people. This practice, along with a high solidarity among adult siblings, links individuals into large networks of households. Because individuals are expected to support their offspring, both "inside" and "outside" the household, and because of adult sibling solidarity, there are flows of material resources among households with these links. Dressler hypothesized that this comprised a social support system that would buffer the stressful effects of lifestyle incongruity, and this hypothesis was also supported.

These results were replicated in a variety of settings (Bindon, Knight, Dressler, & Crews, 1997; Dressler, 1993; McGarvey, 1999). It is worth noting, however, what varied, more and less, across cultural contexts. Generally speaking, lifestyle incongruity could be operationalized in very similar ways across different contexts, and had very similar effects. This is because the process leading to status incongruence of this sort is a function of how capitalist markets make their way into local settings. The market for mass-produced goods and services, and the social value attached to those goods and services, is global in nature, as is the generally slow growth of local economies. Therefore, this aspect of the process looks very much the same in different places. Social support systems, however, are rooted in social structure within each local setting, and are therefore much more variable. In a sense, then, the status incongruence/social support model represents an examination of how processes of globalization intersect with local social structures in terms of cardiovascular health outcomes.

There are, however, ways in which stressors can be culturally modified. A good example of this can be found in Janes's (1990) study of blood pressure among Samoan migrants to northern California. Culture change in Samoa accelerated with the advent of World War II, and initiated a process of migration from Samoa to Hawaii and the mainland United States. Like so many migrants, Samoans in the United States were able, in part, to re-create village life in the context of urban centers such as San Francisco. This re-creation could, however, lead to difficulties. On the one hand, there were Samoans who continued their aspirations for status along traditional dimensions, especially seeking chiefly statuses (*matai*) and a leadership role in the extended family. On the other hand, there were Samoans who sought status along more traditional American middle-class dimensions, especially in terms

of achieving white-collar occupational status. In the former case there is a relatively heavy financial investment to achieve status. In the latter case the investment is more in the form of increased educational qualifications. Janes created two measures of status incongruence, one “internally” oriented toward the Samoan community, and the other “externally” oriented toward the American community. Each of these was associated with an increased risk of high blood pressure.

With respect to social supports, in Samoa the extended family would be the appropriate unit for examining social support. But migration to the United States makes the extended family unit a source of difficulty as well, especially because of the economic demands that lead people to focus more on the nuclear family as the relevant social unit in American urban centers. Therefore, Janes argued that it is only a subset of extended family relationships (again, in this case adult siblings) that can truly be considered a source of support in times of felt need. Consistent with these ethnographic observations, higher support from siblings buffered the effects of stressors on blood pressure.

These studies, incorporating insights from the stress model, proved to be very effective in moving medical anthropologists beyond the modernization paradigm in studying the risk of cardiovascular disease. It is important to emphasize that all these studies were embedded within ethnographic research on these communities. Without careful attention to local meaning and local understanding, it would have been impossible to identify relevant variables in each setting and to develop culturally appropriate measures of those variables for inclusion in multivariate models. Ethnography provides the context for the research.

At the same time, this research is somewhat limited in its investigation of cultural influences in these processes. Like so much anthropological research, the concept of culture provides a general interpretive context for the research, leading investigators to identify certain kinds of social and behavioral factors as important because of the meaning attached to those factors in those specific settings. But what about more direct effects of culture? This is what Cassel and his collaborators were arguing for in their earlier papers, but the methodological and conceptual tools were not available for making those ideas operational. In more recent work, using innovations in culture theory and method, researchers have returned to these questions.

CULTURAL CONSONANCE, STRESS, AND BLOOD PRESSURE

One of the challenges in trying to examine more direct (as opposed to contextual) effects of culture on disease risk is finding a definition of culture that is both theoretically satisfying and yet can be used to understand how individuals come to be at risk. The problem of linking culture to the individual is one that has been prominent throughout the history of anthropological theory; however, employing a cognitive definition of culture suggests a resolution (Dressler & Bindon, 2000). Cognitive approaches define culture as the knowledge one must possess to function as a member of society. Culture is composed of sets of schematic, representational models of cultural domains that individuals learn. These models consist of the elements within domains and the relationships among those elements. From mundane social interactions to the most symbol-laden rituals, we as individuals and groups learn and share cultural models of how any given social context is constituted, the meaning of events and circumstances, and hence the ability to interpret others' behaviors as well as direct our own. Furthermore, culture cannot be reduced to what individuals know, but rather should be understood as the aggregate of knowledge that is distributed across individual minds.

Generally speaking, anthropologists have dispensed with the problem of relating that cultural knowledge to individual behavior, instead assuming that there is a close correspondence between the two. At the same time, the ethnographic literature is replete with examples of how people claim one set of principles as their culture, and proceed to behave in different ways. The relationship between culture and behavior is, in other words, problematic. And, there may be a variety of reasons why individuals do not or, perhaps more importantly, cannot behave in a way strictly congruent with community cultural models.

Dressler and associates (Dressler & Bindon, 2000; Dressler & Santos, 2000) used these ideas in research on blood pressure in Brazil and in the African American community in the southern United States. They suggested that the degree to which individuals are able to approximate in their own behaviors the cultural model of a particular domain, which they referred to as “cultural consonance,” would be related to blood pressure. Operationalizing

cultural consonance in a precise way was made possible by using the cultural consensus model, developed by Romney, Weller, and Batchelder (1986). The cultural consensus model uses the responses from a set of key informants to a standardized set of questions about some cultural domain to test for the degree of sharing among the informants, under the assumption that knowledge must be shared to be considered to be cultural. If there is sufficient sharing, then it can be inferred that all the informants are drawing on a single cultural model in responding to the questions (intracultural diversity in responses can also be detected using the technique). Then, giving higher weight to informants who are more central in the space of cultural meaning, the culturally best set of responses to the questions can be estimated.

Dressler and associates applied this model to the cultural domains of lifestyles and social supports. Informants were asked to rate a set of lifestyle items and behaviors in terms of their importance in defining a good life. They were also asked to rate a number of potential social supports as likely alternatives in response to crisis situations. These data were then analyzed using cultural consensus analysis, and, in each society, significant consensus was found, indicating widely shared models of lifestyle and social support (which of course differed between societies). It is important to note that informants rated events and circumstance in terms of their cultural, not individual, salience.

Then, extensive epidemiologic survey research was carried out in which respondents were asked about their own individual behaviors in the domains of lifestyle and social support, and in which data on blood pressure, diet, physical activity, and other factors were obtained. Cultural consonance was calculated as the degree to which individuals in their responses matched the culturally prototypical responses as derived from consensus analysis. In both Brazil and the southern United States it was found that the higher the degree of cultural consensus in both domains, the lower the blood pressure (controlling for usual covariates, diet, and a variety of psychological variables). The investigators argue that low cultural consonance is a chronically and profoundly stressful experience. Individuals who, at some level, know and understand the widely shared cultural models for behavior in some domain find themselves lacking in their own behaviors. Most likely, this sense of being outside of accepted conventions is reinforced as well in

mundane social interactions. The end result is enhanced risk of cardiovascular disease.

Why are individuals low in cultural consonance? Evidence points to economic factors as the primary (although not the only) limiting factor. In advanced capitalist society, without sufficient economic resources, generally accepted conventions for how life is to be lived are virtually impossible to attain and to maintain. But, these results clearly indicate that the health effects of a particular structural position in society are mediated by cultural processes.

SUMMARY

The cross-cultural study of cardiovascular disease risk has been remarkably productive for building theory within medical anthropology and in anthropology writ large. As Caudill (1958) pointed out many years ago, disease can be used to trace the fault lines within sociocultural systems. As such, the study of blood pressure cross-culturally has provided insight into how culture and social structure come together to generate obstacles and barriers, and to create supports and resources, for persons in their everyday lives. Furthermore, medical anthropologists studying cardiovascular disease have been sensitive to world systems and how macro-level change can have measurable consequences at the level of the individual and her health status.

In one sense, research in this area has come full circle. Early researchers such as Scotch and Cassel interpreted their results in terms of a culture theory emphasizing shared meaning, and how inconsistencies or incongruities in meaning could lead to stress and disease. Later researchers, applying the stress model, were able to identify factors at the individual level and to more directly test the importance of those factors. The importance of culture in the process was not lost, but continued a role as defining context and an interpretive framework for more specific findings.

More recent work, taking advantage of innovations in culture theory and research methods, has been able to empirically demonstrate how the cultural is linked to the individual, which in turn is linked to the biological. This direction in research is likely to be productive in terms both of building culture theory, and in terms of uncovering new dimensions of human health.

Diabetes Mellitus and Medical Anthropology

Leslie Sue Lieberman

INTRODUCTION AND DEFINITIONS

Diabetes mellitus is a group of metabolic diseases characterized by high blood sugar or hyperglycemia. Chronic hyperglycemia results from defects in insulin secretion from the pancreas and/or insufficient insulin action in muscle and adipose tissue. Diabetes is characterized by both under- and over-secretion of insulin, the hormone that transports glucose across cell membranes. Diabetes is associated with long-term damage and dysfunction of the pancreas, eyes, kidneys, nerves, heart, and large and small blood vessels (American Diabetes Association [ADA], 2002a; Harris, 1995).

In type 1 or juvenile diabetes the insulin-producing beta cells of the pancreas are attacked by the individual's immune system resulting in a decrease in insulin

production. Type 1 diabetes is designated as an autoimmune disease and accounts for approximately 5% of the cases of diabetes worldwide. Individuals with type 1 diabetes require insulin.

Type 2 diabetes or adult-onset diabetes is characterized by hyperinsulinism in response to the resistance of target tissues to the transport of glucose into cells. Obesity is a significant risk factor for type 2 diabetes. Type 2 diabetes accounts for approximately 90% of diabetes worldwide and is often considered a “disease of modernization” since it occurs disproportionately among populations adopting a Westernized lifestyle (Baschetti, 1998; Joe & Young, 1994; Popkin, 2001). It may be controlled through diet, exercise, and medication.

Approximately 5–10% of diabetes is due to other causes that are often transient rather than chronic.

These include gestational diabetes occurring during pregnancy (2–5%), drug or chemically induced diabetes, genetic syndromes, infections, and other endocrine diseases. A classification of diabetes lists more than 50 specific causes (ADA, 2002a; Centers for Disease Control, 2001).

DIAGNOSTIC CRITERIA

Symptoms of diabetes include: frequent urination (polyuria), hunger, thirst (polydipsia), weight loss, blurred vision, and skin itchiness. In children there may be growth impairment. Among type 2 diabetics insulin resistance may be present for a number of years prior to the development of elevated blood glucose levels. When insulin production can no longer compensate for peripheral tissue resistance, blood glucose levels rise, reaching the criteria for a diagnosis of diabetes.

The World Health Organization (WHO) diagnostic criteria for diabetes mellitus include a medical history of diabetes or a fasting plasma glucose level ≥ 140 mg/dl (7.8 mmol/L) or a plasma glucose level 2 hr after a meal of ≥ 200 mg/dl (11.1 mmol/L). However, the National Diabetes Data Group in the United States has a criterion of a fasting plasma glucose level of ≥ 126 mg/dl (7.0 mmol/L) (ADA, 2002a; WHO, 1985). An oral glucose tolerance test is also used for diagnosis. If the plasma glucose level is ≥ 200 mg/L (11.1 mmol/L) 2 hr after consuming a standard 75 mg oral glucose load, then a provisional diagnosis of diabetes is made. Normal plasma glucose levels are ≥ 110 mg/L (6.1 mmol/L). Individuals with “pre-diabetes” or impaired glucose tolerance have fasting plasma glucose levels between 110 mg/dl and 126 mg/dl, or an oral glucose tolerance test equal to or exceeding 140 mg/L (7.8 mmol/L).

The 2-hr plasma glucose levels have been set at a cut point where the prevalence of eye disease (retinopathy) and kidney disease (nephropathy) increase dramatically. However, in certain populations (e.g., Pima Indians and Pacific Islanders) with high a prevalence of type 2 diabetes the cut point at which there is a marked increase in complications is lower (≤ 126 mg/dl). These include the Pima Indians of Arizona and several Pacific Island populations.

The American Diabetes Association (ADA) Expert Committee on the Diagnosis and Classification of Diabetes Mellitus (ADA, 2002a) recommend testing

for diabetes for individuals who have the following characteristics: (1) are overweight with a body mass index (BMI) ≥ 25 kg/m²; (2) have a first-degree relative with diabetes; (3) are members of high-risk ethnic populations (e.g., African American, Hispanic American, Native American, Asian American, or Pacific Islander); (4) delivered a baby weighing > 9 lb; (5) have ever had gestational diabetes mellitus; (6) are hypertensive ($\geq 140/90$ mmHg); (7) have HDL cholesterol ≥ 35 mg/dl (0.90 mmol/L); (8) have triglycerides ≥ 250 mg/dl (2.82 mmol/L); or (9) had impaired glucose tolerance or impaired fasting glucose levels on previous testing.

DIABETES COMPLICATIONS

Diabetes is the sixth leading cause of death in the United States. Among diabetics heart disease is the primary cause of diabetes-related deaths and is 2–4 times higher in people with diabetes than those without the disease (ADA, 2002a; Centers for Disease Control, 2001). A life-threatening consequence of type 1 diabetes is diabetic coma due to ketoacidosis resulting from the exclusive use of fat as an energy source.

The most frequent complications of long-term diabetes occur because of abnormalities in the blood vessels and nerves caused by chronic hyperglycemia. Diabetes is the leading cause of blindness, kidney failure, and amputations of the lower limb. There are also abnormalities that occur in the immune, cardiovascular, and digestive systems as well as periodontal disease, sexual dysfunction, and complications of pregnancy (ADA, 2002a; Harris, 1995). Diabetes also is associated with psychological and social dysfunction. Because type 2 diabetes often does not have an acute onset, it may go undiagnosed for a number of years until a consequence of the disease is treated and the underlying diabetes is diagnosed (ADA, 2002a; Centers for Disease Control, 2001).

In the United States, Native Americans exhibit the highest mortality and complication rates of any ethnic groups. The Native American population’s age-adjusted diabetes mortality rates for 1991–93 were 11.9/100,000 for the United States but 31.7/100,000 for all Indian Health Service areas (Gohdes & Acton, 2000). Native American diabetics are four times more likely than their white counterparts to experience a lower limb amputation and six times more likely experience end stage renal disease or kidney failure. In Oklahoma, a state with more

than 30 tribes, 24% of Oklahoma Indians have diabetic retinopathy (ADA, 2002b).

DIABETES EPIDEMIOLOGY

In 2000 the worldwide estimate by the International Diabetes Federation (IDF) was 151 million adults (20–79 years) with type 2 diabetes. This is an increase from 30 million in 1985 and 135 million in 1995. There is a projected global estimate of 300 million people in 2025 (IDF, 2001). Because higher energy intakes and lower energy expenditures are having differential impacts on developed and developing countries, the prevalence of type 2 diabetes in developing countries is expected to increase by 170% compared with a rise of 41% in developed countries between 1995 and 2025 (IDF, 2001). Approximately half this increase will be Asian and Pacific Islander populations. China is predicted to have a prevalence increase of 68%, followed by India (59%) and other Asian countries and the Pacific Islands (41%) (Joslin Diabetes Center, 2002). By comparison, the worldwide estimate for type 1 diabetes was 4.9 million in 2000 and is not expected to show a major increase in prevalence.

The *Diabetes Atlas 2000* (IDF, 2001) contains estimates of diabetes prevalence in 130 countries including more than 5.5 billion people within the seven regions of the IDF. Lowest regional rates are in Sub-Sahara Africa and the highest rates in the Western Pacific. Countries with a prevalence of diabetes between 1.5% and 3.9% include Chile, China, the Philippines, Ireland, Brazil, Argentina, the United Kingdom, Peru, Thailand, Norway, South Africa, Columbia, and Venezuela. Countries with a prevalence of diabetes between 4% and 8% include Turkey, Indonesia, Portugal, Finland, Poland, India, Greece, Korea, Melanesia, Hungary, Israel, Japan, the United States (6.2%), and New Zealand. Countries between 8% and 12% include Egypt, Cuba, and Singapore. A number of Caribbean and South Pacific Island countries, Mexico, Papua New Guinea, Bahrain, Hong Kong, Pakistan, and the Czech Republic range from 12% to 15% (Table 1) (IDF, 2001).

The three tiers of prevalence represent countries from all parts of the world demonstrating genetic and ethnic diversity. Because most of these countries are small, the top 10 countries in terms of numbers of individuals with diabetes is very different. In descending order these are: India, China, the United States, Pakistan, Japan,

Indonesia, Mexico, Egypt, Brazil, and Italy (Table 2) (IDF, 2001). In the United States the adult prevalence rates vary widely among and within ethnic groups. These are: 15.1% of American Indians and Alaska Natives, 13% non-Hispanic “Blacks,” 10.2% Hispanic/Latino Americans, and 7.8% non-Hispanic “Whites” (Harris, 1995).

The most comprehensive epidemiological data exist for Native Americans. Among Native Americans one of every five is affected with diabetes (Indian Health Service, 2000). Age-adjusted rates of diagnosed diabetes in the Indian Health Service Areas for fiscal year 1995 are highest (115/1,000) for the Pima and Papago of Arizona

Table 1. Prevalence of Diabetes (20–79 Age Group) in the Top 10 Countries

Country	Prevalence (%)
Papua New Guinea	15.5
Mauritius	15.0
Bahrain	14.8
Mexico	14.2

and lowest (26/1,000) for Alaskan populations (Gohdes & Acton, 2000). These rates have increased dramatically over the last two decades. Approximately 50% of Pima adults aged 35 and older have diabetes (Knowler, Pettitt, Bennett, & Williams, 1983). Other dramatic increases have been reported for the Navajo Indians (Glass, 1996), Cree and Ojibwas Indians in Canada (Young & Harris, 1994), and Alaskan Natives (Gohdes et al., 1996). Most prevalence studies indicated that females have higher rates of diabetes than males (Lee, Howard, & Savage, 1995). In addition, rates of diabetes are higher with increasing Indian heritage (Lee et al., 1995). Genetic studies have determined that there is a genetic propensity for diabetes among the Pima (Baier, Bogardus, & Sacchettini, 1996; Farook et al., 2002).

Starting in the 1990s there has been a rapid increase in the number of Native American children with type 2 diabetes. The primary factor is obesity (Salbe et al., 2002) associated with centrally distributed fat (Goran, & Gower, 1999) and high fasting insulin levels or insulin resistance (Pettitt, Moll, & Bennett, 1993). Many of these children were exposed to high circulating glucose levels in mothers with type 2 diabetes or with gestational diabetes (Gohdes & Acton, 2000), therefore there is an inter-generational affect of diabetes during pregnancy.

Latinos are the fastest growing minority group in the United States: Mexican American (60%), Puerto Rican (12%), and Cuban (6%) with smaller numbers of Central American and South Americans. Puerto Ricans live primarily in the North East corridor, Cuban Americans primarily, in Florida, and Mexican Americans in the Southwest. By age 45, 20% of Latino Americans have diabetes and by age 65 diabetes has been diagnosed in more than 33% of Latinos regardless of their country of origin (Davidson, Seltzer, & Bressler, 1994; Harris, 1991; Weller et al., 1999). Sixty percent of the increase in diabetes prevalence in the United States in the 1990s is attributed to Latino populations (ADA, 1994). Heredity is an important factor and Latinos with a higher percentage of Native American admixture are at greater risk for diabetes (Stern et al., 1992).

The prevalence of type 2 diabetes in second- and third-generation Japanese Americans, particularly males, in the Seattle area is twice as high as the prevalence for the population with European ancestry and four times greater than the non-migrant population in Japan (Fujimoto, Leonetti, Kinyoun, Newell-Morris, & Shuman, 1987).

Diabetes is a costly disease. The economic burden of diabetes is estimated in direct healthcare costs to patients and the additional costs of lost wages, disability, and premature death. In the United States this was \$98 billion in 1997 (approximately \$12,000/patient) (Diabetes Public Health Resource, www.cdc.gov/diabetes/pubs/estimates.htm, May/2002). Per patient costs for other countries in U.S. dollars are estimated to be over \$3,000 for Belgium, Germany, and France with slightly lower levels for other European countries and the United Kingdom (\$2,000) (IDF, 2001). The rising incidence and prevalence of type 2 diabetes will present a tremendous economic burden for many countries.

POPULATIONS STUDIED BY MEDICAL ANTHROPOLOGISTS

A search of the Human Relations Area Files in 2002 indicated only 46 documents with brief references to diabetes. Wiedman (2001) notes that the majority of research on diabetes by anthropologists has occurred in a very limited number of societies primarily in North American and Canadian Native populations (Harris et al., 1997). In Canada the Dogrib in the Northwest Territory have been the focus of research by Eموke Szathmary and her colleagues since the late 1970s (Ritenbaugh, Szathmary, Goodby, & Feldman, 1996; Szathmary, 1986, 1990, 1994a, 1994b; Szathmary & Ferrell, 1990; Szathmary, Ritenbaugh, & Goodby, 1987). Other populations that have been studied are the Sandy Lake Cree (Gittelsohn et al., 1995, 1996), Anishinaabe Ojibway (Garro, 1987, 1995; Garro & Lang, 1994), urban Indians in Toronto (Hagey, 1984), the Metis, who are a heterogeneous group of Indians and Europeans (Bruce, 2000), and a number of Inuit and non-Inuit Indians in the Canadian Arctic (Young, 1987, 1993; Young, Chateau, & Zhang, 2002; Young, Szathmary, Evers, Wheatley, 1990; Young, Scharer, Shubnikoff, Szathmary, Nikitin, 1992).

In the Continental United States extensive multi-disciplinary studies have been made with the Pima Indians of Arizona since the 1960s (Knowler et al., 1983; Knowler, Williams, & Pettitt, 1988; Knowler, Pettitt, Saad, & Benett, 1990; Kozak, 1996; Ravussin, Valencia, Esparza, Bennett, & Schulz, 1994; Reid et al., 1971). Anthropologists have studied other southwestern populations including the Navajo (Evaneshko, 1994; Hall,

Hickey, & Young, 1991, 1992, 1994; Ritenbaugh, 1981), the Zuni (Cole, Teufel-Shone, Ritenbaugh, Yzenbaard, & Cockerham, 2001; Leonard, Wilson, & Leonard, 1986; Teufel & Ritenbaugh, 1998), and Yuman tribes (Smith, 1970). Other Native American populations that have been studied by anthropologists include: the Oklahoma Cherokee and Kiowa Apache (Wiedman, 1987, 1989), the Creek (Russell et al., 1994), the Oklahoma Choctaw (Carson-Henderson, 2002), the Florida Seminole (Joos, 1984; Smith & Weidman, 2001), the North Dakota Sioux (Garro & Lang, 1994; Lang, 1985, 1989, 1990), the Seneca of New York (Judkins, 1975), and the Oregon Kalamath (Joos & Ewart, 1988). In addition to the classic article by epidemiologist Kelly West (1974), physician Dorothy Gohdes has published a number of useful overviews of diabetes among Native American populations (Gohdes, 1996; Gohdes & Acton, (2000); Ghodes, Kaufman, & Valway, (1993); Ghodes, Rith-Najarian, & Acton, 1996). Rokala, Bruce, and Meiklejohn (1991) have published an extensive annotated bibliography of studies of North America Native populations. In 1994 Szathmary reviewed the diabetes literature for Native American populations.

Mexican Americans have been studied by a number of anthropologists (Caldwell et al., 1996; Chakraborty et al., 1993; Hunt, Arar, & Akans, 2000; Hunt, Arar, & Larne, 1998; Joos, Mueller, Hanis, & Schull, 1984; Mueller et al., 1984; Urdaneta & Krehbiel, 1989; Weller et al., 1999). Diabetes among African Americans has been studied by Frate, Ginn, and Keys (2000); Lieberman (1987); Lieberman, Probart, and Schoenberg (1999); Winter et al. (1987). Leonetti and colleagues (Fujimoto et al., 1987) describe work with Japanese Americans.

Little work has been done by anthropologists or with an anthropological perspective in Mexico, Latin America, or the Caribbean. The Mexican Pima have been studied by Ravussin and colleagues (Ravussin et al., 1994; Valencia, Bennett, Ravussin, & Esparza, 1997) and Winkleman (1989) has published on ethnopharmacology in Baja California. Crews, Kamboh, Mancilha-Carvalho, and Kotke (1993) worked among the Yanamami in Brazil. Gulliford (1996) has worked in Trinidad and Tobago.

A significant body of research has been accomplished for Australia, New Zealand, and the Pacific Islands. Zimmet and anthropology colleagues have been involved in long-term, multidisciplinary studies among a number of Pacific Island populations (Zimmet, Kirk,

Serjeantson, Whitehouse, & Taylor, 1982; Zimmet, Kirt, & Serjeantson, 1995; Zimmet, Taft, Guinea, Guthrie, & Thoma, 1977). Anthropologists have produced an in-depth record of diabetogenic lifestyle changes among the Samoans (Bindon & Baker, 1985; Bindon, Crews, & Dressler, 1991; McGarvey, 1994; McGarvey, Bindon, Crews, & Schendel, 1989). O'Dea and colleagues have studied acculturation among Australian Aborigines (O'Dea, 1984; O'Dea, Spargo, & Akerman, 1980).

Wiedman (2001) notes that there are uninvestigated areas of the world that in the future will be of interest for medical anthropologists engaged in diabetes research. Little or no anthropological research on diabetes has been done in Asia, Africa, the Middle East, India, or Europe. Gang (1995) was the first anthropologist to study diabetes in Korea and Ramachandran, Snehalatha, Latha, and Manoharan (1999) studied urbanization and diabetes among Asian Indian populations.

MEDICAL ANTHROPOLOGY AND DIABETES

Since the 1960s anthropologists have published on a diversity of topics related to type 2 diabetes. Weidman (2001) cites over 130 articles, chapters, and books published from 1975 to 2001 by anthropologists. These articles have appeared in anthropology, medical, epidemiology, and nutritional science journals

Diabetes research is multifold: evolutionary and genetic aspects; lifestyle factors, especially dietary factors; traditional and contemporary explanatory models of illness; and interactions with the biomedical health-care system. Research has been spurred by the wide range of differences in the prevalence of type 2 diabetes among populations, its devastating societal impact, and its rapidly increasing worldwide incidence and prevalence.

In addition to Weidman's (2002) review, there are other comprehensive reviews by anthropologists. Eaton was the first to present a biocultural overview of diabetes in *Medical Anthropology* (Eaton, 1977). In 1989 *Medical Anthropology* devoted an entire issue to diabetes with an introduction by Urdaneta and Krehbiel (1989). Lieberman published reviews of diabetes in 1993 with a focus on history and in 2000 with a focus on diet. The following sections are an overview of these major themes.

BIOMEDICAL ANTHROPOLOGY AND THE EVOLUTION OF DIABETES: THRIFTY GENOTYPES AND PHENOTYPES

Anthropologists have been interested in evolutionary models of type 2 diabetes that explain the vastly different prevalence rates among worldwide populations. Of interest is the current epidemic in populations with multiple generations of high diabetes rates (i.e., Pima Indians), in newly designated populations with rapidly increasing incidence rates (i.e., urban South African populations), and in children and adolescents in populations that have had a history of high prevalence rates among adults (i.e., African American youth) (Lieberman, 1993, 2000).

Geneticist J. V. Neel first proposed a thrifty genotype for glucose utilization among Native American populations as an evolutionary explanation for their high prevalence rate of type 2 diabetes (Neel, 1962, 1982; Neel, Weder, & Julius, 1998). He hypothesized that a feast and famine existence conferred a selective advantage and increased reproductive fitness for those individuals who had the ability to release insulin quickly, to thriftily store energy during times of food abundance, and to efficiently utilize energy depots during dietary deprivation (Neel, 1962, 1982). Recently, Campbell and Cajigal (2001) postulate specific selection for thriftiness of the physiological mechanisms enhancing energetic efficiency of skeletal muscle.

Shifts to modern lifestyles with increased food abundance, a lack of periodic food shortages, and a reduction in energy expenditure rendered a once adaptive genotype detrimental. The result is obesity, type 2 diabetes, and other characteristics of Syndrome X or insulin-resistance metabolic syndrome, including high blood lipids and hypertension (Raven, 1988). Many authors have expanded on this hypothesis in other populations including additional selective pressures of cold stress from water and long ocean-going voyages for Pacific Island populations (Bindon & Baker, 1985; Zimmet et al., 1982) and extreme cold stress for Eskimo and Aleut populations (Shepard & Rode, 1996). High seasonal energy demands during slavery for African Americans posed an additional stress (Gibbs, Cargill, Lieberman, & Reitz, 1980; Lieberman, 2003).

Weiss (1990), Weiss, Cavanagh, Buchanan, and Ulbrecht (1989), and Weiss, Ferrell, and Hanis (1984) have hypothesized that New World Syndrome, a collection of metabolic disorders characterized by diabetes, obesity, high blood lipids, gallstones, and gallbladder cancer,

resulted from a combination of founder effect and selective pressures encountered in harsh Arctic environments by the first New World immigrant populations. Wendorf (1989) has a slightly different scenario. He suggested that selection for thrifty genotypes occurred when the ancestors of Paleoindians migrated south of the northern ice-free corridor and were confronted with unfamiliar non-Arctic hunting conditions. These conditions, he hypothesized, precipitated food shortages and selection favoring those who are able to store calories efficiently. These scenarios are confounded by evidence of multiple migrations. For example, there are low rates of diabetes among the more recent Canadian Athapascan speakers; however, this is not the case for U.S. Athapascans. These differences in prevalence suggest that gene-environmental interactions play important roles in diabetes risk (Sievers & Fisher, 1981; Szathmary, 1986).

Most of the literature on genetic thriftiness has focused on selective pressures operating in adulthood. Kuzawa (1998) focuses on human infancy and early childhood. He reviewed the literature supporting a strong selective advantage of a quick insulin trigger with enhanced fat storage as a hedge against infant morbidity and mortality. Refeeding after starvation or respiratory and diarrheal illnesses is accompanied by increases in insulin production. Furthermore, infants who have suffered nutritional compromise in utero and are small for their gestational age gain weight with appropriate nutritional interventions but demonstrate reduced glucose tolerance and are at high risk for insulin resistance metabolic syndrome, or Syndrome X, later in life (Barker, 1994, 1999; Phipps et al., 1993; Raven, 1988). The Barker hypothesis of prenatal origins of later life diseases, including diabetes, compliments the thrifty gene hypothesis (Kuzawa, 1998).

Szathmary (1986, 1990) and Ritenbaugh and Goodby (1989) questioned the utility of the thrifty gene model for explaining high rates of diabetes in indigenous North American populations because the diets of the founding New World populations were likely high in protein and fats and low in carbohydrates. Therefore, they hypothesized there would not be intense selection pressure for rapid glucose uptake but instead enhanced gluconeogenesis whereby glucose is produced from proteins. This thriftiness for metabolic conversion would have been an adaptation rendered disadvantageous by modern diets high in carbohydrate. Allen and Cheer (1996) write of a non-thrifty genotype with a slow insulin trigger that would have conferred protection against

diabetes and obesity in dietary environments of abundance with high carbohydrate and fat intakes. They suggest this might have been the case for some European and Middle Eastern populations who also have a high rate of lactase sufficiency in adulthood.

Data from other parts of the world also suggest similar but more recent dietary transitions, among Australian Aborigines (O'Dea, Spargo, & Akerman, 1980) and other Pacific Island populations (Zimmet et al., 1982, 1995). On the island of Nauru in Micronesia more than 30% of individuals over the age of 15 have diabetes (Zimmet et al., 1977). These high rates are most likely the result of nutritional and cold selection as well as founder effect in which members of the small initial island population carried thrifty genes. Expanded beyond carbohydrate utilization, the model has implications for thriftiness in the metabolism of other previously limited dietary constituents that have now become abundant (e.g., salt, cholesterol); and, conversely, dietary constituents that were once abundant and are now limited (e.g., dietary fiber) (Broadhurst, 1997). Broadhurst (1997) makes a case for diabetogenic effects of reduced omega-3 polyunsaturated fatty acid (PUFA), chromium, plant phytochemicals, and fiber in contemporary Western diets relative to paleonutrition and traditional diets.

In conclusion, the thrifty gene hypothesis does not fit all cases well, but it does raise the possibility of a strong genetic explanation for the high rates of type 2 diabetes for many populations in conjunction with other microevolutionary processes and recent lifestyle changes. Understanding thrifty genotypes has implications for health policy (Benyshek, Martin, & Johnston, 2001).

BIOMEDICAL ANTHROPOLOGY AND OBESITY: THE PRIMARY RISK FACTOR FOR TYPE 2 DIABETES

More than 80% of new cases of type 2 diabetes are associated with obesity. This association has been demonstrated in many populations worldwide. Furthermore, risks correlate not only with the degree of adiposity but with the duration and distribution of body fat. A centripetal distribution of fat is a separate risk factor for both cardiovascular disease and diabetes and occurs more frequently in populations with high diabetes prevalence (Harris, 1991; Joos et al., 1984; Lieberman et al., 1999; Mueller et al., 1984). The risk occurs for both adults and

increasingly in youth (Chakraborty et al., 1993; Dietz, 1998; Young & Rosenbloom, 1998).

Obesity and diabetes are linked to each other, and both are linked to dietary acculturation that involves the consumption of a surfeit of energy regardless of the food source (Kuhnlein & Receveur, 1996; Popkin, 2001; Teufel, 1996). Obesity has been extensively studied in populations with high diabetes prevalence. Overweight and obesity are in excess of 60% of the adults among Native Americans (ADA, 2002b; Hall et al., 1992; Hanley et al., 2000; Joos, 1984; Knowler et al., 1990; Young, 1996), Mexican Americans (Joos et al., 1984), African Americans (Kuczmarowski et al., 1994; Kumanyika, 1993, 1994; Lieberman, 2000, 2003; Roseman, 1985), Native Hawaiian, Samoan and other Pacific Island populations (Baker, Hanna & Baker, 1986; Bindon & Baker, 1985; Kumanyika, 1993; Zimmet et al., 1995) and population in developing countries (Drewnowski & Popkin, 1997; Lieberman, 2003; Popkin, 1998; 2001). In addition to the health risks associated with excessive adiposity, it also plays a significant role in the microevolutionary models of diabetes etiology and epidemiology developed by geneticists and biological anthropologists.

DIETARY TRANSITIONS, LIFESTYLE FACTORS, AND DIABETES

Anthropologists have explored cultural models of illness and the experience of being a person with diabetes. Cultural etiological models often include dietary elements, especially sugar and processed foods, that represent a departure from traditional, ethnically important diets (Kuhnlein & Receveur, 1996). Although many studies discuss the historical trends in type 2 diabetes as a result of modernization, Westernization, or even "cocacolonization" and "McDonaldization" as creating obeseogenic and diabetogenic environments (Drewnowski & Popkin, 1997; Eaton, Eaton, & Konner, 1999; Popkin 1998, 2001; Wickelgren, 1998), only a few anthropological studies have explicitly documented these changes.

Dietary acculturation takes many forms depending on: (1) food availability including the influences of the environment, technology, and politics; (2) food selection including the influences of cultural preference, affordability, and education; and (3) biological needs, including the influences of age, sex, physical activity, and state of health (Kuhnlein & Receveur, 1996; Stinson, 1992).

Szathmary et al. (1987) found that the Dogrib of Canada retained traditional dietary items and added new foods, thereby increasing diet breadth and caloric intake. The Sandy Lake Cree classified foods and illnesses into "Indian" and "White Man's" groups with the notion that the consumption of "White man's" junk foods leads to diabetes (Gittelsohn et al., 1996).

A series of studies dating from the 1970s have documented changes in diet, activity level, stress, migration patterns, and concomitant biological and pathological trends among Samoans (Baker, Hanna, & Baker, 1986). The Samoans represent a natural laboratory for studying modernization because genetically similar populations occupy traditional, transitional, and modern environments, Western Samoa, American Samoa, and Hawaii, respectively. Acculturation has increased obesity, diabetes, hypertension, and cardiovascular disease (Bindon & Baker, 1985; McGarvey et al., 1989).

The National Institutes of Health have been studying the Pima Indians of Arizona since the 1960s (Knowler et al., 1983). The Pima provide an opportunity for looking at both transitions within the Arizona Pima and contrasts with a genetically similar but culturally traditional segment of the population having separated about 1,000 years ago and residing in North West Mexico. Both Pima groups have a history of arid land agriculture, growing corn, beans, squash, and cotton. Irrigation systems attracting game and fish were used to supplement the diet with hunting, trapping, and fishing. The Pima also forage for desert food plants. Data collected for both Pima Indian groups include anthropometric measurements, body composition, and metabolic, dietary, and physical activity data. The Mexican Pima have a lifestyle characterized by high-energy expenditures with subsistence and wage labor (i.e., road construction, mining, and wood milling) and a traditional diet very low in fat, especially animal fats and high in fiber (>50 g/day) (Ravussin et al., 1994; Valencia et al., 1999; Narayan et al., 1998).

For Mexican Pima, the main dietary staples are four varieties of beans, corn processed as tortillas, and potatoes. The main source of protein and carbohydrates is from corn and wheat flour tortillas that are prepared with vegetable fat and beans that are fried with vegetable oils or shortenings. In addition, coffee with sugar, eggs, milk, rice, soda, pasta soups, green pepper, tomatoes, and cabbage are consumed frequently. Little meat is eaten. This diet is slightly higher in calories than the traditional diet of the Tarahumara Indians (McMurphy, Cesqueira, Connor, & Connor, 1991). By contrast, diets among the

Arizona Pima are highly acculturated, comprised of processed and fast foods (Narayan et al., 1998).

Mexican Pima are short with body mass indices (kg/m^2) (BMIs) averaging 25.1 for women and 24.8 for men relative to the Arizona Pima with BMIs of 35.0 and 30.8 for women and men, respectively. A person with a BMI of 30 or larger is considered to be obese. The prevalence of type 2 diabetes for Mexican and Arizona Pima was 6.3% and 54% for women and 10.5% and 37% for men (Ravussin et al., 1994).

A similar comparison between Mexican Americans living in San Antonio and Mexicans living in Mexico City suggests that environmental factors play a significant role in the etiology of type 2 diabetes (Stern et al., 1992). These genetically identical groups showed marked differences in type 2 diabetes with Mexican Americans having far greater obesity and type 2 diabetes prevalence rates than their Mexican counterparts.

O'Dea (1984) and O'Dea et al. (1980) performed an interesting experiment among diabetic Australian Aborigines. A temporary reversion to traditional lifestyle led to marked improvements in both carbohydrate and lipid metabolism.

A dietary change common to all these cases has been the increased consumption of sugar and refined carbohydrates (Popkin, 1998, 2001). Since the key diagnostic feature of diabetes is high blood sugar, often accompanied by sugar in the urine, diabetes is frequently spoken of as "sugar diabetes" and "I've got sugar" or "I've got high sugar" (Carson-Henderson, 2002; Ferzacca, 2000; Lieberman et al., 1999). All carbohydrates cause a rise in blood glucose, and the glycemic index, a measure of the impact of food or a meal on the rise in blood glucose, has a significant but transitory effect on both insulin production and glucose homeostasis (Jenkins et al., 2002; Lieberman, 1993). In general, processed carbohydrate foods have higher glycemic indices than the traditional or unprocessed forms (Jenkins et al., 2002). The modernization of diets has reduced dietary fiber and increased both the fat and refined carbohydrate content of meals (Eaton & Konner, 1985; Trowell & Burkitt, 1981). These changes are linked to both obesity and diabetes among Native North Americans (Gittelsohn et al., 1995; Reid et al., 1971; Ritenbaugh et al., 1996; Smith & Wiedman, 2001; Szathmary, 1990, 1994b); African Americans (Kumanyika, 1988; Lieberman, 1987); Japanese Americans (Fujimoto et al., 1987); Caribbeans (Gulliford, 1996), and Hispanics populations (Stern et al., 1992).

Wiedman (1987, 1989) tracked economic changes from subsistence farming to a cash economy and the rise of diabetes prevalence among the Cherokee of Eastern Oklahoma. He notes that diabetes was unknown prior to 1940. Economic and dietary ethnohistorical data have illuminated the epidemiological transition and the rise of diabetes among the Pima of Arizona (Knowler et al., 1983; Ravussin et al., 1994); the Seminole of Florida (Joos, 1984); the Navajo (Hall et al., 1994); First Nation populations of Canada (Bruce, 2000; Szathmary, 1986, 1990, 1994a, 1994b; Young, 1987, 1993), Australian Aborigines (O’Dea, 1984; O’Dea et al., 1980; Thompson & Gifford, 2000), and Samoans (Baker et al., 1986).

An area affected by modernization of diet, ecological changes, and transitions in medical care is the use of traditional herbal medications for diabetes and its complications (Gang, 1995; Winkleman, 1989). This is an area that has not been well studied by medical anthropologists. Grover, Yadav, and Vats (2002) and Dharmananda (1996), respectively, provide primers on Indian and Chinese herbal medicines for diabetes. Studies have demonstrated the efficacy of herbal compounds in controlling hyperglycemia (Chen, Gong, & Zhai, 1994; Gang, 1995).

TRADITIONAL HEALTHCARE BELIEFS AND PRACTICES

This section briefly examines traditional healthcare beliefs and practices concerning diabetes etiology, pathogenesis, treatment, and prognosis in selected cultures by anthropologists and other social and medical scientists.

Korean, Chinese, and Asian Indian Traditional Medicine

Type 2 diabetes mellitus is known as “the rich man’s disease” in Korea. It was not until after the 1960s that diabetes began a rapid increase at an estimated rate of 3–4% per year, with an estimated 500,000 in the year 2000 (Korean National Federation of Medical Insurance, 1993). Gang (1995) investigated traditional and biomedical practices among diabetic Koreans aged 20–80 years. Fifty patients used primarily Western medicine and 33 used primarily traditional therapies. Western therapies included diet, exercise, insulin, or oral medications. Fasting blood glucose levels for patients using traditional treatments averaged 165.8 mg/dl compared with

206.1 mg/dl for patients using Western medicine. Both groups of patients avoided fatty foods, alcohol, and foods containing sugar. Some diabetics substituted unpolished rice, black soybeans, and barley in place of the traditional polished rice at main meals. Black soybeans are the most popular item in a diabetic diet. The majority of patients also included increases in exercise, especially walking. Gang (1995) also studied social support and life satisfaction that were higher among those practicing traditional therapies.

Korean traditional medicine includes elements of Chinese and Japanese medical traditions. Health and disease are explained in terms of the balance of *Ki* (or *Chi* in Chinese medicine). Diabetes in Korean medicine is defined as the imbalance of two *ki*’s, defined as energy, force, breaths of air, or vital fluids. The symptom *So*, meaning exhaustion, refers to weight loss resulting from abnormal heat in the stomach and large intestine further causing hormonal changes and/or abnormalities in the energy force among the kidneys, liver, gallbladder, and *Samcho*, an imaginary organ in Korean medicine. The abnormal heat inside the body results in thirst. Three types of diabetes are defined according to where energy is trapped in the body (Gang, 1995).

The function of the body is also regulated by five elements: wood, fire, earth, metal, and water. These elements form an ever-flowing cycle in a particular production sequence. A violation of this sequence can lead to a disease. Severe anger exemplified by the element wood also can cause diabetes (*Sogalbyong*) because anger causes heat to enter the liver, creating a malfunction. The wood *Ki* also controls sugar addiction. According to the relationship sequence based on the five elements, metal controls wood. When salt is heated to 1,000°C it produces a white metal. This pure salt is used for the treatment of diabetes.

Another popular traditional therapy is Raw Vegetable Therapy based on the balance between *Yin* and *Yang* and six elements. Diabetes in the Raw Vegetable Therapy approach is identified in terms of pulse rates. These pulses are taken at various sites in the body detecting problems of the spleen and stomach that generally cause diabetes. Beta cells that produce insulin are *Yang* and blood sugar is considered *Yin*. Normal blood sugar levels are achieved with the balance of these two forces.

Breathing Therapy includes both cleansing the body and energizing it so that *Ki*, the energy force in air, is regarded as a nutrient. According to Taoism the nutrition provided by air through breathing is even more vital to health and longevity than that provided by food and water through digestion (Reid, 1989).

In addition, herbs are recommended for the control of diabetes and 99 different herbs have been promoted as therapeutic in the control of diabetic symptoms. These include root of the wild rose, aloe, plantains, mushrooms, willow leaves, ginseng, chicory, and various enzyme-including foods. The ingestion of certain animal products are efficacious: dog, snake, deer horns, and mudfish (Gang, 1995). An ongoing health ethnography project in Florida provides unpublished data for Korean Americans using herbs and acupuncture to treat diabetes.

The development of type 2 diabetes in China was first recognized as a problem in 1980, especially in the urban areas (Xiu & Shang, 1985). Factors that influenced the increased prevalence of type 2 diabetes included increased caloric intake, increases in refined carbohydrate, urbanization, mental stress, and aging of the population. Xiu and Shang (1985) note major public health efforts focusing on education, organization, and prevention of type 2 diabetes in China using traditional Chinese medicine, herbs, and biomedicine.

Diabetes in Indian Ayurvedic medicine has a complex etiology and pathogenesis. The human body is composed of three fundamental elements, or *dosas* (wind, bile, phlegm). Health is maintained by a balance of these elements and consequentially a disturbance of equilibrium leads to disease. There are three *dosas* that control various aspects of physiology; each *dosa* has five divisions and a disturbance in anyone of these can cause diabetes. In addition, the body contains 13 categories of *srotas* or channels of circulation through which pass basic tissue elements, *doshas*, and waste products. Lack of exercise, sleeping during the day, an excessive intake of fatty food, and alcohol consumption can disturb the *srotas* involved in carrying the vital substances that comprise fat tissue, thereby resulting in diabetes. Excessive consumption of yogurt, the flesh of animals living in water and marshes, rice, wheat, starch, and especially refined foods, are seen to play a role in the etiology of diabetes in Ayurvedic medicine. Traditional approaches involve reducing the body fat to effectively regulate the function of the pancreas and the use of glucose. Medications include the use of bitter melon and other botanicals: long pepper, fenugreek, turmeric, Indian pennywort, bitter melon, gurmar, aconite, blue rocket, Frier's cap, caltrops, ground burnut, and puncture vine (Broadhurst, 1997; Grover et al. (2002). Most vegetables are recommended for individuals with diabetes, but sugar, rice, potato, bananas, cereals, and fruit are to be avoided and fat is to be ingested in limited quantity.

African-American Traditional Medicine

African Americans, the second largest minority in the United States, have a diabetes rate 33% greater than "Whites" (Tull & Roseman, 1995). The heterogeneous traditional medical system combines African healing, Civil War era medicine, West Indian Voodoo, fundamentalist Christianity, and European medical and anatomical systems (Snow, 1974). A fundamental belief is the direct connection between the forces of nature and health. Seasonal (e.g., phases of the moon) and natural climatic events as well as lucky numbers play a role in illness prevention, etiology, treatment, and prognosis. Health is considered to be "good fortune" and is part of God's plan but must include appropriate self-care of the mind, body, and spirit (Lieberman et al., 1996, 1999). Traditionally, the major causes of illness were: (1) exposure to "cold" causing mucus and the clotting of blood that can lead to headache, hypertension, and stroke; (2) "dirt" or germs leading to heat, fever, rashes, and inflammation; (3) improper diet resulting in "high" or "low" blood and high sugar or diabetes; and (4) improper conduct or parental transgressions causing disorders in children. The author has encountered this in the explanatory model for type 1 diabetes among children at an outpatient clinic in the Southeast U.S.

Grannies, herbalists, herb doctors, root doctors, and spiritual healers engaged to diagnose and treat conditions. Supernatural or magical illnesses caused by sorcery or voodoo, or rootwork that can hex an individual, require healers with supernatural powers (www.diversityresources.com/health2k/health/african2.html, accessed 8/2002). Today these healers rarely treat type 2 diabetes. African Americans generally rely on biomedicine although herbal home remedies and dietary precautions are employed along with insulin and oral medication. "Worriation" or stress has been stated as a cause of type 2 diabetes and its complications (Lieberman et al., 1996).

Native American Traditional Medicine

American Indian patients have a range of diabetes causal agents: traumatic events, infectious agents, transgression of cultural or supernatural norms, an imbalance of the harmonious processes of nature, an affliction of malevolent spirits, the loss of one's soul, or the malicious intent of another individual (Levy, 1983). In contrast, Choctaw

patients in Carson-Henderson's study do not attribute diabetes to supernatural influences or taboo transgression, but to diet, especially sugar, and "White man's culture" (Carson-Henderson, 2002). The idea that the illness occurs without external causation is difficult for many persons to understand. The concept of obesity, an internal state, causing the disease is puzzling since overweight and large body size are signs of prosperity and health. In particular, elderly patients view obesity as healthy because in their youth being slender was considered a sign of illness (Brosseau, 1994; Gohdes, 1988). Furthermore, a plump body is considered to be attractive to the opposite sex (Gohdes, 1988; Hickey & Carter, 1994). Therefore, when diabetics are placed on a special diet and told to lose weight, this creates problems for other family members as well (Joe & Young, 1994).

The high rates of diabetes-related mortality and complications among Native Americans have led to a resignation concerning the inevitability of developing diabetes. There is also resentment focused on "the White man" for creating the conditions for a diabetogenic lifestyle (Carson-Henderson, 2002). There is a distrust of physicians based on the perception that diabetes is due to White man's food and pollution of the environment. These ideas are found among Dakota Native Americans (Lang, 1985, 1989), the Papago (Hoffman & Haskell, 1984), the Ojibway, and the Cree (Garro, 1995; Hagey, 1984).

Home management dietary and medication complexities coupled with a fatalism regarding complications can elicit fear and grieving related to the diagnosis of diabetes. Goforth-Parker (1994) conducted a study in rural Oklahoma using unstructured interviews and clinical observations to elicit disease processes and insights into the lived experience of diabetes. The responses were constructed into thematic patterns that illuminated these concerns.

Some Indian patients utilize traditional healers. The Indian Health Service estimates the use of traditional Indian medicine by tribes ranging from 70% to 90% depending on the age group (Carson-Henderson, 2002; Hollow, 1999). Within the Choctaw nation the traditional healers are called *Chattah Alikchi* or "Choctaw Doctor." The *alikchi* occupies the role of a spiritual leader and is similar to a shaman. The *alikchi* deal with both spiritual and biological complaints. Among the Ojibway, healers are consulted on diabetes care. Healers provide herbal medicines said to be effective in controlling diabetes. Individuals taking these medicines must abstain from alcohol. Healers are described as "gifted" because of their

ability to communicate with and be guided by spiritual beings. However, most Native Americans and Canadian Natives also access biomedical physicians when a diagnosis of diabetes has been made.

Latino and Hispanic Traditional Medicine

Many cultural factors, including diet, activity patterns, and health beliefs and practices, are involved in the high prevalence of diabetes among Latino populations. Most Latinos believe diabetes is hereditary. Fifty-eight percent in the ADA survey (1994) agreed with the statement "Diabetes is hereditary, and therefore there is nothing anyone can do avoid getting it." This fatalistic attitude toward diabetes truncates both preventative and treatment measures. In the ADA survey, 60% of respondents indicated that a healthy diet was the best way to reduce the chances of getting diabetes by eating less sugar (38%), controlling one's weight (17%), and exercising (18%). Most Hispanics receive biomedical care for their diagnosed diabetes.

Health beliefs show great heterogeneity within and between ethnic groups. The traditional system is based on a hot–cold dichotomy of foods, physiological states, illnesses, and medications (Weller et al., 1999). Diabetes is classified as a hot ailment. Health is restored or maintained by a balance of hot and cold elements. Traditional healthcare practitioners such as *curanderos* are consulted for treatment of diabetes and its complications. Herbs and medicinal preparations may be purchased from *botanics*. Many herbs are thought to have a beneficial effect on diabetes. Nopal or prickly pear cactus lowers blood glucose (Broadhurst, 1997). Papaya is also thought to cure diabetes. Prayer is an important component of healing activities. The majority of Latinos are Catholic (Hunt, Arar, & Akana, 2000; Hunt, Valenzuela, & Pugh, 1998; Weller et al., 1999).

MEDICAL ANTHROPOLOGICAL STUDIES OF PATIENT–PROVIDER INTERACTIONS

A number of anthropologists have explored the beliefs, discourse, and behaviors of diabetes patients and their healthcare providers. Carson-Henderson (2002) found four distinctive patterns on the Choctaw Reservation in Oklahoma. Her dissertation focused on the cultural

construction of diabetes among Choctaw diabetics and native Health Care Providers. The traditional model was characterized by delayed care-seeking, reduced dietary compliance, and the perception that non-compliance was part of traditional culture. The mainstream model was characterized by more immediate care-seeking, and increased dietary compliance. Native American providers held either a uniform practice model characterized by the idea that there were no differences in cultural constructions of diabetes among the Choctaw diabetics relative to main stream medicine, or they articulated a negotiated practice model characterized by acknowledgment that two culturally different systems coexist in terms of care-seeking and compliance. The greatest discordance was seen in the traditional model patients and the uniform practice model providers since the latter group did not acknowledge that there were cultural differences.

Lang (1989) explored the problems of home management of diabetes, particularly the prescribed dietary changes among the Dakota. She found a lack of knowledge concerning treatments, a concern over their efficacy, and a depersonalization of the illness that was conceptualized in terms of Dakota ethnic identity.

Lieberman, Probart, and Schoenberg (1991, 1996) found similar problems implementing dietary changes among elderly, rural southern African American women. Some of the issues related to communication. For example, dietitians prescribing "fresh" foods were unaware that the term had two meanings. The first was the common meaning of recently grown and unprocessed, while the second negative meaning referred to unseasoned and tasteless foods. In addition, there were conceptual differences with regard to the food categories of "carbohydrates" and "fats." Dietitians conceptualize these as macronutrients and dietary exchange categories but African American women combined these categories in a taxon labeled "fattening foods" or "foods diabetics should not eat."

Garro's work among the Canadian Anishinaabe employed a formal cultural consensus methodology to define causal explanations for diabetes (Garro, 1995) and extended this to a study of the Dakota (Garro & Lang, 1994). These models cite the rapid change in lifestyle with modernization and acculturation as the causal agents. Like other groups, modernization has led to a sense of loss of balance, a loss of control over one's life, and uncertainty about the future.

Clinical encounters between patients and providers often involve linguistic and meta-linguistic miscommunication and misdirected expectations based on differences

in world views (Hagey, 1984; Hunt, Arar, & Akana, 2000; Hunt, Arar, & Larme, 1998; Hunt, Valenzuela, & Pugh, 1998; Larme & Pugh, 1998; Miewald, 1997; Ferzacca, 2000; Woolfson, Hood, Seckler-Walker, & Macauley, 1995). Physicians describe the difficulty in explaining the complex etiology and pathophysiology of diabetes and its long-term consequences (Cohen, Tripp-Reimer, Smith, Sorofman, & Lively, 1994; Loewe, Schwartzman, Freeman, Quinn, & Zuckerman, 1998). Physician and patient communication is further complicated by the vastly different cultural constructs embodied in language (Evaneskho, 1994; Ferzacca, 2000; Garro, 1995; Garro & Lang, 1994). Other issues concern widely held perceptions by health providers (Loewe et al., 1998) and that patients are non-compliant. However, Hunt and colleagues (Hunt, Arar, & Larme, 1998; Hunt, Valenzuela, & Pugh, 1998) found that repeated exposure and long-term interactions altered Mexican American patients' concepts of diabetes.

Other researchers have brought into focus the ethnocentrism of the biomedical paradigm that emphasizes individual motivation and self-care denying both community and family-based cultural priorities. Economic, political, and racial inequalities act as barriers to all aspects of healthcare (Miewald, 1997; Wiedman, 2001).

Medical anthropologists have examined the interactions of cultural and structural barriers in the healthcare system. For example, Latinos have a late diagnosis of diabetes and high rates of complications because of low socioeconomic status, reluctance of patients to visit a doctor, lack of access to adequate healthcare, no health insurance, language barriers including a lack of basic English (25%), and a low number of bilingual/bicultural physicians (Davidson, Seltzer, & Bressler, 1994). Stern et al. (1992) estimate that among Mexican Americans 60% of diabetes-related blindness, 60% of diabetes-related foot and leg amputations, and 51% of kidney failures could have been prevented with proper care.

DIABETES EDUCATIONAL AND COMMUNITY-BASED INTERVENTIONS

A number of Native American and Canadian populations have recognized the importance of lifestyle changes in diabetes prevention (Stolarczyk, Gilliland, Lium, & Owen, 1999). Consequently, Native populations are becoming more actively involved in the planning, implementation, and evaluation of diabetes programs

(Gohdes & Acton, 2000; Joe & Young, 1994; Olson, 1999; Wiedman, 2001). Community interventions have developed with the cooperation of tribal and indigenous organizations, public health agencies, and healthcare professional organizations (Young, 2001). These interventions often focus on community rather than individual responses to diabetes preventive activities. A good example is the program among the Sandy Lake Cree that focused on collective responsibility for the burden of diabetes in their community (Gittelsohn et al., 1995, 1996; Hanley, Harris, Gittelsohn, & Andres, 1995).

A public health campaign of educating tribal members on low-fat diets, cigarette smoking, and exercise was developed by a Mohawk community (Hood, Kelly, Martinez, Shuman, & Secer-Walker, 1987). An important and successful school and community-based project was initiated among the Zuni Indians of New Mexico (Cole et al., 2001; Teufel & Ritenbaugh, 1998). The Zuni Diabetes Prevention Program eliminated soft drinks and snack foods from school vending machines, provided good-tasting water, promoted a school-based wellness and exercise program, and developed supportive social networks. These interventions resulted in increased activity, decreased soft drink consumption, and a decrease in the incidence of hyperglycemia.

A unique curriculum has been adapted and implemented in Pueblo communities (Carter, Gilliland, & Perez, 1997; Gohdes, Rith-Najarian, & Acton, 1996; Teufel & Ritenbaugh, 1998). Most Indian Health Service prevention and treatment programs involve dietary advice, food preparation techniques, and exercise (Broussard, 1991; Indian Health Service, 1990). Culturally targeted educational materials on gestational diabetes have been developed (Rhoades, 2000). Hagey's (1984) innovative pedagogical approach used Native American metaphors in a diabetes prevention narrative incorporated into traditional story-telling for urban Canadian Indians.

However, for most tribes, prevention education, monitoring, and cultural appropriate counseling are lacking or very limited (Carson-Henderson, 2002; Rhoades, 2000). Additionally, a lack of resources and rapid staff turnover confound the problems of education, follow-up, and long-term care. Loewe et al. (1999) add another dimension, namely the fatalism and pessimism on the part of physicians and other healthcare providers for diabetic patients to engage in successful self-management of their illness.

Native American health issues are further complicated by the enormous heterogeneity within and between tribes. There are 554 federally recognized Indian tribes in the United States. Materials developed for one patient

population are not easily transferable to others. Carson-Henderson (2002) warns against trait listing of specific characteristics of tribes and the use of trait lists in over-generalizing homogeneity resulting in inappropriate programs and educational materials.

The ADA's Diabetes Assistance and Resource (DAR) Program is an innovative project designed to provide education and motivation to Latinos by working with government agencies and Latino community-based organizations. Recognizing that women are the gatekeepers of a family's health and welfare in Latino communities, the DAR Program developed a successful community-based outreach activity called "Diabetes Home Health Parties" where peer educators, Diabetes Lay Counselors, or *Consejeras De Diabetes* are trained (Davidson et al. 1994). The ADA has been active in developing educational materials and programs that target U.S. ethnic groups (www.diabetes.org).

CONCLUSION

Type 2 diabetes is rapidly becoming a worldwide epidemic as populations adopt modernized or Westernized lifestyles. Evolutionary evidence for the selective advantage of diabetes thrifty genotypes and phenotypes predisposes humans to the deleterious and diabetogenic effects of contemporary culture. Recent dietary changes are characterized by an abundance of calorically dense, sugary and fatty foods with low fiber content. In addition, labor-saving, energy-efficient daily activity patterns reduce caloric needs and energy expenditure. The result is a high prevalence of obesity, insulin resistance, hyperglycemia, and other physiological abnormalities comprising Syndrome X.

Medical anthropologists have investigated the medical, social, and cultural responses to diabetes among ethnic groups in the United States and Canada where diabetes is in high prevalence. Less attention has been paid to other parts of the world where diabetes is just now becoming a chronic disease of epidemic proportions. The topics reviewed in this entry include: diabetes diagnosis and epidemiology; descriptions of dietary beliefs, consumption patterns, and subsistence activities; traditional medical system beliefs, attitudes, and healthcare patterns; problems of diagnosis and treatment encountered within the biomedical healthcare system; and the development of educational and community-based diabetes intervention programs. The research and publication trends documented by Weidman (2001) clearly indicate that medical anthropologists will

continue to respond to the increasing prevalence and growing cultural disruption of type 2 diabetes with theoretical, methodological, and applied research.

Diarrhea

Elois Ann Berlin

INTRODUCTION

The digestive tract begins at the mouth, transits the esophagus, stomach, small and large intestines, the colon, and terminates at the anus. The digestive system is the greatest avenue of transfer of elements between the human body and the external environment. While the respiratory system serves the vital function of transporting oxygen into the body, which is key for cell metabolism, the digestive system transports many nutrients and other substances that directly affect body structure and function. These beneficial elements are sometimes accompanied by disease causing agents or organisms. This physiological reality is reflected in the epidemiologic patterns of disease and health concerns cross-culturally.

ETHNOMEDICAL PERSPECTIVES

Ethnomedical systems generally base classification of health problems on signs and symptoms. This does not mean that there is no attention paid to etiology. All explanatory models include concepts of cause, source, and course, as well as palliative and curative treatment, of health problems.¹ However, numerous studies have demonstrated that folk systems focus on the personal experience of the disease and that this experience is strongly symptom-based. While the frequency, number, and quantity of liquid stools that define a case of diarrhea may vary from one culture to another, all three signs are generally key criteria for folk diagnosis and classification of diarrheal disease.

BIOMEDICAL PERSPECTIVES

One natural defense of the body is to flush out the offending substances or organisms. This can be accomplished by increasing the rate of peristalsis to rush the food bolus, which has been liquified in the stomach and small intestine, through at such a rapid rate that there is no time for absorption of the nutrient-containing liquids. Another method of flushing is through increased secretion of fluids across the intestinal mucosa into the intestine. Both produce watery diarrhea. The alternative option to rid the gastrointestinal tract of offending substances is to send it back the way it came, as vomitus. Like any inflammatory process, diarrheal disease may be accompanied by fever.

Ethnomedical Classes or Diagnostic Categories

Folk perceptions and practices concerning diarrheal disease are based on empirical observation. Stools that are watery in consistency are signs for concern although repeated bouts may be required before a decision that stools are not normal and a diagnosis of diarrhea is made. Frequency of evacuation may also be a key variable for determination that a case of diarrhea is occurring. For some conditions that would be classed as a kind of diarrhea, stools demonstrate an abnormal color or consistency, such as the presence of frank red blood, mucus, or undigested food particles. In these cases, watery consistency and/or frequency may not be the criteria of focus. White, yellow, and green are colors frequently attributed

to classes of diarrhea. These color deviations generally represent abnormal digestion or infection. Some folk diagnoses also describe a characteristic odor for the fecal matter such as “smells like rotten eggs.” Examples of the naming and classification of diarrhea by two distinct cultures are seen in Tables 1 and 2. (See also Coriel & Mull, 1988; Hogel, Lwanga, Ksiamba-Mugerwa, & Musonge, 1991 & Weiss, 1988, for analysis and review.)

Other signs and symptoms are also used in diagnosis of diarrhea. The concept of “fallen fontanel” is very

widespread as is its association with infantile diarrhea. The sinking of the fontanel or soft spot on an infant’s head (one of the first signs of dehydration) is a widely recognized correlate of diarrhea. In folk explanations, the sequence of occurrence is frequently reversed, with the onset of diarrhea being viewed as a consequence of the fallen fontanel which itself may have been triggered by some event or reaction (e.g., startle response). “Sunken eyes” (also a sign of dehydration) are frequently associated with diarrhea in folk systems.

Table 1. Classification of Diarrhea by Tzeltal Maya of Chiapas, Mexico

Class of diarrhea		
Tzeltal	English	Distinguishing characteristics
Tsa'nel	General, watery diarrhea	Frequent liquid stools
Ch'ich'tsa'nel	Bloody diarrhea	Frank red blood in the stool
Sim nak'al tsa'nel	Mucoid diarrhea	Diarrhea with mucus-containing
Bosbos tsa'nel	Lienteric diarrhea	Undigested food particles visible in stool
T'ilt'il tsa'nel	Droplet diarrhea	Severe straining and small amounts of stool, frequency
Xenel tsa'nel	Diarrhea and vomiting	Frequent liquid stools accompanied by vomiting
Yaxal tsa'nel	Green diarrhea	Frequent green liquid stools, affects infants and small children
Sakil tsa'nel	White diarrhea	Milky white stools, affects infants and small children

Table 2. Classification of Childhood Diarrhea by Shona-Speakers of Manica, Mozambique^a

Shona	Distinguishing characteristics
Manyoka	General diarrhea, simple, common, non-dangerous
Phiriganiso	Frequent and watery diarrhea with vomiting, sunken fontanel, and dry wrinkled skin
Chinhamukaka	Whitish, milky diarrhea, frequently accompanied by vomiting that may also be milky
Chikamba	Greenish diarrhea, accompanied by a lump or pain in upper left quadrant of abdomen
Nntsanganiko	Chronic diarrhea mixed or streaked with blood, also accompanied by weight loss and fever
Kuamwissira	Milky or mucus-containing
Nyongo	Diarrhea with vomitus that contains brownish mucous

^aInformation from Green (1999, pp. 112–115).

Biomedical Diagnosis and Classification

Biomolecular medicine focuses on the etiologic agent (e.g., bacteria, virus, parasite, yeast) to define most diseases. Since diarrhea is a natural response of the body to expel infectious agents, organisms from any of these classes can produce diarrhea. When stool samples are analyzed to determine pathogens, it is usually the case, especially in developing countries, that a definitive causal organism is not identified. More commonly a “mixed infection” of several pathogenic organisms is present. In those cases that require treatment, the initial step is fluid replacement. Antibiotic therapy, when applied, tends not to be pathogen-specific.

The most important signs include stool characteristics such as quantity, consistency, color, and presence of parasites. The quantity of diarrhea produced is particularly significant in that frequency and volume of stools determines whether the patient will become dehydrated and how rapidly. Dehydration is the primary cause of fatality in diarrheal disease. The more liquid is the stool, the greater is the threat of dehydration. In addition to loss of fluids and electrolytes, the rapid transit time of frequent, liquid diarrhea means that few nutrients are being absorbed from the intestinal tract.

Other key signs that physicians look for include color of stool. Green is said to indicate bacterial infection; bright red is a sign of bleeding from the lower bowel or hemorrhoids. Black (sometimes referred to as “coffee-grounds” effect) is indicative of bleeding from the stomach and upper portions of the digestive tract. The blood is black because it is partially digested. The appearance of the profuse liquid stools characteristic of cholera are known as “rice water” stools. White or very light stool may be associated with hepatitis or other liver problems that impede the ability of the liver to remove the bilirubin

from the blood which tends to spill into the urine and stain it a darker color. Absence of stool with a small amount of bloody mucus (“currant jelly” effect) is suggestive of a telescoping of the intestine (due to severe peristalsis) or intestinal blockage (possibly by a worm mass).

Ethnomedical Transmission and Cause

The concept of contagion is a common characteristic of ethnomedical systems and diarrheal events are explained as contagious especially when there is an abnormal outbreak of diarrheas with shared symptoms. Virtually every study that describes folk attribution of cause includes foods (spoiled, bad, prohibited, etc.) as a source. However, air and wind may enter the body to cause any number of illnesses, including diarrhea. Ethnomedical causative explanations for diarrheal disease can be characterized as contagious, disruptive, fatalistic, and personalistic (in which the victim of the disease is specifically targeted).

Contagious. Foods and beverages are probably the most commonly recognized contagious source of diarrhea. Foods may be considered spoiled, unclean, contaminated, or inappropriate for the person, circumstance, or event. Empirically, the foods consumed prior to a diarrheal event are sometimes visible or scentable in the stool. Nausea, vomiting, and a Garcia effect (avoidance of foods and beverages that are associated with prior illness events) may be triggered. Wind and air that are perceived to carry contaminants can enter the body and cause disease, including diarrhea.

Disruptive. From ancient humoral systems comes the most prominent disruptive theory of causation—humoral imbalance. Eating or drinking too many hot or cold foods can cause humoral imbalances that produce diarrhea (as well as many other kinds of health problems). However, disharmony in social and spiritual relations is also a widespread disruptive concept of causation.

Fatalistic. Conditions that occur as commonly as diarrhea in contexts characterized by poor sanitation and public health infrastructure are quite often viewed as inevitable events of life. Most anthropologists and their subjects have developed a tolerance for occasional bouts of mild diarrhea. In most cases no treatment is necessary

or sought. Folk explanatory models are heavy with “stuff happens” kinds of explanations. Anthropologists do not talk much about these fatalistic explanations because they are not subject to very interesting analysis. However, they are ubiquitous.

Personalistic. “Why me?” is the cry of the severely threatened. When a familiar condition such as diarrhea turns fatal or life-threatening and/or is resistant to treatment, exceptional explanations must be sought. The high mortality associated with untreated or inadequately treated diarrhea certainly makes it a candidate for this classification. The need to answer why this disease event is extraordinary leads to the search for explanations for why this person at this time is suffering this life-threat. It is now generally uncontested that any condition, including diarrhea, can be attributed to personalistic causes. It is also clear from the literature, however, that most cases of diarrhea begin with a more mundane diagnosis and move into the personalistic etiology only when treatment fails or signs and symptoms are extraordinary.

Epidemiologic Cycles and Transmission Routes

Most diarrheal disease organisms enter, usually with food or beverages, through the mouth. In areas of high contamination, there is increasing evidence that fecal matter and its pathogens may become airborne. These may be inhaled through the mouth and possibly the nose and reach the digestive system via the pharynx and esophagus. Many successfully transit the esophagus, stomach, small and large intestines and exit the digestive tract in a viable form capable of infecting a subsequent host. The cycle is completed when a pathway from the terminus of the alimentary tract to the beginning, called the fecal–oral transmission, is established. Fecal–oral transmission is usually hand-to-mouth. However, the route need not be direct. The use of human waste as fertilizer, use of agricultural plots as latrine areas, and accidental contamination of soils for food crops can contaminate foods. Unless these foods are adequately disinfected the transmission cycle can be completed when they are consumed. Unintentional contamination of water by runoff of rains or use of rivers and streams for waste disposal can close transmission cycles if the contaminated waters flow to areas where they are used as household or agricultural water sources. Even delivery of water through damaged pipes can result in contamination.

Common bacterial sources of diarrhea include *Bacillus cereus*, *Campylobacter*, *Clostridium difficile*, *Escherichia coli*, *Salmonella*, *Shigella*, *Vibrio cholera*, and *Yersinia*. Common viral sources of diarrhea include rotavirus, Norwalk Agent, Calciviruses and cytomegalovirus. Common parasitic causes are *Giardia lamblia*, *Cryptosporidium*, *Entamoeba histolytica*, and the “holy trinity” of the tropics *Ascaris lumbricoides* (ascaris, a class of roundworms), *Necator americanus* (hookworm), and *Trichuris trichiura* (whipworm). General signs and symptoms associated with most common causative agents are shown in Table 3.

Some organisms can survive for periods of time outside the human host, either in soils, water, or alternative animal hosts. Champions of survival include *Ascaris* spp. which can live in moist shady soil for up to nine years, and spore-forming organisms that can survive for long periods and survive drying (e.g., *Trichuris trichiura*) and boiling (*Clostridium* spp.).

Not all cases of diarrhea can be attributed to infectious processes. Vitamin deficiencies (e.g., niacin, vitamin A, and zinc) may play a key role in diarrheal disease (cf. Bhan & Bhandari, 1998) can produce diarrhea as can stress or anything else that compromises the

Table 3. General Signs and symptoms of some Typical Diarrheal Pathogens

Agent	Stool characteristics							
	Liquid	Blood	Mucus	Worms	Fever	Vomit	Pain	Other
Bacterial								
<i>Bacillus cereus</i>	Yes					Yes	Abdomen	
<i>Campylobacter</i>	Yes	Maybe	Maybe		Low grade	Mild	Head	Runny nose, malaise
<i>Escherichia coli</i> (enterotoxigenic)	Yes		Maybe		Low grade	Yes/nausea	colon	
<i>E. coli</i> (entereoinvasive)	Initial	Later	Later		Yes	Yes/nausea	Abdomen severe	Malaise, toxemia
<i>E. coli</i> 0157:H7	Possible	Often			None/little			Kidney failure possible
<i>Salmonella</i>	Yes	Yes	Maybe		Yes	Possible		May enter blood
<i>Shigella</i>	Yes	Maybe severe	Often		Yes		Colorectal	Tenesmus, Maybe rectal prolapse
<i>Staphylococcus aureus</i>					High	Maybe, severe		
<i>Vibrio cholera</i>	Yes					Yes		“Rice water” stool rapid dehydration
<i>Yersinia</i>	Yes				Low grade		Abdomen	Urinary tract and respiratory infections
Viral Agent								
Cytomegalovirus	Yes							Often AIDS assoc.
Norwalk virus	Yes							
Rotavirus	Yes				Medium	Maybe, severe		
Parasite								
<i>Ascaris</i> spp.	Maybe	“Currant jelly stools”		Yes		Worms	Abdomen	“Pot belly” worms migrate, intestinal obstruction
<i>Cryptosporidium</i>	Yes							Often AIDS associated
<i>Entamoeba histolytica</i>		Maybe	Maybe		Maybe		Abdomen	Tenesmus, maybe chills
<i>Giardia lamblia</i>			Maybe				Possible straining	Intestinal gas
<i>Trichuris trichiura</i>	Maybe	Maybe	Often	Yes			Straining at stool	Rectal prolapse

immune system. Other non-infectious sources of diarrhea include nutritional causes such as food allergies and intolerances, lactose intolerance being the classic example. Certain intestinal disorders and diseases can also produce diarrhea. The symptoms in these usually produce chronic or recurrent bouts of diarrhea. Opportunistic infections secondary to diseases such as AIDS or any condition that suppresses the immune system can also produce diarrhea.

Environmental Relationships

As pragmatic observers in close contact with their environment, members of small-scale societies usually can give a good description of seasonal variation in occurrence of diarrhea. Since manipulation of environmental factors is not an option of such societies, these normally remain descriptive observational data such as “There is more diarrhea when the rains come” or “Children get a lot of diarrhea in the summer from eating unripe fruit.”

Environmental Factors. There is seasonal variation in the frequency of diarrheal diseases. This variation is consistent with what we know of the reproductive requirements of the organisms, namely bacteria flourish in warmth and viruses grow best in cold conditions. However, the importance of seasonality is significantly influenced by the general sanitation level (see, e.g., Ackers, Quick, Drasbek, Hutwagner, & Tauxe, 1998). In areas where there is plenty of potable water readily available and quality sewage disposal, the principal transmission routes are disrupted and seasonal variation, indeed overall infection rates, are reduced.

Small children are the least likely to observe good hygienic practices and are, predictably, the most often affected with diarrhea. This likely does not reflect greater susceptibility so much as greater exposure. When infants and small children share a dirt floor or yard with creatures such as dogs, poultry, and pigs, they tend to share their parasites as well. Young children in child-care facilities exchange many infections, diarrheal pathogens included.

Ethnomedical Care and Treatment

Traditional treatments can be divided into those having generally positive effects, those having negative effects, and perhaps those having neutral consequences.

Positive treatment practices include nursing babies and small children as a comfort response. Breast milk is the best resource, especially for preventing dehydration. Human breast milk is relatively high in sodium and sugars, in addition to being a sterile medium containing maternal antibodies and other important nutritional properties.

Household remedies include many plant-based treatments. These usually are administered orally as liquids. This kind of medication would assist in the prevention of dehydration. In recent years, greater attention has been given to the potential efficacy of the preparations themselves, with the result that there is renewed respect for traditional medical knowledge. The use of rice water, for example, for fluid intake during diarrhea is a well-known home remedy. Biomedical practitioners initially reacted negatively to this nutrient-poor fluid. It is now understood that the large molecule starches in rice water are released gradually. This gradual release of starch reduces the risk of worsening the diarrhea through osmotic retention of fluids in the intestine. Many traditional healers encourage healing teas and fluids, sometimes accompanied by specialized prayers and rituals.

The efforts of caregivers to focus on decreasing the output of diarrhea sometimes results in withholding of foods and fluids. There is the danger that a resulting diminished flow of diarrhea is due to dehydration rather than lessening of the disease. This can have serious to fatal results. Purging is a rather common practice for the treatment of diarrhea and carries the potential risk of hastening dehydration. There is always the possibility that folk treatments can have harmful effects, just as biomedical practices are sometimes found to require re-thinking and modification. There is also some risk that traditional therapies may be pursued to the extent that life-saving measures of medical intervention are applied too late or not at all.

Biomedical Recommendations for Home Treatment

For many years, physicians focused on reducing the volume of diarrhea by withholding foods. However, it is now understood that, despite an increase in total quantity of diarrhea, when bland foods and nutritious beverages are consumed, some of the nutrients are absorbed and the patient returns to normal nutritional and health status

more rapidly. Maintenance of fluid balance is viewed as the most important home health care measure. Current recommendations for preventing and treating dehydration include beverages enriched with essential salts and electrolytes, especially for children. Most developing countries have distribution programs for oral rehydration solutions (ORS is also referred to as oral rehydration therapy, ORT). Grocery stores and pharmacies carry a variety of flavored rehydration beverages and Popsicles to prevent or combat dehydration. Pediatricians recommend what is referred to as a BRAT diet of bananas, rice, applesauce, and tea. Bananas are a relatively good source of potassium, although not enough potassium is present in normal servings to correct a serious potassium imbalance. Rice has large starch molecules that release glucose gradually. Applesauce contains pectin, which aids in decreasing diarrhea. Tea leaves have been shown to have numerous pharmacological properties including antibacterial, antiviral, anticholesterol, and tumorstatic activity. The first two might be useful in treating diarrhea.

The World Health Organization (WHO) and other international agencies involved in the control and management of diarrheal diseases, dehydration prevention, and rehydration therapy have undertaken many programs and studies to determine the best medical, practical, feasible, and acceptable methods for preventing and treating diarrhea and dehydration. The general conclusions suggest that prevention of dehydration is the best home treatment procedure. However, most studies demonstrate that caregivers have difficulty in mixing the proper amounts of salts, sugars, and water, especially in making the mixture over-concentrated. This in itself can pose a danger for dehydration by pulling water into the intestine through osmosis and increasing diarrheal output. Traditional home preparations of fluids and foods are now encouraged, especially continued breast-feeding when applicable. If feeding, particularly fluids containing nutrients and calories, are continued throughout the diarrheal event, most cases of diarrhea are self-limiting. Traditional healers have also proven to be amenable and effective at promotion of rehydration when trained in preparation and administration of ORS.

Over-the-counter remedies are available for diarrhea. However, the use of antidiarrheals that simply stop the diarrhea can be potentially harmful because of the danger of prolonging retention of an invasive organism in the intestine and providing prolonged opportunity for penetration and erosion of the intestinal lining.

Recognizing when Home Treatment is No Longer Sufficient

If frank red blood is seen in the stool, or if the feces is black or contains pus, then medical consultation is recommended. Dehydration is evidence for consulting a physician and may require hospitalization. Signs and symptoms of dehydration in adults include thirst, reduced frequency of urination and/or dark color of urine, dry skin that loses its elasticity and remains in a pleat when pinched, fatigue, and light-headedness. In children, dehydration is noticed from the top down. First signs are the absence of tears when a child cries, the mouth and tongue become dry, urine flow and frequency is decreased. A child is considered dehydrated if it fails to urinate for a period of three hours. Other signs of dehydration include high fever, listlessness, and pleating up of skin after pinching.

Theoretical and Applied Implications

Much of modern medical anthropology has its origins in anthropologists' interaction in international public health and medical programs of the post World War II era. Anthropologists, like their medical colleagues, assumed that Western medicine was superior to traditional medicine and that the natural course of things was to replace the latter with the former. The skills of anthropology were needed to gain public acceptance of the new medicine and its practitioners. Both anthropology and medicine have come a long way in the succeeding decades.

Medical anthropologists have dealt with diarrhea primarily from a systems approach, based on theory derived from medical ecology, and to some extent political ecology, biocultural anthropology, including evolutionary and adaptationist perspectives, critical medical anthropology, and epidemiology. Numerous theories have addressed both the proximate and ultimate causes of diarrheal disease patterns. Anthropologists make contributions at several levels as scientists, formulators of policy, and social activists. Some draw on field experiences to argue that the solution is political and/or economic change. Some work to identify such culturally sanctioned treatments and to guide health policy toward encouragement of effective local herbal formulae. Increasing numbers are integrated into epidemiological surveillance, health policy, and health care delivery systems.

Irrespective of one's theoretical or professional orientation, it is clear that those whose lives are characterized

by frequent bouts of diarrhea also live at the bottom of the socioeconomic scale, in settings lacking in basic sanitation and public health infrastructure. They frequently tend to live in marginal areas peripheral to cities or outside economically developed regions. They may inhabit regions of high biological diversity, though population pressures and a shrinking land base are compromising the health of both the environment and its people in increasing numbers of such contexts. When they move to urban areas, they often live on the periphery, both geographically and socially. They gather in shanty towns on the outskirts of cities or in degenerated inner cities where dwellings are poorly constructed and/or maintained and often vermin infested. There frequently exist situations of over-crowding, poor sanitation, and a general lack of public health infrastructure and services. Whatever the specific description of the physical context, the perpetuation of transmission cycles that make fecal pathogens part of oral intake is the first problem in diarrheal disease. Resources, knowledge, and tools for survival is the second. Sanitary waste disposal and an adequate source of safe, accessible water are the key elements to breaking the transmission cycle. Adequate and acceptable treatment should be the intervention of last resort when prevention has failed.

Table 4. Pharmacological Properties of some Plants used by the Highland Maya to Treat Diarrhea

Genus	Mode of action in treatment of diarrhea			
	Antimicrobial	Spas. ^a	Hemo. ^b	Other
<i>Acacia</i>	<i>S. aureus</i> , <i>E. coli</i>	Yes	Yes	Cytotoxic
<i>Ageratina</i>	<i>S. aureus</i>	Yes		Cytotoxic
<i>Baccharis</i>	<i>S. aureus</i>	Yes		
<i>Byrsonima</i>	<i>S. aureus</i> (mild)			
<i>Cissampelos</i>	<i>S. aureus</i> , <i>E. coli</i> , <i>Candida albicans</i>	Yes		Anti-malarial
<i>Crataegus</i>	<i>S. aureus</i>			
<i>Helianthemum</i>	<i>S. aureus</i> , <i>E. coli</i> , <i>Candida albicans</i> , <i>Pseudomonas aeruginosa</i>			
<i>Verbena</i>	<i>S. aureus</i> , <i>E. coli</i> , <i>Candida albicans</i>			
<i>Psidium</i>	<i>S. aureus</i> , <i>E. coli</i> , <i>Candida albicans</i> , <i>Pseudomonas aeruginosa</i>	Yes		Sedative
<i>Tagetes</i>	<i>S. aureus</i> , <i>E. coli</i> , <i>Candida albicans</i>	Yes		

^a spas. = spasmodic

^b hemo. = hemostatic

Table 5. Genera used to Treat Diarrhea in the Highlands of Chiapas, Mexico, and Other Regions

Genus	Some areas or systems reporting use
<i>Acacia</i>	India, North Africa, Mexico
<i>Cassia</i>	Egypt, Mexico
<i>Chenopodium</i>	Africa, Mexico, Trinidad
<i>Cornus</i>	United States, Mexico
<i>Croton</i>	Colombia, Peru, Mexico
<i>Equisetum</i>	China, Mexico
<i>Gaultheria</i>	North and Central America
<i>Geranium</i>	United States, Mexico and Central America
<i>Lobelia</i>	Homeopathy, Mexico
<i>Myrica</i>	United States, Mexico and Central America
<i>Piper</i>	Ayurveda, Yunani, Mexico
<i>Plantago</i>	East and SE Asia, Central America
<i>Ranunculus</i>	Homeopathy, North America, Mexico
<i>Rumex</i>	Africa, Mexico
<i>Senecio</i>	Ayurveda, Mexico
<i>Solanum</i>	Homeopathy, Ayurveda, Bengal, Japan, United States, Mexico

With respect to treatment, it has now been amply demonstrated that in many cases the pharmacological properties of herbal formulary specifically treat signs, symptoms, and/or probable pathogens. Table 4 lists some of the documented pharmacological properties of some genera used by the Highland Maya of Chiapas, Mexico, to treat diarrhea. A growing body of evidence demonstrates that folk systems are logical systems with significant empirical explanatory and predictive value. We have discovered that there are other healing systems built on distinct empirical/theoretical foundations that have high predictive power. Furthermore, the same genus, if not species, may be used in geographically dispersed and culturally distinct regions. Table 5 illustrates examples of the wide distribution of a small set of medicinal plants used for the treatment of diarrhea by the Maya of highland Chiapas, Mexico.² This wide distribution is no doubt due in part to the commonality of these genera in local environments and over a wide geographic range. However, it is also dependent on some general selective process employed by humans (and, indeed, other primates), and based on principles that have yet to be clearly defined.

NOTES

1. The term health problems is used here to avoid the illness and disease dichotomy. (1) Although the dichotomy is useful in some discussions, it treats the physiological experience (sickness) in a way that is not helpful in this discussion. (2) That dichotomy fails to recognize the difference between infection and disease. (3) Such a dichotomy seems to assume that a systems approach (i.e., one that incorporates the patient's family, social, and physical environments) does not exist in biomedicine. (4) Many conditions that are neither illness nor disease are recognized health problems in ethnomedical systems (such as deformities and dysfunction). Ethnomedical systems also distinguish conditions that are health-related, but not necessarily problems, and certainly neither illness nor disease (such as menstruation).
2. This is intended neither as a representative sample nor as an exhaustive survey of the distribution of use. It is merely a demonstration of the fact that many plant genera are widely and probably independently used for the same conditions.

Disability/Difference

Russell P. Shuttleworth

INTRODUCTION

This entry has three primary aims: (1) to provide a brief overview of the kinds of bodily and behavioral differences perceived as anomalous in a range of societies and the various social responses to these differences; (2) to review and critique research and theory in the anthropology of impairment–disability; and (3) to suggest several conceptual advancements that would move this area of study forward.

CROSS-CULTURAL REVIEW OF RESPONSES TO BODILY AND BEHAVIORAL DIFFERENCES

As a broad inclusive category, and from a strict constructionist perspective, disability exists only in locally specific relation to Western European notions of medicalization, employment, and welfare (Groce, 1999; Whyte & Ingstad, 1995). Yet, some range of physical and behavioral

differences are recognized in all societies and there are often social consequences that follow from this recognition. While it is of paramount importance to elucidate local contexts, knowledge, and responses in the study of these differences (Devlieger, 1999; Groce, 1999; Ingstad, 1999b), anthropology is a comparative discipline and in their research on impairment–disability cross-culturally, anthropologists implicitly or explicitly make comparisons between the local worlds of their informants and their own usually Western European or North American societies. This can prove difficult given the variation in cultural conceptualizations of bodily and behavioral differences.

This brief review uses Mary Douglas's (1966) notion of anomaly, "matter out of place," as a baseline concept to orient a comparative approach. This notion has been widely acknowledged by many anthropologists and cultural theorists as providing a starting point from which to begin to understand the cultural meanings and implications of these kind of differences (see, e.g., Murphy, 1987; Shakespeare, 1994; Shuttleworth, 2000b; Stiker, 1999a, 1999b; Thompson, 1997; Whyte, 1995b). Of a different order than liminality, "matter out of place is a culturally constituted perception" that does not fit within recognized cultural categories "and not a phase in a (ritual) process" (Shuttleworth, 2000b, p. 80). Douglas views anomaly as inherently threatening to the social order. Devlieger (1999) refers to disability as an interstitial category, which adds a structural component to the concept of liminality. This section considers the kinds of bodily and behavioral differences perceived as anomalous in a range of societies and the various social responses to these differences. The question of how to define disability-related terminology will be explicitly addressed in a later section, but for now it is enough to mention that much of the research reported on below does not often sustain an effort to analytically distinguish between anomalous bodily and behavioral differences from impairment and disability.

In terms of body and behavior, any out of the ordinary manifestation may be perceived as anomalous. This does not necessarily mean that people exhibiting certain recognized differences will either be stigmatized or viewed as sacred (Rosing, 1999; see also Douglas, 1966). Ingstad (1999a) makes the observation that in many societies "physical and mental impairment is not necessarily what determines the status and inclusion of a person More important are family and kinship ties, competence in doing useful tasks for the good of the household, and

the ability to behave in a socially acceptable manner" (p. 757). For example, Marshall (1996) notes that among societies of the Caroline Islands in Micronesia "individuals impaired from birth defects, accidents, or diseases are not necessarily considered disabled unless the impairment is coupled with an inability to speak and/or hear; that is with an inability to manipulate culture and to participate in the social life of the community" (p. 254). These Micronesian societies appear not to stigmatize people with many kinds of physical impairments, as long as one is personally and culturally competent.

Much depends on the interplay of beliefs, social expectations, and economic imperatives of the particular society as to whether some bodily or behavioral anomaly will be considered a disability (Groce, 1999). For example, in China today the ability to be active and mobile outside the home in terms of public life and also in one's livelihood is highly prized. Combined with ideas about national development and mobility and the Confucian emphasis that transmutes bodily imperfection into social meaning, men who have difficulty walking experience stigma and discrimination (Kohrman, 2000, n.d.). Here cultural beliefs, social and gender expectations, and also economics conspire and contribute to the creation of an identity based on a negatively perceived bodily difference. In some less modernized societies the situation may be entirely different, as alternative tasks and roles are found that contribute to the group. As Scheer and Groce (1988) state, "although specific occupations or trades might be closed to a disabled person because of his or her specific impairment (such as hunting to a mobility impaired man), there seems no single role or group of roles to which most disabled adults are limited" (p. 29).

Negative social consequences can range from mild stigmatization through infanticide. For example, among the Shona of Zimbabwe, Burck (1999) reports that children who get their upper teeth first are considered seriously disabled and this has lifelong consequences. A 1980 survey on leprosy in Nepal found that a majority of persons would separate family members who got leprosy, and a third said they would put them out of the village. Ten years later in 1990, there was little change in expectations (Hyland, 2000). Turmusani (1999a, 1999b) reports widespread negative social attitudes toward physically disabled people in Jordan resulting in charity, the attribution of cognitive impairment, and an asexuality (not unlike some of the attitudes and responses in the United States). The birth of twins constitutes a social disgrace among the

Punan Bah and one of them is usually given away or withers away (Nicolaisen, 1995). Similar data exist from other societies including those in the past. Dasen (1993), for example, states that in Greco-Roman Egypt protection against evil by oracles was sought in the case of multiple births. The extreme exclusionary practice of infanticide occurs in some societies (see, e.g., Devlieger, 2000; Scheer & Groce, 1988). Although not as widespread as previously thought, neglect of impaired infants is usually not included as infanticide (Scheer & Groce, 1988; see also Scheper-Hughes, 1990, 1992). The most common justification across cultures for infanticide, as Scheer and Groce (1988) state, is the "belief in the linkage between evil spirits and/or parental misconduct" (p. 28). Yet, as Talle (1995) notes, integration is not necessarily always the answer. Among the Maasai, children with an impairment are treated the same as other children, given the same food, ritual blessings, ceremonial procedures, and level of support. However, the lack of special treatment often results in early death (p. 67).

On the other hand, some physical and behavioral differences in various societies can be accorded positive significance of a sacred or trans-personal character. For example, Rosing (1999) maintains that among the Quecha-speaking people in the Kallawaya region of the Bolivian Andes, they do not necessarily perceive people who are blind or with crippled hands, among other differences, as disabled. She notes that "there is initially a culturally defined, positively evaluated area of meaning which can be seen as a cultural resource" (p. 38). If other personal, social, internal, and external resources are met, such as reciprocity and exchange, and personal representation by some personal object is fulfilled, then "disabling characteristics" may be perceived not as illness, impairment, and disability but of vocation, sometimes of a trans-personal concept. One example Rosing provides is of a blind man who is ascribed a type of trans-personal vision, which allows him to see the unseen.

Many bodily and behavioral differences recognized as anomalous in other societies, such as the birth of twins and upper teeth coming in first, are not especially important to societies influenced by Western European orientations. In fact, this points to a significant difference noted by some cross-cultural researchers: lack of perceived function seems to be the core negative meaning that characterizes an impairment–disability in the latter societies (Burck, 1999). The extreme version of this, of course, is the biomedical model of impairment–disability. In many

societies, however, other ethnophysiological or ethnopsychological concepts or indices may be highlighted instead of or in addition to function. For example, among the Shona, "dryness of the affected part" (presumably) within their humoral system, is the essential factor in determining disability (Burck, 1999, p. 203). In addition, in many non-Western societies, interpreting fault often takes precedence over assigning blame to the individual or wanting to improve the individual's condition or situation (Devlieger, 1995). As Devlieger notes, "The idea of rehabilitation as a continuous effort of improving and accommodating the living conditions of persons with disabilities is basically a Western idea that is foreign to Songye thought" (p. 95).

All societies recognize and respond to cognitive differences and erratic behavior. However, Nicolaisen (1995) says the Punan Bah do not hold the mentally impaired responsible for their situation (see also Marshall, 1996). Epilepsy and madness are caused by non-human spirits who invade or partly take over the body, relegating the soul of the body to a secondary position. Effort is made by families to cure madness by way of spirit mediums. Persons so affected are regarded as dangerous only if violent. For the most part, effort is made to include them as part of regular social relationships. On the other hand, for the Hubeer stupidity and madness are viewed as similar to infertility and death and the mentally impaired are often treated with abuse outside of their family (Helander, 1995, p. 89). Talle (1995) states that among the Kenya Maasai mentally retarded or mad persons are regarded not as disabled in a physical sense but as "abnormal" ("fool"). Nicolaisen (1995) echoes an observation made by many cross-cultural researchers that some forms of severe cognitive difference such as severe forms of mental retardation, "... among the Punan Bah. I suspect that children born with such impairments 'wither away' ... or die at an early age" (p. 44).

Examining a particular social context within a society can further reveal that those with certain physical and behavioral differences may encounter restricted access. Anthropologists often note in their studies of impairment–disability in other societies that physical and/or cognitive impairment does not necessarily determine status and exclusion, that family and kinship ties are more important (see, e.g., Ingstad, 1999). What are we then to make of the fact that in the context of sexual and/or marriage negotiation and family formation, it has also paradoxically been observed that people with bodily

and behavioral differences often encounter difficulties in a range of societies (see, e.g., Ablon, 1984, 1995, 1999; Devlieger, 1995; Fassin, 1991; Guldin, 1999, 2000; Kohrman, n.d.; Nicolaisen, 1995; Sentumbwe, 1995; Shuttleworth, 2000a, 2000b)? This is not to say that impaired people are always excluded from these institutions and activities (see, e.g., Guldin, 1999, 2000; Sentumbwe, 1995; Shakespeare, Gillespie-Sells, & Davies, 1996; Shuttleworth, 2000b; Wolf & Dukepo, 1969). However, impairment or some other ethnophysiological or ethnopsychological indicator interacting with differences of gender, class, etc. will often be significant in determining negative cultural beliefs, social expectations, and responses regarding sexual and/or marriage negotiation and family formation for people with certain bodily and behavioral differences.

Joan Ablon (1996), for example, exploring the differential access to intimacy and sexual experiences for men and women with neurofibromatosis found that two thirds of the women she interviewed were married, as opposed to only one third of the men. The single men in her sample were much less likely to have had sexual experiences than the women. Ablon notes the persistence of women in finding a partner. She hypothesizes that they continue strategizing to connect with a man because in U.S. society women are socialized to be interpersonal communicators. However, the lack of achievement by many of the men, due to early learning disabilities and social failures, negatively impacts their gender identity, which significantly contributes to their social withdrawal. Nayinda Sentumbwe working in Uganda (Sentumbwe, 1995), provides another instance: he found that cultural beliefs that blindness is incapacitating contributed to the fact that sighted men will have sexual relations with blind women and/or keep them as mistresses but rarely marry them because of their desire for a domestically competent wife. This dynamic was missing for blind Ugandan men who would often marry sighted women. Matthew Kohrman's (2000) research on disabled men in China provides a somewhat different example: for men with mobility impairments and their families, during negotiations for a wife, they must continually negotiate downward in terms of the social position of their prospective partner, which indicates to them their diminished social value and disabled identity.

What is interesting to note is that, as alluded to above, exclusion from the primary institutions of marriage and/or family or from effectively negotiating

sexual intimacy with others often occurs in many societies for people with certain physical and behavioral differences, despite their being accorded other aspects of personhood. One must question anthropological observers who report that disabled people are well integrated into a society and yet cannot negotiate sex, marry, and/or form a family. Despite the importance of detailed views of how well particular sociocultural contexts do or do not integrate people with culturally recognized physical/behavioral differences, we need this kind of in-depth information for multiple contexts within a society and across many societies in order to perform effective cross-cultural analyses.

REVIEW AND CRITIQUE OF THEORY AND RESEARCH

While some early anthropologists remarked on the social position of disabled people cross-culturally (see the discussion in Hanks & Hanks, 1948), it was not until the 1960s with the theoretical impetus of Goffman's (1963) elaboration of the stigma concept and Edgerton's (1993) research on people with "mental retardation" that a focused interest in the systematic study of the sociocultural aspects of impairment and disability began to develop. The seminal work on disability conducted from the 1970s up through the late 1980s by cross-cultural researchers was notable in orienting this area of study in certain theoretical directions, toward stigma, liminality and, to a lesser extent phenomenology, that still hold influence (see, e.g., Ablon, 1981, 1984, 1988; Becker, 1981; Duval, 1984; Estroff, 1981; Frank, 1984, 1986, 1988; Goerdt, 1984; Goldin, 1984; Groce, 1985; Gwaltney, 1970; Langness & Levine, 1986; Murphy, 1987; Scheer, 1987; Scheer & Groce, 1988; Schep-Hughes, 1979). Empirically what strikes one about this body of work, as Whyte and Ingstad (1995) note, is that the majority is "based on research in North America" (p. 4). Additionally, except for the review of the research literature offered by Scheer and Groce (1988), all of this work focuses on single impairments with no attempts at cross-impairment analysis within a society and between societies (Kasnitz & Shuttleworth, 1999, 2001b).

More recently, anthropologists and other cross-cultural researchers have investigated impairment-disability using various perspectives in a wide range of

societies including, among others, those in Africa (Devlieger, 1995; Fassin, 1991; Helander, 1995; Ingstad, 1995; Kaplan-Myrth, 2001; Sentumbwe, 1995; Talle, 1995; Whyte, 1995a), South America (Block, 1997, n.d.; Bruun, 1995; Rosing, 1999), Native Americans (Pengra & Godfrey, 2001; Schact, 2001), Borneo (Nicolaisen, 1995), China (Kohrman, 2000, n.d.), India (Ghai, 2002), Nepal (Hyland, 2000), Micronesia (Marshall, 1996), Mexico (Holzer, 1999), Southeast Asia (French, 1994; Predaswat, 1992), the Middle East (Colligan, 1994, 2001; Dshen, 1992; Turmusani, 1999a, 1999b), Western Europe (Corker & Davis, n.d.; Davis, 1998; Hubert, 2000a; Monks & Frankenberg, 1995; Raji & Hollins, 2000), and North America (Ablon, 1995, 1996, 1999; Angrosino, 1992, 1994, 1998; Block, 2000; Eames & Eames, 1997; Frank, 1984; 2000; Gold, 1994, n.d.; Kaufert, 2001; Landsman, 1997, n.d.; Luborsky, 1994; Pawlowski, 2001; Peace, 2001; Preston, 1994, 1995; Scheer & Luborsky, 1991; Shuttleworth, 1998, 2000a, 2000b, 2001a, 2001b, 2002). An important volume appeared in 1995 edited by Benedicte Ingstad and Susan Reynolds Whyte, which examines disability through the general theoretical lens of personhood (see also Bruun & Ingstad, 1990). Other edited works that have recently appeared include those by Holzer, Vreede, and Weigt (1999), which highlights the dialogue between scientific praxis and practical rehabilitation efforts, and Hubert (2000c), significant for including archeological perspectives as well as current ethnographic research on the issue of social exclusion of those with physical or behavioral differences. One critique of past as well as some present work is that detailed taxonomies of what are perceived to be impairments in different societies and which impairments are disabling are often not presented (however, see, e.g., Devlieger, 1995; Nicolaisen, 1995; Talle, 1995). Likewise, this body of research does not give us much of an understanding of the interactions occurring in multiple contexts/domains during everyday life for people with bodily and behavioral differences.

Until recently, much of the anthropological research on impairment–disability has been conceptualized in terms of a relatively few theoretical notions, the most notable of which are liminality and stigma. Anthropological and other cross-cultural research utilizing the concept of stigma, that is, a discrediting attribute or an undesired differentness from social expectations, have contributed significantly to understanding the socio-cultural construction of certain chronic illnesses and impairments (see, e.g., Ablon, 1981, 1984, 1988, 1999;

Angrosino, 1992; Becker, 1980; Becker & Arnold, 1986; Edgerton, 1993; Gussow & Tracy, 1968, 1970; Herskovits & Mitteness, 1994; Predaswat, 1992). Goffman, however, has been criticized on several grounds including for lumping together all sources of stigma and overgeneralizing (Murphy et al., 1988; Wendell, 1996), for not being sensitive to issues of politics and empowerment (Anspach, 1979; Hahn, 1985) and for reflecting some of the cultural stereotypes and meanings of disability at the time he was writing, in the late 1950s and early 1960s (Wendell, 1996).

Goffman's critics hold him to an impossible hermeneutic demand—to step outside his historical moment and render a disability-centric analysis. Showing that “the meaning of disability is a social, therefore changeable, construction” (Susman, 1994, p. 15), he actually paved the way for today's more critical disability discourse (Shuttleworth, 2000b). Important theoretical expansions include Herskovits and Mitteness's (1994) model, which shows how the degree of stigma varies for different chronic illnesses and impairments depending on the different cultural values that are transgressed, and Shuttleworth's (2000b) model that shows how degree of stigma will vary from context to context for someone with a certain impairment as the particular social context calls for the use of some culturally defined abilities and invokes some values but not others.

Stigma, however, remains a disembodied notion in much of the above research. That stigma can often lead to internalized oppression or, conversely, to self-empowerment needs to be theoretically grounded in intersubjective processes. How do disabled people engage and contend intersubjectively with a particular form of stigmatization and other impediments to full societal participation at an embodied level of experience? Phenomenology may be able to uniquely elucidate this process. Frank's (1986) research on the life of a woman with missing limbs, Diane DeVries, was an early attempt to bring a phenomenological perspective into the anthropological study of disability. Yet, Frank's phenomenological work only focused on one disabled person's image of her body. Her later work (Frank, 1988, 2000), albeit some of it is informed by phenomenology, does not attempt to describe the process of empowerment in existential and intersubjective terms. In fact, she philosophically rejects interpreting Diane's “ultimately unnamable, lived experience” (Frank, 2000, p. 123; Shuttleworth, 2000b; Shuttleworth & Kasnitz, n.d.). However, in the last few years several attempts within anthropology and sociology to develop

phenomenological and existential–phenomenological perspectives further have been presented (see French, 1994; Hughes, 1999; Hughes & Paterson, 1997; Paterson & Hughes, 1999; Shuttleworth, 1998, 2000a, 2000b, 2001; Shuttleworth & Kasnitz, n.d.). For example, Paterson and Hughes (1999) outline a phenomenological perspective on impairment that draws much from the work of Leder (1990) and shows how embodied contexts of meaning are structured by non-disabled embodiment.

The symbolic anthropological study of impairment–disability has not moved much beyond a focus on the ritual notion of liminality. In a much-cited article, partially intended to move beyond what they perceived to be the inadequacies of the stigma concept and the language of deviance, Murphy et al. (1988) propose that the concept of liminality could also apply to the social response to disabled people in American society (Goldin & Scheer, 1995; Murphy et al., 1988; see also Willett & Deegan, 2001). Disabled people have indeed often been isolated, made invisible, seen as contaminated, avoided, without status, and economically marginalized. These and other responses are reminiscent of the social responses to initiates who undergo the liminal phase of many rites of passage (Turner, 1967). Thus, Murphy et al. (1988) argue that, “disability is not a thing, it is a juncture within a process—an arrestment in life history that is dramatized in a rite of passage frozen in its liminal stage” (p. 241).

However, Murphy and his associates err by trying to force the processual notion of liminality onto the lived experience of disability in general. The problem is that they draw almost entirely from the experience of persons with late-onset impairments. Extrapolating from the experience of this population, Murphy et al. (1988) suggest that “the physical laws of the disabled are better seen as ‘losses,’ rather than as ‘deficiencies,’ for most of the sightless once saw and most of the crippled once ran” (p. 241). However, people with early-onset impairments do not experience the first phase of the proposed liminal model, that is, separation from “normal bodies.” Therefore, their physical laws cannot be considered “losses” in any sense of the term (Kasnitz & Shuttleworth, 1999; Shuttleworth, 2000b).

As mentioned earlier in this entry, a more consistent model, that would not only apply to disability in the U.S. context but also cross-culturally, is that certain bodily and behavioral differences are perceived as anomalous or as “matter out of place” (Douglas, 1966). Matter out of place falls in between cultural categories and is thus

interstructural, or interstitial in Devlieger’s (1999) scheme. This accords more with the social and lived experience of people with early-onset impairments, since they do not experience the prior phase of being in place, which is necessary in a strict liminal model (Kasnitz & Shuttleworth, 1999; Shuttleworth, 2000b).

While there has been some attention to metaphor in ethnographic research with disabled people (see, e.g., Angrosino, 1992; Duval, 1984; Phillips, 1990), this work has been intermittent (Shuttleworth, 2000b). Stiker’s (1999a, 1999b) historical semiotic approach perhaps represents the most ambitious attempt to move the symbolic study of disability forward. Stiker asks: What is the semiosis within a society that integrates and/or excludes persons exhibiting particular bodily or behavioral differences? How a society views the biological integrity of the species (their ethnophysiology) will be a contributing factor in its forms of integration or exclusion. Stiker, reviewing biblical and historical texts, situates his analysis of the meaning of disability in the West on several isotopies—biological, ethical, religious, social, and medical—with some isotopies moving to the foreground in certain historical epochs and some receding more into the background or merging with other isotopies. Depending on the interplay of these levels of meaning and imaginative investment in the normal during a particular historical epoch, the West has moved between the poles of integration and exclusion of disabled people. For example, in the biblical system disability is primarily a question of biological integrity, which the ethical–religious perspective can situate but not necessarily integrate or treat. Exclusion exists centrally in the prohibition of people with certain impairments from participating in religious rituals (Stiker, 1999a). Transposing his semiotic method of textual analysis and interpretation of disability to societies beyond those in the West has so far not been systematically attempted, albeit Devlieger (1998) renders a social semiotic analysis of representations of physical disability in colonial Zimbabwe through the movie *Pitaniko*, the Film of Cyrene.

Some anthropologists have attempted to conceptualize and theorize about disability in general, often across cultures (see, e.g., Luborsky, 1994; Murphy et al., 1988; Scheer & Groce, 1988). These attempts, as well as many disability ethnographies themselves, often overlook important understudied variables such as age at onset, time since onset, course, level of pain, visibility, “hideability,” predictability, availability of accommodations,

and social acceptability of impairments (Kasnitz, 1995; Kasnitz & Shuttleworth, 1999). Another significant problem with some of these attempts is that focusing on people with a mature age at onset of impairment in their empirical examples, they attempt to generalize to early-onset impairments without providing any extended analysis that their models fit this very different population. Murphy et al. (1988) are not the only culprits. Luborsky (1994), using a model of disablement developed by Verbrugge and Jette (1993), implicitly makes this generalization when reporting on a sample of post-polio, middle-aged, and elderly people whose conditions deteriorated after years of relative stability. Luborsky (1994) talks about disability as “loss” and “erosion of full adult personhood.” Collapsing early- and late-onset impairments, impairments that worsen and improve and otherwise change or remain stable obscures the very different social and experiential dynamics that exist for people with different impairment trajectories and devalues the experience of persons with early-onset impairments (Kasnitz & Shuttleworth, 1999). A more recent methodology for cross-cultural research proposed by Vreede (1999), one which relates activities of daily living (ADLs) to physical/mental functions and structures (ODLs) that are motivated by personal/social purposes (IDLs), seems promising.

Susan Whyte (1995b) advocates for the use of innovative new theoretical approaches to broaden the anthropology of disability, most notably the cultural-historical approach of scholars such as Stiker (1999a, 1999b) and Foucault (1973); a symbolic approach in the line of Douglas (1996); Kleinman and Kleinman’s (1991) phenomenological approach to suffering, among other points of view. While not forsaking medical anthropology’s more traditional ethnographic focus on cause and cure, she and also Ingstad (Whyte & Ingstad, 1995) generally emphasize the theme of personhood in their work. Whyte’s call for an eclectic theoretical mix is slowly being taken up by anthropology—reader response theory, semiotics, Foucaultian analyses, existential-phenomenological perspectives and a radical concern for reflexivity, dialogics, insider analyses, and capturing what it is like to be impaired-disabled in divergent societies are current examples of theoretical perspectives and methodological approaches being utilized (see, e.g., Angrosino, 1992, 1998; Colligan, 1994, 2001; Corker & Davis, n.d.; Davis, 1998, 2000; Devlieger, 1998; Duval, 1994; Gold, 1994; Kasnitz, 1993; Kohrman, 2000, n.d.; Landsman, 1997, n.d.; Preston, 1994, 1995; Raphael, Saloveh, & Laclave,

2001; Shuttleworth, 1998, 2000a, 2000b, 2001a, 2002; Shuttleworth & Kasnitz, n.d.). However, there are many perspectives currently circulating in sociocultural theory that are not yet being utilized in the anthropology of impairment-disability.

Those anthropologists utilizing innovative new perspectives are necessarily conversant with the current theoretical ferment in disability studies, which has moved well beyond its social movement beginnings and is making significant strides in conceptualizing the impairment-disability experience. Disability studies theory is expanding from an initial focus on independent living and social models to sophisticated phenomenological and post-modern conceptualizations of impairment and disability including notions that decenter the non-disabled subject and subvert normative societal conceptions of physical/behavioral difference (see especially Allan, 1996; Corker, 1998a, 1998b, 1999; Corker & Shakespeare, 2002; Davis, 1995; Hughes, 1999, 2000; Hughes & Paterson, 1997; Linton, 1998; Paterson & Hughes, 1999; Thompson, 1997). Disability studies researchers are also increasingly venturing abroad to study the meanings of disability and disabled people’s experience in diverse societies and seeing if the models developed in disability studies are applicable or not cross-culturally (see, e.g., Ghai, 2002; Stone, 1997, 1999; Valentine, 2002).

NEW DIRECTIONS IN THE ANTHROPOLOGY OF IMPAIRMENT-DISABILITY

Defining the Terms as Heuristic Notions of Negative Meaning and Oppression

In the cross-cultural study of other groups deemed “vulnerable” to oppression, such as women, ethnic/racial minorities, sexual minorities, the working class, and the elderly, subtle constructionist analyses have emerged in a variety of local contexts that have shown the complex constitution of social personhood and subjectivity and the asymmetrical relations of power that can sometimes result in their subordination in certain socio-cultural contexts (see, e.g., Bourdieu, 1984; Kondo, 1990; Weston, 1991; Willis, 1977). Yet, in past anthropological work on impairment-disability there has been minimal analysis of relations of power. In fact, many

anthropologists currently studying impairment–disability subscribe to a radical relativistic approach and a weak view of oppression that can sometimes diminish the significance of certain problematic cultural responses to people with bodily and behavioral differences. And while it is important to note some of the positive cultural responses to bodily and behavioral differences and to provide a holistic picture of a society's understanding and response to these kind of differences, recognizing and critiquing social exclusions and oppressive social relations against impaired people is also paramount.

An example of the downplaying of a problematic cultural response to differences is provided by Nicolaisen (1995), who notes the fact that among the Punan Bah, people who are significantly physically or mentally impaired, infertile, lame, blind, deaf-mutes, and have harelips are hampered in getting married and begetting children. Yet, Nicolaisen rationalizes restrictions of this sort with the argument that these kind of issues are dealt with as “social and moral problems, not of the individual but of the family” (p. 52). Yet, logically, without the individual's impairment, there is no problem. He then asserts that through certain adoptive practices few Punan Bah are left without children and none is denied full personhood. Yet, his article presents a bleak appraisal of the chances of people with these kinds of bodily and mental impairments ever achieving marriage, certainly a valued institution, and he never even mentions whether they do or do not enjoy an erotic sexual life. This is not to say that impaired people are never fully incorporated into the social fabric and into meaningful roles in different societies, just that up to this point in the anthropology of impairment–disability, a critical gaze has been woefully absent.

This lack of critical focus is compounded with the terminological imprecision that plagues the field. Disability often becomes the default term even when bodily/behavioral difference or impairment or another ethnophysiological or ethnopsychological term would be more precise. Even when citing disability's Western medical and economic origins, scholars lapse into using it uncritically throughout an article. In 1999, Kasnitz and Shuttleworth offered what they called a pragmatic working understanding of disability-related terminology. The key is to consider the anthropology of impairment within any model of disability (see Hughes & Paterson, 1997, 1999, on the sociology of impairment). The following conceptual schema builds on this previous attempt.

Adapting from Douglas (1966), anomaly is a bodily and/or behavioral difference that falls in between cultural categories and is potentially threatening to social order. Cultures imbue anomalies with meanings and structure responses to its occurrence. Sociocultural groups may see persons whom they perceive to exhibit these anomalous differences as transgressing cultural values and threatening cultural cohesiveness, as in Douglas's model. In this case anomaly is socially construed as an impairment. Or, the group may resolve the perceived anomaly and imbue the bearer with a socially integrated role or status that is not negatively valued and does not constitute impairment. Sociocultural group members apply various indices to anomaly to determine its meaning and whether it constitutes impairment. For example, the American view of impairment is oriented toward indices of perceived functional limitations. Elsewhere, other salient ethnophysiological or ethnopsychological indices, such as balance between hot/cold, wet/dry, play a key role in identifying an anomaly as a sociocultural impairment (see, e.g., Burck, 1999). In this schema a particular society with its cultural meaning system defines and situates any functional limitation or other physical/psychological statuses (see also Marshall, 1996) as impairments, just as it also constructs health and illness.

There are at least three possible responses to impairment. The person so affected may be socially integrated into a society because of prevailing cosmology and other value-orientations that center on group cohesion. A society may respond by disabling/excluding to varying degrees the persons so affected thereby constructing disability. Or, a society may reserve a transpersonal or sacred role for the persons so affected. Obviously, this schema is for analytical purposes only and that in actuality a society may combine the above kinds of perceptions/meanings/responses to certain anomalous bodily and behavioral differences depending on the contexts of everyday life.

The above view attempts to disengage as much as possible the terms impairment and disability from their original biomedical meanings with the intent of transforming them into heuristic notions for sociocultural research on oppression against people with bodily and behavioral differences. Impairment in this understanding is thus a negative sociocultural meaning stemming from the perception–constitution of a particular physical and behavioral anomaly in terms of physical/psychological function or other ethnophysiological or ethnopsychological status

(see also Hughes & Paterson, 1997; Paterson & Hughes, 1999). This negative meaning may not appear in all domains of life, making impairment (like illness) a complex situational construct. When negative sanctions and exclusions, however, explicitly come into play in the form of particular social responses, this constitutes disability. From this perspective, the impairment–disablement sociocultural process is inherently negative. Whereas impairment is situated at the level of the cultural constitution of phenomena, that is, negatively following through with anomaly, disability is situated at the level of sociocultural response.

This is not the way that those conducting cross-cultural research usually define these terms. The World Health Organization (WHO) defines disabilities as “any restriction or lack resulting from an impairment of ability to perform an activity in the manner or within the range considered normal for a human being” (WHO, 1980, p. 28). However, even when disability is acknowledged as a negative process/response occurring between sociocultural contexts and individuals (which it is in the current anthropological research literature), cross-cultural researchers will lapse into the familiar medical and lay meaning that implicates only individual bodies and minds. Rosing (1999), for example, in an otherwise insightful article on bodily/behavioral difference among the Quechua-speaking people in the Kallawaya region in the Bolivian Andes shows on the one hand an understanding of the disablement process as a sociocultural oppressive response to anomaly but yet continues to use the term disability to refer an individual’s bodily/behavioral difference or impairment. She states, for example:

In the Andes disability can lead to two attributions (disability and vocation). In Western culture there is only one. In other words, in the Andes there is a culturally positive legitimization of disability—doubtlessly a great social resource for those affected. This is missing in Western culture. (Rosing, 1999, p. 40). Yet, this kind of dual usage simply obscures what is actually occurring and renders any analytical distinctions between terms of no consequence.

In the anthropology of impairment–disability a radical relativism and the terminological messiness that characterizes the field has tended to stand in the way of the development of critical approaches focusing on relations of power as reproduced in an actor’s everyday practices that have taken root in anthropology as a whole (see, e.g., Dirks, Eley, & Ortner, 1994; Ortner, 1984). Yet, critical perspectives are essential in studying impairment and disability across cultures where multiple

forms of integration and exclusion often exist side by side). However, some recent work in the anthropology of impairment–disability is finally beginning to take a critical view of certain social responses to anomalous bodies or behaviors (see, e.g., Hubert, 2000a, 2000b; Hyland, 2000; Kasnitz & Shuttleworth, 1999, 2001a, 2001b; Raji & Hollins, 2000; Sentumbwe, 1995; Shuttleworth, 2000b; Shuttleworth & Kasnitz, n.d. Turmusani, 1998, 1999a, 1999b).

Mapping the Relations of Meaning Between Illness and Disability

Within medical anthropology the study of impairment–disability is peripheral to the core concerns of the subdiscipline (Kasnitz & Shuttleworth, 1999; Shuttleworth, 2000b). Unless there is a strong connection to a phenomenology of illness, therapeutic treatment, and/or a culture’s ethnomedical system, many medical anthropologists choose not to study disability/difference. While some medical anthropologists have expanded their focus beyond ethnomedical and therapeutic systems per se to models of social suffering and affliction (see, e.g., Kleinman, Das, & Lock, 1997), the study of impairment–disability can yet still sit uneasily within these kinds of frameworks. The fact that impairment–disability is so variously constructed cross-culturally in relation to sickness, illness, pain, and suffering often requires an initial exploratory phase of research before knowing exactly what one will be studying. One cannot simply say, “I am going to X society to study their illness meanings and patterns of therapy seeking!” or “I am going to X society to study their experience of impairment and disability!” An emically driven study must first discover which physical/behavioral differences are considered significant for a particular society.

A requisite for future ethnographic research on impairment–disability is a mapping of local meanings of anomalous physical/behavioral differences in relation to etic distinctions between illness meanings, therapeutic treatments, and pain associations across a societies’ contexts. Different societies’ models of bodily and behavioral difference would variously range across a continuum of meanings and complexes involving impairment–disability that at one end are almost completely mapped onto illness meanings and at the other end almost exclusively involve meanings of sociocultural stigma, adversity, and contention. Discerning where particular kinds of

physical/behavioral differences fall on this continuum in terms of local meanings in different societies and the multiple contexts within these societies should constitute a major task of the disability ethnographer.

For example, Helander (1995) states, that “the Huber do not discriminate firmly between disability and disease. The practices and ideas surrounding disabled people can be described within the framework of health seeking and health management through which all health problems are processed.” This is probably the case in many non-Western societies. Devlieger (1995), for instance, also notes that among the Songyem, disability is initially perceived and responded to as illness. However, Helander also shows how Huber health-seeking behavior for what we would perceive as a functional-limitation-defined impairment eventually falls off when funds run out and the gamut of therapies is exhausted. At this point, family members give up the cure and the affected individual is increasingly left to him or herself. These kinds of trajectories need to be presented in much more detail to provide us with the above kind of mapping, which would thus provide a strong basis for cross-cultural comparison. Yet, a further question is also relevant: Can this partial withdrawing of support, albeit framed within a health-seeking model, in the critical conceptual model briefly sketched above, be considered disabling?

CONCLUSION

The anthropological study of impairment–disability is becoming more cross-cultural and is beginning to develop innovative theoretical perspectives. However, the mapping of local meanings of anomalous physical/behavioral differences in relation to etic distinctions between illness meanings, therapeutic treatments, and pain associations, across different societies’ totality of contexts, is virtually non-existent. Additionally, the anthropological study of impairment–disability has not much benefited from the critical work of the last 20 years within anthropology and medical anthropology. In reference to the latter, there has not been much engagement with the critical approaches of medical anthropologists such as Hans Baer, Nancy Scheper-Hughes, Margaret Lock, and Paul Farmer (however, see Kasnitz & Shuttleworth, 1999, 2001a, 2001b; Peace, 1997, 2001). While it is never wise to assume asymmetrical power

relations and oppression, in the cross-cultural study of impairment–disability, a resistance to ever conceptualizing in these terms prevails.

ACKNOWLEDGMENTS

I would like to acknowledge the critical feedback of Devva Kasnitz in assisting me in formulating several ideas in this entry. Additionally, I wish to thank the members of our course, Anthropology and Disability, at the University of California, Berkeley, for their spirited discussion of some of the key issues, which also assisted in clarification.

Drug Use

J. Bryan Page

INTRODUCTION

Among all the things that people do in the quest for health, ingestion of materials thought to improve an individual's state of mind and body appears to be universal. Human beings have discovered and learned to consume myriad preparations derived from plants and minerals, usually in the course of seeking food, but human foragers must have had some degree of receptivity to possible remedies or ways of achieving altered states of mind. This entry will point out that the discovery of altered consciousness and of remedies for ills have been, and still are inextricably interconnected. Anthropologists, using their holistic perspective in examining how herbal remedies and mind-altering drugs fit into the lives of the people who use them, have provided especially useful information and perspective on human variability related to drug use.

The archeological record of humankind's Paleolithic epoch holds little evidence of early consumption of plants or plant products as drugs.¹ Nevertheless, in the thousands of years that our ancestors spent foraging in shifting and changing ecologies, the search for the edible likely led to the discovery of the pleasurable, or at least the interesting effects of certain plants (Naranjo, 1995). The first clear evidence of use of a drug plant in the Western Hemisphere involves the discovery of mescal beans in a cave site in Coahuila, Mexico (Adovasio & Fry, 1976) about 8,500 years ago. Use of alcohol is implied in materials found in Old World sites of about the same antiquity, and use of other drug plants somewhat later. As with most invention, accidental occurrences probably shaped the process of discovering the first medicines and other drugs. Biodiversity in the local ecology, the numbers of different species per square meter, probably also played a part in adding to the list of novel plant preparations found by early humans.

If we assume that accident and biodiversity combined to lead to the identification of drug plants, then we could anticipate the relative productivity of different parts of the world, taking into account density of population. Not surprisingly, zones known to be tropical, but not

very populous, have contributed substantially to the human pharmacopia, both of medicines and hallucinogens, as demonstrated by generally accepted medicines such as digitalis and quinine, as well as the famous hallucinogens ayahuasca and iboga. We do not know, however, why the Western Hemisphere has dominated in the identification and production of hallucinogens (Schultes, 1977). Zones that are temperate but populous have contributed strongly to that pharmacopia, as Europe's linden, camomile, datura, and wormwood demonstrate. Tropical zones with dense populations have by far the most extensive list of plant-derived medicines and drugs, exemplified by the massive herbal pharmacopia of the Chinese and Indian traditions. Arctic tundras, with low population and low biodiversity, produce the fewest herbal remedies and drugs, although *Amanita muscaria* and its use among reindeer herdsman show that even these parts of the world produce traditional uses of drug plants.

The principles of biodiversity and population interact to yield large numbers of medicinal and psychotropic plants. High biodiversity occurs in the tropics, especially where there is variability of altitude, and combined with high population, the two factors increase the likelihood that people will accidentally discover plant-derived drugs. A third factor, however, comes into play in the specific case of hallucinogens, as most of them are found in sparsely populated tropical zones in the New World. Receptivity to radical, potentially frightening effects of plants may help to explain the disproportionate contribution of hallucinogenic plants by the Western Hemisphere (Schultes, 1977).

The principles of accident, biodiversity, and receptivity have exercised influence on the anthropological study of drugs throughout the history of pre-anthropology, as well as the current discipline established in the latter half of the 19th century. From Herodotus' accounts of Scythians using *Cannabis* to Schultes' encyclopedic descriptions of drug plants in Central and South America, human interaction with local ecologies provided the basic material that anthropologists eventually represented as herbal drug use to the Western audience.

This entry will take the approach that interactions between ecology and human populations underlie all of the other phenomena to be discussed.

BACKGROUND AND HISTORY

Early Accounts of Drug Use

Before anthropology was a separate discipline, travelers, explorers, and scholars wrote accounts of how people lived in cultural settings different from their own. These chronicles became the first literature on intercultural variation, albeit often riddled with the writers' own prejudices and misinterpretations of what they had observed. Some of the early ethnographic writings contained descriptions of drug use.

Besides being the recognized father of the Western approach to recording and reporting history (reservations about method and accuracy notwithstanding, cf. Pritchett, 1993), Herodotus provided some accounts of how non-Greeks, or "barbarians," lived in their respective natural habitats. In the course of describing the Scythians in what could be termed an early ethnography, Herodotus mentions their use of "hemp," which was probably cannabis, including an account of his hosts' consumption of the plant, which, when burned, produced intoxicating smoke (Wheeler, 1854, p. 159).

Lack of botanical and pharmacological expertise characterizes many of the early explorers' descriptions of non-Western people using unfamiliar plants. Europeans first thought the tomato poisonous because of its apparent taxonomic relationship to poison ivy. Prejudice against the people being described is evident in the conquistadores' encounters with the Aztecs' consumption of peyote and psilocybin and the Incas' consumption of coca (Carter & Mamani, 1986; Furst, 1995). European men of the 16th century gave disparaging and lurid accounts of these practices, setting the stage for centuries of prejudice against those who continued them. Consumption of tobacco as observed by Columbus and his crewmen, on the other hand, contributed to the eventual establishment of a highly lucrative trade good.

As travelers' agendas evolved from conquest, subjugation, and profit to subtler ones of governance and academic understanding, descriptions of drug use and healing practices became more detailed, although not necessarily less ethnocentric. Sir Richard Burton (n.d.)

wrote in the 19th century on his travels in Africa and the Middle East, including medicinal and drug-using patterns in these places. Frazer (1915) commented on the origin of the concept of souls and the relationship of that concept to dreaming and mind-altered states. The rise of behavioral science brought decidedly less ethnocentric views of the variants of human behavior along with assiduous attention to detail.

Anthropology of Drug Use

By the late 19th century, some academic travelers, calling themselves anthropologists, were beginning to write highly detailed ethnographic monographs. Because of their attention to detail, these works included accounts of whatever drug-using patterns were found in the groups being described. In terms of the anthropological view in its purest sense, this approach, the inclusion of drug use in the context of full ethnographic monographs that richly contextualize the described cultural patterns, may still represent the ideal in reporting on drug use. A focus on patterns of drug use without full attention to the cultural contexts in which it occurs can lead to overly facile representations of how people use drugs.

The cultural contexts in which drug use occurs, however, may not lend themselves to the production of a definitive monograph. In most parts of the contemporary world, whether people are using tobacco, ayahuasca, or heroin, societies have multicultural components in highly interdependent systems of symbols and exchange. For this reason, the specialized study of drug use had to arise, and it began to do so by the middle of the 20th century. One of the earliest examples of this kind of specialized study was Lowie's (1919) monograph on the Crow Tobacco Society. It related tobacco use with many other aspects of Crow life, including religion, social structure, linguistics, and ethnobotany, demonstrating the aptness of the anthropological view in studying patterns of drug use. Lowie also exemplifies anthropologists who did not necessarily focus on drug use, but in the course of their investigations, characterized drug use in specific cultural contexts (cf. Honigmann & Honigmann, 1945; Mangin, 1957).

Historical Context of Interest in Drugs

Before moving into the chronology of focused anthropological studies of drugs, the general historical context of drugs deserves brief attention. Western European

biomedicine and its power to discover palliatives and topical remedies have exercised strong influence on the place of drug use in Western life. By the time anthropology was emerging as a discipline, the European pharmacopia included numerous remedies derived from plants, many of which were not native to Europe. Opium and its tinctures had many uses in 19th-century English medical practice, and cocaine hydrochloride, a water-soluble transformation of a single alkaloid extracted from coca leaves, appeared in scores of patent medicines marketed in Europe and the United States (Morgan, 1981; Musto, 1987). Avant-garde artistic enthusiasm for some drugs arose in 19th-century Europe and England, exemplified by Coleridge's enthusiasm for laudanum (a tincture of opium) and Baudlaire's *Club Les Hachichins* (a group of French literati who took hashish, or concentrated Cannabis resin, as a source of inspiration).

Hazards of Drug Use. A perception of the hazards presented by these and other drugs if taken for purposes of pleasure also began to develop in the 19th century (Morgan, 1981; Musto, 1987). Reports of obsessive use, called addiction, had become associated with consumption of laudanum, an opium preparation. Patent medicines containing cocaine somewhat later attracted the attention of journalists as stories of addiction to Vin Mariani and Coca-Cola began to circulate in late 19th-century newspapers and magazines (Morgan, 1981; Musto, 1987). Exotic, foreign patterns of drug use, particularly the smoking of opium among Chinese (a practice promoted by English trade in Asia), were portrayed in the print media as particularly debilitating and dangerous (Barth, 1964). Drugs, if misused, could become pathways to depravity and death, and the similarity between drug addiction and alcoholism was not lost on the burgeoning temperance movements in England and the United States of the early 1900s (Morgan, 1981).

Western Moralism and Drugs. Somehow, people had to be protected from the potential ruin brought by drugs used for pleasure or personal enjoyment, and for the 70 years between 1880 and 1950, adherents to Western biomedicine and Victorian moralism set out to protect people from ruining themselves through drug use. This movement was particularly convenient for politicians and police who at the same time had to deal with massive cultural diversity in their home polities. The United States was receiving people of color from all parts of the world

at that time, many of whom used drugs other than alcohol and tobacco. France had intense interaction with Egypt in the 19th century. England received people from all over the world.

Prohibition of drug use gave the police a ready excuse to arrest and harass people who were non-white and culturally distinct, because they often brought with them different ways of consuming drugs. Attacks on opium smoking among Chinese immigrants, cocaine raids among African Americans, and, perhaps most egregiously, Harry Anslinger's famous onslaught against marijuana, primarily directed toward people of color, set the tone for intolerance of culturally distinctive drug-consuming behavior in the United States. These assaults also set a precedent for later persecution of the Native American peyotist practices in the 1960s.

The drugs targeted by prohibitionist fervor in the early 20th century, particularly opium, cocaine, and alcohol, in fact had extensive records of association with ruined lives, and therefore the cause of protecting people against ruin had legitimacy from a public health perspective. Curiously, tobacco, by far the most important killer among all drugs, slipped under the scrutiny of those who would police drug use in the world. Tobacco does not appreciably change users' behavior in the state of acute intoxication, and its sequelae either were missed altogether in the era when people did not live long enough to contract lung cancer or emphysema, or were confused with important killers such as pneumonia.

Prohibition and the Culturally Distinct "Other". In order to protect people against the ravages of addiction, polities prohibited people from using drugs such as alcohol, opium, and cocaine altogether, and this approach doomed all subsequent efforts to use law enforcement as the principal arm for prevention of drug misuse. Furthermore, prohibition gave law enforcers license to continue policies aimed at controlling the behavior of culturally distinct groups in their respective communities. On the other hand, culturally distinctive communities had an advantage in the continued procurement, sale, and distribution of forbidden commodities, because police forces did not understand them very well. Moreover, culturally distinctive sub-communities in large cities, such as San Francisco's Chinatown, New York's Harlem, and Miami's Overtown developed reputations as places where rules of "decent" behavior were in suspension, and one could seek pleasures there that one could not find in

the city's "respectable" neighborhoods. In fact, the vast majority of the enclaves' inhabitants behaved as "decently" as the people in the "respectable" neighborhoods. It was only natural that some individuals in the enclaves of people who were excluded from the advantages enjoyed by their culturally different neighbors would take advantage of the opportunity to profit at the expense of those same neighbors by providing drugs and sex in covert fashion.

The perception of drug users as a kind of threatening "other" whose actions and lifestyle undermined the structure of mainstream society persisted, complete with interwoven threads of racism and xenophobia that had become established in the early 20th century. Anslinger's declarations that marijuana was associated with jazz musicians and people of color, newspaper reports of cocaine-crazed "black" fieldhands, and the ubiquitous portrayal of the heroin user as desperate dope fiend fostered a public perception of deviant otherness with racial and cultural undertones. These perceptions were reflected in sociological approaches to studying social problems in terms of deviance (Becker, 1963) rather than adaptation.

Mid-20th-Century Reaction to Prohibition. Specific questioning of policies on drugs and attitudes about their use spontaneously changed social environments of the late 1960s, both in the United States and in Europe. Young people who experimented with marijuana concluded that the official government position on that drug was riddled with disinformation. If the government's policies on that drug were flawed, then perhaps other drugs' properties were also misrepresented in the official literature. The United States and Europe experienced an epidemic of drug use between 1965 and 1975 driven by the questioning of questionable information on the drugs of choice—marijuana, LSD, and heroin (Chambers & Ball, 1970).

Participants in the epidemic aroused the concern of the medical community and curiosity among social and behavioral scientists. The former group asked if the widespread experimentation with illegal drugs would have health consequences in the future, and the latter group asked if the "tribal" lifestyles associated with drug experimentation constituted transitory or evolving cultural patterns (Partridge, 1973). The emergence of a "counter-culture" rebellion against policies aimed at eradicating the use of illegal drugs marked the beginning of an era in which anthropological inquiry about drug use

of all kinds received increasing encouragement, both from the reading public and from agencies that fund research. That encouragement grew out of historical processes set in motion by would-be enforcers as well as the intellectually curious. The following sections attempt to chronicle subsequent developments in the anthropology of drug use while taking note of the social processes that supported them.

DEVELOPMENT OF METHODS AND MODELS

Pioneers and Hallucinogens

Anthropological inquiry seems to be driven primarily by curiosity about some aspect of the human condition, and the early investigation of drug use by anthropologists was no exception. The true pioneers in this area of inquiry were Richard Schultes and Weston La Barre, both of whom began their studies in the 1930s, in an era when North America was advocating for prohibition of specific drugs throughout the world. Schultes was in the process of accumulating information on the uses of a vast array of plant species (e.g., Schultes, 1938, 1940, 1963) in the course of establishing the larger sub-discipline of ethnobotany (Schultes & von Reis, 1995). La Barre began a career-long inquiry into the uses of peyote for religious purposes (cf. La Barre, 1938a, 1960). These specialized studies became models for the work of anthropologists who focused on drug use in ethnographic research.

Furst (1990), Dobkin de Rios (1968, 1970, 1971), and Harner (1974) exemplify the next generation of studies that focused on the use of hallucinogens in non-Western cultural contexts. Single-mindedly seeking evidence of drugs in far-flung cultural materials, these anthropologists found representations of drugs and their uses in artifacts (Furst, 1970) and monumental structures (Dobkin de Rios, 1977). They also conducted edifying ethnographies, reporting on how the use of specific drugs interacted with specific cultural traditions (cf. Dobkin de Rios, 1970; Furst, 1990). A contemporary of these earnest students of non-Western drug use, Carlos Castaneda (1969), published accounts of his "research" on Yaqui drug use as "elicited" from a shaman, spawning a series of books on the relationships among personal power, spirituality, and ingestion of hallucinogens. The widespread

popularity of these books made them vehicles for teaching the public about the process of learning about a cultural "other," but further examination led to the conclusion that they were works of fiction (De Mille, 1976, 1990). Still, the message that drug use in ritual applications could lead to positive, life-affirming experiences remained consistent in both the ethnographic and fictional works on non-Western drug use.

Alcohol and the Ritual Setting Hypothesis

Alcohol, perhaps the most universally consumed drug, attracted the attention of anthropologists in the context of holistic ethnographies, but by the 1930s it had also drawn the attention of anthropologists who focused on its use in a cultural context. La Barre (1938b) characterized grain-derived, fermented alcoholic beverages among Native Americans, and Heath (1958) embarked on his lifelong inquiries into patterns of alcohol consumption. These investigations either compiled extant ethnographic descriptions or provided ethnographies focused on the consumption of alcoholic drinks.

Whatever their approach, the early anthropological investigations of alcohol use attempted to avoid judgment on the manner in which people consumed the drug, focusing instead on the meaning of alcohol consumption within specific cultural contexts. Heath (1958) asserted that even drinking highly potent preparations of alcohol (aguardiente at 190 proof) to the point of drunken stupor does not carry severe health or social consequences. His justification for this view involved direct observation of life in a community where this kind of alcohol use took place only within ritual contexts. Studies of other drugs in other settings had come to similar conclusions: restriction of drug use to ritual contexts, regardless of the potency of the drug, reduces the likelihood of negative effects in the human community. This view of drug use as benign within strictures of ritual remains controversial, as anthropologists and non-anthropologists alike cite examples of the deleterious effects of alcohol and other drugs, even when they are only consumed in ritual contexts.

Broadening Perspectives on the Consequences of Drug Use

Later investigations of alcohol use, both in non-Western cultural settings (cf. Marshall, 1979) and in the

United States (Ames, 1985; Bennett, 1985; Spradley, 1970) acknowledged and attempted to explain proportions of problematic and non-problematic alcohol use within the same populations. Cultural adaptations to the presence of negative consequences of alcohol use have become legitimate topics in the study of alcohol use. Heath himself, in a later revisitation of the same cultural setting, the Camba of eastern Bolivia, allowed that under changing circumstances and community structure, alcohol use may not have the benign impact that it once had among the same people (Heath, 1994).

Acknowledgment that drug use may have different impacts under different cultural circumstances, regardless of the drug being consumed, provided an important perspective on the impact of drugs in different cultural settings. Heath (1958) and Carter (1977) concluded that problems related to alcohol consumption may have markedly different frequencies in cultural settings that restricted drinking to ritual contexts. Wilbert (1990) and Lowie (1919) made the same point about tobacco in traditional Native American cultural environments. On the other hand, in circumstances of poverty and marginalization, Singer (1986) made a convincing case for expecting increases in alcohol-related problems among Puerto Rican immigrants to the northeastern United States. Problems related to fully commercialized tobacco use, the most ruinous drug in terms of impact on the public health, have also drawn the attention of anthropologists attempting to find strategies for preventing the onset of addiction to tobacco (Nichter & Cartwright, 1991).

Drugs after 1960

The florescence of wide varieties of recreational drug use in the United States and Western Europe occurred in an historical setting in the 1960s in which for decades, drug use had been the object of negative public opinion (Morgan, 1981; Musto, 1987). The emergence of these patterns, despite the widespread negative perceptions of drugs, excited curiosity about the true impact of consuming drugs such as marijuana and cocaine.

Cannabis Initiative. Attempts to determine the impact of marijuana smoking occurred at all levels, from the individual, who experimented by smoking Cannabis, to the national blue-ribbon commission, whose members assessed all available information about the drug. In 1971, the Shafer Commission, having reviewed

copious materials on the social, health, and legal impact of marijuana use, could find no justification for its scheduling as a narcotic (National Commission on Drug Abuse, 1973).

According to the executive branch officials of the time (Richard Nixon's appointees), the primary flaw of the Shafer Commission's report lay in its lack of time depth. In places where marijuana smokers had been using Cannabis for long periods of time, the health and social consequences of their behavior would be obvious. Therefore, the fledgeling National Institute on Drug Abuse contracted for three studies of patterns of Cannabis use in places where long-term use was common: Jamaica, Costa Rica, and Greece. Anthropologists Vera Rubin, Lambros Comitas, William Carter, and Paul Doughty formed teams to conduct studies of Ganja in Jamaica (Rubin & Comitas, 1975) and Cannabis in Costa Rica (Carter, Coggins, & Doughty, 1980). These studies applied ethnographic methods to the study of drug use in the context of large, complex societies. They also combined medical and psychological assessments with anthropological findings to determine the consequences of smoking Cannabis for over 10 years. The studies failed to accomplish the desired characterization of the ills that accompany long-term use of Cannabis. They in fact found little evidence of health risks related to Cannabis use. Subsequent studies (Dreher, 1984; Fletcher et al., 1996; Page, 1983; Page, Fletcher, & True, 1988) enhanced the precision of the original ones, still concluding that the consequences of long-term Cannabis use are subclinical in nature, entailing considerably smaller health risk than that associated with heavy consumption of alcohol or tobacco.

Ethnography of Street Drug Use. Ethnographic perspectives on another pattern of drug use that expanded in the 1960s, namely injection of heroin, began to receive anthropological attention in the late 1960s. Michael Agar (1973) applied ethnomethodology in the form of free listing and pile sorting to the study of intravenous drug use, and the results of his inquiry, conducted at the Lexington facility for treatment of opiate addiction, shed new light on the activities involved in maintaining a heroin habit. Agar later conducted street-based participant observation under the tutelage of Edward Preble, author of the breakthrough article on addicts' behavior, "Taking Care of Business" (Preble & Casey, 1969). Works by Agar included further elaboration of his ethnography of drug

use (Agar, 1980), as well as works of methodological and theoretical importance.

During the late 1960s and early 1970s, street-based research on patterns of illegal drug use attracted increasing interest on the part of the United States' newly formed National Institute on Drug Abuse (NIDA). Administrators in that agency envisioned qualitative, observational perspectives on the drug use that takes place in street settings (hereafter, street drug use) through ethnographic research. Publications supported by NIDA included various combinations of both sociologists and anthropologists (e.g., Feldman, Agar, & Beschner, 1981, a collection of ethnographies on use of phencyclidine; and Weppner, 1977, brief reports on various aspects of street ethnography by anthropological and sociological researchers). From the mid-1970s, NIDA, the principal agency funding research on patterns of drug use, consistently supported ethnographic studies of drug users.

AIDS and its Impact on Drug Research

Between 1975 and 1985 the group of ethnographic researchers on the use of illegal street drugs remained very small, roughly 20 people. In 1987, an initiative to slow the spread of infection by the Human Immunodeficiency Virus (HIV) among injecting drug users (IDUs) sought to establish ethnographic capabilities in interventions throughout the United States. This initiative, funded by NIDA, led to the gainful employment of more than 20 doctoral level anthropologists in cities all over the United States. Each site in the initiative was required to have an ethnographic component, which provided observational data and in-depth interviews with IDUs in order to characterize local patterns of self-injection behavior. This feature attracted already accomplished investigators from other varieties of research, as well as newcomers to drug research. None had studied illegal drug use before, but their inclusion in the effort to prevent HIV infection among IDUs brought fresh perspectives and new capabilities to the mix of anthropologists studying illegal drugs.

Among the senior anthropologists involved in this new endeavor were Robert Trotter and Merrill Singer. Among the newcomers were Stephen Koester, Robert Carlson, and Claire Sterk. All eventually distinguished themselves with significant contributions to the study of street-based drug use. Trotter and colleagues focused on networks of informal social relations among IDUs

(cf. Trotter, Bowen, & Potter, 1995). Singer wove his studies of IDUs in Hartford into his well-known critical perspective (Baer, Singer, & Johnson, 1986; Singer, Baer, & Susser, 1999) in medical anthropology. Koester (1994), taking a cue from observational studies by Page (Page, 1990; Page, Chitwood, Smith, Kane, & McBride, 1990; Page, Smith, & Kane, 1990) used direct observation to explain the aversion of IDUs to carrying their own syringes. Carlson (Carlson, Wang, Siegal, Falck, & Guo, 1994) elaborated a sampling scheme for studying communities with drug-related HIV contagion. He also provided a fully contextualized perspective on injecting drug use in the United States (Carlson, 1996). Sterk (1999) thoroughly characterized the status of women who become involved in intensive drug use and the sex trade.

The most intensive study of street drug use by anthropologists has taken place in the United States, but ethnographers in Europe have also conducted important studies. Gamella (1990, 1994) analyzed the lives of IDUs in Madrid, tracing the trajectory of a new heroin epidemic and its concomitant spread of HIV infection. He also produced the definitive work on methylenedioxy-n-methylamphetamine (MDMA) and its use among youth in Spanish nightclubs (Gamella, 1999). Also in Spain, Page and Salazar (1999a, 1999b, 2001) have offered ethnographic evidence that the mere availability of needles and syringes may not suffice to slow the spread of HIV.

Other North American contributions to the anthropological literature on drug use have included Bourgois' *In Search of Respect* (1995), which used a contemporary critical perspective to humanize crack users in East Harlem, and Waterston's *Street Addicts in the Political Economy* (1993), which placed Philadelphia's IDU population in a political and economic context. These works drew upon the growing richness of ethnographic literature on drug use.

IMPACT AND CONTRIBUTIONS

Anthropological studies on how human beings use drugs have had major impact in at least eight areas:

1. They have extended the general understanding of how many different variants of drug use there are in the world.
2. They have conveyed the valuable message that the cultural context in which people use drugs helps to determine whether or not those who use suffer negative consequences.
3. They have developed paradigms for addressing questions of health and avoidance of harm related to drug use.
4. They have contributed mid-level theory about social process and structure in regional and transnational cities.
5. They have improved the precision of field interventions to prevent consequences of drug use through characterization of environments in which risk takes place.
6. They have built approaches to cognitive mapping of how drugs are perceived and how those perceptions are enacted.
7. They have analyzed the process of clinical interventions with an eye toward improvement of fit between cultural background of clientele and clinical approach.
8. They have offered methods for the study of covert behavior in urban contexts.

The impacts outlined above fall into three basic categories: descriptive, theoretical, and methodological. One cannot over-emphasize the importance of the descriptive impact. With all of their bewildering complexity and detail, it would seem that the thick descriptions contributed by Furst (1990), La Barre (1938a, 1938b), and Lowie (1919) were the antithesis of science, which seeks unifying and simplifying principles. Nevertheless, these descriptions ultimately will help to define the boundaries of human variation and provide the wherewithal for building theory. The works of Heath (1958, 1994) articulated the theory that ritual contexts provide protection against the harmful consequences of drug use, and La Barre's, Furst's, and Wilbert's work on peyote and tobacco supported this concept by characterizing the use of strong drugs in non-Western cultural contexts where they were not associated with health problems and addiction. Although this position remains controversial, it forces us to question the assumption that the use of drugs for mind-altering purposes ultimately visits harm upon users. Works by Page et al. (1990, Page & Salazar, 1999a), Gamella (1994), and Koester (1994) defined the nature of health risk among IDUs in terms of contextual factors, providing information necessary to improve interventions for preventing HIV infection. This contribution takes an approach to the relationship between drug use and its consequences that advocates for close examination of cultural context to determine the nature of risk.

Beyond theory specific to the consumption of drugs and its consequences, anthropological studies of drug use have analyzed the human condition in broad strokes, relating drug use to the general distribution of wealth (Waterston, 1993) and health care (Singer, Baer, & Susser, 1999). Trotter et al.'s (1995) conceptual struggle

with networks among IDUs also has edified with implications for the structure of human relations.

The anthropology of drug use can trace its origins to some of the first descriptions of one people by another. It has grown into a thriving branch of the discipline populated by active scientists. Their contributions to the state of knowledge have been important not just to medical anthropology, but to anthropology as a whole. In a world where cultural traditions swirl together into complex recombinations, the study of drug use represents an exemplary application of the anthropological view. It is a behavior that has implications for many aspects of the human condition, and therefore it demands an holistic perspective in order to achieve adequate understanding of its impact. The anthropological works cited here demonstrate this principle clearly. Furthermore, the humanity of the people who use drugs comes through vividly in these writings, and this is perhaps their most important contribution.

NOTE

1. A word about nomenclature is in order. Many well-meaning publications, some quoted in this entry, refer to drugs as "substances." That term is too broad for purposes of discussing what people take to make them feel better, or at least different. This entry will refer to all preparations ingested by human beings to alter the state of the body-mind continuum as "drugs," including tobacco, alcohol, antibiotics, and heroin, among many others. The term "preparation" will refer to a specific form of a drug, as it usually takes some preparing to render naturally occurring material into a consumable drug. The entry will also refer to misuse of these drugs, not abuse, except when referring to NIDA.

Emerging Infectious Diseases

Vinh-Kim Nguyen

INTRODUCTION

Epidemics emerge from specific, local concatenations of biological *and* social processes. Through the prism of culture, medical anthropologists have sought to understand how social processes both constrain and shape infectious diseases. In an era of self-conscious globalization, anthropologists have moved beyond the realm of “traditional” culture to examine how the cultures of biomedicine and of transnational institutions interact with local forms of knowledge, practice, and power. This makes anthropologists well-placed to examine the cultural dynamics of the interface between global and local social relations and, from this viewpoint, examine the biosocial processes underlying emerging infectious diseases today. Advances in the application of molecular biological techniques to the study of epidemics promise to deepen understanding of these biosocial processes. Coordinated mapping of biosocial processes through ethnographic and molecular methods holds the potential to make a substantial contribution to the emerging discipline of emerging infectious diseases.

Most commentators agree that the 1992 publication of an expert committee report on emerging infections was a seminal moment that set the stage for subsequent efforts to address this issue. The committee defined emerging infections as “new, re-emerging, or drug-resistant infections whose incidence in humans has increased within the past two decades or whose incidence threatens to increase in the near future” (Institute of Medicine, 1992, p. 3; see also Woolhouse & Dye, 2001, p. 981). This definition sets out a distinction between three microbial causes of new epidemics: new pathogens, old pathogens that have resurged, and pathogens that have changed through the acquisition of drug resistance. Research on emerging epidemics has described an ever-expanding array of pathogens and their effects, largely using epidemiological and laboratory methods (Krause, 1998; Thompson, 2000; Woolhouse & Dye, 2001). Examples of new pathogens include HIV, of course, but also prions — the cause of “mad cow disease”—and Hepatitis C virus

(HCV). Tuberculosis has re-emerged as a serious threat to public health in many parts of the world, riding on the coattails of the HIV epidemic. A large part of this threat comes from the creation of drug-resistant tuberculosis resulting from inadequate tuberculosis (TB) control mechanisms. To this medically induced, or iatrogenic, epidemic we may add the continuing evolution of drug-resistant strains of other common bacterial species; for example, methicillin-resistant staphylococci (MRSA), penicillin-resistant neisseriae gonorrhoea (PRNG), and vancomycin-resistant enterococci (VRE).

This biomedically inspired classification is a useful first approach, but only hints at the processes that trigger such epidemics. This taxonomy of pathogens (new, re-emerging, transformed) points to their historical dimension, that is, to how their ability to produce epidemics differs through time. The anthropology of emerging infectious diseases investigates the processes by which new or old pathogens produce infectious disease epidemics. In other words, rather than being a “surface” science concerned with describing the distribution of epidemics across a geographical landscape, anthropologists pose archeological questions, concerned with recovering the myriad social processes that sediment as epidemics in different social and geographical contexts. In seeking to explain differences between epidemic scale and intensity in different localities in terms of their social context, anthropologists are concerned both with unearthing “root causes” of epidemics, as well as accounting for the full social dimension of their impact on societies and individuals. These tasks call for both an ethnographic approach devoted to understanding everyday life in all its complexity, and a historical approach that traces the biosocial genealogies of epidemics (Inhorn & Brown, 1997; Kiple, 1993).

As more anthropologists research emerging infections, the full comparative potential of this research will become more visible. By working across cases, the anthropology of emerging infectious diseases aims to identify common “deep” biosocial processes that register on the epidemiological surface, at the same time as it
